In the US workplace testing, the Department of Transportation (DOT) has codified saliva ethanol testing (DOT 1994). The screening cut-off is 0.02 g% saliva or 0.02 g/210 L of breath. Because the saliva alcohol tests are non-specific, chemical screening tests that may react with oxidising agents other than alcohol and with ketones and alcohols other than ethanol, it is necessary to confirm any positive results greater than 0.02 g% with an independent test based on a different chemical principle. Breath alcohol tests are usually either fuel cells or infrared spectrometers with optical filters and computer software safeguards for specificity and sensitivity. Specifically, they must be able to distinguish acetone from ethanol at the 0.02 g% alcohol level. A time limit is put on confirmation of saliva ethanol results since ethanol is rapidly metabolised by the liver. Initially the confirmation breath test had to be performed within 20 min. The DOT now requires the confirmation test to be done within 30 min.

The DOT (1994) requires a 15 min waiting period before saliva or breath alcohol tests. The DOT describes this as a safeguard against false high readings due to accumulation of mouth alcohol, but the 15 min waiting period will also protect against false-positive readings from food or drink components, such as ascorbic acid, which might cause false-positive readings in saliva tests. To obtain a correct test, the most important factor is that a waiting period be observed in which the donor does not eat, drink, smoke or belch (i.e. nothing by mouth).

CHAPTER

19 Hair Analysis

P Kintz

Introduction

In the 1960s and 1970s, hair analysis was used to evaluate exposure to toxic heavy metals such as arsenic, lead or mercury; this was due to the availability of atomic absorption and neutron activation analysis that allowed detection in the nanogram range (Curry, Pounds 1977) At this time, examination of hair for organic substances, especially drugs, was not possible because analytical methods were not sufficiently sensitive. Examination by means of drugs marked with radioactive isotopes, however, established that these substances can move from blood to hair and are deposited there (Lindquist, Ullberg 1974). Ten years after these first investigations, it was possible to denominate various organic drugs by means of radioimmunoassay (RIA). In 1979, Baumgartner and colleagues (Baumgartner, Hill 1992) published the first report on the detection of morphine in the hair of heroin abusers using RIA. They found that differences in the concentration of morphine along the hair shaft correlated with the time of drug use. Today, gas chromatography coupled with mass spectrometry (GC-MS) is the method of choice for hair analysis and this technology is routinely used to document repetitive drug exposure in forensic sciences, traffic medicine, occupational medicine, clinical toxicology and more recently in sports drug testing.

The major practical advantage of hair testing compared with urine or blood testing for drugs is that it has a larger surveillance window (weeks to months, depending on the length of the hair shaft, against 2–4 days for blood and urine). For practical purposes, the two tests complement each other. Urinalysis and blood analysis provide short-term information of an individual's drug use, whereas long-term histories are accessible through hair analysis. While analysis of urine and blood specimens cannot distinguish between chronic use or single exposure, hair analysis can offer the distinction.

Biology of hair

Hair is a product of differentiated organs in the skin of mammals. It differs in individuals only in colour, quantity and texture. Hair composition is primarily protein (65–95%, essentially keratin), as well as water (15–35%) and lipids (1–9%). The mineral content of hair is from 0.25% to 0.95%. The total number of hair follicles in an adult is estimated to be about 5 million, with 1 million found on the head (Harkey *et al.* 1991). Hair follicles are embedded in the epidermal epithelium of the skin, approximately 3–4 mm below the skin's surface.

Hair growth

The hair shaft begins in cells located in a germination centre, called the matrix, found in the base of the follicle. Hair does not grow continually, but in cycles, alternating between periods of growth and quiescence. A follicle that is actively producing hair is said to be in the *anagen* phase. Hair is produced during 4–8 years for head hair (<6 months for non-head hair) at a rate of approximately 0.22–0.52 mm/day or 0.6–1.42 cm/month (Saitoh *et al.* 1969) for head hair (the growth rate depending on hair type and anatomical location). After this period, the follicle enters a relatively short transition period of about 2 weeks, known as the *catagen* phase, during which cell division stops and the follicle begins to degenerate. Following the transition phase, the hair follicle enters a resting or quiescent period, known as the *telogen* phase (10 weeks), in which the hair shaft stops growing completely and the hair begins to shut down. Factors such as race, disease states, nutritional deficiencies and age are known to influence both the rate of growth and the length of the quiescent period. On the scalp of an adult, approximately 85% of the hair is in the growing phase and the remaining 15% is in a resting stage.

Types of hair

Pubic hair, arm hair and axillary hair have been suggested as alternative sources for drug detection when scalp hair is not available. Various studies have found differences in concentrations between pubic or axillary hair and scalp hair. Comparison of methadone, cocaine, morphine and phenobarbital concentrations provides the highest values in the axillary hair, followed by pubic hair and the hair of the head. In contrast, the highest morphine concentrations were found in pubic hair (0.80–1.34 ng/mg), followed by head hair (0.62–27.10 ng/mg) and axillary hair (0.40–24.20 ng/mg). The significant differences of the drug concentrations in these studies were explained by a better blood circulation, a greater number of apocrine glands, a totally different telogen/anagen ratio and a different growth rate of the hair (axillary hair 0.40 mm/day, pubic hair 0.30 mm/day). Beard hair grows at about 0.27 mm/day and is considered a suitable alternative, as it can be collected on a daily basis with an electric shaver and can be used to evaluate the incorporation rate of drugs (Mangin 1996).

Mechanisms of drug incorporation into hair

It is generally proposed that drugs can enter into hair by two processes: adsorption from the external environment and incorporation into the growing hair shaft from blood supplying the hair follicle. Drugs can enter the hair from exposure to chemicals in aerosols, smoke or secretions from sweat and sebaceous glands. Sweat is known to contain drugs present in blood. Because hair is very porous and can increase its weight up to 18% by absorbing liquids, drugs may be transferred easily to hair via sweat. Finally, chemicals present in air (smoke, vapours, etc.) can be deposited onto hair. Drugs appear to be incorporated into the hair during at least three stages: from the blood during hair formation, from sweat and sebum, and from the external environment. This model is more able than a passive model (transfer from blood into the growing cells of the hair follicle) to explain several experimental findings; for example, (1) drug and metabolite ratios in blood are quite different from those found in hair; and (2) drug and metabolite concentrations in hair differ markedly between individuals receiving the same dose. Evidence for the transfer of the drug via sweat and sebum can be supported as drugs and metabolites are present in sweat and sebum at high concentrations and persist in these secretions longer than they do in blood. The parent drug can be found in sweat long after it has disappeared from the blood (Henderson 1993; Cone 1996).

The exact mechanism by which chemicals are bound into hair is not known. It has been suggested that passive diffusion may be augmented by binding of drug to intracellular components of the hair cells such as the hair pigment melanin. For example, codeine concentration in hair after oral administration is dependent on melanin content (Kronstrand *et al.* 1999). However, this is probably not the unique mechanism since drugs are trapped into the hair of albino animals, which lack melanin. Another proposed mechanism is the binding of drugs to

sulfhydryl-containing amino acids present in hair. There is an abundance of amino acids such as cystine in hair that form cross-linking S–S bonds to stabilise the protein fibre network. Drugs diffusing into hair cells could be bound in this way. The course of appearance of drugs in hair was evaluated in beard hair. A time lag of various duration between the administration and appearance in hair was observed in all cases: 1 day for codeine to 8 days for morphine and codeine (Mangin 1996). This time lag is probably a result of the growth time necessary for the hair shaft to emerge from the bulb area in the follicle to a height above the skin surface sufficient for collection.

It has been demonstrated from various studies that, after the same dosage, black hair incorporates greater quantities of drugs than blond hair (Henderson *et al.* 1998; Höld *et al.* 1999). This has resulted in discussion of a possible racial or genetic bias of hair analysis, and the matter is still under evaluation.

Specimen collection and procedures

Collection procedures for the analysis of drugs in hair have not yet been standardised. In most published studies, the samples are obtained from random locations on the scalp. Hair is best collected from the area at the back of the head, called the *vertex posterior* (Figure 19.1). Compared with other areas of the head, this area has less variability in the hair growth rate, the number of hairs in the growing phase is more constant, and the hair is less subject to age- and sex-related influences. Hair strands are cut as close as possible to the scalp, and the location of the root-tip must be indicated. Storage is achieved at ambient temperature in aluminium foil, an envelope or a plastic tube. The sample size required for analysis varies considerably between laboratories and depends on the drug to be analysed and the test methodology. For example, when fentanyl or buprenorphine is investigated, a 100 mg sample of hair is recommended. Sample sizes reported in the literature range from a single hair to 200 mg, cut as close to the scalp as possible. As a guide, many laboratories recommend that a hair sample equivalent to the thickness of a pencil should be collected and submitted for analysis. When sectional analysis is performed, the hair is cut into segments of about 1, 2 or 3 cm, which correspond to about 1, 2 or 3 months' growth.

Stability of drugs in hair

The presence of opiates was detected in five hair shafts (about 7.5 cm in length) from the Victorian poet John Keats 167 years after his death (Baumgartner *et al.* 1989). It is believed he took laudanum (opium) to control the pain of tuberculosis. The scalps of eight Chilean and Peruvian mummies dating from 2000 BC to AD 1500 also tested positive for benzoylecgonine (Cartmell *et al.* 1991). All of these studies indicate that drug incorporation is very stable in hair and that modern medical technology can assist other disciplines. Clearly, organic substances are capable of surviving in hair for thousands of years under favourable conditions (ambient temperature, dry atmosphere).

Decontamination procedures

Contaminants of hair would be a problem if they were drugs of abuse or their metabolites or if they interfered with the analysis and interpretation of the test results. It is unlikely that anyone would intentionally or accidentally apply anything to their hair that would contain a drug of abuse. The most crucial issue facing hair analysis is the avoidance of technical and evidentiary false positives. Technical false positives are caused by errors in the collection, processing and analysis of specimens, while evidentiary false positives are caused by passive exposure to the drug. Various approaches for preventing evidentiary false positives due to external contamination of the hair specimens have been described.

Most but not all laboratories use a wash step; however, there is no consensus or uniformity in the washing procedures. Among the agents used in washing are detergents such as Prell shampoo, surgical scrubbing solutions, surfactants such as 0.1% sodium dodecylsulfate, phosphate buffer, or organic solvents such as acetone, diethyl ether, methanol, ethanol, dichloromethane, hexane or pentane of various volumes for various contact times. Generally, a single washing step is employed; sometimes a second identical wash is performed. If external contamination is found by analysing the wash solution, the washout kinetics of repeated washing can demonstrate that contamination is rapidly removed. According to Baumgartner and Hill (1992), the concentration of drug in the hair digest after washing should exceed the concentration in the last wash by at least 10 times. Moreover, the total concentration in

Figure 19.1 Sampling a specimen of hair.

the three phosphate washes should be greater than 3.9 times the concentration in the last wash and the concentration in the hair digest must be greater than one-third of that of the three phosphate washes.

Detection in hair of drug metabolite(s), the presence of which could not be explained by hydrolysis or environmental exposure, would unequivocally establish that internal drug exposure had occurred (Cone *et al.* 1991). Cocaethylene and norcocaine would appear to meet these criteria, as these metabolites are formed only when cocaine is metabolised. Because these metabolites are not found in illicit cocaine samples, they would not be present in hair as a result of environmental contamination, and thus their presence in hair could be considered as a marker of cocaine use. This procedure must be extended to other drugs.

However, there is still great controversy about the potential risk of external contamination, particularly for crack, cannabis and heroin when smoked, as several authors have demonstrated that it is not possible to fully remove the drugs (Blank, Kidwell 1995; Kidwell, Blank 1996). In conclusion, although it is highly recommended to include a decontamination step, there is no consensus on which procedure performs best. Therefore, each laboratory must validate its own technique.

Effects of cosmetic treatments

An important issue of concern for drug analysis in hair is the change in the drug concentration induced by the cosmetic treatment of hair. Hair is continuously subjected to natural factors, such as sunlight, weather, water, pollution, that affect and damage the cuticle, but hair cosmetic treatments enhance that damage. Particular attention has been focused on the effects of repeated shampooing, 'perming', relaxing and dyeing of hair. Repeated shampooing was found to have no significant action on the drug content of hair (Baumgartner, Hill 1992). After cosmetic treatments, drug concentrations decline dramatically, decreasing from 50% to 80% of the original concentration. The products used for cosmetic treatments, such as bleaching, permanent waving, dyeing or relaxing, are strong bases. They will cause hair damage and affect drug content (by loss) or directly affect drug stability (Cirimele *et al.* 1995a).

Drug solubilisation

To determine the amount of a drug remaining in hair after washing, it is necessary to solubilise the drugs in the hair. Solubilisation must be done such that the analytes are not altered or lost. For example, care is necessary to prevent the conversion of cocaine to benzoylecgonine or of 6-monoacetylmorphine to morphine. Prior to testing, the hair sample can be pulverised in a ball-mill, cut into segments or dissolved/digested to yield a uniform matrix for subsequent extraction.

The preparation techniques are generally based on one of the following procedures:

- Drug incubation in an aqueous buffer and analysis with immunological techniques, mostly RIA
- Drug incubation in a chemical (acid or base), liquid–liquid extraction or solid-phase extraction and analysis with chromatographic techniques, mostly GC-MS
- Drug incubation in an organic solvent (generally methanol with or without hydrochloric acid), liquid extraction or solid-phase extraction and analysis with chromatographic techniques, mostly GC-MS
- Hair digestion in an enzymatic solution, liquid extraction or solid–phase extraction and analysis with chromatographic techniques, mostly GC-MS.

Incubation of the hair sample in sodium hydroxide completely destroys the protein matrix. Parameters to be determined are the molarity of NaOH, the time of incubation and the temperature of incubation. The alkaline hydrolysis of hair is not suitable for the extraction of chemically unstable compounds, such as cocaine, 6-monoacetylmorphine, benzodiazepines or esters of anabolic steroids, which are hydrolysed under strong alkaline treatment. To provide extraction of hair containing cocaine or 6-monoacetylmorphine, Jurado *et al.* (1995) and Girod and Staub (2000) proposed the use of acid hydrolysis. The samples can be incubated in 0.1 mol/L HCl overnight at room temperature, at 45°C or at 56°C, or in 0.6 mol/L HCl for 30 min at 120°C. The organic solvent incubation method is the simplest. It involves placing hair samples in methanol or ethanol and then putting them in an ultrasound bath at 45°C for several hours. GC-MS analysis can be carried out directly following the evaporation of the organic solvent (Rothe, Pragst 1995; Pragst 2007). With this method, it is possible to detect heroin in the hair of heroin addicts. Next to chemical hydrolysis and direct extraction of hair with organic solvents, various types of enzymatic digestion of keratin matrices have been proposed (Höld *et al.* 1998). Hair samples can be treated with pronase solution, glucuronidase-arylsulfatase or proteinase K. The enzymes act upon the keratin without altering the chemical structure of the analytes present in the hair. This fact seems to be particularly important when the substances are chemically unstable, such as heroin or cocaine (Sachs, Kintz 1998). An interesting extraction procedure has been developed using supercritical fluid extraction with CO_2 (Edder *et al.* 1994). Adding polar modifiers such as water, methanol or triethylamine leads to a subcritical fluid with high extractive properties. The high speed of the extraction (30 min) and the possibility of connecting on-line with a GC-MS system are advantages that have to be paid for high instrumental costs compared with solid-phase or liquid–liquid extraction. Only small amounts of non-halogenated organic solvents are needed, which result in low environmental pollution (Edder *et al.* 1994).

Drug analysis

The first publication dealing with the analysis of morphine in hair for determining opiate abuse histories reported on analysis with RIA (Baumgartner *et al.* 1979). This paper was followed by a great number of procedures, which mostly used RIA and/or GC-MS. Chromatographic procedures seem to be a more powerful tool for the identification and quantification of drugs in hair owing to their separation ability and their detection sensitivity and specificity, particularly when coupled with MS. Proposed cut-off concentrations and expected concentrations for drugs of abuse in hair are presented Table 19.1.

Immunological methods

Immunoassays are used as screening tests in several laboratories because of their sensitivity, speed and convenience. The procedure must be compatible with the screening test used, i.e. detergents or hair-digestion products must not interfere with the assay. Neutralisation, in the case of chemical hydrolysis, is always necessary. The destruction of the organic

Table 19.1 Proposed cut-off concentrations (when tested by GC-MS) and expected concentrations for drugs of abuse in hair

Drug	*GC-MS cut-off concentration*	*Expected concentrations*
Heroin	0.5 ng/mg for 6-acetylmorphine	0.5–100 ng/mg, in most cases <15 ng/mg
Cocaine	0.5 ng/mg for cocaine	0.5–100 ng/mg, in most cases <50 ng/mg, in crack abusers >300 ng/mg is possible
Amfetamine, MDMA	0.5 ng/mg for both drugs	0.5–50.0 ng/mg
Cannabis	0.05 ng/mg for THC 0.5 pg/mg for THC-COOH	THC: 0.05–10 ng/mg, in most cases <3 ng/mg THC-COOH: 0.5–50 pg/mg, in most cases <5 pg/mg

MDMA, methylenedioxymethamfetamine; THC, tetrahydrocannabinol; THC-COOH, tetrahydrocannabinol-11-oic-acid.

protein matrix of hair must be done under sufficiently mild conditions that will not damage the entrapped analyte or the protein antibodies subsequently added for the immunoassay. Quantification by immunoassay is difficult to achieve as the specificity of most kits is directed to a group of drugs and drug metabolites rather than to a single substance.

Radioimmunoassay

RIA is the most common screening test for hair. Kits, generally proposed for urine, can be used without any modification, at pH greater than 7.0. Calibration curves are obtained either from the control urines in the kit or from extracts of drug-free hair samples spiked with the drugs. Duplicate determinations are recommended. The RIA results should be confirmed by GC-MS. In the absence of a second independent method, RIA detection will thus be interpreted with caution. Sometimes, however, the sensitivity of GC-MS is not sufficient, especially with a small amount of material. For these reasons, it is necessary to carry out immunological drug analysis in hair only with specific RIA kits for the selective estimation of a determined drug, such as fentanyl, LSD or buprenorphine.

Enzyme-multiplied immunoassay

Enzyme-multiplied immunoassay (EMIT) (*see* Chapter 31), based on spectroscopic measurement, is subject to interferences by colour and turbidity, and therefore should not be used to analyse hair samples.

Fluorescence polarisation immunoassay

First reported in 1987 (Franceschin *et al.* 1987), fluorescence polarisation immunoassay (FPIA) seems to be correlated to GC-MS, at least when the antibody has a good cross-reactivity with the parent drug, such as for dextropropoxyphene, amfetamine or methadone. FPIA can be proposed for toxicological screening in hair samples, but results must always be confirmed (Kintz *et al.* 1992).

Chromatographic methods

Chromatographic methods have been used as screening and confirming tests. Moreover, they allow quantification of drugs and drug metabolites present in hair as well as confirmation of drug identity. Some classic procedures are given in detail Table 19.2.

Thin-layer chromatography

In 1980, Klug reported a thin-layer chromatography (TLC) method to detect morphine in the hair of drug abusers in which drug detection and quantification were achieved using fluorimetry (Klug 1980). A high performance TLC method was used to determine morphine in human hair with quantification by densitometry (Jeger *et al.* 1991).

High performance liquid chromatography

High performance liquid chromatography (HPLC) methods were used in some studies for the detection of morphine, haloperidol, β-blockers, some antiepileptic or psychotropic drugs, and buprenorphine (Kintz *et al.* 1994; Couper *et al.* 1995). Different kinds of detectors were involved, including ultraviolet, fluorimetry and coulometry. The latter two detectors allow enough sensitivity for low drug concentrations (Sachs, Kintz 1998). At this time, most of the recent literature is focused on the use of LC-MS(-MS) owing to its excellent specificity and its extraordinary sensitivity, which allow, in some special cases, the detection of a single exposure to a specific drug (Müller *et al.* 2000; Huang Y *et al.* 2008; Huang DK *et al.* 2009; Stout *et al.* 2010).

Gas chromatography

Gas chromatography coupled to flame ionisation or nitrogen detection procedures is less useful for the analysis of drugs in hair since the great number of interfering substances (exogenous and endogenous compounds) makes the interpretation of chromatograms very difficult. GC-MS is the most powerful tool for the detection of drugs in hair. In 1992, Moeller presented a screening procedure in which amfetamines, cocaine, benzoylecgonine, codeine, morphine and tetrahydrocannabinol-H-oic acid (THC-COOH) were analysed in one procedure (Moeller *et al.* 1992a). More recently, Kauert and Rohrich (1996) presented a screening procedure based on methanolic incubation that was suitable for opiates, cocaine, amfetamines, methadone and cannabis. Today, this procedure is considered as the standard in hair testing.

Other methods

Capillary electrophoresis (CE) has been proposed for the quantitative determination of cocaine and morphine in the hair of cocaine and heroin users (Tagliaro *et al.* 1997). Infrared (IR) microscopy can delineate passive exposure from drug use by analysing only the central core of the unextracted hair shaft with either cross-sectionally microtomed or laterally microtomed hair. IR spectra can be obtained of the medulla, cortex and cuticle of the single hair with a nominal spatial resolution of 10 μm (Kalasinsky *et al.* 1994). Fourier transform-IR (FTIR) microscopy was presented to be more sensitive than classic GC-MS procedures by Kalasinsky *et al.* (1994). Fluorescence microscopy has been used to

Table 19.2 Screening procedures for the detection of illegal drugs in hair[a]

Method	*Kauert*	*Moeller*	*Kintz*
Analytes	Heroin, 6-MAM, dihhydrocodeine, codeine, methadone, THC, cocaine, amfetamine, MDMA, MDEA, MDA	6-MAM, dihhydrocodeine, codeine, methadone, THC, cocaine, amfetamine, MDMA, MDEA, MDA	6-MAM, codeine, methadone, cocaine, amfetamine, MDMA, MDEA, MDA, most pharmaceuticals
Decontamination step	Ultrasonic 5 min each	20 mL H_2O (2×)	5 mL CH_2Cl_2
	5 mL H_2O	20 mL acetone	(2 × 5 min)
	5 mL acetone		
	5 mL petrol ether		
Homogenisation	100 mg hair cut into small sections in a 30-mL vial	Ball mill	Ball mill
Extraction	4 mL methanol Ultrasonic 5 h, 50°C	20–30 mg powdered hair, 2 mL acetate buffer + β-glucuronidase/arylsulfatase, 90 min/40°C	50 mg powdered hair, 1 mL 0,1 mol/L HCl, 16 h/56°C
Clean-up	None	$NaHCO_3$; SPE (C_{18}), elution with 2 mL acetone–CH_2Cl_2 (3 : 1)	$(NH_4)_2HPO_4$;extraction 10 mL $CHCl_3$–2-propanol–*n*-heptane (50 : 17 : 33); organic phase purified with 0.2 mol/L HCl; HCl phase to pH 8.4; re-extraction with $CHCl_3$
Derivatisation	Propionic acid anhydride	1000 μL PFPA–75 μL PF-*n*-propanol; 30 min/60°C; N_2/60°C; 50 μL ethyl acetate	40 μL BSTFA–1%TMCS or HFBA; 20 min/70°C

detect organic substances in hair and presents a good alternative to chromatographic procedures (Pötsch and Leithoff 1992).

Drug identification

Opiates

In 1979, Baumgartner and colleagues (1979) published the first results on morphine concentrations in the hair of 25 heroin users (Baumgartner *et al.* 1979). Morphine was in the range 0.3–6.6 ng/mg. Since heroin samples always contain codeine, codeine is also detected in cases of heroin abuse. Morphine is a metabolite of codeine and can be detected when codeine is abused. The quantification of both drugs was proposed to differentiate between codeine and heroin abuse (Sachs and Arnold 1989). If the morphine concentration is clearly higher than the codeine concentration in the examined hair sample, heroin or morphine abuse is highly probable. If the codeine concentration is clearly higher than that of morphine then it may be assumed that codeine has been ingested. However, the discrimination of heroin users from individuals exposed to other sources of morphine alkaloids can be achieved by directly identifying heroin or 6-monoacetylmorphine (Nakahara *et al.* 1992; Sachs, Uhl 1992). In this case, no alkaline hydrolysis must be performed so as to avoid hydrolysis. In most samples, it was demonstrated that the concentration of 6-monoacetylmorphine exceeded that of morphine, which is a less lipophilic compound. Other opioids have been detected in hair including dihydrocodeine, pholcodine, ethylmorphine, dextromoramide, methadone, fentanyl, sulfentanyl, pentazocine, zipeprol and buprenorphine (Sachs, Kintz 1998). A comprehensive review concerning the analysis of opioids in hair has been published by Yegles and Wennig (2006).

Cocaine

Procedures for the detection of cocaine have been published in several papers (Sachs, Kintz 1998; Moore *et al.* 2007; Barroso *et al.* 2008; Hoelzle *et al.* 2008; Vogliardi *et al.* 2009). There is considerable variety in the work-up and derivatisation conditions. In most cases, cocaine is found in higher concentrations than benzoylecgonine and methylecgonine (Moeller *et al.* 1992a; Kidwell 1993; Henderson *et al.* 1996). The determination of the pyrolysis product of cocaine, anhydroecgonine methyl ester (AEME), is helpful in distinguishing cocaine smoking from crack use. Kintz found AEME in the range 0.2–2.4 ng/mg for seven crack users (Kintz *et al.* 1995b).

An important study with controlled doses of cocaine-d_5 was published in 1996 (Henderson *et al.* 1996). The deuterium-labelled cocaine was administered intravenously and/or intranasally in doses of 0.6–4.2 mg/kg under controlled conditions. A single dose could be detected for 2–6 months; the minimum detectable dose appeared to be between 22 and 35 mg.

As an example, the procedure for simultaneously testing for opiates and cocaine is as follows (from Kintz, Mangin 1995).

Decontamination

- Take a hair strand (~100 mg)
- Wash with 5 mL methylene chloride, for 2 min
- Dry with adsorbent paper
- Second wash in 5 mL methylene chloride, for 2 min.

Homogenisation/pulverisation

- Pulverise the sample in a ball mill for 10 min at 100 cycles/min.

Solubilisation

- Take 30–50 mg of powdered hair and add:
  - 1 mL phosphate buffer pH 8.4
  - 100 ng of deuterated opiates and cocaine derivatives
- Incubate for 16 h at 56°C.

Extraction

- Homogenize with 10 mL dichloromethane–isopropanol–*n*-heptane (50 : 17 : 33, v/v)
- Agitate on a horizontal shaker for 20 min at 95 cycles/min
- Centrifuge for 15 min at 3000 rpm
- Purify the organic phase by acid extraction (5 mL 0.2 mol/L HCl), then alkaline back extraction (1 mL NaOH 1 mol/L plus 2 mL phosphate buffer pH 8.4 in dichloromethane)
- Collect the organic phase and evaporate to dryness.

Derivatisation

- Dry the extract using 30 µL BSTFA (bis(trimethylsilyl)trifluoroacetamide) plus 1% trimethylchlorosilane (TMCS)
- Incubate for 30 min at 70°C.

Analysis

- Inject a 1.5-µL portion in splitless mode onto a HP5-MS capillary column (30 m × 0.25 mm)
- GC parameters:
  - Flow rate, helium N55: 1.0 mL/min
  - Injector temperature: 270°C
  - Temperature programme: 60°C for 1 min, 30°C/min to 295°C for 6 min.

Amfetamines

Papers dealing with amfetamine and methamfetamine (MA) have mostly been published by Japanese authors (Nakahara *et al.* 1990). The work-up (liquid–liquid extraction after acid or alkaline hydrolysis) and derivatisation procedures (trifluoroacetic anhydride, TFA) are similar in most of the publications.

After intake of methamfetamine, its major metabolite, amfetamine, can be detected in hair samples, and the differentiation of intake is shown by the ratio between the drugs.

In 1992, methylenedioxy-*N*-methamfetamine (MDMA or ecstasy) was first detected in the hair of an abuser at a concentration of 0.6 ng/mg (Moeller *et al.* 1992b). In Europe, MDMA is one of the most frequently identified amfetamines. Since the first screening procedure in 1995, different methods have been published (Kikura *et al.* 1997; Rothe *et al.* 1997). These procedures allow the determination of amfetamine, methamfetamine, methylenedioxyamfetamine (MDA), MDMA, methylenedioxyethamfetamine (MDEA) and *N*-methylbenzodioxolylbutanamine (MBDB) by electron impact GC-MS.

As an example, the procedure for testing for several stimulants is as follows (from Sachs, Kintz 1998).

Decontamination

- Take a hair strand (~100 mg)
- Wash with 5 mL methylene chloride, for 2 min
- Dry with adsorbent paper
- Wash again in 5 mL methylene chloride, for 2 min.

Homogenisation

- Pulverise the sample in a ball mill for 10 min at 100 cycles/min.

Solubilisation

- To 30–50 mg of powdered hair, add 1 mL 1 mol/L NaOH and 200 ng by weight of deuterated drugs
- Incubate for 10 min at 95°C.

Extraction

- Homogenise and add 5 mL ethyl acetate
- Agitate on a horizontal shaker for 20 min at 95 cycles/min
- Centrifuge for 15 min at 3000 rpm
- Collect organic phase, addition of 20 µL methanol–HCl (99 : 1 v/v) and evaporate to dryness.

Derivatisation

- Dry the extract and add 150 µL ethyl acetate–heptafluorobutyric anhydride (1 : 2 v/v)
- Incubate for 30 min at 60°C
- Re-evaporate to dryness.

Analysis

- Dissolve the derivatised extract in 25 µL ethyl acetate. Inject a 1.5-µL portion in splitless mode into a HP5-MS capillary column (30 m × 0.25 mm)

- GC parameters:
  - Flow rate, helium N55: 1.0 mL/min
  - Injector temperature: 240°C
  - Temperature programme: 60°C for 1 min, to 295°C at 30°C/min for 6 min.

Cannabis

In 1995, the first results on cannabis in hair using GC-MS and the determination in the same run of Δ^9-tetrahydrocannabinol (THC) and its major metabolite 11-nor-Δ^9-THC carboxylic acid (THC-COOH) were reported (Cirimele *et al.* 1995b; Jurado *et al.* 1995). The measured concentrations were low, particularly compared with other drugs. Some authors suggested the use of negative-ion chemical ionisation (Kintz *et al.* 1995b) to target the drugs or the application of tandem mass spectrometry (Cirimele *et al.* 1996b). More recently, a simpler method was proposed (Uhl 1997), based on the simultaneous identification of cannabinol (CBN), cannabidiol (CBD) and THC. This procedure is a screening method that is rapid and economic and does not require derivatisation prior analysis. To avoid potential external contamination (since THC, CBD and CBN are present in smoke), the endogenous metabolite, THC-COOH, should be shown to be present in order to confirm drug use. The concentrations measured are very low, particularly for THC-COOH, which was identified in the picogram/milligram range.

The simple procedure to test for cannabinoids is as follows (from Cirimele *et al.* 1996b).

Decontamination

- Take a hair strand (~100 mg)
- Wash with 5 mL methylene chloride for 2 min
- Dry with adsorbent paper
- Wash again in 5 mL methylene chloride for 2 min.

Homogenisation

- Pulverise the sample in a ball mill for 10 min at 100 cycles/min.

Solubilisation

- Take 50 mg of powdered hair
- Add1 mL 1 mol/L NaOH plus 100 ng of deuterated THC
- Incubate for 10 min at 95°C.

Extraction

- Homogenise with 5 mL *n*-hexane–ethyl acetate (9 : 1, v/v)
- Agitate for 20 min at 95 cycles/min
- Centrifuge for 15 min at 3000 rpm
- Collect the organic phase and evaporate to dryness.

Analysis

- Dissolve the extract in 20 µL cyclohexane
- Inject a 1.5-µL portion in splitless mode into a HP5-MS capillary column (30 m × 0.25 mm)
- GC parameters:
  - Flow rate, helium N55: 1.0 mL/min
  - Injector temperature: 250°C
  - Temperature programme: 60°C for 1 min, to 295°C at 30°C/min for 6 min.

Analytical data The data are given in Table 19.3; ions with the *m/z* values shown in italic type are used for quantification.

Cannabinol	9.84	*295*, 310, 238

[a]From Cirimele *et al.* (1996b).

Benzodiazepines

Surprisingly, until 1995 the chromatographic detection of benzodiazepines, the most commonly used class of pharmaceuticals in the world, did not appear to be documented. Large series of results were obtained using incubation in buffer, such as Sörensen buffer (Cirimele *et al.* 1996a; Kintz *et al.* 1996). In the early stages of benzodiazepine determination, GC-MS in either electron impact (EI) or negative chemical ionisation (NCI) mode was used; however, to detect diazepam, nitrazepam, oxazepam or alprazolam, liquid chromatography with UV detection (HPLC-UV), gas chromatography with electron capture detection (GC-ECD) or liquid chromatography with diode array detection (HPLC-DAD), respectively, were employed. An extensive review of analytical procedures to test for benzodiazepines, particularly flunitrazepam, was published in 1998 (Sachs, Kintz 1998). As demonstrated by the quantitative levels found, benzodiazepine concentrations are generally low, in the picogram/milligram range. This is why today LC-MS (-MS) represents the state of the art for testing benzodiazepines in human hair.

As an example, the procedure for screening for most benzodiazepines is as follows (from Villain *et al.* 2005).

Decontamination

- Take a hair strand (~100 mg)
- Wash with 5 mL methylene chloride for 2 min
- Dry with adsorbent paper
- Wash again in 5 mL methylene chloride for 2 min.

Homogenisation

- Pulverise the sample in a ball mill for 10 min at 100 cycles/min.

Solubilisation

- Take 20 mg of powdered hair
- Add 1 mL phosphate buffer pH 8.4
- Add 5 ng of diazepam-d_5
- Incubate for 12 h at 40°C.

Extraction

- Homogenise using 5 mL diethyl ether–dichloromethane (80 : 20, v/v)
- Agitate on a horizontal shaker for 20 min at 95 cycles/min
- Centrifuge for 15 min at 3000 rpm
- Collect the organic phase and evaporate to dryness.

Analysis In the source paper (Villain *et al.* 2005), the residue was reconstituted by adding 50 µL of methanol. A 10-µL aliquot of the extract was injected onto the column (XTerra MS C_{18} 3.5 µm, 100 × 2.1 mm i.d.), protected by a 1-mm C_{18} frit. Each 20 min chromatographic run was carried out with a gradient (5% acetonitrile–95 % formic acid to 80 : 20 at 10 min), at a flow rate of 200 µL/min. The HPLC system was a Waters Alliance 2695.

Detection was carried out by a Micromass Quattro Micro tandem mass spectrometer equipped with an ion spray atmospheric pressure interface (APCI). The instrument was operated in the positive ionisation mode. Best results were obtained with a capillary voltage of 1 kV, source block temperature of 120°C and desolvation gas (N_2) heated to 350°C delivered at 550 L/h. Collision cell pressure was 300 Pa (3 mbar) of argon. Data were recorded in the multiple reaction monitoring (MRM) mode.

Analytical data The data are given in Table 19.4; ions with the *m/z* values shown in italic type are used for quantification.

Doping agents

Very few papers dealing with the identification of anabolic steroids in hair have been published and only a few studies are available (Kintz 1998; Rivier 2000). In a fatal case of a male bodybuilder who was known to abuse various anabolic steroids regularly and who died of cardiac infarction at the age of 32, testosterone esters, nandrolone decanoate, metenolone and metandienone were identified in hair (Thieme *et al.* 2000). In a forensic case involving French customs, two bodybuilders were arrested with 250 ampoules and more than 2000 tablets of anabolic steroids. In both subjects, hair tested positive for stanozolol (135 and

[a]Data from Villain *et al.* (2005).

156 pg/mg), nandrolone (196 and 260 pg/mg) and testosterone (46 and 71 pg/mg), clearly indicating chronic exposure to anabolic drugs (Kintz *et al.* 1999). During the last few years, various other performance-enhancing drugs have been identified in hair, such as β-adrenergic drugs (agonists and antagonists) (Machnik *et al.* 1999; Kintz *et al.* 2000b), ephedrine (Dumestre, Kintz 2000) and corticosteroids (Bévalot *et al.* 2000; Cirimele *et al.* 2000).

Miscellaneous drugs

Several other drugs have been identified and quantified in human hair samples, including antidepressant drugs, antiepileptics, neuroleptics, cardiovascular drugs, barbiturates, caffeine, phencyclidine, fentanyl, pentazocine, methadone, chloroquine, digoxin, buprenorphine (Tracqui *et al.* 1997), nicotine and fenfluramine (Kauert, Rohrich 1996; Sachs, Kintz 1998).

Little has been published concerning the analysis of pesticides in hair (Cirimele *et al.* 1999). This seems to be due to a lack of interest on the part of physicians.

Sectional analysis

Multisectional analysis involves taking a length of hair and cutting it into sections to measure drug use during shorter periods of time. The hair must be cut as close as possible to the scalp. Particular care is also required to ensure that the relative positions of the sections of cut hair are retained. The further away from the hair root, the more cautious the interpretation of the quantitative findings of the individual hair sections has to be. It has been claimed that this technique can be applied to provide a retrospective calendar of an individual's drug use. For example, one can perform multisectional analysis for people who test positive on an initial screen. This information can be used to validate an

individual's claim of prior drug use but of abstinence during the most recent several months. Baumgartner and colleagues have proposed that another use of such information is to compare the results with the individual's self-reported drug use history, to establish the level of denial prior to referring the individual to rehabilitation (Baumgartner *et al.* 1989). The most extensive study on sectional analysis for drugs of abuse involved patients in rehabilitation centres. Segmental hair analysis was used to verify both their previous drug history and their recent enforced abstinence. In cases where abstinence has been observed, the lowest drug concentrations are found in the segments nearest the root, thus confirming decreased drug use or recent abstinence. Abstinence from tobacco can be demonstrated by sectional analysis. The switch from heroin to another drug (codeine, ethylmorphine, dihydrocodeine) can be established with accuracy. Given the variation of hair growth rates and the long half-life of particular drugs (cannabinoids) that can be retained in the body for weeks or months after last use, results from a multisectional analysis should not be used to determine a precise period of drug abuse or to compare individuals.

Dose–concentration relationship

A critical question about hair analysis that remains controversial is the relationship between intake dose and resultant concentration in hair. In cases of chronic abuse, daily doses vary significantly from day to day, and the establishment of a dose–response relationship requires a large amount of data to take individual differences into consideration. Weak dose–concentration relationships can be explained by the following points: the drug dose of abusers is uncertain, the purity of illicit compounds is unknown and the uptake of the drug from blood to hair varies with the individual. On the other hand, some papers report that a significant dose–concentration relationship exists for digoxin, cocaine, phencyclidine, cannabinoids, morphine, meprobamate, haloperidol and amitriptyline. These results strongly suggest that a dose–response relationship exists between drug levels in hair and the administered dose, and this seems particularly true in controlled studies in which a drug was taken for the first time or under close supervision (Kintz 1996).

The possibility of ethnic/genetic bias due to differences in melanin concentrations or those due to hair porosity is still under discussion. Melanins are responsible for the colour of hair. Two types of melanin are present, eumelanin (with low sulfur content) and pheomelanin (with high sulfur content). Black and brown hair contain more eumelanin than red and blond hair. It appears that it is not simply the concentration of drugs in blood that determines the concentration in hair. Numerous factors may influence the incorporation of drugs into hair, such as the nature of the compound (pK_a, lipid solubility, metabolism pattern) and variation in hair growth cycles. Until these mechanisms are elucidated, the quantitative results and extrapolation to the amount of drug intake of such a hair analysis should be considered with extreme caution (Harkey *et al.* 1991; Nakahara *et al.* 1992).

Applications

Comparison with urine testing

There are essentially three types of problems with urinalysis drug testing: false positives when not confirmed with GC-MS, embarrassment associated with observed urine collection and evasive manoeuvres, including adulteration. These problems can be greatly mitigated or eliminated through hair analysis. It is normally possible to obtain a fresh, identical hair sample if there is any claim of a specimen mix-up or breach in the chain of custody. This makes hair analysis essentially fail-safe, in contrast to urinalysis, since an identical urine specimen cannot be obtained at a later date.

Another potential use of hair analysis is to verify accidental or unintentional ingestion of food or drink that has been laced with drugs. In case of a single exposure, the hair will not test positive using the Society of Hair Testing cut-offs. Ingestion of poppy seeds appears to be sufficient for the creation of a positive urine result, while ingestion of up to 30 g of poppy seeds did not result in a positive hair identification (H. Sachs, personal communication, 1994). Its greatest use, however, may be in identifying false negatives, since neither abstaining from a drug for a few days nor trying to 'beat the test' by diluting the urine will alter the concentration in hair. Urine does not indicate the frequency of drug intake in subjects who might deliberately abstain for several days before biomedical screening. While analysis of urine specimens cannot distinguish between chronic use or single exposure, hair analysis can make this distinction. Table 19.5 illustrates the differences between hair and urine analysis.

Table 19.5 Comparison between urine and hair

Parameter	*Urine*	*Hair*
Major compound	Metabolites	Parent drug
Detection period	2–5 days	Weeks, months
Type of measure	Incremental	Cumulative
Screening	Yes	Difficult
Invasiveness	High	Low
Storage	−20°C	Ambient temperature
Risk of false negative	High	Low
Risk of false positive	Low	Undetermined
Risk of adulteration	High	Low
Control material	Yes	Needed

Verification of history of drug use

By providing information on exposure to drugs over time, hair analysis may be useful in verifying self-reported histories of drug use in any situation in which a history of past, rather than recent, drug use is desired, such as in pre-employment and employee drug testing or patient compliance monitoring as required in therapeutic drug monitoring. In addition, hair analysis may be especially useful when a history of drug use is difficult or impossible to obtain, such as from psychiatric patients. During control tests of hair fragments, a drug addict will not be capable of hiding the fact of drug abuse. Hair analysis will even detect the case of an addict who takes drugs only every few days; this behaviour cannot be proved by means of urine and blood tests, even when the tests are repeated.

Determination of gestational drug exposure

Maternal drug abuse is a health hazard for the foetus, and the effects of cocaine, phencyclidine, nicotine and other compounds are well documented. In 1987, Parton and colleagues first reported quantitation of foetal cocaine exposure by RIA of hair obtained from 15 babies (Parton 1987). Others studies have demonstrated placental transfer of maternal haloperidol and the presence of nicotine, morphine, amfetamine and benzodiazepines in neonatal hair (Klein *et al.* 2000). It has been suggested that foetal accumulation of cocaine and its metabolites follows a linear pattern within the clinically used doses (Forman *et al.* 1992) and that there is a dose-dependent transfer of maternal nicotine to the baby (Kintz *et al.* 1993). Analysis of newborn hair may overcome the disadvantages of the methods currently used to verify drug abuse, such as maternal self-reported drug history, maternal urinalysis (risk of false negatives), and analysis of the urine or the meconium of the baby at time of delivery (risk of false negative information during the preceding 1–3 days).

Applications in forensic science

Numerous other forensic applications have been described in the literature where hair analysis was used to document the case: differentiation between a drug dealer and a drug consumer, chronic poisoning, crime under the influence of drugs, child sedation and abuse, suspicious circumstances associated with death, child custody, abuse of drugs in

jail, body identification, survey of drug addicts, chemical submission, obtaining a driving licence and doping control (Moeller *et al.* 1993; Sachs 1996a).

To date, more than 600 articles concerning hair analysis have been published reporting applications in forensic toxicology, clinical toxicology, occupational medicine and doping control. The major practical advantage of hair for testing drugs, compared with urine or blood, is its larger detection window, which is weeks to months, depending on the length of hair shaft analysed, versus a few days for urine. In practice, detection windows offered by urine and hair testing are complementary: urine analysis provides short-term information of an individual's drug use, whereas long-term histories are accessible through hair analysis. Although there is reasonable agreement that the qualitative results from hair analysis are valid, the interpretation of the results is still under debate because of some unresolved questions, such as the influences of external contamination or cosmetic treatment, and possible racial bias.

Specific problems associated with doping control using hair

Although hair is not yet recognised as a valid specimen by the International Olympic Committee (IOC) for sports testing, it is accepted in most courts of justice. The credibility of hair testing in sport has been associated with uncertainty because of some conflicting results observed, involving athletes who tested positive in urine in accredited IOC laboratories and negative in hair in forensic certified laboratories. A great deal of experience has been acquired in the detection of opiates and cocaine in hair. In contrast, there is a serious lack of suitable references with which to interpret the analytical findings for doping agents. In hair, doping agent concentrations, such as those of anabolic steroids, corticosteroids or β_2-agonists, are in the range of picograms/milligram, whereas cocaine, amfetamines and opiates are generally found in the range of several nanograms/milligram.

It is clear that there is a great deal of research to be performed before the scientific questions and curiosity surrounding hair drug testing is satisfied. Some of this uncertainty is due to a lack of consensus among the active investigators on how to interpret the results of an analysis of hair. Among the unanswered questions, five are of critical importance:

1. What is the minimal amount of drug detectable in hair after administration?
2. What is the relationship between the amount of the drug used and the concentration of the drug or its metabolites in hair?
3. What is the influence of hair colour?
4. Is there any racial bias in hair testing?
5. What is the influence of cosmetic treatments?

Several of these specific topics were addressed by Kintz *et al.* (2000a).

Alcohol abuse

Considering the large scale of alcohol-associated problems in society, the diagnosis of excessive alcohol consumption is an important task from a medical point of view. The methods used for this purpose are based on indirect alcohol markers such as increased liver enzyme activity (γ-GT or GPT), increased erythrocyte mean cell volume or the presence of carbohydrate-deficient transferrins, which can also originate from other pathological causes. Ethyl glucuronide, phosphatidylethanol and fatty acid ethyl esters (FAEEs) are all markers of ethanol consumption. The first investigations of a marker of alcohol consumption in hair were reported by Sachs and colleagues and focused on ethyl-glucuronide (Sachs 1997). Detection of ethyl glucuronide in hair is always associated with alcohol consumption, whereas a negative result does not unambiguously exclude alcohol abuse (Jurado *et al.* 2004; Yegles *et al.* 2004). Recently, new investigations on the FAEEs were proposed by Pragst and colleagues to monitor alcohol consumption (Pragst *et al.* 2001). FAEEs are formed in the presence of ethanol and free fatty acids, triglycerides, lipoproteins or phospholipids by a FAEE synthetase found in the liver as well as in hair roots. FAEE determination is of interest as the esters appear to be formed in cases of alcohol-induced organ damage. In blood, FAEEs can be used as a marker of an actual or recent alcohol intake at least 24 h after completion of alcohol intake. Hair concentrations of four FAEEs (ethyl myristate, ethyl palmitate, ethyl oleate and ethyl stearate) found in the hair of children, adult teetotallers and social drinkers in comparison with FAEE concentrations found in hair of alcoholics led the authors to conclude that FAEEs are suitable markers for the detection of heavy alcohol consumption. Segmental hair analysis in a case of alcohol withdrawal treatment showed a decrease in FAEE content from the distal to the proximal root segment (Pragst *et al.* 2001; Yegles *et al.* 2004).

Driving licence regranting

The major practical advantage of hair testing compared with urine and blood testing for drugs is the longer detection window, which is weeks to months depending on the length of the analysed hair shaft, against a few days for urine. It is generally agreed that the qualitative results obtained from hair analysis are valid and that long-term histories are accessible through hair analysis. This approach is being used in Italy and Germany in cases where applications are submitted for the regranting of driving licences after suspension (Sachs 1996b; Tagliaro *et al.* 2000). Persons whose driving licence has been refused, revoked or suspended for addiction to psychoactive drugs or for 'driving under the influence', and who claim to have quit all drugs of abuse, can obtain a licence after a medical committee has confirmed the actual and complete abstinence from illicit drugs and excluded any additional risk of future relapse of drug abuse. To provide objective evidence of abstinence from drugs with an acceptable chronological window in order to support the clinical decision of this medical committee, hair analysis has been included in a panel of clinical and laboratory tests aimed at investigating retrospectively the toxicological behaviour of subjects. Comparison between hair analysis and urinalysis shows a much higher diagnostic sensitivity for hair tests.

Drug-facilitated crime

The use of a drug to modify a person's behaviour for criminal gain is not a recent phenomenon. However, the recent increase in reports of drug-facilitated crimes (sexual assault, robbery, incapacity, etc.) has caused alarm in the general public. Drugs involved can be pharmaceuticals such as benzodiazepines (flunitrazepam, lorazepam), hypnotics (zopiclone, zolpidem), sedatives (neuroleptics, some anti-H_1) or anaesthetics (GHB, ketamine); drugs of abuse such as cannabis, ecstasy or LSD; or more often ethanol. Owing to their low dosage, except for GHB, a surreptitious administration into beverages such as coffee, soft drinks (cola) or even better alcoholic cocktails is relatively simple Most of these substances possess amnesic properties and the victims are therefore less able to accurately recall the circumstances under which the sexual offence occurred. As they are generally short-acting, they impair an individual rapidly. In these situations, blood or even urine can be of little interest. To address this important deficiency, hair was suggested as a valuable specimen in situations where, as a result of a delay in reporting the crime, natural processes have eliminated the drug from typical biological specimens. The use of LC-MS(-MS) today allows the detection of a single dose of most sedatives (Kintz *et al.* 2004; Villain *et al.* 2004a, 2004b).

Discrimination between a single exposure and long-term use can be documented by multisectional analysis. With the concept of absence of migration along the hair shaft, a single spot of exposure must be present in the segment corresponding to the period of the alleged event, using a growth rate for hair of 1 cm/month. As this growth rate can vary from 0.7 to 1.4 cm/month, the length of the hair section must be calculated accordingly. A delay of 3–5 weeks between the offence and hair collection for sectional analysis (2-cm segments) can be considered as satisfactory to have the hair shaft including the spot of exposure. The hair must be cut as close as possible to the scalp. Particular care is also required to ensure that the individual sections of the hair strand retain their relative positions.

Table 19.6 Recommended cut-off concentrations (when tested by GC-MS) and expected concentrations for drugs of abuse in hair

Drug	*GC-MS cut-off concentration*	*Expected concentrations*
Heroin	0.2 ng/mg for 6-acetylmorphine	0.5–100 ng/mg, in most cases <15 ng/mg
Cocaine	0.5 ng/mg for cocaine and 0.05 ng/mg for benzoylecgonine and cocaethylene	0.5–100 ng/mg, in most cases <50 ng/mg, in crack abusers >300 ng/mg is possible
Amfetamine, MDMA	0.2 ng/mg for both drugs	0.5–50.0 ng/mg
Cannabis	0.1 ng/mg for THC 0.2 pg/mg for THC-COOH	THC: 0.05–10 ng/mg, in most cases <3 ng/mg THC-COOH: 0.5–50 pg/mg, in most cases <5 pg/mg

MDMA, methylenedioxymethamfetamine; THC, tetrahydrocannabinol; THC-COOH, tetrahydrocannabinol-11-oic-acid.

Conclusions

The value of hair analysis for the identification of drug users is steadily gaining recognition. This can be seen from its growing use in pre-employment screening, in forensic sciences and in clinical applications. Hair analysis may be a useful adjunct to conventional drug testing in toxicology. Specimens can be more easily obtained with less embarrassment, and hair can provide a more accurate history of drug use.

Although there are still controversies about how to interpret the results, particularly concerning external contamination, cosmetic treatments, ethnic/genetic bias or drug incorporation, pure analytical work in hair analysis has reached a sort of plateau, having solved almost all the analytical problems.

GC-MS is the method of choice in practice, although GC-MS(-MS) and LC-MS(-MS) are today used in several laboratories, even for routine cases, particularly to target low-dosage compounds such as THC-COOH, fentanyl, flunitrazepam or buprenorphine. Electrophoretic/electrokinetic analytical strategies, chiral separation or application of ion mobility spectrometry constitute the latest new developments of the analytical tools reported to document drug testing in hair.

Today, quality assurance is a major issue of drug testing in hair. Since 1990, the National Institute of Standards and Technology (Gaithersburg, MD, USA) has developed inter-laboratory comparisons, more recently followed by the Society of Hair Testing (Strasbourg, France). The Society of Hair Testing has recommended cut-off concentrations (Table 19.6) together with the expected concentrations.

CHAPTER

20 Method Development and Validation

FT Peters

Introduction

Reliable analytical data are of utmost importance in the analysis of drugs and poisons. In drug registration, they support decision-making of pharmaceutical companies and regulatory authorities from pre-clinical phase I studies to post-registration bioequivalence studies. In therapeutic drug monitoring (TDM) and clinical and forensic toxicology, they are the prerequisite for the correct interpretation of the respective cases. In these areas, unreliable results might not only lead to wrong treatment of the patient but also have unjustified legal consequences for the defendant or be contested in court.

Reliable analytical methods are the basis for the acquisition of high-quality analytical results. Therefore, the quality of analytical methods must be ensured throughout their lifetime. In this continuous process of quality assurance, method validation stands at the pivotal point between method development and quality control (QC) during routine application of the final method. It includes all analytical experiments and statistical procedures required to demonstrate that a particular analytical method is reliable for the intended purpose. It is important to note that the method's inherent quality is a result of the method development process. Method validation can only objectively document this inherent quality but cannot enhance it.

This chapter gives an overview of general aspects of analytical method development and of the state of the art in analytical method validation. Experimental designs and statistical procedures for estimation of validation parameters will be presented and discussed, using examples from the literature where appropriate. Readers not familiar with basic statistical procedures are referred to the *Handbook of Chemometrics and Qualimetrics* (Massart *et al.* 1997) for further reading.

Method development

The most appropriate strategy for the development of an analytical method depends very much on the type and purpose of the method. It is obvious that there is a big difference between the development of an assay for determining the content of a pharmaceutical substance and an assay for determining ng/mL concentrations of a drug in a complex matrix such as blood, urine or hair. A detailed presentation and discussion of the best strategies for all or even only a few different method development situations is of course far beyond this chapter. However, there are some general principles that apply to many different situations and these are discussed below.

When developing a new analytical method, it is reasonable to first consider a number of factors relating to the analytical problem to be addressed, on the one hand, and different options of approaching the problem, on the other. As illustrated in Figure 20.1, these factors will influence the design of the new analytical method. In a first step, it is important to clearly define the analytical purpose, i.e. which analyte is supposed to be determined in which matrix and whether qualitative or quantitative analysis is required. It may seem trivial to define the analyte (s) and in fact it is, if only a single analyte is to be covered. However, in many situations it will be reasonable not to look at just one compound but also to include others related to the analytical problem to be addressed. This could involve impurities in an assay for a drug in pharmaceutical product, allowing assay and purity testing in one step. In clinical and forensic toxicology, it is often reasonable to include many or all compounds from one drug class in a single analytical method. This will allow application of the same method, if the presence of a compound from a certain drug class is suspected but it is not known exactly which one in particular. Moreover, this approach saves time and resources during method validation and routine QC, because calibrators and control materials containing all analytes have to be analysed only once rather than it being necessary to use a different method for each analyte. In analysis of pharmaceutical products, the matrix is predetermined by the product to be analysed. In bioanalytical methods to be used in pharmacokinetic, bioavailability and bioequivalence studies, the analytical matrix is generally blood plasma or serum. In analytical toxicology, however, the choice of an appropriate sample matrix is pivotal for successful application of the method in routine work. For example, whole blood or serum is generally the most appropriate matrix if the extent of impairment by certain drugs is to be estimated, but they would be poorly suited for the determination of drugs supposedly taken more than a couple of days or even weeks before. In the latter case, hair analysis is generally a more appropriate solution. For toxicological screening analysis, urine is usually the matrix of choice, because large sample volumes can be obtained non-invasively, most analytes are physiologically concentrated in urine and the presence of urinary metabolites can corroborate findings of the parent drug.

Once the analytical purpose has been defined, the separation and detection systems must be chosen. In a first step, it is reasonable to check whether one of the analytical methods already established in the laboratory can be adapted for the analysis of a new analyte with minor or major modifications. If this is not the case, the value of a thorough literature search can hardly be overestimated. Often, analytical methods for the same or structurally very similar analytes can be found in the literature. If identical analytical equipment is available, one of these methods may theoretically be used, but this is hardly ever the case in practice, at least in the author's experience. Nevertheless, methods from the literature are generally a good starting point for method development and often they can be established with a few modifications of equipment and analytical parameters. A point that should be considered when developing new methods is that there should always be a balance between the difficulty of an analytical problem and the equipment used. Expensive high-end equipment should be used only if required by the analytical problem.

When starting development of the separation system, a high analyte concentration may be used and hence highly sensitive detectors may not be needed at this stage. For example, separation systems for a liquid chromatography–(tandem) mass spectrometry (LC-MS)(-MS) method may well be developed on a high performance liquid chromatography (HPLC) system with UV detection, provided that the mobile phase buffers used are compatible with a later transfer to LC-MS(-MS). Once separation of the analyte(s) has been achieved, analyte concentrations corresponding to those expected in samples or extracts analysed in the final method should be used. If these can be detected with a simple low-cost detector, and the selectivity or identification power of the latter is sufficient for the intended analytical purpose, the development of sample preparation can continue. If not, the separation system should be coupled with a more sensitive/selective detector. After separation and detection have been established, the penultimate step of method development is sample preparation. This may involve pre-extraction steps such a homogenisation of tissue samples in postmortem toxicology or

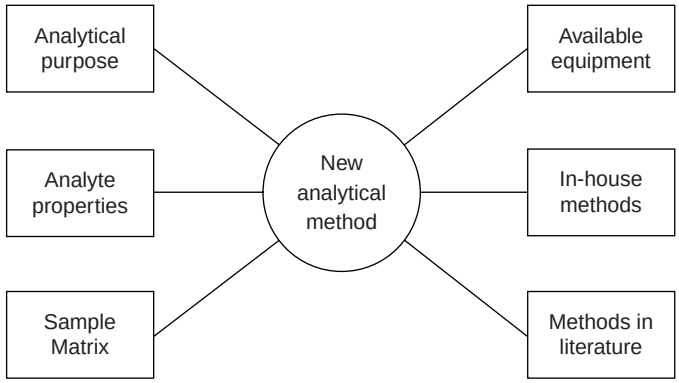

Figure 20.1 Factors to be considered in the development of a new analytical method.

cleavage of glucuronide metabolites present in urine samples. With respect to extraction, the most appropriate technique very much depends on the method's purpose. If a method is developed for systematic toxicological analysis, i.e. if it is supposed to cover a large number of compounds with a wide spectrum of physicochemical properties, then it is important to use a non-selective extraction technique, because part of the analytes might otherwise be lost during workup. If the method is developed for the analysis of a particular compound, or a class of compounds with similar physicochemical properties, differences between these properties and those of the matrix compounds may be exploited to achieve clean sample extracts. For example, basic drugs may be effectively isolated from blood plasma by solid-phase extraction (SPE) with a cation-exchange sorbent retaining the analytes while most matrix compounds can be washed from the extraction cartridges. Thereafter, the cleaned-up analytes can be eluted to yield very clean extracts.

The last step of method development is optimisation of the method. It may be necessary to modify chromatography to separate an analyte from a co-eluting matrix compound. Also, it may become necessary to increase the sensitivity of detection or the sample volume used for extraction to compensate for analyte loss during sample workup. The optimisation process should be continued until the results of the optimisation experiments strongly indicate that the final method is applicable for the intended purpose. Then, and only then, the final method should be taken to method validation.

Method validation

Analytical method validation is a process in which a series of validation experiments are performed and (statistically) evaluated to objectively demonstrate the method's applicability for the intended purpose. Since the type and extent of validation experiments depend very much on the purpose of the method, various guidance documents specifically addressing analytical method validation in different fields of analysis have been issued by various organisations.

Guidelines and literature on validation

The most widely accepted guidance documents on validation of methods in pharmaceutical analysis of drugs, drug preparations or drug products (henceforth called pharmaceutical analysis) were developed by the International Conference on Harmonisation of Technical Requirements for Registration of Pharmaceuticals for Human Use (ICH) and approved by the regulatory agencies of the European Union, the United States of America and Japan. The first, approved in 1994, concentrated on the theoretical background and definitions (ICH Topic Q2A 1994). The second, approved in 1996, on methodology and practical issues, concerned validation of methods used to acquire data for drug approval submissions (ICH Topic Q2B 1996). In 2005, the second document was incorporated into the first, resulting in the current guidance document Q2(R1) *Validation of Analytical Procedures: Text and methodology* (ICH Topic Q2(R1) 2005), which addresses validation of the following types of analytical methods: identification tests, quantitative tests for impurities content, limit tests for the control of impurities, and quantitative tests of the active moiety in samples of drug substance or drug product or other selected component(s) in the drug product. It can be downloaded from the ICH homepage free of charge (www.ich.org). Very helpful guidance on the validation of high performance liquid chromatography methods for analysis of pharmaceutical products can also be found in a review article by Epshtein (2004).

The validation of bioanalytical methods for bioavailability, bioequivalence and pharmacokinetic studies (henceforth called pharmacokinetic studies) was extensively discussed by experts from the pharmaceutical industry and regulatory authorities during a conference on 'Analytical Methods Validation: Bioavailability, Bioequivalence and Pharmacokinetic Studies' held in Washington DC in 1990. The consensus of this conference was summarised in a report by Shah *et al.* (1991) (Conference Report I), which soon became one of the most important guidance papers in the field of drug analysis in biological matrices. Ten years later, the experience and progress since the first conference were discussed in the first follow-up workshop 'Bioanalytical Method Validation – A Revisit with a Decade of Progress', the results of which were published in a report by (Shah *et al.* 2000) (Conference Report II). Like the previous document, this report set the standard for bioanalytical method validation in the area of drug registration studies; its impact is underlined by the fact that it was used as a template for the respective regulatory guidance for the pharmaceutical industry published by the US Food and Drug Administration (FDA) that is still valid today (FDA 2001). In 2007, the second follow-up workshop 'Quantitative Bioanalytical Methods Validation and Implementation: Best Practices for Chromatographic and Ligand Binding Assays' was held. This workshop focused mainly on ligand-binding assays used in the analysis of macromolecular drugs, but also dealt with topics relevant to validation of analytical methods for analysis of low-molecular-weight drugs and poisons. Analysis of incurred samples (biological samples from persons or animals after the administration of a drug), carryover issues, and the evaluation of matrix effects in the validation of methods employing LC-MS(-MS) were the most important topics in this respect. The outcome of this workshop was reported by Viswanathan *et al.* (2007) (Conference Report III) and it can be expected that this paper will have as much impact as the two previous documents. In an excellent review on the validation of bioanalytical chromatographic methods, Hartmann *et al.* provided not only a detailed overview and critical discussion of Conference Report I and related papers, but also helpful information on the design of validation experiments and statistical analysis of the analytical results (Hartmann *et al.* 1998).

In the field of analytical toxicology, no widely accepted validation guideline currently exists. Specific guidance documents on the validation of analytical methods have been published by the Gesellschaft für Toxikologische und Forensische Chemie (GTFCh) (Peters *et al.* 2009) and by the Société Française de Toxicologie Analytique (SFTA) (Nicolas *et al.* 2004), but their widespread use is hampered by the fact that they are currently available only in German and French, respectively. Besides these validation guides, The International Association of Forensic Toxicologists (TIAFT) (De Zeeuw *et al.* 1994) and the Society of Forensic Toxicology/American Academy of Forensic Sciences (SOFT/AAFS) (SOFT/AAFS Guidelines Committee 2006) have published laboratory guidelines aimed at ensuring the high quality of routine toxicological analyses. Both of these documents acknowledge the need for method validation, but apart from listing the parameters that should be evaluated they contain only little or no specific information or acceptance criteria that might be used as guidance in a validation study. Owing to this lack of widely accepted guidance documents for the validation of bioanalytical methods in analytical toxicology and because of the close relationship to bioanalysis in the context of bioavailability, bioequivalence and pharmacokinetic studies, many toxicologists have validated their bioanalytical methods according to the recommendations of Conference Reports I and II (Shah *et al.* 1991, 2000), which have

also clearly influenced the guidance documents of the GTFCh (Peters *et al.* 2009) and SFTA (Nicolas *et al.* 2004). Specific aspects of method validation in forensic and clinical toxicology have also been covered in two review articles and a book chapter by Peters and colleagues (Peters, Maurer 2002; Peters 2006; Peters *et al.* 2007a).

In addition to the above-mentioned documents and reviews, several other guidance papers on analytical methods have been published by various organisations. Although these documents do not have a particular focus on the analysis of drugs and poisons, they are worth considering in the context of analytical method validation. The EURACHEM guide *The Fitness for Purpose of Analytical Methods* published in 1998 (EURACHEM/CITAC 1998) provides definitions of validation parameters as well as useful practical guidance on performance and evaluation of validation experiments. It is available free of charge on the EURACHEM website (www.eurachem.org). More recently, the International Union of Pure and Applied Chemistry (IUPAC), the International Organization for Standardization (ISO) and the Association of Official Analytical Chemists (AOAC) developed a *Harmonized Guideline for Single-Laboratory Validation of Methods of Analysis* (Harmonized Guide) (Thompson *et al.* 2002). It provides guidance on principles of method validation, but practical aspects such as experimental designs are not included. Analytical method validation in general has been focused on two further review articles. One, by Taverniers *et al.* (2004), gives an excellent overview on the position of analytical method validation in the greater context of QC, accreditation and proficiency testing. This paper includes a table listing definitions, expressions (calculations), requirements for acceptance and practical assessment (experimental design) for the most important validation parameters. The other focuses on validation of qualitative analytical methods (Trullols *et al.* 2004).

A common drawback of many validation guidelines is that they often address general concepts and acceptance criteria rather than providing detailed guidance on how to perform and evaluate validation experiments. In order to overcome this problem, the Société Française des Sciences et Techniques Pharmaceutiques (SFSTP) has issued guidance documents specifically addressing experimental designs and statistical concepts in establishing quantitative parameters in analytical method validation (Hubert *et al.* 2003, 2006). Most importantly, it proposes combining bias and precision into so-called accuracy profiles as opposed to their separate consideration (see below). The concept described is not limited to a particular field of analytical chemistry but can rather be seen as an integrative approach that is in line with the majority of the above-mentioned validation guidelines. Hence, it is a valuable tool for all analysts looking for practical and statistically sound guidance on how to design and evaluate their validation experiments. The document itself is available only in French, but the concepts have been described and discussed extensively in English in several articles that may be used as guidance by analysts not speaking French (Boulanger *et al.* 2003; Hubert *et al.* 2004, 2007a,b; Rozet *et al.* 2007).

Validation parameters

Which validation parameters have to be evaluated depends on the purpose of the analytical method. The validation parameters to be evaluated for different types of analytical methods in pharmaceutical analysis according to ICH (ICH Topic Q2(R1) 2005) are reported in Table 20.1.

Bioanalytical methods in drugs analysis are generally used for identification and/or quantification of drugs, poisons and/or their metabolites in biological fluids or tissues. For quantitative bioanalytical procedures, there is general agreement that at least the following validation parameters should be evaluated: selectivity, calibration model (linearity), stability, accuracy (bias and precision) and the lower limit of quantification (LLOQ). Additional parameters that might have to be evaluated include the limit of detection (LOD), recovery, reproducibility and ruggedness (robustness) (Shah *et al.* 1991, 2000; De Zeeuw *et al.* 1994; Hartmann *et al.* 1998; Peters *et al.* 2007a, 2009; Viswanathan *et al.* 2007).

Table 20.1 Parameters to be evaluated depending on the type of analytical procedure according to the ICH (ICH Topic Q2(R1) 2005)

Parameter	*Type of analytical procedure*			
	Identification	*Testing for impurities*		*Assay (dissolution, content)*
		Quantitative	*Limit test*	
Bias	−	+	−	+
Precision				
Repeatability	−	+	−	+
Intermediate precision	−	+	−	+
Selectivity/specificity	+	+	+	+
Limit of detection (LOD)	−	−	+	−
Lower limit of quantification (LLOQ)	−	−[(a)]	−	−
Linearity	−	+	−	+
Range	−	+	−	+

[(a)]May be needed in some cases.

Qualitative bioanalytical methods are often used in forensic and clinical toxicology, especially for so-called systematic toxicological analysis. A general validation guideline is currently not available for such qualitative procedures (Trullols *et al.* 2004). However, there seems to be agreement that at least selectivity and the LOD should be evaluated and that additional parameters such as precision, recovery and ruggedness (robustness) might also be important (Jimenez *et al.* 2002; Rivier 2003; Trullols *et al.* 2004).

Nowadays, LC-MS(-MS) is by far the most widely employed technique for the quantitative analysis of drugs and/or their metabolites in the context of pharmacokinetic studies. It is also of tremendous and still increasing importance in TDM as well as forensic and clinical toxicology. The most important drawback of this analytical technique is the problem of so-called matrix effects, i.e. ion suppression or enhancement, which must therefore be adequately covered in the validation of any LC-MS(-MS) method, particularly of those employing electrospray ionisation (ESI) (Shah *et al.* 2000; Annesley 2003; Matuszewski *et al.* 2003; Maurer 2005; Taylor 2005; Viswanathan *et al.* 2007).

Before moving on to detailed discussions of the various validation parameters, it must be pointed out that in the literature on method validation different sets of terminology have been employed by different guidelines and authors. This may lead to confusion and misunderstandings. A detailed discussion of this topic is beyond the scope of this chapter but can be found in the review of Hartmann *et al.* (1998).

Selectivity (specificity)

In Conference Report II (Shah *et al.* 2000), selectivity was defined as 'the ability of the bioanalytical method to measure unequivocally and to differentiate the analyte(s) in the presence of components which may be expected to be present. Typically, these might include metabolites, impurities, degradants, matrix components, etc.'. This definition is very similar to that used in the ICH document (ICH Topic Q2(R1) 2005), although that used the term specificity rather than selectivity. At this point it should be noted that specificity is often used interchangeably with selectivity, although in a strict sense specificity refers to methods that produce a response for a single analyte, whereas selectivity refers to methods that produce responses for a number of chemical entities, which may or may not be distinguished (Karnes *et al.* 1991). Selective multi-analyte methods (e.g. for the analysis of different drugs in blood) should of course be able to differentiate all interesting analytes from each other and from the matrix. One approach to establishing method selectivity is to prove the lack of response in blank matrices, i.e. that there are no signals interfering with the signal of the analyte(s) or the internal

standard (IS) (Shah *et al.* 1991, 2000; Hartmann *et al.* 1998; Taverniers *et al.* 2004; Peters *et al.* 2007a). The second approach is based on the assumption that, for merely quantitative procedures, small interferences can be accepted as long as accuracy (bias) and precision at the LLOQ remain within certain acceptance limits (EURACHEM/CITAC 1998; Hartmann *et al.* 1998; Thompson *et al.* 2002; Taverniers *et al.* 2004). This is usually the case in pharmaceutical analysis, TDM or pharmacokinetic studies. However, in forensic and clinical toxicology, analysis is often mainly performed to prove the intake of an (illicit) substance and qualitative data are therefore also important. Here, the approach to proving selectivity by absence of interfering signals seems much more reasonable (Peters, Maurer 2002; Peters *et al.* 2007a).

Establishing selectivity by demonstrating absence of interfering signals The selectivity experiments should be performed very early in the validation study, when it is still possible to switch back to the development phase without having spent a lot of time and expense on further validation experiments.

In pharmaceutical analysis, demonstration of the absence of interfering signals can be used to establish selectivity of identification and impurity tests (Epshtein 2004; ICH Topic Q2(R1) 2005). The aim is to demonstrate that other compounds likely to be present in the samples to be analysed do not interfere with the compound of interest. If the potentially interfering compounds (impurities and/or excipients) are available, appropriate concentrations of the compounds of interest should be analysed. Sufficient separation of the latter from the spiked impurities/excipients demonstrates sufficient selectivity/specificity. If potentially interfering impurities are not available, samples stored under stress conditions, i.e. exposure to light, heat, humidity, acid/base hydrolysis and oxidation, should be included in the selectivity studies. Such samples might be expected to contain at least a certain amount of impurities that may be formed during storage of real samples and hence may be used to study impurity profiles and their potential interference with the analytes of interest (Epshtein 2004; ICH Topic Q2(R1) 2005).

In bioanalysis, absence of interference from other compounds is much more complex, because not only endogenous matrix compounds but also co-ingested exogenous compounds and/or their metabolites may interfere with the analyte(s) of interest. The requirement established by Conference Report I (Shah *et al.* 1991) to analyse at least six different sources of blank matrices has become state of the art during the last decade and this number has been used in the validation of many published bioanalytical methods. However, Hartmann *et al.* (1998) stated from statistical considerations that, with analysis of such a small number of matrix blanks, relatively rare interferences will remain undetected with a rather high probability. For the same reason, Dadgar and colleagues (Dadgar, Burnett 1995) proposed the evaluation of at least 10–20 sources of blank samples, which seems to be a good compromise between reducing the workload during method validation and lowering the risk of unexpected interferences during routine application. In Conference Report II (Shah *et al.* 2000), however, the required number of matrix sources was even reduced to a single source for methods using hyphenated mass spectrometric methods such as LC-MS(-MS) for detection. This confinement does not seem reasonable for toxicological applications because of the great importance of selectivity in this field. Furthermore, it increases the risk of falsely assuming sufficient selectivity of the tested procedure. Some working groups, including the author's, have taken such considerations into account and checked matrix samples from at least 10 or even 20 sources for absence of interfering matrix peaks (Peters *et al.* 2003, 2007b; Pichini *et al.* 2003; Sottani *et al.* 2003; Kratzsch *et al.* 2004; Maurer *et al.* 2004).

In contrast to samples from pharmacokinetic studies, where usually only a single drug or a very limited number of drugs are administered under controlled conditions, samples from forensic or clinical toxicology cases often contain many different drugs, poisons and/or their metabolites. In this field, it is therefore also important to check for possible interferences from other xenobiotics that may be expected to be present in authentic samples (Peters, Maurer 2002). This can be accomplished by analysing blank samples spiked with possibly interfering compounds at their highest expectable concentrations. The number and type of compounds to be used in such spiking experiments depend on the purpose of the procedure. For example, Pichini *et al.* (2003) checked interference from various amfetamines, cannabinoids, benzodiazepines and antidepressants (altogether 23 compounds) during the selectivity experiments of an assay for the determination of opiates and cocaine in meconium. Crommentuyn *et al.* (2004) studied possible interference from over 30 often coadministered drugs in an assay for atazanavir and tipranavir, two human immunodeficiency virus (HIV) protease inhibitors used in the treatment of acquired immune deficiency syndrome (AIDS). At first sight, this may look exaggerated, but it is not, considering that the treatment of AIDS usually involves at least three different anti-HIV drugs and coadministration of further drugs is the rule rather than the exception. In addition, spiking mixtures of possibly interfering compounds rather than single compounds allows effective simultaneous investigation of interference from many compounds, while the workload is kept at a minimum.

Another way to exclude interference from other drugs or their metabolites is to check authentic samples containing these, but not the analyte of interest. This approach is preferable if the possibly interfering substance is known to be extensively metabolised as it also allows for exclusion of interferences from such metabolites, which are usually not available as pure substances. An example can be found in Streit *et al.* (2004), which describes an assay for the immunosuppressant mycophenolic acid. Here, the authors used 30 samples from transplant recipients not treated with mycophenolic acid but treated with a number of other immunosuppressive drugs and other drugs commonly prescribed in transplant recipients.

It must be noted that metabolites of the target analyte can also be an important source of interference. This is of particular relevance for methods employing less selective detectors such as ultraviolet/visual wavelength (UV/VIS) or diode array detection (DAD), because metabolites with an unchanged chromophore often have spectral properties very close to those of the parent drug. However, interference from metabolites may also occur in highly selective LC-MS(-MS) analysis, because metabolites that are in principle amenable to this type of analysis, such as glucuronides or *N*-oxides, can convert back to the parent drug by in-source collision-induced dissociation (CID) and thus lead to cross-talk in the channel of the parent drug (Ackermann *et al.* 2002; Jemal *et al.* 2002; Sun, Naidong 2003; Zhang *et al.* 2004). Similarly, labile prodrugs may be converted to the active metabolite, in this case the target analyte, by in-source CID and lead to cross-talk in the metabolite channel. As such phenomena occur only when there is insufficient separation between the respective compounds, they can be avoided by optimising the chromatographic conditions. However, this type of interference must be detected in the first place to be avoided. If the metabolite is available, this can be achieved by spiking experiments as described above. If not, the only way to check for this type of interference is by the analysis of incurred samples, i.e. samples from persons (or animals) who have ingested the parent drug (Jemal *et al.* 2002; Sun, Naidong 2003). A useful strategy for performance of such studies is presented in Jemal *et al.* (2002).

Stable-isotope-labelled analogues of the target analytes are often used as the internal standard (IS) in MS-based methods. Owing to their similar physicochemical properties, they can ideally compensate for variability during sample preparation and measurement but can still be differentiated from the target analyte by mass spectrometric detection. However, isotopically labelled compounds may contain the non-labelled compound as an impurity, or their mass spectra may sometimes contain fragment ions with the same mass-to-charge ratios (m/z) as the monitored ions of the target analyte. In both cases, the peak area of the analyte peak would be overestimated, thus compromising quantification. The absence of such interference caused by the IS can be checked by analysing so-called zero samples, i.e. blank samples spiked with the IS, as exemplified in Janda *et al.* (2002), Peters *et al.* (2003), de Jonge *et al.* (2004), Kratzsch *et al.* (2004) and Zhang *et al.* (2004). The importance of this is underlined by the findings of Janda *et al.* (2002), who found a low signal of non-labelled ethyl glucuronide in a blank hair sample spiked only with ethyl glucuronide-d_5, most probably caused by traces of the non-labelled drug in the stable-isotope-labelled standard. These authors

stated that it may be useful to reduce the total amount of IS to eliminate this interference.

In a similar way to that described above, the analyte might interfere with a stable-isotope-labelled IS. This can become a problem even with deuterated analogues when the number of deuterium atoms of the analogue or one of its monitored fragments is three or less (Bogusz 1997). Blank samples spiked with the analyte at the upper limit of the calibration range, but without IS, can be used to check for absence of such interferences (Zhang *et al.* 2004).

Establishing selectivity by acceptable bias and precision data In the ICH guideline (ICH Topic Q2(R1) 2005), this approach is recommended for assay and impurity tests. If potentially interfering compounds are available, the compound of interest can be analysed in the presence and absence of appropriate concentrations of the potentially interfering compounds and the results can be compared. If they do not show relevant differences, the analytical method can be considered sufficiently selective. If potentially interfering compounds for such spiking experiments are not available, the quantitative results obtained with the method to be validated can be compared with results obtained with an established validated method, e.g. from a pharmacopoeia. Such studies should also include samples previously stored under stress conditions (see previous section). If the results obtained with the method to be validated are in good agreement with those of the alternative method, sufficient selectivity can be assumed.

In bioanalysis, the approach of establishing selectivity by acceptable bias and precision was preferred by Dadgar and Burnett (1995) and Hartmann *et al.* (1998). These authors proposed the analysis of up to 20 different blank samples spiked with analyte at the LLOQ and with possibly interfering compounds at their highest likely concentrations, if available. In this approach, the method can be considered sufficiently selective if precision and accuracy (bias) data for these LLOQ samples are acceptable. For a detailed account of experimental designs and statistical methods for establishing selectivity, see Dadgar and Burnett (1995).

An important disadvantage of this approach is that it requires quantification and can therefore be performed only in the main validation phase. If the selectivity of the method is found to be insufficient at this late stage of validation, the method needs further development and validation experiments may have to be repeated. In their spiking experiments discussed above Crommentuyn *et al.* (2004) used an intermediate approach and defined the maximum acceptable area of interfering peaks to be 20% of the peak area of the analyte at the LLOQ. This semiquantitative approach can be used in the early phases of validation, because it requires no calibration or precision estimate.

Calibration model (linearity)

The choice of an appropriate calibration model is necessary for reliable quantification. Therefore, the relationship between the concentration of analyte in the sample and the corresponding response (in bioanalytical methods mostly the area ratio of analyte versus IS) must be investigated. The range of the calibration curve depends on the purpose of the analytical method. In pharmaceutical analysis, the ranges should be: 80–120% of the test concentration in the analysis of drugs or drug products; from 70% to 130% for methods to be used in content uniformity testing; ±20% of the specified range for methods to be used in dissolution testing of drug products; and from the reporting level to 120% of the specification in quantitative impurity testing (ICH Topic Q2(R1) 2005). In bioanalysis, the calibration range should cover the majority of concentrations to be expected in the samples to be analysed. This might be the concentration range expected after a certain dosage in pharmacokinetic studies, the therapeutic concentration range of the respective drug in TDM, or even wider ranges for methods to be used for quantitative analysis in clinical or forensic toxicology.

The calibration curve can be established by analysing (spiked) calibration samples and plotting the resulting responses versus the corresponding concentrations. A plot of an exemplary dataset and the corresponding calibration line obtained from simple linear regression is shown in Figure 20.2a. The resulting standard curves can then be further evaluated by graphical methods such as residual plots or by mathematical methods. The latter also allow statistical evaluation of the response functions. Residuals are the deviations of the observed values from the values predicted by the applied calibration model. They can be calculated according to equation (20.1). In residual plots, these residuals are plotted against the respective concentrations, which ideally results in a random distribution of residuals around zero. A residual plot corresponding to the calibration plot in Figure 20.2a is shown in Figure 20.2b. The plotted residuals are clearly not ideally distributed; the reasons for this phenomenon will be discussed below.

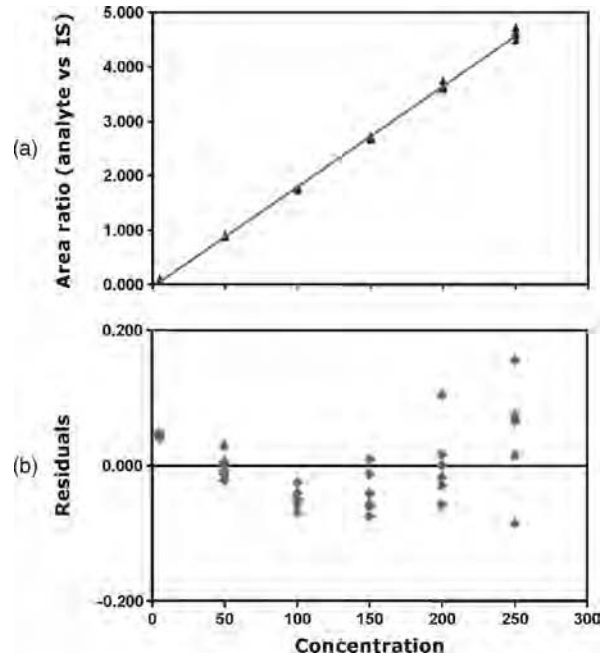

Figure 20.2 Regression plot of an exemplary data set with calibration curve calculated using simple linear regression (a) and the corresponding residual plot (b).

$$e_{ij} = y_{ij} - \widehat{y_j} \tag{20.1}$$

where e_{ij} = the ith residual at the jth concentration level; y_{ij} = the ith observed value at the jth concentration level; $\widehat{y_j}$ = the predicted value at the jth concentration level.

There is general agreement that, for bioanalytical methods, calibrators should be matrix-based – i.e. prepared by spiking the blank matrix – and that calibrator concentrations must cover the whole calibration range (Dadgar *et al.* 1995; Hartmann *et al.* 1998; Lindner, Wainer 1998; Shah *et al.* 2000; Peters *et al.* 2007a). However, recommendations on how many concentrations should be studied with how many replicates per concentration differ significantly in the literature on analytical method validation (Dadgar *et al.* 1995; EURACHEM/CITAC 1998; Hartmann *et al.* 1998; Lindner, Wainer 1998; Shah *et al.* 2000; Thompson *et al.* 2002; Taverniers *et al.* 2004; Peters *et al.* 2007a). In Conference Report II (Shah *et al.* 2000), 'a sufficient number of standards to define adequately the relationship between concentration and response' was demanded. Furthermore, it was stated that at least five to eight concentrations should be studied for linear and maybe more for non-linear relationships. However, no information was given on how many replicates should be analysed at each level. The guidelines established by the ICH (ICH Topic Q2(R1) 2005) also required at least five concentrations, but again no specific requirements for the number of replicates at each level were given. In the validation guide by EURACHEM (EURACHEM/CITAC 1998) and in the Harmonized Guide (Thompson *et al.* 2002), at least six concentrations are stipulated. The latter has further specified that the concentrations should be evenly spaced over the concentration range and that at least two and preferably three or more replicates should be

analysed at each concentration (Thompson *et al.* 2002). On the basis of studies by Penninckx *et al.* (1996), Hartmann *et al.* (1988) proposed in their review to use rather fewer concentrations with a greater number of replicates, e.g. four evenly spread concentrations with nine replicates, in order to achieve more reliable variance estimations while still having enough concentrations for a preliminary indication of possible non-linearity. These different recommendations probably explain why almost every thinkable combination of concentrations and replicates per concentration has been used for individual assays in the literature. However, two important points need to be considered. First, with a decreasing number of concentrations, the evaluation of non-linear models becomes increasingly unreliable and, thus, their evaluation requires more concentrations than for linear models (Shah *et al.* 1991, 2000; Penninckx *et al.* 1996; Hartmann *et al.* 1998). Second, assessing the behaviour of variance across the calibration range becomes increasingly difficult with a decreasing number of replicates (Penninckx *et al.* 1996).

The initial step of studying the calibration function is to check for outliers. This can first be done visually, e.g. by evaluation of residual plots. In Figure 20.2b, the highest data point of the second highest concentration level might be suspected to be an outlier. Such suspected outliers should be checked by appropriate statistical procedures such as the Grubbs test, and eliminated if found to be significant. The suspected outlier in Figure 20.2b was found to be not significant and was left in the dataset. The presence of more than two outliers in a complete data set of a calibration model experiment may indicate serious problems with the method that require further investigation (Penninckx *et al.* 1996).

The next step is to check for homogeneity of variance (homoscedasticity) over the calibration range. Again, this can first be done visually using residual plots. For example, in the residual plot in Figure 20.2b, one can clearly see that the scatter of the replicates increases with concentration, indicating inhomogeneous variances (heteroscedasticity) over the calibration range. In such cases, homoscedasticity should be checked by an appropriate statistical procedure, e.g. by a simple one-sided *F*-test between the variances at the highest and the lowest concentration levels. For a more detailed account and alternative statistical procedures, see Penninckx *et al.* (1996).

The evaluation of the behaviour of variance is very important for the choice of the correct regression model. Ordinary least-squares regression models are applicable only for homoscedastic datasets, whereas in a case of heteroscedasticity the data should mathematically be transformed or a weighted least-squares model should be applied (Penninckx *et al.* 1996; EURACHEM/CITAC 1998; Hartmann *et al.* 1998; Shah *et al.* 2001; Thompson *et al.* 2002). It should be noted that, for calibration ranges spanning more than one order of magnitude, heteroscedasticity is the rule rather than the exception. Regarding the usually wide concentration range of assays used in analytical toxicology or in the area of pharmacokinetics, it is not surprising that weighted regression models have been used in the vast majority of the validated bioanalytical assays published in the scientific literature. The weighting factors $1/x$ and $1/x^2$, i.e. the inverse of the concentration or the inverse of the squared concentration, respectively, are by far the most often used. Only few authors have used $1/y$ or $1/y^2$, i.e. the inverse of the response or the inverse of the squared response, respectively.

Theoretically, the suitability of a weighting factor can easily be checked by comparing the variances of the weighted residuals. Figure 20.3a shows the calibration line obtained by weighted linear regression with the weighting factor $1/x^2$ of the same data as in Figure 20.2. Figure 20.3b shows the corresponding plot of the weighted residuals. It can clearly be seen that the scatter of the weighted residuals is comparable at all concentration levels, indicating that the weighting factor used was appropriate. Such a finding can again be tested statistically by performing an *F*-test on the variances of the weighted residuals at the highest and lowest concentrations. However, some authors chose the weighting factor in a more practical way (Pereira *et al.* 2000; Breda *et al.* 2004; de Jonge *et al.* 2004). They evaluated alternative weighting schemes and back-calculated the concentrations of the calibrators using the respective regression models. Then they added the relative deviations of these back-calculated values from the nominal values and chose the weighting scheme as the most appropriate with which the smallest total relative deviation had been obtained.

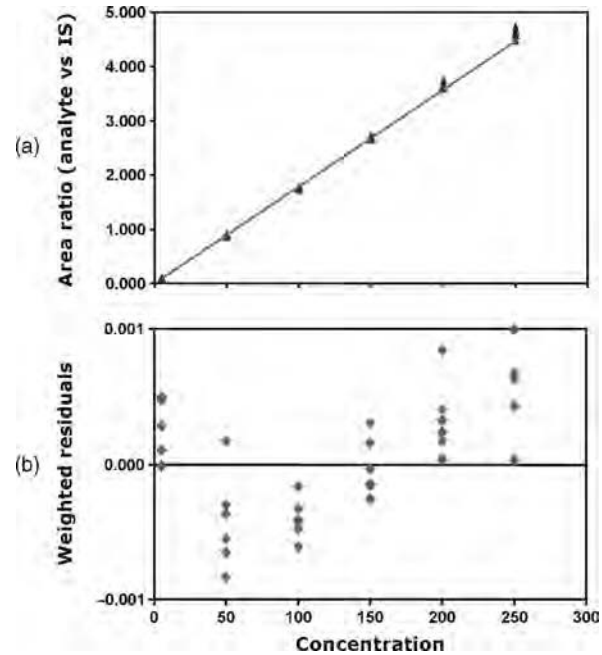

Figure 20.3 Regression plot of an exemplary data set with calibration curve calculated using a weighted ($1/x^2$) linear regression model (a) and the corresponding plot of the weighted residuals (b).

After significant outliers have been purged from the dataset and, if applicable, an appropriate weighting factor for regression has been found, a mathematical model has to be found that adequately describes the relationship between analyte concentration in the sample and response. Usually, linear models are preferable, but, if necessary, the use of non-linear models is not only acceptable but even recommended. Examples of the use of second-order polynomial (quadratic) (Chang *et al.* 1999; Jemal *et al.* 1999; Mortier *et al.* 2002b; Li *et al.* 2004) and more complicated non-linear regression models (Egge-Jacobsen *et al.* 2004) have been described in the literature. The model-fit can again first be evaluated visually using residual plots. For example, the plot of weighted residuals in Figure 20.3b corresponds to a weighted linear regression model applied to the same data as in Figure 20.2. One can see that the residuals at the lowest and the two highest concentration levels are above the zero line, while the majority of those at the intermediate concentration levels are below the zero line. Such patterns are typically obtained when linear models are fitted into curved datasets. This indicates that, in the example presented, a non-linear model might be more appropriate to describe the data. In any case, the model-fit should also be tested by appropriate statistical methods (Shah *et al.* 1991, 2000; Penninckx *et al.* 1996; Hartmann *et al.* 1998; Thompson *et al.* 2002; ICH Topic Q2(R1) 2005). For example, the fit of simple regression models (homoscedastic data) can be tested by the analysis-of-variance (ANOVA) lack-of-fit test (Penninckx *et al.* 1996; Hartmann *et al.* 1998). Testing the fit of weighted regression models is somewhat more complicated. For example, deviation from a weighted linear model can be tested by evaluation of an alternative weighted second-order regression model. If the quadratic term describing the curvature of the second-order model is significantly different from zero, non-linearity has to be assumed. Such significant non-linearity was also found for the data in Figure 20.3. The regression line of the alternative second-order model and the corresponding plot of the weighted residuals are shown in Figure 20.4a and 20.4b, respectively. It can be seen that the weighted residuals are now randomly distributed around zero, indicating that the weighted second-order model adequately describes the dataset. A detailed discussion of alternative statistical procedures for testing the model-fit of both unweighted and weighted calibration models can be found in Penninckx *et al.* (1996).

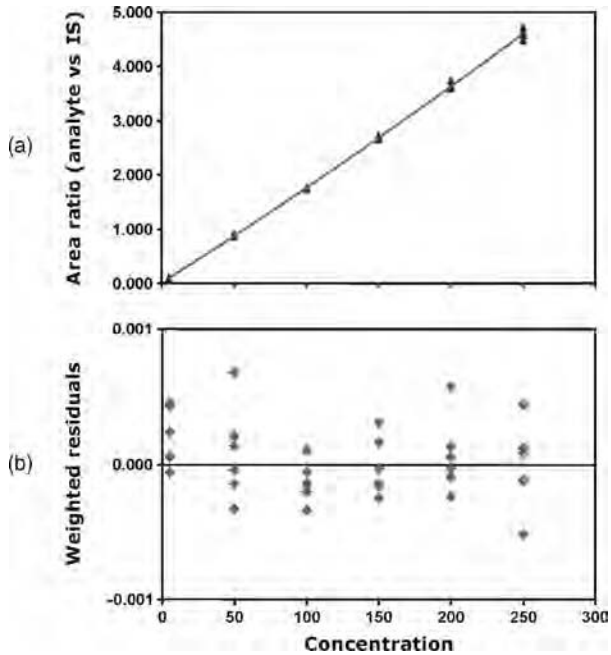

Figure 20.4 Regression plot of an exemplary data set with calibration curve calculated using a weighted ($1/x^2$) second-order regression model (a) and the corresponding plot of the weighted residuals (b).

The widespread practice of evaluating a calibration model via its coefficients of correlation or determination is not acceptable from a statistical point of view (Hartmann *et al.* 1998; Hubert *et al.* 2007b).

One important point should be kept in mind when statistically testing the model fit: the better the precision of a method, the higher the probability of detecting a statistically significant deviation from the assumed calibration model (Hartmann *et al.* 1998). Therefore, the practical relevance of the deviation from the assumed model should also be taken into account. If the accuracy (bias) and precision data or accuracy profiles are within the required acceptance limits or an alternative calibration model is not applicable, slight deviations from the assumed model may be ignored (Hartmann *et al.* 1998; Hubert *et al.* 2004, 2007a,b).

Besides the above-mentioned classic way of evaluating the calibration model, an integrated approach is suggested by the SFSTP guidance documents (Hubert *et al.* 2003, 2006). This approach is based on statistical considerations, but practical aspects such as the purpose of the method as well as the experience of the analyst are also considered. A full description is beyond the scope of the present chapter, but is available and is discussed in great detail by Hubert *et al.* (2003, 2004, 2006, 2007a, b). These references should be valuable sources of information, particularly for experienced analysts with advanced understanding of statistical concepts in method validation.

Once a calibration model has been established, the calibration curves for other validation experiments (precision, bias, stability, etc.) and for routine analysis can be prepared with fewer concentrations and fewer or no replicates (Hartmann *et al.* 1998; Hubert *et al.* 2004, 2007a,b).

Accuracy

The accuracy of a method is affected by systematic (bias) as well as random (precision) error components (Hartmann *et al.* 1994, 1998). This fact has been taken into account in the definition of accuracy as established by the ISO (1994). However, it must be mentioned that accuracy is often used to describe only the systematic error component, i.e. in the sense of bias (Karnes *et al.* 1991; Shah *et al.* 1991, 2000; ICH Topic Q2(R1) 2005).

Bias

According to the ISO, bias is 'the difference between the expectation of the test results and an accepted reference value' (ISO 1994). It may consist of more than one systematic error component. Bias can be measured as a percentage deviation from the accepted reference value. The term 'trueness' expresses the deviation of the mean value of a large series of measurements from the accepted reference value. It can be expressed in terms of bias. Owing to the high workload of analysing such large series, trueness is usually not determined during method validation, but rather from the results of a great number of QC samples during routine application or in inter-laboratory studies. It should be noted that trueness and bias are sometimes reported in terms of (analytical) recovery of an acceptance reference value (Thompson *et al.* 2002). This must not be confused with the validation parameter recovery (RE), in the sense, for example, of extraction efficiency (see below).

Precision

According to the ICH, precision is 'the closeness of agreement (degree of scatter) between a series of measurements obtained from multiple sampling of the same homogeneous sample under the prescribed conditions and may be considered at three levels: repeatability, intermediate precision and reproducibility' (ICH Topic Q2(R1) 2005). Precision is usually measured in terms of imprecision expressed as an absolute or relative standard deviation (RSD) and does not relate to reference values.

Repeatability 'Repeatability expresses the precision under the same operating conditions over a short interval of time. Repeatability is also termed intra-assay precision' (ICH Topic Q2(R1) 2005). Within-run or within-day precision is also often used to describe repeatability.

Intermediate precision 'Intermediate precision expresses within-laboratories variations: different days, different analysts, different equipment etc.' (ICH Topic Q2(R1) 2005). The ISO definition uses the term 'M-factor different intermediate precision', where the M-factor expresses how many and which factors (time, calibration, operator, equipment or combinations of those) differ between successive determinations (ISO 1994). In a strict sense intermediate precision is the total precision under varied conditions, whereas so-called inter-assay, between-run or between-day precision measures only the precision components caused by the respective factors (see below). However, the latter terms are not clearly defined and are obviously often used interchangeably with each other and also with the term intermediate precision.

Reproducibility 'Reproducibility expresses the precision between laboratories (collaborative studies, usually applied to standardisation of methodology)' (ICH Topic Q2(R1) 2005). Reproducibility has to be studied only if a method is supposed to be used in different laboratories.

Unfortunately, some authors also used the term reproducibility for within-laboratory studies at the level of intermediate precision (Causon 1997; Lindner, Wainer 1998). This should be avoided in order to prevent confusion.

Bias and precision experiments and calculations As already mentioned, precision and bias can be estimated from the analysis of QC samples under specified conditions. Both bias and precision can vary substantially over the calibration range. It is therefore generally recommended to evaluate these parameters at least at three concentration levels: low, medium and high relative to the calibration range (Karnes *et al.* 1991; Shah *et al.* 1991, 2002; Hartmann *et al.* 1998; Taverniers *et al.* 2004; ICH Topic Q2(R1) 2005). In Conference Report II (Shah *et al.* 2000), it was further defined that the concentration of the low QC sample must be within three times the LLOQ. Four concentration levels (LLOQ, low, medium, high) were studied in the experimental design proposed by Wieling *et al.* (1996). Owing to the often higher concentration ranges in the fields of forensic and clinical toxicology, it might be reasonable also to validate the analysis of QC samples containing concentrations above the highest calibration standard after dilution or after reduction of sample volumes, as it has been described by Dadgar and Burnett (1995). These authors also described the use of QC samples with concentrations below those of the lowest calibration standard using greater sample volumes. The Harmonized Guide (Thompson *et al.*

2002) recommends studying precision at the extremes of the working range while the EURACHEM guide (EURACHEM/CITAC 1998) recommends various concentrations across the working range without any further specification. Neither of these two guides contains any specific recommendations concerning the number of concentration levels for studying bias.

The acceptance criteria for bias and precision are very much dependent on the purpose of the method, i.e. which level of accuracy is required during routine use of the method. This is probably the reason why most validation guidelines intended only for a specific type of analytical procedure (including the ICH document (ICH Topic Q2(R1) 2005) do not contain specific acceptance criteria for these two parameters. However, acceptance limits for bias and precision in bioanalysis of drugs were specified in the Conference Reports (Shah *et al.* 1991, 2002; Viswanathan *et al.* 2007) and have been widely accepted throughout the field of bioanalytical analysis of drugs, poisons and/or their metabolites. In these documents, bias was required to be within ±15% of the accepted true value, except at the LLOQ where ±20% was accepted. Precision was required to be within 15% RSD except at the LLOQ where 20% RSD was accepted. These requirements have been subject to criticism in the analysis of Conference Report I by Hartmann *et al.* (1994). These authors concluded from statistical considerations that it is not realistic to apply the same acceptance criteria at different levels of precision (repeatability, reproducibility) because RSD under reproducibility conditions is usually considerably greater than under repeatability conditions. Furthermore, if precision and bias estimates are close to the acceptance limits, the probability of rejecting an actually acceptable method (β-error) is quite high. These concerns were shared by the expert group of the SFSTP and were one of the main reasons for introducing the concepts of accuracy profiles in the respective guidance documents (Hubert *et al.* 2003, 2004, 2006, 2007a,b) (see below).

Again, the proposals on how many replicates at each concentration should be analysed vary considerably. In pharmaceutical analysis, analysis of triplicates may be acceptable (ICH Topic Q2(R1) 2005), while the Conference Reports (Shah *et al.* 1991, 2000) required at least five replicates at each concentration level. However, one would assume that these requirements apply only to repeatability studies; at least no specific recommendations were given for studies of intermediate precision or reproducibility.

The EURACHEM guide (EURACHEM/CITAC 1998) recommends performing for each concentration level 10 independent determinations under each repeatability, M-factor- different intermediate precision, and reproducibility conditions. In this straightforward approach, the corresponding precision data can simply be calculated as RSDs of the values obtained under these stipulated conditions. Examples of this approach can be found in Tracqui *et al.* (1996), Mortier *et al.* (2002b), He *et al.* (2004) and Nordgren and Beck (2004).

Other authors have proposed an approach whereby replicates are analysed on a number of different occasions (e.g. different runs, days) (Wieling *et al.* 1996; Hartmann *et al.* 1998; Thompson *et al.* 2002; Hubert *et al.* 2003, 2006, 2007a). In their experimental design, Wieling *et al.* (1996) analysed three replicates at each of four concentrations on each of 5 days. Similar approaches were suggested by Causon (1997) (six replicates at each of four concentrations on each of four occasions), Hartmann *et al.* (1998) (two replicates at each concentration level on each of 8 days), and the Harmonized Guide (Thompson *et al.* 2002) (duplicates in a number of successive runs). The SFSTP documents do not recommend a fixed number of days and replicates, but rather recommend variable numbers of days and replicates depending on the results of preliminary bias and precision estimates as derived from the pre-validation used to determine the calibration model (Hubert *et al.* 2003, 2004, 2006, 2007a,b).

Using one-way ANOVA with the varied factor (e.g. day) as the grouping variable, such experimental designs allow separate calculation of repeatability and of the precision component caused by the grouping variable from the same datasets, as well as the calculation of factor-different intermediate precision as the combination of the previous two (Krouwer, Rabinowitz 1984; Massart *et al.* 1997; NCCLS 1999). Thus, repeatability, expressed as RSD in per cent, can be calculated from equation (20.2):

$$\mathrm{RSD_r}[\%] = \frac{\sqrt{\mathrm{MS_{wg}}}}{\overline{X}} \times 100 \qquad (20.2)$$

where $\mathrm{RSD_r}$ = repeatability, within-group precision, expressed as percentage RSD; $\mathrm{MS_{wg}}$ = mean square within groups, obtained from ANOVA table; $\overline{X}$ = grand mean of all observations.

The precision component caused by the varied factor or grouping variable corresponds to the standard deviation (SD) of the group means after subtraction of the contribution from within-group variability. Expressed as RSD, this precision component can be calculated from equation (20.3). From a strictly statistical point of view, this is the between-group precision (component). Unfortunately, this term is often used for total precision or factor-different intermediate precision, which is not correct.

$$\mathrm{RSD_{bg}}[\%] = \frac{\sqrt{\frac{\mathrm{MS_{bg}} - \mathrm{MS_{wg}}}{n}}}{\overline{X}} \times 100 \qquad (20.3)$$

(set $\mathrm{RSD_{bg}} = 0$ if $\mathrm{MS_{bg}} < \mathrm{MS_{wg}}$)

where $\mathrm{RSD_{bg}}$ = between-group precision (component), expressed as percentage RSD; $\mathrm{MS_{bg}}$ = mean square between groups, obtained from ANOVA table; $\mathrm{MS_{wg}}$ = mean square within groups, obtained from ANOVA table; n = number of observations in each group; $\overline{X}$ = grand mean of all observations.

The factor-different intermediate precision or total precision can be calculated according to equation (20.4) as a combination of within- and between-group effects:

$$\mathrm{RSD_{I(F)}}[\%] = \frac{\sqrt{\frac{\mathrm{MS_{bg}} + (n-1)\mathrm{MS_{wg}}}{n}}}{\overline{X}} \times 100 \qquad (20.4)$$

where $\mathrm{RSD_{I(F)}}$ = factor-different intermediate precision, expressed as percentage RSD and other symbols are as before.

This value corresponds to the intermediate precision estimate obtained with the previously mentioned alternative design proposed by EURACHEM (EURACHEM/CITAC 1998). However, in the author's opinion, the ANOVA approach should be preferred, because more information can be derived from this approach with a comparable number of analyses. For example, in case of unacceptably high intermediate precision values, the ANOVA approach allows easy comparison of the precision components. This can be very helpful in finding the cause of the problem.

The ANOVA approach has been used in many publications, e.g. Bennett *et al.* (1997), Yao *et al.* (1998), Jemal *et al.* (2003), Peters *et al.* (2003, 2007b), Xue *et al.* (2003, 2004), Kratzsch *et al.* (2004). In the majority of these publications, four to six replicates were analysed on 3–4 days, i.e. a total number of 15–20 samples (Bennett *et al.* 1997; Yao *et al.* 1998; Jemal *et al.* 2003; Xue *et al.* 2003, 2004). With such designs, repeatability is estimated with quite a large number of degrees of freedom (12–16), while there are only a few degrees of freedom for the between-day component (2–3), making its estimation quite unreliable. In the designs proposed by Hartmann *et al.* (1998) and in the Harmonized Guide (Thompson *et al.* 2002), the degrees of freedom for both estimations are more balanced, e.g. 8 for repeatability and 7 for the between-day component in case of the Hartmann design. For this reason the latter design is preferred by the author's (former) working group (Kratzsch *et al.* 2003, 2004; Maurer *et al.* 2004). As already mentioned, optimum numbers of days and replicates are recommended for certain combinations of expected bias and precision in references (Hubert *et al.* 2003, 2004, 2006, 2007a,b).

Bias experiments usually include a number of replicate measurements from which a mean value is calculated. The EURACHEM guide

(EURACHEM/CITAC 1998) recommended 10 replicates. The mean value is then compared with a certain reference value, e.g. the target value of a certified reference material, the results obtained for the same sample using a reference method, or the theoretical concentration of a spiked sample (EURACHEM/CITAC 1998; Shah *et al.* 2000; Thompson *et al.* 2002; Taverniers *et al.* 2004; ICH Topic Q2(R1) 2005). Bias is then usually calculated as the percentage deviation of the observed mean value from the respective reference value according to equation (20.5).

$$\text{Bias}[\%] = \frac{\overline{X} - \mu}{\mu} \times 100 \qquad (20.5)$$

where $\overline{X}$ = observed mean value; μ = accepted reference value.

Bias experiments can be carried out together with the precision experiments, i.e. the same results are used for the calculation of both. In the approach using separate experiments for the evaluation of precision under repeatability and intermediate precision conditions, this will yield two bias values, one from the mean value of the repeatability experiment (within-day or within-run bias), and one from the mean of the factor- different intermediate precision experiment (between-day or between-run bias). Using the ANOVA approach, usually only a single bias value is obtained from the grand mean of all observations.

It is important to note that daily variations of the calibration curve can influence bias estimation. Therefore, bias estimations should be based on data calculated from several calibration curves (Hartmann *et al.* 1998). In the experimental design of Wieling *et al.* (1996), the results for QC samples were calculated via daily calibration curves. Therefore, the overall means from these results at the different concentration levels reliably reflect the average bias of the method at the corresponding concentration level.

The concept of accuracy profiles An alternative approach to separate evaluation of bias and precision, the concept of accuracy profiles, has been proposed by the SFSTP (Hubert *et al.* 2003, 2006). A detailed discussion of this concept is beyond the scope of this chapter, where only the most important aspects can be addressed, but it is available in references (Hubert *et al.* 2004, 2007a,b). On the basis of the argument that for individual measurements the total error (i.e. the combination of systematic and random error) is more important than the two error components, the SFSTP document proposes using acceptance intervals for accuracy, i.e. the combination of bias and precision, rather than separate acceptance criteria for the two error components. Consequently, a larger bias can be partly compensated by good precision and vice versa. The combined error at each concentration level can be expressed as confidence intervals calculated from the respective bias and intermediate precision data. Plotting these confidence intervals against the respective concentrations, the so-called accuracy profile is obtained. If the entire accuracy profile lies within the predefined acceptance interval, the method can be considered sufficiently accurate. A major advantage of this approach is that accuracy profiles provide at-a-glance information about the method's performance with respect to the expected accuracy of individual measurements. However, it must be noted that, in the accuracy profile approach, the above-mentioned acceptance criteria of $\pm$15% for bias and 15% cofficient of variation for intermediate precision would correspond to an acceptance interval of approximately 45% for the accuracy profile. The GTFCh document (Peters *et al.* 2009) also recommends the use of accuracy profiles with acceptance intervals of $\pm$30% ($\pm$40% near the LLOQ).

Incurred sample reanalysis In bioanalysis, standard and QC samples prepared by spiking blank matrix are not necessarily representative of the samples from dosed subjects (incurred samples) that are analysed during routine application of the analytical method. For example, re-conversion of metabolites to the parent compound, different protein binding in samples from patients with certain diseases, etc. may influence the results. In Conference Report III (Viswanathan *et al.* 2007), it was therefore recommended to check as early as possible whether bias and precision data obtained by repeated analysis of incurred samples are in line with the respective findings obtained during the validation study. Although Conference Report III left the decision on the extent and nature of the incurred sample analysis to the analytical investigator, it recommended that analyte concentrations and special study populations (e.g. renally impaired patients) should be considered in sample selection. A more detailed discussion of incurred sample analysis for validation purposes can be found in Rocci *et al.* (2007).

Limits

Lower limit of quantification The LLOQ is the lowest amount of an analyte in a sample that can be quantitatively determined with suitable precision and accuracy (bias) (Shah *et al.* 2000; ICH Topic Q2(R1) 2005). There are different approaches for the determination of LLOQ.

LLOQ based on precision and accuracy (bias) data This is probably the most practical approach and defines the LLOQ as the lowest concentration of a sample that can still be quantified with acceptable precision and bias (Shah *et al.* 1991, 2000; Hartmann *et al.* 1998; ICH Topic Q2(R1) 2005). In the Conference Reports (Shah *et al.* 1991, 2000), the acceptance criteria for these two parameters at LLOQ are 20% RSD for precision and $\pm$20% for bias. When using the concept of accuracy profiles, the LLOQ corresponds to the lowest concentration at which the accuracy profile is completely inside the acceptance interval (Hubert *et al.* 2003, 2006). It should be pointed out, however, that bias and precision or accuracy profiles must be determined using an LLOQ sample independent of the calibration curve. The advantage of this approach is that the estimation of LLOQ is based on the same quantification procedure as used for real samples. In order to include the possible influence of matrix differences into the LLOQ evaluations, many authors used 6–10 different sources of blank matrix to prepare QC samples at the LLOQ (Bennett *et al.* 1997; Yao *et al.* 1998; Chang *et al.* 1999; Jemal *et al.* 1999; de Jonge *et al.* 2004; Li *et al.* 2004; Xue *et al.* 2004).

LLOQ based on signal-to-noise ratio This approach can be applied only if there is baseline noise, e.g. in chromatographic methods. The signal-to-noise ratio (*S/N*) can then be defined as the height of the analyte peak (signal) and the amplitude between the highest and lowest point of the baseline (noise) in a certain area around the analyte peak. For LLOQ, *S/N* is usually required to be $\geq$10 (ICH Topic Q2(R1) 2005). While this approach should be applicable in pharmaceutical analysis, estimation of baseline noise can be quite difficult for bioanalytical methods if matrix peaks elute close to the analyte peak.

LLOQ based on the standard deviation of the response from blank samples Another definition of LLOQ is the concentration that corresponds to a response that is k times greater than the estimated SD of blank samples (ICH Topic Q2(R1) 2005). From the response, the LLOQ can be calculated using the slope of the calibration curve using equation (20.6) (for blank corrected signals).

$$\text{LLOQ} = k\frac{\text{SD}_{\text{bl}}}{S} \qquad (20.6)$$

where k = factor, usually 10; SD_{bl} = standard deviation of blank response; S = slope of the calibration curve.

This approach is applicable only for methods where SD_{bl} can be estimated from replicate analysis of blank samples. It is, therefore, not applicable for most quantitative chromatographic methods, as here the response is usually measured in terms of peak area units, which of course cannot be measured in a blank sample analysed with a selective method.

LLOQ based on a specific calibration curve in the range of LLOQ In this approach, a specific calibration curve is established from samples containing the analyte in the range of LLOQ (ICH Topic Q2(R1) 2005). The calibration curve must not be used over the whole range of quantification for this determination, because this may lead to overestimation of the LLOQ. The SD of the blank can then be estimated from the residual SD of the regression line or the SD of the *y*-intercept.

Upper limit of quantification (ULOQ) The ULOQ is the maximum analyte concentration of a sample that can be quantified with acceptable

precision and accuracy (bias). In general, the ULOQ is identical with the concentration of the highest calibration standard (Shah *et al.* 2000).

Limit of detection Quantification below LLOQ is by definition not acceptable (Shah *et al.* 1991, 2000; Dadgar *et al.* 1995; Hartmann *et al.* 1998). Therefore, below this value a method can produce only semi-quantitative or qualitative data. However, it can still be important to know the LOD of the method. According to the ICH, it is the lowest concentration of analyte in a sample that can be detected but not necessarily quantified as an exact value (ICH Topic Q2(R1) 2005). According to Conference Report II (Shah *et al.* 2000), it is the lowest concentration of an analyte in a sample that the bioanalytical procedure can reliably differentiate from background noise.

In many bioanalytical methods to be used in pharmacokinetic studies, the LOD is not evaluated because of their purely quantitative character. However, authors from the field of toxicology often report the LOD of their analytical methods because, in this field, qualitative data can also be very important. The approaches most often applied for estimation of the LOD are basically the same as those described for LLOQ with the exception of the approach using precision and accuracy data, which cannot be used here for obvious reasons. In contrast to the LLOQ determination, for LOD a *S/N* or *k*-factor ≥ 3 is usually chosen (EURACHEM/CITAC 1998; Hartmann *et al.* 1998; Thompson *et al.* 2002; Taverniers *et al.* 2004; ICH Topic Q2(R1) 2005). If the calibration curve approach is used for determination of the LOD, only calibrators containing the analyte in the range of LOD must be used to avoid overestimation of the LOD. All these approaches evaluate only the pure response of the analytes. In toxicology, however, unambiguous identification of an analyte in a sample requires more complex acceptance criteria to be fulfilled. Such criteria were reviewed by Rivier (2003). In forensic toxicology and doping control, it would certainly be more appropriate to define the LOD as the lowest concentration of analyte in a sample at which specific identification criteria can still be fulfilled.

Stability

The definition of stability according to Conference Report II (Shah *et al.* 2000) was 'the chemical stability of an analyte in a given matrix under specific conditions for given time intervals'. Stability of the analyte during the whole analytical procedure is a prerequisite for reliable quantification. Therefore, full validation of a method must include stability experiments for the various stages of analysis, including storage prior to analysis, unless such data are already available in the literature.

Long-term stability The stability in the sample matrix should be established under storage conditions, i.e. in the same vessels, at the same temperature and over a storage period at least as long as the one expected for authentic samples (Karnes *et al.* 1991; Shah *et al.* 1991, 2000; Dadgar *et al.* 1995; Dadgar, Burnett 1995; Hartmann *et al.* 1998).

Freeze/thaw stability As samples are often frozen and thawed, e.g. for reanalysis, the stability of analyte during several freeze/thaw cycles should also be evaluated. The Conference Reports (Shah *et al.* 1991, 2000) require a minimum of three cycles at two concentrations in triplicate, which has also been accepted by other authors (Dadgar, Burnett 1995; Wieling *et al.* 1996; Hartmann *et al.* 1998).

In-process stability, bench-top stability The stability of analyte under the conditions of sample preparation (e.g. ambient temperature over time needed for sample preparation) is evaluated here. There is general agreement that this type of stability should be evaluated to find out whether preservatives have to be added to prevent degradation of analyte during sample preparation (Dadgar, Burnett 1995; Hartmann *et al.* 1998; Shah *et al.* 2000).

Processed sample stability Instability may occur not only in the sample matrix but also in processed samples. It is therefore important also to test the stability of an analyte in the prepared samples under conditions of analysis (e.g. autosampler conditions for the expected maximum time of an analytical run). The stability should also be tested in prepared samples under storage conditions, e.g. in a refrigerator, in case prepared samples have to be stored prior to analysis (Dadgar *et al.* 1995; Dadgar, Burnett 1995; Wieling *et al.* 1996; Hartmann *et al.* 1998; Shah *et al.* 2000).

Stability experiments and evaluations A detailed account of experimental designs and statistical evaluations of stability experiments can be found in Dadgar *et al.* (1995), Dadgar and Burnett (1995) and Hartmann *et al.* (1998). Stability can be tested by comparing the results from QC samples analysed before (comparison samples) and after (stability samples) being exposed to the conditions for stability assessment. It has been recommended to perform stability experiments at least at two concentrations (low and high) (Dadgar *et al.* 1995; Dadgar, Burnett 1995; Wieling *et al.* 1996; Hartmann *et al.* 1998). For both comparison and stability samples, analysis of at least six replicates was recommended (Hartmann *et al.* 1998). Ratios between comparison samples and stability samples of 90–110% with 90% confidence intervals within 80–120% or 85–115% (Dadgar, Burnett 1995) have been regarded as acceptable. Alternatively, the mean of the stability samples can be tested against a lower acceptance limit corresponding to 90% of the mean of the comparison samples (Causon 1997; Hartmann *et al.* 1998). An alternative approach for statistical testing of processed samples in the autosampler was used in the experimental design proposed by Wieling *et al.* (1996). A sample extract was injected repeatedly at certain intervals for a total time period corresponding to the time required to measure a batch of samples under routine conditions. The peak areas of the analytes were then plotted against the respective injection times. Subsequently, regression analysis was performed to check for a significantly negative slope, which would indicate instability.

The importance of stability is obviously widely accepted in the bioanalytical community, which can be deduced from the fact that the majority of papers published in this area in recent years included descriptions of stability experiments. Because of the many different experimental designs used in these papers, a comprehensive overview over all of them would be beyond the scope of this chapter. Exemplary stability studies can be found in Jemal *et al.* (1999, 2000), Jemal and Mulvana (2000), Lin *et al.* (2001), Skopp and Pötsch (2002), Kratzsch *et al.* (2003, 2004), Egge-Jacobsen *et al.* (2004), Maurer *et al.* (2004), Naidong and Eerkes (2004), Ramakrishna *et al.* (2004), Scheidweiler and Huestis (2004) and Shou *et al.* (2004). The papers of the group of Maurer and colleagues (Kratzsch *et al.* 2003, 2004; Maurer *et al.* 2004) describe studies on bench-top, freeze/thaw, long-term, and autosampler stability including statistics and acceptance criteria. The last are generally missing in most other papers. The papers by the group of Jemal and colleagues (Jemal *et al.* 1999, 2000; Jemal, Mulvana 2000) describe stability studies including the effect of modifications introduced to stabilise labile analytes. Egge-Jacobsen *et al.* (2004) performed a comprehensive stability study of various anti-HIV drugs including stability under conditions usually applied for HIV inactivation in blood samples. Skopp and Pötsch (2002) studied the stability of the labile 11-nor-Δ^9-carboxy-tetrahydrocannabinol glucuronide in plasma and urine at various temperatures ranging from -20°C to 49°C. Lin *et al.* (2001) described a comprehensive stability study including the stability of stock solutions at -20°C, which should also be of special interest for forensic and clinical toxicologists because this paper deals with the analysis of cocaine and benzoylecgonine, two potentially unstable compounds relevant in these fields of toxicology. In another interesting paper, Scheidweiler and Huestis (2004) studied hydrolysis of cocaine and 6-monoacetylmorphine during sample preparation of an LC-MS (-MS) assay for quantification of opiates, cocaine and metabolites in hair. They spiked blank hair with cocaine and 6-monoacetylmorphine and estimated their hydrolysis by quantification of the degradation products benzoylecgonine and morphine after sample preparation. All these examples show that, besides the above-mentioned types of stability studies, which should be performed in any validation study, additional experiments might be necessary for certain analytes.

A serious problem encountered during stability testing for bioanalytical methods in forensic and clinical toxicology is that there are a great number of different sampling containers. Furthermore, the anticoagulants used also differ. Both factors make it difficult to assess long-term stability, as the workload to analyse all possible combinations of

containers and anticoagulants is far too great. However, for some analytes relevant to forensic and clinical toxicology (e.g. cocaine), stability problems with different sampling containers have been reported (Toennes, Kauert 2001), which shows that at least for some analytes such extensive studies may have to be considered.

Recovery

As already mentioned above, recovery is not among the validation parameters regarded as essential for method validation and it is not covered by the ICH guidance document for method validation in pharmaceutical analysis (ICH Topic Q2(R1) 2005). In bioanalysis also most authors agree that the value for recovery is not important, as long as the data for LLOQ, (LOD), precision and bias are acceptable (Dadgar *et al.* 1995; Hartmann *et al.* 1998; Shah *et al.* 2000). It can be calculated as the percentage of the analyte response after sample workup compared with that of a solution containing the analyte at a concentration corresponding to 100% recovery. Therefore, absolute recoveries usually cannot be determined if the sample workup includes a derivatisation step, as the derivatives are often not available as reference substances. Nevertheless, some guidance documents request the determination of the recovery at high and low concentrations (Lindner, Wainer 1998; Peters *et al.* 2009) or even specify that the recovery should be greater than 50% (Lindner, Wainer 1998; Peters *et al.* 2009).

In LC-MS(-MS) analysis, a different experimental design must be used to determine recovery, because part of the change of the response in prepared samples in comparison with respective standard solutions might be attributable to matrix effects. In the validation of LC-MS (-MS), it is therefore more appropriate to perform the recovery experiments together with ion suppression/enhancement experiments as described below.

Robustness/ruggedness

According to ICH Topic Q2(R1) (2005), robustness is a measure of an analytical method's capacity to remain unaffected by small but deliberate variations in method parameters and provides an indication of its reliability during normal usage. In other words, it measures the effects that small changes of 'internal' method parameters such as buffer pH, mobile phase compositions, etc. have on the analytical results. Ruggedness refers to a method's capacity to remain unaffected by changes encountered when transferring a method from one laboratory to another, meaning that it focuses more on 'external' parameters of the method such as analysts, instruments, laboratory environment, etc. However, in practice it is difficult to separate robustness and ruggedness, because these parameters do of course interact. It is therefore not surprising that the terms robustness and ruggedness are often used interchangeably.

Full validation does not necessarily include ruggedness testing; it can, however, be very helpful during the method development/prevalidation phase, as problems that may occur during validation are often detected in advance. Ruggedness should be tested if a method is going to be transferred to another laboratory (Karnes *et al.* 1991; Hartmann *et al.* 1998; Vander-Heyden *et al.* 2001; ICH Topic Q2(R1) 2005; Dejaegher, Heyden 2007). A detailed account and helpful guidance on experimental designs and evaluation of ruggedness/robustness tests can be found in Vander-Heyden *et al.* (2001) and Dejaegher and Vander-Heyden (2007).

Matrix effects (ion suppression/enhancement)

Suppression or enhancement of analyte ionisation by co-eluting compounds is a well-known phenomenon in LC-MS(-MS) analysis, depending mainly on the sample matrix, the sample preparation procedure, the quality of chromatographic separation, mobile phase additives and ionisation type (King *et al.* 2000; Ackermann *et al.* 2002; Muller *et al.* 2002; Annesley 2003; Matuszewski *et al.* 2003; Dams *et al.* 2003; Liang *et al.* 2003; Mallet *et al.* 2004; Souverain *et al.* 2004). While ESI has been reported to be much more prone to such effects, they may also occur with atmospheric pressure chemical ionisation (APCI) (King *et al.* 2000; Ackermann *et al.* 2002; Annesley 2003; Dams *et al.* 2003; Liang *et al.* 2003; Matuszewski *et al.* 2003; Mallet *et al.* 2004; Souverain *et al.* 2004). It is obvious that ion suppression as well as ion enhancement may affect validation parameters such as LOD, LLOQ, linearity, precision and/or bias. Sojo *et al.* (2003) demonstrated that mutual suppression of analytes and their stable-isotope-labelled IS in the ESI mode should not affect quantification, but they were concerned about a negative influence on the LOD if too high a concentration of IS was used. In principle, these findings were confirmed by Liang *et al.* (2003), who also reported mutual suppression of analytes and IS in the ESI mode resulting in negative effects on LOD and LLOQ. They also confirmed the findings concerning linearity, but only for certain IS concentrations. For the APCI mode, they reported mutual ionisation enhancement for parts of the analytes and their IS, possibly improving LOD and LLOQ data. Furthermore, the calibration curves were linear when an appropriate concentration of the IS was chosen. From these two studies, one might conclude that, while the limits might be affected by ion suppression/enhancement, quantification would not as long as a stable-isotope-labelled IS was used. However, this is not always true, as could be demonstrated by Jemal *et al.* (2003) who reported, for certain batches of urine, matrix effects that lead to changes in the response ratio (analyte vs IS) that could have a negative influence on quantification. Worse problems have to be expected when no stable-isotope-labelled IS is available.

All this clearly shows that studies of ion suppression/enhancement should be an integral part of the validation of any LC-MS(-MS) method. This is also in line with Conference Report II (Shah *et al.* 2000), which in the case of LC-MS(-MS) procedures explicitly recommends studies on possible matrix effects 'to ensure that precision, selectivity and sensitivity will not be compromised'. However, no specific experimental design was proposed in this document. In the literature, two approaches have been used extensively to study ion suppression/enhancements. In the first approach, a solution of the analyte is constantly infused into the eluent from the column via a post-column tee connection using a syringe pump. The continuous post-column infusion leads to a constant signal in the detector unless compounds that elute from the column suppress or enhance ionisation, which would respectively lead to decreased or increased detector response. Thus, monitoring of the detector response after injection of blank matrix extracts can be used to check for possible ion suppression/enhancement of blank matrix compounds and for their retention times. Applications of this approach can be found in Muller *et al.* (2002), Naidong *et al.* (2002), Dams *et al.* (2003), Liang *et al.* (2003) and Streit *et al.* (2004). Strategies for the second, the so-called post-extraction addition approach, were published by Matuszewski *et al.* (2003). This paper provides excellent guidance on how to perform and evaluate studies on matrix effects (ME) in LC-MS(-MS) analysis. The principal approach involves determination of peak areas of analyte in three different sets of samples: one consisting of neat standards (set 1), one prepared in blank matrix extracts from different sources and spiked after extraction (set 2), and one prepared in blank matrix from the same sources but spiked before extraction (set 3). From these data, the ME (ion suppression/enhancement), RE and process efficiencies (PE) can then be calculated according to equations (20.7)–(20.9), respectively (Matuszewski *et al.* 2003).

$$\mathrm{ME}[\%] = \frac{B}{A} \times 100 \tag{20.7}$$

$$\mathrm{RE}[\%] = \frac{C}{B} \times 100 \tag{20.8}$$

$$\mathrm{PE}[\%] = \frac{C}{A} \times 100 = \frac{\mathrm{MR} \times \mathrm{RE}}{100} \tag{20.9}$$

where A = peak area in sample from set 1(neat standard); B = peak area in sample from set 2 (spiked blank matrix extract); C = peak area in sample from set 3 (extract of spiked blank matrix); ME = matrix effect (ion suppression/enhancement); RE = extraction efficiency (extraction recovery); PE = process efficiency.

The full experimental design proposed in Matuszewski *et al.* (2003) involves analysis of 105 samples (3 sets with 7 concentration levels and

$n = 5$ per level). Thus a tremendous amount of data is acquired that can provide valuable information concerning the performance of the assay studied. As analysis of such large numbers of samples is time-consuming and expensive, a number of simplified experimental designs are also described in Matuszewski *et al.* (2003). Other examples using the same or very similar approaches for evaluation of matrix effects can be found in Matuszewski *et al.* (1998, 2003), Mortier *et al.* (2002a,b), Naidong *et al.* (2002), Jemal *et al.* (2003), Pichini *et al.* (2003), Breda *et al.* (2004), Crommentuyn *et al.* (2004), He *et al.* (2004), Li *et al.* (2004), Ramakrishna *et al.* (2004) and Scheidweiler and Huestis (2004).

Recently, the post-extraction addition approach was adapted in Conference Report III (Viswanathan *et al.* 2007). In this document the matrix effect was termed matrix factor (MF) and expressed as a factor rather than a percentage, but the calculations were essentially the same as described above for ME. It was further specified that MF should be evaluated for at least six individual lots of blank matrix and that its variability (expressed as RSD) should be less than 15%. Based on the assumption that stable-isotope-labelled IS normalised the MF to the theoretical value of 1 (or 100%), evaluation of six individual blank matrix sources was not considered necessary for methods using such stable-isotope-labelled IS (Viswanathan *et al.* 2007). However, this seems highly questionable considering two recent reports of incomplete compensation of matrix effects despite the use of stable-isotope-labelled IS (Wang *et al.* 2007; Lindegardh *et al.* 2008).

Carryover and contamination

Carryover and contamination can seriously affect the precision and bias of an analytical procedure, particularly in samples containing low analyte concentrations. This potential problem was addressed in Conference Report III (Viswanathan *et al.* 2007), which states that carryover should be assessed during validation by injecting one or more blank samples after a high-concentration sample or standard. A standard acceptable magnitude of carryover was not specified in this paper, but it is obvious that for methods to be used in pharmacokinetic studies carryover might be tolerated as long as quantification near the LLOQ is not compromised to a relevant extent. In toxicological analysis, however, where qualitative information about the presence or absence of the analyte can be crucial, even minimal carryover might be unacceptable.

Experimental design for method validation

In the following, a rational experimental design for method validation will be described, which is summarised in Table 20.2. It is based on the experimental design proposed by Wieling *et al.* (1996), the modification introduced by the author of this chapter (Peters *et al.* 2003) and, of course, the considerations presented above. Similar experimental designs have been used in several publications from the group of Maurer (Peters *et al.* 2002; Kratzsch *et al.* 2003, 2004; Peters *et al.* 2003, 2005, 2007b; Maurer *et al.* 2004).

It is recommended to start the validation studies with its selectivity and, in the case of LC-MS(-MS) methods, with ion suppression/enhancement experiments; if either of these two parameters is not acceptable, major changes of the method might be required. For the reasons outlined above, 10 instead of only 6 sources of blank matrix are evaluated to exclude interference from the blank matrix. The zero samples (blank + IS) are analysed to exclude interference from the IS. If appropriate, spiking experiments with compounds likely to be present in real samples should also be performed. If no interferences are detected during these selectivity experiments, the next set of validation experiments can be performed. For LC-MS(-MS)-based methods these are the experiments on matrix effects. A post-extraction addition approach as proposed by Matuszewski *et al.* (2003) is best suited for this purpose, because it allows simultaneous evaluation of ME, RE and PE. In the design proposed in Table 20.2, six sources of blank matrices are used to account for variability between matrix source. If selectivity (and ME) results are satisfactory, processed sample stability should be assessed next to ensure stability of processed samples under the conditions on the autosampler tray during analysis of large batches of samples. For this purpose, 10 extracts each at low and high concentration can be pooled, thoroughly mixed, and divided again into aliquots which are then injected at certain time intervals until the maximum expected run-time is reached. If the processed samples are stable, the linearity experiments follow. If not, the processed samples must be stabilised, e.g. by cooling the autosampler tray, or further optimisation of the method must be undertaken. For the evaluation of the calibration model (linearity experiments) six concentration levels are analysed in replicates of six. This allows for checking for outliers and for studying the behaviour of variance across the calibration range as well as the evaluation of

Table 20.2 Experimental design for analytical method validation

Selectivity	*ME/RE/PE*[a]	*Processed sample stability*	*Linearity*
10 different sources of blank matrix, 2 zero samples, *x* spiked samples	36 samples (6 neat standards, 6 spiked blank extracts, 6 extracts of spiked blanks, 2 concentrations each)	16 injections of extracts (at certain time intervals, 8 at each of 2 concentrations)	36 samples (6 concentration levels, 6 replicates each)

Main validation phase

Run	Calibration 6 levels	Validation samples								
		Low			Medium	High			Optional

8	6	2			2	2			2	2

F/T, freeze/thaw stability; LLOQ, lower limit of quantification; ME, matrix effect; P & B, precision and bias; PE, process efficiency; RE, extraction efficiency. For details see text.
[a]LC-MS(-MS) methods only.
[b]Not for LC-MS(-MS) methods.

non-linear models, at least in a preliminary fashion. After an appropriate calibration model has been established, the early validation phase is completed and the main validation phase can begin.

During the main validation phase, bias and precision as well as freeze/thaw stability are evaluated. For methods not employing LC-MS(-MS), recovery experiments may also be performed in the main validation phase. For determination of bias and precision, duplicate QC samples are analysed at a minimum of three concentration levels on each of 8 days. Where applicable, a QC sample at very high concentrations can be analysed in the same fashion after an appropriate dilution to check whether reliable quantification is possible after dilution of real samples containing very high concentrations. In addition, QC samples corresponding to the LLOQ can be analysed in the same way to investigate whether precision and bias are acceptable at such low concentrations. From the data obtained during these experiments, the precision components and intermediate precision can be calculated using one-way ANOVA as described above. The bias values can be calculated as the percentage deviations of the observed mean values from the nominal concentrations of the respective QC samples. It should be noted that a calibration curve is run on each of the 8 days to include variability of daily calibration curves into the precision and bias estimates. Performing the freeze/thaw experiments together with the precision and bias experiments allows use of the daily calibration curves for the stability evaluations also. Freshly prepared control samples are analysed on the first day to obtain the control value. Samples from the same pools are then frozen and thawed three times, before they are analysed on the basis of the calibration curve of the fourth day. The initial mean values and those obtained after storage are then compared as described above. If the stability samples are kept at room temperature for the time needed to prepare a batch of samples before they are frozen again, the freeze/thaw stability evaluation also includes benchtop stability. Recovery samples at low and high concentrations (five controls and five extracted samples, each) can be run with the precision and bias samples on days 2 and 3, respectively, of the main validation phase.

Method development and validation example

In the following, the strategies described above for method development and validation will be illustrated using an example from the author's research work. An assay for enantioselective analysis of amfetamine, metamfetamine, 3,4-methylenedioxyamfetamine (MDA), 3,4-methylenedioxymetamfetamine (MDMA) and 3,4-methylenedioxyethylamfetamine (MDEA) in oral fluid is used as model method (Peters *et al.* 2007b). Method validation will be exemplified using validation results obtained for the analyte (*S*)-(+)-amfetamine.

Two methods already established in the laboratory were used as starting points for method development. The first was a method for enantioselective analysis of amfetamine and metamfetamine (Peters *et al.* 2002), the second a method for enantioselective analysis of MDA, MDMA and MDEA (Peters *et al.* 2005) in human plasma samples. Both methods employed mixed-mode SPE followed by chiral derivatisation with optically pure (*S*)-heptafluorobutyrylprolyl chloride transforming enantiomers to diastereomeric derivatives. The latter could be separated on standard achiral gas chromatography (GC) column and sensitively detected by negative-ion chemical ionization (NICI) MS allowing the use of small volumes of plasma (200 µL). These methods for highly sensitive enantioselective determination of these analytes from small sample volumes were chosen as starting points, because often only small sample volumes of 50–100 µL are available for oral fluid analysis.

In the first development step, a new GC oven temperature programme was developed that allowed separation of the enantiomers of all five analytes from each other and from those of the other analytes within 16 minutes. Considering that the derivatisation reaction had been carried out under aqueous alkaline conditions (Peters *et al.* 2002, 2005) and that oral fluid consists mainly of water, the next step was to study the feasibility of derivatisation directly in the oral fluid samples. It was found that this indeed worked very well and so the sample preparation could be considerably simplified by eliminating the SPE step. During the final optimisation prior to method validation, the electron multiplier voltage (EMV) settings in the different time windows were set to values that led to comparable signal intensities for all analytes. Thereafter, the method was taken through the validation process.

In the selectivity experiments with blank oral fluid samples from 10 healthy volunteers, no matrix peaks interfering with the detection of the analytes were detected. Results from a blank oral fluid sample and low QC samples spiked with high concentrations of other sympathomimetic amines (ephedrine, pseudoephedrine, norephedrine, norpseudoephedrine, phentermine, gepefrine, and pholedrine) gave no indication of potential interference of these drugs with detection or quantification of the analytes.

Processed sample stability was evaluated by injecting 10 aliquots of QC sample extracts at intervals of 2 hours covering a total of 18 hours. Regression analysis of the absolute peak areas for (*S*)-amfetamine yielded a slope not significantly different from zero for the low QC sample and a slight but significant positive slope for the high QC samples. The latter might be explained by evaporation of part of the reconstitution solvent. In any case, there was no indication of degradation of the analyte in processed samples.

The calibration model for (*S*)-amfetamine was evaluated by the analysis of six calibrators, the concentrations of which were evenly distributed over a range of 25–1250 ng/mL. Six replicates of each calibrator were analysed. One outlier was identified at the highest concentration level and eliminated. A weighting factor of $1/x^2$ was found appropriate to compensate for heteroscedasticity across the calibration range. Comparison of linear (straight line) and a polynomial second-order (quadratic) fit using an *F*-test showed that the response function was best described by the linear calibration model ($R^2 = 0.996$) with a slope of 0.0041 ng/mL and *y*-intercept of −0.005, the latter not being significantly different from zero.

Besides QC levels containing low (LOW), medium (MED) and high (HIGH) analyte concentrations relative to the calibration curve, two additional QC levels containing analyte concentrations below the calibration range (BCR) and above the calibration curve (ACR) were included in the bias and precision experiments. This was done to account for the extremely wide range of analyte concentrations to be expected in authentic oral fluid samples. While 50 µL volumes were used for analysis of LOW, MED and HIGH samples, an increased volume of 250 µL was analysed for the BCR samples and a reduced volume of 10 µL was used for the ACR samples. All QC samples were analysed in duplicate on each of 8 days and bias and precision data were calculated using the ANOVA method. The results are listed in Table 20.3. Bias values were acceptable for all QC samples lying well within ±10%. Precision data were all below 15% for all QC samples with the exception of the ACR, where a value of 15.7% was obtained. While in a strict sense this is outside the acceptance limit of 15%, it must be considered that this acceptance limit was established for methods to be used in pharmacokinetic studies, for which the sample matrices are usually blood, plasma or serum. Because the absolute concentrations in oral fluid samples are influenced by many parameters including oral fluid collection (Crouch 2005), and because of their weak correlation with plasma concentrations, the slightly lesser precision obtained for the ACR samples should still be sufficient for quantitative analysis in oral fluid samples.

Another modification to the above-described experimental design was that six rather than three freeze/thaw cycles were used in the respective stability experiments. This was done to account for the fact that repeated freezing and thawing is often used to reduce the viscosity of oral fluid samples. QC samples at two concentrations were analysed before and after six freeze/thaw cycles with six replicates at each time point. The ratios between (*S*)-amfetamine concentrations in control and stability samples were 99.2% for the LOW QC samples and 96.1% for the HIGH QC samples and hence well within the acceptance interval of 90–110% for this parameter. The respective 90% confidence intervals were 94.3–104.1% and 82.5–109.6% and thus also within their acceptance interval of 80–120%. These results showed that up to six freeze/thaw cycles have no relevant effect on (*S*)-amfetamine concentrations in oral fluid samples.

Table 20.3 Nominal QC concentrations, samples volumes, bias, repeatability and intermediate precision data for the determination of (*S*)-amfetamine in oral fluid

QC sample	*Nominal concentration (ng/mL)*	*Sample volume (μL)*	*Bias (%)*	*Repeatability (CV %)*	*Intermediate precision (CV %)*
BCR	10	200	−9.4	2.7	3.2
LOW	50	50	−6.1	7.9	10.6
MED	500	50	0.4	6.1	7.0.
HIGH	1000	50	3.4	6.0	8.8
ACR	5000	10	−0.7	15.7	15.7

ACR, QC sample with analyte concentrations above the calibration range; BCR, QC sample with analyte concentration below calibration range; CV, coefficient of variation; HIGH, QC sample with high analyte concentrations relative to the calibration range; LOW, QC sample with low analyte concentrations relative to the calibration range; MED, QC sample with medium analyte concentrations relative to the calibration range; QC, quality control.

CHAPTER

21 Quality Control in the Pharmaceutical Industry

P Graham

Introduction

A pharmaceutical industry quality control laboratory has the important function of testing raw materials, packaging components, materials being processed and finished products for quality. It is important to recognise that quality control plays an important role in the quality assurance of pharmaceuticals all the way from research and development on investigational medicinal products, through to scale-up and commercial manufacture. Key decisions are made from the analytical data generated and so the reliability of the results is paramount. The safety of patients depends upon the body of knowledge generated by analytical chemists on active pharmaceutical ingredients (APIs) and drug products during product research and development, process validation studies, stability testing, in-process control and finished product testing. When problems occur, the data generated by the quality control laboratory will help to determine the root cause and improve process and product quality.

Testing laboratories involved in the generation of data for product development, marketing authorisation and batch release of medicinal products face the challenge of undertaking their activities in a heavily regulated environment. In addition, as a functional and costly part of the business, testing laboratories must run their operations as efficiently as possible.

Regulatory authorities such as the Medicines and Healthcare products Regulatory Agency (MHRA), the Food and Drug Administration (FDA) or the European Agency for the Evaluation of Medicinal Products (EMEA) enforce national and international regulations. In order to comply with these, pharmaceutical companies are required to put appropriate quality systems in place. Maintaining the quality system in good working order draws heavily on resources, and costs can be high. Regulatory compliance versus lean and efficient operational costs can be the dichotomy that every manufacturer faces.

The balance, however, favours compliance for two reasons. First, serious lack of compliance may put a company out of business by regulatory action, and the remedial actions to re-instate compliance could prove very costly. Second, adequate compliance can help to achieve 'right first time', contributing to the efficient operation of the testing laboratory; this is because regulations and guidelines are broadly based on good scientific and business practices.

The reliability of the results generated depends upon a solid foundation of interdependent quality systems in operation within the quality control laboratory and with their roots firmly embedded in good manufacturing practice (GMP) (MHRA 2007a,b). The pharmacopoeias play an important part in establishing and maintaining standards of testing and control that can be used by all pharmaceutical quality control laboratories, not only for established drugs but also as a good starting point for setting specifications for new chemical entities.

This chapter lays out the various quality systems embedded within the quality control laboratory operating to assure the reliability of the data produced.

Equipment qualification, calibration and maintenance

Before generating reliable analytical data it is essential that all equipment is operating correctly (Bedson, Sargent 1996). The requirements for the qualification of equipment are set out in the US Code of Federal Regulations, 21 CFR Part 211 §211.160(b)(4), §11.10(a), and the European Annex 15 and Annex 11. The purpose of the qualification of laboratory equipment is to ensure that the instrumentation has been installed correctly, that the instrument functions according to specifications and that the overall performance is satisfactory for its intended use. This is usually achieved through a qualification plan containing a Design Qualification, an Installation Qualification, an Operational Qualification and a Performance Qualification. It is for good business, financial and compliance reasons that the analytical instruments perform as intended. The procurement of equipment should be a well-structured and documented process, leading to adequate testing during the qualification in the testing laboratory. The instrument configuration and validation status should be managed throughout its life cycle: from installation to retirement.

The Design Qualification (DQ) must be written and approved before the purchase of the equipment. The DQ documents the specification of the equipment that will meet all expected needs and encompass all regulatory, business, methodological and pharmacopoeial requirements. For example, if an ultraviolet/visible (UV-Vis) spectrophotometer is to be purchased, it is necessary to specify in the DQ the wavelength range to cover all the assays made now as well as those that are likely to be made in the future in the UV and visible ranges. Compliance with the British Pharmacopoeia UV-Vis spectrophotometer monograph (or similar) regarding wavelength and absorbance accuracy is usual.

Once the equipment has been purchased, an Installation Qualification (IQ) is performed. This checks that all the parts of the equipment are present and undamaged, all the serial numbers are recorded, including firmware/software revision numbers, and the equipment is appropriately located in the laboratory with all required services and that it powers up.

Next an Operational Qualification (OQ) is performed wherein the instrument is checked to ensure that it is set up correctly and calibrated to the manufacturer's specification and national standards where appropriate. This is typically undertaken by the supplier, although this must be overseen and approved by laboratory personnel.

Finally, a Performance Qualification (PQ) is carried out to verify and document the ongoing performance of the equipment. This is typically carried out periodically at an appropriate frequency. This can be daily (e.g. pH meters) to 6 monthly (e.g. high performance liquid chromatography (HPLC) systems). PQ is documented in log books or pro-forma worksheets. For larger equipment, the PQ will follow routine maintenance activities to ensure that the equipment is within calibration following maintenance. This is because the maintenance may have involved intervention to replace worn parts that could have rendered the instrument out of calibrated status.

Maintenance records must be maintained and signed off by laboratory personnel. These records will demonstrate that appropriate care is being given to the equipment and are often requested as part of regulatory inspections.

One aspect that must not be forgotten in the pharmaceutical laboratory is the grade of volumetric glassware such as pipettes and volumetric flasks. These must be of the appropriate grade (Grade A) that guarantees the accuracy of the glassware for quantitative work.

Analytical development and validation

The testing methods should be developed to comply strictly with the overall purpose of the method. This may seem obvious, but, frequently, methods are not appropriate for the purpose of the testing, for example because of lack of specificity or sensitivity. The subject of development of testing methods is far too complex to discuss here. Nevertheless, in the same way that equipment is designed for a certain purpose, the development of testing methods should be preceded by a careful consideration of objectives, purpose, intended use and the capability of the techniques employed.

The validation of the testing methods is a well-established requirement in the pharmaceutical industry. This legal aspect is documented in *Rules governing medicinal products in the European Union*, Vol. 4, chapter 6, section 6.15 and *21 Code of Federal Regulation* (CFR) part 211 §211.194(a)(2). The International Conference on Harmonisation (ICH) guidelines, *Validation of Analytical Procedures: Terminology* (Q2A) and *Validation of Analytical Procedures: Methodology* (Q2B) have been in place for several years. Adherence to these guidelines is not mandatory, although the rationale for deviating from these guidelines should be clearly documented in the method validation protocol.

As it is established in the guideline Q2A, 'The objective of the validation of the testing method is to demonstrate that it is suitable for its intended purpose'. This objective is achieved by demonstrating that the results of the validation characteristics obtained during the validation are within the acceptance criteria included in the validation protocol, which has to be written and approved before the validation exercise is started.

ICH Q6A and Q6B specifications can provide significant assistance for the establishment of rational, sound acceptance criteria.

The development and validation of analytical methods and procedures for the stability testing of medicines are a particular and extremely important requirement; 21 CFR 211, §211.166 demands the existence of such testing. Adequate guidance for the conduct of these tests can be found in the ICH guidelines Q1a, Q1b, Q1c and Q1d.

The ICH guideline Q2(R1) on *Validation of Analytical Procedures: Text and Methodology* defines eight characteristics to be considered when validating testing methods (ICH Topic Q2(R1) 1994). These are:

1. Specificity
2. Accuracy
3. Precision:
   - — Repeatability
   - — Intermediate precision
   - — Reproducibility
4. Detection limit
5. Quantification limit
6. Linearity
7. Range
8. Robustness.

Table 21.1 shows which characteristics should be evaluated for identity tests, impurity tests (quantitative and limit tests) and assay methods. Before the publication of the ICH guidelines on analytical validation there was a plethora of validation terms used by analysts. The guidelines have therefore helped to standardise the terminology. The terms used in analytical validation information are now clear to regulators, academia and the industry.

The following sections describe the ICH validation characteristics that may be applied in pharmaceutical analysis. For a description of the validation of methods for the analysis of drugs and poisons in biological materials see Chapter 20.

Specificity

Specificity is defined as the ability of a method to selectively respond to the analyte of interest. When developing methods for drug products it is important to consider related substances, including synthesis or fermentation impurities (by-products) and degradants as well as excipients.

Specificity is built into a chromatographic analytical method during its development by systematically varying the system variables (column, mobile phase composition, temperature, flow rate, etc.) until satisfactory resolution is achieved. The use of expert systems for automatic optimisation of chromatographic separations is commonplace in research and development analytical departments. The use of diode array detectors and peak deconvolution software can aid the analytical chemist in demonstrating that the analytical method is specific for the analyte of interest. Closely eluting impurities should be used in a system suitability test solution and appropriate limits for resolution set. System suitability checks are performed each time an assay is performed to verify that the test was set up correctly to generate meaningful data.

In early drug development, the potential routes of degradation of a drug substance may not be known. Nevertheless, the analytical chemist must develop a stability-indicating assay procedure to determine the

Table 21.1 Parameters to be evaluated during method validation

Characteristics	*Type of analytical procedure*			
	Identification	*Testing for impurities*		*Assay*
		Quantification	*Limit*	■ *Dissolution (measurement only)* ■ *Content/potency*
Accuracy	–	+	–	+
Precision				
Repeatability	–	+	–	+
Intermediate precision	–	+[a]	–	+[a]
Selectivity/specificity[b]	+	+	+	+
Limit of detection (LOD)	–	–[c]	+	–
Limit of quantification (LOQ)	–	+	–	+
Linearity	–	+	–	+
Range	–	+	–	+

– signifies that this parameter is not normally evaluated.
+ signifies that this parameter is normally evaluated.
[a]In cases where reproducibility has been performed, intermediate precision is not needed.
[b]Lack of specificity of one analytical procedure could be compensated by other supporting analytical procedure(s).
[c]May be needed in some cases.

inherent stability of the drug substance. This is done by subjecting the drug substance to extremes of temperature, light, pH and oxidation, and then examining the resulting solutions using the proposed chromatographic conditions.

Absence of excipient interference should be verified by preparing a placebo mix of a drug product formulation and taking this through the analytical procedure. In the case of a spectroscopic method, no absorbance reading should be observed at the quantification wavelength for the analyte. However, for chromatographic procedures, a peak from an excipient may be acceptable provided that it is well resolved from the analyte(s).

It is also advisable to consider the effects of ageing of the excipients on the analytical method where decomposition products may interfere. Accelerated stability studies on placebo formulations are useful in this respect.

Accuracy

Accuracy expresses the closeness of agreement between the value that is accepted, either as a conventional true value or an accepted reference value, and the value found. Expressing this another way, it is a measure of how close, on average, the results of a method come to the true value of sample. It is sometimes called 'bias' or 'systematic error'.

Accuracy is usually demonstrated by carrying out recovery experiments through the spiked addition of active drug to a placebo formulation. The experiments must be planned so that the results may be statistically evaluated. It should be shown that the recoveries are independent of the concentration of the active, over a reasonable concentration range, typically 50–150% of the nominal concentration. The range should cover different dose levels if this is appropriate. The experiments will involve adding known amounts of API to a given weight (or volume) of the placebo formulation as required by the method. Each spiked sample must be taken through the whole analytical process, from sample preparation, through extraction to measurement.

The results are expressed as percentage recovery. A typical acceptance criterion for chromatographic methods is a recovery of 98–102% with a relative standard deviation of less than 2%.

Precision

This is a measure of the variation or scatter between replicate measurements as a result of random errors. It is usually expressed quantitatively as the relative standard deviation (or coefficient of variation) of the method.

Precision is an important parameter especially when investigating the homogeneity of a product. It is important that the precision of a method be sufficiently low that it does not affect any interpretation of the results for the degree of uniformity of a batch. As with accuracy, it is important to take the sample through the whole procedure. It is not sufficient, for example, to quote simply the precision of injection or the repeatability of a spectrophotometer reading, as the precision of a method must include the effects of sample preparation.

Precision is considered to have three components: repeatability, intermediate precision and reproducibility.

Repeatability

This is the intra-assay precision of the method obtained under the same operating conditions, i.e. the precision obtained by one analyst on the same HPLC equipment on the same day. It is determined by replicate analysis (at least six times) of a homogeneous sample and calculation of the standard deviation. The homogeneity of the sample is crucial.

Intermediate precision

This is the within-laboratory precision of the method, i.e. the variability obtained by different analysts on different days using different equipment but within the same laboratory. As with repeatability, it is usually expressed as the standard deviation (or coefficient of variation).

Reproducibility

This expresses the precision of the method between laboratories. It is determined by inter-laboratory collaborative studies using homogeneous samples split between the laboratories. It is important that each laboratory follows the method exactly. Reproducibility is an important parameter for regulatory and control purposes.

As might be expected, the repeatability of the method is always less than the reproducibility. Studies have shown that the ratio of the repeatability to the reproducibility is usually in the range 0.5–0.7. A ratio considerably less than 0.5 indicates a very 'personal' method. This may indeed indicate that the method requires considerable personal skill (for example, counting particles in an ophthalmic solution), or that the method instructions need to be clarified.

A survey by Horwitz of the data from over 150 collaborative studies showed that the precision varied with the concentration of the analyte (Royal Society of Chemistry 2004). A curve (Fig. 21.1) was generated relating the coefficient of variation to concentration of analyte. From this it was determined that assays of the active in a formulation at the 1–10% w/w level would be expected to have a reproducibility of about 1–2%, while analysis of trace impurities at the parts per million (ppm) level would be expected to have a coefficient of variation of about 15–20%.

Detection limit/quantification limit

Detection limits and quantification limits must be determined when quantifying trace impurities such as process impurities and degradants.

Detection limit is expressed as the lowest amount of analyte in a sample that can be detected but not necessarily quantified as an exact value. It is often quoted as three times the relative standard deviation of the method.

Quantification limit, on the other hand, is the lowest amount of analyte that can be quantitatively determined with acceptable accuracy and precision. It is often quoted as 10 times the relative standard deviation of the method.

A quantification limit check standard is usually prepared and run during tests for trace impurities. In this way, meaningful results can be reported; for example, impurity X: not detected less than 0.05% w/w.

Linearity

It is important to demonstrate that the response of the detector system is linear over the range of interest of the method. This is determined by means of plotting a calibration curve using increasing amounts of a standard solution and plotting a graph of response vs concentration.

The data can be evaluated statistically by linear regression. If the linearity is confirmed, then it is satisfactory to make calculations against a single standard during routine use of the method. The demonstration of linearity of response is an important criterion for all methods of analysis.

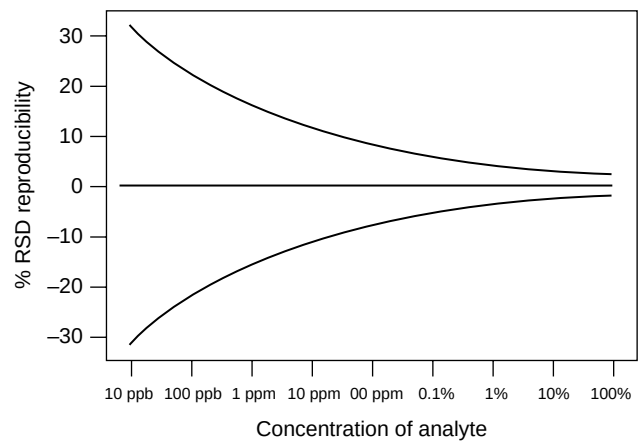

Figure 21.1 The 'Horwitz Trumpet' showing how reproducibility deteriorates with decreasing concentration of the analyte. Reproduced from AMC Technical Brief No.17, Thompson M, ed. Royal Society of Chemistry, July 2004

Range

The range of an analytical method is the interval between the upper and lower concentrations of the analyte in the sample for which it has been demonstrated that the analytical procedure has a suitable level of precision, accuracy and linearity. It is usually demonstrated during recovery experiments. This is particularly relevant to, say, dissolution testing where a dissolution profile is being determined. The analytical method must be capable of accurately and precisely quantifying the analyte over a range of 10–110% of the nominal concentration of the analyte in the dissolution vessel during the course of the experiment.

Robustness

It is not unknown, when an analytical method is transferred to another site, that problems are encountered and equivalent results are not obtained during the technology transfer process.

There can be many reasons for this; for example, the procedure may not be written clearly or may be ambiguous, or the use of different equipment, standards, reagents, solvents, etc. may have an adverse effect on the operation of the method.

These problems can be overcome if, at the completion of the method development programme, the robustness of the procedure is formally checked. This can be done by examination of the effect of making small changes in the experimental conditions. The changes made should be of the order expected in normal daily operation (slight changes in temperature, reagent concentration, reaction time, etc.). If significant effects are noted, then critical limits can be specified in the method. By obtaining a better insight into the effects of method variables, a much smoother handover process can be achieved, and considerable effort can be saved in investigating discrepancies and avoiding problems that may occur at a later stage.

Youden (in the *Statistical Manual of the Association of Official Analytical Chemists*) has put forward a simple experimental plan in which the effect of seven different factors can be studied (Youden, Steiner 1984). If the factors were varied individually this would result in the need for 128 individual experiments. By adopting a 'partial factorial' approach that allows several changes to be made at once by careful choice of these subsets, it is possible to examine the effect of seven factors in only eight experiments.

When performed, this approach can highlight method variables that must be carefully controlled such as mobile phase composition or pH of test solutions.

Note, however, that this procedure is intended only to study the effects of minor changes in the factors. The assumption is that minor changes in any one factor have no effect on the others. The procedure should not be used as an optimisation procedure during method or process development. Substantial changes in factors seldom act independently and the situation is more complex, for which this procedure is not suitable.

Sampling and retained sample management

Sampling is a crucial step in obtaining meaningful results. The sample must be representative of the batch and the sample integrity must be maintained prior to testing. If this is not the case, erroneous conclusions on the quality of the batch will result.

The taking of samples should be performed in such a manner as not to contaminate the batch being sampled. For this reason, raw materials (APIs and excipients) are usually sampled in laminar airflow booths using clean or disposable sampling implements by staff trained to do so.

Samples must be collected in accordance with approved procedures using an accepted sampling plan (British Standards Institution 1999) such as BS6001-1 : 1999/ISO 2859-1 : 1999. Each container of an API is sampled for identity and a composite sample is made for testing. Full testing may be relaxed if a supplier certification programme is in place that rates suppliers on the basis of audit, quality history of the material being sourced and skip lot testing.

Each container of some excipients with a high-risk profile is sampled to provide adequate assurance of quality; for example, each received container of glycerol is sampled to verify the absence of diethylene glycol due to recent contamination alerts.

The sample container needs to be adequately labelled so that the laboratory can identify it when commencing testing.

The sample size is important when assessing certain attributes such as blend uniformity. Here the sample size should be the same as the single dose size so that it is representative of the single dose unit for solid dose products.

Sufficient sample of a batch needs to be kept for re-test purposes should a quality problem be uncovered during the shelf-life of a product. This can then be re-examined in order to help identify the root cause and extent of the problem. Finished packed products are retained and visually examined periodically in order to highlight any product deterioration, e.g. leakage or degradation.

Reagent and reference standard management

Reagents are routinely used in the analytical laboratory, from titrations to preparing HPLC mobile phases. The analytical procedure should specify the required grade of reagent which is usually analytical reagent (AR) grade. The suitability of the reagents will have been verified during the validation of the analytical procedure. Some trace analysis work will require high-purity reagents to reduce interference from impurities.

The shelf-life of the reagents must be considered. In one laboratory, a storeman performing a stock take/clearout asked an analyst about a bottle of picric acid that he had found in the stores and read out the label which stated 'explosive when dry'. It was so old it had dried out completely to the extent that picric acid crystals could clearly be seen around the lid, ominously waiting to explode on any unsuspecting person innocently opening the container. The Bomb Squad calmly dealt with that one with a controlled explosion in a nearby field.

Shelf-life must take into account not only the chemical stability, but also microbial spoilage and potential cross-contamination when the reagent container is continuously opened and closed to remove aliquots for use. For these reasons, it is good practice to assign a shelf-life, both closed and opened, by attaching an expiration date label to the container. The supplier can (and often does) specify a shelf-life and required storage conditions for the reagent. If not, then experience must be used to assign a realistic shelf-life. The opened shelf-life should not exceed the unopened shelf-life.

A standard operating procedure (SOP) documenting the management of reagents (receipt, storage, use and shelf-life) is useful.

Laboratory-prepared reagents and solutions such as buffers, diluents and HPLC mobile phases will have a short shelf-life, e.g. one week to one month. This is to ensure that the effects of microbial spoilage, evaporation and uptake of CO_2 are minimised.

The reference standards need to be fully characterised to ensure their correct identity and purity. Purity is usually expressed as % w/w 'as is' or on the dry basis. For the latter, the reference standard needs to be dried prior to use or the moisture determined and factored into the assay calculation. The reference standard of a new chemical entity (NCE) will be characterised by the manufacturer using spectroscopic techniques such as mass spectrometry (MS), nuclear magnetic resonance (NMR) and infrared (IR) spectroscopy to confirm the structure. Purity is determined by a primary method such as non-aqueous titration or by subtraction of related substances, moisture and volatile organic substances (e.g. recrystallisation solvents) from 100%.

If the drug has a pharmacopoeial monograph, it usually has an associated chemical reference standard from that pharmacopoeia, e.g. British Pharmacopoeia (BPCRS), European Pharmacopoeia (EPCRS) and United States Pharmacopeia (USPCRS). These are available from LGC Standards: www.lgcstandards.com.

Once received, the standards must be stored as directed to prevent degradation that would alter the purity and cause bias in results calculated using the reference standard.

Cleaning of laboratory glassware

It is rare to use dedicated glassware for particular tests so the glassware that is to be used must be cleaned prior to next use to prevent cross-contamination.

A variety of glass washing methods are available from hand washing to specialist laboratory glassware washers. Irrespective of the method employed to clean the glassware, it is good practice to validate the washing method to ensure that traces of the previous drug have been removed and also that no residues of cleaning agents that may interfere with subsequent tests have remained on the glassware following rinsing.

This can be achieved by first defining the cleaning regime in a protocol; for example, specify cleaning agents and concentrations to be used, reference the cleaning cycle to be used, and so on.

The protocol will then define a 'marker drug' to be used that can be quantified. This will typically be a 'difficult to clean' drug that is used in the laboratory. A variety of glassware will be spiked with the drug and then subjected to the defined washing process. Following washing and drying, the cleaned glassware is rinsed with a suitable solvent and the rinse solutions are assayed for residual marker drug. Residual cleaning agent can also be checked with purified water as the solvent by using a specific method from the supplier, if available, or using non-specific but sensitive methods such as conductivity or total organic carbon (TOC) using the input purified water as the reference. The non-specific methods can be calibrated by setting up a calibration curve using serial dilutions of the cleaning agent.

Recording of the UV spectrum of the rinse solutions as well as the pH can also be employed to show that no interfering substances are present in the rinse solutions.

Once the cleaning procedure has been validated, it needs to be documented in an SOP to ensure that compliance with the validated procedure is maintained during routine use.

The cleaning of pipettes and burettes is particularly important since a build-up of grease can alter the volume through incomplete drainage. Pipette washers can be used that soak the pipettes in a suitable cleaning agent which removes grease. This is followed by a rinse cycle with potable water followed by a final rinse in purified water.

Training and compliance

High on the list of critical requirements in the testing laboratory is to have and to follow written procedures and to have an educated, trained workforce. The *Rules governing medicinal products in the European Union*, chapter 1, section 1.4; chapter 2, chapter 6, and the 21 CFR, part 211, §211.22(d) §211.25 establish this as a legal requirement.

Analysts and operators must be trained and knowledgeable in all necessary procedures to carry out their job duties effectively. They must have the appropriate education and experience to carry out these in a responsible manner.

Training of laboratory personnel is a critical element in the generation of valid analytical results. New starters, whether from school or university, will need to be trained in the laboratory procedures, equipment and test methods so that procedures are followed accurately (Pharmaceutical Analytical Sciences Group 2009).

Best practice involves talking the trainee through the procedure, SOP or method and then assessing competency through either a knowledge assessment or a skill assessment. A knowledge assessment could involve multiple-choice questions on a procedure, while a skill assessment will involve the trainer observing the trainee performing the method: for example, correct set-up, calibration and use of an IR spectrometer or following a test method and obtaining the correct results.

It is also important to give new starters GMP training at induction and then provide periodic refresher training to all laboratory staff on at least an annual basis. Training packages and videos are available to provide variety to this element of training and also to focus on areas to improve as identified in out-of-specification investigations and periodic reviews of laboratory performance.

Recording of laboratory data

21 CFR Part 211 and, in particular, §211.194 and *Rules governing medicinal products in the European Union*, Vol. 4, chapter 1, section 1.4 (iv) (vi); chapter 6 establish the regulatory requirements for documentation. Adequate procedures should be in place in order to generate, preserve and archive the laboratory documentation. Part 11 and Annex 11 requirements must be taken into consideration because most of the documentation created in modern laboratories is electronic. There are important demands to be placed on the documentation systems:

- Records must be complete, containing the necessary information and signed off by the person in charge.
- Records must be traceable.
- Records must be cross-referenced.
- Amendments made to a record must be duly documented and an audit trail must exist to ensure that information such as by whom, why and when the record was amended is available.
- Records must be kept for the relevant period; appropriate measures must be taken to ensure that records are preserved through time, use and disaster.

Recording laboratory data legibly and accurately is of crucial importance. The data will be checked before the results are used and they can also be reexamined in years to come in the event of a customer complaint, during regulatory inspections and customer audits.

The data can be recorded in a laboratory notebook or on a pro-forma template, but both must be controlled to ensure that data are not intentionally or accidentally discarded. Laboratory note books must have a unique identifying number and each page must be numbered. A proforma must be version controlled and issued to laboratory personnel in a controlled manner. The reason for the version number is to ensure that any superseded copies in the laboratory can be identified and destroyed. For example, a test method may have been changed, requiring a change to the calculation in the proforma.

The recorded data should form a permanent record with full traceability to verify the validity of the results. The following is an example of what needs to be recorded:

- Product name and strength
- Test method and specification number and version
- Name of the person performing the test
- Date
- Instrument numbers
- Reference standard lot number, expiration date and purity
- Weighings for the test article and reference standard(s), ideally with printouts
- Reagent lot numbers and expiration date
- HPLC column number
- Microbiological media lot number
- Variable instrument settings if not recorded on raw data printouts
- Calculation of results
- Name of the person checking the data.

From this information it is possible to trace back to verify that the person conducting the test was trained, that the instruments were maintained and calibrated, that the reagents were within their expiration date, and so on.

Out-of-specification investigations

As with any failure investigation, an out-of-specification (OOS) result is an opportunity to improve. The caveat is that the investigation must be conducted thoroughly in order to determine the root cause.

First and foremost, the OOS investigation is designed to determine whether the OOS is a result of a laboratory error, a processing error or a product problem (Food and Drug Administration 2006). At the outset there must be a standard methodology to investigate the OOS result in a structured manner in order to correctly determine whether the result is valid. Some years ago the manner in which the industry handled OOS investigations was inconsistent and ranged from performing repeat testing until an in-specification result was obtained to following a systematic approach to assign root cause. This has now ceased and robust procedures to investigate OOS results are routine.

There are three reasons why an OOS result is obtained:

1. Laboratory error, e.g. a 250 mL volumetric flask was used instead of a 200 mL flask.

2. Processing error, e.g. the stirrer in the production vessel stopped due to a mechanical problem when homogenising a suspension.
3. A flaw in the process or product design, e.g. the process when run correctly did not result in a uniform blend.

Use of decision trees is commonplace in investigating OOS results (Fig. 21.2). The first stage of an OOS investigation involves the analyst informing the supervisor that an OOS has been obtained and performing an initial investigation. At this stage it is crucial to retain all test solutions, reference standard solutions and glassware so that these can be examined during the investigation, if required.

The following aspects will be checked at this stage:

- The calculations are correct and there are no arithmetic errors.
- The correct method has been used.
- The analyst is trained and is competent in performing the test.
- The correct weighings, dilutions and glassware have been used.
- The test solutions and reference standard solutions are examined to show that they are typical.
- The instruments used during the test have been calibrated and are working correctly.
- The chromatograms and spectra are examined to highlight any anomalous or suspect information. The response factors of reference standards are determined to see whether these are anomalous, which could point to incorrect preparation.
- The correct reagents, solvents and reference standards have been used and these are within their expiration dates.
- Anything anomalous that the analyst observed or noted during the conduct of the test.

The test solutions may be reanalysed and dilutions re-performed to verify a hypothesis formed during the initial investigation. For example, if it is suspected that the diluted test sample was not mixed thoroughly, then the dilution can be performed again from the primary test solution, ensuring thorough mixing, and the result compared with the original OOS result to take the investigation forward.

If the OOS result can be directly attributed to an issue identified during this initial review, the OOS result can be invalidated and the corrective action will be to repeat the test on the same sample. It is important that preventive actions are considered that could stop the problem recurring.

Should this initial investigation not highlight any laboratory error, a full-scale OOS investigation is initiated. This involves a detailed manufacturing review. Here, the batch records and associated documentation will be reviewed to determine any atypical events that occurred during the manufacture of the batch that could explain the OOS result. If this is the case, the OOS investigation may be terminated and the batch rejected. However, the laboratory may assist in performing further testing to establish appropriate preventative actions in the manufacturing process.

If the manufacturing review shows no atypical event, and all in-process results are satisfactory and all process critical control points have been achieved, then the laboratory investigation proceeds to the next stage.

Here, a re-test plan is developed to identify the source of the OOS, which will involve re-testing and if justified re-sampling (if, for example, the integrity of the initial sample is suspect for reasons such as inappropriate storage or non-compliance with the approved sampling plan).

At the end of the investigation, if the initial result is invalidated then it should not be used to evaluate the quality of the batch for release or rejection. However, if a scientifically justified reason cannot be found to invalidate the initial result, even if all repeat results are within specification, then the initial result must be included in the data set used by the qualified person (within the European Union) or the quality control unit responsible for the release/reject of the batch.

One final word on OOS. The procedure is also applicable to atypical or out-of-trend results. Such results can signal an alarm that not all is well with the batch and further re-testing in an OOS investigation could reveal this and prevent a poor-quality batch being released to the market.

Management of SOPs, specifications and test methods

Laboratory SOPs are best written by staff who understand the equipment or process. SOPs must have a unique identifier number and version number (e.g. SOPXXXX/YY) and they must be periodically reviewed to ensure that they reflect current practice and are in the current format. Sometimes events supersede the review period, such as a firmware upgrade for a piece of laboratory equipment that affects the output screen or sequence of operation. Such changes require an immediate update of the SOP. Probably the biggest cause of SOP update is the high level of mergers and acquisitions in the pharmaceutical industry, with the resulting changes in company names and logos.

When well written, SOPs can have a positive impact on laboratory compliance by encouraging their use as a result of their being user friendly. The use of photographs and process flow diagrams can help to reduce human error. A picture is worth a thousand words, so the saying goes. The SOP should ideally be laid out into chronological steps and segmented to encourage staff dipping into the relevant section. The use of flowery language or too many words should be avoided as staff will be reluctant to seek out the information that they require if it is buried deep in a huge SOP.

Turning to specifications, these also need to be uniquely numbered and version controlled and the product to which the specification relates should be clearly documented in the title. The units of measurement must be included and particular attention needs to be paid to the correct number of decimal places.

Test methods must be well written in manageable steps so that it is easy to keep track of where you are should the reader be distracted. Human error can occur through skipping or repeating steps, and a good document layout can help to reduce this.

During robustness testing of the method, critical limits such as mobile-phase pH limits and the grade of reagents should have been defined.

Trending and periodic reviews

In a pharmaceutical quality control laboratory, numerical data should be trended to flag up potential problems before they occur. Sometimes processes drift and, if the laboratory can highlight that a process is going out of control, then an investigation may identify the root cause before a situation is reached requiring batch rejection. There are a variety of trending methods available that highlight whether a process is drifting. These include Acceptance Control Charts (see ISO 7966), Control Charts with Arithmetic Average and Warning Limits (see ISO 7873), Cumulative Sum Charts (see ISO 7871) and Shewhart Control Charts (see ISO 8258).

Periodic product reviews are useful in spotting step changes in processes that may be linked to, say, a planned and validated process change. The validation of the change may have verified that the resulting product was within the specification limits. However, the step change may not have been identified at the time of the change approval.

Periodic equipment reviews in the laboratory are useful in verifying that the equipment has been adequately maintained and calibrated. It will highlight whether the calibration frequency is appropriate or whether it needs to be shortened or can be lengthened, thereby freeing up valuable laboratory resources. It can also highlight when a piece of equipment is coming towards the end of its serviceable life if the review picks out that the level of breakdowns has increased.

Stability testing of pharmaceuticals: ICH conditions and shelf-life prediction

Stability testing of pharmaceuticals is an integral part of the development programme. Initially, stability results will assist in selecting appropriate primary packaging materials such as amber vials to protect light-sensitive products and aluminium blister strips to protect hygroscopic products.

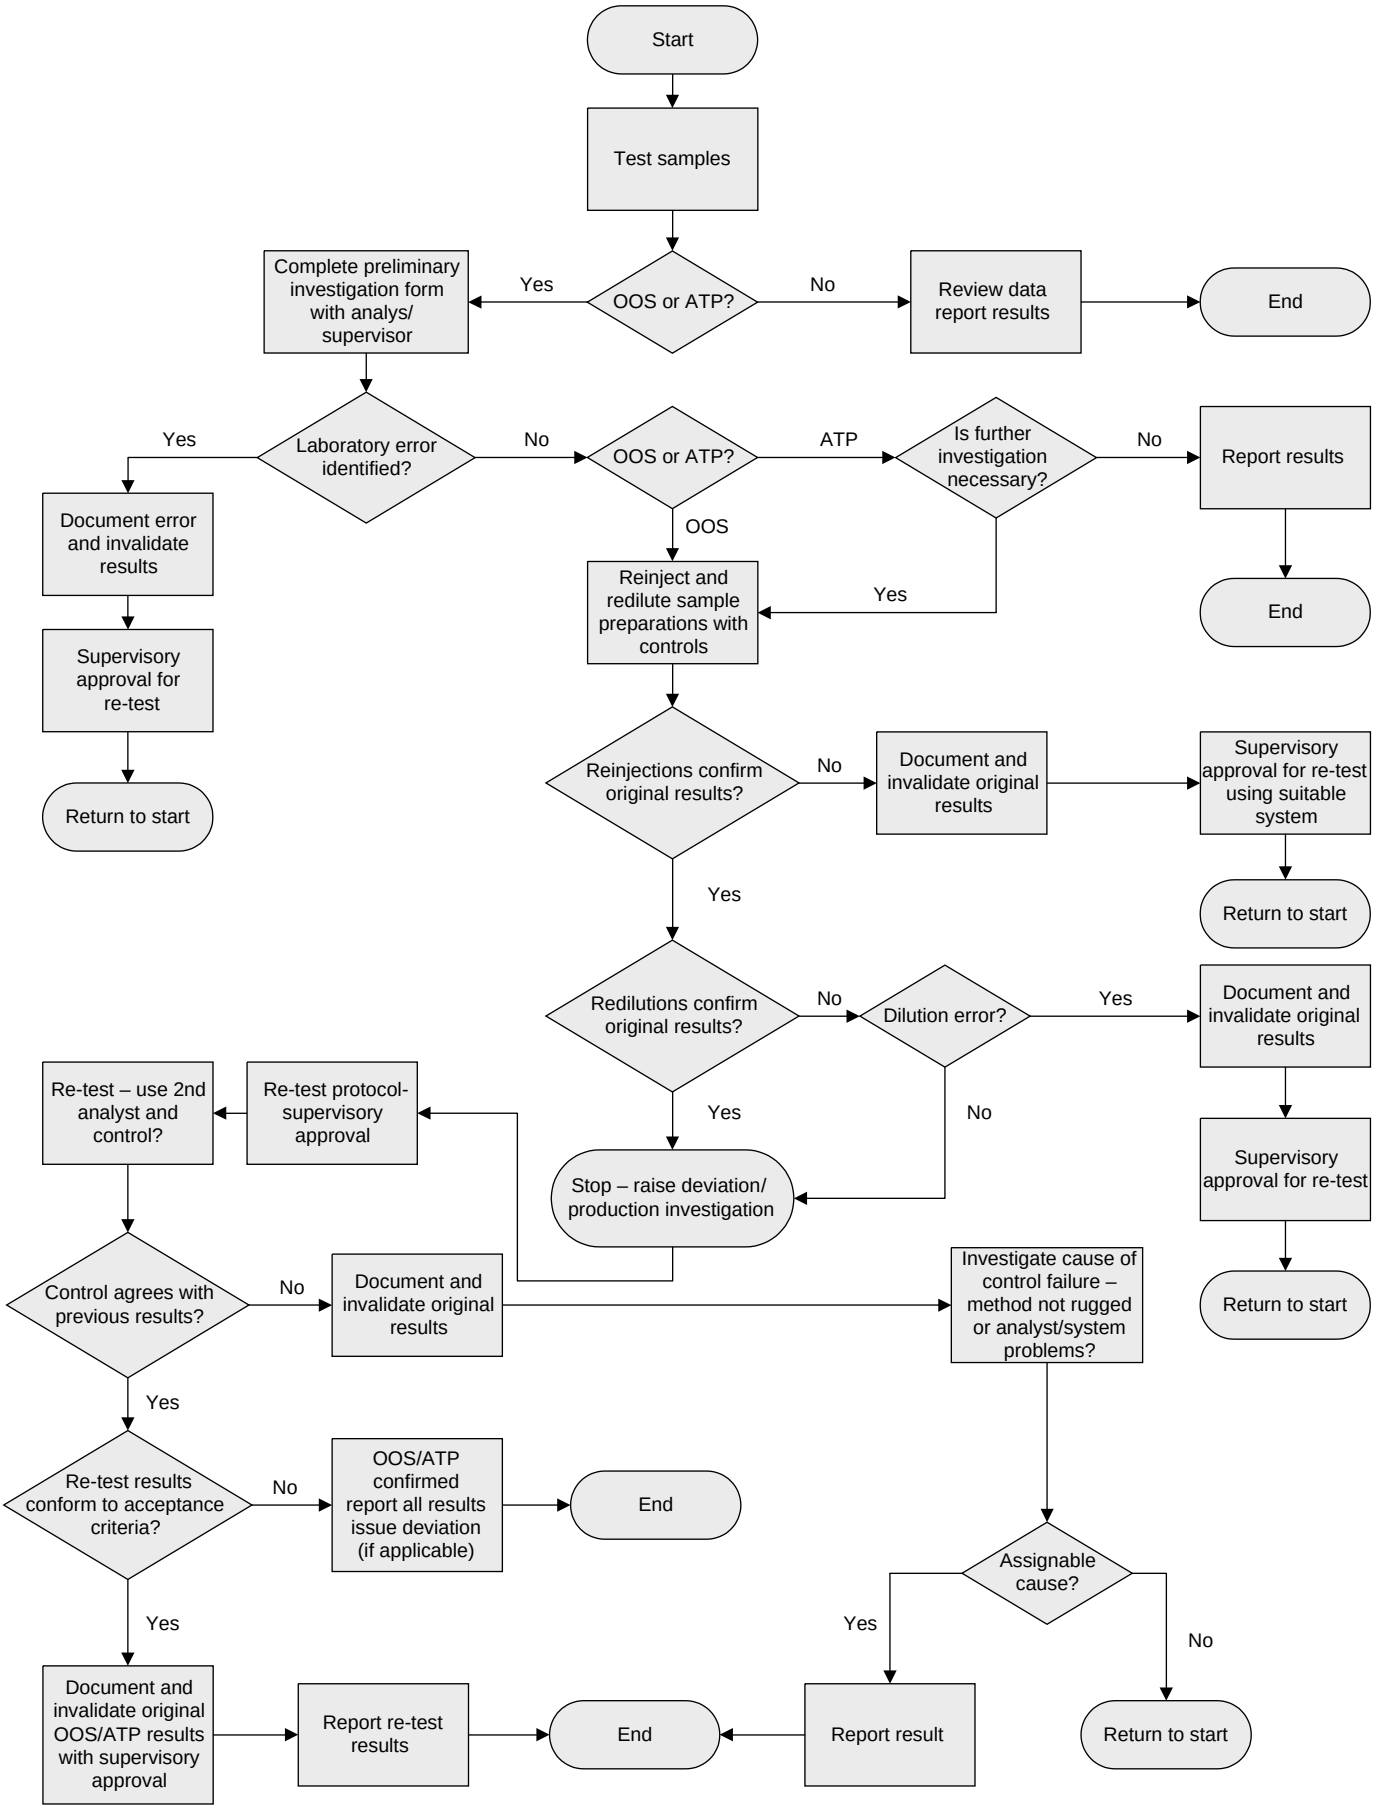

Figure 21.2 Typical out-of-specification (OOS) investigation decision tree.

Once the pack configuration has been selected, a stability programme can be initiated. ICH have published standardised storage conditions in the guideline Q1A (R2): *Stability Testing of New Drug Substances and Products* (Second Revision) (ICH Topic Q1A(R2) 2003) These are as follows:

Product intended for storage in a freezer:

$-20°C \pm 5°C$
$5°C \pm 3°C$ (accelerated storage condition).

Product intended for storage in a refrigerator:

$5°C \pm 3°C$
$25°C \pm 2°C$ and 65% relative humidity (RH) $\pm$ 5% RH (accelerated storage condition).

Product intended for room-temperature storage:

$25°C \pm 2°C$ and 60% RH $\pm$ 5% RH or
$30°C \pm 2°C$ and 65% RH $\pm$ 5% RH or
$40°C \pm 2°C$ and 75% RH $\pm$ 5% RH (accelerated storage condition).

A typical stability protocol will involve testing at initial, 1 month, 3 months, 6 months, 9 months, 12 months, 18 months, 24 months, etc. with testing of the accelerated storage samples up to 3–6 months.

Testing will depend upon the dosage form, but the following tests are typically performed:

- Appearance, assay, degradants, functionality tests such as dissolution for tablets or fine particle dose for metered dose inhalers.
- Once sufficient real-time stability data are available, extrapolation can be used to estimate shelf-life as shown in Fig. 21.3. Up to four times the real-time data can be granted for investigational medicinal products provided that this is supported by data extrapolation; for example, 3 months' real-time data can support up to 12 months' shelf-life.
- Stability studies are also performed on a sample of routine production batches to determine whether any change in stability characteristics occur over time. Here, the long-term storage condition is employed with no accelerated conditions used. Some product recalls have occurred because stability testing has predicted that the product will not meet the labelled expiration date.

Functionality testing

Quality control is not only about determining the concentration and identity of the active ingredient and potential impurities in a dosage form. It is important also to control the manufacturing process to ensure that the delivery of the drug will meet the design characteristics of the formulation so that a patient receives the right dose over the correct duration. For instance, if a patient has a blinding headache, the analgesic tablet must dissolve rapidly in the stomach to release the active ingredient into the bloodstream as rapidly as possible. Similarly, an enteric-coated tablet is designed to release the active ingredient in the duodenum and not in the stomach, so it is essential to check that the enteric coat works and the drug is not released in the acidic environment of the stomach where it may be degraded before it is released into the bloodstream.

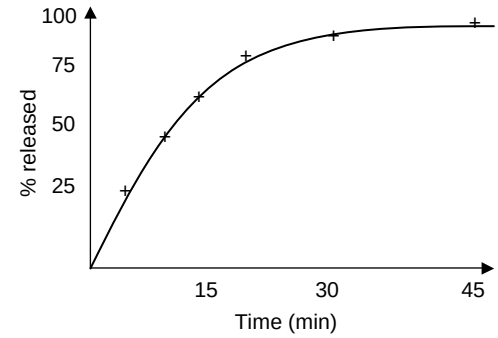

Figure 21.4 Dissolution curve showing percentage released against time.

Standardised methods are employed to confirm the correct functioning of the dosage form, and these are described in the pharmacopoeias. The testing of tablet functionality involves the use of dissolution equipment.

The basic equipment consists of a glass pot with a rotating basket (or paddle) immersed in a water bath at $37 \pm 0.5°C$. The pot is filled with a specified volume of de-aerated medium and a tablet is added to each of six pots. The paddle is rotated at a fixed speed and samples are taken for quantitative analysis at the prescribed time(s). The samples are then assayed and the results are expressed as percentage released (Fig. 21.4).

The equipment is highly standardised with tight tolerances in order to ensure consistent results test to test (Fig. 21.5). Regular calibration is undertaken to ensure that the equipment remains within tolerance. The checks include dimensional checks, speed of rotation of the paddle, degree of wobble of the paddle and temperature of the medium. For calibration of the dissolution apparatus the US Pharmacopeia uses calibrator tablets of salicylic acid and prednisolone with predefined acceptance criteria for release, although these rely heavily on the consistency of the batch of calibrator tablets, which has been a problem over the years. For this reason, it is proposed to discontinue the use of calibrator tablets. The sample location is important for reliable results, so the sampling tube is fixed at a defined height and distance from the vessel wall.

A typical specification for a rapid release tablet is not less than 70% released in 45 min.

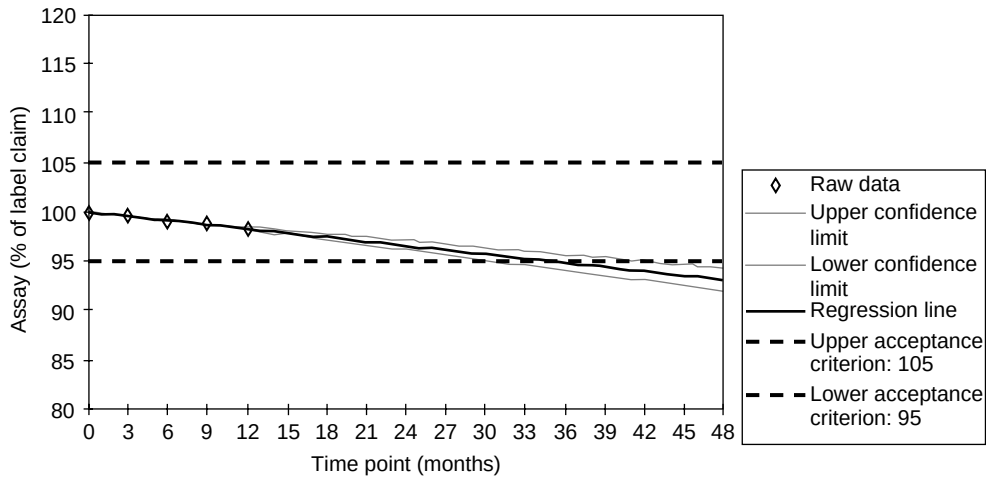

Figure 21.3 Extrapolation of stability data to estimate shelf-life. Reproduced from ICH Q1E.

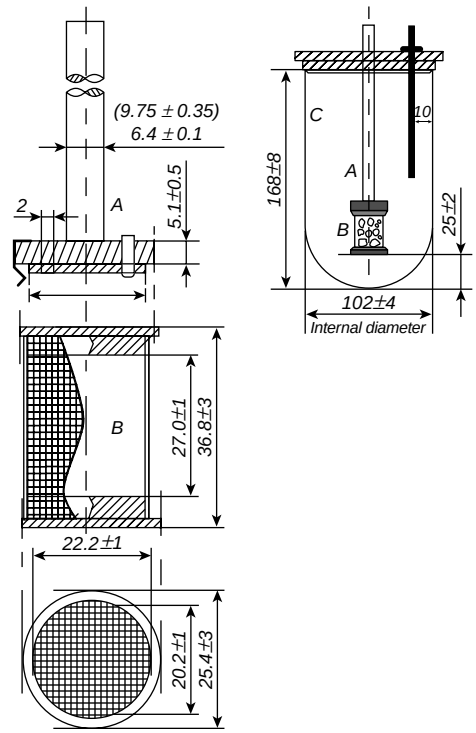

Figure 21.5 Dissolution pot and basket configuration with dimensions for Apparatus I. Reproduced from the British Pharmacopoeia.

Functionality testing is also important for inhalation products such as metered-dose inhalers. The correct dose delivered to the patients lungs is dependent upon the correct operation of the metered-dose valve, the correct particle size of the aerosol cloud and the homogeneity of the drug in the propellant.

For inhalation products, an impinger device such as a glass impinger (Fig. 21.6) is used to confirm that the correct dose is delivered to the lungs. Note that, as with the dissolution apparatus for solid dose products, the glass impinger has similarly tight tolerances specified for the apparatus.

Testing for impurities

The control of impurities in an API and drug product is important to ensure the safety and quality of the drug product for the patient. Impurities in APIs can be classified as organic impurities (also referred to as related substances) such as starting materials and by-products, inorganic impurities such as reagents and catalysts, and residues of solvents used in the synthesis or purification steps.

Acceptable limits for residual solvents in APIs are defined in ICH Q3C (ICH Topic Q3C 1997). Quantification is usually by GC.

Inorganic impurities are normally detected and quantified using pharmacopoeial methods, often as limit tests. The limits are established from known safety data on the particular impurity.

The ICH guideline Q3A(R2) *Impurities in New Drug Substances* (ICH Topic Q3A(R2) 2002; ICH Topic Q3B(R2) 2003) gives a standardised approach to impurity specifications. For organic impurities, the guideline specifies thresholds for reporting, identification and qualification of impurities based on the maximum daily dose as shown in Table 21.2.

For example, a drug that has a maximum daily dose of less than or equal to 2 g per day must have all impurities present at a level greater than 0.05% w/w reported. Of these, any impurity found to be present at a level greater than 0.10% w/w (or has a daily intake greater than 1.0 mg, whichever is the lower) must be identified. Furthermore, if the impurity is present at a level greater than 0.15% w/w (or 1.0 mg per day intake, whichever is lower) then it must be qualified. Qualification in this context is the process of obtaining data to establish the biological safety of the impurity.

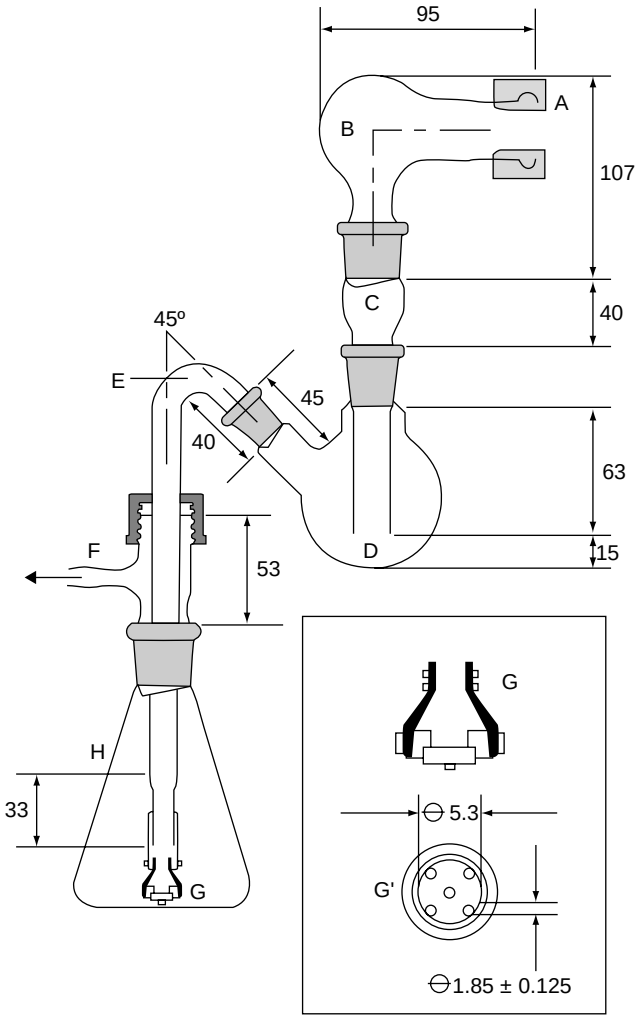

Figure 21.6 Glass impinger for metered dose inhaler functional testing. Reproduced from the British Pharmacopoeia.

As an example, a new drug substance that is to be administered at 100 mg per day has the following impurities by HPLC:

Impurity A	0.12% w/w
Impurity B	0.03% w/w
Impurity C	0.07% w/w
Impurity D	0.19% w/w

ICH guideline Q3A (R2) would require that impurities A, C and D be reported, that impurities A and D be identified (i.e. the structure elucidated), and that impurity D be qualified before clinical trials can take place.

It is also a requirement to set a total impurity specification.

For the example above, a typical related-substances specification and results would be as shown in Table 21.3.

For drug products, the ICH guideline Q3B (R2) *Impurities in New Drug Products* applies, which follows the same principles of thresholds as for new drug substances. Since impurities in the drug substance are already controlled by the drug substance specification, such impurities need not necessarily be controlled in the drug product. A drug product specification only needs to control impurities that are formed during the manufacturing process or degradation products formed during storage. It could well be that an impurity in the drug substance is also a degradant in the drug product and so will need to be controlled in both the drug substance and drug product specifications.

So how does one go about setting a specification for an API or a drug product? This is usually done at an early stage of the development process during initial validation studies of the analytical method,

Table 21.2 Thresholds for reporting, identifying and qualifying impurities

Maximum daily dose[a]	*Reporting threshold*[b,c]	*Identification threshold*[c]	*Qualification threshold*[c]
≤2 g	0.05% w/w	0.10% w/w or 1.0 mg per day intake (whichever is lower)	0.15% w/w or 1.0 mg per day intake (whichever is lower)
>2 g	0.03% w/w	0.05% w/w	0.05 w/w

[a]The amount of drug substance administered per day.
[b]Higher reporting thresholds should be scientifically justified.
[c]Lower thresholds can be appropriate if the impurity is unusually toxic.

Table 21.3 Typical related substances specification and results

Related substance	*Specification*	*Result*
Specified impurity A	Not more than 0.15% w/w	0.12% w/w
Specified impurity C (unidentified)	Not more than 0.10% w/w	0.07% w/w
Specified impurity D	Not more than 0.30% w/w	0.19% w/w
Unspecified impurities	Not more than 0.10% w/w	Detected[a] <0.05% w/w
Total impurities	Less than 1.00% w/w	0.38% w/w

[a]Impurity B (unspecified impurity) was detected but below the reporting limit of 0.05%.

usually HPLC with UV detection, to control the assay and purity of the drug.

Known reference materials of synthesis impurities/degradants, if available, can be used to develop the chromatographic separation so that the active is resolved from its impurities. Forced degradation studies are also performed to understand the potential degradation pathways of the drug substance. These will look at the effect of pH, light and oxidation on the drug substance. (See the section on Analytical development and validation, Specificity.) Major degradants will be identified and characterised as this information may be useful in selecting an appropriate container/closure system and in developing the formulation to prevent or reduce the degradation of the drug to provide a usable shelf-life of the product. The retention times of the impurities are recorded. If unknown impurities are observed during the method development, these can be identified using HPLC with MS detection. It is usual then to confirm the correct identification by synthesising the impurity and verifying that the retention time and spectral characteristics match. It can occur that an impurity is closely related to the drug substance and co-elutes owing to its similar chromatographic behaviour. It is important during the development of the method that the chromatography is challenged by checking the peak purity using deconvolution software and varying the chromatographic conditions to tease out any co-eluting impurities. If this occurs, the chromatography is modified to ensure that resolution is achieved in order to control the impurity. Closely eluting impurities are often used in chromatographic system suitability resolution checks to demonstrate that the method is performing as intended on the day of testing.

Quantification of impurities can be performed by calculation against a known concentration of a reference standard of the impurity with a known purity. However, if a reference standard is not available then percentage normalisation against the drug substance peak can be employed. The assumption is that the impurity has the same or similar response factor as the drug substance. If this is not the case, then a response factor of the impurity can be determined against the drug substance and then used in the calculation.

The use of mass balance calculations when assessing the purity of a drug substance can give the analyst a clue that there is a response factor difference between the drug substance and the impurity. For example, if the assay (on a dry basis) of a drug substance is 97.5% w/w and the sum of the impurities is 5.5% w/w, then this suggests that an impurity has a greater response factor than the drug substance which required further investigation. This may reveal that an impurity has twice the response factor in comparison to the drug substance, which will need to be taken into consideration for accurate quantification of the impurity. This may be achieved by quantification of the impurity against a reference standard of the same response factor or by employing response factor compensation in the calculation.

As drugs become more and more potent, the accurate quantification of low levels of impurities becomes increasingly more difficult and more sensitive methods must be employed to control them. Analytical instrument manufacturers must develop detectors with increasing sensitivity, or the analysts must devise strategies to quantify impurities down to the required specification with currently available technology. For genotoxic impurities for which a toxicological threshold level cannot be determined, the regulatory expectation is that the analyst must develop a method sufficiently sensitive to control the level to as low as is reasonably practicable (European Medicines Agency 2006) (the so-called ALARP principle).

CHAPTER

22 Quality Control and Accreditation in the Toxicology Laboratory

AC Moffat

Introduction

It is important in many spheres to have reliable, interchangeable data on the recovery, identification and quantification of drugs. In the pharmaceutical industry, quality control and assessment are required to monitor production and assess the quality, safety and efficacy of its products. In clinical analysis, it is vital to the quality and safety of patient care, to the diagnosis and control of therapy for the individual patient, and for research and public health purposes. For toxicologists and pathologists, it helps to distinguish between therapeutic and overdose levels and to determine the cause of death. In law enforcement, it is used to provide information to link drugs offences, to identify drugs distribution networks and to provide evidence of possession or misuse for the courts. It is also essential for monitoring individuals on drug rehabilitation programmes and for workplace testing of employees in certain occupations.

To produce reliable and interchangeable data, toxicology laboratories have to employ competent analysts and use validated methods. These analysts need appropriate accommodation and environmental conditions in which to work and access to all the equipment and other materials required to carry out their analyses safely and to an acceptable standard. They must also have systems that monitor and maintain the quality of their results and establish the uncertainty of their measurements, and they should participate in relevant external quality assessment (inter-laboratory proficiency testing) exercises (ISO/IEC 1997).

These requirements all fall within the ambit of the quality assurance programme to which laboratories must work if they seek accreditation to national or international quality standards or to protocols relevant to the field of drugs testing, such as ISO/IEC 17025:2005 (ISO/IEC 2005), ISO 15189 (ISO 2007), good laboratory practice (GLP; OECD 1998) or the Mandatory Health and Human Services Guidelines for Federal Workplace Drug Testing Programs (DHHS 2004).

Accreditation to ISO 17025 is now becoming the international standard for forensic toxicology laboratories. For example, in Australia all laboratories must be accredited to ISO 17025 to undertake any kind of forensic toxicology testing. Also, in the UK the Forensic Science Regulator has made it a firm requirement that all forensic science providers shall gain accreditation to his draft published standard and to ISO 17025 for the scope of their work (Forensic Science Regulator 2009a). There was overwhelming support from the forensic science community that providers with a laboratory function should be accredited to ISO 17025 and agreement that the standard be applied rigorously to all providers, including those working for the defence and in-house provision by law enforcement bodies (Forensic Science Regulator 2009b). In addition, the World Anti-Doping Agency (WADA) requires laboratories to be accredited to ISO 17025 to be eligible for WADA accreditation (see Chapter 6).

Quality assurance terminology

Quality is the totality of features and characteristics of a product or service that bears on its ability to satisfy stated or implied needs. It is its fitness for the purpose or use specified by the customer. It is determined by the competence of the people who produce the product or provide the service, the facilities available to them and the processes and procedures that they employ.

Quality assurance (QA) is a global term to describe those means of ensuring that the results and interpretations issued by a laboratory are dependable and sufficiently unbiased and precise to allow decisions to be taken with confidence. It is an internal management tool concerned with the prevention of quality problems through planned and systematic activities. These include the establishment of a documented *quality system* that sets out the organisational structure, responsibilities, procedures, processes and resources to implement quality management, assessment of the adequacy of this quality system, audit of its operation and review of the system itself.

Quality control (QC) is that aspect of QA concerned with the practical activities and techniques employed to achieve and maintain the product or service quality. It thus also involves monitoring the processes and procedures used, and the identification and elimination of causes of quality problems so that the requirements of the customer are met continually. The aim of QC is to ensure compliance with the quality specification and to provide economic effectiveness by eliminating causes of unsatisfactory performance at the relevant stages of the operation.

Internal audit is a process of critical review of the laboratory's processes. It is conducted by quality managers and experienced laboratory staff. Audits usually aim to monitor the accuracy, timeliness and cost of work and compliance with the quality management system, and to identify for action areas where errors can occur.

External audit involves customers or other stakeholders in the evaluation of the quality and usefulness of the laboratory's services. It facilitates comparison of methods, working practices, costs and workload between laboratories (testing sites), and forms part of the cyclic process of setting standards, examining compliance and re-examining the standards.

External quality assessment (EQA) is a way to benchmark the performance of one laboratory with that of other testing sites by comparing the results of their analyses of an identical specimen with each other's results and with the 'correct' answer. It allows laboratories to identify areas for improvement and best practice.

Assessment is the process by which an independent accrediting body inspects and evaluates the operation of an organisation that produces the product or provides the service against a relevant national or international quality standard. The factors considered vary from one standard to another, but may include the management structure, the numbers, qualifications and training of staff, the facilities available, the methods and processes adopted, the QA and QC arrangements, documentation, reporting procedures, communications within the laboratory and with users, safety and participation in EQA schemes. In essence, the accrediting body has to ensure that the organisation's quality system is sufficiently comprehensive for the operation being assessed and that the organisation consistently does what the quality system says it should. If the assessment is satisfactory, the organisation may be *accredited* for the particular operation.

Accreditation is thus one way to demonstrate the quality of an organisation's products or services to its customers. Accreditation may be voluntary or may be linked to a formal system of licensing, whereby only accredited laboratories are legally entitled to practise (or to receive payment for their services).

Quality systems

The quality system should address all stages of an operation that could affect the reliability of the end result and the monitoring of performance, so that timely corrective action can be taken where necessary. The technical requirements of ISO 17025 requires specification, determination and documentation of the: personnel; accommodation and environmental conditions; methods, method validation and measurement uncertainty; equipment; measurement traceability; sampling, handling and storage; assuring quality; and reporting results. These requirements are described below.

Personnel

Staff in toxicology laboratories should demonstrably be competent to do the range of work for which they are employed. This requires a code of ethics to which the individual must conform, clearly stated expected standards of performance and behaviour, a programme of training to help the individual attain those standards, and a mechanism in place to assess independently that they are working to the standards in the workplace. Training itself does not guarantee competence, so the assessment stage is vitally important. As soon as possible, the individual should be formally certified as competent by an appropriate authority and the scope of his or her competence should be recorded with the date on which competence was confirmed. Any extensions to scope should require the individual to go through the same process for the new area of work, and his or her competence should be reassessed regularly through task-related performance monitoring and participation in internal and external proficiency testing programmes. Job descriptions should be continuously reviewed. Continuing professional development is essential to keep up to date with developments in the field of work.

Accommodation and environmental conditions

Laboratory facilities and conditions should be suitable for the purposes for which they are being used. Contamination risks should be avoided by the use of appropriate air handling systems, designated areas for particular tasks and cleaning regimens. Attention should be given to features such as humidity, electrical supply, temperature, sound and vibration levels, and so on, and appropriate records made. Staff should have appropriate protective clothing as well as access to isolation facilities when known contaminated material, e.g. from an AIDS patient, is being analysed.

Methods, method validation and measurement uncertainty

Methods

Analytical methods should be characterised and documented fully by the use of manuals, standard operating procedures, checklists, reference data, etc. Their reliability in the specified area of application should be demonstrated before they are brought into use. Method validation ensures that methods are under statistical control and are fit for their intended purpose. Validation should cover all stages through sample selection and preparation, analyte recovery, calibration of equipment, the analysis protocol, and the assessment, interpretation and reporting of results. The measurement of uncertainty should form part of the method and reporting procedure.

Data should be controlled to ensure that they are not lost, or corrupted, and that confidentiality is maintained. Thus, computers should be adequately maintained and software validated before use. This is especially true where software is developed in house. Care must also be exercised when critical observations are made, calculations are performed and data are transcribed, to ensure that the results are recorded correctly and attributed to the right sample. It is best practice to use standard forms to facilitate these processes and to demonstrate that these records have been checked independently (e.g. by double-entry systems), where appropriate. The use of automated processes under the control of laboratory information management systems reduces the risks of error significantly.

Method validation

Validation of methods for the quantitative analysis of drugs involves determining, as a minimum:

- Selectivity
- Calibration model (linearity)
- Accuracy (bias and precision)
- Limit of quantification.

Additional parameters that might be evaluated include: limit of detection, working range, recovery, reproducibility and ruggedness under the conditions, and with the typical sample matrices that will be met in practice. For qualitative analysis, usually only the selectivity, limit of detection and ruggedness are important. Where there is a predefined threshold concentration for reported results, the accuracy and precision should be determined at the threshold level. For methods that are to be used by more than one laboratory, each laboratory should verify the method, and the inter-laboratory variation should be determined. These data should be used to define how the performance of the method is to be monitored through QC and to specify what performance is fit for purpose. If it is necessary to compare the results with those from other methods, the compatibility of data from the different methods should also form part of the validation (see Chapter 20 on method validation for a description of how to achieve this).

Any subsequent change at any stage of the method, or in the sample matrix or concentration range, will require revalidation of the method. The extent and requirements of revalidation will depend on what changes have been made.

Where a laboratory adopts an already validated method, it should demonstrate that the performance characteristics it can achieve are fit for the intended purpose of the method. Particularly important in this respect are selectivity (if the sample matrix is different), limit of detection, accuracy and precision.

In addition to analytical validation, it may also be necessary to carry out clinical validation. This requires:

- Determination of expected concentrations
- Differences associated with age, sex or other factors
- Cut-off values to classify results as 'normal' or 'abnormal', or as decision points in screening
- Clinical sensitivity ('positivity in users')
- Clinical specificity ('negativity in non-users').

Measurement uncertainty

The uncertainty associated with any measurement is made up of contributions from sample selection, sample preservation/transport, sample preparation, sample analysis and data evaluation. Those from sample selection are discussed below. During sample preparation, the uncertainty may arise from preferential selection, because of the different hardness of particles when crushing the sample, for example, through incomplete dissolution or through density separation during the attempted homogenisation of liquids. It may also result from the loss of sample material or analyte by adsorption or degradation, interference or contamination, or chemical changes in the material composition through oxidation or various other factors. Analytical measurement errors can be caused by breakdown of the analyte in the process, incomplete reaction processes, instrumental errors or maladjustments, poor calibration or matrix effects. Data evaluation errors can result from the use of incorrect or incomplete algorithms and the response can be additive, multiplicative or non-linear.

The errors that affect analytical measurements are of four types:

- Random errors, which are manifested as a spread of results of repeat determinations to higher and lower values around a mean for the sample, and determine the reproducibility or precision of the measurements.
- Systematic errors, which displace the results of measurement to higher or lower values and the existence and magnitude of which characterise the trueness of the measurement.
- Outliers, which are random errors of such large deviation that they would distort the mean if they were not eliminated.

- Gross errors, which are caused by human mistakes, or instrumental or mathematical problems, and may have either a random or systematic character.

A comprehensive guide to analytical uncertainty is available (EURACHEM 2000; also see Chapter 23 for a practical guide).

Random errors are a fundamental characteristic of the design of the processes and analytical method chosen. They can be minimised but not eliminated, and are usually characterised in terms of a confidence interval in an assumed normal distribution of results about the mean value. If this is determined simply by repeat measurement in the analytical method, the confidence interval represents only the error of the result caused by measurement. If the total error of the procedure is to be reflected in the confidence interval, parallel samples have to be selected and taken through the whole process.

Systematic errors can be recognised only if the results fall outside the random error confidence interval on one side of the mean, but they can be eliminated once their cause is known. They are best identified by analysis of chemical reference materials (where these are available), by comparison with results from independent validated methods or by EQA. The observed mean result is said to be correct if its confidence interval includes the true value.

Gross errors and outliers are usually, but not always, easy to identify and correct if other aspects of QA are working effectively.

Equipment

All equipment should be maintained and calibrated according to the manufacturer's recommendations and laboratory requirements. This may include ensuring traceability to calibration reference materials (e.g. for mass and volume measurements). Records should include:

- The name of the equipment and associated software
- Manufacturer's name, model and serial number
- Date of commissioning and verification of design qualification
- Location
- Manufacturer's instructions
- Name of person responsible for its maintenance
- Maintenance plan and records: calibration certificates, maintenance records, QC records, etc.
- Damage, malfunction or repair to the instrument.

Measurement traceability

All measurements made by a laboratory should be traceable to the international system of units (SI units). Thus, all equipment used in testing procedures should be calibrated before use and periodically tested with QC samples to prove that it is still working to specification. This is usually accomplished by the use of reference standards and reference materials.

Reference standards used for the calibration of instruments should be traceable to international standards. These may be obtained from a competent supplier of such materials to give reliable physical or chemical characterisation of the standard. Alternatively, the value of the standard may have been established by a consensus value obtained from the results of inter-laboratory trials.

Reference materials used for identification or quantification should also be traceable to international standards. There are ISO guidelines for companies providing reference materials (ISO 2000) and those so accredited should be chosen as providers of reference materials. One major supplier of forensic, clinical and pharmaceutical reference materials is LGC Standards (http://lgcstandards.com/home/home_en.aspx) and pharmacopoeial authorities provide drugs and impurities as well.

Sampling, handling and storage

The laboratory should have a plan to encompass sampling, handling and storage to ensure the integrity of the samples at all times. Records should be maintained of who was in possession of the samples for chain-of-custody purposes.

Selection

Ideally, the entire item of interest is made available for examination. However, in most circumstances this is not possible and only a sample can be provided and it is important to ensure that the correct sample is obtained in the right way by competent personnel. The use of a formal toxicology request form detailing the laboratory's requirements can be an invaluable aid to getting the correct samples.

A variety of sampling protocols from which meaningful statistical inferences can be drawn is available. Which protocol is used depends on the size of the whole material involved, its characteristics, access and location, and the sampling objective. These protocols include random sampling, systematic sampling, stratified sampling and sequential sampling.

The objective is that the results for the analytical sample can be considered as representative of the entire population or subject from which the sample originated. This primarily involves consideration of any non-homogeneity in the material being sampled. For illicit drugs seizures and biological specimens, non-homogeneity can result from segregation or separation, and from variable analyte content and distribution in the population. In drugs manufacture it can arise from periodicity in continuous processes. It can be reduced by good mixing, small particle size and taking large samples, or by repeated sampling in small increments in continuous processes.

Where drugs are encountered as discrete packages, tablets or capsules, large numbers may be available, so it would be impracticable to consider analysing them all. The issue is then to select a meaningful composite sample to obtain a result representative of the whole, to estimate either the proportion that contains drugs or the quantity of drug present. The customer or the analyst can carry out this selection, but it should be undertaken only by agreement between the two. A common approach is to select not fewer than 10 samples to form the composite if the number of packages, tablets or capsules is less than 100, and the square root of the total if there are more than 100. In postmortem toxicology, drugs may be distributed unevenly between tissues, or even within one particular tissue, and may also undergo redistribution after death. Careful consideration with respect to sampling and subsequent interpretation of results is therefore required (see Chapter 10 for a more in-depth discussion).

Collection

Samples should be collected in such a way as to avoid both loss of analyte and the introduction of contaminating substances that could interfere with the analysis and interpretation of the analytical results. The provision and use of quality-assured sampling kits, sampling materials and collection protocols is helpful in this respect, as is a comprehensive standard operating procedures policy.

For forensic purposes, it is often a requirement not only to identify what is present in a sample but also to compare this with the results from another sample, to establish that they came from the same source. It is thus vital that such samples should not come into direct contact with each other and that steps are taken to ensure that no secondary transfer of material occurs, for example via the person taking the samples or the sampling equipment.

It may be necessary in some circumstances (e.g. obtaining samples of urine for workplace drugs testing or from patients in addiction clinics) for the collection process to be supervised, to remove the risk of substitution or adulteration and thus false-negative or false-positive results (see Chapter 3). In procedures to detect doping in human sport, most international federations always provide a second portion of the urine sample from the athlete for defence use, so the sampling procedure must involve splitting the urine sample (see Chapter 6).

Preservation

Drugs and the sample matrix itself can, in some circumstances, deteriorate prior to analysis and subsequently interfere with analysis and the interpretation of the results unless precautions are taken to avoid this. It is important that the analyst is made aware if any preservative has been added so that the level present, and thus its effectiveness, can be determined, if necessary, and an appropriate analytical protocol can be used

in which the preservative does not interfere. In some areas, such as analysis for ethanol, different preservative concentrations may be needed for clinical and for forensic applications.

Packaging

The choice of sample container depends on its intended purpose and should be prescribed by the analyst. Special considerations are required to avoid loss of analyte or leakage of sample where volatile and liquid materials are involved. Additional packaging requirements may also need to be specified to protect sample containers against damage during transport to the laboratory for examination or to comply with regulations that apply when body fluids are involved.

For forensic purposes, samples must also be sealed in such a way that any evidence of tampering would be evident.

Identification

It is essential that sample containers and any intermediate containers used to carry the sample be labelled in sufficient detail to remove any doubt about the sample origin. It is necessary to have documentation as to who took the sample, where it came from, and when and how it was obtained. A unique identification number that accompanies the sample at all stages is a valuable safeguard. Transposition errors in clinical analysis can prove harmful or even fatal to the patient. In the legal context, it must also be possible to demonstrate the chain of evidence through a record of who had possession of the sample, what they did with it and when.

Storage

If the sample cannot be analysed immediately, it must be stored at an appropriate temperature in a safe and suitable environment, accessible only to authorised staff, so as to ensure its security and integrity. In some circumstances, these considerations may also have to be applied to the transport and continued storage of samples after analysis.

Where the laboratory deals with both trace amounts of material (e.g. illicit drugs on balance pans or other paraphernalia) and bulk drugs, it is essential prior to analysis to separate spatially or temporally those activities that may result in contamination. It is also important for QA purposes to have effective cleaning regimes in place before, between and after the examination of separate samples, and to control and monitor the environment carefully (clothing, benches, equipment, etc.) in the trace analysis laboratory.

Transport

Transport is normally the responsibility of the customer, but there will be constraints on what can be transported or posted legally. Where drugs are involved, even in the smallest quantities, transportation across national frontiers is a criminal offence without appropriate import/export licences. Temperature and other environmental factors may also need to be controlled.

Sample disposal

There must be a clear policy in place for the disposal of materials on completion of examination and analysis. In some instances, this involves returning what remains of the samples to the customer, subject or legal custodian. In other cases, the samples need to be destroyed safely, immediately or after a specified time period, and statutory requirements may have to be observed in doing this. However, in no circumstances should anything be disposed of without the customer's or other relevant authority's consent, and records should be maintained of what has been disposed of and what has been retained.

Assuring quality

Appropriate QC procedures should be in place to monitor calibrations and the results of analyses to ensure their accuracy.

In-process performance monitoring

Internal QC assesses, in real time, whether performance is sufficiently similar to the individual laboratory's own previous performance for the results to be reported. It helps control reproducibility (precision) and facilitates continuity of service over time. Most internal QC procedures employ analysis of a control material and comparison of the results obtained on this with preset limits of acceptability, which thus allows unsatisfactory sets of results to be identified and corrected before release to the customer.

For qualitative testing, it is important to include characterised positive and negative control materials with each batch of analyses. In both qualitative and quantitative analysis, it is essential that these QC samples be taken through as much of the process as is possible, otherwise errors may go undetected. Sample collection may represent a major source of variation that is not possible to control using internal QC measures and so must be minimised through careful training and supervision procedures.

Some internal QC procedures can be simple and inexpensive to implement, and include:

- Recording lot numbers of all reagents, calibrants and controls used, with particular attention when reagent and/or calibrant lots change
- Recording and monitoring instrument readings (e.g. absorbance for the calibration material) as a check on reagent and instrumental drift
- Recording and monitoring assay properties (e.g. non-specific binding and signal for zero and highest standards in immunoassays) as a check on drift
- Analysis of one or more samples (at different concentrations) from the previous analytical batch, as a check on assay stability (provided that the samples are stable for the intervening period).

These procedures do not require sophisticated statistical techniques or expensive materials, but can provide invaluable information on assay performance.

Replication

The validity of results is sometimes checked by repeating the analysis of a proportion of the samples. This can be achieved in a variety of ways, such as by:

- The laboratory itself carrying out the repeat analyses, either openly or blindly
- Comparison of results obtained by the laboratory with those from samples submitted independently to reference laboratories
- Selecting an appropriate percentage of samples reported as negative and as positive by the laboratory and re-examining these in a reference laboratory.

Statistical monitoring of performance

Most in-process performance monitoring procedures rely on introducing QC samples into each batch of analyses. These samples must be stable and of known, reproducible composition, and the results obtained on them must be able to reflect the assay's performance with test samples. Graphical or statistical analyses can then be applied to the results to confirm whether or not the analytical process is 'in control' and thus whether or not the results can be reported. It is important that different materials are used for the calibration and in-process performance monitoring functions, or the monitoring will not be effective.

The number of control samples included in each batch processed depends on the size of the batch and its homogeneity. For the routine analysis of large numbers of samples of a similar type it is common to have 5–10% as controls, with a minimum of two per batch. For smaller, inhomogeneous batches this level may need to be increased to 25% or even more.

Shewhart QC charts are plots of measurements on the control samples over time in relation to the assigned value for the analyte, with upper and lower warning limits related to the customer requirement or the expected standard deviation (SD) when the process is under control. These charts can be used to plot single values of measurements, means, medians, blank values, SDs, ranges, etc. Decision making on whether to accept a batch of results or to take corrective action is facilitated if horizontal lines are drawn at the target value and at 2 and 3 SD above and below this value. If the analysis is in control, the results are scattered randomly above and below the assigned value, with a distribution such that only 5% are more than 2 SD from this value and only 1% more than 3 SD from it. Bias causes a shift to higher or lower values, while loss of precision yields a wider scatter of results. A result of

more than 2 SD should act as a warning to investigate the method to avoid future problems, and a result of more than 3 SD should prompt rejection of the batch and investigation of the problem before the analyses are repeated. Trends away from the mean should particularly be investigated.

More complex and effective control rules have been formulated, with validation of their power to reject unsatisfactory batches and accept satisfactory batches. The so-called 'Westgard rules' are based on the analysis of two controls in each batch (usually one with 'normal' and one with 'abnormal' values). If both results fall within 2 SD of the target value (the 'warning' limit) the batch is accepted, but otherwise the remaining rules are evaluated in turn and the batch is rejected if any fail. If none fails, the batch is accepted but the situation should be investigated before the next batch is analysed.

Where automated systems incorporate internal QC software, this should be reviewed to confirm its appropriateness to the application.

Cusum control charts provide an alternative sensitive method of identifying when processes are out of control by displaying cumulative deviations from the assigned value.

Work undertaken on analytical goals in relation to biological variation provides a rational basis for limits of acceptability. Initial studies addressed primarily precision criteria, with the general guidance that analytical imprecision should not exceed half the within-individual variation, but the scope has been broadened to include assessment of factors such as bias, interference and exogenous analytes such as drugs. Continued development may be expected to provide a rational basis for future performance standards.

Materials for internal quality control and external quality assessment

The materials used as controls for internal QC or EQA purposes must be selected to behave in the analyses as similarly as possible to routine samples. They must also be homogeneous, stable, safe, available in sufficient quantity and affordable.

Many QC materials are obtained from commercial sources and are produced in large quantities to specified quality standards. However, these standards may not always cover the properties of interest and care still has to be taken to ensure that they are fit for the particular analysis required. For example, materials may be guaranteed to be 95% pure, but the impurities may not be specified; these impurities could interfere with the analysis required. Also, biological materials may be stabilised by lyophilisation and their behaviour may therefore not mimic that of the test samples (e.g. matrix effects). It is therefore essential when using commercial materials to be aware of their often limited range of suitability (sometimes to one system only) and to test their suitability. It is good practice to use third-party controls (i.e. from a different manufacturer from those of the reagents and instrument used).

An alternative is to prepare the QC materials locally. However, reproducibility of preparation and homogeneity of such materials is sometimes difficult to achieve and, where a biological fluid matrix is involved, the addition of pure analyte may not produce a control sample directly comparable with a routine sample. In some circumstances, it may be possible to obviate this by obtaining samples from volunteer donors (e.g. serum or urine known to contain the analyte of interest) and to use these singly or pooled to achieve the concentration levels required. However, both ethical and safety issues need to be considered in this approach.

Proficiency testing

Participation in appropriate proficiency testing programmes is now becoming mandatory in many areas of toxicology, see below.

Reporting the results

Once analytical results are obtained, the analyst needs to be certain of their validity. This involves checking that the results of the in-process performance monitoring fall within the limits of acceptance and that the test results can be demonstrated to relate to the appropriate sample. The effects of transposition or transcription errors can often be severe.

It is also advisable to apply a common-sense test of plausibility to the results in the circumstances known about the sample or against previous experience of samples of the same type or from the same source. Specimen source (e.g. femoral or cardiac blood *post mortem*) and sampling time may also be relevant. An 'unusual' result may not be wrong, but usually merits further investigation.

A report should be accurate, clear, unambiguous and objective to answer the question(s) posed by the customer. A standard report format is very helpful to the customer and results should be reported in appropriate units, preferably written out in full to avoid confusion (e.g. between mU/L and μU/L), with appropriate reference data or information to help the customer understand their significance. This may, for example, be a reference to legislation, production criteria, published details in the scientific literature or the expected values for clinical investigations. It may also be a requirement to indicate the measurement uncertainty.

Reports should contain the following:

- Title
- Name and address of the laboratory where the tests were performed
- Unique identification of the report, unique page numbering and identification of its end
- Name and address of the customer
- The methods used
- Identification and description of the items received and tested, together with their date of receipt
- Sampling plan
- Test results with appropriate units of measurement
- Name(s), function(s) and signature(s) of those authorising the report
- A statement explaining that the results relate only to the items tested.

Any opinions or interpretations should be clearly differentiated from the test results in the report.

Management requirements

Although meeting the technical requirements for laboratory work is vital, having appropriate management systems is just as important. The management requirements of ISO 17025 encompass: organisation; management system; document control; review of requests, tenders and contracts; subcontracting; purchasing; service to the customer; complaints procedure; control of non-conforming testing and/or calibrations; improvement; corrective action; preventive action; control of records; internal audits; and management reviews. These requirements are described below.

Organisation

The laboratory should be organised to continually satisfy the agreed needs of the customer and the accrediting authority. The staff of the laboratory should have the authority and resources to accomplish this. In addition, the staff should not have any undue internal and external commercial, financial and other pressures that may adversely affect their work. In this regard there should be appropriate policies to prevent any loss of confidence in the work of the laboratory. There should be an organisational chart defining the relative positions of quality management, technical operations and support services within the laboratory and any parent organisation. Associated with this should be specified the responsibilities and authorities of all staff who carry out, or are associated with, the tests. In addition, there should be adequate supervision of testing and calibration staff.

The position of quality manager is crucial within the organisation and their position should be clearly shown in the organisation chart. It is their job to ensure that the management system is working at all times and it is vital that they have direct access and the support of the highest level of management in order to do this. In their turn, the highest level of management must support the staff in every way possible to carry out their jobs and have excellent communication with them. The quality manager's main tasks are: ensuring that processes needed for the management system are established, implemented, maintained and kept

current; monitoring compliance of the provider's staff with the management system; ensuring appropriate validation/verification of new technical procedures; selecting and training internal auditors and evaluating their performance; reporting to top management on the performance of the management system and any need for improvement; recommending training to improve the quality of the provider's staff; and ensuring the promotion of awareness of the customer requirements throughout the organisation (Forensic Science Regulator 2009a). The quality manager needs to have the trust and support of the top management and staff alike and needs to be diplomatic in nature as well as having sufficient experience, knowledge, communication skills, seniority and authority to successfully carry out the job.

Management system

The management system must be fit for the tasks carried out by the laboratory and its policies should be documented in a quality manual. Among the most important contents of the quality manual is the top management's commitment to the development and implementation of the management system and to continually improving its effectiveness. The manual gives the structure of the documentation as well as a list of the individual documents used in the management system such as the supporting procedures and the technical procedures for testing.

Document control

All the quality management documents should be controlled by having authorised personnel to approve them. These personnel sign and date each version of a document, with a future review date, and ensure that old copies are replaced by the new version at all appropriate locations of the laboratory where they are to be used.

Review of requests, tenders and contracts

It is useful to review the requests made by customers to ensure that their requirements may be adequately met by appropriate methods and that the laboratory has the resources to meet these needs. The tender contents may be subject to negotiation with the customer before the contract is signed but, on signing, both laboratory and customer should agree its contents. If changes to the contract are made as the work progresses, these too should be agreed and documented and all relevant personnel should be informed. Where there is deviation from the contract, the customer should be informed promptly.

Subcontracting

Laboratories often contract work because another specialist laboratory has a specific expertise or when a larger than normal workload makes it effective to have some of the work temporarily carried out by another laboratory. A register should be maintained of all such subcontractors, who should also be compliant with ISO 17025. Customers should be informed that some of the work is being carried out by a subcontractor.

Purchasing

A laboratory needs a policy and procedures for the selection and purchasing of services and supplies used that affect the quality of its tests. Procedures need to exist for the purchase, reception and storage of reagents and laboratory consumable materials relevant for the tests and calibrations.

Service to the customer

Communicating with the customer to clarify their requests and to monitor the laboratory's performance in meeting their requirements should be continuous. The use of standard forms is very useful in ensuring that the analyst has all the relevant information before the analyses are made. This is especially important when interpretations of the results of the analyses are to be made. Getting the customer's feedback, whether it is positive or negative, is particularly helpful to continuously improve the laboratory's performance.

Complaints procedure

This is particularly important to allow managers of laboratories to monitor how well the laboratory is satisfying its customers. Complaints should be documented, speedily resolved and reviewed on a regular basis.

Control of non-conforming testing and/or calibrations

There needs to be policy and procedures for the situation when non-conforming work, i.e. work not complying with the laboratory's procedures or agreed customer requirements, has been carried out. Corrective action should be made immediately. If such non-conforming work has already been reported, the customer should be informed and the relevant work/report recalled.

Improvement

Laboratory personnel should have continuous improvement in their minds at all times. This applies to all aspects of the laboratory's performance and regular reviews of performance at all levels are useful in this respect. Among methods of formally examining a laboratory's efficiency are:

- *Lean approach* – a systematic approach for identifying and eliminating waste through continuous improvement (Chalice 2007)
- *Six sigma* – a disciplined data management approach and methodology for eliminating defects and variability (driving towards 6 SD between the mean and the nearest specification limit) in any process (Pande, Holpp 2002)
- *Total quality management* – to identify the root causes of defects and implement solutions to stop their recurrence (Oakland 2003).

Corrective action

When non-conforming work has been identified, suitable corrective action should follow. When the root cause(s) of the problem have been determined, the actions to rectify the problem and prevent a recurrence should be put in place and documented. Learning from errors through improvement and corrective actions is an important element of any QA regime. Such changes need to be reinforced through staff training and audited post implementation to ensure that they are effective.

If issues related to sample identity or integrity are identified, the problem is likely to be caused by poor sample collection or identification, data transposition, sample handling errors or contamination, and changes to the process should be introduced to prevent recurrence.

Where issues are indicated through the statistical monitoring of performance, the nature of the problem depends on whether it has resulted in the analysis becoming imprecise (random errors) or biased (systematic errors). Loss of precision can be caused by:

- Specimen non-homogeneity (uneven particle size, poor mixing, clots, etc.)
- Inconsistent amounts of sample or reagents being taken
- Instability in the instrumentation employed or the analysis conditions.

Possible causes of bias include:

- Incorrect sample or reagent volumes being routinely used
- Deterioration of calibration material
- Incorrect settings on the instrumentation
- Incorrect analysis conditions
- Systematic calculation errors.

Preventive action

It is obviously better to prevent problems occurring than to have to put them right after they have happened. To do this, there should be a proactive process to identify opportunities for improvements, and potential weaknesses and sources of non-conformities.

Control of records

It is vital that all records of all types are maintained adequately. This includes procedures for identification, collection, indexing, access, filing, storage, maintenance and disposal of these records. A regular back-up system for electronic records is essential to prevent the loss of information. When a mistake is made in a record, it should be crossed out and the correct entry put alongside together with the initials of the person making the correction, so that it is obvious who made the correction and what it was.

Internal audits

Regular audits of a laboratory's activities should be made to ensure that the operations are conforming to all the requirements of the management system. It is best that these audits are carried out by competent people who are independent of the activity being audited to provide an objective view of that activity. If the audit indicates that there is non-compliance in an activity, the normal procedure for corrective action should be undertaken, which could include informing the customer of the situation if that is relevant.

Management reviews

The top management of a laboratory should carry out a regular review of the laboratory's management system and all its testing activities to determine that everything is working properly or that some improvements or changes are necessary. These reviews are normally conducted annually as they are at such a high level. The review should take into account the outcomes of audits, corrective and preventive actions, assessments by outside bodies, results of inter-laboratory or proficiency tests, customer feedback and complaints. Any actions flowing from such reviews should have agreed timescales attached to them to ensure that they are completed in a timely manner.

Quality standards

There are a number of quality standards that are used internationally by laboratories to ensure that their results may be relied upon and as a basis for proving their competence by accreditation bodies. In addition, there are guidelines produced by professional bodies and learned societies to assist laboratories in their work. The main quality standards and protocols used in the analytical sector are ISO 9000, ISO/IEC 17025, ISO 15189, and Good Laboratory Practice and Compliance Monitoring. These standards are described below.

ISO 9000

ISO 9000 'Quality management' (ISO 2009) is a series of 18 standards that represents an international consensus on good quality management practices. It consists of standards and guidelines relating to quality management systems and related supporting standards. Of these standards, ISO 9001:2008 is the standard that provides a set of standardised requirements for a quality management system, regardless of what the user organisation does, its size, or whether it is in the private or public sector. It is the only standard in the family against which organisations can be certified, although certification is not a compulsory requirement of the standard. The other standards address fundamentals and vocabulary, performance improvements, quality plans, projects, configuration management, measurement processes and measuring equipment, system documentation, realising financial and economic benefits, training, the selection and use of consultants, quality and/or environmental management systems auditing, complaints handling, codes of conduct for customer satisfaction and dispute resolution.

ISO/IEC 17025

ISO/IEC 17025: 2005 'General requirements for the competence of testing and calibration laboratories' (ISO/IEC 2005) specifies the general requirements for the competence to carry out tests and/or calibrations, including sampling. The general requirements have already been given above under the sections on quality systems and management requirements. The standard covers testing and calibration performed using standard methods, non-standard methods and laboratory-developed methods. It is applicable to all organisations performing tests and/or calibrations. This includes subcontracted laboratories and laboratories where testing and/or calibration forms part of inspection and product certification. The standard is applicable to all laboratories regardless of the number of personnel or the extent of the scope of testing and/or calibration activities. When a laboratory does not undertake one or more of the activities covered by ISO/IEC 17025:2005, such as sampling and the design/development of new methods, the requirements of those clauses do not apply. ISO/IEC 17025:2005 is for use by laboratories in developing their management system for quality, administrative and technical operations. Laboratory customers, regulatory authorities and accreditation bodies may also use it in confirming or recognising the competence of laboratories. The standard is not intended to be used as the basis for certification of laboratories. Compliance with regulatory and safety requirements on the operation of laboratories is not covered by ISO/IEC 17025:2005.

ISO 15189

ISO 15189:2007 'Medical laboratories – particular requirements for quality and competence' (ISO 2007) specifies requirements for quality and competence particular to medical laboratories. It is for use by medical laboratories in developing their quality management systems and assessing their own competence, and for use by accreditation bodies in confirming or recognising the competence of medical laboratories. The standard requires an ISO 9000 quality system and includes the consultative and interpretative elements as well as responsibilities for point-of-care testing.

Good Laboratory Practice and Compliance Monitoring

The Principles on Good Laboratory Practice (GLP) guidance (OECD 1998) is one of the Organization for Economic Development and Cooperation (OECD) series on Good Laboratory Practice and Compliance Monitoring, which evolved in response to the need to regulate the design, conduct and reporting of studies carried out in support of the licensing of pharmaceuticals and other chemicals for human or animal use. It is recommended for the setting up and maintenance of a laboratory QA system; compliance with its principles is applied mainly to analytical chemical laboratories concerned with genetic, clinical, pharmacological, toxicological and other biochemical studies, in particular where laboratory animals are used. Its main function is to enable licensing authorities to reconstruct research studies exactly and to internationally recognised standards.

There is no conflict between GLP and ISO/IEC 17025, and the GLP regulations can be considered as complementary to the general criteria for specialised chemical laboratories. However, on its own, GLP does not provide an assurance of fitness for purpose.

Guidelines

Specific guidelines have also been produced in some areas of drugs testing: Mandatory Guidelines for Federal Workplace Drug Testing Programs; SOFT/AAFS Forensic Toxicology Laboratory Guidelines; UK Laboratory Guidelines for Legally Defensible Workplace Drug Testing; and TIAFT Laboratory Guidelines for Toxicological Analysis. These guidelines are described below.

Mandatory Guidelines for Federal Workplace Drug Testing Programs

These guidelines were developed by the Department of Health and Human Services (DHHS) in the USA and contain comprehensive standards for laboratory testing for drugs in the workplace. They were first

published in the Federal Register in 1988, revised several times with the latest version published in 2008 (DHHS 2008). The DHHS also developed the National Laboratory Certification Program to certify compliance with the standards by laboratories that test specimens collected for the federal agency drug testing programmes. The National Laboratory Certification Program includes a requirement to participate in a performance testing programme that includes blind sample submissions.

SOFT/AAFS Forensic Toxicology Laboratory Guidelines

The Society of Forensic Toxicologists (SOFT) and the Toxicology Section of the American Academy of Forensic Sciences (AAFS) first produced these guidelines in 1991. They have been revised four times since then and the current version is the 2006 version (SOFT/AAFS 2006). They cover both postmortem forensic toxicology and human performance forensic toxicology, with the exclusion of forensic urine drugs testing (which is covered by the DHHS Guidelines and College of American Pathologists' Accreditation Program), and provide detailed guidance for laboratory practices. They also originally contained a checklist for self-evaluation and preparation for accreditation, but this was removed when it was adopted by the American Board of Forensic Toxicology as the basis of their Forensic Toxicology Accreditation Program in 1996.

UK Laboratory Guidelines for Legally Defensible Workplace Drug Testing

These guidelines have adopted the general principles established internationally and represent an overview of best practice in the UK. They were prepared by a steering group representing UK analytical laboratories and other parties (Workplace Drug Testing Forum 2001). The guidelines are also now being used as the basis for new European guidelines for best practice. They focus on urine specimens, but are equally applicable in principle to all specimen types.

TIAFT Laboratory Guidelines for Toxicological Analysis

The International Association of Forensic Toxicologists (TIAFT) was one of the first organisations to produce guidelines for toxicology laboratories when they produced their Laboratory Guidelines for Toxicological Analysis in 1993 (TIAFT 1993), which were intended to serve as a basis on which adequate working practices and methodologies could be developed. The detection and identification sections of these guidelines were expanded in 2003 (TIAFT 2003).

External quality assessment

External quality assessment addresses differences between testing sites, for comparability of results. It usually involves the analysis of identical samples at many laboratories and comparison of the results with each other and the 'correct' answer. The process is necessarily retrospective. Tests where the intention is to determine whether the laboratory is proficient in carrying out particular analyses should be differentiated from those inter-laboratory trials where the intention is to set a value for a new reference standard or to investigate the capabilities of a new technique or method.

Purpose of external quality assessment

EQA is concerned primarily with the assessment of an individual laboratory's performance and is one means for the laboratory to identify areas for improvement. However, this is only truly possible if the EQA samples have been processed in the same way as routine samples.

It is essential that the EQA scheme provider respects the confidentiality of the laboratory's performance data, but EQA can give information on the following:

- Overall inter-laboratory standard of performance and best practice
- Influence of variations in analytical procedures (e.g. methods, reagents, instruments and calibration)
- Quality of the samples provided.

Such information can be useful to participants (e.g. in identifying more reliable procedures and encouraging adoption of best practice).

Participation in an EQA scheme should thus be seen as essential to the maintenance of professional standards and a requirement for accreditation. Results should not be used to police or license laboratories, and the level of confidentiality of data must be agreed between the scheme and participant laboratories.

Selection of an external quality assessment scheme

Where alternative EQA schemes are available, laboratories may need to make a choice between them, though participation in more than one can provide complementary information. Factors to be taken into account when making the selection include:

- Scheme design validity, especially sample appropriateness and concentration range, report and scoring quality
- Independence from manufacturing and marketing interests
- Scheme service and responsiveness, including turnaround time and response to enquiries
- Reputation and previous experience
- Accreditation status
- Cost (value for money).

Scheme design

The theoretical and practical principles of EQA across all analytical sectors have been comprehensively reviewed in ISO/IEC Guide 43 (ISO/IEC 1997). The World Health Organization has also provided recommendations for EQA scheme design and operation in the clinical sector.

Participants should have confidence in the scientific validity of the scheme design and the reliability of its operation, or they will not take action on information from the scheme. Experience with many schemes indicates the essential design criteria to be:

- Provision of EQA samples that are stable, homogeneous and behave like routine samples
- Reliable qualitative and/or quantitative data and target values for the analytical results
- Appropriate frequency of distribution of the EQA samples
- Rapid feedback on initial performance to participants after analysis
- A scoring system that is clear, robust, reliable and amenable to trend analysis
- Consistent and reliable assessment
- Well-structured, informative and intelligible reports.

Scoring systems

Suitable scoring systems are available for qualitative and quantitative investigations and were introduced to make EQA information more comprehensible to participants. Combination of information for an analyte, which includes results within a rolling time window, should permit appraisal of performance relative to other participants at that time or to the individual laboratory's past performance. For the latter, the score must be independent of other participants' performance.

The deviations from target value may be scaled to reflect the general standard of performance and to yield scores in a 'common currency'. This is important where attainable performance is concentration related (in many cases agreement is substantially worse at low drug concentrations) and a combination of percentage deviations across the full concentration range is inappropriate.

Report format

The most helpful scoring system will fail in its objective if the scores are not presented in such a way as to simplify the interpretation. Each

participant has only limited resources (in terms of time, effort and ability) to devote to this interpretation, and experience suggests that those in most need to act as a result of EQA data devote the least resources. A well-designed combination of scoring system and report format can assist considerably, and thus contribute not only through stimulation of improvement, where this is indicated, but also by removing the need for unnecessary investigation.

Target values

If participants are to have confidence in taking action based on EQA data, the targets against which performance is assessed are critical. The primary purpose of EQA is bias assessment, so the target should ideally be traceable.

The main approaches to determine target values are:

- From the known amount of analyte added during preparation (added analyte value)
- From analysis in one or more laboratories using a reference method (reference method value)
- From analysis in one or more reference laboratories (reference laboratory value)
- From the mean or median derived from participants' results (consensus value).

Target values for drug assays cannot always be predetermined from the amount of added analyte because of differences in behaviour between endogenous and added analyte and the effects of metabolites or adulterants. Depending on assay specificity, metabolites may constitute interferents or part of the measured analyte.

Reference method values are theoretically the best to use, but such methods are not available for all analytes and the cost of obtaining them may be prohibitive. Also, the EQA materials may not behave exactly as routine samples and they may produce different values by different methods through matrix effects. This can lead to incorrect conclusions being drawn about method performance.

Reference laboratory values take account of method variation and the laboratories are usually selected on the basis of past reliable performance. They can thus provide a practical benchmark for which other participants can strive.

There is no scientific reason for consensus values to be accurate, but practical experience shows that in most cases the mean of many participants' results is sufficiently reliable to be used as the target value, given robust procedures for elimination of outliers. They are also convenient to obtain, available when required and essentially free. However, their validity must not be assumed, and should be demonstrated through repeatability, recovery and comparison studies with other EQA schemes wherever possible. A subset of participants who satisfy these criteria may be used.

How to use external quality assessment data

When assessing its performance in an EQA scheme, the laboratory should always:

- Check that the report is the correct one for the laboratory (i.e. it has the correct laboratory code)
- Check that the results are those obtained and reported by the laboratory (i.e. there have been no transcription or transposition errors)
- Examine the deviation from target for each sample and analyte in the distribution
- Compare current performance scores with those of other participants and particularly other users of the same method
- Examine its performance scores for trends
- Compare the relationship of the mean value for the method used by the laboratory against the target value
- Examine the relationship between the laboratory's results and target values for several previous distributions.

As with all quality system elements, the outcome of this assessment should be recorded. Where an apparent problem is noted, it should be investigated and both the investigation and conclusion (whether action or inaction) documented. Accreditation inspectors can learn more about a laboratory's competence from their record of resolving problems than from current performance scores. EQA data should always be considered in conjunction with current internal QC performance.

Use of new techniques

The use of information gained from the use of new techniques has always been of concern to courts as the new techniques may not have been proven to be capable of giving accurate results by the scientific community. Thus laboratories should have a robust policy of introducing new techniques into the laboratory and using the results from such techniques in evidence presented in court.

In the USA, the challenging of the admissibility of evidence gained from the use of new techniques has a long history and a major milestone was the *Frye* judgement in 1923 (*Frye v. United States*, 293 F. 1013 (D.C. Cir. 1923)).The D.C. Circuit Court held that scientific evidence was admissible only if it was based on a scientific technique generally accepted as reliable by the scientific community. Thus, an expert witness testimony was admitted in court based on the expert's credentials, experience, skill and reputation. It was believed that any deficiencies or flaws in the experts' conclusions would be exposed through cross-examination. This decision became known as the *Frye* test or the general acceptance test.

In 1993 the US Supreme Court ruled that the Federal Rules of Evidence passed by the US Congress in 1975 (Act to Establish Rules of Evidence for Certain Courts and Proceedings, Pub.L. 93-595, 88 Stat. 1926. (1975)) in effect had overturned the *Frye* standard and a new standard known as the *Daubert* standard was introduced (*Daubert v. Merrell Dow Pharmaceuticals*, Inc. (1993) 509 U.S. 579, 589). There are four major points to a *Daubert* standard concerning the admissibility of the results of a new technique in court:

1. Has the technique been tested in real conditions?
2. Has the technique been subject to peer review and publication?
3. What is the known or potential rate of error?
4. Has the technique been generally accepted within the relevant scientific community? Which is effectively the same as the Frye test.

Although the *Daubert* standard was developed in the USA, it has had an influence around the world. For example, in the UK, the House of Commons Science and Technology Committee recommended the creation of a Forensic Science Committee to regulate forensic science in the UK and further recommended (House of Commons Science and Technology Committee 2005) that

> The absence of an agreed protocol for the validation of scientific techniques prior to their being admitted in court is entirely unsatisfactory. Judges are not well-placed to determine scientific validity without input from scientists. We recommend that one of the first tasks of the Forensic Science Advisory Council be to develop a 'gate-keeping' test for expert evidence. This should be done in partnership with judges, scientists and other key players in the criminal justice system, and should build on the US *Daubert* test.

It is likely that other countries will follow this lead and forensic scientists across the world will have to have in place a robust procedure for the introduction of new techniques in their laboratories as part of their quality management system.

The accreditation process

A laboratory that seeks accreditation must first develop a documented quality management system in a form that addresses all the requirements of the relevant quality standard for the range of activities that it wishes to be included in its scope of accreditation. Assessors from the accrediting body review this and may make a pre-assessment visit to the laboratory to help identify areas that still need to be addressed. Once the necessary follow-up actions have been completed, the assessors

return to carry out the formal assessment. Any further deficiencies in the quality management system and any perceived non-compliances of practice in relation to the documented quality management system are brought to the laboratory's attention. If the laboratory responds satisfactorily within the specified timescale, accreditation is awarded. The awarding body carries out regular surveillance visits to monitor continued compliance with the standard and there is normally a process for formal re-accreditation after a few years.

In many countries there are established accreditation bodies that carry out the accreditation of laboratories and regularly audit them afterwards to maintain the accreditation. In addition, there is the International Laboratory Accreditation Cooperation (ILAC) which is an international cooperation of laboratory and inspection accreditation bodies formed more than 30 years ago to help remove barriers to trade. They have provided Guidelines for Forensic Science Laboratories to be used by accreditation bodies to provide appropriate criteria for the assessment and accreditation of laboratories providing forensic services (ILAC 2002). Individual laboratories can be kept up to date by organisations such as the European Network of Forensic Science Institutes (ENFSI) who raise awareness of member laboratories on international accreditation standards and provide the guidance available to achieve accreditation. Sometimes governments of countries consider accreditation so important that they conduct the process themselves. For example, in Belgium, the accreditation of clinical chemistry laboratories is carried out by the Belgian Ministry of Public Health who lay down the regulation requirements.

In some countries this accreditation will now be checked by the regulators of forensic science. For example, in the UK, the Forensic Science Regulator has made arrangements for the United Kingdom Accreditation Service to carry out audits on his behalf to the Standard set out by him and to advise him of failure to comply with its requirements (Forensic Science Regulator 2009a).

The future

There is no doubt that forensic scientists and laboratories will more and more have to prove to their customers that they get the correct answers. Accreditation by third parties to international standards will become increasingly the case and in some countries is already mandatory. This can only improve the quality of work of laboratories and should be viewed as a benefit and not just an extra cost.

CHAPTER

23 Measuring and Reporting Uncertainty

MA LeBeau

Introduction

To the layperson, uncertainty suggests doubt. To others it may suggest error. This confusion can create problems in the area of forensic chemistry and forensic toxicology when the term is first introduced to judges, attorneys and jurors. This chapter will address the concept of measurement uncertainty, explain some of the more common approaches to estimating uncertainty, introduce a simple eight-step approach for this estimation, and provide examples of how this approach can be applied in forensic chemistry and toxicology laboratories.

The choice of the term 'uncertainty' is unfortunate because the true intent of the process of determining measurement uncertainty is to express the level of certainty or confidence that can be placed on a given measurement. The International Organization for Standardization (ISO) defines *uncertainty* (*of measurement*) as 'a parameter associated with the result of a measurement, that characterises the dispersion of the values that could reasonably be attributed to the measurand' (ISO/IEC 2007).

To evaluate the uncertainty associated with the determination of the amount of an analyte – whether it be expressed as mass, concentration, purity or volume – the analyst must carefully consider all the possible sources that contribute to the uncertainty in that particular measurement. While this may at first take a great amount of effort, once established, it can easily be applied to subsequent measurements obtained by the same method in the same laboratory provided that neither the procedure nor the instrumentation changes. Additionally, a good estimate of a method's uncertainty can be made by focusing on the most significant sources of uncertainty within that method.

On this note, it is very important to understand that the true uncertainty of a measurement will never really be known. To establish the range of values within which the true measurement result is expected to lie at a given level of confidence, reasonable approximations must be made. Therefore, it is useful to remember that measurement uncertainty is a good-faith estimate of this range of possible values and is not an absolute range. This is because of the vast number of variables that contribute to measurement uncertainty (e.g. sampling, matrix effects, interferences, environmental sources, equipment, instrumentation, assumptions and random variations). Later in this chapter, real-life examples will be presented to allow the reader to begin to recognise the most significant sources of uncertainty in their measurements.

Error and measurement uncertainty

A common mistake is to confuse measurement uncertainty with error. Uncertainty is not error. Error is the difference between a true value and the value that is measured by a given technique. So to determine error, the true value of the measurand must be known. Obviously, the true value of the substance being measured in forensic chemistry or forensic toxicology is usually not known, otherwise laboratories would not need to perform the analysis in the first place.

In contrast, uncertainty is a calculated range that does not require the true value of the measurand to be known. In fact, when uncertainty calculations are performed correctly, they allow the analyst to say, with a given confidence level, that the true value has a high probability of falling somewhere within the calculated range. Further, uncertainty calculations allow for the reliability of a result to be assessed or for different measurement results (e.g. by different techniques within the same or different laboratories) to be compared. Most importantly, measurement uncertainty allows for an assessment of the confidence that can be placed on a result when that result is to be used in decision-making (evaluation of drug concentrations, courts of law, compliance evaluations, etc.).

A practical example can demonstrate the importance of this concept. Say that two different laboratories perform a quantitative analysis for ethanol in the same blood sample. The first laboratory reports a result of 910 mg/L The second laboratory reports a result of 760 mg/L. To the average person looking at these results, they would likely conclude that one result is correct and the other is incorrect. If both laboratories were instead to report their results as 910 ± 140 mg/L (95% confidence level) and 760 ± 30 mg/L (95% confidence level), it becomes very easy for the results to be properly compared and evaluated for credibility. When results are reported as the measured value with the estimated uncertainty at a defined confidence level, it is known as the *expression of uncertainty*.

Traceability and uncertainty

Traceability is another important concept in that it allows results from different laboratories (or results from the same laboratory conducted at different times) to be compared. It is established through a chain of calibrations that can be directly linked to a primary national or international standard.

Traceability provides the means of placing all related measurements on a consistent measurement scale, while uncertainty characterises the strength of the links in the chain and the agreement to be expected between laboratories making similar measurements.

There are many ways to help establish traceability in a measurement. One way is to ensure that the standards used to calibrate the measurement equipment can be linked back to a primary national or international standard, whenever possible. Another complementary or separate technique is to use a standardised method in performing the measurement or, alternatively, to compare the results of a method with those of a standardised method. Pure reference materials or appropriate matrix-matched certified reference materials can be used. The use of accepted, closely defined procedures will help establish traceability in a measurement as well.

Establishing traceability is particularly important when making critical measurements that will be used in determining an individual's guilt or innocence or will play a role in an individual's sentencing by a court. This is less of an issue in postmortem toxicology where the primary goal in most cases is to determine whether the decedent had traces of a drug or metabolite, as opposed to a therapeutic or lethal amount.

Methods for estimating the uncertainty associated with a quantitative method

Many forensic chemists and toxicologists envision that there will be a great degree of rigor and difficulty involved in estimating the uncertainty in a quantitative method, which causes reluctance to embrace the process. The reality is that there are many different options in *how* measurement uncertainty can be estimated. Some are very time-consuming and should be left only to statisticians. Others are overly simplistic and will mislead the laboratory's customers. A good rule of thumb is to base the amount of effort put into the uncertainty estimate on the intended use of the results and the requirements of the laboratory's customers.

Some laboratories choose to rely solely on professional judgement in estimating the measurement uncertainty of a method. Others may consider their repeatability data associated only with controls. Both of these techniques may be too simplistic for many quantitative measurements in forensic laboratories, but again, will be based on the intended use of the results.

Conversely, there are very advanced techniques that require sophisticated computer programs or an extensive amount of work and effort for each individual case that is undertaken by the laboratory. Obviously, this is likely to be far more than what is needed for most quantitative work in forensic laboratories with, perhaps, the exception of those that calibrate breath alcohol devices.

There are numerous reference texts on the subject of measurement uncertainty, but the 'gospel' on uncertainty is the *Guide to the Expression of Uncertainty in Measurement* or the 'GUM' (ISO/IEC 1995). In reality, the GUM is much more complicated than is necessary for anything other than the work performed in national laboratories such as the National Institute of Standards and Technology (NIST). While providing the basic theory behind measurement uncertainty, the GUM uses a substantial amount of mathematical language that is difficult for non-mathematician scientists to understand. Additionally, it introduces new terminology that is not well defined. Conversely, the GUM approach does establish a universally accepted method for determining measurement uncertainty.

Using a simplified GUM approach to estimating measurement uncertainty

Over the years, various authors and international groups have made the GUM approach more straightforward (EURACHEM/CITAC 2000; UKAS 2007). Using the GUM to estimate uncertainty leads to a better understanding of the analytical method and helps identify the major causes of uncertainty. It also ensures that an internationally agreed technique is used in making the estimate. On the other hand, it is likely to require the development of some new skills for many forensic chemists and toxicologists and, if interpreted too rigidly, will become burdensome and very costly to the laboratory.

A simplified GUM approach can be broken down into eight steps (Fig. 23.1). Step 1 involves the specification of what is being measured. The sources of uncertainty in each stage of the measurement are listed in step 2. Step 3 allows for removal of components that are adequately accounted for by other data (usually reproducibility data). In step 4, the uncertainty components are separated into categories of type A and type B data and quantified. Conversion of these quantified uncertainties into standard uncertainties occurs in step 5 so that they can be combined in step 6. Finally, the combined uncertainties are expanded on the basis of a chosen confidence level in step 7 and reported in step 8. An *uncertainty budget sheet* (Fig. 23.2) allows these steps to be easily documented and retained for auditing purposes.

Examples at the end of this chapter provide clarification for each of these steps. The reader may wish to refer to these examples as they learn about each of the steps below.

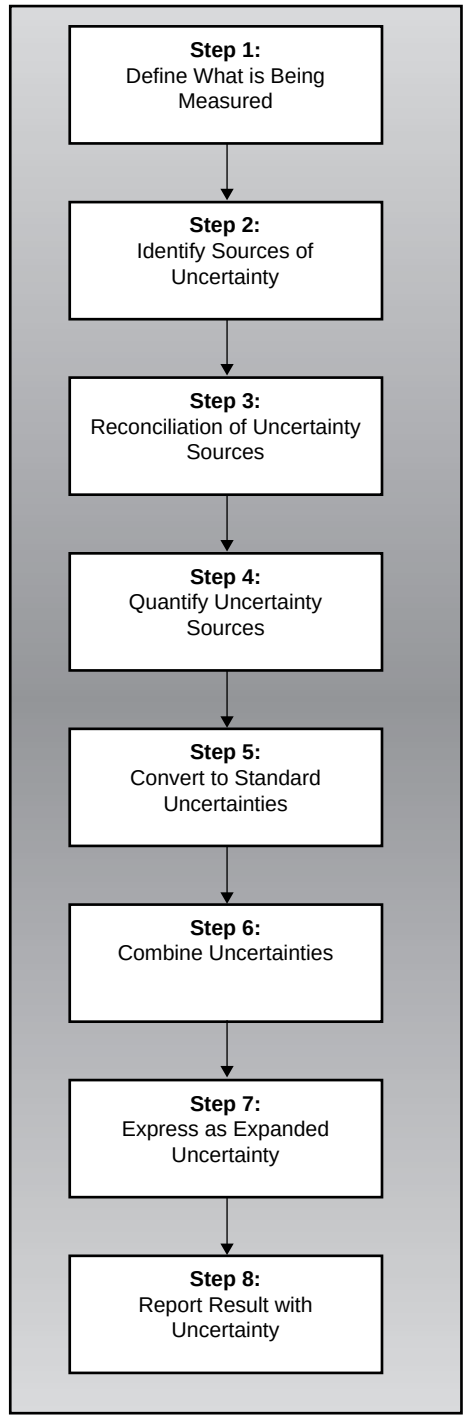

Figure 23.1 Simplified GUM approach.

Step 1: Define what is being measured

The first step is the easiest – clearly define what is being measured by the quantitative method for which the uncertainty is being determined. It is also important to include the date on which the uncertainty budget sheet is prepared, as well as identifying its author. Some sources also recommend generating a mathematical expression relating the quantitative result to the parameters on which that result depends: this may help the user better identify the sources of uncertainty in the next step. Examples 1 and 2 later in this chapter demonstrate how a quantitative expression may be used.

Step 2: Identify sources of uncertainty

Possible sources of uncertainty associated with making the measurement should be assembled into a reasonably comprehensive list. Table 23.1 contains sources of uncertainty that may be considered in this process.

If a quantitative expression was generated in step 1, it is usually best to start with this expression, as all of its parameters are potential sources of uncertainty. Once all potential sources of uncertainty are listed, the quantitative expression can be reworked to represent each effect that contributes to the overall uncertainty.

Another way to identify sources of uncertainty is a *cause-and-effect diagram* (Fig. 23.3). This tool helps visualise how different sources of uncertainty relate to one another and minimises the chances of counting the same source of uncertainty more than once.

There are four steps in creating a cause-and-effect diagram. The first involves the quantitative expression that was generated in step 1 above

Uncertainty Budget Form :

(or a suitable alternative). The parameters of the expression form the main branches of the diagram. Next consider each step of the method and add any additional factors to the diagram using Table 23.1 to assist in this brainstorming endeavour. For each branch, add contributory factors. Do not add contributing factors that seem only remotely possible. Resolve duplications using the rules explained in Table 23.2. Examples 2, 3 and 5 show how such diagrams may be useful in setting up an uncertainty budget.

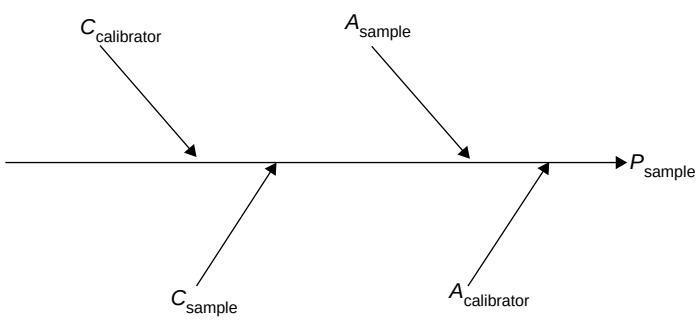

Figure 23.3 Sample cause-and-effect diagram.

Step 3: Reconciliation of uncertainty components

Reconciliation is another useful tool to simplify the uncertainty budget (Ellison 1998). In this step, a review is conducted to determine whether a listed uncertainty source is adequately accounted for by existing data (usually reproducibility data) or by small, planned experiments. The basis for this step lies in the fundamental assumption that, if an effect is representatively varied during the course of a series of observations, the uncertainty associated with that effect is adequately accounted for in the standard deviation of those observations. Of course, it is important that those uncertainty components that are reconciled in this step are truly represented through the existing data or planned experiments. See examples later in this chapter.

Step 4: Quantifying the uncertainty components

Once the sources of uncertainty have been identified and reconciled, the size of each must be measured or estimated. An easy way to start this process is to first determine what information is readily available for each of the listed sources. Not only does this help in the organisation of information, but it also allows for the recognition of sources of uncertainty for which existing data are not adequate. The later situation may require that further literature research or planned experiments be undertaken. Once the available information has been collected, each

Table 23.2 Rules for resolving duplication in lists of uncertainty sources

Cancelling effects, remove both

When the uncertainty source's effect is shown to have no net effect on the result, both sources can be cancelled or removed from the list. A common example occurs when determining a mass by difference. Two masses are determined, both subject to the balance 'zero bias'. The zero bias will cancel out of the mass by difference and can be removed from the branches corresponding to the separate weighings.

Same effect, same time

When a similar source is uncovered on multiple branches of a cause-and-effect chart, they can be combined into a single input since the effect is happening at the same time. For example, reproducibility will likely occur on many of the input branches, but they can be combined into a single overall reproducibility branch on the diagram.

Different instances, relabel

When similarly named effects that refer to different instances of similar measurements (i.e. cannot be combined into one effect) are found, these effects should be re-labelled to clearly distinguish them from each other. For example, 'calibration' may appear as an effect on more than one intermediate measurement. These must be clearly distinguished before proceeding.

potential source of uncertainty is categorised as either *type A* or *type B* uncertainty data.

Type A uncertainty

Uncertainty data determined by repeating a measurement a number of times and performing a statistical analysis on the results are categorised as type A. In general, these data are usually already available to laboratories through quality control data, validation studies, collaborative studies and/or results from proficiency tests. Occasionally, a laboratory may find that individual components of uncertainty must be evaluated when few or no method performance data are available. Means of using these data in each of these scenarios are described briefly below.

Use of historical quality control (QC) reproducibility data

Accredited laboratories performing quantitative measurements demonstrate good method performance through the use of QC samples and an effective quality assurance programme. The QC samples may be certified reference materials or purchased spiked samples, or may be prepared in-house as spiked matrix controls.

The data contained in the historical quantification of QC samples provide useful information about the reproducibility of the analytical method. These data capture the day-to-day capability of the laboratory, take into account many variables (e.g. different working calibration standards, various instruments, several operators and assorted environmental conditions), and tend to capture the method's performance over an extended period of time. Examples 1 to 4 demonstrate how historical QC data can be used to assist in estimating a procedure's uncertainty.

Use of in-house validation study data

Newer methods or methods that are used infrequently will be unlikely to have an extensive amount of QC sample data generated. In these instances, the validation studies that were conducted to bring the method on-line provide another source of data to assist in uncertainty determinations. For example, precision and bias studies are typically conducted on QC samples for which the samples are analysed several times over a period of different days, resulting in data that can be statistically analysed. For guidance in conducting appropriate validation experiments, the reader is referred to Chapter 20. Example 5 shows how in-house validation data can be useful for uncertainty determinations in a non-routine quantitative analysis.

Use of collaborative study data

Occasionally, collaborative studies are carried out to develop and validate a published method. In doing so, valuable validation and/or reproducibility data are generated that capture an even broader range of variables than those represented in a single laboratory's historical QC data. Therefore, the multi-laboratory validation and QC data may provide useful information to support the uncertainty estimate.

Use of proficiency test data

Some of the more common analytes encountered by a laboratory are routinely included in the proficiency tests that are analysed as part of the laboratory's quality assurance programme. A laboratory's results on these proficiency samples can be valuable for uncertainty estimates when the assigned values of the analyte are traceable to an appropriate value with an uncertainty that is small compared with the distribution of results. The reproducibility of the reported values can assist in uncertainty estimates. The only difficulty is that there must be a sufficient number of proficiency tests analysed and reported for the specific analyte measured by the procedure for this approach to outweigh other type A approaches.

Statistical analysis for type A uncertainty data

No matter which of the above type A data are used in the uncertainty estimation, the statistical analysis of these data can be quite simple. Since measurement values should generally be randomly scattered around the mean, it follows that the distribution should be 'normal' or gaussian-shaped (Fig. 23.4) provided that a sufficient number of measurements (n) have been made. The above data sources all allow for the laboratory to statistically calculate the mean ($\overline{X}$) measured value of the spiked sample (x) using equation (23.1):

$$\overline{X} = \frac{\text{sum of all measured values}}{\text{number of measurements}} = \frac{\sum_{i=0}^{n} x_i}{n} \tag{23.1}$$

Since the data used will only be samples of a larger population, the standard deviation of the population is estimated from the standard deviation of the sample data (s) using equation (23.2):

$$s = \sqrt{\frac{\sum_{i=0}^{n} \left(x_i - \overline{X}\right)^2}{n-1}} \tag{23.2}$$

Throughout the remainder of this chapter, s and σ are used interchangeably with the understanding that the population standard

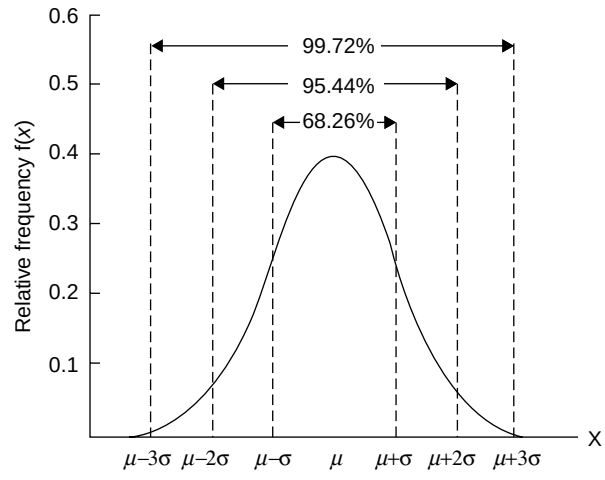

Figure 23.4 Normal distribution model.

deviation (σ) is better characterised by the sample standard deviation (s) as the number of measurements increase. Likewise, the sample mean also becomes a better estimation of the population mean as the number of measurements increase. The reader is referred to basic statistical textbooks for more information on the relationship between a sample and the population that it represents.

With sufficient measurements (usually more than 100) of a spiked sample, a Gaussian-shaped distribution of the results can generally be assumed such that $\pm 1\sigma$ should include 68% of the measurement results, $\pm 2\sigma$ should include 95% of the measurement results and 99.7% of the results should be distributed within $\pm 3\sigma$ (Fig. 23.4). With this distribution assumption applied to the historical measurement results for a quantitative QC sample, standard deviation and confidence level can easily be related. For example, if 200 measurements have been made on a QC sample over the course of a year and the mean measured value is 748 units with a standard deviation of 23.1 units, to express this at a 95% confidence level these data would be written as $748 \pm 2\sigma$, or 748 ± 46 units. Similarly, it may also be represented as $748 \pm 3\sigma$ (748 ± 69 units) at a 99.7% confidence level.

In instances where there are not a great deal of historical data to rely upon (e.g. newly validated quantitative methods or non-routine methods), compensation for the greater uncertainty associated with estimates based on small data samples should be made using a Student's t distribution table (Table 23.3). Using this table and the degrees of freedom (the number of measurements of the spiked sample that are available minus one $(n-1)$), a correction factor is provided for the selected confidence interval. This concept becomes more important and will be revisited in step 7 when expanded uncertainties are calculated.

Table 23.3 Student's *t* distribution table. The cover factor (*k*) is determined by the degrees of freedom ($n-1$) and desired confidence level.

$n-1$	95% confidence level	99.75% confidence level
1	12.7	318.3
2	4.3	22.3
3	3.2	10.2
4	2.8	7.2
5	2.6	5.9
6	2.5	5.2
7	2.4	4.8
8	2.3	4.5
9	2.3	4.3
10	2.2	4.1
11	2.2	4.0
12	2.2	3.9
13	2.2	3.9
14	2.1	3.8
15	2.1	3.7
16	2.1	3.7
17	2.1	3.6
18	2.1	3.6
19	2.1	3.6
20	2.1	3.6
30	2.0	3.4
40	2.0	3.3
50	2.0	3.3
60	2.0	3.2
70	2.0	3.2
80	2.0	3.2
90	2.0	3.2
100	2.0	3.2
∞	2.0	3.1

It goes without saying that, in general, the more replicate analyses that are made on a material, the more confidence can be placed on the final result. The uncertainty associated with that measurement will also be improved. In other words, when a measurement result is expressed as the mean of a number of measurements, the improvement in the uncertainty is found from the number of measurements that went into the mean. This is known as the *standard deviation of the mean* (σ_{mean}) in which the standard deviation of the historical data is divided by the square root of the number of measurements (p) made on the material (equation 23.3).

$$\sigma_{\text{mean}} = \frac{\sigma}{\sqrt{p}} \tag{23.3}$$

For example, assume a laboratory is asked to determine the concentration of morphine in a blood sample collected from a patient. This laboratory has performed this analysis for years, so they have a record of measuring a 500 µg/L morphine control in blood. These data show that the standard deviation of measuring the morphine control is 52 µg/L, so, if they were to quantitatively measure the patient's blood sample only once, the standard deviation associated with the reproducibility data remains 52 µg/L. If they instead quantify the patient's sample three times and report a mean result of those three measurements, the standard deviation is then calculated as $\sigma_{\text{mean}} = (52\ \mu g/L)/\sqrt{3} = 30\ \mu g/L$. For additional clarification, the reader is referred to examples 2 and 5.

Type B uncertainty data

Uncertainty data that are derived from techniques other than repeated analyses and statistical calculations are called *type B uncertainty*. Simply put, type B uncertainty data are those that are not measured statistically by the laboratory and usually must be considered individually. These arise because of a particular error in the measurement method and can be minimised by optimising the system, but they can never be completely eliminated. Some examples include reference standards calibrated by an external laboratory, environmental parameters that cannot be readily measured, instrument resolution and personal bias when performing visual measurements.

The values associated with type B sources of uncertainty data may be obtained from a number of sources such as calibration certificates of laboratory standards or equipment, manufacturer's specifications, or reference data from handbooks or certificates. These documented sources of uncertainty from other processes are sometimes reported at a 95% confidence level, so to derive the standard uncertainty the reported uncertainty may need to be divided by 2.

In other instances, data are not available from a certified laboratory. On other occasions a laboratory must rely on experience or general knowledge of the behaviour and properties of the relevant materials and instruments to make a good-faith estimate of the worse-case effect, absent blunders. In both of these scenarios, the laboratory should take these data or personal experiences to establish the outside limits ($\pm a$) for a given source of uncertainty. A standard deviation can then be computed based on a *rectangular distribution* or *triangular distribution*.

Rectangular distribution

If a measurement has an equal chance of being any value within the outside limits ($\pm a$), it follows a rectangular (or uniform) distribution. The standard deviation for this type of distribution is calculated using $\sigma = a/\sqrt{3}$. For example, if a drug sample must be diluted into a 10 mL volumetric flask in order to perform the purity determination, it may be that the manufacturer's specification of the flask is ± 0.3 mL. The standard deviation for the measurements using this flask is $0.3\ \text{mL}/\sqrt{3} = 0.17$ mL. In general, assuming a rectangular distribution for many type B uncertainty data sources will introduce a conservative 'safety' factor into the uncertainty estimation.

Triangular distribution

If there is reason to expect that the extreme outside values associated with $\pm a$ are unlikely to occur, it is acceptable to assume a triangular distribution. The standard deviation for a triangular distribution is determined using $\sigma = a/\sqrt{6}$. If the same 10 mL volumetric flask used in the above example has been subject to routine in-house checks to demonstrate that the extreme values are rare, the standard deviation for measurements with the flask could alternatively be expressed as 0.3 mL/$\sqrt{3} = 0.12$ mL.

Step 5: Conversion to standard uncertainties

For discussions of uncertainty, the standard deviation is also known as the *estimated standard uncertainty*. In this step, all previously calculated standard deviations are now simply expressed as standard uncertainties. However, to facilitate the next step in the simplified GUM approach to determining measurement uncertainty, it is also useful to ensure that common units are used throughout the budget. If this is not the case, then all units are converted into percentages, keeping in mind that the reverse conversion will be necessary later in the process.

For example, if measuring 7.0 mL has a standard deviation of 0.2 mL associated with it, the percentage standard deviation of the volumetric measurement is calculated as $(0.2\text{ mL}/7.0\text{ mL}) \times 100 = 2.9\%$.

Step 6: Combining standard uncertainties

At this point it should be understood that not all of the listed sources of uncertainty will have a significant contribution to the measurement's overall uncertainty. In most cases, only a few of the sources actually contribute significantly. As a general rule of thumb, components with standard uncertainty values that are less than one-third of the component with the largest standard uncertainty value can be ignored at this point. Simply cross a line through each of these minor contributors on the uncertainty budget form to document that the component was considered but was determined to be insignificant. This will also simplify the calculations involved in combining uncertainties.

Another important task is to determine whether any of the remaining sources of uncertainty are correlated. If sources of uncertainty are related to one another, they may cancel each other out or, if working in concert, have a larger impact on the final combined uncertainty. If a cause-and-effect diagram was used in step 2, it is easy to determine any correlated uncertainties that may exist with the method. To combine correlated uncertainties (U_{corr}) the individual correlated uncertainties are added to or subtracted from one another using equation (23.4):

$$U_{\text{corr}} = (U_1 U_2 U_3 U_4 \cdots) \tag{23.4}$$

Only those uncertainties determined to be dependent on one another should be combined in this fashion.

Fortunately, most sources of uncertainty are independent of one another. This allows for an assumption to be made that uncertainties combine in a random fashion and that small components will have an insignificant impact on the overall uncertainty. The mechanism of calculating uncorrelated uncertainties (U_{uncorr}) is the *root sum square* (RSS) technique. Each of the remaining standard uncertainty values (as well as any combined correlated uncertainty) is squared and then added together prior to taking the square root of the sum as expressed in equation (23.5):

$$U_{\text{uncorr}} = \sqrt{\left(U_{\text{corr}}^2 + U_1^2 + U_2^2 + U_3^2 + U_4^2 + \cdots\right)} \tag{23.5}$$

As the procedures above are meant to be a simplified GUM approach, the reader is referred to the reference list for more detailed discussions on calculating combined standard uncertainties.

Step 7: Expressing expanded uncertainties

The GUM approach requires that a coverage factor (k) be applied in the final step of the uncertainty estimate. The coverage factor is a number that, when multiplied by the combined standard uncertainty, produces an interval around the measurement result that is expected to include a large specified percentage (usually 95% or 99.7%) of the values. Usually k is set to a value of 2 to represent a 95% confidence level and 3 to represent a 99.7% confidence level. The reader will recognise that the k value is the equivalent to the number of standard deviation values in a normal distribution pattern (see Fig. 23.4).

When the type A uncertainty component is dominant *and* the number of measurements used to calculate the standard deviation is small, there will be reduced confidence in that calculated standard deviation. The normal distribution model indicates that results close to the mean are more probable than results far from the mean. So if only a few measurements are made in determining the standard deviation, it will likely be an underestimate of the true standard deviation. To account for this, a correction factor can be applied based on the Student's t distribution. Table 23.3 shows the corrected values for k when fewer than 100 measurements have been made in determining the standard deviation for type A uncertainty data. In contrast, the value of k is not affected by type B uncertainties since they are considered reliable given that outer limits are used to estimate these components. Examples 2 to 5 demonstrate how a corrected coverage factor is used in expressing expanded uncertainties.

Finally, it is important to remember that, if standard uncertainties were converted to percentages in step 4, the final combined uncertainty should be converted back to the units of measurement of the material in question.

Step 8: Reporting results with uncertainties

The most important rule in reporting uncertainties is to use common sense. Since an uncertainty range is only an estimate, it should generally never exceed two significant figures. Furthermore, it is good practice to round up, as opposed to normal rounding conventions.

The reported measurement should be reported only to the level of precision to which the uncertainty is reported. For example, if the 99.7% confidence level for the uncertainty of a measurement of metamfetamine in blood is 29 ng/mL, it would not make sense to report the result as 498.23 ng/mL. Instead it should be reported as 498 ng/mL.

When reporting uncertainties, it is equally important to include the confidence level. The above metamfetamine example should be reported as 498 ± 29 ng/mL (99.7% confidence level). Failure to report the confidence level will leave the user of the information without any basis for evaluating the estimated uncertainty.

Conclusion

This chapter has presented a simplified, eight-step approach to the GUM technique for determining and reporting measurement uncertainty. Laboratories should not fear measurement uncertainty, as it helps both internal and external recipients of the information to better understand that a measurement is not an absolute. Instead, the true value falls within an estimated range of values with the centre of that range serving as the most probable place that the true value will fall.

The examples that follow are meant to assist in the understanding of measuring and reporting uncertainty. The reader is encouraged to follow through the examples in order. Each one offers a unique approach to making a fair estimate of the uncertainty associated with the presented measurements. Furthermore, a laboratory performing similar types of examinations should be able to use these examples as templates for determinations of uncertainty in their own quantitative measurements.

Examples

Example 1: Measurement uncertainty associated with the determination of the mass of a sample of cannabis

A laboratory is asked to determine the mass of a seized sample of suspected cannabis. The laboratory's standard operating procedure calls

for the mass to be determined as the difference in the packaging containing the cannabis inside and the packaging with the cannabis removed. The laboratory records each mass once. The mass of the packaging containing the cannabis (m_{p+c}) is 479.20 g. The mass of the empty packaging (m_p) is 4.10 g. Therefore, it is determined that there is 475.10 g of suspected cannabis.

The laboratory also conducts a quality check on the balance used for these mass determinations utilising a 100 g certified weight before and after each measurement. These quality check readings are recorded in a logbook and the historical performance is re-evaluated every 6 months. They have 210 separate measurements of the 100 g certified weight recorded in a logbook.

Step 1: Define what is being measured

A simple but clear title for the uncertainty budget might be 'Uncertainty Associated with the Mass Determination of Cannabis Samples'. A simple quantitative expression for such a measurement might be $m_c = m_{p+c} - m_p$, where m_c is the mass of the cannabis.

Step 2: Identify sources of uncertainty

As explained earlier, the quantitative expression provides a starting point for identifying potential sources of uncertainty. In this case, the most likely sources of uncertainty come from the calibration of the balance and the reproducibility of performing mass measurements. The balance calibration can be further defined as it is affected by both its bias and its linearity. Both measurements (m_{p+c} and m_p) contribute to the measurement uncertainty, but, since the measurement is a weight by difference, the biases of each measurement cancel each other out (see Rules for resolving duplication, Table 23.2). The uncertainties associated with the balance linearity are still considered as two separate contributions because of the possibility of a non-linear balance response. This leaves four sources of uncertainty: reproducibility of each weighing on the balance in question (U_r and U_{12}) and the linearity of the balance for each measurement (U_{c+p} and U_p).

The uncertainty budget form at steps 1 and 2 is shown in Fig. 23.5.

Step 3: Reconciliation of uncertainty components

The reproducibility data are based on weighing a 100 g certified weight but probably do not take into account the linearity of the balance. So, for this example, reconciliation is not justified.

Step 4: Quantifying the uncertainty components

The laboratory's practice of performing quality checks before and after each measurement provides a means of effectively evaluating the reproducibility of the procedure. The mean and standard deviation for the historical performance of these measurements on the balance used for determining the cannabis mass are 100.00 g and 0.08 g, respectively. As these values were determined statistically within the laboratory, they become categorised as type A uncertainty data. The balance linearity (0.02 g; 95% confidence level) is provided on the balance calibration certificate, thus falling into the category of type B uncertainty data. For this example, it is assumed that the calibration certificate is from a certified vendor.

Step 5: Conversion to standard uncertainties

Standard deviations from the information collected in step 3 are then written as standard uncertainties. The standard deviation associated with the reproducibility data is already expressed as $\pm 1\sigma$, but the balance's linearity is expressed as $\pm 2\sigma$ (95% confidence), so it must be divided by 2 to convert it to a $\pm 1\sigma$ value (Fig. 23.6).

Step 6: Combining standard uncertainties

Before combining the standard uncertainties, remember to use the one-third rule and cross out those sources that do not serve as significant contributors. Clearly the standard uncertainty associated with the calibration linearity of the balance is far less than the uncertainty associated with the type A data related to reproducibility. Both are crossed out, leaving just the uncertainty associated with reproducibility. Since these are uncorrelated, the root sum square equation is used to combine the uncertainty components (Fig. 23.7).

Step 7: Expressing expanded uncertainties

Since the uncertainty related to the type A data for reproducibility was the only surviving source of uncertainty, it is relied upon as a guide in determining the value for the coverage factor (k). There were 210 separate measurements of the 100 g certified weight, therefore a well-established normal distribution pattern is assumed by the laboratory. This laboratory reports uncertainty to their customers at a 95% confidence level, so $k = 2$.

Step 8: Reporting results

Remembering the rules of rounding and significant figures, the laboratory reports the weight as 475.10 ± 0.22 g (95% confidence level).

Example 2: Measurement uncertainty associated with the determination of the purity of a street sample of cocaine base

A laboratory is requested to determine the purity of a 1 kg seized drug sample identified as cocaine base. The laboratory's standard operating procedure calls for the purity to be determined by taking two sets of samples from throughout the bulk of the material. Each sample set consists of 10 random samples of ~10 mg each that are thoroughly homogenised together. For each homogenised sample set of the cocaine base, 10 mg is weighed directly into 10 mL volumetric flasks and then diluted to volume with methanol. Likewise, a single 10 mg reference standard of cocaine hydrochloride is weighed (correcting for the hydrochloride salt) and diluted in methanol in a 10 mL volumetric flask to serve as a calibration solution.

Table 23.4 Results for the purity of sample of cocaine base

	Calibrator	*Sample 1*	*Sample 2*	*QC*
Weighed amount	10.1 mg (after salt correction)	9.8 mg	10.4 mg	9.6 mg
Dilution volume	10 mL	10 mL	10 mL	10 mL

Average purity	100%	57.1%		47.6%
Standard deviation of purity	–	0.6%		–
Differences in purity	–	±0.4%		–

A QC sample of cocaine base that was prepared in-house has been in use in this laboratory for about 10 months. It is mixed with a common cutting agent and targeted to contain about 50% of cocaine base. The QC sample is sampled only once in a similar fashion as for the calibrator sample. This QC sample has been previously analysed eight times over a 10-month period with a mean result of 48.6% and a standard deviation of 6.3%.

The samples, control and calibrator are each injected three times into a high performance liquid chromatograph. The areas of cocaine peaks in the samples and control are individually averaged and compared with the average area of the cocaine calibrator to determine the purity of cocaine base in each sample (Table 23.4). Finally, the two sample concentrations are averaged and reported to the case contributor.

Step 1: Define what is being measured

The title for the uncertainty budget may be 'Uncertainty Associated with the Purity Determination of Cocaine Base'. The quantitative expression for this measurement is:

$$P_{\text{samp}}(\%) = \frac{C_{\text{cal}}}{C_{\text{samp}}} \times \frac{A_{\text{samp}}}{A_{\text{cal}}} \times 100 \qquad (23.6)$$

where P_{samp} is the sample purity, C_{cal} and C_{samp} are the concentrations of the prepared solutions of the calibrator and samples, and A_{cal} and A_{samp} are the integrated HPLC peak areas for the calibrator and sample, respectively. Multiplying by 100 allows for the result to be expressed as a percentage.

Step 2: Identify sources of uncertainty

To visualise the possible uncertainty sources, the laboratory constructs an initial cause-and-effect diagram (Fig. 23.8).

To further define the cause-and-effect diagram, the laboratory recognises that both C_{cal} and C_{samp} are calculated as the mass of the calibrator (m_{cal}) or sample (m_{samp}), respectively, divided by its related dilution volume (V_{cal} or V_{samp}). So equation (23.6) can be rewritten as:

$$P_{\text{samp}}(\%) = \frac{m_{\text{cal}}/V_{\text{cal}}}{m_{\text{samp}}/V_{\text{samp}}} \times \frac{A_{\text{samp}}}{A_{\text{cal}}} \times 100 \qquad (23.7)$$

The laboratory further recognises that the calibration of the flask (*flask cal*), the ambient temperature (*vol temp*) and the repeatability of filling the flask (*flask repeat*) are all potential sources of uncertainty related to V_{cal} and V_{samp}. Sources related to m_{cal} and m_{samp} include the balance calibration (*balance cal*) and linearity (*balance lin*), as well as the reproducibility of determining mass on the balance (*balance repeat*). Additionally, since the laboratory places the volumetric flask on the balance and tares it prior to weighing the calibrator or sample directly into the flask, it considers this as one distinct measurement for each. Additional potential sources of uncertainty include the certified purity of the cocaine hydrochloride used to prepare the calibration solution ($purity_{\text{cal}}$) and the uncertainty associated with the homogeneity of the cocaine base sample ($Homogen_{\text{samp}}$). This leads to a modified cause-and-effect diagram (Fig. 23.9).

Using the rules for resolving duplication (see Table 23.2), the diagram is restructured (Fig. 23.10). From this diagram, the uncertainty budget form can be populated.

Step 3: Reconciliation of uncertainty components

An important step in simplifying the GUM process is to reconcile those sources of uncertainty that are fairly represented in data from reproducibility studies or other experiments. Figure 23.11 demonstrates the usefulness of this step. The laboratory has historical data of its QC sample that cover more than a 10-month period. Presumably these QC data represent separate analytical runs on different days, perhaps even by different analysts. Therefore, the uncertainty associated with the

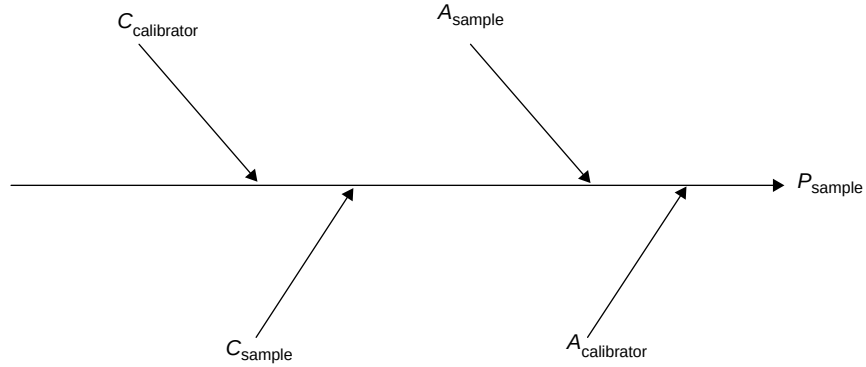

Figure 23.8 Initial cause-and-effect diagram for Example 2.

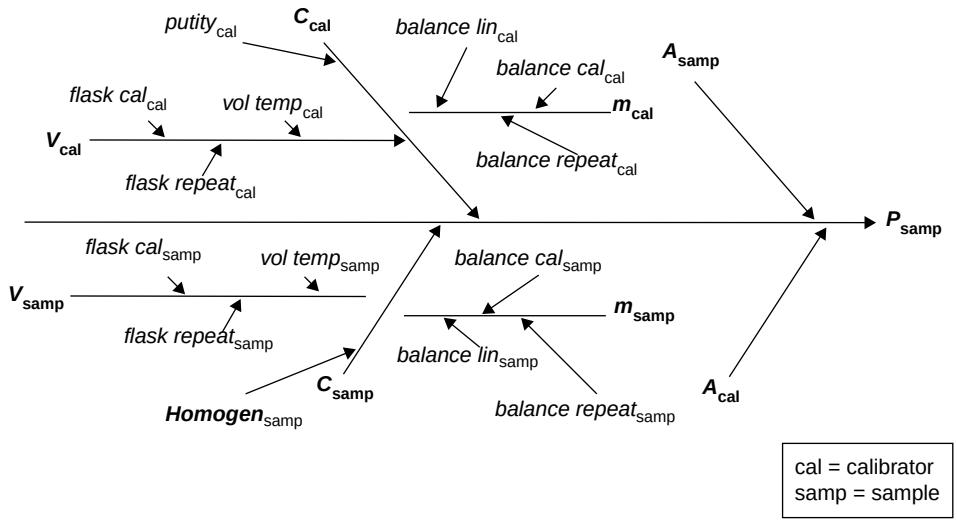

Figure 23.9 Modified cause-and-effect diagram for Example 2.

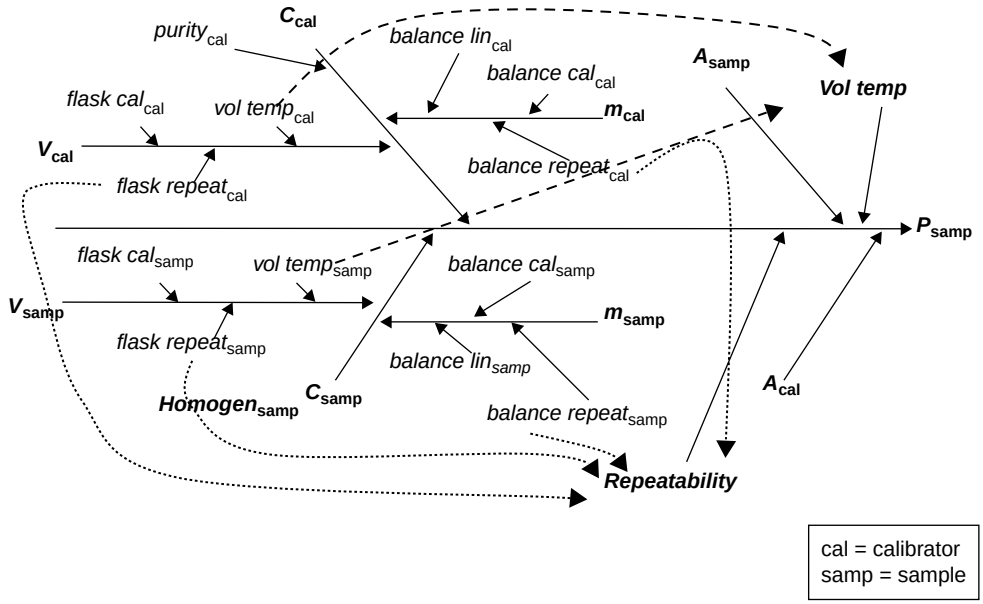

Figure 23.10 Combined cause-and-effect diagram for Example 2.

effects of temperature on volume (*Vol temp*) is likely accounted for in the historical QC data. Likewise, the variabilities in peak integration (A_{samp} and A_{cal}) are also captured by this reproducibility data. Unlike the first example, the laboratory does not rely on quality checks of a certified weight to demonstrate the reproducibility of mass determinations. Instead, if it is assumed that the laboratory is using the same balance when weighing the calibrator, QC sample and the cocaine base, the historical QC data may be considered as capturing the reproducibility associated with these mass determinations. Additionally, since the measured amounts are all relatively the same (unlike the previous example), these data also account for the *balance lin* and *balance cal* (if it is assumed that the balance used for the historical QC determinations is the same balance used for the calibrator and cocaine base samples). The reproducibility data do not, however, adequately account for $purity_{cal}$ (which varies from lot to lot), *flask cal* (assuming different flasks are used) or the potential inhomogeneity of the sample.

Step 4: Quantifying the uncertainty components

Although there are some historical QC data upon which to rely, they are somewhat limited in that only eight measurements of the cocaine QC have been made. None the less, they remain a valuable source for a type A assessment of reproducibility. In this example, samples are taken in duplicate and each is injected three times. The reported purity is actually an average of the two samples. The calibrator and QC are each sampled only once, but are also injected three times. Therefore, the standard deviation of the mean applies here as $\sigma_{mean} = 6.3\%/\sqrt{2} = 4.5\%$. Remember, the standard deviation that is used is the historical standard deviation from reproducibility data and not the standard deviation of the measurements used to determine the mean. While there were a total of six injections of the two sample aliquots, because the QC data are based on an average of three injections and the average values are the source of the historical standard deviation, the improved certainty afforded by the standard deviation of the mean should be based only on the fact that two aliquots of the sample were taken, as opposed to a single sample. The remaining sources of uncertainty data require type B assessments (Table 23.5).

Determination of sample homogeneity can be challenging in forensic chemistry and toxicology. Given the legal need to retain a significant portion of the sample for future testing, it is important that sampling of any potentially inhomogeneous material be done in a random fashion. When possible, the sample should be homogenised to the greatest extent possible. To account for this uncertainty component, a laboratory may

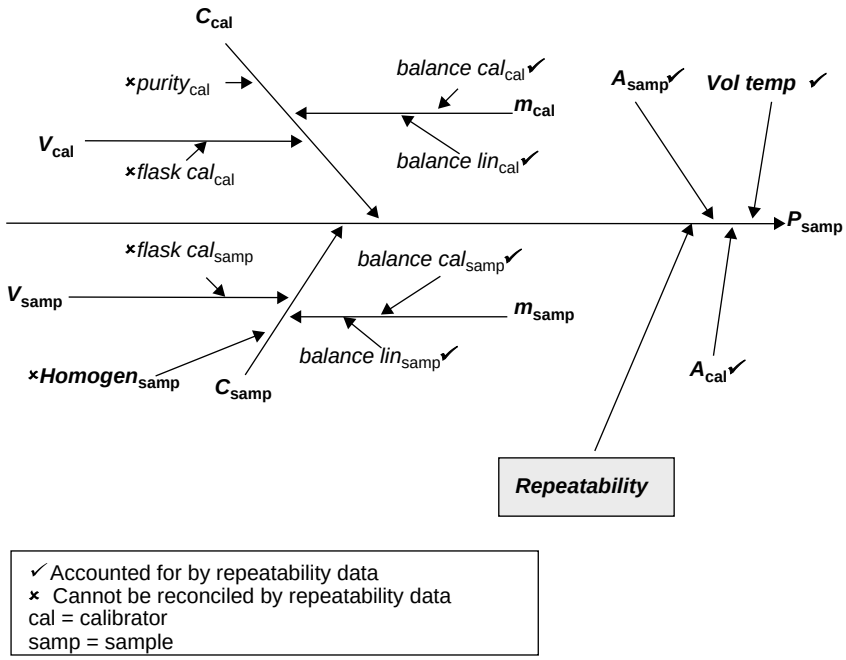

Figure 23.11 Reconciliation of cause-and-effect diagram is Example 2.

rely on a good-faith estimate of the inhomogeneity of the matrix, rely on the standard deviation of multiple measurements or use the differences between multiple measurements of the random samples. For this example, the latter method is demonstrated. The laboratory took steps to ensure that random samples were homogenised prior to taking the two 10 mg samples that were ultimately analysed. The laboratory considers the difference of the two measured purities as representative of the inhomogeneity of the entire sample (Table 23.4). As these are the 'extreme' values, the laboratory treats these data as fitting into a rectangular distribution.

Step 5: Conversion to standard uncertainties

Figure 23.12 shows the uncertainty budget with standard deviations converted to standard uncertainties. The standard deviation for the *flask cal* is obtained from the manufacturer's data and is considered the outside limit. Therefore, a rectangular distribution model is assumed.

Step 6: Combining standard uncertainties

It is clear that the standard uncertainty associated with $purity_{cal}$ and $Homogen_{samp}$ are minor in comparison to the others listed in Fig. 23.12. Therefore, these sources are removed from the uncertainty budget to simplify the combination of the standard uncertainties. Technically, the standard uncertainties for both *flask cal* values could also be removed using the one-third rule (each is approximately one-eighth of the largest standard uncertainty). However, given that these three sources combined do account for about a quarter of the largest standard uncertainty, this laboratory has decided to include these in their uncertainty budget to demonstrate how they affect the combined standard uncertainty.

Table 23.5 Data for uncertainty assessment

Uncertainty source	*Data source*	*Mean*	*Standard deviation*
Repeatability	QC data	48.6%	6.3%
$purity_{cal}$	Certificate from drug standard (95% confidence)	99.98%	0.04%
flask cal	Manufacturer's specifications	10.0 mL	0.1 mL
$Homogen_{samp}$	Experiment	57.1%	0.6%

The remaining standard uncertainties are uncorrelated, so the root sum square technique is employed as follows:

$$U = \sqrt{\left((4.5\%)^2+(0.6\%)^2+(0.6\%)^2\right)} = 4.6\%$$

Step 7: Expressing expanded uncertainties

Since the type A uncertainty data dominate, they are relied upon as a guide in determining the value for the coverage factor (k). However, the relatively small number of measurements ($n = 8$) of the QC sample does limit the confidence in the calculated standard deviation, so the Student's t distribution table (see Table 23.3) is consulted for the appropriate coverage factor. Since this laboratory also reports uncertainty to its customers at a 95% confidence level, $k = 2.4$ ($n = 8$; $n - 1 = 7$). This leads to an expanded uncertainty of 11.1%, but this value will be rounded up to 12% as suggested earlier.

Step 8: Reporting results

The laboratory reports the purity of the cocaine base as $57 \pm 12\%$ (95% confidence level).

Example 3: Measurement uncertainty associated with the quantification of ethanol in a blood sample

A laboratory routinely analyses whole-blood samples for ethanol concentration. Following a thorough mixing, they aliquot 0.25 mL of the blood sample, calibrator or QC sample directly into a headspace sample vial. To this, 0.25 mL of an internal standard solution and about 1 mL of a saturated aqueous solution of sodium chloride are added. The vials are capped and then incubated for 30 min at 60°C before 1.0 mL of the headspace is injected into a gas chromatograph with a flame ionisation detector. Quantification is based on the ratio of the integrated peak area for ethanol versus the peak area for the internal standard. This ratio is converted to a concentration on the basis of the equation of a straight line generated from a 6-point calibration curve.

Two QC samples (800 mg/L and 1500 mg/L) are analysed with each batch of samples. There are 74 entries for each of these QC samples recorded. Statistics for the first QC sample indicates a mean result of 780 mg/L with a standard deviation of 20 mg/L. The second QC sample has a mean result of 1510 mg/L with a standard deviation of 30 mg/L.

Figure 23.12 Uncertainty budget for Example 2.

A request comes into the laboratory to analyse a whole-blood sample collected from a suspected drink driver. Two aliquots of the whole blood are analysed and the lower result of the two (BAC_{samp}) values is reported to the contributor.

Step 1: Define what is being measured

An appropriate title for the uncertainty budget would be 'Quantification of Ethanol in Whole Blood'.

Step 2: Identify sources of uncertainty

The laboratory lists the potential sources of uncertainty (Table 23.6) and then constructs a cause-and-effect diagram to visualise the relationships (Fig. 23.13). At first, it may seem that there should be six instances for each of the sources of uncertainty related to the calibration curve, but the same effect, same time rule (see Table 23.2), allows all to be combined into single branches off the *Cal* branch. A similar situation occurs with the duplicate analysis of the whole-blood sample, as well as the pipette delivery volume of the internal standard (Vol_{IS}) and its integrated peak area (A_{IS}).

Now that all of the potential sources of uncertainty are identified, some of these sources can be eliminated by logic alone. For example, while the laboratory initially considered that sample homogeneity might be an important source of uncertainty, the fact that they thoroughly mix the blood samples prior to pipetting most likely eliminates this source as a major contributor to the overall uncertainty. Similarly, since the amount of saturated sodium chloride added is only meant to be an approximate amount, it seems logical that all sources related to it can be eliminated. Also, since the laboratory prepares a calibration curve with each batch of samples, the uncertainty associated with the calibration of the internal standard is irrelevant. With regard to the internal standard, the important aspect is that the same volume (Vol_{IS}) is added to each sample, calibrator and QC sample.

Table 23.6 Potential sources of uncertainty

Reproducibility of method (*Reprod*)
Calibration curve (*Cal*)
- Certification of calibrator solutions (Cal_{cal})
- Pipetting calibration solutions (Vol_{cal})
- Integration of calibrator peaks (A_{cal})

Samples (*Samp*)
- Homogeneity (H_{samp})
- Pipetting samples (Vol_{samp})
- Integration of sample peaks (A_{samp})

Internal standard (*IS*)
- Certification of internal standard stock (Cal_{IS})
- Preparation of internal standard solution ($Prep_{IS}$)
- Pipetting internal standard solution (Vol_{IS})
- Integration of internal standard peaks (A_{IS})

Sodium chloride (*NaCl*)
- Preparation of sodium chloride solution ($Prep_{NaCl}$)
- Pipetting of sodium chloride solution (Vol_{NaCl})

Step 3: Reconciliation of uncertainty components

The laboratory evaluated the sources of uncertainty for which its historical reproducibility data should sufficiently account (Fig. 23.13). They felt that it was reasonable to consider that the uncertainty associated with the individual integrated areas for the peaks related to ethanol and the internal standard were represented by the reproducibility data. The same cannot be said for the remaining sources of uncertainty (Cal_{cal}, Vol_{cal}, Vol_{IS}, and Vol_{samp}), so they should still be considered in developing the uncertainty budget.

Step 4: Quantifying the uncertainty components

Given that two separate QC samples have been in use and that each has its own established standard deviation, there are two different approaches that can be taken for determining the standard deviation for these QC data. The first is to convert the standard deviation for each of the QC levels into percentages (2.6% and 2.0%, respectively) and then, since there are equal numbers of entries for each QC level, take the average of the two percentages as the standard deviation for the historical data (in this case, 2.3%).

Second, and easier, is to simply use the higher of the two percentages (2.6%) as the reproducibility standard deviation. For this example, the latter is demonstrated, but since only 74 QC measurements are reflected in this value, the laboratory must remember to refer to the Student's *t*-test distribution table when expanding the combined uncertainty. Additionally, since the laboratory reports the lower of the two quantitative measurements, it should not take the standard deviation of the mean for the type A assessment of the reproducibility data.

Calibration certificates for pipettes used in the delivery volumes were referenced for the uncertainty budget. Additionally, a certificate was obtained for each pre-made calibration solution and the worst of the listed standard deviations of the calibrators was used to represent the uncertainty on the budget form (Fig. 23.14).

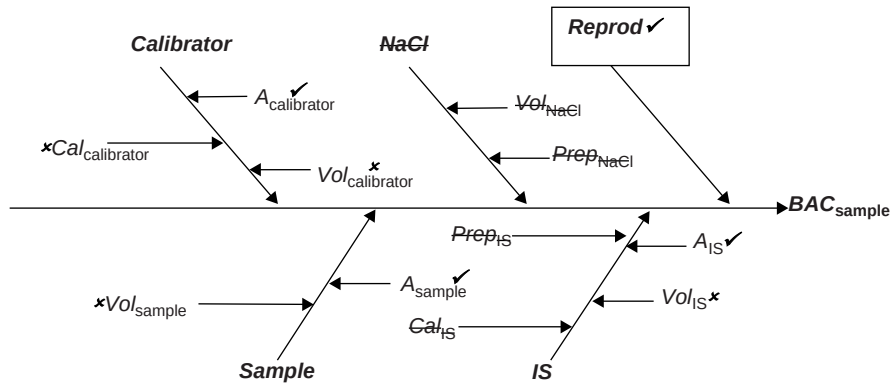

Figure 23.13 Cause-and-effect diagram for Example 3.

Uncertainty Budget Form: Quantification of Ethanol in Whole Blood					
Method: SOP #3					
Analyst: D. Trump			Date: 09-May-2008

Confidence Level:		99.7% Confidence Level (k = 3.2)			
Expanded Uncertainty:		9.3%			

[(a)]Refer to Student's *t* table.

Figure 23.14 Uncertainty budget for Example 3.

Step 5: Conversion to standard uncertainties

At this point, it is useful to remember that most calibration certificates should provide the standard uncertainty at a 95% confidence level. To convert these values back to $\pm 1\sigma$ value, it must be divided by 2. When it is unclear whether the calibration is actually done by a certified laboratory, a rectangular distribution (divide by $\sqrt{3}$) is a more conservative option.

Step 6: Combining standard uncertainties

Using the one-third rule, the uncertainty associated with the volume of the internal standard added to the samples (Vol_{IS}) can be eliminated from the uncertainty budget. Others could also be excluded, but the laboratory decides to include the rest in the combined uncertainty.

The RSS technique will be used to combine the uncertainties as none appears correlated. Doing so will result in a combined uncertainty value of 2.9%.

Step 7: Expressing expanded uncertainties

The type A uncertainty data appear to have the largest influence on the overall uncertainty, so they are relied upon in determining the k value. Once again, due to the relatively small number of measurements ($n = 74$) of the QC samples, the Student t distribution table (see Table 23.3) is consulted for the coverage factor. This laboratory reports uncertainty to its customers at a 99.7% confidence level, so $k = 3.2$, resulting in an expanded uncertainty of 9.3%.

Step 8: Reporting results

The laboratory's first measurement of the ethanol in the whole-blood sample was 1210 mg/L. Their second aliquot measured 1240 mg/L. The lower of the two values (1210 mg/L) is reported to the customer. The expanded uncertainty associated with this measurement must be converted from a percentage into mg/L. So the 9.3% expanded uncertainty correlates to 110 mg/L at a 99.7% confidence level. The customer should receive a report that indicates that the concentration of ethanol in the whole blood sample was 1210 ± 110 mg/L (99.7% confidence level).

Example 4: Measurement uncertainty associated with the quantification of alprazolam and α-hydroxyalprazolam in a blood sample

A toxicology laboratory routinely analyses blood samples for common benzodiazepines and provides quantitative results of their findings to their customers. Their procedure calls for 1 mL of a matrix-matched calibrator, control or sample to be mixed with 0.1 mL of a deuterium-labelled internal standard and 4 mL of an aqueous buffer. Following vortexing and centrifugation, solid-phase extraction is utilised. The resulting eluent is taken to dryness, reconstituted, and analysed by liquid chromatography–tandem mass spectrometry. Quantification is based on the ratio of the integrated peaks for the benzodiazepine (or metabolite) versus its corresponding internal standard. Each ratio is converted to a concentration based on the equation of a straight line generated from a 5-point calibration curve.

The laboratory has prepared a set of in-house calibration standards in whole blood that contain common benzodiazepines and their metabolites. Similarly, their internal standard solution contains a mixture of deuterium-labelled benzodiazepines and their metabolites.

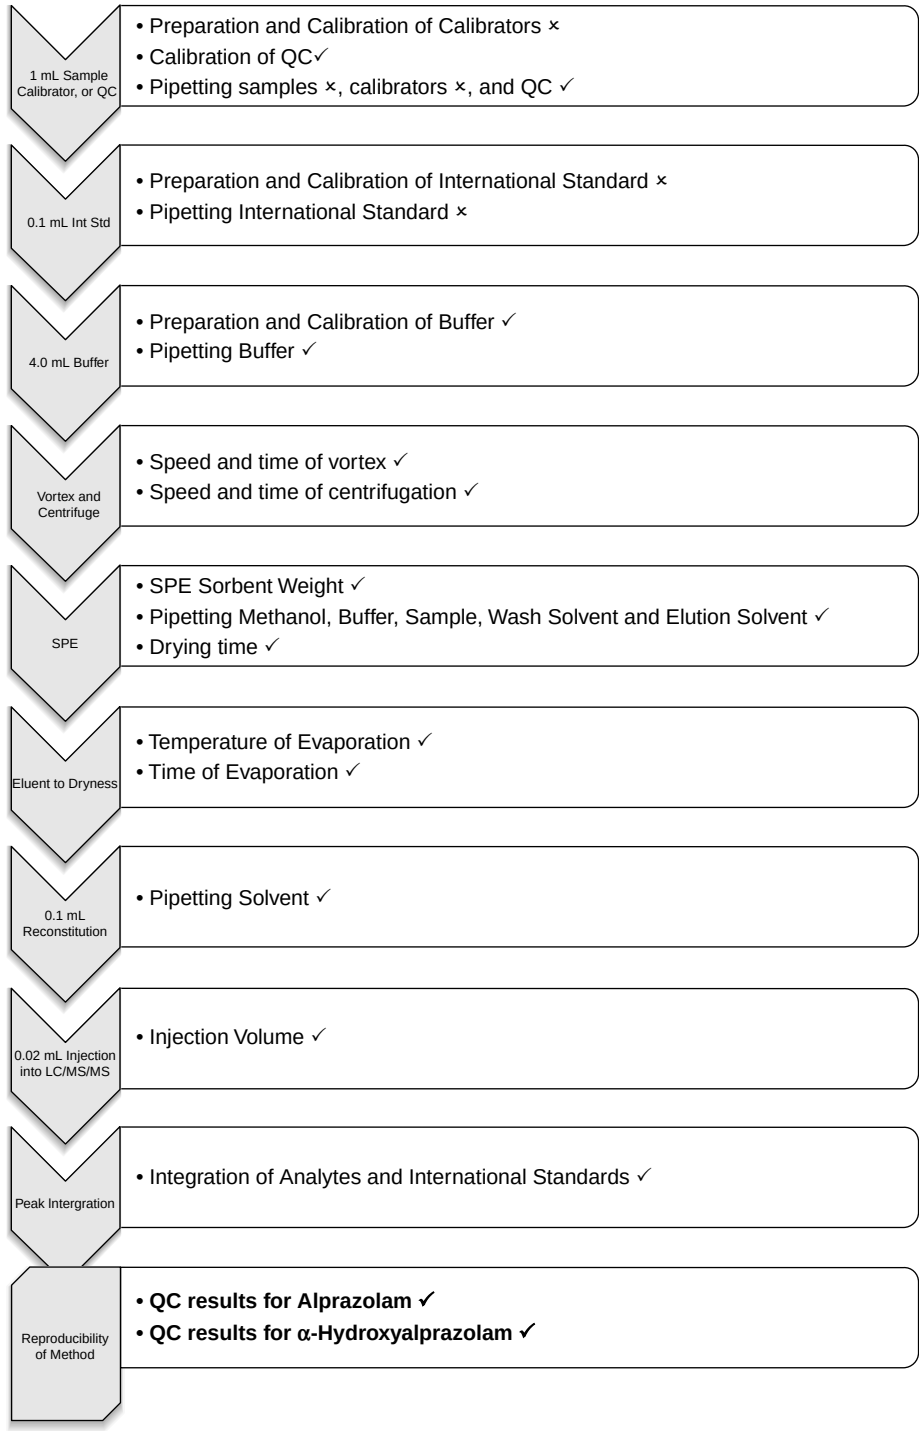

Figure 23.15 Sources of uncertainty in Example 4.

The laboratory uses a commercially prepared QC sample that contains the same common benzodiazepines and metabolites in whole blood. Although the QC sample has been analysed in over 200 batch runs, the laboratory documents only the QC results of individual benzodiazepines and metabolites if they are actually quantified in one of the samples within that batch run. Therefore, there are far fewer actual QC results recorded for individual benzodiazepines and metabolites.

A blood specimen arrives in the laboratory for analysis. Screening results suggest that a benzodiazepine may be in the sample, so confirmatory and quantitative analysis is undertaken using the above procedure. The unknown specimen, as well as the calibrators and QC specimens, are analysed by taking single samples of each.

The results confirm the presence of alprazolam at 0.08 mg/L and its metabolite, α-hydroxyalprazolam, at 0.10 mg/L in the blood sample. The laboratory's QC data for alprazolam (0.03 mg/L) and α-hydroxyalprazolam (0.03 mg/L) show standard deviations of 0.002 mg/L and 0.003 mg/L, respectively ($n = 49$).

Step 1: Define what is being measured

Since two analytes are being quantified, there will actually be two uncertainty budgets developed. The titles could reasonably be 'Quantification

of Alprazolam in Blood' and 'Quantification of α-Hydroxyalprazolam in Blood'.

Step 2: Identify sources of uncertainty

At first glance, it may seem that there is a large number of uncertainty sources in quantitative procedures such as these (Fig. 23.15). But the rules of Table 23.2, as well as common sense (and the reconciliation performed in step 3), help keep things manageable.

Step 3: Reconciliation of uncertainty components

As can be seen in Fig. 23.15, the vast majority of the listed sources of uncertainty can be removed as they are adequately taken into account in the reproducibility data. In reality, most sources of uncertainty become irrelevant once the internal standard is added to the samples, calibrators and controls. Provided that the same volume of the internal standard solution is added to all samples, the uncertainty associated with most of the remaining steps should be compensated by the fact that the quantification is based on the ratio of analyte to internal standard. After all, this is the very reason for using internal standards in quantitative methods. So, after reconciliation, the sources of uncertainty can be limited to those listed in Table 23.7.

Step 4: Quantifying the uncertainty components

Table 23.7 also includes the sources for the standard deviations of each listed uncertainty source. Of particular note for this example is that the laboratory prepares a working calibrator solution of alprazolam and α-hydroxyalprazolam in whole blood at 1.00 mg/L. This solution is then further diluted to make additional calibrators by mixing with whole blood in the actual extraction tube. To include the potential source of uncertainty into these dilutions, a low calibrator is chosen to represent the entire calibration curve dilution. In this example, the laboratory prepares 5-point calibration curves in the concentration range 0.01–1.00 mg/L. Choosing the 0.25 mg/L calibrator (prepared by mixing 250 µL of the 1.00 mg/L working calibration solution with 750 µL of drug-free whole blood) allows the laboratory to apply the uncertainties of two pipettors into the uncertainty budget.

Step 5: Conversion to standard uncertainties

Table 23.7 explains the calculations performed for this step. Figures 23.16 and 23.17 shows how these values are applied to the two uncertainty budgets.

Step 6: Combining standard uncertainties

Once again, the one-third rule helps simplify the calculations involved in combining the standard uncertainties (Figures 23.16 and 23.17). The RSS technique is utilised, as none of the remaining standard uncertainties is correlated.

Step 7: Expressing expanded uncertainties

As usual, the type A uncertainty data are the largest contributor to the overall uncertainty and are relied upon in determining the k value. With only 49 measurements of each of the controls, the Student's t distribution table (see Table 23.3) provides the coverage factor. This laboratory uses a 99.7% confidence level in reporting uncertainty to its customers, so $k = 3.3$, resulting in an expanded uncertainty of 27% and 36% for alprazolam and α-hydroxyalprazolam respectively.

Step 8: Reporting results

The final step before reporting the uncertainty to the customer is to convert the expanded uncertainty back into the units of measurement. For alprazolam, this conversion involves multiplying 27% (0.27) by the measured concentration of the drug in the blood sample (0.08 mg/L). Similarly for the metabolite, the measured amount of α-hydroxyalprazolam (0.10 mg/L) is multiplied by 36%. This results in the following

Table 23.7 Sources of uncertainty

Uncertainty source		*% standard deviation*
Reproducibility of method		
■ QC data for alprazolam ($n = 49$)		6.7%[a]
■ QC data for α-hydroxyalprazolam ($n = 49$)		10.0%[b]

CHAPTER

24 Pharmacokinetics and Metabolism

OH Drummer

Introduction

An important part of any investigation involving drugs or poisons is the interpretation of toxicological data. The onset, duration and intensity of action of a drug after administration are controlled by the rate at which the drug reaches its site of action, by the concentration of the drug and by the sensitivity of the individual to the drug. Hence, a good understanding of the basic concepts of pharmacokinetics and metabolism is essential to enable an informed comment to be made on the degree and timing of the exposure, and a likely response to the substance(s) under question. These answers are always predicated by the amount of information available to the toxicologist. However, the health of the subject, particularly disease processes capable of affecting the pharmacokinetics, and whether drug exposure is acute or chronic are essential in any interpretation.

Basic concepts of pharmacokinetics

The disposition of a drug includes the processes of absorption, distribution into and out of tissues, and the metabolism and elimination from the individual. Pharmacokinetics describes the time course of the blood and tissue concentration profile, while pharmacodynamics refers to the relationship between dose and the intended pharmacological response.

The pharmacokinetics of a drug's concentration in blood or plasma consists of the absorption, distribution and elimination phases. The absorption phase relates to the entry of drug from the absorption site. This may be relatively slow, i.e. from the gastrointestinal tract for oral absorption, or rapid if given intravenously. During the absorption phase, drugs are distributed by the circulation to all parts of the body. The uptake of drugs into the various tissues is a time-dependent process and will differ between tissues and from drug to drug. Shortly after entry into tissues, drugs are subject to both metabolism and elimination from the body. These two processes are often the more important for toxicologists and are also often the most variable.

Most drugs given intravenously or orally will give blood (or plasma) concentration–time curves of the type shown in Fig. 24.1A and Fig. 24.1B, respectively. Following intravenous administration, there is a rapid decrease in plasma-drug concentration in the early period (α phase) when distribution is the major process, followed by a slower and more constant rate of decrease in the elimination phase (β phase). After oral administration, plasma concentrations initially increase while the drug is being absorbed and then decrease when elimination becomes the major process. The drug distribution phase is often not considered since it tends to be more rapid than either the absorptive or elimination phases. However, in some situations it will need to be considered.

Absorption

Drug absorption is an important process of drug pharmacokinetics. The route of administration is an important factor in determining the rate and extent of absorption. Routes of administration can include oral, rectal, ocular, inhalation through the nose or mouth absorption, through the skin and other body surfaces, and by injection into muscle or veins. All of these routes have different rates and extents of absorption.

Most drugs are administered orally, hence an understanding of the mechanism of absorption by this route is most important for the toxicologist.

Absorption from the gastrointestinal tract

Drugs are absorbed either by passive diffusion of the un-ionised drug or by active transport. Passive diffusion is by far the most common mechanism. Drug absorption occurs predominantly in the small intestine primarily because of its large surface area and the relatively long contact time.

Absorption is possible throughout the gastrointestinal tract, from stomach to rectum, although the major site is the upper small intestine. This has high peristalsis, a high surface area, high blood flow and optimal pH for the absorption of most drugs, all of which result in a high absorption rate. Drug absorption tends to be much less rapid from other parts of the gastrointestinal tract.

Some drugs are absorbed to a small extent in the stomach, although these are largely acidic drugs that are un-ionised in the low pH environment in this organ. These drugs include aspirin, non-steroidal anti-inflammatory drugs and some angiotensin-converting enzyme inhibitors.

Absorption also occurs if drugs are given rectally as suppositories. In this situation absorption may be less efficient than oral administration. For example, oxycodone suppositories require a higher dose to achieve the desired response than oral administration. However, those drugs subject to large first-pass metabolism via the liver may have higher absorption when administered rectally since they will bypass the liver by this route.

Absorption of ionised drugs also occurs. For example, paraquat is highly ionised but appears to be absorbed slowly from the gastrointestinal tract throughout its length and over a considerable time from the moment of ingestion.

Poisoning by orally active drugs can be treated effectively by the prompt administration of an oral adsorbent, such as charcoal, which prevents further absorption of the drug. This is effective only if the drug has not passed significantly down the gastrointestinal tract. Figure 24.2 shows the factors that influence gastrointestinal absorption of drugs.

Absorption from other sites

Absorption through the lungs occurs for substances that are smoked or inhaled, e.g. smoked cocaine or heroin, nicotine smoked from cigarettes, tetrahydrocannabinol smoked from cigarettes and compounds involved in volatile substance abuse. The lungs are an efficient organ for transporting drug from the air into the blood supply, such that the rate of absorption approaches intravenous injection.

Absorption of drugs through membranes is also common. This includes nasal insufflation of cocaine ('snorting'), sublingual and buccal absorption of nitroglycerin-like vasodilators and buprenorphine, as well as absorption of drugs through skin patches, such as oestrogens, fentanyl or nicotine. Less commonly, vaginal absorption and ocular absorption of drugs are also encountered by toxicologists. The rate of absorption can vary significantly from one site to another. Sublingual absorption is very rapid, with drug effects noticeable within minutes, while drugs are absorbed relatively slowly through the skin.

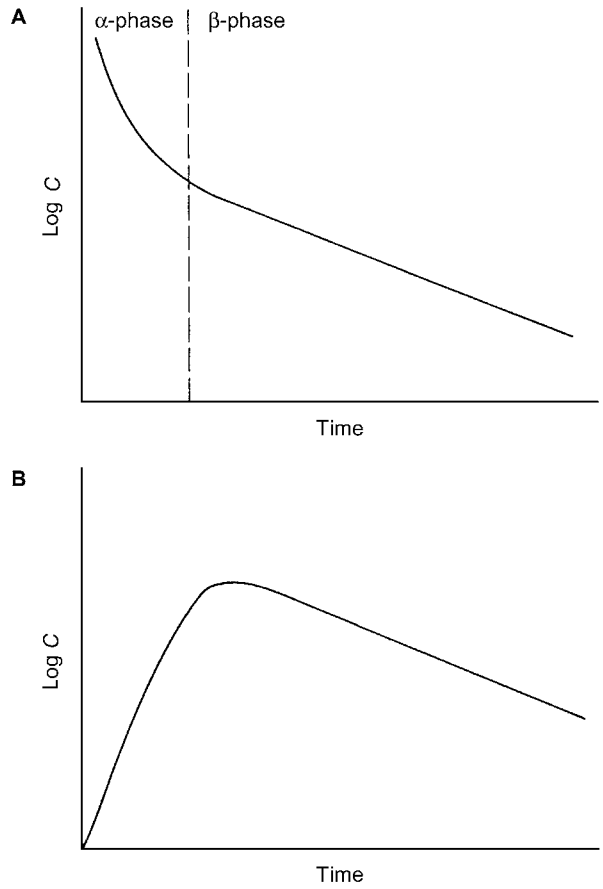

Figure 24.1 Typical semilogarithmic plots of plasma concentration (*C*) versus time for a drug given (A) by intravenous injection and (B) orally. The terminal rate of decline of plasma concentration is the same irrespective of the route of administration.

Drugs injected into the spinal canal, and into muscle or surface tissues (intramuscularly, intraperitoneally), usually exhibit relatively rapid absorption. However, absorption of even intramuscularly injected drugs can be slow if the site of injection is poorly perfused by a blood supply and the site is very fatty.

Drugs that are absorbed and bypass the gastrointestinal tract will not be subject to first-pass metabolism (see next section). These drugs will therefore show higher bioavailability than the same drug delivered through the gastrointestinal tract.

First-pass metabolism and bioavailability

Drugs absorbed following oral ingestion pass through the mesenteric circulation into the liver before entering the systemic circulation. In the 'first pass', drugs can be substantially metabolised by the liver before ever having a pharmacological effect. The proportion of the drug reaching the systemic circulation following oral administration to that obtained following intravenous dosing is the oral (or absolute) bioavailability (F). This is measured by comparing the area under the curve (AUC) for the oral and intravenous doses from zero to the time point at which most or all of the drug is finally eliminated by the body.

This bioavailability is given by the formula:

$$F = \frac{\text{AUC (oral route)}}{\text{AUC (intravenous route)}}$$

where AUC (the area under the plasma concentration–time curve) represents the amount of drug entering the systemic circulation from zero to infinite time.

The relative bioavailabilities of drugs can be determined by comparing other routes of administration with oral or another reference route of administration, or even between drug formulations.

The oral bioavailabilities of selected drugs are shown in Table 24.1. In general, drugs that are readily metabolised by liver enzymes have lower bioavailabilities than drugs that are not as readily metabolised by the liver. While the effect of first-pass metabolism is to reduce the action of the parent drug, drugs that are metabolised to active forms will have a different profile of activity than when the drug is given parenterally (not through the gastrointestinal system). For example, the activity of cannabis is increased substantially by the presence of the 11-hydroxy metabolite of tetrahydrocannabinol (THC) in addition to THC. This 11-hydroxy metabolite is present only in blood (and tissues) in relevant amounts when cannabis is consumed orally (cookies), but not when it is smoked. This is due to the actions of the liver on absorbed THC as the drug passes through the liver from the mesenteric circulation. Smoking (of cannabis) bypasses this 'first-pass' effect allowing little 11-hydroxy metabolite to be produced.

Prodrugs activated by liver metabolism are preferentially taken orally to maximise the activity of the drug. An example is enalapril, which is converted to enalaprilic acid. The latter form is much more active than the parent drug. Drugs given rectally will be subject to only a small degree of first-pass metabolism since only about one-third of the contents of the lower part of the gastrointestinal system passes though the liver.

Enterohepatic circulation

Drugs and metabolites present in the liver are often also excreted into bile. These pass into the jejunum and may be reabsorbed back into the mesenteric circulation or passed into the faeces. The process of biliary excretion and re-absorption may occur a number of times before drug is completely eliminated by the body. This recycling of drugs is known as enterohepatic circulation.

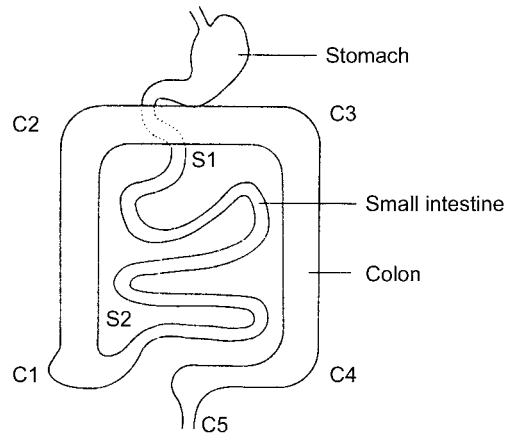
Common examples include the glucuronide conjugates of drugs that are excreted in significant amounts in the bile, such as morphine. Enterohepatic circulation prolongs the persistence of a drug in the body and may lead to delayed toxicity. Drugs that undergo enterohepatic circulation may be detected in the faeces even if they have been administered by a parenteral route. Drugs may even be detected in gastric contents (small amounts) following reflux or vomiting. It is therefore important that small amounts of drug in the gastric contents are not automatically assumed to be from oral administration.

Drugs are found in bile both as parent species and as metabolites such as the glucuronide conjugates. In the absence of urine, bile can be a useful body fluid, e.g. for opioids, the benzodiazepines and colchicine.

Distribution of drug into tissues

The uptake of drugs into tissues depends on a number of factors. These include the blood flow to the tissues, the partition coefficient of the drug between blood and the tissue, the degree of ionisation of the drug at the pH of plasma, the molecular size of the drug, and the extent of tissue and plasma protein binding. For example, the distribution of plasma protein-bound drugs such as the warfarin-type anticoagulants is restricted to plasma and extracellular fluid, whereas alcohol distributes equally into the total body water.

The approximate volumes of the body water compartments for a person of average weight are intracellular water 25 L and extracellular water 17 L (of which 3 L is plasma water). An intravenous dose of a drug that is distributed immediately into the total body water (approximately 42 L) would give an initial plasma concentration (dose divided by 42) approximately two-fifths of that obtained if the same dose were distributed only into extracellular water (dose divided by 17). If the drug is extensively bound to tissue proteins, an even lower initial plasma concentration would be obtained and the volume term relating the dose to the plasma concentration could exceed the volume of the body. The approximate proportions of drugs with nominated volumes of distribution in the plasma water are given in Table 24.2.



Organ	pH	Surface area	Blood flow*	Motility and transit time of contents
Stomach†	1 to 3	$<5\,m^2$	Rises on stimulation of gastric secretions	Relatively 'quiet'. Transit time of contents depends on their chemical and physical nature, including pH and osmotic pressure. Placed in order of increasing transit times, liquids < solids; carbohydrates < proteins < fats. Times vary from 0.5 h for a small amount of liquid carbohydrate to 20 h for a large fatty meal
Small intestine, S	S1, 5 to 7 S2, 7 to 8	$200\,m^2$	Very fast counter-current flow in villi. Blood transit time – 1 s after meals; 5 s resting; 30 s in shock	Food churned, and propelled by very active movements in waves, by both peristalsis and segmentation Transit time – about 2 h
Colon, C	7 to 8	$<5\,m^2$	Average	Residues of meals found at C1 after 4 h, C2 after 6 h, C3 after 9 h and C4 after 12 h. Residues are held up in the rectum (C5) and then egested in faeces over a period of time. Earliest traces may be egested within 6 h, the last may take 1 week. On average, 75% of residues are egested by the third day

* Average is 36 mL/min per 100 g intestine, 50 to 75% of which circulates in the mucosal layers.
† The volume of the stomach can change markedly: 50 mL during fasting and up to 2 L when full.

Figure 24.2 Factors that influence the passage and absorption of drugs in the gastrointestinal tract.

Table 24.1 Bioavailabilities and volumes of distribution for selected drugs

Drug	*Bioavailability (%)[a]*	*Volume of distribution (L/kg)*	*Clearance (mL/min per kg)*
Alprazolam	90	~0.7	~0.7

0.6	6.7
1.0	4
10	0.4

This has implications in cases involving loss of blood and when trauma victims are given fluid replacements (artificial blood replacements, transfusions, etc.). Provided that some re-equilibrium has occurred and elimination time is not too long, the drug concentration after blood replacement will be quite similar to the concentration seen before blood loss for drugs with volumes of distribution greater than about 0.5 L/kg.

The instantaneous equilibrium of drug concentrations throughout the body as considered above does not necessarily require that the concentrations are equal throughout the body. In fact, drug concentrations in tissues are rarely equal to those in plasma. For example, the tissue : plasma concentration ratio will be very low immediately following intravenous administration. As time progresses, the amount of drug

in the tissue compartment will increase and, like that in the plasma compartment, will eventually reach a plateau. If the drug is actively stored in a particular tissue compartment, then the ultimate concentration ratio between the tissue and plasma will be relatively high. It should also be noted that the tissue : plasma concentration ratio depends not only on the processes of distribution but also to a large extent on the route of drug administration and on whether single or multiple doses have been given.

Blood and plasma concentrations

Many drugs show differences in concentration between whole blood and plasma (or serum). This occurs because uptake of drugs into red blood cells (erythrocytes) can be limited by the physiochemical properties of the drug and its ability to move through cellular membranes. For example, THC is almost absent in red blood cells, hence the plasma concentration will be twice that of whole blood, assuming a haematocrit of 0.5. In contrast, chloroquine has a much higher red blood cell concentration than plasma.

Toxicologists should be wary of performing this calculation in haemolysed specimens, since haemolysis will liberate the contents of red blood cells into the plasma (serum), and thereby affect this equilibrium. This applies particularly to postmortem specimens.

Since most of the pharmacokinetic data have been obtained in plasma, it may be necessary to make some allowances for blood concentration data for drugs that exhibit different blood and plasma concentrations.

Binding of drugs to plasma proteins

Many, if not most, drugs bind to proteins in plasma with sufficient affinity to effectively remove that portion of the drug from having biological activity. For example, if a drug is 90% bound to plasma proteins, only 10% can exhibit biological activity. Plasma-binding data for drugs are given in the monographs.

The binding sites for drugs in plasma are predominantly albumin, although β-globulin and α_1-acid glycoprotein are also significant sites for some drugs.

The significance of protein binding of drugs is that the 'free' or unbound fraction in plasma may be affected by illness and by the use of other drugs. In disease states, particularly kidney and liver dysfunction, protein binding can be markedly reduced, often increasing the apparent effects of drugs. Since binding sites are saturable, other drugs can compete with binding and reduce the net binding of drugs. This can cause a net increase in drug action for some drug combinations, although in practice this is rarely of clinical significance.

Volume of distribution

The apparent volume of distribution (V_D) is the amount of drug in the body (A_P) divided by the plasma concentration (C_p) after distribution equilibrium has been established:

$$V_D = A_P / C_p$$

An estimate of V_D can be obtained by calculating the concentration before elimination has occurred by extrapolating the concentration versus time curve for intravenous doses to time zero (C_0) and dividing this value into the dose delivered.

If oral doses are used, the dose must be adjusted for the bioavailability (F). For example,

$$V_D = FD_o / C_o$$

where D_0 is the dose at time 0.

Drugs that are taken up into body fat or bind to cellular structures will have a higher V_D. It is not uncommon for volumes of distribution to be over 10. Morphine has a V_D of 2–5 L/kg. A range of 0.5–5 is seen for most of the amfetamines and many of the benzodiazepines. The highly lipid-soluble THC has a volume of distribution of approx. 10. Drugs with high octanol/buffer partition coefficients will generally have high volumes of distribution. Examples of these parameters are contained in the monographs in Volume 2.

The drug concentration in body fluids other than plasma may be used, e.g. whole blood, but different values for V_D are obtained for each. It is important, therefore, to note which fluid is being used. In the monographs, volumes of distribution, unless otherwise stated, are based on plasma concentrations.

The value of the volume of distribution is determined mainly by the physiological processes of perfusion and protein binding, but it seldom has a true physiological meaning. For example, the volume of distribution of highly protein-bound furosemide is of the order of 15 L, and that of alcohol is about 35 L. However, the value for digoxin, which is extensively distributed and bound in extravascular tissues, is of the order of 450 L.

After distribution equilibrium has been established, knowledge of the volume of distribution allows the amount of drug in the body (D) to be estimated from a single measured blood concentration:

$$D = V_D \times C$$

If the time elapsed since drug administration (t) is known, together with some pharmacokinetic data for the drug, then it should be possible to estimate the original dose (D_0) of the drug. Thus, for a drug given by intravenous injection:

$$D_o = V_D C e^{k_{el} t}$$

where k_{el} is the elimination rate constant (see later).

However, if the drug is given orally, a much more complex relationship applies. It is necessary to know the bioavailability (F) and the absorption rate constant (k_a). Then the dose is given by the expression

$$D_o = \frac{V_D C (k_a - k_{el})}{F k_a (e^{k_{el} t} - e^{k_a t})}$$

If a drug were distributed instantaneously throughout the body, then the volume of distribution would be constant at all times and the decrease in plasma concentration could be attributed solely to elimination of the drug. However, in practice, there are time-dependent changes in tissue concentration including absorption and distribution. In a drug overdose, non-linear pharmacokinetics occur, i.e. the plasma concentration does not increase in proportion to dose since many of the pharmacokinetic processes have reached saturation. Hence, calculation of dose from the volume of distribution can be substantially wrong and misleading. It is recommended to use volume of distribution only when an overdose has not been taken and there is a reasonable chance of equilibrium.

Elimination of drugs

Most drugs are eliminated from the body by metabolism in the liver and/or by excretion of the drug and its metabolites by the kidneys. Other mechanisms for drug metabolism and excretion apply for some drugs and poisons. For example, ethanol and other volatile substances are partially removed by transpiration through the lungs, although other mechanisms may also apply (e.g. via sweat and faeces).

Two terms, clearance and half-life, are frequently used to quantify the rate and extent of drug removal from the body.

Clearance

Overall, the efficiency of elimination by an organ can be expressed as the proportion of drug entering the organ that is eliminated from the plasma in a single passage; this is called the *extraction ratio*. The other major factor that controls the overall ability of an organ to remove drug from the body is the rate of delivery of the drug (i.e. blood flow) to the

organ. Drug elimination can be represented as the product of this rate of delivery and the extraction ratio. This product gives the volume of plasma from which drug is completely removed per unit time, and is given the name clearance (Cl). Clearances by different organs are additive. Although the reference fluid normally used is plasma, whole blood may also be used.

In the drug monographs, clearance has been included wherever possible and usually refers to the total plasma clearance (or total whole-blood clearance) after intravenous administration. In some instances, the total clearance calculated after oral administration has been included if the drug is known to be well absorbed and is not subject to significant first-pass metabolism.

The concept of clearance has found particular application in clinical work as it offers a simple relationship between dose rate (dose divided by the time interval between doses, D/τ), and the average plasma concentration (C_{av}) of the drug:

$$C_{av} = (D/\tau)/\mathrm{Cl}$$

Renal clearance is often measured with creatinine. Creatinine is a metabolic by-product of protein metabolism that is neither reabsorbed nor secreted by the tubules. Its concentration can therefore be used to measure the degree of concentration of urine from the glomerular filtrate.

The efficiency of an eliminating organ in removing drug from plasma depends on the health of the organ. Thus, the net change in clearance is proportional to the extent of renal impairment.

Despite its clinical utility, the concept of clearance has certain limitations for the forensic toxicologist because it does not give an immediate indication of the persistence of a drug in the body. For example, although gentamicin and digoxin have similar clearances (about 100 mL/min), digoxin will stay in the body much longer than gentamicin. This is because the volume of distribution of digoxin is several times that of gentamicin, hence there is a much greater volume of fluid from which the drug must be cleared before it is all eliminated. It is therefore of some advantage to the toxicologist to be able to relate clearance to the persistence of a drug in the body.

This can be done by expressing clearance as a fractional clearance, i.e. clearance divided by the volume of distribution. Fractional clearance (Cl/V_D) has the dimension reciprocal time and represents the proportion of drug removed from the body per unit time, i.e. it is a first-order rate constant for drug elimination (k_{el}). This rate constant is given by the gradient of the terminal part of the concentration–time curves shown in Fig. 24.3.

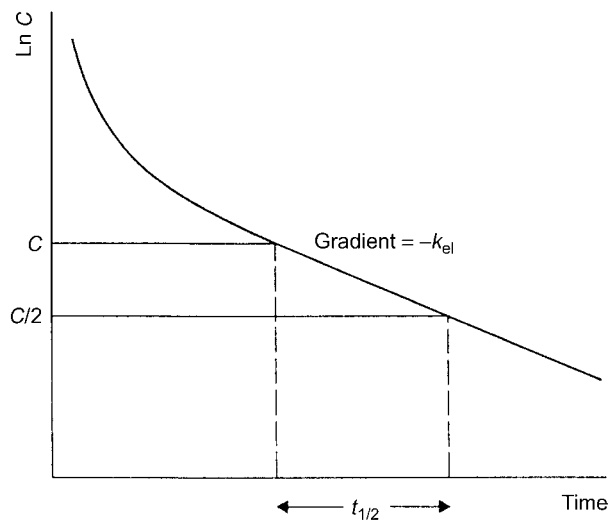

Figure 24.3 Plot of the natural logarithm of plasma drug concentration (ln *C*) versus time (*t*) after intravenous administration. The gradient of the linear part of the curve is equal to the elimination rate constant ($-k_{el}$).

Half-life

The half-life of a drug ($t_{1/2}$) is the time required for plasma concentrations to decline by 50%, provided that elimination occurs by a first-order process (Fig. 24.3). It is related to the elimination rate constant (k_{el}) by the equation:

$$t_{1/2} = 0.693/k_{el}$$

The half-life of a drug provides a measure of the rate of drug loss from the blood. If the dose is known, the half-life of a drug can be used together with information on the volume of distribution, and bioavailability where necessary, to estimate the time elapsed since administration. Conversely, if the elapsed time is known, the half-life can be used to estimate the drug dose, subject to the limitations discussed earlier. The half-life is a function of volume of distribution, clearance and the proportion of drug elimination in unit time. This last term depends on both the extent of its distribution and the efficiency of its elimination. Thus the half-life of a drug may differ between children and adults because of size and weight differences, even though the clearances are equivalent.

For many drugs, the estimated half-life will depend on how the elimination phase is determined. All too often half-lives are calculated while significant absorption and/or tissue distribution is occurring, underestimating the true terminal elimination half-life. It is therefore essential that sufficient time points are used beyond the absorption and distribution phases. For example, the apparent half-life of THC can be an hour or so if only the first several hours of plasma concentrations are determined following smoking of marijuana. Sensitive analytical methods that can detect plasma concentrations below 1 ng/mL indicate that the terminal elimination half-life of THC is actually 2–3 days.

Zero-order processes are best described as a loss of drug per unit time. For example, ethanol elimination is approximately zero order over 200 mg/L. The rate of elimination is expressed as a loss of ethanol per unit time, i.e. 0.10–0.25 (g/L/h) (mean 0.17 (g/L)/h)).

Excretion

Drugs and metabolites are excreted by the kidneys into urine (Fig. 24.4). This process is the single most important mechanism for excretion of most drugs. Renal clearance can result either from glomerular filtration or through tubular secretion. In some cases reabsorption occurs, reversing the secretion process.

The drug is brought to the kidneys with a total plasma flow for both kidneys of approximately 1.4 L/min. Plasma is filtered at the rate of 125 mL/min in the glomeruli, which are the principal sites of excretion. Filtration is passive and only the non-protein-bound drug in the plasma is eliminated by this pathway. A considerable amount of filtered drug may be reabsorbed into the plasma by diffusion back across the tubule wall (which is permeable to un-ionised, lipid-soluble species). The filtrate (125 mL/min) is gradually concentrated as it passes down the tubule to give a final production of urine of about 1 mL/min. About 575 mL/min of plasma circulates in intimate contact with the proximal and distal renal tubules.

The renal tubule may contribute to elimination by active secretion (tubular secretion), and in such cases protein-bound drug may also be eliminated from the plasma.

The extent of elimination by the kidneys can be extremely variable depending on which of the three processes of filtration, secretion and reabsorption predominates for the drug in question. Thus, procainamide is eliminated partly by metabolism and partly as unchanged drug through the kidney. Its renal clearance is of the order of 450 mL/min, indicating major involvement of tubular secretion. By contrast, digoxin has a renal clearance of about 120 mL/min and this could be explained either by filtration alone or by the fact that secretion is balanced by reabsorption. In practice, it is known that filtration accounts for almost all of the renal clearance of digoxin. A further example is methaqualone,

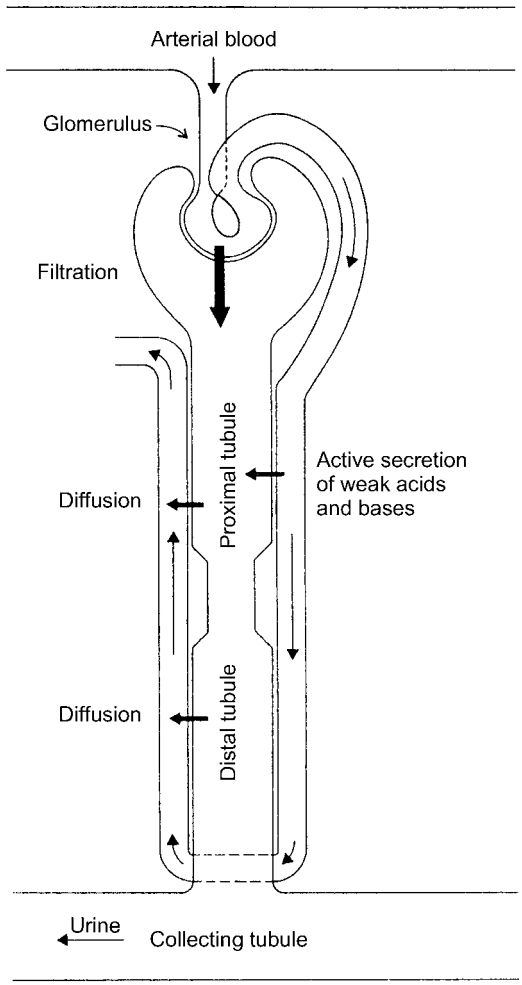

Figure 24.4 Drug elimination by the kidneys. Schematic of a nephron to illustrate the sites of filtration, diffusion and active secretion of drugs.

which has a renal clearance of ~1 mL/min, indicating extensive reabsorption of filtered drug.

One of the major physiological factors that determine the variability in the rate of drug excretion into the urine is the pH of the urine. Only un-ionised species are available for reabsorption by the tubules along the concentration gradient. Thus, acidic drugs (e.g. barbiturates, salicylates) are excreted more rapidly at high pH than are basic drugs (e.g. amfetamines). Conversely, basic drugs are excreted more rapidly at low pH. For example, about 85% of a dose of aspirin is excreted as free salicylic acid in alkaline urine, but only about 5% is excreted when the urine is acidic. Conversely, about 75% of a dose of amfetamine is excreted unchanged in acidic urine but less than 5% if the urine is alkaline.

The effect of varying urinary pH has been used in the treatment of drug overdoses by applying forced alkaline diuresis as an adjunct to the treatment of salicylate or phenobarbital poisoning. The success of the treatment is limited by the extent to which these drugs are distributed and by the presence of alternative pathways of elimination. Unfortunately, drugs with a high volume of distribution will often have a relatively long half-life; hence any increase in clearance will not make much difference to its pharmacological or toxicological effect.

Persons who abuse amfetamines have used the effect of urinary pH on excretion to advantage by simultaneously ingesting bicarbonate. This produces alkaline urine which delays elimination of the amfetamine and therefore prolongs its stimulant effect. Conversely, substances that acidify urine have been taken to enhance elimination of amfetamine-like stimulants in the hope of avoiding detection in routine doping-screening procedures. Exercise in itself can also decrease urinary pH somewhat and thus increase the renal clearance of basic drugs.

Although the quantity of drug in a urine sample is the product of the renal clearance of the drug, the average plasma concentration of the drug during the interval that the urine was produced, and the duration of that interval, the calculation of a likely plasma concentration or even a dose is ill advised since urinary flow rate and the degree of metabolism must also be considered. Many drugs also show non-linear pharmacokinetics, i.e. their excretion rate and degree of metabolism are subject to dose dependency.

Chronic dosing

Drugs accumulate in plasma or tissues if more than one dose is administered and the interval between doses is less than the time taken to eliminate the previous dose. Under these circumstances, there will also be a change in the shapes of the plasma concentration–time curve and the tissue concentration–time curve. In all cases, accumulation is controlled by the size of the dose, the dose interval and the terminal elimination phase for loss of drug from the body (k_{el}). The problems of drug accumulation are of particular interest to the toxicologist because the resulting high drug concentrations may lead to a progressive and insidious toxicity.

The extent to which a drug will accumulate in multiple dosing can be estimated. After each successive dose, the maximum, minimum and average plasma concentrations will be higher than those for the previous dose. This is so in the early stages, but, since drug elimination is often a first-order rate process, the total amount of drug in the body will increase only until the amount eliminated during a dose interval equals the amount taken in (total injected dose or the net absorbed dose after oral dosing). This is called steady state. The clearance (Cl) can be related to dose rate ($DR = D/\tau$) divided by steady-state plasma concentration (C_{ss}).

$$Cl = DR/C_{ss}$$

A good example of the importance of this concept is the use of methadone to treat opioid dependency. Methadone has a long pharmacokinetic half-life of approx. 1 day. With once-a-day dosing the plasma concentrations of methadone will accumulate for at least 5 days. Accordingly, the effects of methadone increase during the first 5 days of therapy. If the dose consumed is too high, or dose increases are made during these 5 days, potentially life-threatening respiratory depression can set in.

Similarly, for other drugs steady state is achieved after about five terminal elimination half-lives.

Drug metabolism

Metabolism is an integral part of drug elimination. As well as facilitating excretion of a drug, it may also affect the pharmacological response of a drug by altering its potency and/or duration of action. With few exceptions, metabolites of drugs are more polar (and water soluble) than the parent drug and are therefore more likely to be excreted from the body.

Metabolites may be pharmacologically inactive (e.g. salbutamol sulfate) or they may be active. This is the case with many drugs of toxicological interest. For example, glucuronidation of morphine on the 6-hydroxyl moiety yields an opioid with more activity than morphine itself. The hydroxylation of THC to the 11-hydroxy form yields an active cannabinoid. Hydroxylation and demethylation of the benzodiazepine diazepam give the metabolites temazepam and oxazepam, both of which are also available as drugs. Similarly, amitriptyline, a tricyclic antidepressant, is demethylated to yield another antidepressant, nortriptyline. Diamorphine is deacetylated to 6-acetylmorphine and morphine, both potent opioids.

Active metabolites may also have different modes of action and different potencies; thus dealkylation of the antidepressant drug iproniazid gives the tuberculostatic drug isoniazid, while the anticonvulsants primidone and methylphenobarbital are both metabolised to phenobarbital, another anticonvulsant with a much longer duration of action.

Clearly the formation of active metabolites changes the profile of drug action.

Pathways of drug metabolism can be divided into two types. Phase I reactions include oxidation, hydroxylation, *N*- and *O*-dealkylation, and sulfoxide formation as well as reduction and hydrolysis reactions. Phase II processes involve conjugation reactions, such as with glucuronic acid, as well as acetylation, methylation and conjugation with amino acids and sulfate. Phase II reactions remove or mask functional groups (amino, carboxyl, hydroxyl, sulfhydryl, etc.) on the drug or phase I metabolites by the addition of an endogenous substrate.

Many drugs undergo a combination of phase I and phase II reactions. The major phase II reaction is conjugation of glucuronic acid with the phenolic or alcoholic hydroxyl groups that are common products of phase I reactions. Thus, chlorpromazine gives rise to at least twenty metabolites by its three major routes of metabolism, i.e. hydroxylation, *N*-demethylation and sulfoxidation. Fortunately, such complicated patterns of metabolism are not a major problem to the analyst since at most only one or two key metabolites are usually targeted.

A new generation of hypnotics and sedatives belong to different structural classes from the benzodiazepines – the azapirones (buspirone), the imidazopyridines (alpidem, zolpidem), the cyclopyrrolone class (suriclone, zopiclone) and the pyrazolopyrimidine zaleplon. These are metabolised by a variety of different pathways to inactive metabolites.

Many of the critical pathways are catalysed by microsomal membrane-bound enzymes in the hepatocytes (parenchymal cells of the liver). For example, the cytochrome P450 mixed-function oxidase system that catalyses oxidations and glucuronyltransferase, and the enzyme responsible for conjugation with glucuronic acid, are both located on microsomal membranes.

Metabolism can occur in tissues other than the liver. The major additional sites are the gastrointestinal tract, kidneys and lungs. Their contribution will clearly depend on the route of administration. For example, many metabolic reactions occur in the gastrointestinal tract before an orally administered drug is absorbed, carried out by enzymes in the mucosal lining or by microflora. Most of these reactions involve reduction and hydrolysis because of the anaerobic environment. Plasma esterases cause extensive hydrolysis of drugs such as diamorphine, cocaine and procaine.

In postmortem cases, anaerobic bioconversion occurs by endogenous enzymes active in such situations or by invading gastrointestinal bacteria. The nitrobenzobenzodiazepines nitrazepam, clonazepam and flunitrazepam are subject to reduction to the 7-amino metabolite.

Using drugs principally of forensic interest, a number of examples are given below to illustrate the variety of metabolic routes that can be followed in humans and the effects that these might have on disposition and pharmacological activity. The list is not intended to be exhaustive with regard to either the pathways or the drugs covered.

All the major oxidative mechanisms can be illustrated by considering the metabolism of the benzodiazepines, amfetamines, antidepressants and opioids.

Benzodiazepines and other sedatives

The benzodiazepines are one of the most widely prescribed groups of drugs and are frequently found in toxicological cases. They undergo extensive metabolism by *N*-dealkylation, hydroxylation and conjugation pathways (Fig. 24.5). Many of the metabolites of the prototype benzodiazepine, diazepam, show pharmacological activity, including desmethyldiazepam (nordazepam), 3-hydroxydiazepam (temazepam) and desmethyl-3-hydroxydiazepam (oxazepam).

Ring-substituted benzodiazepines based on the triazolam structure show much higher potency than the first-generation benzodiazepine based on chlordiazepoxide and diazepam (Fig. 24.6). These also include midazolam and alprazolam. For example, triazolam is the most potent member in active use, with daily doses starting at 0.125 mg. By comparison, a typical dose for diazepam is 5–20 mg, and for chlordiazepoxide 100 mg.

2-Nitro	Methyl	2-Fluoro	Hydrogen	Flunitrazepam
2-Nitro	Hydrogen	Hydrogen	Hydrogen	Nitrazepam
2-Chloro	Hydrogen	2-Chloro	Hydroxy	Lorazepam
2-Chloro	Diethylamino-ethyl	2-Fluoro	Hydrogen	Flurazepam

Figure 24.5 Metabolic scheme for 1,4-benzodiazepines.

Benzodiazepines that do not belong to these two classes are still likely to be metabolised by the same routes (Fig. 24.7). The atypical benzodiazepine chlordiazepoxide is metabolised by demethylation and deamination to desmethylchlordiazepoxide and demoxepam. Demoxepam is further metabolised to nordiazepam by hydrolysis and cleavage of the lactam ring.

The pharmacokinetic half-lives of benzodiazepines are largely used to determine their principal medical use. Benzodiazepines with a relatively short half-life are used predominantly as hypnotics and as supplements to preoperative anaesthesia, whereas the longer-acting benzodiazepines (such as diazepam) are used as minor tranquillisers (anxiolytics).

The urine usually contains extensive metabolites of benzodiazepines, often with little parent drug present. It is essential that individual metabolites of target benzodiazepines are known when assessing the urine of persons exposed to this class of drug.

The clearance of benzodiazepines is decreased by liver disease, although the greatest effects occur with those drugs metabolised by the P450 system. Lorazepam and oxazepam and other similar drugs metabolised by glucuronidation are least affected. Kidney disease particularly affects benzodiazepines metabolised to active drugs and those showing a high degree of protein binding.

Advanced age has similar effects to liver and kidney disease owing to the reduction in output of major organs and changes in the volume of distribution. Doses of sedatives are usually halved in the elderly (>65 years), although those benzodiazepines that are primarily conjugated such as oxazepam, lorazepam and temazepam are least affected by age.

Amfetamines and other stimulants

The amfetamines are metabolised by a combination of hydroxylation of the ring and the side-chain carbon atom adjacent to the ring, and

Figure 24.6 Metabolic scheme for diazolo- and triazolo-benzodiazepines.

removal of the nitrogen (Fig. 24.8). Drugs with alkyl groups on the nitrogen are dealkylated, e.g. metamfetamine and methylenedioxymetamfetamine (MDMA) to other active amfetamines (amfetamine and methylenedioxyamfetamine (MDA), respectively) (Fig. 24.8). Methylenedioxyethylamfetamine (MDEA) and MDMA are both metabolised to MDA as well as other metabolites. The methylenedioxy amfetamines are also transformed to dihydroxy compounds (catechols) following opening of the ring. These hydroxy metabolites can be either monomethylated or conjugated with sulfate esters or with glucuronic acid.

The side-chain of non-*N*-substituted amfetamines is oxidised to form benzoic acid derivatives (e.g. amfetamine), which are excreted as the glycine conjugate, or the sulfate or glucuronide conjugate. Amfetamine and metamfetamine are also oxidised at the beta-carbon to form the pharmacologically active ephedrine analogues.

A number of legal stimulant drugs are metabolised to metamfetamine or amfetamine. These include fenethylline, clobenzorex, mefenorex, fenproporex and benzfetamine. The antiparkinsonian drug selegiline is metabolised to the weakly active L-isomer of metamfetamine. Detection of the parent drug and possibly the conduct of chiral analyses are essential to determine the source of the amfetamine.

As expected from its different structure, cocaine undergoes substantially different routes of metabolism than the amfetamine class. Cocaine is rapidly hydrolysed by ubiquitous enzymes to the inactive benzoylecgonine. This is the main metabolite in both blood and urine. Other significant metabolites are ecgonine methyl ester (EME) and ecgonine (Fig. 24.9).

Anhydroecgonine methyl ester (AEME, also known as methylecgonidine) is a pyrolytic substance formed by smoking cocaine. Cocaethylene is also found as a metabolite in persons co-consuming alcohol. Metabolism of cocaine to norcocaine allows the oxidation of the nitrogen to *N*-hydroxynorcocaine. *N*-Nitrosonorcocaine and the *N*-oxide are also produced in small amounts.

Antidepressants

Modern antidepressants can be divided into several chemical classes. The traditional tricyclic antidepressants include amitriptyline, clomipramine, dothiepin, doxepin and imipramine. The newer-generation antidepressants include the selective serotonin reuptake inhibitors (SSRIs): citalopram, fluoxetine, fluvoxamine, paroxetine and sertraline. Other antidepressants include the monoamine oxidase inhibitor moclobemide and other mixed uptake inhibitors venlafaxine, nefazodone and mitazepine.

The tricyclic antidepressants are metabolised by three major pathways: *N*-oxidation, hydroxylation of the alicyclic ring and of the aromatic ring, and *N*-dealkylation of the dialkylamino group. The last route gives rise to the most important metabolites since the *N*-demethylated metabolites are themselves pharmacologically active. Amitriptyline is metabolised to nortriptyline, and imipramine to desipramine; both metabolites are also available as therapeutic agents (Fig. 24.10).

When monitoring concentrations of tricyclic antidepressants for their therapeutic effect, it is important to determine both the parent drug and the desalkyl metabolites as the latter may be present in a significant quantity. These can be added to provide an estimate of therapeutic activity. The hydroxy metabolites predominate in the urine, usually occurring as glucuronide conjugates.

The other classes of antidepressants have varied chemical structures, hence their fate is very much dependent on the drug concerned (Fig. 24.11).

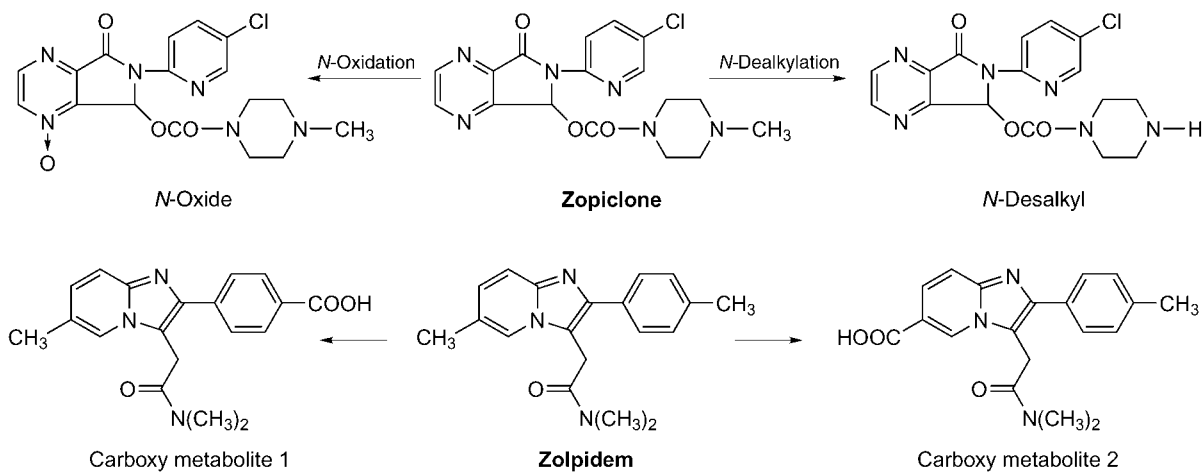

Figure 24.7 Metabolic pathways for zopiclone and zolpidem.

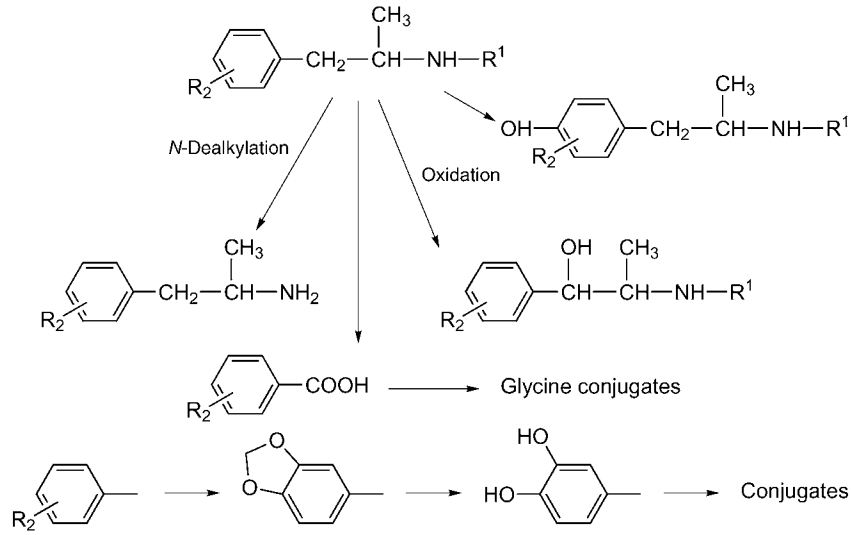

Figure 24.8 Major routes of amfetamine metabolism.

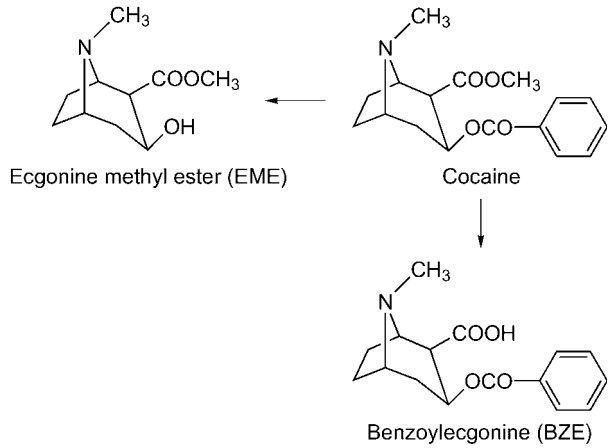

Figure 24.9 Main cocaine metabolic pathways.

Antipsychotic drugs

The antipsychotic drugs represent diverse classes of chemical compounds.

The first drugs of this type were largely of the phenothiazine type represented by thioridazine and chlorpromazine. They undergo sulfoxidation to yield sulfoxides and sulfones. In addition, oxidation at the nitrogen, hydroxylation of one or both of the aromatic rings, *N*-dealkylation of the side-chain and fission of the side-chain may also occur. The phenolic metabolites are then conjugated with glucuronic acid or sulfate and excreted in both the urine and the bile.

The number of different metabolic routes that are possible results in a complex mixture of metabolites for many phenothiazines. For example, many of the drugs that contain an *N,N*-dialkylaminoalkyl side-chain (e.g. chlorpromazine) are extensively metabolised by *N*-oxidation, together with hydroxylation, sulfoxidation and *N*-dealkylation. Thioridazine is predominantly oxidised on the side-chain sulfur to active sulfoxide and sulfone metabolites (Fig. 24.12).

Haloperidol is metabolised by side-chain oxidation to a propionic acid derivative (Fig. 24.13), which is then conjugated, or by reduction of the keto group. Clozapine is metabolised to the active desmethyl form, norclozapine, which is often measured with the parent drug in therapeutic drug monitoring situations. Olanzapine is metabolised by *N*-demethylation and oxidation to a 2-hydroxymethyl metabolite and *N*-glucuronidation. Risperidone is metabolised to the active 9-hydroxy metabolite (see below under Prodrugs) and inactive 7-hydroxy- and *N*-dealkyl forms.

Opiates and centrally active analgesics

The opiates include the analogues of morphine, such as codeine, ethylmorphine and diamorphine, as well the synthetic opiates methadone,

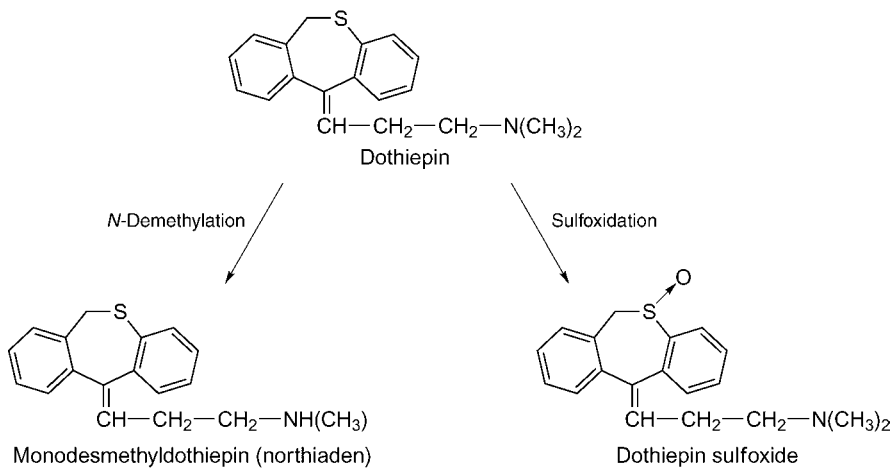

Figure 24.10 Major pathways of dothiepin metabolism.

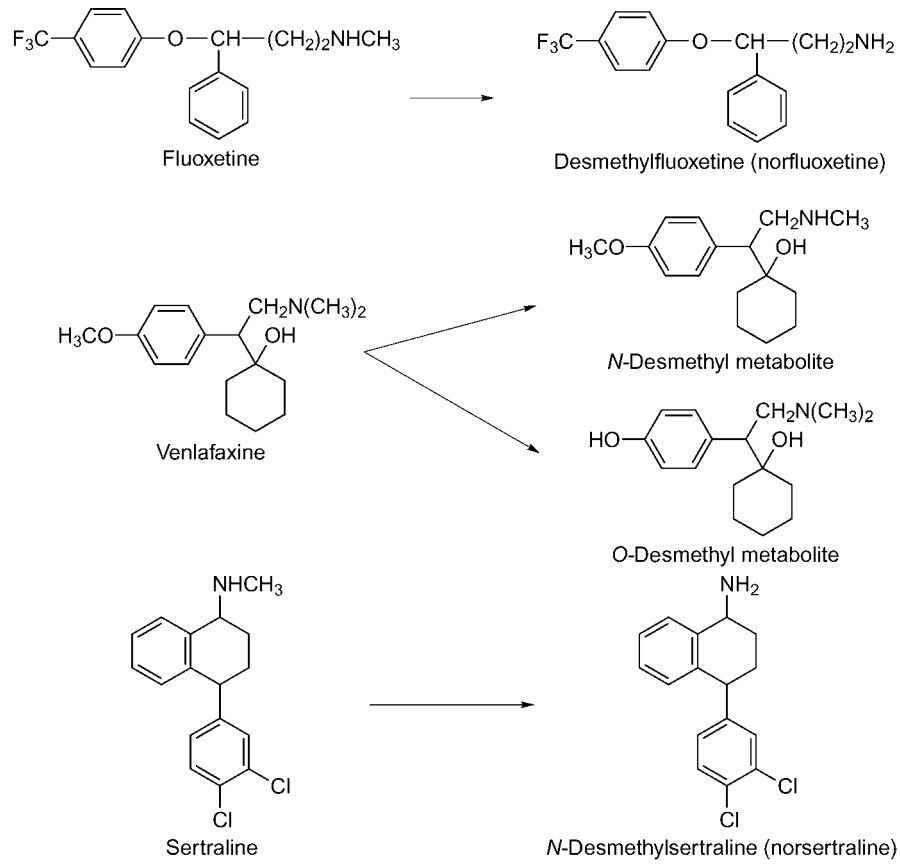

Figure 24.11 Key metabolic pathways for selective serotonin reuptake inhibitors.

pethidine, propoxyphene and the highly potent fentanyl derivatives. Depending on their structural features, the metabolism of opiates can vary widely.

The morphine analogues are metabolised by *O*-dealkylation or de-esterification and conjugation with glucuronic acid. Thus diamorphine (heroin) is rapidly hydrolysed in the body to 6-acetylmorphine, which is further and more slowly hydrolysed to morphine. The morphine so formed is excreted largely as the 3- and 6-glucuronides together with some free morphine. Codeine and ethylmorphine are conjugated and metabolised by *O*-dealkylation to morphine. Morphine is also metabolised to a minor extent by *N*-demethylation to normorphine (Fig. 24.14).

Oxycodone is subject to demethylation and conjugation (Fig. 24.15).

Methadone, propoxyphene and pethidine are largely dealkylated. In the case of methadone, a cyclisation product known as EDDP is formed (Fig. 24.16).

The non-opioid centrally active analgesic tramadol is metabolised to *N*- and *O*-demethylated products followed by sulfation and glucuronidation of the phenol. The *N*-demethyl metabolite (known as M1) is the active form of tramadol (Fig. 24.17).

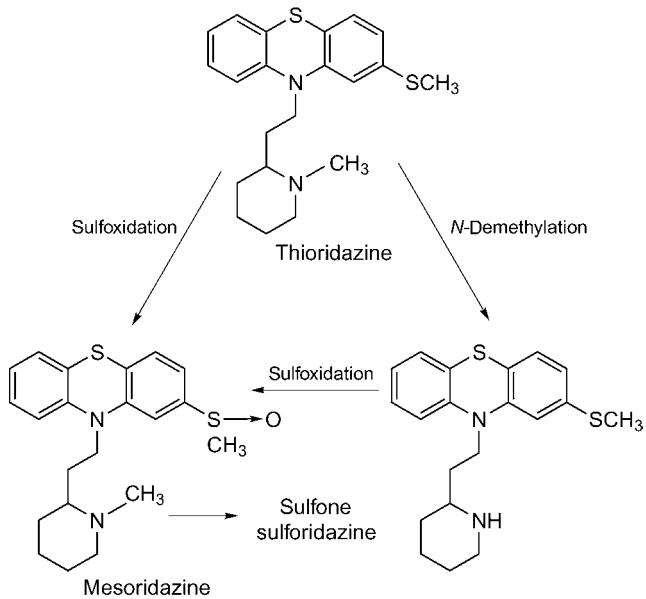

Figure 24.12 Thioridazine metabolic pathways.

Activation of drugs

Drugs can be activated or the pharmacological activity can be modified by metabolism, by design (prodrugs) or through the formation of active metabolites.

Prodrugs

A number of drugs have been modified such that metabolism is required to produce an active species. This is often done to facilitate oral absorption or to reduce toxicity, although for some drugs the active form was not established until after clinical use. Examples include: the esters of many angiotensin-converting enzyme (ACE) inhibitors, e.g. enalapril and quinapril, which are hydrolysed to potent di-acid forms; azathioprine, which is metabolised to mercaptopurine; and zidovudine, which is metabolised to zidovudine triphosphate.

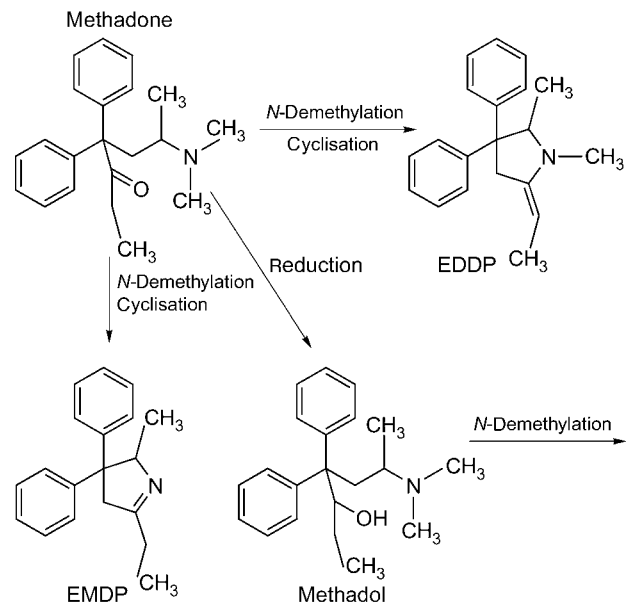

Figure 24.16 Methadone metabolism.

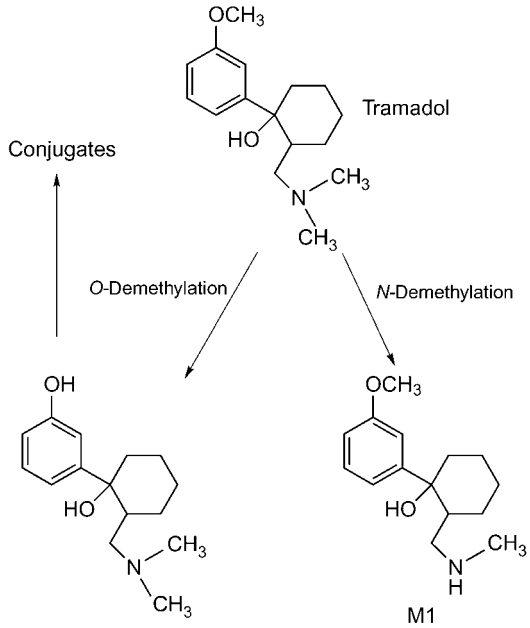

Figure 24.17 Tramadol metabolism.

Some metabolites of earlier antihistamines are now used as drugs in their own right. For example, fexofenadine is a carboxy metabolite of terfenadine, and cetirazine is the carboxy metabolite of hydroxyzine.

A more recent example is the activation of risperidone by the formation of 9-hydroxy metabolite, now known as paliperidone.

Active metabolites

When an active metabolite makes an important contribution to the overall pharmacological response, the interpretation of toxicological data is further complicated. Toxicological situations involving such metabolites (e.g. oxazepam, nortriptyline, desipramine and phenobarbital, derived from diazepam, amitriptyline, imipramine and methylphenobarbital, respectively) can be misinterpreted if only the parent drugs are assayed. The concentrations of active metabolites must be taken into account. Although there is controversy over the best way to evaluate the contribution of metabolites, the individual concentrations of drug and metabolites are often added together to provide an estimate of the total amount of active drug species present in the sample. This assumes that their relative pharmacological activities are equal, which is not generally true.

Reactive metabolites

Toxic metabolites can occur in the same way that pharmacologically active and/or inactive metabolites are produced. For example, deacetylation of phenacetin yields *p*-phenetidine, the precursor of substances believed to be responsible for methaemoglobinaemia.

Similarly, paraoxon, the oxygenated metabolite of parathion, is responsible for the severe toxicity observed after the ingestion of parathion.

Changes in the pathways of metabolism of a drug can also result in toxicity. In paracetamol intoxication, the pathways responsible for sulfate and glucuronide conjugation become saturated and the concentrations of cysteine and mercapturic acid metabolites increase. When the production of the latter two metabolites increases sufficiently to deplete stores of glutathione, the active intermediate can no longer be conjugated and is thought to bind irreversibly to cellular macromolecules such as DNA, RNA and proteins, resulting in a dose-related hepatic necrosis. It is believed that the toxic molecule arises from the oxidation of paracetamol to *N*-acetyl-*p*-benzoquinoneimine (Fig. 24.18).

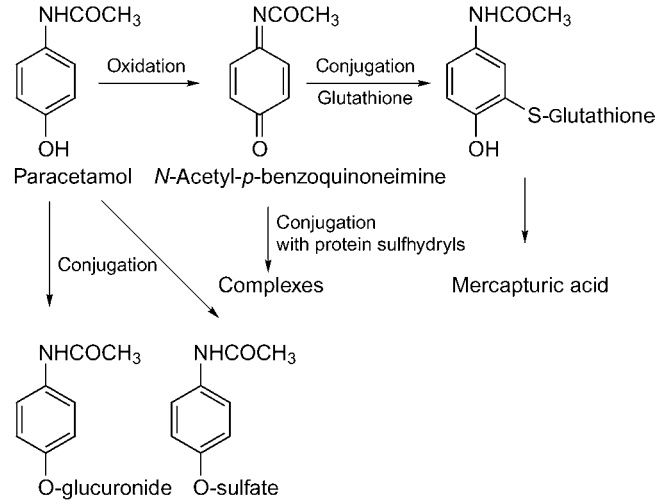

Figure 24.18 Paracetamol metabolism.

Whatever the actual pathway, the administration of compounds containing sulfhydryl groups has been shown to be effective in paracetamol intoxication, presumably because they are able to bind to the electrophilic species in the same way as glutathione.

Another example of drug toxicity induced by metabolism is that associated with acetylation. The rate of acetylation is controlled by an *N*-acetyltransferase that shows genetic polymorphism; about 60% of white people are classified as 'slow' acetylators. The extent of acetylation is related to the toxic effects of certain drugs. For example, the *N*-hydroxy metabolite of acetylated isoniazid is thought to cause isoniazid-related hepatotoxicity. This toxicity is more severe in 'rapid' acetylators than in 'slow' acetylators but, as with paracetamol, some protection can be given by sulfhydryl compounds.

In contrast, 'slow' acetylators appear to show a greater incidence of systemic lupus erythematosus following administration of hydrazine drugs than do 'rapid' acetylators as this toxic reaction is related to the parent drug. Fortunately, modern drugs are not frequently acetylated, so this is no longer an important problem in clinical pharmacology and toxicology.

Factors affecting the pharmacokinetics of drugs

Metabolic effects

There are many examples of drugs affecting the metabolism or pharmacology of other drugs. For example, cimetidine (an anti-ulcer drug) and a number of the newer generation of antidepressants inhibit the metabolism of many of the benzodiazepines by a subtype of the cytochrome P450 enzymes, CYP3A. This occurs either by competitive inhibition of the enzyme(s) involved in their mutual metabolism or by inhibition of the enzyme(s) by the interfering drug. Many of the newer SSRIs, including fluoxetine, paroxetine and sertraline, as well as some of the antifungal drugs, such as fluconazole and antiviral drugs, are relatively potent inhibitors of this enzyme.

The activity of another P450 enzyme, CYP2D6 (debrisoquine hydroxylase), has activity that is genetically determined. For example, the main metabolic pathway for codeine, dextromethorphan and ethylmorphine is the metabolism to morphine through *O*-dealkylation. Some 7% of white people are deficient in this enzyme and are unable to produce significant amounts of morphine. In these people, codeine and ethylmorphine appear to be far weaker analgesics than in those who are able to produce morphine. The same enzyme is involved in the bioconversion and activation of oxycodone to oxymorphone, of hydrocodone to hydromorphone, and of risperidone to 9-hydroxyrisperidone, and metabolism of olanzapine. The efficacy and toxicity of these drugs will therefore be affected by this genetic difference.

Cimetidine (used in the treatment of gastric and duodenal ulcers) will inhibit metabolism of opioids requiring microsomal cytochrome enzymes.

Monoamine oxidase inhibitors nialamide, phenelzine and tranylcypromine also inhibit cytochrome P450 enzyme metabolism and have been shown to increase the effects of alcohol, amfetamines, appetite suppressants, barbiturates, pethidine and other opioids. The analgesic propoxyphene may have similar activity.

A further variable is that drugs such as the barbiturates and the anticonvulsants phenobarbital and phenytoin enhance the production of the enzymes and therefore induce metabolism of drugs metabolised through this and related enzyme systems. In fact, barbiturates also induce their own metabolism, causing a time-dependent increase in clearance as the liver produces more enzymes.

Effect of age

Neonates and elderly people generally have a lower metabolic capacity than subjects between these extremes of age. The enhanced sensitivity of the very young to drugs is related to immaturity in the development of microsomal enzymes within the first several months of birth. Hence neonates can have quite different clearance rates from adults. Differences may also occur in older children.

Furthermore, very young children do not have the necessary plasma-binding proteins which help to compartmentalise drugs. Infants (over 1 year old) require lower doses to produce comparable effects because the drugs are distributed into a smaller volume. It is important that the known pharmacokinetics of a drug in question are examined when neonates and even children generally are the focus of an investigation relating to drug effects, since some drugs may behave differently than in adults.

In elderly subjects (over 65 years old) there is a decreasing capacity for drug metabolism as a consequence of a gradual decline in overall physiological function of organs. This includes effects on volume of distribution, protein binding and both hepatic and renal clearances. The change in the pharmacokinetics is an explanation of the increased sensitivity to drug effects in the elderly. For example, doses of benzodiazepines are reduced in the elderly to avoid excessive sedation and adverse effects on cognition.

Effect of disease

Diseases can affect all the processes by which a drug is absorbed, distributed, and eliminated from the body. A drug may be poorly absorbed during gastrointestinal disturbance; the rate of uptake of drugs that rapidly cross tissue membranes may be altered in cardiovascular diseases that alter blood flow to critical organs such as the liver, kidney, lungs and heart, and of course diseases that fundamentally affect metabolic and excretory pathways of drugs.

Diseases that affect the liver or kidneys probably have the greatest effect on drug concentrations because normal functioning of these organs is essential for efficient metabolism and excretion. The liver has a large metabolic reserve; however, severe disease such as cirrhosis or drug-induced necrosis will cause the terminal elimination half-life to increase dramatically.

Renal disease leads to a decreased ability to excrete drugs and/or their metabolites. A drug will accumulate in plasma or tissues if the interval between doses is such that not all of the previously administered drug is removed before the next dose. Even for those drugs where excretion into the urine does not normally appear to be an important route of elimination, there can be a risk of increased toxicity during disease if significant drug accumulation takes place. This is especially true where potentially serious interactions can occur with the accumulated drug or metabolite. For example, metabolites can displace their parent drugs from binding sites on plasma and tissue proteins if their concentrations build up sufficiently.

Drug concentration and pharmacological response

The relationship between drug action and the processes of absorption, distribution and elimination has been successfully applied in clinical pharmacology for the optimisation and individualisation of therapy for many drugs. This is termed therapeutic drug monitoring (TDM). In clinical and forensic toxicology, similar relationships can be applied in the interpretation of analytical results.

For most drugs there is a correlation between the dose given, the concentration of the drug in blood and the duration and intensity of the biological effect. In general, as blood concentrations rise above those associated with a therapeutic effect, the frequency and severity of toxic side-effects increase. It should be stressed that this correlation is at best poor for most drugs and there is considerable individual variability. Hence any prediction of response from a drug concentration may be poor.

The significance of toxicological data is assessed by attempting to explain the clinical or toxicological effects in terms of the drug concentrations found. Before this can be done, the toxicologist must be satisfied that the clinical and analytical data are valid.

In some situations drugs have long-lasting or even irreversible biochemical effects such that there is little correlation between concentration and response. For example, reserpine and some monoamine oxidase inhibitors still have clinical effects long after drug administration has stopped and when plasma concentrations of the drug are negligible. Similarly, unless the time of ingestion is known with reasonable accuracy, it is almost impossible to relate drug concentrations with the secondary and potentially fatal responses to substances such as paracetamol (liver damage) and paraquat (lung necrosis). Incorporation of drugs or chemicals into endogenous metabolic cycles may result in a toxicity (lethal synthesis) that is not related to blood concentrations of the drug.

Finally, assessment of drug pharmacokinetics is made difficult or impossible when underlying disease has substantially altered the pharmacokinetics and even pharmacological action of the drug.

It is therefore essential that any assessment of drug concentrations considers as far as reasonably possible the factors that may affect drug clearance.

CHAPTER

25 Pharmacogenomics

SHY Wong

Introduction

From Gregor Mendel to pharmacogenomics, personalised medicine, forensic toxicology and personalised justice

Gregor Mendel characterised his early scientific genetic findings, to his contemporary, Eichling, as a 'little trick – long story'; the continuation of that 'story' may be partially developing now in pharmacogenomics and personalised medicine (PM), and in the emerging field of personalised justice. Some of the landmarks in pharmacogenetics are summarised in Figure 25.1 (Weber 2002), which has been modified to include nutritional genomics and proteomics. After Mendel established early genetics in 1865, pharmacogenetics emerged in 1955, followed by pharmacogenomics in the early 1990s. According to Weber, PM may be achieved by 2015, when drugs will be prescribed according to a patient's genetic profile. Further, personalised justice complements the practice of PM, and may be defined as the applications of genomic and other molecular biomarkers in the interpretation of the effect of genetic variations and other epigenetic factors on the efficacy of drug therapy and, therefore, on individual behaviour (Wong 2007). Thus, translational pharmacogenomics will contribute to various clinical and forensic practices in the near future.

The emerging practice of pharmacogenomics as part of genomic medicine (Linder *et al.* 1997; Weber 1997; International Human Genome Sequencing Consortium 2001; Venter *et al.* 2001; Jicinio, Wong 2002; Evans, McLeod 2003; Weinshilboum 2003; Guttmacher *et al.* 2004; White, Wong 2005; Wong *et al.* 2006a) and PM is one of the most tangible benefits as a result of the completion of the human genome project (Personalized Medicine e-Symposium 2006). This was recently addressed by the September 2008 report of the President's Council of Advisors on Science and Technology, 'Priorities for Personalised Medicine' (President's Council 2008). The report focused on three inter-related areas: technology and tools, regulation and reimbursement as follows:

- To develop a strategic, long-term plan coordinating public and private sector efforts for advancing research and development (R&D) relevant to PM
- To stimulate and facilitate modernisation of the regulatory process affecting PM. These processes would be transparent, systematic and iterative approaches utilised in the regulation of PM technologies and tools
- To achieve cost-containment objectives so that health care should not arbitrarily hinder the application of innovative PM products
- To establish a Department of Health and Human Services office to specifically coordinate activities related to PM.

In the 15 December 2008 issue of *Newsweek* the future of PM was illustrated in three areas: HIV, lung cancer and depression (Newsweek 2008). These areas will be described in more detail later in this chapter. In a recently published commentary in the *Journal of the American Medical Association*, the benefit of genomic medicine was demonstrated by reviewing its use in preventive medicine (Offit *et al.* 2006). With preimplantation genetics for cancer, the molecular diagnosis may be regarded as one of the assisted reproductive technologies. Embryos without a familial variation are chosen for implantation. Another example is in the treatment of lung cancer. *UGT1A1*28* homozygosity is associated with developing neutropenia, while slow partial response might be attributed to *GSTP1 1105 G/A* or *G/G* genotypes (Pillot *et al.* 2006). In another study the combination of five gene biomarkers (*DUSP6, MMD, STAT1, ER BB3, LCK)* was proposed as an independent predictor of relapse-free and overall survival (Chen *et al.* 2007). The accompanying editorial (Herbst, Lippman 2007) proposed four phases of applying molecular signatures of lung cancer, along with other biomarkers – proteomic and molecular imaging – in enabling PM for lung cancer, as shown in Figure 25.2. For example, phase 2 prospective studies should be performed to demonstrate improved benefit–risk ratios. This was also suggested by Eichelbaum *et al.* (2006).

Pharmacogenomic biomarkers and personalised medicine

> *If it were not for the great variability among individuals, medicine might as well be a science and not an art.* Sir William Osler 1892 (Roden *et al.* 2006).

Pharmacogenomic biomarkers, in combination with other well-accepted biomarkers such as therapeutic drug monitoring (TDM) and other functional testing, the emerging proteomic biomarkers and possibly molecular imaging, may be used to assess inter-individual variability, thus enabling PM. The combination of these biomarkers identifies the right patient, with the right diagnosis/treatment, matching with the right drug, the right dose and the right time, thus achieving clinical efficacy with little or no toxicity.

Although the terms 'pharmacogenomics' and 'pharmacogenetics' are used interchangeably in practice, pharmacogenetics is the study of the effects of individual genetic variations (e.g. single nucleotide polymorphism (SNP), gene duplications and deletions, and others) on drug therapy such as an individual's ability to metabolise a drug or compound, while pharmacogenomics is the study of the whole genome and its effect on drug metabolism, transport, receptor sensitivity, signalling pathways and target modulators, and the resultant effects on drug efficacy. This is shown in Figure 25.3 and further defined in the glossary at the end of this chapter (Roden *et al.* 2006).

In bringing about translational pharmacogenomics, various groups and networks in the USA and Europe have been organised to provide coordinated planning and developments. For example, an authoritative review article (Roden *et al.* 2006) outlined the various investigations of the Pharmacogenetics Research Network (PGRN, a group of researchers), including the mechanisms resulting in variable drug responses, the possible contribution of genetic factors, and the current and emerging approaches to identifying these genetic factors. A recent update of PGRN (Giacomini *et al.* 2007) described interest in correlating drug response with genetic variation for disorders including depression, cardiovascular disease, addiction to nicotine and cancer, and in studies involving drug protein transporters and phase II drug-metabolising enzymes. The report summarised recent developments in informatics, cardiovascular, pulmonary, addiction, cancer, transport and metabolism. Long (2007) reaffirmed that PGRN's ultimate goal was to identify clinically significant sequence variations for PM, and to implement the findings for health-care improvement.

Complementing these efforts, colleagues in pharmaceutical research and development areas also embraced the integration of chemistry and biology, recognising the important contributions to pharmacogenomics of drug metabolism enzymes as well as transporters (Yengi *et al.* 2007).

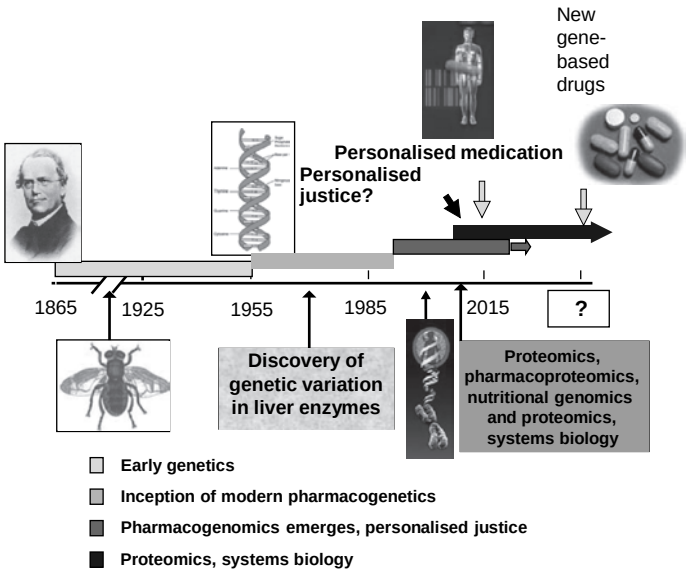

Figure 25.1 Landmarks in pharmacogenetics and proteomics according to Weber at 2002, modified by Wong in 2007 (Weber 2002; Wong 2007).

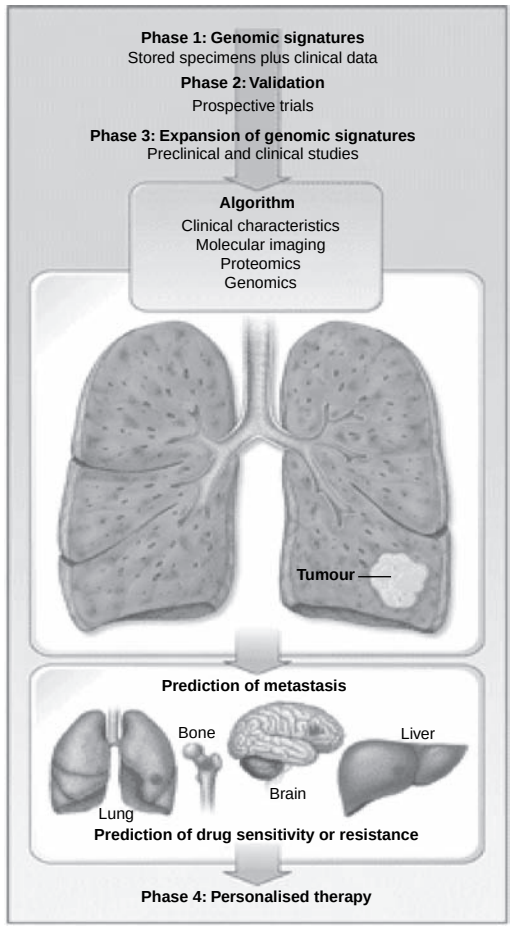

Figure 25.2 Development of personalised drug for lung cancer, from identification of genomic signatures (biomarkers) to prospective trials of personalised therapy (personalised medicine) (Herbst, Lippman 2007).

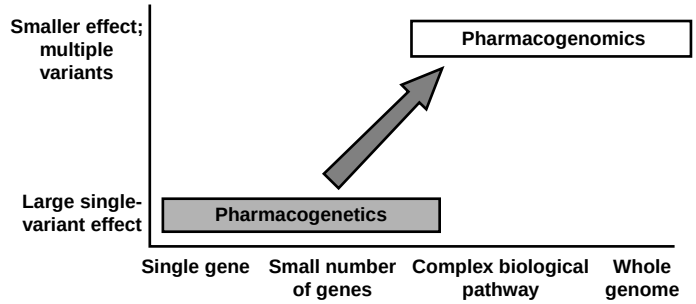

Figure 25.3 Pharmacogenetics and pharmacogenomics. (Roden *et al.* 2006).

Other efforts included the HapMap project (O'Shaughnessy 2006) and a proposed Genomic Prescribing System (GPS; Ratain 2007). The practice of PM (O'Shaughnessy 2006) would be enhanced by understanding the effect of genetic variations beyond pharmacokinetics to include pharmacodynamics – variations in receptors and their signalling molecules, enabled by data from the human genome sequence and the HapMap project. In achieving PM, Ratain proposed the concept of a GPS, which will result in a better outcome and lower drug cost (Ratain 2007). This might be achieved through lower genotyping cost, research and informatics. However, the market might be limited because the genotyping is needed only once in the lifetime of a patient, because there is a difficulty in patenting alleles, and because unanticipated regulatory requirements might become more rigorous in the future. Whether a new pharmacogenomics industry will develop is questionable. However, the public should support it, possibly through federally funded agencies. For example, when Barack Obama was still a senator he proposed the 'Genomics and Personalised Medicine Act of 2006', in support of the formation of a GPS foundation. Another perspective – The art and science of PM' (Piquette-Miller, Grant 2007) – traced the origin to a quote from Sir William Osler as shown at the beginning of this section. From this historical perspective, authors described the earlier development of pharmacogenetics of drug metabolism, followed by drug target polymorphisms. Further, the transitioning of pharmacogenetics to pharmacogenomics for effects of polygenic variations on pharmacokinetics and pharmacodynamics would enable targeted drug therapy for patient subgroups. The authors also included the following challenges: interpretation, regulatory compliance, testing cost and education of health-care professionals. However, error-free PM might not be achievable because of pharmacogenomic complexities and gene expression changes that are time dependent (Kalow 2006). Thus, PM would require the use of bioinformatics to interpret multiple gene modifiers (Davies 2006).

As a result, the Personalised Medicine Coalition (Abrahams *et al.* 2005) was founded as a non-profit umbrella organisation of pharmaceutical, biotechnology, diagnostic and information technology companies, health-care insurers/financers, patient advocacy groups, industry policy organisations, major academic institutions and government agencies. It defines PM as the delivery of individual medical care based on genomics and molecular profile and uses various strategies to achieve PM.

Translational pharmacogenetics and pharmacogenomics have been enabled by the availability of several Food and Drug Administration (FDA)-approved genotyping methodologies and platforms, their inclusions in scientific and clinical national and international meetings, and a recently introduced 2007 pharmacogenomic survey programme offered by the College of American Pathologists. All of these positive developments, however, should be interpreted with some probing questions of the available evidence-based studies to support clinical pharmacogenomic applications. The emerging reality is one of pharmacogenomics serving as an 'adjunct' to other testing and practice. The term 'convergence' is often mentioned in its use in combination with functional testing such as therapeutic drug management and, in the future,

pharmacoproteomics (Turck 2005) and pharmacometabonomics (Nebert, Vesell 2006) biomarkers.

Pharmacogenomics, forensic toxicology and personalised justice

In furthering the applications of genome, proteome and other molecular discovery and development, Wong proposed the definition of personalised justice as the inclusion of molecular analysis – genomic and proteomic – in criminal and forensic proceedings in the deliberation of possible genetic and proteomic contributions to adverse behaviour/outcome. This complements the current forensic applications such as DNA fingerprinting.

In the September 2008 Santorini conference, Wong proposed the complementary and balanced relationship of personalised medicine and personalised justice – both enabled by the understanding provided by molecular biomarkers such as pharmacogenomics (Wong *et al.* 2008). Whereas PM strikes to optimise drug therapy, personalised justice focuses on the application of molecular/pharmacogenomics biomarkers in legal proceedings such as driving and working under the influence of drugs. For example, pharmacogenomics (PGx) may be useful in explaining an elevated drug concentration in a driver involved in an accident, or in workers medicated for pain management and involved in an accident at work. The concept is depicted in Figure 25.4, showing the complementary nature and check-and-balance relationship.

Thus, this chapter characterises pharmacogenomics not only as an emerging, interdependent discipline but as a complementing field in optimising drug therapy and as an adjunct to forensic pathology/toxicology. Following this introduction, a section is devoted to the pharmacogenomics 'space' and the enabling drivers, including the FDA, professional organisations and academic centres. Then, the principles of pharmacogenetics/pharmacogenomics will be introduced, with an update on the candidate pharmacogenomics tests. References are provided for readers interested in the details of the clinical findings of the applications of pharmacogenomics and the technical details of pharmacogenomics protocol. In applying pharmacogenomics for purposes of forensic pathology/toxicology, a previously published algorithm emphasises the integral use of PGx with case history including drug use/abuse, scene investigation, and postmortem findings. Recent PGx opioids and antidepressants cases are included.

Historically, DNA fingerprinting – genetic policing – is the use of molecular diagnostics/genetic testing for identity testing in the forensic sciences. More recently, pharmacogenomics as molecular autopsy involves the assessment of genetic contributions to drug toxicity in postmortem forensic toxicology. Subsequent findings will add to the understanding of disease mechanisms of action and optimisation of drug therapy by lowering/eliminating drug toxicity due to genetically predisposed impaired drug metabolism. These findings may be 'back extrapolated' for the benefits of optimisation of 'live, antemortem' drug therapy. Thus, PGx in forensic toxicology would result in better interpretation, indirectly enabling the emerging personalised medicine. The chapter will conclude with the projected development of the application of pharmacogenomics biomarkers in personalised justice.

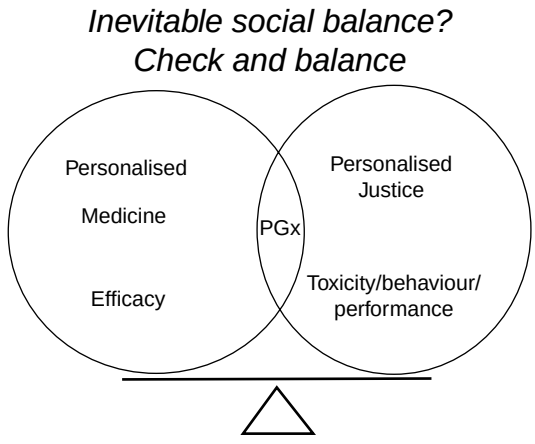

Figure 25.4 Complementary relationship of personalised medicine and personalised justice. PGx, pharmacogenomics.

Proactive roles of governmental agencies, pharmaceutical corporations, academic centres and professional organisations

> The FDA in the next century will be at the forefront of changes, just like you have been in the last century. FDA personnel will be playing a leading role in the transformation of the critical path to medical product development, finding better ways to rapidly develop and improve safety in the treatments that we all look forward to, treatments that are highly personalised, that will come at lower cost and with a greater degree of success. That transformation of the critical path will be a larger part of the transformation toward personalised medicine, one that will improve the health of this nation in ways that Roosevelt and Wiley could have never imagined. Michael O. Leavitt, Secretary of Health and Human Services. Remarks delivered at the FDA Centennial, 30 June 2006. (Available at www.hhs.gov/news/speech/2006/060630.html.)

In assessing the status of pharmacogenomics for drug discovery and development and clinical adaptation, a recent market analysis was completed by O'Dell and Doyle (2004). The market analysis was conducted by surveying 53 out of a 200-person contact database. These individuals were representatives from pharmaceutical and diagnostic companies, regulatory and clinical colleagues, and others. The market was small: $800 million in 2002 compared with the pharma market of $433 billion in 2003. Some of the key findings included the encouraging and engaging roles of the FDA, and the need for physician education. It concluded that PGx approached a 'tipping point' in 2003–04. With the recent development of several new FDA approvals of PGx testing/devices, PGx 'tipped' forward in the clinical PGx/PM space, in part owing to the proactive roles of the FDA in collaboration with other professional organisations for the past several years.

In 2005, Woodcock stressed the proactive roles of the FDA in bringing about the use of pharmacogenomics for PM (Woodcock 2005). She outlined the FDA outreach to pharma, National Institutes of Health (NIH) and scientific/academic communities through workshops and meetings. The FDA envisioned the increase of drug application with more PGx information. She predicted that the then-limited submission would be greatly increased by 2010.

In a state-of-the-art article about PM, Lesko concluded that the practice and reality of PM will emerge but was currently an eventual dream that has not yet been achieved in reality (Lesko 2007). The vision of the FDA for PM was addressed by Michael Leavitt, Secretary of Health and Human Services in June 2006, as shown at the beginning of this section. With recognition of the limitations of the traditional model of 'one size fits all' for dosing drugs with therapeutic index such as warfarin, the molecular and genetic biomarkers of the patients may be used to individualise therapy. PM examples included: targeted therapies – trastuzumab (Herceptin) for treatment of *HER2*-positive metastatic breast cancer, imatinib (Gleevec) for Philadelphia chromosome-positive (Ph+) chronic myeloid leukaemia, and erlotinib (Tarceva) for non-small-cell lung cancer – and targeted dosing – warfarin dosing guided by *CYP2C9* and *VKORC1* genotypes, and treatment of acute lymphoblastic leukaemia by thiopurine methyltransferase (*TPMT*) genotype. Five driving forces shaping the emergence of PM were:

- Availability of low-cost and point-of-care testing genotyping technologies
- Decrease in productivity and innovation in drug discovery
- The increasing use of genomics in drug development towards a 'mini-blockbuster model'

- The desire to increase drug safety
- Recent trends pointing to eminent practice of PM.

In addition, other health-care changes point to an evolving infrastructure for PM including clinician education and PM test interpretation, the emerging 'concierge' or 'boutique' medical practice, and electronic medical records. In enabling PM, pharmacologists will be key as they were in the practice of TDM in the 1980s and 1990s. The evidence for PM would be dependent on prospective, randomised controlled trials and prospective or retrospective observational studies and clinical end points. Dose–exposure–response relationship for dosing adjustment would be based on genotypes. Thus, pharmacometrics or quantitative clinical pharmacology would be used to develop the scientific basis and application of 'personalised medicine'.

Another recent study funded by the European Commission examined the status of pharmacogenetics and the challenges for applications (Hopkins *et al.* 2006). It reviewed the science and industry base in the USA, Europe and Japan. Pharmacogenomics is regarded as interdisciplinary in 60 research institutions. The countries with more than 10 institutions are as follows: USA 73, Germany 35, UK 27, Japan 25, the Netherlands 21, Sweden 14, Italy and Switzerland 13, and France 12. The US institutions are usually better funded by the NIH. European institutions received funding from national governments but not from the European Union. The major areas of research study are drug metabolism, disease mechanisms and disease predisposition. These institutions collaborated more with other research groups than with companies, with the possible outcome of limiting the clinical applications. The commercial sector comprised about 47 companies, mostly small to medium in size with a high turnover rate of about 40%. However, the influx of new companies seemed to have maintained the total number. The business model may be divided into 12 options under the areas: drug discovery, drug safety in development, drug efficacy in development, marketed drug safety, and stratification of diseases and infectious agents. The top five stratified areas are:

- CNS
- Drug metabolism/toxicity
- Cardiovascular disease
- Cancer
- Infection.

The FDA and the European Agency for the Evaluation of Medicinal Products (EMEA) are both proactive but they follow different paths. While the FDA provides guidance documents, EMEA conducts meetings with sponsors. The established clinical pharmacogenomics tests for the European countries would include *HER2* testing for breast cancer and *TPMT* for acute lymphoblastic leukaemia (ALL). The recent study concluded that many interdependent variables would contribute to clinical applications of pharmacogenomics.

The FDA has proactively outreached to scientific colleagues in pharmaceutical companies, partially for the purpose of developing a rational approval process. A series of workshops were held in the Washington DC area (Pharmacogenomics: 1st workshop May 2002, 2nd workshop November 2003 and 3rd workshop April 2005; Pharmacogenomic drug-diagnostic co-development workshop July 2004; Application and Validation of Genomic Markers October 2005). This was followed by the publication of guidance documents (First draft November 2003 and final draft March 2005), and white/concept papers (Critical Path Initiative March 2004, and Drug-diagnostic co-development April 2005; Salerno 2004; Salerno, Lesko 2004a, 2004b; www.fda.gov/downloads/Drugs/ScienceResearch/ResearchAreas/Pharmacogenetics/ucm085716.pdf 2005; Lesko *et al.* 2003; Lesko, Woodcock 2004; Leighton *et al.* 2004; Gualberto *et al.* 2004; Trepicchio *et al.* 2004, 2011; Wang 2011).

The topics included co-development of drug and diagnostics, sometimes regarded as 'theranostics', and the voluntary genomics data submission (VGDS) process. More recently, VGDS was modified to VXDS – voluntary 'X' data submission, with 'X' representing diagnostic proteomic and other 'omics' biomarkers in the future. In September 2006, the Center for Clinical Device and Radiological Health (FDA-CDRH) issued a draft of a guidance document, 'In Vitro Diagnostic Multivariate Index Assays', that addressed test systems and data processes, with implications for genetic testing. For practitioners of clinical pharmacogenomics, it will be important to follow the outcome of the final draft of this and other documents. Two recent chapters by the FDA-CDRH (Tezak, Hackett 2006) and FDA-Center for Drug Evaluation and Research (Goodsaid *et al.* 2006) provided guidance on the various regulatory issues related to use of PGx biomarkers. In summary, the FDA workshops, the guidance documents and publications of concept and white papers serve as enabling tools towards the practice of clinical pharmacogenomics.

As a result of the decreasing number of submissions, the Critical Path has been advocated by the FDA to facilitate the co-development of drugs along with genomic and proteomic diagnostic biomarkers (Feigal *et al.* 2006).

As an example and extension of that concept and practice, the Critical Path Institute (C-Path), founded by the University of Arizona as part of the Arizona Biosciences Roadmap in July 2005, is an independent, neutral, community-funded, non-profit/tax-exempt organisation. Other key members are SRI International and the FDA. Funding sources include public sector, foundation, the FDA and the Agency for Healthcare Research on Quality. It also has partnerships with universities such as George Washington University, and professional organisations such as the Drug Information Association, the American College of Clinical Pharmacology and others. It has a consortium of 13 pharmaceutical companies – Merck, Johnson & Johnson, Pfizer, Novartis, GlaxoSmithKline, Schering, Roche, AstraZeneca, Boehringer-Ingelheim, Amge, Sanofi-Aventis, Bristol-Myers Squibb and Abbott.

As shown by the model of collaboration in Figure 25.5, the C-Path Institute will share methods, data and strategies in order to ensure the safety of newly marketed drugs. Some of the projects enlisted a consortium of diagnostic and pharmaceutical companies to develop better treatments of lung cancer, to develop an approach for stroke treatment and to lower the incidence of death due to embolism via warfarin dosing therapy, all possibly by using PGx biomarkers. According to the article by Feigal *et al.* (2006), C-Path is currently undertaking 76 projects in 6 main categories:

- Better evaluation tools
- Streamlining clinical trials
- Harnessing bioinformatics
- Modernising manufacturing
- Developing products to address urgent public health needs
- Specific at-risk populations – paediatrics.

Another major factor in adapting clinical pharmacogenomics is the educational outreach to both patient and clinician. To that end, the International Society of Pharmacogenomics recently published a position paper recommending the education effort to the deans of schools of medicine, pharmacy and allied health care (Gurwitz *et al.* 2005). The following 10 recommendations are proposed:

- Encouragement of the deans to include the teaching of pharmacogenomics
- Global outreach to policy makers and government leaders to educate physicians, pharmacists and nurses

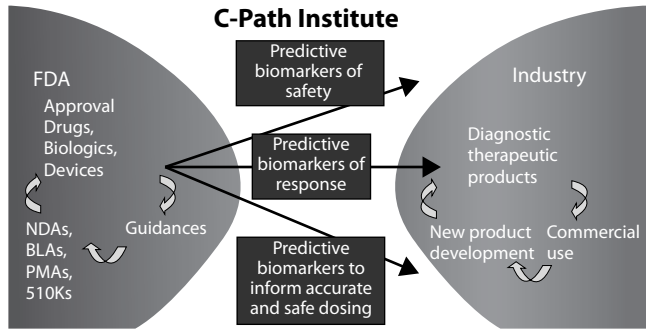

Figure 25.5 FDA–C-Path–industry collaboration to solve common roadblocks in medical product development (Feigel et al. 2006).

- Basic medical teaching to include 4–8 hours of lectures
- Graduate medical and pharmacy schools
- Continuing medical education
- Pharmacogenomics for oncology
- Pharmacogenomics update
- Pharmacogenomics-dedicated issues in journals
- Educational tools using web-based learning
- Better general education for outreach to patient and general public.

If these recommendations were adopted by the deans, they would pave the way to preparing graduating physicians for clinical pharmacogenomics. For example, a PM e-Symposium held on 21 June 2006 addressed the various issues (Personalized Medicine e-Symposium 2006).

The need for developing information for educating physicians and patients on the possible benefit of pharmacogenomics was demonstrated by a recent German study (Rogausch *et al*. 2006). Of the invited 328 patients and 378 general practitioners, 60% and 28%, respectively, consented to participate. There were 96% patients and 52% physicians who were also in favour of the availability of pharmacogenetic tests for a disease such as asthma. Patients worried about the results and privacy, while the physicians worried about putting the patient under pressure and the possible negative impact on obtaining health insurance. Another major educational effort in enhancing the practice is the Laboratory Medicine Practice Guidelines for Clinical Pharmacogenetics, prepared by the National Academy of Clinical Biochemistry (NACB) and the academy of the American Association for Clinical Chemistry (AACC; Nebert, Vesell 2006). The document was drafted with input from NACB and AACC members as well as selected colleagues from other professional societies and regulatory agencies both in the USA and in Europe. There are 10 sections: introduction, pharmacology and populations genetics, methodologies and quality assurance, services consideration, reporting, clinical considerations, TDM and PGx interface, and ancillary considerations – dose and forensic, regulatory and glossary.

Principles of pharmacogenetics/pharmacogenomics

The basic principles of pharmacogenetics and pharmacogenomics have been reviewed in depth (Linder *et al*. 1997; Weber 1997; Jicinio, Wong 2002; Evans, McLeod 2003; Weinshilboum 2003; White, Wong 2005; Wong *et al*. 2006a). Additionally, a more recently published primer provided a quick review of the central dogma of molecular biology, followed by descriptions on genetics, genomics and proteomics (Tsai, Tsao 2007). Other topics included structure, evolution, genetic variation such as SNP alleles, haplotype and linkage disequilibrium, enabling technologies (genomics, proteomics and bioinformatics), implications for gene discovery and mechanisms of human disease, therapeutic and predictive medicine, and dermatology and dermatopathology. Identifying gene clusters responsible for biological processes, the primer suggested that the individual genomic signatures would enable the practice of predictive medicine.

According to the central dogma, the genetic code is passed, through transcription, from DNA to mRNA, and subsequently, through translation, from mRNA to protein synthesis. These proteins may be drug-metabolising enzymes, transporters, receptors, target modulators and other biomolecules involved in signalling pathways. Thus, DNA genetic variations would change the enzyme activity, transporters and receptor sensitivity. The discovery of RNA interference and the emerging evidence for epigenetics have impacted on this simple relationship.

Genetic variations of drug-metabolising enzyme genes can result in normal, deficient or higher enzyme activities. Variations include SNPs, deletions, duplications and others. The polygenic determinants of drug response are illustrated in Figure 25.6 (Evans, McLeod 2003).

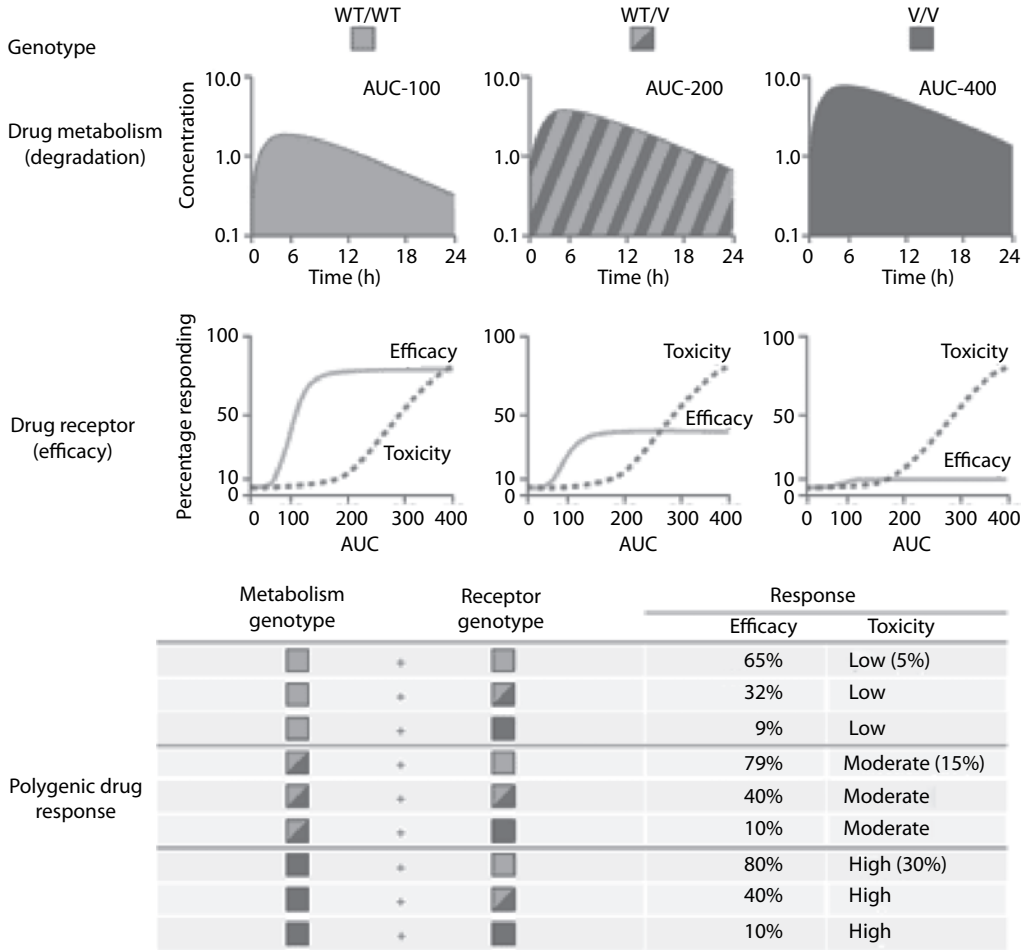

Figure 25.6 Polygenic determinants of drug response (Evans, McLeod 2003).

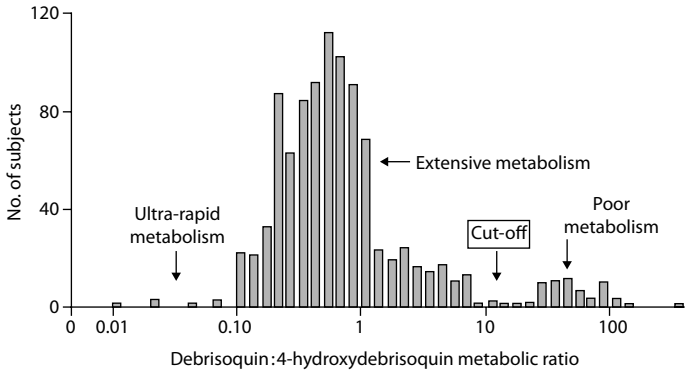

Figure 25.7 Pharmacogenetics of CYP2D6 (Bertillsson *et al.* 1992).

An individual with two wild-type alleles, an extensive metaboliser, when compared with an individual with two variant alleles, a poor metaboliser, has higher enzyme activity and consequently, a lower area under the curve (AUC) with minimal toxicity and adequate efficacy. The heterozygous individual in the middle with one variant allele, an intermediate metaboliser, achieves AUC, toxicity and efficacy intermediate between those of the extensive and poor metabolisers. The possible combination of nine metabolism and receptor genotypes would result in a therapeutic index ranging from 13 to 0.125. Further, individuals with multiple copies of the genes, not shown in Figure 25.6, correspond to ultra-rapid metabolisers. These individuals, with increased enzyme activities, often overmetabolise drugs, sometimes with adverse consequence such as the overconversion of codeine to morphine. Figure 25.7 shows the debrisoquine metabolic ratios of these four phenotypes (Bertillsson *et al.* 1992).

This relationship might be readily further conceptualised by a pharmacology triangle, proposed by Linder and Valdes (1999) (Figure 25.8). Pharmacogenetics provides the fundamental basis, the independent variable for the two interrelated, dependent variables – pharmacokinetics (drug metabolism) and pharmacodynamics (drug action).

Weinshilboum (2003) reviewed the pharmacogenetics of phase 1 drug-metabolising enzymes (including CYP2D6, -2C9, -2C19, dihydropyrimidine dehydrogenase and butyrylcholinesterase) and phase 2 enzymes (*N*-acetyltransferase 2, uridine diphosphate-glucuronosyltransferase 1A1, thiopurine *S*-methyltransferase and catechol *O*-methyltransferase). Weinshilboum and Wang (2006) asserted that, while pharmacogenomics studies are rapidly expanding to include entire signalling pathways, targets and whole genome expressions, it may also be characterised as translational for emerging clinical application and drugs. Evans and McLeod (2003) reviewed the influence of polymorphism of drug target genes on drug effect (angiotensin-converting enzyme, arachidonate 5-lipoxygenase, β_2-adrenergic receptor, bradykinin B_2 receptor, dopamine receptors, oestrogen receptor α, glycoprotein and serotonin transporter), and the effect of polymorphism in disease- or treatment-modifying genes (adducin, apolipoprotein E, HLA, cholesterol ester transfer protein, ion channels, methylguanine methyltransferase, parkin, prothrombin and factor V, and stromelysin-1). Wong and Jannetto (2006) supplemented the information in a recent book chapter.

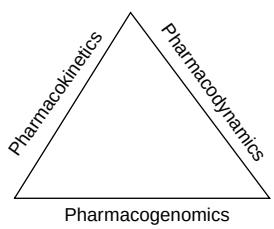

Figure 25.8 The pharmacology triangle (Linder and Valdes 1999).

Several recent reviews have addressed the current status in accounting for race, ethnicity, and ethical and social issues. Race was not an ideal proxy for PGx owing to genome variation, environment–gene interactions and definitions of 'race' in the USA (Jones, Perlis 2006). Another study asserted that race and ethnicity were social constructs reflecting culture, behaviour, diet, environment and socioeconomic status such as income, education and occupation, which cannot be measured by genetic variations (Doyle 2006). Combining the AmpliChip CYP450 prototype microarray assay and other assays, 222 African–Americans (healthy controls, $n = 131$, and psychiatric patients, $n = 91$) were genotyped. This revealed 3 poor metabolisers and 10 poor metabolisers, a new *CYP2D6* allele (*58) and two new duplicated *CYP2D6* alleles (*17xn and *2Lxn) (Cai *et al.* 2006). These latter variations would require dosage adjustment for African–Americans. In a Chinese population (Wang *et al.* 2006), *CYP2D6*10* was most prevalent, ranging from 51% to 70%. Of the 70 cancer patients recovering from gastrectomy, the numbers of patients without *CYP2D6*10*, heterozygous for *CYP2D6*10* and homozygous for *CYP2D6*10* were 17, 26 and 20, respectively. The last group required more tramadol in 48 hours, possibly explaining variable response to pain management to these three groups. A commentary was concerned with race being a complex genetic and non-genetic biomarker (Nguyen *et al.* 2007). In order to optimise pharmacogenetic therapy based on race, non-genetic biomarkers should be used in combination. A paper by Paul and Fangerau (2006) attempts to understand the specific, crucial ethical and social questions surrounding depression in order to assess patients' situations, disease entities and phenotypes, and how they relate to genetic variations.

In assessing the current situation of application of clinical pharmacogenomics, Roden *et al.* (2006) outlined the challenges as shown in Table 25.1.

The scarcity of pharmacogenomic information available from prescription drug package inserts was evident from a recent study (Zineh *et al.* 2006). Of the top 200 prescribed drugs in 2003, there was

Table 25.1 Challenges in pharmacogenomics (Roden 2006)

Challenge	*Potential approaches*
Establishing that drug responses are heritable	Twin studies; family studies
	Linkage between drug response and genomic loci in cell lines, or model organisms
Defining candidate genes	Pharmacokinetic
	Pharmacodynamic:
	Drug targets Biological milieu in which drugs act Disease genes and pathways
	Whole-genome approaches
Defining drug responses	Biomarkers
	Surrogates
	'Hard' end points
Data management, including uniform representation of phenotypical data	Improved informatics
	Centralised, web-accessible public database relating genetic variants and drug responses: www.PharmGKB.org
Reproducibility	Replication sets
	Large study populations
Statistical analysis of associations	New statistical methods, including consideration of haplotypes
Interrogating very large sets of polymorphisms in large numbers of patients	New platforms (e.g. chip or bead -based)
Moving to practice	Reproducible study results Cost-effectiveness Health-care provider education

Table 25.2 Updated top 12 pharmacogenomics tests[a]

Abbreviation	*Name and function*
1. *CYP2D6*	Cytochrome P450 (CYP) 2D6, phase I drug-metabolising enzyme
2. *TPMT*	Thiopurine *S*-methyltransferase, phase II drug-metabolising enzyme
3. *CYP2C9*	CYP2C9, phase I drug-metabolising enzyme
4. *CYP2C19*	CYP2C19, phase I drug-metabolising enzyme
5. *NAT*	*N*-Acetyltransferase, phase II drug-metabolising enzyme
6. *CYP3A5*	CYP3A5, phase I drug-metabolising enzyme
7. *UGT1A1*	Urindine diphosphate glucuronosyltransferase 1A1, phase II drug-metabolising enzyme
8. *MDR1*	Multidrug resistance (P-glycoprotein), drug protein transporter
9. *CYP2B6*	CYP2B6, phase I drug-metabolising enzyme
10. *MTHFR*	Methylenetetrahydrofolate (CH_2THF) reductase, converts CH_2THF to 5-methyltetrahydrofolate
11. *VKORC1*	Vitamin K epoxide reductase complex protein 1, mediates vitamin K reduction
12. *CYP4F2*	CYP4F2, phase I drug-metabolising enzyme

eQPCR LC	TrimGen	Yes[a]
PCR bead-based detection	TM Biosciences	Yes
dHPLC	Transgenomics	–
FISH	Abbott	Yes
MALDI-TOF	Applied Biosystems	–

Modified from Payne (2006).
[a]Warfarin.

discordance between pharmacogenetic package insert information. Pharmacogenetic data were available for 71%, with drug-metabolising enzyme genes accounting for 34.5% and drug targets and transporters for 65.5%. Package inserts for only three drugs among the top 200 – celecoxib, fluoxetine, pantoprazole – contained pharmacogenetic information for prescribing. The lack of pharmacogenetic information might be due to uncertainty about clinical relevance.

Pharmacogenomics tests and methodologies

Current clinical testing is primarily pharmacogenetics, i.e. SNPs, gene deletions, duplications and, to a much lesser extent, gene expression, which has been used in drug discovery, and screening of candidate genes. A 2005 AACC survey of the top 10 tests is now supplemented by three more tests: *VKORC1* (Reider *et al.* 2005) and *CYP4F2* as a result of recent studies for genotype-based warfarin dosing, and HLA (human leukocyte antigen gene) for drug sensitivity such as the development of Steven–Johnson syndrome in some Asians medicated with carbamazepine; see Table 25.2.

CYP and other phase 2 enzymes such as UGT1A1 account for the majority of drug/substrate metabolism for drugs approved in the USA, about 75% involving CYP3A4 and CYP2D6 enzymes. According to the draft of Laboratory Medicine Practice Guidelines by NACB (listed in the website: www.nacb.org/lmpg/LMPG_Pharmacogenetics.pdf), the proposed alleles to be initially included for clinical pharmacogenetics are: *CYP2D6 *1* to **12, *17* and **2A, 2C9 *1* to **6*, and *2C19 *1* to **8* and **17*. The final recommendations are pending. During the third FDA-DIA workshop, O'Kane presented an assessment of possible routine pharmacogenomics testing for medical care (O'Kane 2005). He summarised some of the barriers including the current findings of more than 160 alterations for *CYP2D6* genes. Assay problems include allelic drop-out, intra-allelic recombination, the need for specific assays not affected by pseudogenes *CYP2D7* and *CYP2D8*, and the need to address gene conversion of *CYP2D6* from *CYP2D7*. Caution was recommended that *CYP2D6* genotyping might not be purely routine. The top pharmacogenomic tests are readily performed either by 'home-brew' assay or by some commercially available, FDA-approved test/platform. Payne (2006) reviewed how to choose a method. Jannetto *et al.* (2006), Weber (2006) and other recent publications (e.g. Wong *et al.* 2006a) have also summarised the currently available technologies. Table 25.3 shows an updated list of the methodologies, companies and status of FDA approval/clearance. According to Payne, the methodologies might be readily classified as non-amplification (e.g. fluorescent *in-situ* hybridisation (FISH)), target and signal amplification methods including end-point polymerase chain reaction (PCR) detection, allele-specific primers, length analysis using restriction fragment length polymorphism (RFLP) and Oligonucleotide Ligation Assay (OLA), real-time PCR, signal amplifications, limited sequencing, and new methods including solid-phase 'low-density' microarrays and fluorescence-based bead assay (liquid microarray) and nanotechnology.

Some laboratories performing genotyping have adapted the PCR liquid-bead-based detection (personal communications). Platform and assay choices depend, similar to the selection of clinical chemistry analysers and tests, on the experience of the personnel, FDA approval, the ease of 'home-brew' assay development, and the cost of the instrument and reagents.

Several articles updated on the PGx testing methodologies. An example is the comparison of genotyping 159 samples from *CYP2D6* by Amplichip and *RFLP* (Heller *et al.* 2006), and Amplichip correctly identified gene duplications in 7 discordant samples. The authors concluded that it was a fast and efficient procedure. Using an electronic array by Toshiba, N-acetyltransferase2 *(NAT2)* gene polymorphisms (*C481T G590A G857A*) were determined for 38 samples and the results were in complete concordance with the RFLP results (Nakamura *et al.* 2007). The electrochemical DNA chip and the compact, automated DNA detection system offered fast turnaround time of about 90 minutes. An array-based allele-specific primer extension (AsPEX) was used to detect about 14 variations in 8 genes (*TPMT*, *NQO1*, *MTHFR*, *GSTP1*, *CYP1A1*, *CYP2D6*, *ABCB1* and *SLC19A1*) from 371 specimens of cord blood. In comparison with RFLP, concordance was 99% (Lu *et al.* 2007). Using oligonucleotide ligation/PCR and capillary electrophoresis, the SNPlex Genotyping System detected 48 SNPs simultaneously (Tobler *et al.* 2005). By analysing 521 SNPs in 92 individuals, 99.84% concordance was achieved in comparison to the TaqMan probe-based assays.

Clinical applications

Wong *et al.* (2006a) classified the clinical applications of pharmacogenomics according to drug group, specialties and diseases, including opioids, pain management, nicotine addiction, HIV treatment, immunosuppressants, TPMT for ALL, psychiatry, and clinical and forensic toxicology. A previous publication by Jicinio and Wong (2002) offered extensive basic and clinical information for pharmacogenomics. Readers are directed to these references for further details.

Several reviews are recommended for inter-related developments in pharmacogenomics. In addition to reviewing the uses of predictive genotype *UGT1A1*28*, haplotypes such as *VKORC1* haplotype A, and somatic mutations such as epidermal growth factor receptor, it also demonstrated a genotype-guided thymidylate synthetase (TYMS) TSER in the treatment of rectal cancer (Marsh, McLeod 2006). An extensive review of CYP pharmacogenetics in drug metabolism emphasised that prospective studies should be performed prior to adapting genotype-based dosing (Kirchheiner, Seeringer 2007). Polymorphisms of the neurotransmitter transporters (Kirchheiner *et al.* 2006) serotonin, noradrenaline (norepinephrine), dopamine and P-glycoprotein showed limited effect on selective serotonin reuptake inhibitor (SSRI) response, suggesting that transporter genotypes are not yet proven to be contributory to predictive therapy. However, a later review article (Roots *et al.* 2007) demonstrated that there was evidence to support the use of genotype-based dosing for drug transporters such as P-glycoprotein (ABCB1) and OATP-C (SLC21A6), and other CYP enzyme genes. Table 25.4 shows important and emerging areas including AIDS, cancer, cardiovascular disorders, infectious diseases, haematology and psychiatry (Roden *et al.* 2006).

In complementing pharmacogenomics, TDM and toxicology play a pivotal role as global phenotypic indexes in contributing pharmacokinetic, pharmacodynamic and drug–drug interactions, epigenetics and other environmental factors. As such, pharmacogenomic biomarkers serve as adjuncts to enable the practice of PM. The following recent examples are summarised: warfarin therapy, the treatment of colorectal cancer by irinotecan, the use of carboplatin and irinotecan for non-small-cell lung cancer, alcoholism, psychiatric disorders and opiates.

Warfarin

Warfarin, an antithrombotic agent, has a narrow therapeutic index and large interindividual variation. Recent publications proposed a new dosing regimen based on pharmacogenetics of genes of *CYP2C9* and vitamin K epoxide reductase complex protein 1 *(VKORC1;* Higashi *et al.* 2002; Rieder *et al.* 2005; Sconce *et al.* 2005). Warfarin is racemic, with the active enantiomer, (*S*)-warfarin metabolised by CYP2C9. Variants *CYP2C9*2* and **3* correspond to decreased enzyme activities. For white people, the prevalence of extensive, intermediate, poor and ultra-rapid metabolisers are 58%, 38%, 4% and 4–18% respectively. *CYP2C9* genotype accounts for 6–10% of warfarin dosing variability (Higashi *et al.* 2002; Sconce *et al.* 2005). VKORC1 mediates the reduction of vitamin K, and its genetic variations account for 25% of warfarin dose variability. Mean doses for *VKCORC1 A/A*, *A/B*, and *B/B* genotypes are 2.7, 4.8 and 6.1 mg/day (Nguyen *et al.* 2007). The additional contribution from *CYP2C9* and non-genetic factors accounts for up to 60% of warfarin variability (Marsh, McLeod 2006). A dosage adjustment model is proposed along with INR measurement with dosage reduction to 33% for *CYP 2C9*3/*3* genotype. Recently, Caldwell and colleagues showed that CYP4F2 variations contributed about 5% of the warfarin dosing requirement (Caldwell *et al.* 2008). Increased warfarin dosing is needed on the basis of *CYP4F2* genotyping (TT > CT > CC), with an increase of 1 mg/day for TT homozygotes. Cole recently reported on warfarin resistance due to *VKORC1*5* haplotype, which includes g.−1320G>A, g.−679A>G and a missense SNP, p.Asp36Tyr (Cole 2008). This haplotype is <5% for Europeans, but higher in Ashkenazi Jews and eastern Mediterranean populations. Other resistance genotypes might be identified in the future.

Colorectal cancer

The latest example in the use of pharmacogenomics for cancer is the FDA-approved test for uridine diphosphate-glucuronosyltransferase 1A1 (Third Wave Technologies) for stratifying patients undergoing colorectal cancer treatment with irinotecan. UGT1A1 mediates the conjugation of irinotecan active metabolite, SN-38, to a glucuronide metabolite (Araki *et al.* 1993; Rivory *et al.* 1996; Iyer *et al.* 1999, 2002). Individuals homozygous for the *UGT1A1*28* allele would have reduced enzyme activity, and therefore require a lower dose.

Table 25.4 Examples of associations between drug response and genetic variants (Roden *et al.* 2006)

Drug	*Variable clinical effect*	*Genes with associated variants*	*Possible mechanism*
Azathioprine and mercaptopurine	Bone marrow aplasia	*TPMT*	Hypofunctional alles
	Reduced therapeutic effect at standard doses		Wild-type alleles
Some antidepressants and β-blockers	Increased side-effect risk	*CYP2D6*	Hypofunctional alleles
	Decreased efficacy		Gene duplication
Omeprazole	*Helicobacter pylori* cure rate	*CYP2C19*	Hypofunctional alleles
Irinotecan	Neutropenia	*UGT1A1*	Decreased excretion due to regulatory polymorphism
HIV protease inhibitors	Central nervous system levels	*MDR1*	Altered P-glycorotein function
β-Blockers	Blood pressure lowering and heart rate slowing	*ADRB1*	Altered receptor function or number
Diuretics	Blood pressure lowering	*ADD1*	Altered cytoskeletal function by adducin variants
Warfarin	Anticoagulation	*VKOrC1*	Variant haplotypes in regulatory regions leading to variable expression
		CYP2C9	Coding region variants causing reduced (*S*)-warfarin clearance
Abacavir	Immunological reactions	*HLA* variants	Altered immunological responses
QT-prolonging antiarrhythmics	Drug-induced arrhythmia	Ion-channel genes	Exposure of subclinical reduction in repolarising currents by drugs
General anaesthetics	Malignant hyperthermia	*RYR1*	Anaesthetic-induced increased release of sacroplasmic reticulum calcium by mutant channels
Inhaled steroids	Bronchodilatation	*CHCR1*	Unkown
HMG-CoA reductase inhibitors (statins)	Low-density lipoprotein	*HMGCR*	Altered HMG-CoA reductase activity

Non-small-cell lung cancer

In a phase II study (Pillot *et al*. 2006) of patients with non-small-cell lung cancer treated with carboplatin and irinotecan, pharmacogenomic analysis included *ABCB1, CYP3A4*1B, ERCC2, GSTP1, UGT1A1*28* and *XRCC1*. Common haematological toxicities included neutropenia and thrombocytopenia. Grade 4 neutropenia was more prevalent among patients who were homozygous *UGT1A1*28 (7/7)* than among *6/6* or *6/7* genotypes. Patients with *GSTP1 I105V G/A* or *G/G* genotypes achieved partial response compared with no response for *A/A* genotype. It was concluded that future studies should include pharmacogenomics analysis as possible biomarkers for response and toxicity.

Alcohol

A recent review on alcoholism (Enoch 2003), a complex psychiatric disorder with high heritability (50–60%) showed the lifetime prevalence of alcohol dependence to be 20% in men and 8% in women in the USA. Type 1 alcoholism is characterised by later onset with feelings of anxiety, guilt and high harm avoidance, while type 2 alcoholism is associated with early age of onset (usually in men), impulsive and antisocial behaviour, and low levels of brain serotonin (Enoch 2003). Genetic variations of alcohol-metabolising genes might affect drinking behaviour owing to the accumulation of acetaldehyde. The unpleasant 'flushing' sensation might result in decreased alcohol consumption. Thus, therapeutic targets may include genes of neurotransmitter 'reward pathways' (serotonin, dopamine, GABA, glutamate and β-endorphin) and the behavioural stress response system (corticotrophin-releasing factor and neuropeptide Y). Furthermore, the type 1/2 systems enhance the understanding of the pharmacogenomic response to the current pharmacotherapy. Alcohol inheritability is attributable to genetic variations of alcohol dehydrogenase 1B and aldehyde dehydrogenase 2 (Oroszi, Goldman 2004). COMT Val158Met mutation affects executive cognitive function, stress/anxiety response and opioid function. Opioid receptor micro1 (OPRM1) Asn40Asp, a gatekeeper molecule affecting naltrexone, and HTTLPR, possibly affecting serotonin transporter function, stress response and anxiety/dysphoria, are contributory to initial vulnerability, addiction and relapse.

Psychiatric disorders

In reviewing the current psychiatric practice of using polypsychopharmacology for the treatment of depression, psychosis, anxiety and mood disorders, Preskorn (2006) indicated that the scientific literature had provided clinicians with more on patient safety than on efficacy. With the advent of pharmacogenomics and bioinformatics, this will change as the pathophysiology of these illnesses becomes more established. A review (Black *et al*. 2007) of phase 1 antidepressant-metabolising enzyme genes focused on the CYP superfamily polymorphism and the impact on antidepressant metabolism, antidepressant substrates, inhibitors and inducers, and others. Prathikanti and Weinberger (2005) reviewed the literature and noted that schizophrenia-associated genes included *NRG-1*, *DISC1*, *RGS4*, *COMT*, *PRODH*, *DTNBP1*, *G72*, *DAAO* and *GRM3*, while *5-HTTLPR* and *BDNF* are associated with affective disorders. Along with advances in pharmacogenomics, these developments will enable PM. Murray (2006) reviewed the impact of CYP pharmacogenomics and drug–drug interaction for antipsychotic therapy. Besides CYP2D6, CYP1A2 and CYP3A4 also mediate antipsychotic metabolism as shown in Table 25.5. Since CYP1A2 is inducible, individuals with *CYP1A2* variants and some SNP combinations (haplotypes) in the 5′-regulatory regions may demonstrate variable responses. The author cautioned that, in addition to genotyping of CYP, phenotyping may complement and may be complicated by drug–drug interactions.

A report by Yu *et al*. (2006) examined the relationship between serotonin receptor polymorphisms and fluoxetine treatment. Desensitisation of somatodendritic 5-hydroxytryptamine 1A (HTR1A) autoreceptors was implicated in the SSRI response. Variation of HTR1A Gly272Asp and linkage disequilibrium between C-1019G were analysed in 222 Chinese major depressive patients treated with fluoxetine. These two variations showed strong linkage disequilibrium. Response to fluoxetine was established for the HTR1A haplotype of the two polymorphisms. Female patients with − 1019C/C genotype had a better response than – 1019G carriers. Provisional recommendations (de Leon *et al*. 2006) were drafted for identifying and treating CYP2D6 poor metabolisers with tricyclic antidepressants (TCAs), venlafaxine, typical antipsychotics and risperidone; CYP2C19 poor metabolisers with TCAs and perhaps citalopram, escitalopram and sertraline; and CYP2D6 ultra-rapid metabolisers. For patients taking "new" drugs – aripiprazole, duloxetine and atomoxetine – the efficacy of genotyping *CYP2D* was pending. Another review (Kirchheiner 2001) developed recommendations for dosing 14 antidepressants based on either *CYP2D6* or *2C19* genotype or phenotype. A dose reduction of about 50% of tricyclic antidepressants was recommended for poor metabolisers of these two enzymes. A review on pharmacogenetics for antipsychotics (Bondy, Spellmann 2007) again confirmed the emerging importance of CYP polymorphism, the pending response prediction by candidate genes, and the possible link between genes of the serotoninergic system and weight gain. With the rapid development of pharmacogenomics, the authors concluded that new and cost-effective assays and research findings will advance the understanding and treatment of schizophrenia. Since CYP2D6 is often involved in antipsychotic metabolism, Dorado *et al.* (2006) reviewed and summarised the impact of physiological and environmental factors on CYP2D6 hydroxylation, CYP2D6 inhibition, the use of metabolite ratio (MR) for evaluating CYP2D6 hydroxylation, and the influence of CYP2D6 on drug levels and QTc interval elongation.

Table 25.5 Cytochrome P450s (CYPs) with major roles in the *in-vivo* clearance of antipsychotic agents (Marsh, McLeod 2006)

CYP	*Antipsychotic drug*	*Altered drug substrates and inhibitors that may be used in psychotic patients*	*Inducers*	*Numbers of allelic variants*
1A2	Clozapine	Omeprazole	Omeprazole	24 plus wild-type (also 9 predicted haloptypes)
	Olanzapine		Cigarette smoke	
			Barbecued meats	
2D6	Risperidone	Dextromethorphan	None	94 plus wild-type
	Chlorpromazine	Codeine		
	Thioridazine	Imipramine		
		Nortriptyline		
		Paroxetine		
3A4	Ziprasidone	Erythromycin	Rifampicin	38 plus wild-type
	Quetiapine	Diltiazem	Carbamazepine	
	Aripiprazole	Ciclosporin	Phenytoin	
	Haloperidol	Ethinylestradiol	Dexamethasone	

Olanzapine therapy and P-glycoprotein (PGP) polymorphisms were investigated in 41 schizophrenia patients (Lin *et al*. 2006). The rationale of the study was based on the effect of three common PGP polymorphisms – C1236T, G2677TA and C3435T – which result in a decrease in olanzapine transport out of the CNS. 3435T allele carriers demonstrated possible effects on the penetration of olanzapine into the CNS, as shown by olanzapine plasma levels, and by the positive symptom reduction. Baumann *et al*. (2006) gave a case report of a 14-year-old girl treated for obsessive–compulsive disorder who suffered a generalised tonic–clonic seizure after daily doses of 200 mg/day of sertraline, 10 mg/day of olanzapine and lorazepam (0.5–1.5 mg/day). On day 65, sertraline and olanzapine plasma concentrations were 352 μg/L and 20 μg/L respectively (recommended range, 20–80 μg/L). Since CYP2C9, CYP2B6, CYP2C19, CYP2D6 and CYP3A4 contribute to the *N*-demethylation of sertraline, the patient was genotyped and phenotyped, showing genetic deficiency of *CYP2D6* (**4/*4*) and *CYP3A5 (*3/*3)*, and homozygosity for the allele **6* of *CYP2B6*. The authors concluded that her rare pharmacogenetic profile and the co-medication with olanzapine could have contributed to the epileptic seizure.

Opioids

A review on pharmacogenomics and addiction to opiates (Lichtermann *et al*. 2000) summarised association studies of 11 candidate genes – both pharmacokinetics (CYP2D6) and pharmacodynamics (transporters and receptors) as shown by Table 25.6. While findings of animal studies with opioid, cannabinoid or dopamine receptor-disrupted genes were not confirmed in humans, whole-genome expression in animals will be used with more success in the future.

Table 25.6 Association studies of 11 candidate genes in probands with opiate dependence (Lichtermann *et al*. 2000)

Protein	*Gene symbol*	*Cytogenetic location*	*Number of cases*	*Number of control subjects*	*Results*
Cytochrome P450 subfamily II	*CYP2D6*	22q13.1	83 (oral opiate)	276	Protective effects of homozygote deletion
			93 (multi-drug)		(no poor metabolisers in 83 opiate abusers)
					[$P = 0.05$, OR = 7.2 (95% CI, 0.4–124.1)]
Dopamine receptor D_2	*DRD2*	11q23	232 (poly-substance)	56	Alleles B1 and A1 ∧ in cases ($P < 0.01$, $P < 0.05$)
			40 (opiate preferring)	119	No association
			465 (heroin addicts)	298	141 D17 Ins/Del (insertion/deletion polymorphism) associated in nasal inhalers ($P = 0.006$)
Dopamine receptor D_3	*DRD3*	3q13.3	54 (opiate addicts)	70	Ser9Gly homoz.∧ in sensation seekers ($P = 0.034$)
			193 (heroin addicts)	134	No association with Srin9Glycin polymorphism
			121 (heroin addicts)	180	No association with Srin9Glycin polymorphism
Dopamine receptor D_4	*DRD4*	11p15.5	141 (heroin addicts)	110	Allele 7 ∧ [$P = 0.001$,RR 2.5(95% CI, 1.4–4.4)]
			121 (heroin addicts)	154	Long allele ∧ [$P = 0.02$, OR 2.3(95% CI, 1.1–4.9)]
			55 (opiate dependent)	144	No association with four coding polymorphisms
			285 (heroin addicts)	197	No association (allele 7, $P = 0.19$)
			111 parent–offspring trios		Transmission/disequilibrium test (TDT), $P = 0.74$
Solute carrier family 6, member 3	*SLC6A3*	5p14.3	32 (opiate preferring)	38	No association with 40 base-pair variation in the number of tandem repeats polymorphism the in 3′-untranslated region
Dopamine transporter	*DAT1*				
Solute carrier family 6, member 4	*SLC6A4*	17q11.1-q12	63 (heroin addicts)	72	Allele 10∧ [$P = 0.005$, OR = 3.5(95% CI, 1.4–8.6)]
5-Hydroxytryptamine transporter	*5-HTT*		186 (heroin addicts	217	No association with promoter variant ($P > 0.1$)
5-Hydroxytryptamine receptor 2A	*HTR2A*	13q14-q21	121 (heroin addicts)	180	No association with A-1438G and T102C single nucleotide polymorphisms
γ-Aminobutyric acid receptor γ-2	*GABRG2*	5q31.1-q33.1	121 (heroin addicts)	180	No association with G3145A single nucleotide polymorphism
Cannabinoid receptor 1	*CNR1*	6q14-q15	29 (opiate users)	114	No association with AAT triplet repeat
Opioid receptor μ-1	*OPRM1*	6q24-q25	113 (heroin addicts)	39	No association with C17T ($P = 0.054$) or A118G ($P = 0.16$; except in Hispanics, $P = 0.004$)
Opioid receptor δ-1	*OPRD1*	1p36.1-p34.3	103 (heroin addicts)	115	T921C:CC homoz ∧[RR 4.4 (95%, 1.8–10.8)]
			233 (heroin addicts)	173	T921C: no association ($P = 0.30$)
			90 parent–offspring trios		Transmission/disequilibrium test (TDT), $P = 0.68$

Opioid pharmacogenomics was reviewed by Somogyi *et al.* (2007), showing that codeine and other opioids are metabolised by CYP2D6, with poor metabolisers experiencing reduced antinociception. Since P-glycoprotein is an opioid transporter, the influence of the *ABCB1* genotypes on opioid pharmacodynamics and dosage requirements was highly variable. SNPs of the μ-opioid receptor gene were correlated with increasing morphine sensitivity.

Since codeine is metabolised by CYP2D6 to morphine (Kirchheiner *et al.* 2007), ultra-rapid metabolisers may suffer exaggerated and toxic opioidergic effects. A study compared the pharmacokinetics of 11 ultra-rapid, 10 extensive and 3 poor metabolisers, and the results showed that there was a significantly higher morphine area under the curve and higher frequency of sedation for ultra-rapid metabolisers than for extensive metabolisers. The authors suggested that genotyping ultra-rapid metabolisers would be helpful for codeine dosing. In a case report (Gasche *et al.* 2004) an ultra-rapid CYP2D6 metaboliser developed life-threatening opioid-morphine toxicity following the ingestion of a therapeutic dose of codeine. The toxic morphine concentration was partially attributed to the ultra-rapid metaboliser genotype, drug–drug interaction and metabolite accumulation due to acute renal failure as shown in Figure 25.9.

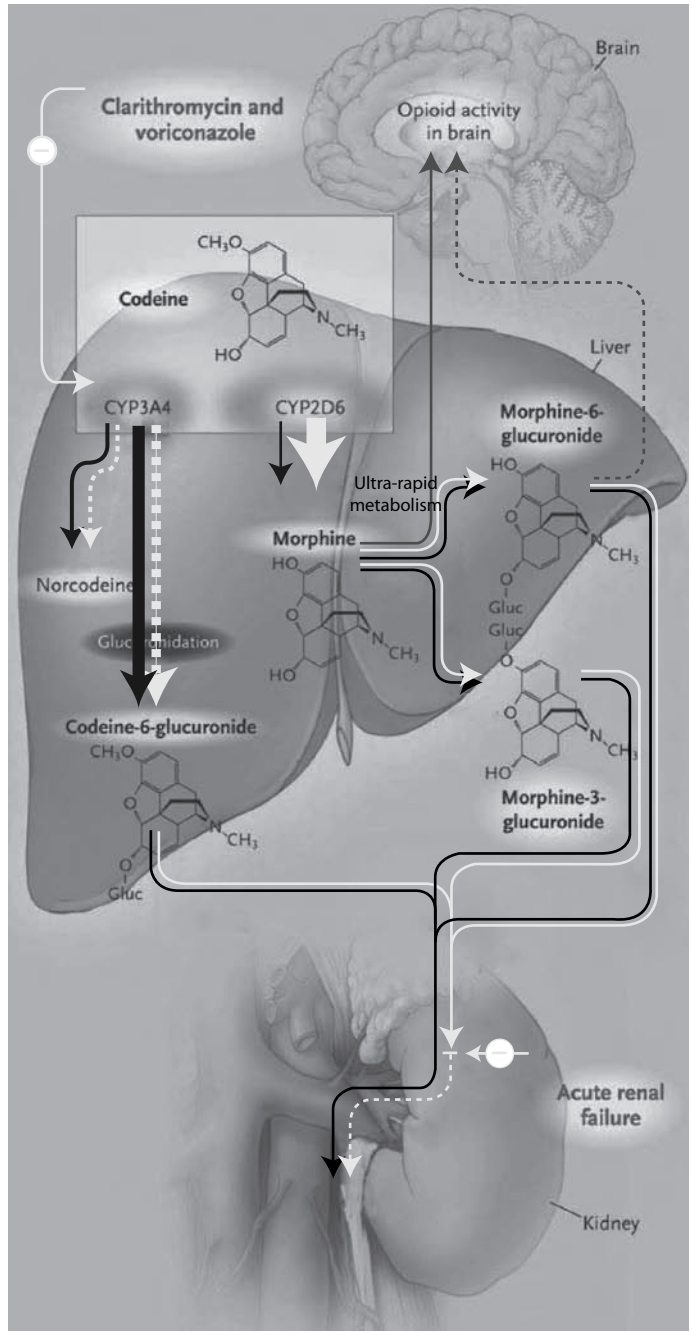

Figure 25.9 Metabolic pathways of codeine biotransformation. The conversion of codeine into norcodeine by CYP3A4 and into codeine-6-glucuronide by glucuronidation usually represents 80% of codeine clearance, and conversion of codeine into morphine by CYP2D6 represents only 10% of codeine clearance (black arrows). Morphine is further metabolised into morphine-6-glucuronide and into morphine-3-glucuronide. Morphine and morphine-6-glucuronide have opioid activity (grey arrows). Glucuronides are eliminated by the kidney and are thus susceptible to accumulation in cases of acute renal failure. The patient (white arrows) had ultra-rapid CYP2D6 metabolism, inhibition of CYP3A4 as a result of treatment with clarithromycin and voriconazole, and glucuronide accumulation due to acute renal failure. White arrows with dotted lines indicate low levels of drug conversion or elimination, grey arrows with dotted lines indicate low levels of brain penetration and thick arrows indicate high levels (Gasche *et al.* 2004).

Forensic applications

The application of pharmacogenomics to postmortem forensic toxicology was initially demonstrated by Druid, Holmgren, Carlsson and Ahlner in a 1999 Swedish study (Druid *et al.* 1999), followed by other studies from Finland and the USA. The experiences and observations were summarised in three chapters of a book on pharmacogenomics (Holmgren, Ahlner 2006; Sanjantila *et al.* 2006; Wong *et al.* 2006b). Collectively, these publications emphasised pharmacogenomics as an adjunct to forensic pathology, complementing information including postmortem findings, case history including medication and scene investigation. The molecular autopsy is proposed as an adjunct, similar to the use of molecular analysis of *SCN5A* variant as a contributing factor to sudden infant death syndrome (Ackerman *et al.* 2001).

The selective application of pharmacogenomics as contributing to the molecular autopsy is demonstrated in Figure 25.10, the proposed Milwaukee pharmacogenomic algorithm for forensic toxicology.

Case selection is initiated during the forensic pathology review (Jannetto *et al.* 2002). The algorithm assesses various co-variables such as acute or chronic toxicity, postmortem findings, sample collection sites, postmortem intervals, co-administered drugs, case/medical/medication histories, scene investigations and possible intent. As the case review continues with developing toxicological findings, prime selection criteria include elevated drug concentrations and identification of known and 'unknown' and potentially interacting drugs/metabolites. The postmortem intervals that possibly result in changes in drug concentrations are also considered in case selection and in interpretation. For the selected cases, whole blood samples are then transferred, with chain of custody, for pharmacogenomics testing by the molecular and pharmacogenomics laboratory. Using pyrosequencing, genotyping included *CYP2D6*2-*8*, *CYP2C9*2*3*, *CYP2C19*2-*4*, *CYP3A4*1B* and *CYP3A5*3*. The forensic applications are illustrated by three opioid cases from recent publications: methadone and antidepressants, oxycodone and fentanyl.

Methadone and antidepressants

The decedent was a 41-year-old woman 6 months into her pregnancy (Wong *et al.* (2003), and this is also case 1 in Wong (2009)). She had a heart murmur and rheumatoid arthritis treated with methadone. In addition, amitriptyline was prescribed for her depression. She celebrated New Years' Eve with her husband. On the following morning, she was found dead in her living room. Scene investigation revealed her ingestion of 9×50-mg tablets of amitriptyline within 17 days, and $2–3 \times 95$-mg doses of methadone. Several years previously, she had attempted suicide by drug ingestion. Toxicological analysis of iliac blood showed the following drug concentrations in mg/L: methadone, 0.7; amitriptyline, 1.5; nortriptyline, 2.2; diazepam, 0.19; *N*-desmethyl diazepam, 0.13. No alcohol was detected. The elevated antidepressant concentrations of iliac, peripheral blood would not be due to postmortem drug redistribution and are more likely attributable to acute drug ingestion. Molecular autopsy by pharmacogenomics showed that she was

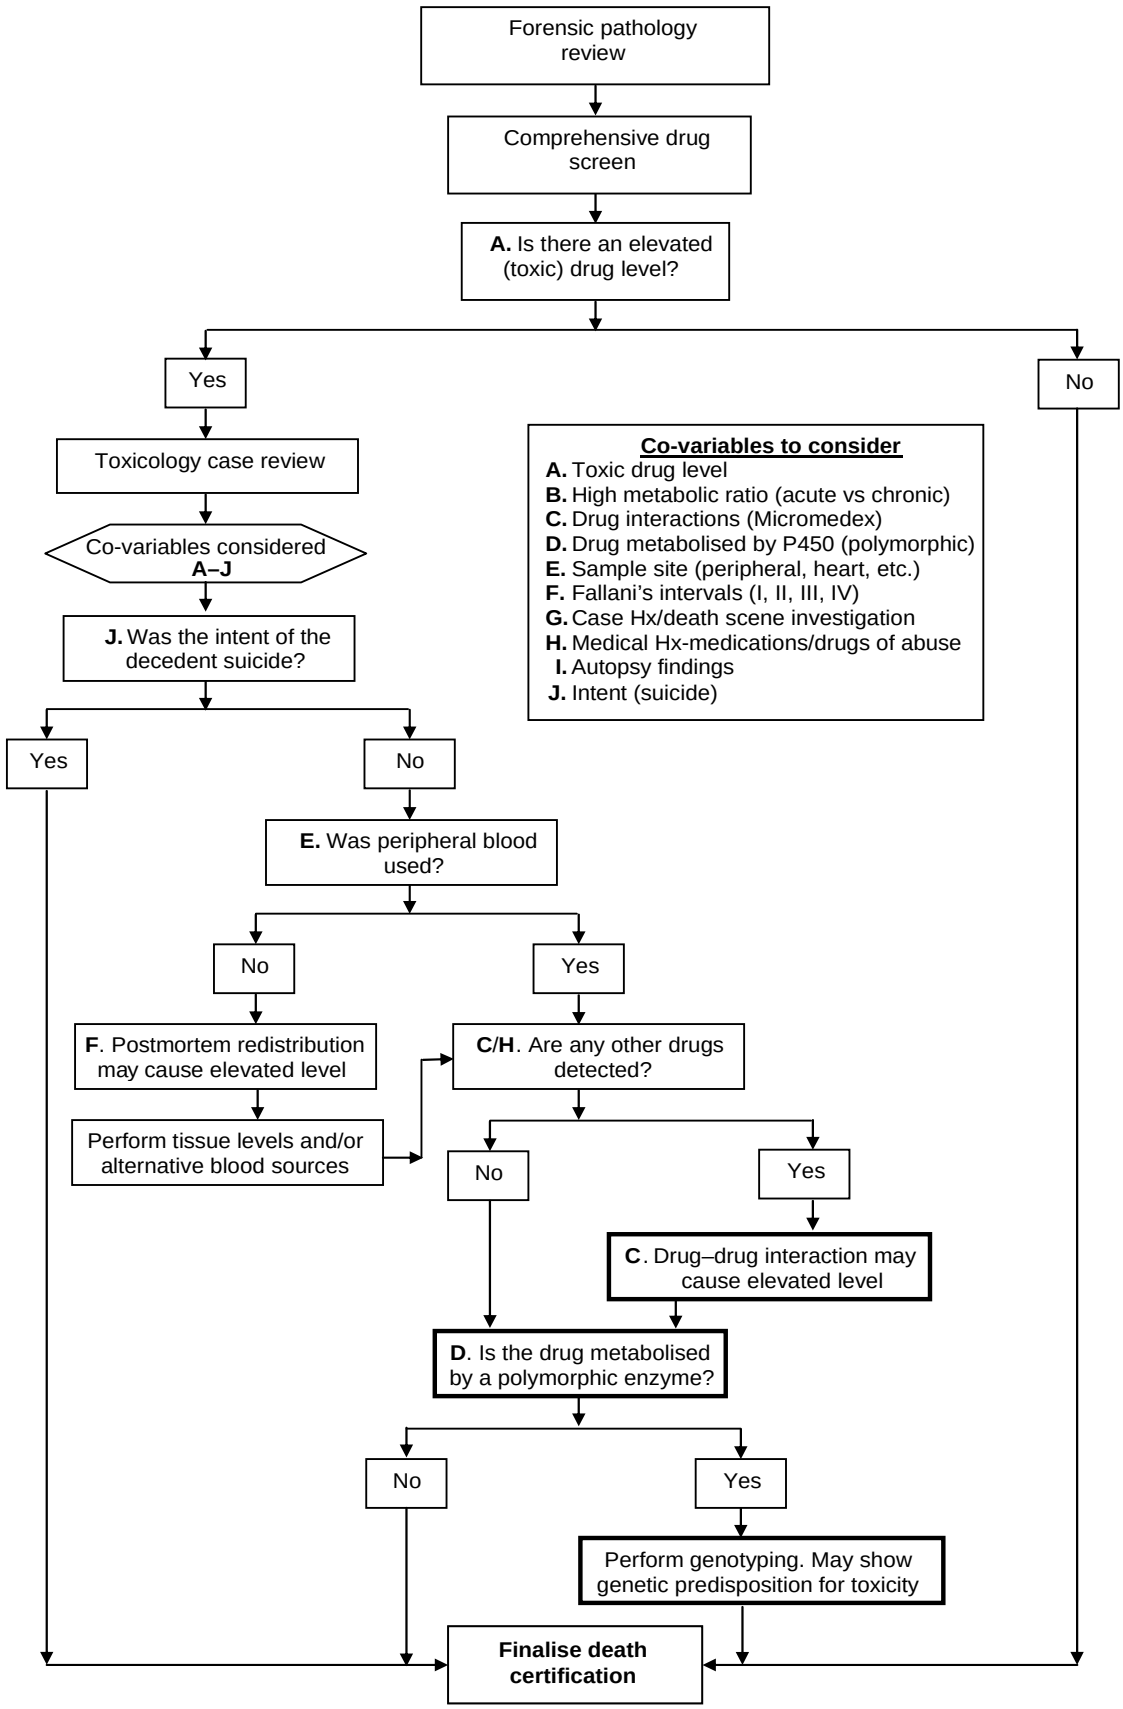

Figure 25.10 A proposed pharmacogenomics algorithm (Jannetto *et al.* 2002).

homozygous for *CYP2D6*4,* corresponding to the poor metaboliser phenotype. This would result in the lack of hydroxylation of methadone, amitriptyline and nortriptyline, thus resulting in elevated parent drug concentrations. Death certification was: cause of death, mixed drug toxicity; manner of death, accident.

The use of pharmacogenomics was shown in a doxepin fatality possibly due to *CYP2D6* variations with resultant poor metaboliser phenotype (Koshi *et al.* 2007). In 2002, a 43-year-old Finnish man was found dead at home. His health record showed that he had recently been involved in an accidental fall, suffered from alcohol withdrawal and demonstrated suicidal tendencies. His medications included disulfiram, fluoxetine, diazepam, and drugs of abuse – hashish and heroin. He had also recently been anxious and aggressive. Postmortem findings showed numerous bruises and abrasions, anthracosis, left-sided bronchopneumonia in the lungs and stasis in the spleen, and haematoma in the internal scalp, possibly due to the fall. Toxicology showed femoral venous blood concentrations of doxepin, 2.4 mg/L (therapeutic range: 0.0–0.15 mg/L) and nordoxepin, 2.9 mg/L. These were the highest when compared with the Finnish database, with concentrations ranging from 0.2 mg/L to 1.4 mg/L for 34 cases. The MR was 0.83, lowest of the range from 0.83 to 75. For 20 fatal doxepin cases in 2002, the lowest MR was 3.8, with an exception of one case with MR of 2.

Molecular autopsy pharmacogenetics showed that the decedent was *CYP2D6*3/*4*, corresponding to a poor metaboliser due to enzyme deficiency, and *CYP2C19*1/*1*, corresponding to an extensive metaboliser. The CPY2D6 enzyme deficiency resulted in the lack of adequate hydroxylation of both doxepin and nordoxepin. Cause of death was doxepin toxicity due to repeated use, and manner of death was undetermined. The authors urged the combined use of toxicology and pharmacogenomics with other postmortem findings.

In a multicentre study on the effect of ABCB1 and cytochrome P450 genotypes on methadone plasma concentrations and treatment response, 245 patients were genotyped for *CYP1A2*, *CYP2B6*, *CYP2C9*, *CYP2C19*, *CYP2D6*, *CYP3A4*, *CYP3A5*, *ABCB1* and *UGT2B7*, and CYP3A activity was phenotyped with midazolam (Crettol *et al.* 2006). CYP3A4 and CYP2B6 contributed significantly to methadone metabolism, with CYP2D6 to a minor extent. ABCB1 accounted for minor pharmacokinetic variability. Other studied CYP genes did not affect methadone metabolism. Further, a recent study of 179 patients receiving racemic methadone (Eap *et al.* 2007) showed that CYP2B6 poor metabolisers were more likely to develop QT elongation. Since PGP is encoded by an ABCB1 gene, a methadone transporter, a study of 60 opioid-dependent individuals was performed by detection of SNPs at positions 61, 1199, 1236, 2677 and 3435 (Coller *et al.* 2006). Higher doses were needed for individuals with two copies of the wild-type haplotype, and lower doses for AGCTT haplotype. Thus, haplotyping may be used to individualise methadone therapy.

Oxycodone (Jannetto et al. 2002)

A 49-year-old man with a history of alcoholism and chronic lower back pain was prescribed OxyContin and Percocet (this is case 2 in Wong 2009). He also had depression and post-traumatic stress disorder and had previously attempted suicide once. The scene investigation revealed only 12 of the 60 oxycodone tablets that had been obtained the day before. Last seen by his roommate in the morning, the decedent was found unresponsive later that afternoon. Toxicological analysis of subclavian blood showed methadone 0.437 mg/L; no alcohol was detected. Molecular autopsy by pharmacogenomics showed that he was *CYP2D6*4* homozygous, corresponding to a poor metaboliser phenotype. Postmortem also showed that he had hepatic cirrhosis and atherosclerotic heart disease. Given the short postmortem interval and subclavian blood source, the elevated oxycodone was not due to postmortem drug redistribution. It might be due to the poor metaboliser phenotype and hepatic cirrhosis, both contributing to impaired drug metabolism. Death was certified as follows: cause of death, oxycodone overdose; manner of death, accident.

Fentanyl (Jin et al. 2005)

A 44-year-old white woman complained about her knee pain and was treated with Duragesic fentanyl patches (this is case 3 in Wong 2009).

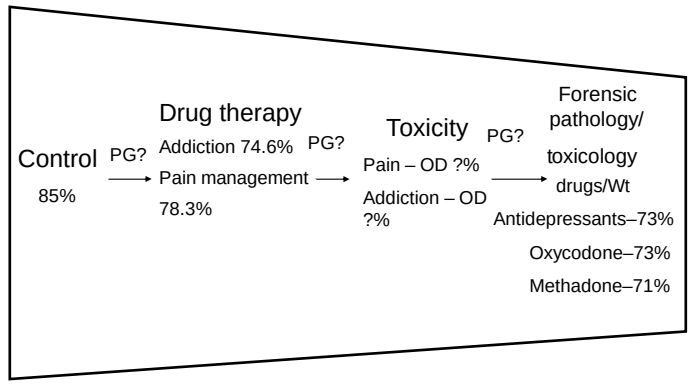

Figure 25.11 A pharmacogenomics converging continuum? (Wong *et al.* 2006b).

She appeared to be 'goofy' and went to bed. She was found dead 24 hours later. The decedent was a drug abuser with a psychiatric history. She had previously cut her arm to obtain drugs and also expressed suicidal ideation. Toxicological analysis of subclavian blood showed the following drug concentrations in mg/L: fentanyl, 0.019; norfentanyl, 0.008; cyclobenzaprine, 0.16; tramadol, 0.06; diphenhydramine, 0.08; citalopram, 0.22. Olanzapine was detected but not quantified and no alcohol was detected. The MR of fentanyl/norfentanyl was 2.5. Molecular autopsy by pharmacogenomics showed that she was heterozygous for *CYP3A4*1B* and *CYP3A5*3*, different from the majority of caucasians *CYP3A4, WT* and *CYP3A5*3 HM*. In this study with a limited number of fentanyl cases, the MR of this case is lower than the MRs of majority of the cases with high fentanyl concentrations. Together, these findings suggested, for the first time, that CYP3A5 co-mediated with CYP3A4 the metabolism of fentanyl to norfentanyl. Death certification for the above case was: cause of death, mixed drug toxicity; manner of death, accident.

From these studies, the wild-type prevalence defined as non-*CYP2D6 *2, *3, *4 and *5*, showed the following trend: antidepressants and oxycodone 73% and methadone 71%, lower than the 85% in controlled group and 78.3% in pain management study. Together, the genetic contribution to drug metabolism impairment may be interpreted as a gene dose effect, resulting in more pronounced drug toxicity. Such an effect might be readily demonstrated as a pharmacogenomics converging continuum as shown by Figure 25.11, and is helpful to understand the effect in a 'live antemortem' population.

Codeine/morphine

A full-term baby died from morphine intoxication (Koren *et al.* 2006) as a result of breast-feeding by the mother, who had been prescribed codeine for episiotomy pain, as well as paracetamol (acetaminophen). The mother was later genotyped to have *CYP2D6*2X2* gene duplication, corresponding to ultra-rapid metaboliser phenotype. Breast milk and postmortem blood concentrations of the baby were 87 and 70 μg/L, respectively, compared with expected concentrations of 2–21 and 0–2.2 ng/mL. The authors suggested management strategies for codeine use by breast-feeding mothers.

Conclusions

Gregor Mendel's 'long story' may continue in personalised medicine and personalised justice

Pharmacogenomics as an adjunct to forensic pathology/toxicology adds to the understanding of one of the contributing factors of drug toxicity. The clinical and forensic applications point to the integrative use with other pertinent clinical information, case history and postmortem findings. The proposed algorithm serves as a preliminary model to initiate the use of pharmacogenomics and would need validation by other centres and future studies. In the meantime, the use of

pharmacogenomics as a molecular autopsy is already showing the translational applications as shown in the two cases of morphine toxicity due to ultra-rapid metabolism of codeine. The postmortem report produced tangible benefits, such as guidelines on the use of drugs for breast-feeding mothers. As shown by the WHO data, warfarin fatalities are listed among the highest worldwide. Thus, the potential application of genotyping for warfarin dosing would achieve the benefit of a more rational dosing strategy, as well as a possible decrease in warfarin fatalities. Perhaps a retrospective study for warfarin-related death would further verify the merit of this protocol. In contrast with other pharmacogenomics applications, the use of pharmacogenomics in forensic pathology/toxicology, according to the proposed algorithm, has been initiated by toxicological findings. This points to the recognition of toxicology and hence of TDM as possible global phenotypic indexes, accounting for other factors such as drug–drug interactions, diet and other epigenetic factors. This convergence – pharmacogenomics with toxicology/TDM – merits prospective pharmacoeconomics studies in the future. In extending the use of molecular diagnostics, other emerging areas such as proteomics, metabolomics, RNA interference, epigenetics and others are rapidly being integrated in clinical investigations and translational medicine. Forensic scientists should be vigilant about their potential applications in death certifications, such as suicide and gene expression. These findings have potential for beneficial extension to decedents' living family members.

Personalised justice

The above experience may be helpful in applying pharmacogenomics in the emerging practice of personalised justice, such as the use of pharmacogenomic biomarkers for the interpretation of possible 'side-effects/behaviour/impaired performance' of drivers arrested in cases involving driving under the influence of drugs. Drivers' impaired driving performance may be partially explained on the basis of genetically predisposed impairment of drug metabolism and hence accumulation, which might result in driving impairment. Similar to the use of DNA fingerprinting in identity testing, the use of pharmacogenomics and other molecular biomarkers in the future as adjunct biomarkers in the above context may constitute a rational approach to understanding and ruling on the driver's liability, hence offering the possibility of personalised justice (Figure 25.12).

As the public gains awareness of the benefits of PM and the role of pharmacogenomics, the public media and scientific groups such as the White House Council of Advisors on Science and Technology are proactive forces. Other encouraging developments have included the availability of a proficiency survey programme by the College of American Pathologists in 2007, and quality assurance/control from commercial sources, indicating increasing clinical adaptations by clinical laboratories. NACB guidelines would certainly pave the way. Challenges include adequate reimbursement, clinical interpretation, ethical guidelines, and education of patients and healthcare professionals. Thus, Gregor Mendel's 'little trick – long story' will continue in new applications of the human genome project and rapid advances in molecular biology and pharmacogenomics.

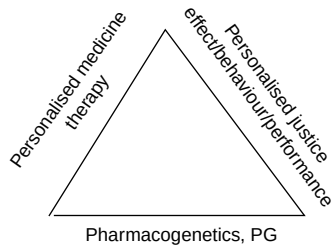

Figure 25.12 Personalised medicine and personalised justice. A new social paradigm? Complementary, tandem, overlapping and inevitable?

Glossary (Roden et al. 2006)

***Alleles*:** Alternate sequences of the same gene, one inherited from each parent.

***Association*:** A statistical finding that the frequency of one or more genetic variants is significantly different in patients with a given phenotype than in those without the phenotype. Often polymorphisms in candidate genes are studied. A more recent method, whole genome association, seeks to identify new genes involved in variable phenotypes; the technique uses new methods to compare genotypes at hundreds of thousands of polymorphic sites in large numbers of patients with and without a specific phenotype.

***Biological pathway*:** A set of proteins that interact to produce normal and abnormal physiology.

***Candidate gene*:** A gene in which variants could plausibly explain a given phenotype, such as severity of disease or variable response to a drug. Methods to identify candidate genes include basic science studies, identifying DNA sequences conserved across species, human genetics or genome-wide analyses. Candidate genes may be in pharmacokinetic or pharmacodynamic pathways.

***Genome*:** The collection of all DNA in an organism. Only a small proportion (probably 3%) of the human genome encodes proteins.

Genetic variant: A difference in DNA sequence compared with a reference sequence.

Genotype: The genetic make-up of an individual, which may refer to the whole genome or to specific genes or regions of genes.

Haplotype: A set of genetic variants that are inherited together. Polymorphisms that are co-inherited more often than by chance alone are in linkage disequilibrium. Haplotype blocks may include many individual polymorphisms in high linkage disequilibrium; as a result, establishing genotype at any single polymorphic site with such a block may establish genotypes at linked sites within the block. Individual single-nucleotide polymorphisms (SNPs) that can be used to establish genotype within a haplotype block are termed tag SNPs.

Heterozygous: Different alleles in a specific region of DNA.

Homozygous: The same alleles in a specific region of DNA.

Mutations: Rare variants, most often in coding regions, which are often associated with genetic diseases, such as cystic fibrosis or sickle cell anaemia.

Pharmacodynamics: The study of the relationship between drug concentrations and drug effects.

Pharmacogenetics: The study of the relationship between individual gene variants and variable drug effects.

Pharmacogenomics: The study of the relationship between variants in a large collection of genes, up to the whole genome, and variable drug effects.

Pharmacokinetics: The study of the relationship between drug dose and drug concentrations (often as a function of time) in plasma or tissue.

Phenotype: Measurable characteristics of an organism. These may derive from genotype, environment or their combination. Organisms with the same phenotype can have different genotypes.

Polymorphisms: DNA variants that are common, often defined as greater than 1% in a given population (although rare polymorphisms are increasingly being recognised). Polymorphisms can be in coding regions (where they may synonymous or non-synonymous) or, more commonly, in non-coding regions, and often vary by ethnicity. The most common type of polymorphism is a change

in one nucleotide (base pair) in a DNA sequence, referred to as an SNP. Other polymorphisms are insertion and deletion of multiple sequential nucleotides ('indels'); variable numbers of repeats, such as doublets or triplets; or large-scale duplications or deletions. Although some genetic variants are known to alter protein abundance or function, the functional consequences of most polymorphisms are unknown.

CHAPTER

26 Interpretation of Toxicological Data

OH Drummer and S Karch

Introduction

Toxicology has a range of applications, as other chapters of this book have shown. One of the main applications of forensic toxicology has been death investigations, i.e. postmortem toxicology. However, investigating a possible drug-affected driver or an alleged assailant and investigations of drug-facilitated sexual assault are important and growing applications.

The assessment of blood or tissue drug results is not always straightforward. Many factors must be considered, and a truly accurate assessment is likely to require discussions between all the relevant specialists involved, and perhaps even with experts from outside, who can bring with them additional expertise.

The purpose of this chapter is to provide information about how interpretation should be carried out and detail the range of factors that must be considered. It is hoped providing readers with actual examples from selected real cases will improve their ability to properly interpret toxicological information.

Initial acquisition of information

Scene information is vital. A toxicologist will often get some initial information from the police investigators or from his or her colleagues in the medical examiner's office. At the very least, the toxicologist must know all the relevant circumstances, i.e. the driver having been seen to be driving erratically and thought to be drug affected by a central nervous system (CNS) depressant, or a possible victim of rape with no clear recollection of the incident. This provides the toxicology laboratory some useful preliminary information on the types of tests that need to be targeted. It goes without saying that all medication bottles at the scene of any suspicious death should be collected at the time of the initial investigation. When specific substances are suspected, these should be clearly stated or, if drugs are collected at a scene, these should be clearly listed and provided to the laboratory. Without this information, the laboratory will not be able to target its screening tests relevant to the case. This limitation becomes particularly important if suspected substances are not detected by routine screening tests.

A case conference with the laboratory helps both the investigators and the laboratory personnel to maximise the effectiveness of the testing process. A 'sit-down' conference may not always be possible in every case, but a telephone call may suffice to exchange information. At a minimum, the investigators should be speaking with each other. The following sections contain illustrations showing how the nature of the information provided determines the extent to which a proper interpretation of any results is obtained.

Toxicology investigations

To some degree the choice of toxicology test to be performed is determined by the client (chiefly the police, the forensic physician or the medical examiner) and unfortunately by the budget. This consideration is particularly true when it comes to expensive procedures such as hair and DNA testing (see below). Depending on the circumstances, testing may be requested for one or more specific substances. Preferably, a full screen for unknown substances should be ordered. There will be instances where only targeted testing is warranted, i.e. alcohol and some illicit drugs such as when drivers are suspected of driving under the influence or following an accident. However, it is the experience of the authors that multiple drug use is common and often the drugs finally detected were not the ones suspected. Consequently, whenever possible, the laboratory should be asked to conduct a reasonably comprehensive drug screen (or series of drug screens) for common drugs.

Each jurisdiction will have their own specific drugs of interest and it is important for the toxicologist to be acquainted with the drugs abused in their jurisdiction. Generally, an adequate screen will include alcohol (ethanol), a range of common illicit drugs (e.g. amfetamines, benzodiazepines, cocaine, opiates and cannabinoids) and a range of common prescription and over-the-counter (OTC) drugs (antidepressants, antipsychotic drugs, etc.). Depending on the circumstances, other drugs or poisons may also need to be targeted, i.e. volatile substances, such as gamma-hydroxybutyrate (GHB). It is impossible to perform a comprehensive toxicology investigation without first discussing with the relevant investigators the type of substances likely to be involved.

It is also vital that all information pertaining to the specimen itself is provided to the analyst. In the living, this would include the name of the person, date of birth, type of specimen type (serum, blood, etc.) and time and date of sampling. In postmortem cases, it is mandatory to specify the site of blood collection (see Chapter 10) and the conditions of storage. The following questions may also need to be answered:

1. Was the body refrigerated, or at room temperature, and for how many hours?
2. How was the body positioned? Was the body prone or supine? Had the body been moved?
3. Had putrefaction begun and did the specimens show any signs of decomposition? If it did, that might affect the concentration of substances detected.
4. Was there any trauma to the body? This may have affected the integrity of the specimens (postmortem alcohol formation is a particular problem).

As mentioned above, death investigators need to examine the scene in order to determine what medications were present (including OTC preparations and unregulated herbal supplements), record the relevant data and bring the medicine bottles back to the office for further investigation if warranted. If drug abuse is suspected, then neighbours and/or friends may be useful sources of information. Neighbouring rubbish bins should be searched and obvious surfaces within the dwelling chemically tested. In poor areas frequented by narcotic users, it is reasonable to assume that any remaining narcotics have been stolen before investigators arrive. In colleges and in the homes of the affluent, it is likely that attempts will be made at concealment, though they generally will not be very sophisticated.

The following data should be recorded about each medical prescription found at the scene or located nearby:

1. Details on the packaging including label, nature of substance, name of pharmacy, name of person to whom prescriptions were made out, date filled and number of tablets/volume of solution/syrup dispensed.
2. Number of tablets/volume of solution/syrup remaining unused.
3. If appropriate, each tablet/capsule can be identified by the laboratory, as they nearly all have unique markings. Chemical analyses can be conducted if identity or strength is unknown.

4. Subject to privacy and legal issues, medical practitioners may also be requested to provide details of prescriptions issued to their patient under investigation.
5. Again, subject to privacy and legal issues, a report of dispensed drugs can also be obtained from nominated pharmacists.
6. Residues in glasses or containers suspected of containing drugs/poisons, or powders located at the scene should be collected and sent to the laboratory for chemical analysis if deemed appropriate.

The final laboratory report should: (1) clearly show exactly what tests have been conducted; (2) indicate substances that can reasonably be excluded; (3) list the substances that were detected in the relevant specimen; and (4) if appropriate, list the results of an analysis performed on physical exhibits (tablets, powders, etc.). The end user of the report must be able to understand exactly which tests were conducted; testing limitations, if any (including the provision of an inadequate sample for whatever reason), must be stated; if postmortem blood samples have been tested, the origin of the samples should be stated as well (see below) and, if the origin of the sample was a particularly problematic site, such as cavity or heart blood, this problem must be indicated in the final report. The end user must also be told what other tests may be needed if more information comes to hand.

Interpretation: principal considerations

Other chapters explore the use of toxicology in various settings. In both clinical and forensic settings a range of factors can affect the concentration of a drug in a particular specimen. This, in turn, influences the final interpretation. The range of factors that are of most importance in interpreting a drug or poison testing result is shown in Table 26.1.

It may not always be possible to answer precisely all the questions raised in Table 26.1. However, the less that is known, the more likely it is that the conclusions reached are either mistaken or misleading. Each of the 10 factors in Table 26.1 is considered in turn below.

Inherent pharmacological activity and toxicity of a substance

As Paracelsus was reported to have said: 'All substances are poisons, there is none which is not a poison. The right dose differentiates a poison from a remedy.' This is still an apt proverb in modern toxicology.

Not all substances found in toxicology investigations are toxic, and their presence may not even be particularly relevant to a particular case. What is one to make of paracetamol (acetaminophen) detected in the body of a dead diamorphine user? Paracetamol is unlikely to be a factor in the death unless it can be demonstrated that liver necrosis is present. It would be a grave mistake to presume that just because a drug is present and anatomical lesions are absent the drug was responsible for death even if it were to be present in higher than normal concentrations.

Many widely used OTC preparations and herbal supplements produce a sort of 'background noise'. Their detection in postmortem specimens merely acts as an indicator of the prevalence of their use. A report describing the occurrence of a common disorder such as myocardial infarction or cardiac arrest, in a subject taking a common medication such as paracetamol, is much less cause for concern than an agent like digitalis. For example, survey data suggest that 20% of all US citizens, or nearly 60 million people, used paracetamol in 2004. The accepted rate for acute myocardial infarction in the USA is of the order of 0.52% per year. Even assuming that only one half of the paracetamol users were seriously at risk of infarction (i.e. over age 35 years), then more than 312 000 (0.52% of 30 million episodes of myocardial infarction) should occur in individuals taking paracetamol each year. The accepted rate for cardiac arrest resulting in sudden death in the USA is 0.1% per year, which means that another 30 000 paracetamol users should have died suddenly, if only by chance. The rates for stroke are much higher than for sudden cardiac death, with nearly 0.25% per year, or 75 000 episodes, bringing the total number of cardiovascular events occurring in US paracetamol users to well over half a million per year. Yet we know very well that disease, and not paracetamol, was the cause of death. Drawing any other conclusion commits the well-known legal fallacy, *post hoc ergo propter hoc* (literally, 'after this, therefore because of this').

Thus, the mere detection of paracetamol in a decedent's blood, particularly a decedent who has suffered an infarction, or other identifiable natural disease, does not prove that the drug played any role in that individual's death unless, of course, type 3 zonal necrosis liver injury was present.

In the same manner, the mere detection of non-steroidal inflammatory drugs does not prove that they have played a role in the death, unless some pathology relevant to the use of this substance is seen (i.e. gastric erosions). These situations can occur, but they are uncommon and are usually not particularly important from a forensic perspective. It is far more likely that other substances detected are more relevant, but each substance detected must be considered on its own merits. The inherent toxicity of a substance can also be gleaned from epidemiological studies. This type of information is generally obtained by dividing the number of deaths associated with a drug by the number of prescriptions or defined daily doses of that substance (King, Moffat 1983; Buckley, McManus 1998; Frey *et al.* 2002).

Table 26.1 Principal factors that require consideration in interpreting toxicological information

1.	Is the substance capable of exerting significant harmful or toxic effects? If so, how does it work (i.e. by what mechanisms does it exert its unwanted effect)?
2.	What is the most likely source of the drug and the route(s) of administration?
3.	Are the toxicology results obtained on postmortem specimens? If so, what artefacts need to be considered?
4.	Did death occur shortly after administration of substance or after a substantial delay?
5.	Has the substance been used as a single dose or did death follow multiple doses?
6.	What is the age of the person and does the person affected have significant kidney, liver or heart disease (including inapparent heart disease)?
7.	Does the person affected have significant injuries?
8.	Is there a possibility of a genetically related disorder of drug metabolism (pharmacogenomics)?
9.	Is there a possibility that tolerance to the substance(s) has developed?
10.	If other substances are present in the case, how do they interact with each other, or did they even interact at all?

Case example 1

A young woman was admitted to hospital with abdominal pains and possible liver failure. Markedly elevated transaminases were detected together with 300 mg/L of paracetamol in blood. The patient died 2 days later, despite having received appropriate treatment for a paracetamol overdose. Toxicological testing also confirmed the presence of sertraline and diazepam at concentrations of approximately 1 mg/L in blood taken on admission to hospital. Clearly, this patient died from paracetamol-induced necrosis. The other drugs were unlikely to have contributed to the development of liver disease and would not be considered as significant contributors to her death even if they are regarded as being somewhat elevated.

Sometimes the presence of a substance can be used to substantiate other historical information about the circumstance of death; for example, the presence of a drug used to treat hypertension suggests an underlying diagnosis of hypertensive cerebrovascular disease. In the same way the presence of an antiepileptic drug suggests, but does not prove, treatment for seizure-related disorders, as some antiepileptic medications are being used to treat other types of disorders (carbamazepine, valproate, etc.).

Case example 2

A woman was found dead with multiple stab wounds. The accused was detained shortly after the event and was examined medically as well as toxicologically for the drugs. Drug testing disclosed the presence of methamfetamine at a concentration of 1.1 mg/L, amfetamine at 0.2 mg/L, alprazolam at 0.6 mg/L and alcohol at 1.6 g/L, respectively. The presence of alprazolam and alcohol in significant concentrations can be associated with disinhibition, while use of methamfetamine (and its metabolite, amfetamine) is associated with aggression and violence. The accused was a long-term abuser of amfetamines and benzodiazepines and had become increasingly violent and unpredictable with episodes of paranoia. While the drug use and the behaviour associated with it are no legal defence, it does help explain how a simple argument led to a tragic outcome.

The difficulty here is not to become too enamoured with the idea that correlations can be established between blood concentrations in specific behavioural states. A driver weaving erratically in traffic, later found to have sedatives in his blood, was no doubt intoxicated at the time, but a dead body found to contain traces of cocaine metabolite is just a dead body containing a small amount of drug. There is no method by which inferences about actual behaviour could be drawn from just a blood or tissue concentration, except to indicate a range of likely behavioural changes associated with use of this drug.

This situation comes about for two reasons: tolerance to most abused drugs occurs quickly, making it impossible to correlate specific behaviours and specific drug levels. The other problem is that blood drug concentrations change after death, and there is no guarantee that the blood concentration measured at autopsy bears any predictable relationship to blood concentrations in the immediate antemortem period (see below). In such cases there is little that a pathologist can do except to note the presence of the drugs detected.

Behavioural changes associated with substances may also be relevant to the case. For example, a person taking amfetamine may be involved in a serious assault, and amfetamine will be detected in a forensic drug screen. Amfetamines, as with many other substances taken recreationally, produce unpredictable effects on behaviour. They are certainly associated with criminal behaviour but, among those with attention deficit disorder, they are associated with better impulse control (see Case example 2). The net effect of the drug on any individual, however relevant to the case, is still subject to the considerations and limitations listed in Table 26.1. The same considerations apply to drugs used to facilitate sexual assault ('date-rape' drugs). These drugs are given to render a person incapable of effectively resisting assault, and include many of the CNS depressants, as well as ketamine and some of the amfetamines, e.g. MDA and MDMA.

Source of drug and route of administration

In some cases, simple facts give a clear indication of the route of administration. The presence of residual drug in the stomach contents or gastrointestinal tract suggests oral ingestion. A needle mark in the arm may indicate intravenous injection, just as high concentrations of drug found in muscle tissue point to intramuscular injection. However, in the majority of cases it is not reasonably possible to determine with any certainty the route or routes of administration from toxicological data considered in isolation. Many drug takers use multiple routes. Polydrug abuse is an increasing problem. In the USA it is not uncommon to see crack cocaine smokers who also inject diamorphine. It is not uncommon to find both a crack pipe and a diamorphine syringe at a decedent's side.

In reality, toxicology testing alone is rarely able to provide answers about the route of ingestion. The route of administration is best determined from the circumstances of the case and by ensuring forensic examinations.

Substances can be far more toxic if given intravenously rather than orally. The rate at which a drug reaches its site of action is a critical factor governing the duration and the severity of the pharmacological response. Intravenously administered diamorphine, cocaine or amfetamine almost instantaneously reaches high concentrations in the brain and heart, capable of causing serious harm, as will the smoked form of these drugs, but the same dose taken orally may well be comparatively safe. For more information on the pharmacokinetics and metabolism of drugs see Chapter 24. A drug injected as a depot intramuscularly, or applied on a patch on the skin, usually provides a controlled delivery of drug to the circulation. However, when the contents of the patch are injected intravenously or, even worse, volatilised and smoked, they can be dangerous. As the black market for fentanyl patches has grown, so has the number of bizarre deaths reported after their use. Several deaths have been reported in users who have heated the patches and inhaled the vapours, and others have occurred in young women who have inserted the patches intravaginally. These patches will continue to release drug after death, but it is unclear how much will continue to be absorbed after death.

The collection of the gastric contents can provide a useful way to establish possible oral exposure (for death investigations) and even to establish intent, i.e. deliberate ingestion of a large amount of substance. However, when small amounts of substance are present in gastric contents (a fraction of a dosage form), the possibility of contamination from bile during the agonal phase of death must always be considered. Persons in a coma, or persons exposed to drugs that inhibit intestinal motility (opioids and anticholinergic substances), will show delayed transit times in the gastrointestinal system and ion trapping occurs. Drugs injected parenterally may appear in the gastric secretions, as may cocaine that has been insufflated. Once in the circulation, drugs that have been injected can still become trapped in the stomach.

The presence of needle marks in the arm may suggest intravenous drug use. However, attempts at resuscitation by paramedics can also lead to injection marks. These artefacts must be excluded if the route is to be determined accurately. Often the presence of 'resuscitation drugs' can give a clue to paramedical activities. These drugs include lidocaine, diazepam and phenytoin. Subjects undergoing emergency surgery may also have anaesthetics such as propofol, thiopental and ephedrine, not to mention dopamine and other pressor agents. The situation is becoming somewhat problematic as cocaine producers seek alterative cutting agents. The American Drug Enforcement Agency has reported the seizure of several different cocaine shipments that have been diluted with popular medical drugs (one of the most recent is diltiazem and another is levamisole). The explanation seems to be that if the substance is white, and can be stolen, it can serve as a diluent for illicit drugs.

In some cases the measurement of metabolites can assist in determining the route of administration. For example, when diazepam is taken orally, first-pass metabolism produces significant amounts of nordiazepam. This means that blood will contain both substances. Following intravenous administration of diazepam (intravenous abuse of benzodiazepines or after emergency medical administration), little or no nordiazepam (*N*-desmethyl diazepam) is detectable for at least a few hours after administration. This difference in the production of the *N*-desmethyl metabolite also occurs for other drugs that undergo this form of metabolism, or other forms of liver-mediated metabolism for drugs with a high liver extraction ratio (amitriptyline, dothiepin, dextropropoxyphene, codeine, etc.). However, each case needs to be considered on its merits since the rate of *N*-desmethylation may be relatively slow for some drugs and require days of treatment orally before significant amounts are found in blood (e.g. MDMA).

The route-dependent variability of drug disposition into tissues may also provide useful information relating to the route of administration. Because of the physiological processes involved, substantially smaller amounts of an intravenously administered drug are partitioned into the liver than when the same drug is given orally. If death resulted rapidly following a large overdose by intravenous injection, the liver-to-blood drug concentration ratio would therefore be lower than that observed had the drug been given by mouth. Thus, liver : blood ratios of 2.5 and 5.0 have been observed in pentobarbital fatalities involving intravenous and oral administration respectively, and ratios of 1.3 and 4.2 have been found for intravenous and oral fatalities involving morphine.

Anhydroecgonine is produced only when cocaine has been pyrolysed, which means, by definition, that the route of administration was smoking. Pyrolysis products have also been identified after the use of methamfetamine. Cocaethylene is produced only when alcohol and cocaine are consumed at the same time, while ethyl glucuronide and ethyl sulfate are produced after simple alcohol consumption. While of little direct evidential value (the rate-limiting step of the reaction forming cocaethylene is the alcohol concentration, which needs to be so high that it is sure to be detected), cocaethylene has a half-life many hours longer than that of cocaine, so that cocaethylene may persist for many hours after cocaine is long gone from the body.

Case example 3

A 46-year-old man had been found dead in his bed. He had a history of depression and had been on amitriptyline (150 mg daily) for many years. Toxicology showed the presence of amitriptyline in femoral blood at 1.6 mg/L, in liver at 35 mg/kg and in gastric contents at approximately 300 mg. These values indicated the presence of excessive, and potentially fatal, concentrations of amitriptyline in both blood and liver. Concentrations of this drug in blood and liver following therapeutic use usually range up to 0.8 and 10 mg/kg respectively. The presence of several tablets (4×75 mg) of unabsorbed drug in the stomach confirmed oral ingestion of a much higher than normal dose. No significant pathology was otherwise detected at autopsy.

It is also worth noting that oral dosage forms come in a variety of formulations, some of which have modified-release characteristics. For example, most solid oral formulations (e.g. tablets, capsules) release drug almost immediately on impact with the stomach. Sustained-release formulations will slowly release drug over many hours, leading to a slow but sustained absorption. Examples include verapamil, morphine and oxycodone. Enteric coated tablets have a protective coating that dissolves only at pH values higher than that found in the stomach. Accordingly, the contents are released in the small intestine and this avoids gastric irritation. Examples include aspirin and potassium chloride. As a result, the blood concentration versus time profile will be shallower than with immediate-release formulations. Toxicity will also be delayed in the event of an overdose.

Case example 4

A 35-year-old woman was admitted to the emergency department of a major public hospital suffering from a possible opioid overdose. She presented with pin-point pupils and shallow laboured breathing. She was given naloxone (an opioid antagonist), which rapidly reversed the CNS depressant effects. Four hours later she developed laboured breathing and lost consciousness. Further naloxone was given with almost immediate effects. Investigation established that she had taken sustained-release morphine, which continued to be absorbed well after a few hours, resulting in sustained blood concentrations over many hours. In this situation a short-acting opioid antagonist would need to be administered repeatedly until the offending opioid was finally cleared from the body.

Postmortem results

Alcohol

Specimens taken *post mortem* are problematic for many drugs and the situation with alcohol is probably the most difficult. Obvious decomposition or putrefaction will affect the quality of the specimens. When this occurs, any interpretation of quantitative results should be treated with much more caution than when specimens have been taken from a body not long after death. Indeed in most 'decomposed' cases it is best to report only qualitative or semi-quantitative data. The state of the specimen (or tissue) could mean that substances have significantly changed their concentrations, though some substances are surprisingly resistant to postmortem degradation, and some poisons are actually preserved by the embalming process.

In some instances the drug will be lost owing to inherent chemical or bacterial instability. Examples of drugs that are unstable *post mortem* are the benzodiazepines, drugs that contain a sulfur atom (dosulepin, thioridazine, etc.), drugs containing acetyl or ester functionalities (e.g. diamorphine, cocaine) and even drug conjugates (morphine glucuronides and salbutamol sulfate, etc.). The nitrobenzodiazepines (e.g. clonazepam, flunitrazepam) are almost completely converted to their corresponding 7-amino derivatives after death, requiring these forms to be targeted in postmortem screening rather than the parent drug (Roberton. Drummer 1995).

Alcohol can be produced *post mortem* by the action of certain bacteria. This process is also dependent on time and temperature; production is almost predictable under some circumstances. Aircraft crash investigators are well aware that separated body parts are extremely prone to bacterial colonisation and artefactual elevation of the blood alcohol concentration, though the extent of formation cannot be reliably estimated. It is believed that alcohol can be formed *post mortem* up to at least 2 g/L under the right circumstances, even in the collecting tube. It is therefore essential that blood is collected in tubes containing fluoride, which will act as a preservative. Experience suggests that, when dealing with alcohol or cocaine, containers with higher concentrations of sodium fluoride than normally used in the hospital (1% vs 2%) should be used. It is recommended whenever alcohol concentrations are important in a case that vitreous humour concentrations also be measured. If vitreous humour is unavailable, then urine analysis should be performed. And, if the option exists, ureteral or even calyceal urine should be used. This is much more likely to reflect the blood alcohol in the perimortem period than is the pooled urine found in the bladder. In cases of putrefactive formation of alcohol, the vitreous humour will contain little if any alcohol.

Urine measurement can provide useful information, but it too can be affected by prolonged postmortem intervals. Urinalysis is problematic in diabetics, because of the presence of glucose in their urine, which may lead to fermentation. Urine may not always be available (approximately one-third of the time the bladder is empty and perhaps even more often when death is due to trauma). Thus the credibility of results obtained with urine testing depends largely on the source of the urine. Urine from the bladder accumulates over a period of many hours and therefore represents an average concentration, not necessarily the concentration at the time of death. On the other hand, concentrations measured in urine collected from the ureters, or pelvis of the kidney, closely reflect concentrations measured in the vitreous humour.

When no other competing factor is present, both vitreous humour and urine will contain somewhat more alcohol than blood owing to their higher water content. Increases of about 15% and 30%, respectively, occur on average and it is important to raise this issue in court since this may affect the interpretation.

Blood alcohol concentrations may also be increased by diffusion into the bloodstream from neighbouring tissues, e.g. gastric or intestinal tissues, in the dead and in the living. Animal studies have shown that, in experimentally induced haemorrhagic shock followed by fluid resuscitation, alcohol will diffuse from the tissue back into the bloodstream. In jurisdictions where *per se* laws apply, the movement may be sufficient to qualify a patient as intoxicated, even though their blood concentration may have been much lower at the time of the accident.

After death, a person who had recently ingested a large amount of alcohol could have blood concentrations increased *post mortem* owing to diffusion. The collection of blood peripherally can avoid this phenomenon. Even more likely, the decedent will vomit and aspirate as he or she is dying. If the alcohol concentration in the vomitus is high, and the person aspirates on the left side, alcohol may diffuse through the bronchi into the left side of the heart, leading to spuriously high alcohol concentrations. Pathologists should avoid sampling the liver adjacent to the stomach so as to avoid diffusion from the stomach leading to falsely high concentrations in the liver.

Drugs

The postmortem redistribution of drugs is hardly confined to ethanol. Whenever the process has been systematically studied, it has been found that postmortem drug concentrations (obviously excluding drugs like cocaine that continue to break down after death) are consistently higher after death than they were in the immediate perimortem period (Pounder, Jones 1990; Drummer 2004).

In a study assessing postmortem redistribution of MDMA, antemortem and postmortem MDMA concentrations were measured and compared in five patients who died in hospital, having been admitted for MDMA toxicity. Admission plasma concentrations ranged from 0.55 mg/L to 4.33 mg/L for MDMA and 0 mg/L to 0.10 mg/L for MDA. At autopsy, postmortem MDMA concentrations ranged from 0.47 mg/L to 28 g/L, while concentrations for MDA ranged from 0.02 mg/L to 1.33 mg/L. The antemortem-to-postmortem ratios ranged from 0.02 to 1.33 (Elliott 2005). Similar findings have been observed with both abused and therapeutic drugs.

The diffusion of drug from a tissue containing a high concentration into blood at a lower concentration is relatively common since most drugs tend to have higher tissue concentrations than blood concentrations. This process is termed redistribution. Substances most subject to an elevation of blood concentrations after death are those with a high fat solubility. These drugs usually have volumes of distribution (V_d) greater than 2 L/kg. In general, the higher the volume of distribution, the more likely this change is to occur, but the degree of intra-individual variability is very high. For example, in a recent study of methamfetamine users confined to a metabolic ward, the V_d ranged from 2 L/kg to 11 L/kg (Schepers *et al.* 2003). There is, of course, no way to know what the correct V_d is in any individual without actually measuring it in that individual. Table 26.2 summarises the approximate extent of these changes for selected drugs. It must be emphasised that these increases are not predictable and will vary from case to case depending on a range of factors including time, temperature and other variables that cannot be estimated at all, or crudely estimated at best. If ambient room temperature and body core temperature are recorded at the scene, there is a good chance of estimating the time of death with reasonable accuracy. If the time of death is known with some certainty, inferences made about blood concentrations and redistribution have much more credibility.

Postmortem increases in drug concentration can be minimised by taking peripheral blood and by limiting the size of the blood sample. A femoral blood sample of greater than 25 mL is almost certain to contain hepatic blood. For many years the preferred drawing site has been the femoral vessels, but only if the superior portion of the vein or artery is tied off to avoid collection of abdominal blood. Newly published evidence suggests that ligation may not be mandatory since clamped femoral blood concentrations and blind-stick femoral blood gave concentrations similar across all drug classes with ratios around 1.0 (Hargrove, McCutcheon 2008). Even so, drugs with a high volume of distribution will have muscle concentrations higher than those in the blood, allowing diffusion of muscle-bound drug to the pooled blood. When deaths occur in hospital it is prudent, if not imperative, to obtain and analyse specimens taken at the time of admission, as these are more likely to be relevant than postmortem specimens and they will be free of postmortem artefacts.

Antemortem specimens are collected on behalf of the physicians for diagnostic purposes, and are likely to consist of plasma and not whole blood (which could have bearing depending on the distribution of the drug within the blood). They can be valuable for toxicologists and can provide better insight into the 'true' concentration of substances of interest than can be obtained *post mortem*. They do need to be requested soon after death to avoid routine disposal by hospitals.

Table 26.2 Examples of common drugs subject to substantial postmortem redistribution

Amfetamines
Chloroquine/hydroxychloroquine
Digoxin
Methadone
Phenothiazines (e.g. thioridazine, chlorpromazine)
Dextropropoxyphene
Propranolol
Pethidine
Tricyclic and tetracyclic antidepressants

Case example 5

A 63-year-old woman died some hours after admission to hospital for heart rhythm abnormalities. She had a significant history of heart disease with one previous episode of myocardial infarction. She had been on digoxin. Postmortem toxicology on femoral blood disclosed a concentration of 5.6 µg/L, a concentration that is potentially fatal. An antemortem blood specimen taken shortly after admission was found to contain digoxin at 2.5 µg/L, a concentration consistent with normal therapeutic use. In this case, elevation of the postmortem redistribution was the likely explanation given the drug's high volume of distribution. It would have been a mistake to rely on the postmortem blood concentration while at the same time ignoring heart lesions (fibrosis in the zone of infarction) that are known to be associated with rhythm abnormalities and sudden death.

Case example 6

A chronic schizophrenic, treated with 10 mg of fluphenazine twice a day, also suffered from multiple somatic disorders, including decubitus ulcers, poorly controlled diabetes and severe coronary artery disease. When he was found dead in a nursing home, the medical examiner duly noted all the medical conditions, as well as a reported postmortem blood fluphenazine concentration of 72 µg/L. Fluphenazine has an extremely high volume of distribution (of the order of 11 L/kg) which means that redistribution is all but guaranteed. The medical examiner ruled that the level of fluphenazine was a significantly elevated concentration relative to therapeutic concentration and would be contributory if not the actual cause of death. The argument was (quite properly) not accepted by the jury.

Time of exposure

The time elapsed from exposure to specimen collection is important because the concentrations of some drugs decrease substantially over time. For example, in cases of suspected drug-facilitated sexual assault, GHB can be detected at concentrations above endogenous concentrations for only a few hours. Absence of this substance some hours later may not necessarily be consistent with absence of exposure.

Moreover, a drug can cause a toxic response, e.g. death, and not be present in 'lethal' concentrations or even in any concentration at all. This situation comes about for two reasons: it may be that sufficient time has passed to allow most of the substance to be excreted. A person collapsing from the use of diamorphine can eventually become brain dead hours after the injection, at which point little or no morphine is detectable in blood or tissues. The leukoencephalopathy seen in diamorphine smokers is thought to be the result of a toxin that is rapidly absorbed by myelin. By the time neurological symptoms develop, no toxin is circulating in the bloodstream. Alternatively it may be that the drug is entirely absent. Chronic cocaine use leads to changes in heart structure that favour the occurrence of sudden death. These structural changes can cause death even in the absence of cocaine.

There is also the phenomenon of tolerance. This allows the ingestion of massive quantities of drug, leading to spectacular blood concentrations. It is not uncommon to see a living diamorphine maintenance patient with blood morphine concentrations many times higher than a drug-naive individual who died after a first diamorphine exposure. It cannot be overemphasised that the circumstances and the pathology determine the most likely cause of death, not the blood concentration of morphine. Of course, the converse can apply: when a death occurs moments after intravenous injection of diamorphine (provided that it was diamorphine injected and not fentanyl, a potent narcotic that is not detected on routine drug screens) but little or no morphine is found in

urine, that is an indication that the kidney has not had sufficient time to excrete morphine before death, though the blood concentration will often be relatively high.

Case example 7

A 28-year-old man was found lying dead on the floor in his apartment. The scene showed signs of intravenous drug use including some unused diamorphine in a foil. Autopsy disclosed highly congested lungs and viscera and extensive bronchopneumonia in his lungs. Substantial hypoxic damage was observed in the brain. Toxicology showed morphine (free) in femoral blood of 0.04 mg/L and total morphine of 0.2 mg/L, and morphine (total) in urine at 40 mg/L. Alcohol was also detected in urine (0.9 g/L) but not in blood. These data suggest a delayed death that allowed most of the morphine in blood to be eliminated. Oedema of the lungs, bronchopneumonia and ischaemic damage to the brain are consistent with this observation, as is the absence of alcohol in the blood. Ideally in drug-death investigations it is possible to correlate the pattern of toxicology findings with the pattern of anatomical changes. There are two general patterns of anoxic brain injury: the type that results in short-term global ischaemia (as in cardiac arrest survivors) and long-term partial ischaemia, a pattern seen in someone who remains in a comatose state for a prolonged time (or who experiences a problem during cardiopulmonary bypass). In this case, both the toxicological and the pathological findings are consistent and anatomically very distinct, with each helping to confirm the validity of the other. Taken in isolation, both findings are difficult to interpret.

As a rule, it is impossible to estimate with any precision time of ingestion by measuring metabolite ratios, for example the ratio of cocaine to benzoylecgonine, or that of free to total morphine. This approach will not work with cocaine, even in blood taken from the living, because cocaine has a much larger volume of distribution than benzoylecgonine. And, of course, after death cocaine will continue to break down, ruling out any possibility for comparison. The same holds true for morphine, where the metabolites, morphine-3-glucuronide and morphine-6-glucuronide, have a steady-state volume of distribution that is only a fraction of that of the parent compound, which means that most of the free morphine is in tissue and most of the metabolite in the blood.

Single or multiple doses

Many drugs will accumulate on repeated administration, leading to an increasing response until 'steady state' is achieved. Drugs accumulate when the terminal elimination half-life is similar to or greater than the dosing interval. As a simple rule, it takes about five half-lives for the drug to reach steady state, i.e. when the drug intake equals the metabolism and excretion of the drug. For example, GHB has a half-life of less than one hour. Unless repeat dosing occurs hourly (or more frequently), this drug shows no accumulation with repeated dosing. Similarly with cocaine and diamorphine, the half-lives are relatively short and with the exception of (invariably short-term) binge consumption it is quite difficult to cause an accumulation of drug with repeat dosing.

In contrast, many of the antidepressants possess half-lives in excess of one day and will accumulate with daily use. Amfetamines can have long half-lives and regular users can develop increasingly high blood concentrations over a week or two of use.

Blood concentrations following repeated doses will therefore be higher than after a single dose and could cause an unsuspecting toxicologist, who did not know the circumstance of use, to suggest that a large single dose had been administered. Tolerance to the adverse effects of the drug often develops with repeated dosing, further reducing the ability to accurately interpret the possible significance of a blood concentration. Methadone is a model drug to illustrate this concept and the mortality associated with accumulation of drug in non-tolerant persons is well known (Drummer *et al.* 1990; Caplehorn, Drummer 1999).

Case example 8

A 48-year-old woman had been receiving methadone for her chronic pain condition (spinal fusion following a car crash, with degenerative arthritic changes). She had been taking 80 mg of methadone daily for several months. She was found dead in her bed. Autopsy showed significant ischaemic heart disease, with a 90% occlusion of the left anterior descending artery and concentric left ventricular hypertrophy, evidence of either long-standing hypertension or past stimulant abuse. Toxicology testing showed a potentially fatal femoral methadone blood concentration of 1.2 mg/L. No drug was detected in her gastric contents. In this case, if abuse of the drug can be excluded through an examination of her medication and pharmacy records, the most likely cause of death is 'heart disease' and possibly death following a coronary thrombosis. The apparently high methadone concentration derives from accumulation of drug over time and postmortem increases and is accompanied by acquired tolerance.

In fact, it is virtually impossible to interpret an isolated postmortem drug measurement without knowing something about the circumstances of the death. As discussed above, there is enormous intra-individual variation of the V_d for many drugs. Using a reported average for a drug is not acceptable forensic practice. Nor is it acceptable to use the V_d formula to estimate dosage, unless, of course, all the circumstances are known. This formula was derived for use only with intravenous dosage in drug-naive individuals who have no other drug stored in any body compartments from previous doses (see below for more complete discussion). V_d is used in therapeutic drug monitoring situations where a clinical pharmacologist can determine a dose change on the basis of plasma concentration and the body weight of the person. This allows the plasma concentration of drug to be within the optimal range for pharmacotherapy provided that there are no compliance problems.

Age and natural disease

Age can affect the pharmacokinetics of drugs. The very young (under 3 years of age) can have underdeveloped drug-metabolising enzymes, e.g. cytochrome P450 enzymes, which can reduce the ability to clear drugs. For example, benzodiazepines have lower clearance in neonates and very young children because their clearance requires the action of oxidative enzymes, but these concerns do not apply to diamorphine or morphine, which are primarily metabolised by conjugation (Coffey *et al.* 1983; Barrett *et al.* 1996). Age-related sensitivity also applies to antiepileptic drugs (Perucca 2006). Conversely, an elderly person will usually have a lower capacity to metabolise drugs than the young owing to the declining function of organs (Burton *et al.* 2005). Clearance of drugs may drop by a factor of 2–3. Age is also associated with an increased volume of distribution (Noble 2003; Perucca 2006). For example, it is quite dangerous to treat the elderly with dextropropoxyphene on a chronic basis. This drug's principal metabolite is quite cardiotoxic and will accumulate if renal function is diminished.

Significant dysfunction of the major organs is often associated with reduced drug clearance. Liver disease can reduce the ability to metabolise and hence inactivate drugs (Morgan, McLean 1995). This occurs particularly for drugs subject to phase I metabolism (oxidation, *N*-desmethylation, hydroxylation, etc.) since this involves oxidative processes most severely altered by liver disease. Loss of kidney function reduces the ability of the body to remove drugs and drug metabolites from the bloodstream. Even if drugs are extensively metabolised, the accumulation of drug metabolites can cause the biological effects to continue, or even cause concentrations to rise, depending on their activity relative to the parent drug.

Heart disease leading to congestive heart failure reduces the perfusion rate of the liver and kidney and will often be associated with reduced drug clearance. Examples include cardiomyopathy, the presence of which will result in decreased liver and renal perfusion and drug accumulation (not to mention an increased propensity to cardiac arrhythmias), even in the absence of arrhythmia-inducing

Table 26.3 Effect of organ disease on reduced drug clearance

Organ	*Drug examples*
Liver	Paracetamol
	Most antidepressants
	Cannabis
Kidney	Angiotensin-converting enzyme inhibitors
	Morphine
Lung	Volatile substances
Heart	Most drugs

drugs. Table 26.3 lists some drugs for which the main effect of organ disease is to reduce their clearance rates.

Obesity will also affect drug clearance. This is mainly due to an increase in V_d because of the increase in body fat. Drugs with a higher V_d will tend to show the largest increase. For example, the highly lipophilic drugs can show increases by a factor of 3 (Cheymol 2000).

Injuries

It is patently obvious that the cause of death in a person with a life-threatening injury, e.g. gunshot wound to the head, is likely to be from that injury. What is not always recognised is that these persons may have drug concentrations that are also potentially fatal, e.g. the presence of morphine or cocaine. In the circumstance of someone being shot in the head and dying shortly after this injury, the injury was the immediate cause of death. Drug use is usually irrelevant to the cause of death owing to the temporal relationship of the injury and death. However, in other circumstances, when there are no competing causes of death, the same amount of drugs would be regarded as the cause of death. See, for example, Case example 9, in which drug use has been linked to causing death when injuries and natural disease have been excluded as relevant factors. In other cases it is quite possible to find the same amount of morphine (and methamfetamine) in a person with a fatal head wound in which the cause of death would be given as 'gunshot injury to head' or 'gunshot injury to head in a person using diamorphine'.

Case example 9

A 28-year-old man was found dead in a lane. He was a known user of diamorphine, methamfetamine and cocaine and had recently been released after 3 months in prison. A syringe containing traces of diamorphine was found under the body. He had numerous scars on the antecubital region of both arms. Pathology confirmed signs of intravenous drug abuse and signs of a fatty liver, but found no other significant pathology apart from pulmonary oedema. Comprehensive toxicology testing found morphine (free) in femoral blood at 0.3 mg/L and a trace amount of methamfetamine in the same blood specimen. The cause of death was given as 'toxic effects of diamorphine'.

This case illustrates the fact that without knowledge of the circumstances, including the pathology findings, e.g. gunshot wound to head, the role of the morphine (ex diamorphine) can be wrongly attributed. In Case example 9 the knowledge that the decedent had recently been released from prison adds credence to the diagnosis of drug death, since tolerance is lost during imprisonment owing to abstinence (usually persons in this situation become abstinent) from regular supplies of drugs.

The presence of serious injury will impact on drug clearance rates. For example, loss of large amounts of blood causes the body to go into shock. Shock together with blood loss also reduces blood pressure and perfusion of vital organs, reducing drug clearance rates. Attempts to back calculate drug concentrations are almost certain to be misleading. Short of the presence of other debilitating disease, there is no evidence that drug addiction as such makes the outcome of trauma significantly worse than the trauma itself, and several studies have demonstrated that the hearts and other organs of cocaine users are suitable for cardiac transplantation.

Pharmacogenomics

Pharmacokinetic differences resulting from polymorphism of enzymes can have potentially important clinical consequences. Genetic variation of drug-metabolising enzymes, particularly the cytochrome P450 (CYP) enzymes, is recognized as one of the major causes of differences in drug effects between persons (Wong *et al.* 2000).

CYP3A4, CYP2D6, CYP2C9 and CYP2C19 are the most important of the P450 enzymes, all of which are polymorphic. Polymorphism can lead to slow, extensive or even ultra-rapid drug metabolism. Drugs most likely to be subject to these polymorphisms are those subject to *N*- or *O*-dealkylation processes, e.g. codeine and methadone. Genotyping of enzymes is still uncommon in current practice but is likely to become accepted as a standard of care in the near future as drug metabolism polymorphism becomes increasingly important in explaining patient responses to drugs (Jannetto *et al.* 2004; Dorado *et al.* 2005). See Case examples 9 and 10.

However, the most pressing pharmacogenetic issues facing toxicologists and pathologists are mutations and polymorphisms that affect cardiac function. No matter how meticulous the autopsy, non-traumatic deaths go unexplained nearly 10% of the time. The percentage is higher in children and young adults. Advances in molecular biology and DNA technology now make it possible to explain some of those deaths, and emerging evidence suggests that the underlying cause of death in many of these cases is genetic. The problem is that death from a wide variety of genetic defects may leave no histological markers. The ability to identify these 'invisible diseases' with postmortem genetic testing has become a reality far more quickly than anyone had ever imagined. The introduction of these methods will have an enormous effect on the practice of forensic pathology and toxicology.

Long-term drug abuse produces anatomical and neurochemical changes that favour sudden cardiac death, particularly among stimulant abusers. Many of these changes are plainly visible in the heart: microfocal fibrosis, myocyte hypertrophy and hypertrophy of the media of the intramyocardial resistance vessels (Blechman *et al.* 2004; Karch 2005). However, many other changes are invisible, because they involve genetic defects. Cocaine, for example, binds to the hERG (the human ether-à-go-go-related gene) potassium channel and, therefore, has the potential of causing QT interval prolongation and, perhaps, a lethal cardiac arrhythmia called torsades de pointes (TdP). Whether or not this occurs depends on the genetic heterogeneity of the individual, because some changes in the structure of the hERG channel facilitate interaction with the cocaine molecule (Guo *et al.* 2006).

Closing of hERG potassium channels terminates the plateau phase of the cardiac action potential. Although there are many other candidate ion channels, blockade of hERG, which controls the rapid component of the delayed rectifier current, appears to be responsible for most, if not all, clinical cases of drug-induced TdP, no matter what the drug.

The reason why more people with hERG mutations do not die of TdP after taking drugs known to interact with the hERG channel is that hERG blockade is only one of many factors that must act together (the 'multiple hit' theory) to cause prolonged ventricular repolarisation. These other factors include low serum potassium concentrations, slow heart rate, other genetic factors, and the co-administration of other drugs that either block hERG channels or interfere with drug metabolism (Fitzgerald, Ackerman 2005). For example, it has been known for years that high intravenous doses of racemic methadone block the hERG channel and cause Q–T prolongation, but that normal oral dosing is seldom associated with this phenomenon because concentrations are not high enough to block the hERG channel. However, it has recently been demonstrated that, even when the drug is given orally, Q–T prolongation may occur in one special subset of patients: should the methadone user be a CYP2B6 slow metaboliser, they will not be able to break down the *S*-form and it will accumulate, reaching concentrations sufficient to interact with hERG and cause Q–T prolongation (Eap *et al.* 2007).

In other words, the circumstances must be just right, and the decedent very unlucky. The pathologist, on the other hand, needs a bit of luck to make the diagnosis. In practice, a pathologist may detect minor structural variants in cardiac structure, such as minimal perivascular

fibrosis, some interstitial fibrosis or perhaps medial hypertrophy of some small vessels, but no single obvious lesion or set of lesions that could account for death. In the not too distant future, the molecular biologists may be able to diagnose hERG mutations – indeed, mutations of all the other cardiac ion channels and proteins – and this ability is likely have a considerable effect on their final diagnosis.

Case example 10

A 9-year-old boy with multiple developmental disorders was admitted to hospital with seizures. He was under the care of a paediatrician, and was receiving methylphenidate, clonidine and fluoxetine. The seizures proved uncontrollable and the boy died after several days of treatment. Postmortem blood testing disclosed very high concentrations of fluoxetine, but no other apparent cause of death. State authorities immediately intervened, concerned that the parents were incompetent or had actually murdered the child. Several other children were removed from the household. Samples of the decedent's liver were tested using a commercial DNA array system. It was determined that the child had no functional CYP2D6 and could not form the main metabolite of fluoxetine, causing concentrations of that drug to reach toxic levels (fluoxetine is demethylated by CYP2D6).

Case example 11

A 6-month-pregnant, 41-year-old woman, diagnosed with heart murmur and rheumatoid arthritis, was treated with methadone and tricyclic antidepressants for her depression. She was found dead by her husband one morning. Toxicology analysis showed: methadone 0.7 mg/L, amitriptyline 1.5 mg/L and nortriptyline 2.2 mg/L. Pharmacogenomic testing showed CYP2D6*4 homozygously, which means that she was a ' poor metaboliser', unable to hydroxylate methadone, amitriptyline and nortriptyline, so that the active form of amitriptyline and unmetabolised methadone would have accumulated in her body. Death was attributed to an accidental mixed drug overdose.

Perhaps the most striking example yet was reported in 2008 (Case example 12).

Case example 12

The child of a breast-feeding mother being treated with codeine died unexpectedly 12 days after a normal birth. Morphine was detected in the infant's blood, and analysis of the mother's milk disclosed a morphine concentration of 70 µg/L. Genetic testing of the mother showed that she was heterozygous for a CYP2D6* allele with CYP2D6*2-2 gene duplication. In other words, she was an ultra-rapid metaboliser. Codeine is effective after *O*-demethylation to morphine. Under normal circumstances, only a small percentage of codeine is converted to morphine. In this case, nearly all of the codeine was converted and the child died (Koren *et al.* 2006).

Tolerance

The issue of drug tolerance has been raised before in this chapter. Tolerance is a phenomenon whereby a person adapts to the effects of a drug, often requiring higher doses to elicit the same effect as were experienced when use of the drug was first initiated. This process is also termed neuroadaptation. This adaptation is commonly seen with alcohol, diamorphine and cocaine, where doses used by long-term users are much higher than could be tolerated by naive individuals. The mechanisms behind tolerance can be complex but appear to be linked to a reduction in the number of receptors or to a reduced sensitivity of the receptors to a physiological response.

The average 'line' of cocaine contains roughly 50 mg of the drug, but regular abusers can consume many grams of the drug in one day because neuroadaptation has occurred over time. Similarly, diamorphine users can safely inject doses that would almost certainly kill an occasional user who has not yet developed tolerance. In the case of most drugs, tolerance constitutes the pharmacodynamic response of the body to the drug, but the pharmacokinetics of the drug is usually the same as for naive users. This means that tolerant users can survive blood concentrations that would be dangerous, if not fatal, in naive users. Morphine concentrations in otherwise healthy patients receiving the drug chronically for pain control are often higher than fatal concentrations in occasional users of diamorphine. This is because they have developed tolerance to the drug over a period of weeks to months. Consequently, without knowledge of the history of drug use it is not possible to determine whether a blood concentration is necessarily significant with respect to any adverse outcomes.

Tolerance is impossible to measure after death, although in some cases it may be estimated by measurement of hair drug concentrations. Drugs remain stable in hair (usually the parent compound) indefinitely. If a decedent is found with high blood morphine or cocaine levels, but no drug or very low levels of the drug in the hair, that would suggest that the individual was drug naive – certainly that was found to be the case in the Shipman murders where the absence of drug in their hair helped establish that the decedents were not drug users (Pounder 2003).

The disparity between hair and blood concentrations can be a useful finding both in forensic medicine and in postmortem pathology. In cases of drug-facilitated sexual assault, it will often be alleged that the victim was a regular drug user. The question can easily be resolved with simple hair testing.

However, if a person has been taking a drug over a long period of time and becomes tolerant, drug concentrations in the hair will also be high and it will not be possible to estimate the degree of this tolerance. It is possible to become dependent on a substance(s) but not develop significant tolerance. For example, occasional diamorphine users who have not injected daily for weeks at a time will not have developed a significant tolerance and therefore are at risk of an inadvertent overdose if they have used more drug than normal, perhaps owing to a higher street potency than usual.

Tolerance rapidly develops to the sedative effects of phenobarbital and carbamazepine. Indeed, it is a common feature of prolonged therapy with either drug. Epileptic patients treated with these drugs are often free from any adverse effects despite having blood drug concentrations normally associated with serious toxicity in patients not accustomed to taking the drug.

Tolerance invariably extends the upper limit of the therapeutic range of drugs, and there is a more marked overlap between concentrations associated with different clinical responses. When tolerance is suspected, some of the problems of interpreting data can best be resolved by reference to previous results from the same patient (e.g. results of a therapeutic drug monitoring programme). Unfortunately, in most forensic cases such background information is not available and in these instances blood concentrations alone are of little value. A more reliable interpretation of analytical data can be made only by comparison of blood concentrations with those measured in urine, or in liver (where concentrations can be much higher in addicts), and/or by measuring the relative amounts of unchanged drug and its metabolite(s). Documentation of the known history of drug use, prescribed or recreational, can assist in determining the sensitivity of a person to a particular drug.

Whatever tolerance an individual has acquired can change if health is affected. For example, it is likely that persons suffering from an illness as common as influenza can become more sensitive to some drugs and are therefore at risk of an adverse outcome even if the dose has not changed. Methadone metabolism is a perfect example of this phenomenon. Methadone circulates more than 90% bound to plasma protein. Many diamorphine abusers are actually dual substance abusers, and that other substance is often alcohol, a combination that leads to the production of diamorphine addicts with liver disease. As the liver fails, plasma proteins decrease, resulting in an increase in plasma methadone, and possibly even death (see Case example 13).

Case example 13

A 33-year-old woman had been placed on a methadone maintenance programme for her addiction to diamorphine. The medical practitioner assessed her starting dose to be 40 mg on the basis of her stated usage of diamorphine. The woman was found dead on the morning following her third dose. Pathology found no significant disease or injuries; some degree of pulmonary congestion was noted. Toxicology found methadone in femoral blood at 0.4 mg/L and some alprazolam (0.1 mg/L). The cause of death was determined to be mixed drug toxicity due principally to the toxic effects of methadone. If a new patient begins a methadone programme at a dose higher than 30 mg, they will be put at a higher risk of sudden death, which typically occurs while sleeping at night. This usually occurs within 2–7 days of initiation. The exclusion of other relevant causes of death is necessary before this conclusion is reached. Pulmonary oedema is common in narcotic deaths but is by no means a unique finding suggestive of methadone toxicity. The blood concentration of methadone is no help in determining a likely outcome due to redistribution *post mortem*. The alprazolam concentration would be consistent with normal therapeutic use. Access to this drug was confirmed by the treating practitioner.

Drug interactions

Polydrug use is the rule in adult clinical and forensic cases. Common associations include alcohol plus an illicit drug, two or more illicit drugs, or a benzodiazepine (or another sedative) in combination with alcohol and/or an illicit drug. When this occurs it is not surprising to find that the combination of drugs has led to greater behavioural changes or a higher risk of death than if only one psychoactive substance is taken. Impaired drivers are often found to have been using two or more psychoactive drugs.

This synergistic effect is suggested by the lower fatal dose of diamorphine in persons with alcohol concentrations at or higher than 1.0 g/L (Ruttenber *et al.* 1990), while drivers consuming alcohol are at a higher risk of a crash when also using cannabis (Drummer *et al.* 2004), although generalisation to all drugs is probably not warranted. In two-thirds of accidental cocaine-related deaths no ethanol was detected (Karch *et al.* 1999; Karch 2005).

When alcohol was present along with cocaine, no differences between control groups not drinking alcohol were identified. The findings suggest that acute cocaine toxicity is not enhanced by alcohol–cocaine interactions. However, alcohol concentrations were generally low and it is possible that increased toxicity is apparent when much larger quantities of alcohol have been consumed. The same caveat very likely applies for other drugs of abuse.

In most situations, the net effect of drug combinations is the sum of the psychoactive effects, which usually means some form of CNS depression. Occasionally the combination leads to a greater than expected effect, often termed an adverse reaction. This could be the result of a drug inhibiting an enzyme required for the metabolism of another drug, leading to a build-up of tissue concentrations, or some other pharmacokinetic or even pharmacodynamic interaction.

It is well known that the combination of a monoamine oxidase A inhibitor (e.g. moclobemide) with another drug affecting serotonin reuptake (e.g. sertraline) can lead to a potentially fatal serotonin syndrome. Inhibitors of cytochrome P450 enzymes commonly prolong the action of other drugs. Examples include many of the serotonin reuptake inhibitors and many of the antifungal agents (e.g. ketoconazole) and antiretrovirals (e.g. aciclovir). A recently reported case illustrating this issue is described in Case example 14. See also Case example 11.

Case example 14

A 42-year-old man had a history of depression and was being treated with moclobemide. He had becoming increasingly unwell on the day prior to his death: slurring his words, talking slowly, showing signs of muscular rigidity, breathing heavily and shaking, and was very tired. He went to bed but never woke up. Autopsy showed no significant natural disease. Toxicology showed moclobemide in femoral blood at 16 mg/L, citalopram in femoral blood at 0.5 mg/L and some traces of benzodiazepines. He had some days prior gone to another doctor who had prescribed the antidepressant citalopram. These symptoms and circumstances are a classic case of serotonin syndrome provoked by the combination of a monoamine oxidase inhibitor (moclobemide) and serotonin reuptake inhibitor (citalopram). Prescribing recommendations are to cease moclobemide for 2 weeks prior to starting on a serotonin reuptake inhibitor to avoid any adverse reaction.

What are therapeutic, toxic and fatal concentrations and do the terms have any application in the dead?

In this context the term 'therapeutic' is used to describe the concentrations normally expected following the recommended doses of the substance. Clearly, the term has no application for non-therapeutic substances, i.e. illicit drugs and poisons such as organophosphates. Concentrations are described as toxic when the dose of substance causes or has the potential to cause serious adverse reactions. A fatal concentration relates to those concentrations that are associated with fatal poisonings.

Large collections of data are available in various texts and in databases concerning the reported therapeutic, toxic and fatal concentrations of drugs and poisons. These can be an aid to establishing a likely response to a drug when interpreting a toxicological result. Wherever possible, appropriate data have been included in the monographs.

Unfortunately, the use of such data is subject to many restrictions and limitations. These are detailed below. It goes without saying that values derived from therapeutic drug monitoring do not necessarily apply in the postmortem setting, especially since there is no guarantee that the postmortem measurement represents the actual drug concentration at the time of death.

It is essential that, when a specific drug is suspected, the investigator consider the possible involvement of other drugs. Databases may not indicate whether a poisoning was due to that agent alone or in combination with other substances. Common examples here include the presence of alcohol in cases involving other CNS-depressant drugs such as opioids or benzodiazepines. There has, for example, been a long debate as to whether buprenorphine toxicity is enhanced in the presence of benzodiazepines (Drummer 2005). The use of cocaine or amfetamine in combination with diamorphine is alleged to be more toxic than one drug alone, though controlled data are hard to come by, partly because the simultaneous abuse of both drugs is so common as to make it impossible to gather adequate controls.

When proprietary preparations are given by the recommended route, it may occasionally be possible to extrapolate, or estimate, the dose (or range of doses) from blood concentrations because comparable data are usually available. However, when illicit drugs or preparations are involved, prediction of blood concentration is much more difficult.

Particular examples of variable and unpredicted doses include use of volatile substances through inhalation (abuse), and the smoking of cannabis, diamorphine or cocaine. In all of these cases the degree of inhalation together with the technique used greatly affects the amount of substance actually absorbed. Special devices have been devised for controlled laboratory studies; such devices may ensure the consistency of dose delivered, but their relevance to real abusers, on the street, is hard to assess.

There is an enormous amount of variability in absorption after oral dosing and, therefore, enormous variability in resultant blood concentrations. Most of the variability is related to first-pass metabolism (see earlier), a common finding in drugs with low oral bioavailability. A number of factors can influence bioavailability. These include the motility of the stomach and bowel, the pH and, for a small number of drugs, the activity of gut enzymes that metabolise the drug before it is even absorbed. Liver P450 polymorphisms are, or course, an important issue with some drugs, but even liver disease may be a factor. See Case example 15.

Case example 15

A man with a history of dual substance abuse (alcohol and diamorphine) was being treated for hepatitis B and C. He had been on a stable dose of methadone, 60 mg per day, for 23 months, did not smoke and was active in a 12-step programme for his alcoholism. Owing to an administrative error, his prescription for his hepatitis medications was not renewed. He was found dead in bed 3 days later. Autopsy disclosed moderately advanced cirrhosis of the liver, but no haemorrhage or other obvious cause of death and his methadone concentration (the only drug detected) was consistent with his dose. Blood tests drawn in his doctor's office 3 days earlier showed very low levels of serum protein. The cause of death was ruled to be natural. Methadone is highly bound to A-1 glycoprotein. A precipitous drop in glycoprotein production, secondary to his liver disease, led to an abrupt rise in free methadone, causing respiratory arrest.

Several drugs, including salicylate (in overdose), alcohol, and possibly some hydrazines and other drugs that are metabolised by acetylation have saturable elimination kinetics. With these drugs, capacity-limited elimination is complicated further by their low therapeutic index. A good example is phenytoin. A 50% increase in the dose of phenytoin can result in a 600% increase in the steady-state blood concentration and thus expose the patient to potential toxicity.

The combined effect of all of these factors is to make the task of interpreting analytical results even more difficult. Pharmacokinetic and toxicological data, such as those given in the monograph section of this book, must be used circumspectly. When a specific case is being examined there is always the possibility of misinterpretation if consideration is not given to the special circumstances of the case and the other factors discussed above.

Use of pharmacokinetics to predict time and dose

Toxicologists are often asked to use pharmacokinetic data to estimate the time since last administration and dose, but this question can be extremely difficult to answer. The reasons derive from information discussed in previous sections: the large, if not enormous, inter-individual variability, possible effects of disease states and injuries, possible effects of other drugs, frequency of use, and assumptions made about the route of administration.

Estimating the time after administration

In any situation involving the production of a legal opinion or report it is important to establish the known relevant facts. To estimate the time of ingestion it is necessary to determine the likely route of ingestion, and that can be done only by investigating the circumstances of the case, combined with any clinical or pathological data, knowledge about the physiological state of the person, and their relevant personal characteristics (weight, age and sex). Even then, under most circumstances, all that can be determined with any degree of accuracy are the likely minimum and maximum time boundaries.

One of the most useful tests in the assessment of fatal poisonings is the measurement of gastric contents and, if possible, bowel contents. The test is easily performed but must include the whole contents in order to be useful, and must show a mass amount, e.g. milligrams of drug found in the contents. The presence of substantial drug relevant to the dosage form probably indicates oral consumption and, if present in the gastric contents, relatively recent ingestion, i.e. within a few hours.

Care is needed not to over-interpret these data, since coma and certain other physiological states can lead to reduced gut motility, substantially delaying gastric emptying time and prolonging drug absorption time from the bowel. Furthermore, most drugs are excreted into bile and may be present in measurable amounts in gastric and bowel contents even after intravenous injection. For example, morphine biliary concentrations are some 20- to 100-fold higher than blood concentrations. As a consequence, milligram amounts of morphine and its conjugates may be excreted into the bowel.

Another way to assess recency of drug use is by measuring the amount of drug in the urine. This is a very useful test in cases of diamorphine overdose when death has occurred soon after injection. In such cases morphine will be present in the blood, but little or no morphine will be present in urine (<1 mg/L of total morphine). The absence of morphine in the urine indicates that death occurred within several minutes of injection, before renal excretion of morphine could occur. It is important to realise that the absence of drug in urine also indicates that there was no use of this drug in the day or two prior to the most recent dose. However, if the drug was used a day or two before death, it will be present in urine, even if death did occur very rapidly after the last dose. Despite these limitations, this test can be useful in a proportion of diamorphine deaths.

When a drug is rapidly metabolised, the relationship between time of ingestion and drug or metabolite concentrations can help to indicate whether the drug was taken recently or in the more distant past. Diamorphine is rapidly metabolised to morphine via 6-acetylmorphine, followed by a second deacetylation to yield morphine. The first step occurs in less than 5 minutes after injection, the second within 20 minutes or so. However, the half-life of 6-acetylmorphine is quite short. If survival is prolonged following intravenous injection, neither diamorphine nor 6-acetylmorphine will be detected in postmortem tissues. Thus, even if only traces of 6-acetylmorphine are detected in a postmortem sample of blood, it can only be because intravenous diamorphine was administered in the very recent past, or, alternatively, a massive dose was administered. No matter how rapidly death occurs, diamorphine itself is rarely detected because of the hydrolytic action of the plasma esterases.

When metabolism is extensive, and when drug and/or metabolite concentrations in the blood are very low, it can be profitable to determine the urinary concentrations of excretion products. For example, diazepam is metabolised either by *N*-demethylation to desmethyldiazepam (nordiazepam or nordazepam), which then undergoes 3-hydroxylation to yield oxazepam, or by hydroxylation to temazepam (*N*-methyloxazepam), which is then demethylated to oxazepam. All the urinary metabolites appear as their glucuronides.

After administration of a single oral dose of diazepam, the concentration of desmethyldiazepam in the urine reaches a maximum 6–12 h after ingestion, the temazepam concentration reaches its maximum after 12–24 h, and the oxazepam concentration reaches a maximum after 1–3 days. From the second day, oxazepam is the major urinary metabolite. Up to 24 h after ingestion, the oxazepam : desmethyldiazepam concentration ratio is 1 or less, with a corresponding oxazepam : temazepam ratio of less than 0.7. Beyond 24 h, the ratios cover a wider range of times, and estimates of the time since ingestion can be made only by comparing metabolite : metabolite ratios with absolute metabolite concentrations.

The blood concentration of free morphine also correlates well with the survival time, at least for the first 24 h. Average blood concentrations of morphine observed in cases where death from circulatory shock and respiratory arrest occur less than 3 h after administration are 3–10 times greater than those seen after deaths following prolonged coma (3–24 h).

Cannabis provides a similar example. The detection of Δ^9-tetrahydrocannabinol (THC) in blood ($>2\,\mu$g/L) indicates very recent use of the drug (within 8 h). Further, the concentrations of 11-nor-Δ^9-tetrahydrocannabinol-9-carboxylic acid and its glucuronide increase with time, the ratio of the acid to THC increasing to over 50 after about 3 h. This metabolite can be present in blood for several days, whereas the pharmacological effects persist only for a few hours. If acute use of cannabis is known, then pharmacokinetic modelling can be used to estimate time of ingestion (Huestis *et al.* 1992), but only provided that a very short period of time has elapsed since death. THC has the largest volume of distribution of all abused drugs, which means that large amounts accumulate in tissue. As decomposition occurs, THC metabolite, and perhaps even cannabis itself, will inevitably be released from the decomposing tissue. How much will actually reach the blood depends on the sampling site and the method by which the sample

was obtained. The difficulty here is the lack of controlled experiments. The mere detection of 11-nor-Δ^9-tetrahydrocannabinol-9-carboxylic acid does not permit legitimate pharmacokinetic modelling. The question to be resolved is when such calculations are legitimate, particularly in a postmortem setting.

The ratios of drug : metabolite concentrations or the ratio of one metabolite to another can provide a very rough estimate of the time since ingestion. These calculations are relatively meaningless if a drug is very rapidly metabolised (as is the case with diamorphine, cocaine and cannabis), because only very low blood concentrations of metabolites are present a short time after a single dose. Consequently, a relatively high drug : metabolite ratio can be expected in cases of very rapid death following acute overdose. Conversely, the presence of significant amounts of metabolite indicates that sufficient time has existed for metabolism to occur.

When dealing with postmortem tissue it is important to realise that the ratio of parent compound to metabolite is meaningless if the parent and metabolite have very different volumes of distribution. Cocaine is generally thought to have a V_d of 2–3, but the V_d for benzoylecgonine, when measured in human volunteers, is closer to 1. Thus the blood cocaine concentration cannot be divided by the blood benzoylecgonine level to yield a meaningful estimate about the amount of drug taken or the timing of ingestion. The same situation applies to morphine, which has a V_d more than 10 times higher than its metabolites M3G and M6G. There are known exceptions to this rule.

In fatalities due to misuse of dextropropoxyphene, the postmortem blood concentrations of dextropropoxyphene are generally high compared with those of the major metabolite, norpropoxyphene, the dextropropoxyphene : norpropoxyphene ratio being greater than 5. This indicates that death is relatively rapid (less than 1 h). As survival time is increased, the drug : metabolite concentration ratio decreases. Thus, when an individual survives the initial phase of acute intoxication associated with dextropropoxyphene, the drug : metabolite ratio falls dramatically to less than 0.5 within a few hours of ingestion. Parent drug and measurable metabolites can be useful for many of the antidepressants and benzodiazepines, particularly those undergoing *N*-demethylation, i.e. diazepam and nordiazepam, amitriptyline and nortriptyline.

As well as relating drug and metabolite concentrations in the same biological sample, the concentration of the drug in one tissue can be related to the concentration in another. For example, if a fatality occurs shortly after the oral ingestion of a drug, then the liver : blood concentration ratio is higher than if death had occurred after a more prolonged period. In fact, liver concentrations can be more reliable measures of toxicity than blood concentrations for compounds subject to significant postmortem redistribution – tricyclic antidepressants, dextropropoxyphene, phenothiazines, etc.

Toxicologists are frequently called upon to back extrapolate the amount of drug ingested on the basis of concentrations measured in blood some hours later. This can be done in living persons or in deceased cases, but only with the caveat that any such measurements be made shortly after death. If they are not, postmortem redistribution may well have occurred so that the concentration measured bears little or no relationship to the concentration at the time of death. The time of ingestion can be calculated if a reasonable estimate of half-life is available from the equation:

$$C_x = C_s e^{0.692\Delta T/\text{half-life}} \quad (26.1)$$

where C_x is the concentration required at time ΔT before the measured concentration C_t.

This equation works only if the blood concentration versus time curve is in the elimination part of the pharmacokinetic curve relevant to the half-life of first-order elimination, and of course if the half-life has not been affected by disease, injuries or saturable metabolism. It is advised that a range of likely half-life data be used to indicate a likely range of blood concentrations. This will give a much more realistic estimate than a point calculation (see Table 26.4 for example calculations).

For alcohol, Equation (26.1) does not apply since ethanol elimination is for the most part zero-order, or more accurately obeys Michaelis–Menten kinetics. Michaelis–Menten kinetics is defined by the equation:

$$C_t = K_m R/(V_{max} - R) \quad (26.2)$$

where K_m is a constant equal to the plasma concentration at which the rate is one-half of the maximum, R is the rate of metabolism and V_{max} is the maximum rate of metabolism. In practice, the rate of elimination over most of the blood ethanol concentration (BAC) range can be regarded as 0.15 g/L per h, with a range of 0.10–0.25 g/L per h. Back calculation can be done on the basis of a linear model using the point estimate and the likely extremes.

For example, a BAC of 0.12 g/100 mL (%) is likely to be $4 \times 0.015\%$ higher 4 hours earlier, with a range of 4×0.010 and 4×0.025. This calculates at 0.16% (range 0.14–0.22%). If absorption of alcohol is likely to be still occurring, then up to 1 hour can be subtracted from the estimated elapsed time. Alcoholics will be able to eliminate alcohol faster than 0.015%/hour and in some persons a very high BAC microsomal metabolism of alcohol may also occur. However, this is rarely beyond 0.025%/hour.

As a rule of thumb, one measure of alcohol raises BAC by about 0.015–0.02% in an average person. Hence BAC = number of drinks $\times$ 0.02%. For each hour after the first hour (absorption delay) about 0.015% is eliminated. For more accurate estimates use of the formula is recommended, particularly when more than a few hours is involved and the body weight is well below or above average.

For more details readers are referred to Chapter 4.

Estimating the dose

In some cases the estimation of dose may be helpful to confirm other pieces of evidence or to indicate the possibility of an accidental or suicidal death. As indicated previously, many assumptions need to be made if any realistic calculation is to be performed. Of particular importance is the knowledge of whether a single dose has occurred or multiple doses, and the overall health of the person and time elapsed since last dose. When postmortem specimens have been analysed, redistribution and other artefacts will seriously limit the ability to conduct any dose calculation.

Measurement of a blood concentration may not always allow the differentiation of multiple therapeutic doses from large accidental or suicidal doses. Thus, long half-life drugs such as methadone and thioridazine may show a marked overlap in blood concentrations following multiple doses with those seen in fatal poisonings.

In the same way that drug and metabolite concentrations can be linked to time, they can also be related to dose regimens. Thus, steady-state drug : metabolite concentration ratios are sometimes used to check drug compliance. Also, since the extent of drug metabolism tends to decrease with increasing dose, the ratio of unchanged drug to metabolite will increase with increasing dose. Examination of the relative concentrations of parent drug and its major metabolite(s) in blood,

Table 26.4 Estimation of blood concentration at an earlier time

C_1/C_t[a]	*Half-life (hours)*	*Time difference,* ΔT *(h)*
2.0	2	2
4.0	2	4
1.4	4	2
2.0	4	4
1.2	8	2
1.4	8	4
2.0	8	8

[a]Ratio of concentrations from calculated time to measured time point, i.e. if ratio is 2, then concentration at earlier time is double.

or in other tissues as necessary, can provide useful information about the likely size of the dose given. Thus, an amitriptyline : nortriptyline concentration ratio of less than 2 is consistent with steady-state drug concentrations following administration of therapeutic doses, while a ratio greater than 2 is more consistent with the ingestion of larger, potentially toxic doses.

When a drug is extensively metabolised, large acute doses can result in metabolic profiles significantly different from those seen after therapeutic doses. Thus, following administration of normal single doses of phenylbutazone, the ratio of the blood concentrations of its major metabolites oxyphenbutazone and 3′-hydroxyphenylbutazone may be as high as 10 : 1. In overdose, the pattern of metabolism can be reversed, giving ratios as low as 1 : 5.

Similarly, the metabolic profile of diazepam in urine changes dramatically with dose and the ratio of nordiazepam to oxazepam concentrations can provide useful information regarding the relative size of an ingested dose of the drug. When doses are low, demethylation of diazepam appears to be more important than hydroxylation, while hydroxylation becomes more important at higher doses.

Once interpretation of tissue drug concentrations or drug : metabolite concentration ratios has established that an overdose was or was not administered, the actual amount of drug ingested may be estimated. Ideally, the dose should be determined by measuring the total amount of drug remaining in the body (including any unabsorbed drug in the gastrointestinal tract) and adding to this the amount that has been metabolised and/or excreted. Obviously this is rarely possible. A compromise is usually made by estimating the minimum amount of drug ingested. This can be attempted in a number of ways.

Analytical results may be compared with previously recorded data in fatal cases for which drug doses are known. The next best method is the direct comparison of peripheral blood concentrations with clinical data, i.e. blood concentrations following the administration of therapeutic doses. Finally, in extreme cases drug doses may be estimated using pharmacokinetic data.

The half-life of the drug ($t_{1/2}$) and a reasonable estimate of the time elapsed between administrations and sampling (t), together with the blood concentration (C), allow the calculation of a theoretical drug concentration at time zero (C_0) which, for intravenous administration is

$$\ln C_o = \ln C_t + 0.693t/t_{1/2} \qquad (26.3)$$

This concentration can be used to estimate the dose if the volume of distribution of the drug is known (see earlier), or it may be compared with clinical data as described above.

This pharmacokinetic approach probably gives a better estimate of the actual dose administered since it takes some account of the amount of drug eliminated. However, the use of pharmacokinetic equations should be interpreted with great caution, especially if relatively accurate survival times are not available and if the kinetic characteristics of the drug following administration of large acute doses are significantly different from those observed following therapeutic doses. In reality, elimination rates of drugs following overdose are invariably slower than with normal doses due to saturation of normal metabolic and excretory mechanisms, or even drug-induced reduction in physiological state. If these formulae are applied it is advised to use a range of likely pharmacokinetic parameters to estimate a possible range of doses, rather than relying on a point estimate.

Some of these problems can be overcome in a clinical situation if sufficient samples are available to characterise the terminal elimination kinetics of a drug taken in overdose. However, unless all of the assumptions are clearly detailed and a range of possibilities are considered, estimating a dose in a postmortem situation can be misleading and is not advised.

CHAPTER

27 Paediatric Toxicology

D Reith

Introduction

Children differ significantly from adults in their risk of poisoning, response to poisoning and circumstances of poisoning. That children are not just 'small adults' is demonstrably not just a cliché. Children form a large proportion of the population presenting with poisoning symptoms and about whom poisons information/advice is sought. Despite the large number of exposures, the mortality and morbidity of childhood poisoning are low and it is important that interventions for childhood poisoning do not confer greater risks than the exposure. There are some noteworthy issues in childhood poisoning, such as intentional poisoning by a third party and suicidality in adolescents. In addition, there are differences in the disposition of drugs and toxins in children compared with adults and also in the response to poisoning, hence the need to address children as a subpopulation with this chapter.

There are a number of stages in childhood and the clinical priorities differ depending upon the stage. These stages are represented by pre-term neonates, term neonates, infants, young children and adolescents. They are recognised by the International Conference for Harmonisation (ICH) in their recommendations for drug development in children in the following age categories: term newborn infants (0–27 days), infants/toddlers (28 days to 23 months), children (2–11 years) and adolescents (12–16/18 years) (ICH 2000). In clinical practice, pre-term infants form an additional grouping. In pre-term neonates, there are specific issues relating to dermal exposures (due to a thin stratum corneum) and to preservatives in medicines and infusion solutions. In term neonates, the primary issues are the toxicity of therapeutic medicines (e.g. aminoglycosides). In infants/toddlers the issues are exploratory ingestions of household medicines and chemicals. In children, the issues are intentional poisoning by a third party, aberrant behaviour and exploratory ingestions. In adolescents the issues relate to self-harm and substance abuse. Some specific examples of how paediatric toxicology differs from adult toxicology are given below.

Neonatal dermal toxicity

A 2-week-old male pre-term neonate developed skin pustules that appeared to be staphylococcal. In addition to oral antibiotics, he was treated with daily baths using an antibacterial skin preparation as soap. At the end of a 1-week period he was noted to have increasing episodes of apnoea. Hospital staff questioned whether the infant might have developed toxicity from dermal absorption of the antibacterial compound.

In the 1960s and early 1970s hexachlorophene was used routinely as a total body bath in newborn nurseries in order to prevent staphylococcal sepsis. Examination of postmortem specimens from patients under the age of 5 years found vacuolar encephalopathy (distinct vacuoles in the reticular system, predominantly involving the medulla in children who had been born prematurely and the mesencephalic reticular formation in children) (Shuman *et al.* 1974). These findings were similar to those in experimental animals exposed to toxic amounts of hexachlorophene. The vacuolar encephalopathy was related to the number of whole-body baths with hexachlorophene and to prematurity. It was estimated that two or more total-body baths would be required for a premature neonate to develop toxicity. Newborn infants bathed daily with 3% hexachlorophene had blood levels at discharge of 0.009–0.646 mg/L, while blood levels of 0.985–1.48 mg/L were associated with brain injury in rats (Lockhart, Simmons 1973). Seizures were also described in burn patients who had had extensive washing with hexachlorophene.

Infant: poisoning from breast milk

Cocaine

In temporal relation to maternal intranasal cocaine use, a breast-fed 2-week-old female infant developed irritability, vomiting, diarrhoea and pupillary dilatation. On examination the infant was noted to be tremulous, irritable, frequently startling, with a resting heart rate of 130–160 beats/min and a systolic blood pressure of 96 mmHg. Respiratory rate was 36 breaths/min and rectal temperature was 37.4°C. At discharge, the infant's heart rate was 128 beats/min, respiratory rate was 36 breaths/min and systolic blood pressure was 80 mmHg. Cocaine and benzoylecgonine were detected in breast milk and in the infant's urine.

Cocaine has been detected in breast milk at concentrations greater than 12 mg/L. A breast-fed neonate's fluid requirement is in the range 120–180 mL/kg per day. This would result in a daily oral dose to the neonate of approximately 1.8 mg/kg per day. In adults, the estimated minimum lethal dose is 1.2 g, but susceptible persons have died from doses as small as 30 mg when applied to mucous membranes (see the monograph on Cocaine). Hence significant exposure to cocaine can occur through breast milk. Cocaine is metabolised by hepatic and serum esterases and hepatic mixed-function oxidases. There are few data available to determine whether neonatal pharmacokinetics differ from adults. It is therefore not possible to determine whether accumulation may occur.

Codeine

A full-term healthy male infant showed signs of poor feeding and lethargy from day 7 (Koren *et al.* 2006). By day 12 the infant was noted to have grey skin and reduced intake. The infant was found dead on day 13. The postmortem blood concentration of morphine was 70 µg/L. The mother had been taking 30 mg codeine and 500 mg paracetamol for episiotomy pain, initially 2 tablets every 12 h, reduced to 1 tablet every 12 h from day 2 and continued for 2 weeks. The concentration of morphine in her breast milk was measured as 87 µg/L, the typical range normally being 1.9–20.5 µg/L at doses of 60 mg every 6 h. Genotype analysis of the cytochrome P450 enzymes (CYP) demonstrated that the mother was an ultra-rapid metaboliser of codeine to morphine (CYP2D6*2A with CYP2D6*2x2 duplication). It was proposed that the infant died from opioid toxicity because of a reduced capacity for neonates to eliminate morphine.

This case report stimulated some discussion in the literature (Bateman *et al.* 2008). It was suggested that, even if the entire maternal dose of codeine had been converted to morphine, the dose of morphine from breast milk would not have been toxic to the neonate. It was also pointed out that the infant's postmortem blood concentration of paracetamol was 5.9 mg/L and the infant's stomach contained both high levels of morphine and low levels of paracetamol. Hence there were some inconsistencies in the data that could be interpreted as indicating administration of codeine and paracetamol to the neonate. The authors responded, attributing the high blood paracetamol concentration to postmortem redistribution, and stating that the neonate is more sensitive to the respiratory depressant effects of morphine than an adult. The

plasma concentration, corresponding to 0.07 mg/L, is lower than previously reported fatalities in opioid-naive subjects (see monograph on Morphine), but an increased susceptibility for neonates to the respiratory suppressant effects of opioids would account for this discrepancy.

Most drugs are transferred to some degree into breast milk, but for the majority of agents the exposure of the breast-feeding neonate is minimal. Some agents that should be avoided during breast feeding include cytotoxic drugs (cyclophosphamide, ciclosporin, doxorubicin and methotrexate), drugs of abuse (amfetamine, cocaine, diamorphine, cannabis, phencyclidine) and radioactive compounds (American Academy of Pediatrics Committee on Drugs 2001). More complete information can be found in *Drugs in Pregnancy and Lactation* (Briggs *et al.* 2008).

Infant: poisoning from contaminated milk formula

In late 2008 it was reported that in China over 6000 infants became unwell following exposure to melamine in an infant formula. Four infants died and over 1200 required hospitalisation. The melamine had been added to the infant feeding formula in order to increase the measures of protein concentration in the formula.

Melamine causes the formation of renal calculi, which can result in urinary tract obstruction and renal failure. In infants this may manifest as crying, distress when urinating, haematuria, vomiting and failure to thrive. In animal models, the histological features include renal distal tubular lesions with polarisable crystals and striations in the distal tubules and collecting duct, inflammation and interstitial fibrosis. Acute exposure does not appear to be harmful, and trace amounts of melamine are common in some processed foods. However, chronic exposure to larger concentrations is harmful. The occurrence of widespread melamine poisoning in the infants in China highlights the importance of developing food safety standards and their monitoring and enforcement. The freeing up of trade between countries may also contribute to a lessening of food safety standards and spread of such incidents to other countries.

Toddler: caustic ingestion

A 20-month-old male infant was presented to an accident and emergency department after ingesting liquid dishwasher detergent. While briefly unobserved, he had managed to drink some of the substance while the dishwasher was being loaded. On presentation, the child was drooling and was refusing oral intake. On examination, there was some swelling of the lower lip and erythema of the tongue. The child was admitted to hospital and treated with dexamethasone, omeprazole, IV ceftriaxone and IV fluids. An oesophagoscopy was performed at 48 h and there was non-circumferential erythema, sloughing and ulceration of the mid-oesophagus. At the 6-month review, the child was described as having difficulty swallowing. A stricture was found at oesophagoscopy and dilatation of the stricture was performed.

Caustic and acidic ingestions where the pH of the substance is >12 or <2 are a significant cause of morbidity in young children. At oesophagoscopy, around 50% of cases have mucosal injury, and 10% have long-term sequelae such as oesophageal strictures. The most commonly ingested agents are dishwasher dish-cleaning agents, whether in liquid or powder form, as well as oven cleaners, degreasers and drain cleaners. These agents are commonly present in the home and require safe storage in conjunction with child-resistant packaging. Children commonly ingest those substances that are most easily available in the home, such as household chemicals and over-the-counter medicines (Reith *et al.* 2001).

Adolescent: beta-blocker

A 13-year-old girl presented to an emergency department 2 h after ingesting 4 g of propranolol. The propranolol was her own medicine, which had been prescribed for migraine headaches. On presentation, her heart rate was 25 beats/min and her systolic blood pressure was 60 mmHg. In the ambulance on the way to the hospital she had a generalised tonic–clonic seizure lasting for 5 min and on arrival her Glasgow Coma Scale score was 10. Shortly after arrival she had an asystolic cardiac arrest and did not respond to cardiopulmonary resuscitation. At postmortem examination her serum propranolol concentration was 3.8 mg/L and her liver propranolol content was 50 mg/kg.

Propranolol appears to have relatively greater toxicity than other beta-blockers, perhaps related to its potential to cause seizures in overdose, in addition to its cardiotoxicity (Reith *et al.* 1996). It is also prescribed for a younger age group than other beta-blockers because of its use as a preventer for migraine headaches. Headaches may be an indicator of stress, and therefore propranolol may be prescribed to an at-risk group to a greater extent than other beta-blockers.

The interpretation of laboratory data in adolescents is similar to that in adults. During adolescence, developmental differences in toxin disposition are on the basis of body size rather than organ maturation. The postmortem blood and organ concentrations of propranolol in the present case are in the same order as those of previously reported fatalities attributed to propranolol.

Exposures in adolescents predominantly relate to risk-taking behaviours and psychiatric morbidity. Adolescents tend to take their own medications, or household medicines, in overdose, and tend not to plan and obtain a poison on the basis of lethality. Of adolescents presenting with self-poisoning, 9% will re-present with poison exposure within 1 year of initial presentation and 16% within 5 years (Reith *et al.* 2003b). The mortality rate from poisoning in the 10- to 14-year age group is 1.20 : 100 000 per year, which is around 1 per 50 presentations. After an initial presentation with self-poisoning, overall 4% will die within 10 years and 2% will commit suicide within 10 years (Reith *et al.* 2003c). Hence, poison exposures in adolescents have greater mortality and morbidity than those in younger children because of higher doses and greater toxicity. In addition, an increasing severity of subsequent re-exposure is a marker of increased risk for subsequent suicide (Carter *et al.* 2005). Hence, there is an opportunity for psychiatric intervention whenever an adolescent presents with self-poisoning. This is not restricted to cases of deliberate self-harm, because overdoses with recreational drugs are also risk factors for suicide and accidental death and there may be underlying psychiatric morbidity.

Social aspects of paediatric toxicology

Epidemiology

The epidemiology of paediatric poisoning changes from infancy through to adolescence. The presentation rates with poisoning are highest for children aged 0–4 years at around 700 : 100 000/year, decreasing to 40 : 100 000/year for children aged 5–9 years and 70 : 100 000/year for children aged 10–14 years (Reith *et al.* 2001). These changing presentation rates most likely reflect the different motivations for poisoning in these age groupings. Exposures in the 0- to 4-year age group predominantly represent exploratory ingestions where the child is experimenting with potential food sources or flavours. In the 5- to 9-year age group, exposures represent copying/modelling of adult behaviours, aberrant development or behavioural disorder in the child. Rarely, in these groups, the exposure is intentional by a third party. In adolescents, the exposures represent self-harming behaviour or substance misuse. Admission rates vary between countries, with rates of 184 : 100 000/year for 2 year olds in the USA and 462 : 100 000/year in the UK (Woolf, Lovejoy 1993).

Most commonly, children ingest those agents that are closest to hand rather than seeking out agents on the basis of toxicity. Hence, the substances most commonly ingested by children include paracetamol, rodenticides, cough and cold preparations, pesticides and household chemicals (Reith *et al.* 2001). In developing countries, kerosene and plant poisonings are more common than medicinal poisonings. The agents resulting in death from poisoning are more commonly opioids, iron preparations, cardiotoxic drugs such as chloroquine and tricyclics, and, in coronial data, carbon monoxide.

Intentional poisoning of children

In Australia, in the 10-year period 1983–1992 for the 0- to 4-year age group there were 32 accidental deaths from poisoning and 12 homicides by poisoning. However, over the same time period in the 5- to 9-year age

group there were 3 accidental deaths from poisoning and 11 homicides by poisoning. The decrease in accidental poisonings in the older age group reflects the decreased rate of poisons exposures with age, due to increasing maturity and awareness of hazards, but the similar number of homicidal poisoning deaths indicates that the risk of intentional poisoning in children does not decrease with age.

Poisoning is an unusual cause of death in child victims of homicide (Vanamo *et al.* 2001). Head and neck injuries, suffocation and drowning are more common causes of death in intrafamilial child homicide.

Poisoning should also be considered in the investigation of apparent life-threatening events in children (Pitetti *et al.* 2008). In children under 2 years of age presenting with an apparent life-threatening event, 274 of 596 underwent toxicology testing, of whom 50 (18.2%) were positive for drugs other than the child's known medications, and 23 (8.4%) were considered clinically significant (Pitetti *et al.* 2008). Thirteen (4.7%) were positive for medications contained in over-the-counter cough and cold preparations (Pitetti *et al.* 2008).

Illness induced by poisoning in children is a rare but potentially serious presentation (Dine, McGovern 1982; McClure *et al.* 1996). There is a high mortality rate and, in around 30% of cases, the poisoning continues while the child is in a healthcare facility (Dine, McGovern 1982). The most common drugs used are anticonvulsants and opiates (McClure *et al.* 1996). Covert video surveillance may be useful in establishing the diagnosis but must be performed with regard to the local ethical and legal framework (Southall *et al.* 1997). Evidence of other injuries is present in only 20% of cases (Dine, McGovern 1982). It is important to consider the plausibility of the history of the poisons exposure in the context of the child's developmental stage: for example, could a 6 month old access a medicine or chemical?

Munchausen by proxy is a term first used by Roy Meadow in 1977 to describe a condition in which parents fabricate illness in their child for secondary gain (Meadow 1989). The condition may lead to serious illness or even death in the child as a consequence of the parents' actions. The term fell into disrepute following a General Medical Council finding that Professor Meadow gave erroneous and misleading evidence during the Sally Clark case. The General Medical Council ruling was later successfully appealed by Professor Meadow. The case against Professor Meadow was partly based on findings from Carpenter *et al.* (2005), which were themselves controversial because of potential bias in the classification of data (Carpenter *et al.* 2005; Gornall 2006). As a consequence, descriptive terms such as 'factitious', 'fabricated' and 'induced' might be more useful and accurate when describing symptoms and signs attributed to cases in which the medical condition may have been caused intentionally by a caregiver.

Diphenhydramine

In response to an emergency call, paramedics found a 5-year-old boy who had stopped breathing and who did not respond to resuscitation efforts. The paramedics noted marks on the child's wrists, ankles and feet that indicated that he had been tied up and burned, and they reported these findings to the police. A postmortem revealed a skull fracture and toxicology tests demonstrated a serum diphenhydramine level of 0.02 mg/L and diphenylmethoxyacetic acid of 1.6 mg/L from blood collected from the heart. The defendants claimed that the boy had autism and frequently threw temper tantrums with head banging. He had been tied up and burned as a punishment. The diphenhydramine had been administered so that he would sleep through the night.

The toxicologist may be asked to comment on the contribution of a poison to the cause of death. Serum concentrations of diphenhydramine in fatal cases range from 0.3 μg/mL to 119 μg/mL (Pragst *et al.* 2006). Diphenhydramine acts as a sedative at serum levels below 0.7 mg/L, and at serum concentrations above this level anticholinergic symptoms become more dominant with delirium, tachycardia and hypertension progressing to seizures and coma as plasma concentrations increase (Pragst *et al.* 2006). Diphenhydramine undergoes extensive biotransformation and the ratio of parent to metabolites may give some indication to the timing of exposure prior to death. In particular, the ratio of diphenhydramine to one of its metabolites, diphenylmethoxyacetic acid, can be used as an indicator of the time between ingestion and sampling or death. The ratio of diphenylmethoxyacetic acid to diphenhydramine increases from 0.5, prior to 5 h post ingestion, to greater than 20 after 40 h or more post ingestion (Pragst *et al.* 2006). In addition there is also extensive redistribution of diphenhydramine *post mortem*, with higher concentrations found in the heart blood than in peripheral blood (Pragst *et al.* 2006). In the above case, the ratio of diphenylmethoxyacetic acid to diphenhydramine of 80 would indicate ingestion of diphenhydramine at least 48 h prior to death. Hence the intoxication would be expected to have had a minor contribution to the child's death.

Iron

A 7-week-old male infant presented with grunting, tachypnoea and abdominal distension. Physical examination indicated dehydration and he was treated with 2 × 20 mL/kg boluses of normal saline (Black, Zenel 2003). Arterial blood gases demonstrated a metabolic acidosis with a pH of 7.09, P_{CO_2} of 32 and base deficit of −19.6. The metabolic acidosis persisted over the next few days, and in addition he developed elevations in serum transaminases (aspartate aminotransferase (AST) 1603 U/L, alanine aminotransferase (ALT) 1600 U/L) and in serum creatinine (12 mg/L). His mother was noted to be detached from the child, and investigation for physical abuse was performed. A skeletal survey and bone scan showed a posterolateral rib fracture. His mother admitted administering Formula 409 (containing 0.3% alkyldimethylbenzylammonium chloride) and crushed iron tablets to the infant. The iron level at 36 h after admission was 55 μmol/L.

Iron is one of the commonest causes of poisoning death in children but in most cases this is due to accidental exposure. In this case, the child was too young to be able to access the poison on his own and the iron must have been administered to the child. Rib fractures in a child of this age are a major indicator of non-accidental injury. Hence, the iron was administered with the intent of causing injury.

Iron is toxic from doses of greater than 20 mg/kg elemental iron (approximately 3–4 standard iron supplement tablets), and lethal from doses of 180 mg/kg (from approximately 26 tablets). Iron tablets are often attractively presented and may be present in large quantities in households with young families because of the push for iron supplementation in pregnancy. With significant exposures, initial signs and symptoms include vomiting, haemorrhagic gastritis, diarrhoea, lethargy and coma. This may be followed by a quiescent phase for 2–12 h when there may be deceptive improvement. There may be recurrence of symptoms from 12 h to 48 h, including haematemesis, melaena, gut perforation, lethargy, coma, convulsions, vasomotor collapse, pulmonary oedema, hepatorenal failure, coagulopathy and hypoglycaemia. In the case presented above, the co-ingestion of alkyldimethylbenzylammonium chloride may have contributed to the metabolic acidosis and elevation in liver enzymes. Serum iron concentrations are normally 0–18 μmol/L, possibly toxic at 18–63 μmol/L, potentially serious at 63–90 μmol/L, definitely serious at 90–180 μmol/L and potentially fatal above 180 μmol/L. Other abnormal laboratory tests results may include elevated white cell count, decreased blood sugar levels, coagulopathy, and elevated serum transaminases and creatinine.

Medical euthanasia: Dr Arthur Case

In 1980 a neonate was born with Down syndrome and was treated at Derbyshire Children's Hospital in the UK. In addition to Down syndrome the neonate may also have had an intestinal malformation and congenital heart malformations. At the request of the child's parents the treating doctor, Dr Leonard Arthur, ordered 'nursing care only'. The child died at 60 h of age after being given only water (with no other nutrition) and dihydrocodeine. A colleague reported Dr Arthur's actions to the police and he was charged with murder. The possibility of congenital heart disease resulted in the charge being changed to attempted murder. The jury found Dr Arthur not guilty.

The case confirmed the principle, previously established in the case of Dr John Bodkin Adams, that 'the administration of a drug by a doctor when it is necessary to relieve pain is a proper medical practice even when the doctor knows that the drugs will themselves cause the patient's death'. However, Dr Arthur had admitted that the drug was intended to stop the child seeking sustenance as well as being a sedative. At the time this was thought to be justifiable medical practice by an expert witness.

Subsequently, the British Medical Association (BMA) changed its ethical guidelines 'to ensure that newborn handicapped babies were treated with the same respect as normal children'. Currently the BMA offers guidance that oral nutrition and/or hydration should continue to be offered to *all* patients who are able to swallow (BMA 2009). However, 'where there is a problem with the swallowing mechanism which makes oral feeding very difficult or impossible, ... careful thought should be given to whether artificial feeding should be provided or continued'. Such cases may include those where a person has 'no or very minimal awareness of their own existence or surroundings, no ability to interact at any level and no chance of regaining any awareness'. However, with regard to euthanasia, the BMA insists that 'voluntary euthanasia should not be made legal in the UK'. The differentiation between euthanasia and withholding artificial feeding would appear to be the use of drugs in order to cause death.

Victims of chemical warfare; the Holocaust

Children are also disproportionately victims of genocide and chemical warfare (Austin 1996). An estimated 1.5 million children were murdered during the Holocaust. Children were particularly vulnerable because of their low economic value (i.e. they could not be used as forced labour). More recently, in 1988, the use of chemical warfare agents in the town of Halabja in Iraqi Kurdistan resulted in the deaths of around 5000 civilians, many (75%) of them women and children, and injury to more than 10 000 (Hawrami, Ibrahim 2004).

Exploratory ingestions

Exploratory ingestions are characterised by a small dose and lower risk of morbidity and mortality. The mortality rate for the 0- to 4-year age group is around 0.82 : 100 000/year, which is around 1/1000 presentations. The agents ingested are predominantly household medications and chemicals: paracetamol, rodenticides, cough/cold preparations, pesticides and chemicals. A lessening in morbidity and mortality has been associated with a decrease in the toxicity of generally available medicines and household chemicals and also with efforts to restrict access by young children. A smaller number of agents are responsible for mortality, such as opioids, strychnine, iron, tricyclics, propranolol and chloroquine. Hence, given the large number of low-risk exposures, management should be based upon a risk assessment, and decontamination and other possibly hazardous interventions should be restricted to those patients at a defined risk of morbidity and/or mortality from the exposure. Following a poisons exposure, or indeed any serious household accident, a hazard assessment of the child's home/environment could be offered.

Lead

A 4-year-old girl presented to hospital 6 days after her mother noted lead pellets in the family toilet bowl that were also seen over the subsequent 2 days. On questioning, the child admitted swallowing lead pellets from her father's skin-diving weightbelt. A store of such pellets was found in her bedside drawer. She had symptoms of mild intermittent abdominal pain and had vomited once. She was taken to her local general practitioner, who measured her blood lead level as 4.8 μmol/L (990 μg/L). An abdominal radiograph was taken that demonstrated seven lead pellets. The child was admitted to hospital, for treatment with PEG-ELS 4 L over 4 h, dimercaprol (75 mg/m^2 by IM injection 4-hourly for 2 days), calcium disodium EDTA 1500 mg/m^2 daily as an IV infusion, Senokot and Agarol. Her blood lead levels on days 6, 22, 42 and 117 after the initiation of treatment were 2.42, 2.37, 2.17 and 1.86 μmol/L (500, 490, 450 and 390 μg/L), respectively. An abdominal radiograph after 6 days demonstrated four pellets that were subsequently passed. She remained well and there were no observed adverse effects (Reith *et al.* 2003a).

There are a number of sources of lead exposure for children. These include lead-based paint (from flaking and renovation of lead-based paint in old houses), lead weights and sinkers, lead-based paint on toys, parents bringing home lead on clothes from occupational exposure, environmental exposure from lead smelters and contaminated soil, cosmetics and pottery glazes. Lead absorption is increased in the presence of iron deficiency. Children with pica are at increased risk of lead poisoning.

Lead is not an element essential to humans and ideally there should be no lead in the body. However, blood lead concentrations less than 0.48 μmol/L (100 μg/L) are considered acceptable. Lead abatement measures should be performed for blood lead concentrations greater than 0.72 μmol/L (150 μg/L) and, if the patient is symptomatic at concentrations greater than 1.20 μmol/L (250 μg/L), chelation should be performed. Chelation should be performed in all patients with blood lead concentrations greater than 2.40 μmol/L (500 μg/L). It is important that the patient be removed from all sources of lead exposure during chelation otherwise absorption of lead may be increased.

Self-harm/substance misuse

The patterns of substance abuse in children and adolescents are slightly different from those in adults: abuse of volatile agents (hydrocarbons/glues) is more common in children and adolescents, and also agents such as *Datura* (anticholinergic). Lead poisoning can result from inhalation of leaded petrol. Nicotine and ethanol use can occur from childhood, with cannabis, amfetamine and opioid abuse becoming more common in late adolescence. A particular issue arises when a naive opioid user is exposed to a dose intended for a habituated user, resulting in overdose and delay in seeking treatment. Methadone is a particular hazard because of delay in the maximum effect and resulting progressive, greatly reduced level of consciousness. There are legal issues with regard to supply of illicit drugs to minors.

Methadone

A 4-year-old boy was found unresponsive by his mother after he had been sleeping on a sofa for several hours. Resuscitation was performed immediately by his mother but following transportation to the local hospital he was pronounced dead on arrival. His blood and liver methadone concentrations were 0.6 mg/L and 1.6 mg/L respectively. His blood and liver EDDP (2-ethylidene-1,5-dimethyl-3,3-diphenylpyrrolidine, the main metabolite of methadone) levels were 0.09 mg/L and 0.4 mg/L respectively. It was subsequently reported that the child's grandmother was a nurse in a methadone clinic who often stole methadone to take home and sell. The night before the child died a cup containing 40 mg methadone dissolved in orange juice had been left on the dining table (Li *et al.* 2000).

Postmortem methadone concentrations can vary by 100% between samples collected from different sites, implying postmortem redistribution (Milroy, Forrest 2000). Blood methadone concentrations in children who have died consequent to methadone intoxication have been in the range 110–489 μg/L, which is within the range of methadone concentrations reported for adults in methadone maintenance programmes (Milroy, Forrest 2000). This is because of the tolerance that develops with long-term opioid exposure when patients on methadone maintenance programmes may be treated with daily doses well in excess of fatal doses for opioid-naive subjects. For example, methadone doses up to 100 mg per day are commonly used in methadone maintenance programmes. Methadone is equipotent with morphine and a dose of 100 mg morphine to a 14 kg child would be around 70 times the usual dose for that child (if they were in severe pain). A large proportion of dispensed methadone is in liquid form (Milroy, Forrest 2000). These formulations are relatively palatable and easy to ingest. Hence, naive users and children are at greater risk of fatality.

Methadone poisoning in children has high mortality and morbidity. The presentation is similar to that for adult opioid intoxication, with respiratory and central nervous system (CNS) depression, miosis, hypotension and hypoxia (Binchy *et al.* 1994). It is not uncommon for the patient to present with no history of ingestion. The pharmacodynamics differ in some respects in children: in children hyperglycaemia has been reported in association with methadone poisoning (Tiras *et al.* 2006). Children may also be more sensitive to the respiratory depressant effects of opioids.

The ratio of methadone to EDDP concentrations may be used to discriminate between acute ingestion (opioid naive) and chronic ingestion (opioid dependent) (Li *et al.* 2000).

Medication error

Cases of medical misadventure tend not to be published in the literature because of the medicolegal implications. The following fictional case study is therefore being used illustratively.

An 8-month-old infant with a history of complex congenital heart disease presents to a suburban hospital with supraventricular tachycardia. The arrhythmia had previously responded to verapamil, but this had been ceased 1 month previously. The junior doctor on duty at the suburban hospital discusses the patient with a paediatric cardiologist at a tertiary referral centre. The paediatric cardiologist subsequently states the advice given was to treat the patient with IV verapamil at a dose of 0.2 mg/kg. The patient was prescribed IV verapamil at a dose of 2 mg/kg, a total dose of 10 mg, by the junior doctor. The dose was questioned by nursing staff, but they were reassured by the statement that this was what the paediatric cardiologist had recommended. The drug was administered by the junior doctor with continuous electrocardiogram (ECG) monitoring. The patient subsequently reverts from supraventricular tachycardia (SVT) to sinus rhythm but then develops complete heart block, atrioventricular (AV) dissociation and bradycardia. This progresses to asystolic cardiac arrest and death despite cardiorespiratory support.

The case highlights a number of safety issues in the process of prescribing for children. First, dosing errors are common and potentially serious. The 10-fold dosing error is the commonest dosing error in the paediatric population (Wong *et al.* 2004). Second, there are particular hazards in the use of phone orders and in remembering drug doses for children. Phone orders should be recorded by two people, in order to avoid errors in the transmission and transcription of the order. Drug doses, unless for familiar/everyday drugs, should be checked against a printed formulary, such as the *BNF for Children* (Paediatric Formulary Committee, 2009). Ultimately, the prescription is the responsibility of the prescriber and doses given by phone order, or remembered by colleagues, even if senior, should always be checked. However, a supervisor also has the responsibility of overseeing the work of junior doctors and ensuring that standards are met.

Another issue demonstrated by the case is that of ameliorability. Once an error has been made, can steps be taken to ameliorate the effects of the error? In the case of verapamil poisoning there may be treatments available, such as IV calcium or even short-term cardiopulmonary bypass. If a medication error is identified, it is also important to treat the adverse effects promptly.

Injuries resulting from errors in the prescribing or administering of medicines to children (adverse drug events, ADEs) are common and occur at similar rate as in adults. Events where injury could have occurred as a result of medication error (but fortuitously did not) – potential ADEs – appear to be more frequent in children than in adults (Kaushal *et al.* 2001). In a hospitalised, paediatric, patient population, ADEs occurred at a rate of 0.24–2.1 per 100 medication orders, 2.3–12.9 per 100 admissions and 6.6–22.1 per 1000 patient-days (Kaushal *et al.* 2001; Holdsworth *et al.* 2003; Kunac *et al.* 2009). Potential ADEs occurred at a rate of 1.1–2.4 per 100 medication orders, 8–14.6 per 100 admissions and 9.3–29 per 1000 patient-days (Kaushal *et al.* 2001; Holdsworth *et al.* 2003; Kunac *et al.* 2009). The incidence of ADEs and potential ADEs is higher in an intensive care population, 7.9 and 12.2% respectively, than in a general paediatric population, 5.1 and 4.6% respectively (Holdsworth *et al.* 2003). Differences between studies in the rates of ADEs and potential ADEs can to some extent be accounted for by differences in the methodology used in ascertainment and classification (Kaushal *et al.* 2001; Morimoto *et al.* 2004; Kunac *et al.* 2009).

Medication errors in children can result in mortality, morbidity and additional costs to the healthcare system. From 8% to 11% of ADEs are fatal or life threatening, 13–35% are serious and 58–76% are significant (Kaushal *et al.* 2001; Holdsworth *et al.* 2003). Of potential ADEs, 0–16% are potentially fatal or life threatening, 5–45% are serious and 39–95% are significant (Kaushal *et al.* 2001; Holdsworth *et al.* 2003). However, although ADEs and potential ADEs are known to contribute to the overall costs of healthcare, there are few published data quantifying these costs in the paediatric population. In an adult population, the cost of an ADE occurring during a hospital admission is in the range US$2013–3244 and is associated with an additional length of stay of 2.2 days, with preventable ADEs having a greater unit cost of US$5857 and an additional length of stay of 4.6 days (Bates *et al.* 1997; Classen *et al.* 1997; Senst *et al.* 2001). For hospitalised children in New Zealand, the cost of a preventable ADE is NZD900 (Kunac *et al.* 2009).

Paracetamol

Master W., a 13-year-old boy with damaged femoral heads, underwent percutaneous insertion of screws into both hips. His weight was 104 kg, height was 166 cm and body mass index (BMI) was 38 (the typical weight for a child of this age and height would be about 50 kg). He received IV morphine, then paracetamol and codeine as required for analgesia. He was then transferred to a small hospital for 4 weeks' strict bed rest. Eleven days post operation, he developed a spiking temperature, nausea and some restlessness. He was given regular paracetamol for analgesia and temperature control. The next day he was started on IV flucloxacillin for a presumed chest infection. Three days later he had a low-grade fever, nausea and vomiting, and right upper quadrant tenderness. Blood was taken for liver function tests. These showed grossly elevated liver enzymes. He continued to receive paracetamol until the next day. In total, he had been given 32 g of paracetamol in a 14-day period. During transfer to a large regional hospital, he was restless and aggressive, requiring IV diazepam for sedation. Upon arrival he was found to have acute fulminating hepatic failure with acute renal failure and hepatic encephalopathy. Later that day, brain death was diagnosed and he died 18 days after his operation. The postmortem examination showed severe fatty change in the liver, consistent with the boy's obesity, and extensive hepatocellular necrosis secondary to acute paracetamol toxicity (Risk Watch 2003).

This case demonstrates a number of features of chronic paracetamol poisoning in a child and raises the issue of appropriate dosing. First, in the case of a child with obesity, dosing should be modified to reflect lean body weight rather than total body weight. Dosing in a child, when based on body weight, should not exceed the adult dose of the drug. Paracetamol should not be continued in a patient when there is evidence of hepatocellular damage. When there are indications of paracetamol toxicity *N*-acetylcysteine should be commenced immediately and continued until either the diagnosis is refuted or there is clinical evidence of improvement.

Chronic paracetamol poisoning poses a greater risk to children than acute paracetamol poisoning. Chronic paracetamol poisoning refers to multiple, cumulative (usually supratherapeutic) doses of paracetamol over several days. This type of poisoning is a particular hazard for younger children, with acute paracetamol poisoning being more common in adolescents (Mahadevan *et al.* 2006). Hepatotoxicity may occur at total doses as low as 90 mg/kg, with fulminant hepatic failure occurring at doses as low as 220 mg/kg (Mahadevan *et al.* 2006). The range of tolerable doses indicates considerable inter-individual variability in the susceptibility to paracetamol hepatotoxicity. This may relate to variability in the metabolism of paracetamol due to inter-individual/pharmacogenetic variability in enzyme kinetics (Reith *et al.* 2009). Such variability could relate to under-expression of uridine glucuronosyltransferase (UGT) and/or sulfotransferase isoforms, or alternatively to over-expression of CYP enzymes (in particular CYP2E1). Glutathione is also required for neutralising the toxic metabolite of paracetamol. Depletion of glutathione as a result of inflammation or poor nutrition may also increase the risk of paracetamol toxicity. Prodromal illness and fasting have been identified as risk factors for chronic paracetamol poisoning in children (Miles *et al.* 1999). Phenobarbital and phenytoin are inducers of the CYP system, and also inhibitors of UGT and would therefore pose a double risk in paracetamol poisoning (Mutlib *et al.* 2006).

Drug and toxin disposition in children

An understanding of how the processes of drug and toxin disposition differ in children compared with adults is important for the clinical management of childhood poisonings and in the interpretation of laboratory data. For example, the estimation of a dose or time of exposure may be made by back-calculating from serum concentrations. Knowledge of paediatric pharmacokinetics is important in making

plausible estimations. In addition, the systemic exposure to a poison will determine the likely clinical effect, and therefore the need for clinical interventions.

The systemic exposure to a toxin, and therefore the subsequent effects of the poison exposure, depends upon the amount absorbed, which in turn depends upon bioavailability. Bioavailability is influenced by binding or metabolism in the gut, metabolism in enterocytes (principally mediated by CYP3A4), transmembrane solute transporters in enterocytes (principally ABCB1) and metabolism in the liver. These processes may differ in children compared with adults, but knowledge of the extent of these differences is incomplete.

In addition there are issues of scaling. Children are smaller than adults, but, because of some physiological differences, cannot simply be considered as 'little adults'. Various methods have been proposed to scale between children and adults, ranging from simple weight-based approaches, to allometric scaling and to physiologically based models. Validation of these different methods depends upon already knowing the pharmacokinetics of the drug in children, and as yet none of these methods has been validated prospectively.

Absorption of drugs

In general, the absorption of xenobiotics in children is similar to that in adults.

Bioavailability

Contributors to first-pass metabolism include CYP3A4, sulfotransferases and P-glycoprotein in enterocytes, in addition to hepatic metabolism of xenobiotics (Chen *et al.* 2003). Enterocyte CYP3A4 expression may be decreased under the age of 6 months, and increased relative to adults around the age of 1 year (Fakhoury *et al.* 2005). This suggests that for drugs with low bioavailability, greater exposure to these drugs occurs in neonates, with lesser exposure in children around the age of 1 year. There are, however, few data on bioavailability in neonates and infants to confirm this.

ABCB1 (P-glycoprotein) expression is variable at all ages. There is some evidence of age-dependent expression of ABCB1 polymorphisms, with bioavailability of ciclosporin appearing to be influenced by polymorphisms over the age of 8 years (Fanta *et al.* 2008). However, in general, the bioavailability of ciclosporin does not appear to be influenced by age in children (Fanta *et al.* 2007).

Volume of distribution

Body composition changes from infancy to adulthood. Infants have a higher proportion of body mass as water, and boys also have a higher proportion of body weight as water than girls (Wells *et al.* 2005). In term infants, total body fat comprises around 15% of body weight in both males and females, increasing to around 25% by 120 days of age, 39% at 6 months and 29% by 14 months of age (Butte *et al.* 2000; Olhager *et al.* 2003; Tennefors, Forsum 2004). At 2 years of age total body fat comprises around 25% of body weight.

However, despite the differences in proportion of body weight as adipose tissue, this does not necessarily translate into differences in pharmacokinetics. Thiopental, which is highly lipid soluble and redistributes to adipose tissue, does not have a different volume of distribution in children compared with adults, although clearance is higher in children (Sorbo *et al.* 1984)

Renal clearance

The kidney clears xenobiotics and their metabolites through glomerular filtration and tubular secretion.

Filtration

The development of glomerular filtration through childhood has been well described. By 36 weeks' gestation the cortical nephrons are formed, but the glomerular filtration rate (GFR) is around 5% of adult values owing to decreased renal blood flow (Haycock 1998). Glomerular filtration rate per unit surface area increases rapidly in the first week after birth, and then increases at a slower rate until it peaks at 3.25 years. From that time, GFR per unit surface area declines at a steady rate throughout childhood, adolescence and adulthood (Wahl *et al.* 2003). Pre-term neonates have decreased GFR in relation to term neonates. Mean GFR per 1.73 m^2 of body surface area is around 20 mL/min at birth, increasing to 50 mL/min in the first week, peaking at 120 mL/min in the third year and decreasing slightly to 115 mL/min in adolescence.

In 2006 the Centers for Disease Control and Prevention in Atlanta, USA (CDC) and National Association of Medical Examiners conducted a review of deaths associated with cough and cold medications in infants aged $\leq$12 months in the year 2005 (CDC 2007) Three deaths in infants aged from 1 month to 6 months were identified. The infants had postmortem blood concentrations of pseudoephedrine ranging from 4.74 mg/L to 7.10 mg/L. Two infants had detectable dextromethorphan in blood: 390 and 1909 µg/L. One infant had a doxylamine blood concentration of 1.00 mg/L. One of the infants had concurrently received a prescription and an over-the-counter medication both of which contained pseudoephedrine. Two of the infants had postmortem findings of pneumonia and the third had findings of acute anoxic encephalopathy and a small fracture of the left distal tibia. During 2004–2005 it was estimated that 1519 children were treated for adverse events associated with cough and cold medications, including overdoses, in US emergency departments.

In general, cough and cold medicines are not indicated for use in children under the age of 2 years. Since 2008 these medicines have been contraindicated in this age group in the USA, Canada, the UK and other regulatory jurisdictions. In 2009 in Canada and the UK, the age limit for cough and cold medicines was increased to 6 years because of lack of data supporting efficacy, and concerns regarding safety.

Pseudoephedrine is a stereoisomer of ephedrine. It is predominantly excreted in the urine, and in adults has a half-life of 5–8 h. Infants have a reduced GFR relative to adults, and therefore reduced ability to clear pseudoephedrine. Hence with repeated dosing accumulation will occur, resulting in elevated blood concentrations of pseudoephedrine and toxicity. However, older children have relatively greater GFRs than adults and an enhanced ability to excrete pseudoephedrine (Table 27.1 gives information on comparative pharmacokinetics of drugs in children of different ages and adults). Dextromethorphan is metabolised by CYP2D6, so that although its half-life is normally 1.2–3.9 h it may be increased to up to 45 h in patients who are poor metabolisers. Neonates also have decreased expression of CYP2D6. Hence in some patients there may also be accumulation of dextromethorphan.

Renal sodium handling matures at a slower rate than GFR, and the infant kidney has reduced ability both to excrete and to retain sodium (Haycock 1998), hence infants are susceptible to both water intoxication and hypernatraemia. Pre-term infants can lose sodium relative to water, with resultant hyponatraemia, because of immature renal tubules, up to a gestation of 35 weeks. Infants are susceptible to salt poisoning as a result of inappropriate reconstitution of formula, the use of undiluted cows' milk or intentional salt poisoning. Water intoxication (hyponatraemia) may also result from dilution of infant formulas.

A male infant presented at 8 months of age with high fever, profuse diarrhoea, exacerbation of vomiting, hypotonia, weight loss and poor perfusion (Coulthard, Haycock 2003). He had been born prematurely at 28 weeks' gestation and had a history of aortic arch and bronchial anomalies and severe gastro-oesophageal reflux. He had been treated with domperidone, a compound alginate preparation (Gaviscon Infant) and feed supplements that contained glucose polymers. At presentation his serum sodium was 156 mmol/L, and his urine osmolality, sodium and creatinine were 961 mmol/kg, 152 mmol/L and 5.5 mmol/L, respectively. At presentation his fractional excretion of water was 1.04% and of sodium was 1.01%; 1.8 h later the values were 0.86 and 0.42, respectively. Administration of IV fluids dramatically improved his condition and restored his body weight.

Coulthard and Haycock (2003) stated that 'the boy was taken into foster care after he was admitted at age 8 months, because doctors believed his biochemistry results confirmed salt poisoning and because his siblings' medical histories were considered suspicious. Three siblings had become hypernatraemic under similar circumstances: one died after remaining at

Table 27.1 Comparative pharmacokinetics of drugs between children of different ages and adults

Drug/age group	*Volume of distribution*	*Clearance*
Midazolam		
Pre-term	Median (range)	Median (range)
	1.1 (0.4–4.2) L/kg	1.8 (0.7–6.7) mL/kg per min
Infants	3.8 L	0.157 L/min (median weight 9.4 kg)
Child	Mean (SD)	Mean (SD)
	1.7 (1.1) L/kg	5.8 (3.5) mL/kg per min
Adult	0.8–1.86 L/kg	4.0–12.2 mL/kg per min
Paracetamol		
Neonates <10 days	Mean (SD)	Mean (SD)
	0.7 (0.2) L/kg	0.149 (0.067) L/kg per h
Neonates >10 days	0.9 (0.1) L/kg	0.365 (0.219) L/kg per h
Children	0.86/0.89 L/kg	0.277/0.383 L/kg per h
Adult	1.29 (0.37) L/kg	0.28 (0.04) L/kg per h
Theophylline		
Neonate	Mean (SD)	Mean (SE)
	0.69 (0.095)	17.6 mL/kg per h
Infant (3–23 months)	0.34 (0.2)	1.07 (0.55) mL/kg per min
Child	0.44 (0.05)	Mean
		56 mL/kg per h
Healthy non-smoking adults	0.44 (0.053) L/kg	47.4 (10.3) mL per min
		0.65 mL/kg per h
Caffeine		
Neonate		$t_{1/2} > 50$ h
Child		$t_{1/2} = 3.5$ h
Adult	0.61 ± 0.02 L/kg	$t_{1/2} = 8$–9 h
		1.4 ± 0.5 mL/min per kg
Pseudoephedrine		
Infant	Data not available	Data not available
Child 2 to <6 years	3.6 (9%) to 4.2 (21%) L/kg (CV%)	11.4 (21%) mL/kg per min
Child 6 to <12 years	2.4 (17%) to 3.5 (20%) L/kg (CV%)	8.5 to 12.7 (17%) mL/kg per min
Adult	2.8 (15%) to 3.7 (17%) L/kg (CV%)	5.2 (26%) to 7.5 (36%) mL/kg per min
Morphine		
Pre-term neonate (24 weeks)	2.7 L/kg	1.5 mL/kg per min
Term neonate	2.7 L/kg	4.8 mL/kg per min
Neonate–2 years	2.7 L/kg	19 mL/kg per min
Adults	3.3 L/kg	24 mL/kg per min

CV coefficient of variation; SD, standard deviation; SE, standard error.

home (on the general practitioner's advice) with pyrexia, explosive diarrhoea and weight loss but without haemorrhagic encephalopathy. In addition, one sister, who was eunatraemic, died suddenly and unexpectedly. The odds of a second innocent death were suggested (incorrectly) to be 73 million to 1. A court found that the mother was not guilty of manslaughter'. The authors considered the case represented hypernatraemic dehydration secondary to gastroenteritis exacerbated by the continued administration of glucose polymers in the presence of diarrhoea.

Salt poisoning and hypernatraemic dehydration require careful differentiation. Salt poisoning is characterised by vomiting, diarrhoea, failure to thrive and in severe cases coma (Meadow 1993). Plasma concentrations of sodium are high, and may be in excess of 200 mmol/L. Urine concentrations of sodium are also high. The urine sodium : creatinine ratio is elevated above the normal of around 39. The urine sodium : potassium ratio is also elevated, the normal being around 2.8 (range 1.4–5.2). Hypernatraemia with elevated urinary sodium concentrations can also occur with hypernatraemic dehydration. Hence, high urinary concentrations of sodium alone cannot distinguish salt poisoning from dehydration (Coulthard, Haycock 2003). Fractional excretions of sodium and water, which are calculated from the sodium and creatinine concentrations of paired plasma and 'spot' urine samples, can distinguish the two situations (Coulthard, Haycock 2003). The values should be >2% in a child who has been salt poisoned and is volume replete and <1% in a dehydrated child with viable renal tubules. Renal and endocrine disease should also be excluded as explanations for the hypernatraemia. If the salt poisoning is intentional, then the hypernatraemia should resolve when the child is removed from contact from possible perpetrators.

Active transport of xenobiotics in the renal tubules

There are a number of transmembrane solute transporters expressed in the renal tubules and the development of these processes during childhood is largely unstudied (Launay-Vacher *et al.* 2006). Tubular secretion of xenobiotics (mediated by transmembrane solute transporters) appears

to be enhanced to a greater degree than GFR in infants and children, but there are limited data (Linday *et al.* 1981). Digoxin, the pharmacokinetics of which are well characterised in children, can be used as a marker of this process, specifically P-glycoprotein/MDR-1/ABCB1 activity (Ieiri *et al.* 2004). In children, the ratio of digoxin clearance to creatinine clearance is higher and decreases to adult ranges around the time of puberty, suggesting that the change is related to sexual maturation rather than size (Linday 1994) Transmembrane solute transporters may also be upregulated (induced) by some drugs (Launay-Vacher *et al.* 2006).

Hepatic clearance

Hepatic drug clearance occurs through metabolic transformation and drug transportation processes. Hepatic drug clearance becomes a function of the capacity and affinity of facilitated processes, and of hepatic blood flow. Ultimately, all of the facilitated processes are saturable, and therefore clearance is also dependent upon substrate concentration:

$$\text{Rate of metabolism} = \frac{V_{\max} \times C}{K_m + C}$$

where C is the concentration of the substrate, $V_{\max}$ is the maximum rate of metabolism and K_m is the Michaelis–Menten constant.

In children, these processes can be affected by enzyme expression (degree of enzyme expression and differential expression of enzymes and transporters during development), thus affecting $V_{\max}$ and K_m for the processes. Liver size can also affect $V_{\max}$ by influencing the total amount of enzyme or transporter. Hepatic blood flow may also vary during development.

Changes in hepatic blood flow do not appear to influence the differences in drug elimination with development (Alcorn, McNamara 2002). However, there are few data describing hepatic blood flow in children, and in physiologically based pharmacokinetic modelling hepatic blood flow has been assumed to be proportional to body surface area (BSA) (Björkman 2005). Biliary excretion appears to be reduced in infants, based on limited data mainly from animal models (Alcorn, McNamara 2002).

Cytochrome P450 development

There is differential expression of drug-metabolising enzymes among the foetus, neonate, infant and adult (Alcorn, McNamara 2002). CYP1A2 has negligible expression in the foetus, is detectable by 1–3 months of age, and reaches adult levels by 1 year of age (Alcorn, McNamara 2002). This is reflected in the metabolism of CYP1A2 substrates such as caffeine (Ginsberg *et al.* 2004). Similarly CYP2A6 is not expressed in foetal liver and is developed by 1 year of age (Alcorn, McNamara 2002). CYP2B6 appears to mature later than CYP2A6 (Tateishi *et al.* 1997). CYP2C9 has no activity in foetal liver but is detected by 1 day of age, and activity matures to 50% of adult activity by 1 month of age (Treluyer *et al.* 1997; Alcorn, McNamara 2002). CYP2C8 and CYP2C18 appear to parallel CYP2C9 (Treluyer *et al.* 1997). CYP2D6 activity is present from 23 weeks' gestation (25 weeks post-conceptional age), is not fully expressed at birth and reaches levels comparable to the adult activity by 1 year of age (Allegaert *et al.* 2005).

CYP3A expression changes through development by changes in the relative and absolute expression of CYP3A4, CYP3A5 and CYP3A7. CYP3A7 expression is greatest in foetal liver and it is highly expressed through to 6 months' postnatal age, but soon after birth its expression decreases and adult levels of expression are around 10% that of foetal expression (Tateishi *et al.* 1997; Lacroix *et al.* 2003; Stevens *et al.* 2003). CYP3A4 activity is well developed from birth (Alcorn, McNamara 2002). CYP3A4 expression is low in the foetal liver, but reaches 30–40% of adult expression by 1 month of age (Lacroix *et al.* 2003). CYP3A5 expression has high variability that appears to be independent of age (Stevens *et al.* 2003). Although there is some substrate specificity between isoforms of CYP3A, there is considerable overlap; hence overall there is similar CYP3A activity from infancy to adulthood.

A 5-week-old male infant presented with persistent tachycardia, agitation and irritability (Rivenes *et al.* 1997). On examination, the heart rate was 205–237 beats/min, respiratory rate was 60 breaths/min, blood pressure 118/65 and rectal temperature 39.5°C. The liver edge was palpable 4 cm below the right costal margin. ALT was 1079 U/L and AST was 578 U/L. A comprehensive urine toxicology screen indicated the presence of caffeine and the serum caffeine concentration was 117 mg/L (therapeutic range 5–12 mg/L). The infant had initially been treated for suspected sepsis, but subsequently a referral to Child Protection Services was made. The child was subsequently returned to the care of the family provided that there was no contact with the father. Three weeks later the child presented again following resuscitation after a cardiopulmonary arrest. The child was found to have retinal haemorrhages and subarachnoid haemorrhages. Death resulted from hypoxicischaemic encephalopathy, cerebral oedema and multi-organ system failure. At postmortem examination there was evidence of fractures of varying ages including healing rib fractures, a left spiral radial fracture and a right distal clavicular fracture. The father had admitted administering 3 × 200 mg caffeine tablets to the infant prior to the initial presentation.

The child initially presented with a clinical picture mimicking sepsis and the toxicological diagnosis was serendipitous. Caffeine would not normally arouse suspicion in a urine toxicological screen, but because of the infant's young age it was considered unusual that he would have been exposed to caffeine. Hence serum caffeine concentrations were determined. The intentional poisoning was also combined with physical abuse, which ultimately resulted in the death of the child. The case illustrates that abuse by poisoning is as serious as any other form of child abuse and requires the same level of intervention.

Caffeine metabolism is complex and changes from birth through to early childhood. Neonates and young infants have reduced clearance of caffeine compared with adults, and therefore there is a much longer half-life in neonates (Table 27.1). Caffeine is used as a respiratory stimulant in premature neonates, and is present in caffeinated beverages consumed from childhood through to adult life. A typical cup of coffee will contain 100 mg caffeine, and colas contain 97 mg/L. However, in neonates, because of the decreased metabolic clearance of caffeine, the duration of effect is much longer than for adults. In the first month post partum, 85% of identifiable caffeine and its metabolites in urine is parent caffeine (Aldridge *et al.* 1979). The half-life of caffeine in neonates is up to 30 h, while in adults it is around 8–9 h.

Glucuronidation

Glucuronidation is catalysed by a number of different UGTs. Individual processes, e.g. paracetamol glucuronidation, may be catalysed by several different UGTs (Mutlib *et al.* 2006). Glucuronidation of paracetamol is age related, being decreased in infancy and increasing to adult levels over the first 2 years after birth (van der Marel *et al.* 2003). However, it is not clear whether all the drug-metabolising UGTs mature over the same time course. There is little expression of UGTs in the foetus, and at birth there is an increase in their expression, with about 25% of the quantity of adult expression by 3 months of age (Alcorn, McNamara 2002). Morphine glucuronidation is also deficient in neonates and matures by late infancy (Alcorn, McNamara 2002) and was an important factor in the Dr Arthur Case cited above as the neonate could not glucuronidate the dihydrocodeine.

Other metabolic pathways

Sulfation is well developed in neonates (Choonara *et al.* 1990). However, paracetamol sulfation is saturated at relatively low doses/concentrations and it is not clear whether there are relative changes in capacity with age. The acetylator (*N*-acetyltransferase) phenotype undergoes maturation up to 4 years of age and in that time slow acetylators may become fast acetylators (Pariente-Khayat *et al.* 1997). Acetylation may also be decreased under the age of 3 months (Rey *et al.* 2001).

In addition to changes in the expression of enzymes, there are also changes in the relative size of the liver and possibly also in liver blood flow (Murry *et al.* 1995). Relative to total body weight, liver size decreases during childhood. For some drugs, clearance is proportional to liver size (e.g. carbamazepine, (*S*)-warfarin and lorazepam), whereas for others it is not (e.g. antipyrine, (*R*)-warfarin) (Murry *et al.* 1995; Takahashi *et al.* 2000; Reith *et al.* 2001). This may depend on whether the enzyme system is of high or low capacity, e.g. in the case of (*S*)-warfarin

CYP2C9 and (*R*)-warfarin CYP3A4 (Takahashi *et al.* 2000). There are few data on liver blood flow in children and it is not known whether liver blood flow parallels liver size. However, changes in liver blood flow might explain some of these phenomena.

Extrapolation of adult data to children

Where the pharmacokinetics/toxicokinetics of a substance in children are unknown, it may be necessary to extrapolate from adult or even animal data. The two main approaches to this are first allometric scaling and second physiologically based modelling (Björkman 2006). Allometric scaling assumes that the kinetic parameters are related to size, whereas physiologically based models take into account maturational effects, e.g. in renal or hepatic function. Hence after the age of 2 years allometric scaling may be appropriate, but prior to 2 years of age the maturation of renal and hepatic function would make physiologically based models more appropriate. The limitations of both allometric scaling and physiologically based modelling mean that such processes should be used only in the absence of observational data about the disposition of the drug in children, and the results should be interpreted with caution.

Allometric scaling

Drug doses are often scaled on the basis of weight or body surface area, but it may be more appropriate to scale by power functions of weight (allometric scaling). These power functions are usually weight$^{0.67}$ or weight$^{0.75}$ and are based on the observation that physiological processes can be scaled between species and between individuals on the basis of the relationship (Holford 1996). However, there may be some publication bias with regard to papers discussing allometric scaling and use of allometric scaling prospectively during drug development has had patchy success (Bonate, Howard 2000). Hence, allometric scaling is appropriate when the pharmacokinetics of the drug are known to be related to allometric functions of weight.

Habtemariam *et al.* published a population pharmacokinetic analysis of valsartan in children aged 1–16 years (Habtemariam *et al.* 2009). The study used allometric exponents on fat-free mass (calculated on the basis of height, weight and sex) of 0.75 for clearance and of 1 for volume of distribution. This approach fitted the data better than covariate models based on weight and age. However, there is a reliance here on having prior data. Using such models to extrapolate between species, or from adults to childrens is useful when designing dosing regimens for clinical trials but has limited applicability in clinical practice. There is a wide range of allometric coefficients between drugs (from 0.2 to 1.2) when interspecies comparisons are made (Hu, Hayton 2001).

Physiologically based models

Physiologically based models use physiological data such as body weight, organ weights, organ blood flows, body compartments (interstitial and vascular spaces), cardiac output, GFR, enzyme activities, etc. to predict pharmacokinetic parameters in children (Björkman 2005). The inclusion of data such as liver blood flow, liver microsomal protein content, portal vein flow and liver volume can be used to further refine physiologically based models (Edginton *et al.* 2006; Johnson *et al.* 2006). These models have performed well in comparison with historical data but will require further evaluation in prospective studies, such as in drug development.

Ginsberg *et al.* used physiologically based pharmacokinetic modelling applied to caffeine and theophylline in neonates and adults (Ginsberg *et al.* 2004). In this example, the model uses the known expressions of the enzymes involved in the metabolism of the two substrates (caffeine and theophylline) along with the Michaelis–Menten constants for the enzymes, compartmental volumes, organ blood flows, cardiac output and body weight in order to explain the differences in pharmacokinetics between neonates and adults. However, in order to fully explain the differences a novel metabolic pathway, expressed in neonates, but not adults, was proposed. It remains to be seen whether such models can be used to predict pharmacokinetic differences.

Dose calculations for children

In most cases drug dosage for children can be determined from published data, including the product information documents or datasheets provided by the manufacturer. In these cases the dosage guidelines have been determined from pharmacokinetic or clinical trial data. The recommendations usually base the dose on body weight, age categories or body surface area. These different methods can result in quite different mass doses, e.g. the 3rd and 97th centiles for weight for a 4-year-old male are 15 kg and 25 kg, respectively – close to a twofold difference. Hence, age-based dosing is not favoured, but for some drugs there will be clinical trial evidence to support an age-based recommendation, e.g. for omeprazole. Where a drug has a high therapeutic index, age-based dosing is acceptable, but when the therapeutic index is low, dosing by age and weight, or by surface area, is more acceptable (e.g. antineoplastic agents). A good source of information on drug dosing in children is the *BNF for Children*. Where there are no published guidelines, for repeated dosing a child's exposure to a drug relative to an adult could be determined using allometric scaling, or physiologically based models, as previously discussed. The relative exposure for a single dose is best calculated on the basis of volume of distribution, which other than for neonates can be scaled by weight alone. Some examples of the differences of drug dosing for newborn infants, infants/toddlers, children and adolescents are given in Table 27.2.

Formulations for children

Many oral formulations, such as tablets, capsules and most slow-release formulations, are not suitable for children. Even when a drug has paediatric indications, there may not be a suitable formulation (Balakrishnan *et al.* 2007). Adult dose forms may be crushed and administered with food, but this poses difficulties for accurate dosing. Extemporaneous formulations lack stability data, and also require shaking/mixing prior to dosing in order to avoid under- and over-dosing.

Other differences between children and adults

With regard to the effects of poisoning, various physiological parameters may be interpreted differently in children than in adults. This poses problems for the clinical management of children by non-paediatrically trained clinicians. In children, the normal ranges of blood pressure are lower, and heart rate is higher, than in adults. When measuring blood pressure in children, correct cuff size is crucial: specifically a bladder width that is approximately 40% of the arm circumference midway between the olecranon and the acromion (a cuff bladder that will cover 80–100% of the circumference of the arm) (National High Blood Pressure Education Program Working Group on Hypertension Control in Children and Adolescents 1996). A practical formula for the 5th centile for systolic blood pressure, at the 50th centile for height, is 2 times age in years plus 65, and for mean arterial pressure, 5th centile at 50th height centile, 1.5 times age in years plus 40 (Haque, Zaritsky 2007). In patients who are critically ill, particularly where there is raised intracranial pressure, higher values may be needed for the lower threshold of systolic blood pressure and mean arterial pressure.

The threshold for hypertension is also lower in children and adolescents. The diagnosis of hypertension requires the use of nomograms or tables to determine thresholds by age, sex and height (National High Blood Pressure Education Program Working Group on Hypertension Control in Children and Adolescents 1996).

A heart rate of <60 beats/min is considered bradycardia in an infant, whereas a healthy adolescent may have a resting heart rate of <40 beats/min. Hence a heart rate considered normal for an adult can represent bradycardia in an infant. This is of relevance to poisonings resulting in bradyarrhythmias, such as from beta-blockers and calcium-channel antagonists.

Children may present differently from adults following envenomation from snakes or spiders (White 1995). In a small child there may be no history of a bite, and the child may present with symptoms of neurotoxicity (such as seizures), pain (from myotoxicity) and/or coagulopathy. Alternatively, the child may present with a progressive illness

Table 27.2 Examples of differences in drug dosing[a]

Drug	*Newborn infants (0–27 days)*	*Infants/toddlers (28 days to 23 months)*	*Children (2–11 years)*	*Adolescents (12–16/18 years)*
Aminophylline (IV)	6 mg/kg then 2.5 mg/kg every 12 h	5 mg/kg followed by 1 mg/kg per h	5 mg/kg followed by 1 mg/kg per h to 9 years then 0.8 mg/kg per h	5 mg/kg followed by 0.8 mg/kg per h to 16 years then 0.5 mg/kg per h
Omeprazole (oral)	0.7 mg/kg, once daily	0.7 mg/kg up to 20 mg, once daily	10–20 kg BW: 10 mg, once daily; >20 kg BW: 20 mg, once daily	20 mg once daily
Phenytoin	18 mg/kg (IV loading), then 2.5–5 mg twice daily (oral)	1.5–2.5 mg/kg twice daily (oral)	1.5–2.5 mg/kg twice daily (oral)	75–150 mg twice daily (oral)
Cyclophosphamide (IV)		500 mg/m^2 BSA once a month	500 mg/m^2 BSA once a month	500 mg/m^2 BSA once a month
Propofol (IV)		2.5–4 mg/kg	2.5–4 mg/kg to 8 years, then 2.5 mg/kg	1.5–2.5 mg/kg
Digoxin (oral)	Neonate <1.5 kg: 25 µg/kg in 3 divided doses for 24 h then 4–6 µg/kg daily Neonate 1.5–2.5 kg: 30 µg/kg in 3 divided doses for 24 h then 4–6 µg/kg daily Neonate >2.5 kg: 45 µg/kg in 3 divided doses for 24 h then 10 µg/kg daily	45 µg/kg in 3 divided doses for 24 h then 10 µg/kg daily	Up to 5 years: 35 µg/kg in 3 divided doses for 24 h then 10 µg/kg daily From 5 to 10 years: 25 µg/kg in 3 divided doses for 24 h then 6 µg/kg daily After 10 years: 0.75–1.5 mg in 3 divided doses for 24 h then 62.5–250 µg daily	0.75–1.5 mg in 3 divided doses for 24 h then 62.5–250 µg daily

BSA, body surface area; BW, body weight; IV, intravenous.

with generalised symptoms such as lethargy, vomiting, mild pyrexia and neurological signs (e.g. paralysis and fixed, dilated pupils). There may be discoloration of the urine due to myoglobinuria.

Children are at greater risk from envenomation because of the relatively greater dose of toxin. Fatality rates for children are higher than for adults following snake bite (McGain *et al.* 2004). The risk of incurring a snake bite may also be greater in children. Children may develop signs of envenomation sooner than adults and require a higher dose of antivenom.

Clinical aspects

Assessment

History

A thorough history should be recorded for each episode of poisoning. The history should include time of ingestion, probable dose, the poisons the child was exposed to and the circumstances at the time (including extent of supervision, where the episode happened, who was there, where the poisons were stored and whose medicines were ingested). It is important to establish whether the history is consistent with the patient's developmental age. A child who is not rolling will not be able to move towards a poison hazard. A child who is not feeding himself or herself will not be able to take a poison independently.

Preformatted charts aid in the collection of clinical data, improving both accuracy and completeness of the data (Buckley *et al.* 1999). An example of a preformatted chart is presented in Figure 27.1. Data can be collected for patient management but also for epidemiology/accident prevention purposes. Electronic databases are useful for recording the data and for performing audits. Patient management software, as is commonly found in emergency departments and hospital in-patient departments, can be modified to improve data capture for toxicology (e.g. disease-specific data entry screens).

The clinical history of an episode of poisoning in young children is extremely unreliable (Hwang *et al.* 2003). Of children presenting with poisoning, around 60% have actually been exposed to the putative poison (Sugarman *et al.* 1997; Belson *et al.* 1999; Hwang *et al.* 2003). A history from an adult or another child is not more reliable than that from the child him-or herself. Physical evidence, such as an abnormal smell of the breath, staining of the clothes and symptoms/clinical signs consistent with poisoning, increases the positive predictive value to 100%, 86% and 92%, respectively (Hwang *et al.* 2003). Although routine urine drug screens are not useful, urine drug screens may be useful in detecting toxins in symptomatic patients without a history of ingestion or when ingestion is denied (Belson *et al.* 1999), in particular where drugs of abuse, e.g. cocaine or methadone, may have been ingested by small children.

Examination

The initial step in the physical examination of the poisoned child is the measuring and recording of the vital signs: temperature, pulse rate, respiratory rate, blood pressure and oximetry. Temperature is an important component of the paediatric general examination as it may indicate alternative diagnoses, such as infection. There are some poisonings that affect temperature, such as hypothermia with organophosphate poisoning, and hyperthermia with serotoninergic syndrome or the anticholinergic toxindrome. Pulse rate in children should be interpreted in relation to age-appropriate norms (Wallis *et al.* 2005). Abnormal pulse (or heart) rate is an important sign in toxicology, indicating cardiotoxicity. Bradycardia and tachycardia are defined at relatively lower pulse rates in children than in adults. Hence, there are different intervention points. Similarly, both diastolic and systolic blood pressure are lower in children than in adults. This results in different values for defining hypotension and hypertension, and the treatment decision points. Respiration rate is also higher in infants and children than in adults (Wallis *et al.* 2005). Oximetry is useful in assessing respiratory function, particularly when the poison is a sedative or decreases neuromuscular function (e.g. organophosphate poisoning). Arguably, in the context of child poisoning, blood sugar level is also a vital sign. Children are at greater risk of hypoglycaemia than adults (hypoglycaemia may be a differentiating feature in some childhood poisonings compared with adults). Hypoglycaemia, if uncorrected, may lead to tissue/organ injury and long-term morbidity. It is therefore important to identify and correct hypoglycaemia in childhood poisoning.

An assessment of conscious state is important in any toxicological examination because many poisons impair consciousness and this may lead to secondary injury due to impairment of respiration and airway. The Glasgow Coma Scale (GCS) is the most widely applied measure of

state of consciousness, and can be modified for paediatric use. However, the GCS was developed for the assessment and monitoring of patients with head injury and is less useful in poisoning:

A neurological examination focusing upon pupils, nystagmus, muscle tone and reflexes should be performed. Pupil size and response can be important indicators of poisoning: dilated pupils occur particularly in anticholinergic poisoning, while contracted pupils occur in opioid poisoning. Unresponsive pupils can indicate profound coma, such as with barbiturate-induced coma. Horizontal nystagmus is commonly seen in sedative poisoning, and vertical nystagmus may be seen in addition to this with some anticonvulsants, e.g. barbiturates and carbamazepine. An oscillation of horizontal gaze (differentiable from nystagmus by a lack of directional component) may be seen in serotonin syndrome. Hypotonia can also indicate sedative poisoning or neuromuscular blockade (such as organophosphate poisoning). Deep tendon reflexes may be increased as a result of serotonin syndrome, while they are decreased with sedative poisoning or neuromuscular blockade.

Routine examination of the chest should be performed by listening to the sounds of the heart and breathing. Abdominal examination should be performed to determine liver size and condition, and whether there is any abdominal tenderness or rigidity and presence of bowel sounds. Presence of any signs indicating blockage of the intestine or perforation of the viscera would preclude the use of any gastrointestinal decontamination. The skin, scalp and mouth should be examined for any signs of

Use of laboratory analyses

Considerations for blood sampling

Children have smaller blood volumes than adults and there is greater difficulty in collecting serum, plasma and urine samples. The amount of blood that can be sampled from a child without the need for transfusion depends upon the initial haematocrit (Lister *et al.* 2008). Recommendations for paediatric clinical trials are for no more than 3% of blood volume to be sampled on any one study day in a child with a normal red cell mass (haematocrit) (Kauffman 2000). In an infant or toddler this would represent 2.4 mL/kg body weight. As a guide, children can tolerate sampling of 0.25 mL/kg per day without a fall in haematocrit (Lister *et al.* 2008). In critically ill neonates, it is standard practice to transfuse after 10–15 mL/kg has been sampled. In critically ill patients, there may be other influences decreasing the haematocrit, such as blood loss, haemolysis, and expanded intravascular and/or extracellular volume. The potential clinical effects of the poisoning upon blood volume, haematocrit and oxygen transfer will also need to be considered.

Consequently, smaller volumes are available for analysis. More sensitive assays are therefore required for the analysis of samples from children. Capillary electrophoresis (CE), and liquid chromatography–mass spectrometry (LC-MS) are newer methods that enable highly sensitive assays to be performed on small sample volumes.

Topical anaesthetics (lidocaine, prilocaine, tetracaine or amethocaine) are effective in reducing the pain of venepuncture in children aged from the neonatal period through to adolescence. Distraction through the use of play therapy and/or music therapy is an effective means for reducing the stress of venepuncture (Caprilli *et al.* 2007). However, it should be considered whether sampling is necessary and sampling should be avoided when the results will not contribute to patient management.

Samples obtained by heel-prick sampling yield results comparable with those obtained by venepuncture (Webb *et al.* 2007). Heel-prick samples are capillary blood as opposed to venous blood. Therapeutic drug monitoring of drugs such as ciclosporin and tacrolimus can be performed using capillary blood specimens because of a high correlation between capillary and venous concentrations. A pitfall in capillary blood sampling arises if the skin is contaminated with the analyte, e.g. if investigating an exposure where the child has had the putative agent on his or her hands and then a finger-prick specimen is obtained.

In the majority of cases of paediatric poisons exposure, blood sampling will not be necessary. However, where blood concentrations are decision criteria, e.g. paracetamol poisoning, or where intentional poisoning is suspected, then blood sampling will be necessary. Blood concentrations give information about the magnitude of exposure (i.e. they are quantitative), unlike urine concentrations which give less information about the magnitude of exposure (i.e. they are qualitative). Blood concentrations can be used to determine whether to intervene, (e.g. paracetamol, lead, theophylline) or whether to monitor treatment (e.g. phenobarbital).

Urine drug screens

Urine drug screens may be used to confirm exposure to poisons but are of limited utility in the immediate management of acute poisoning. Urine can be collected by the clean catch method in young children, and by using collection bags in infants. Bacterial contamination of the sample is common, and if a sterile sample is required from an infant then a catheter or suprapubic aspirate sample may be collected. Many of the agents involved in paediatric poisons exposure may not be detectable by routine urine drug screens (Hwang *et al.* 2003), the results of the test may not be available until after the clinical presentation has resolved, and the vast majority of paediatric poisons exposures do not pose a significant hazard. Hence, performing urine drug screens routinely is not justifiable. However, where there is a diagnostic dilemma, or where deliberate poisoning by a third party is suspected, urine drug screens are warranted.

When intentional poisoning is suspected it will be necessary to inform the clinicians responsible for the care of the patient, and the police or the coroner (depending on the circumstances). In most jurisdictions there is a legal requirement to report assaults on children to either the police or child protection authorities. Intentional poisoning would constitute an assault under most legal systems. It is the responsibility of the health professional who suspects that the assault has occurred to report the incident to the police/child protection authorities. Hence, reports should be made directly to the police/child protection authorities rather than to other health professionals. The police will be responsible for documenting the chain of evidence. However, the procedures will vary between legal jurisdictions and it will be necessary for the medical scientist to be familiar with procedures in each state or country in which they work.

Saliva

The rate of production of saliva is influenced by hydration status, food, drugs and diurnal variations. In general, drugs are transferred into saliva by passive diffusion and the saliva : plasma ratio of drugs is influenced by the physicochemical properties of the drug (such as pK_a, lipid solubility, molecular weight, spatial configuration and charge), the unbound plasma concentration of the drug and the characteristics of the saliva (production rate, pH, salivary binding proteins and salivary enzymes) (Aps, Martens 2005). Hence, salivary assays may be more useful in documenting exposure than in determining management criteria or the extent of exposure (see Chapter 18).

Hair

Hair analysis can be used to document exposure and give an indication of the timing of exposure in the medium term. When the timing of sampling is late, it may not be possible to detect drugs in blood or urine samples, but it may be possible to detect their presence in hair (Kintz *et al.* 2007). This approach has been used to detect drugs such as benzodiazepines, zopiclone, barbiturates, methadone, glibenclamide, trimeprazine and diphenhydramine (Kintz *et al.* 2006, 2007; Villain *et al.* 2006). More commonly, hair analysis has been used to demonstrate exposure to arsenic or heavy metals (such as mercury, lead, cadmium, chromium, and manganese). Samples of fingernail clippings and teeth ('milk' or deciduous teeth are shed naturally in children) can also be analysed to demonstrate heavy-metal exposure (see Chapter 19).

Neonatal hair can be analysed to determine intrauterine exposure to ethanol and nicotine as well as illicit drugs such as cocaine, methamfetamine, opioids, cannabinoids and benzodiazepines (Koren *et al.* 2008).

Meconium

In utero exposure to opioids, cocaine, benzodiazepines and ethanol can be determined from the analysis of meconium passed by the newborn (Lopez *et al.* 2009; Moller *et al.* 2010; Wang *et al.* 2010). ELISA and LC-MS methods have been reported, as has good correlation between meconium and hair samples. The results have been used by child protection authorities to establish *in utero* exposure to substance misuse, and also for population studies.

Treatment of poisoning

Treatment of poisoning in children requires dose adjustment for size and development. This is complicated by the lack of paediatric dosing information for many antidotes. Dosing information can be obtained from the *BNF for Children*, as well as from electronic resources such as Toxbase, TOXINZ and Poisindex. These electronic resources require a subscription in order to obtain access, but the poisons information services will invariably have access.

Decontamination, although once standard practice, is increasingly being matched to the risk posed by the exposure. Charcoal is used for carbon-based poisons, but is not effective for metals, strong acids or alkalis. Whole-bowel lavage can be used for slow-release preparations and for metals (e.g. lithium) (Buckley *et al.* 1995). However, there is a significant risk of aspiration with paediatric decontamination. Gastric lavage can result in aspiration in around 4% of children (Tibballs *et al.* 1985). Charcoal aspiration, particularly when nasogastric or orogastric tubes are used, is a hazard and can lead to respiratory failure and death (Golej *et al.* 2001). Whole-bowel lavage, with polyethylene glycol electrolyte lavage solutions, requires large volumes of fluid, beyond the capacity of a child to ingest orally. Hence, nasogastric or orogastric tubes are required. Care is also required for the correct placement of these tubes in order to avoid aspiration. It is accordingly important to consider the risk–benefit ratio of decontamination, and to avoid decontamination when no significant toxicity is predicted.

When considering decontamination, the hazard posed by the exposure should be assessed by determining the following:

- Does the agent have known toxicity?
- Has the child been exposed to a significant amount of the poison?
- Are there any confirmatory signs of exposure?
- Are there alternative safer treatments than decontamination, e.g. antidotes, intravenous fluids?

Some treatment protocols need to be modified for children. The administration of *N*-acetylcysteine requires relatively high amounts of dextrose solutions which for a child may result in water intoxication. For children, these administration protocols need to be modified to deliver smaller volumes of dextrose.

Conversely, some antidote doses are based upon the toxin load rather than the size of the patient. For example, with snake or spider bite envenomation, the dose of antivenom is based on the bite/quantity of venom rather than the size/age of the patient. In this case the dose should not be modified for children. However, there should be a lower threshold for treatment in children because the amount of toxin delivered by a snake bite is the same as that for an adult but the dose is proportionately higher because of their smaller body size (White 1995).

When a medicine is used in an off-label or unlicensed manner, it is important to make a clinical assessment of its appropriateness. For medicines that are in common use (i.e. when it is the recognised standard of care) or when good-quality evidence is available, the medicine should be prescribed in the normal manner (Gazarian *et al.* 2006). Where such evidence is lacking, the use of the medicine could be considered experimental or innovative, and measures such as peer-review and informed consent should be conducted prior to use.

Response to poisoning (pharmacodynamics)

Pharmacodynamic differences between children and adults have been described, e.g. prepubertal children show enhanced response to warfarin compared with pubertal children and adults (Takahashi *et al.* 2000). The insulin requirements of children with established type 1 diabetes (after the remission phase) are around 0.7–1.0 units/kg per day, increasing at puberty to around 1.4–1.6 units/kg per day in boys and around 1 unit/kg per day in girls, and then decreasing a few years after puberty to adult requirements of around 0.7–0.8 units/kg per day. These insulin dosing requirements are influenced by rates of growth. Selective serotonin reuptake inhibitors (SSRIs) appear to have less efficacy in children and adolescents than in adults, but this may reflect difficulties in diagnosing depression in this age group. Differences in drug response between children and adults may also parallel different susceptibilities to poisoning, e.g. with aspirin causing Reye syndrome and SSRIs causing aggressive behaviour (see below).

Aspirin

A 14-year-old boy presented with encephalopathy following the use of aspirin for symptom control during a mild influenza-like illness. Laboratory investigations demonstrated an elevated plasma ammonium concentration (>700 μmol/L), elevated AST (3355 U/L), elevated ALT (2488 U/L), elevated serum lactate (108 mmol/L) and a prolonged prothrombin time (23.6 s). He had a serum salicylate concentration of 232 mg/L. Despite intensive support he died as a consequence of cerebral oedema and tonsillar herniation. Postmortem findings included diffuse microvesicular steatosis and some macrovesicular steatosis (He *et al.* 2007).

The presentation is consistent with a diagnosis of Reye syndrome, which has been linked with aspirin. The mechanism of the interaction between aspirin and a viral illness to produce this condition has been linked with β-oxidation of fatty acids, whereby some individuals are predisposed to aspirin-inhibiting fatty acid metabolism (Deschamps *et al.* 1991; Glasgow *et al.* 1999; He *et al.* 2007). Cytokines can also downregulate some enzymes involved in exogenous and endogenous substrate metabolism. Reye syndrome was described predominantly in children, and this resulted in recommendations to avoid aspirin in children under the age of 12 years.

Selective serotonin reuptake Inhibitors

An 11-year-old boy was initially started on atomoxetine 25 mg/day, which was subsequently increased to 60 mg/day after 2 weeks, for the treatment of aggressive behaviour and attention deficit hyperactivity disorder (ADHD). After the increase in dose, he was noted to be increasingly agitated and to have an increase in mood swings. He was reported to have thrown an object at a teacher, and was uncontrollably agitated, crying and threatening to kill himself. These behaviours ceased when his medications were withdrawn (Paxton, Cranswick 2008).

When treated with SSRIs, adolescents and young adults are susceptible to treatment-emergent suicidal ideation and suicide-related behaviour (Reith, Edmonds 2007). This risk appears to be age related, with the vulnerable window being from adolescence through to early adulthood. Although this appears to be a class effect, the risk varies between individual chemical entities. Atomoxetine has its primary mode of action via the inhibition of presynaptic noradrenaline (norepinephrine) reuptake but it also has some effects on serotonin reuptake. Treatment-emergent suicidal ideation and suicide-related behaviour have also been reported with atomoxetine.

Other examples of different susceptibilities to poisoning include response to hypnosedatives and ethanol. Children are more susceptible to the respiratory suppressant effects of hypnosedatives. Ethanol intoxication in children has a higher risk of hypoglycaemia than in adults.

Conclusion

The approach to poisoning in childhood is determined by the nature and circumstances of the exposure, the stage of development of the child and the legal jurisdiction. Apart from the approach to sample collection, the toxicological analysis is similar to that for adults. For example, in a child who presents with suspected chloroquine ingestion (see the monograph on Chloroquine), a 1 g dose can cause death in a child compared with 3 g in an adult. Exposure to chloroquine could be confirmed by clinical signs (hypotension, QRS prolongation). Analysis of blood concentrations might be used to further confirm exposure, to make an assessment of dose, to predict outcome and to inform management (duration of observation, need for elimination enhancement). In paraquat poisoning the ingested dose might be relatively small in a child because of the unpleasant taste, and larger in an adult because of suicidal intent (see the monograph on Paraquat). Serum paraquat concentrations can be used as a guide to prognosis and as intervention criteria. Hence, the interpretation of the laboratory data can be placed within the paediatric context.

CHAPTER

28 Sampling, Storage and Stability

S Kerrigan

Specimen selection, sampling, storage and stability

Appropriate selection, sampling and proper storage of biological evidence are important, yet sometimes overlooked, steps in forensic toxicology. These factors, in combination with drug stability, can profoundly impact the interpretation of results and the outcome of forensic casework. Criteria surrounding each of these are presented and discussed in the material that follows. Further reference to tissue sampling will also be found in other chapters in this book and will be cross-referenced within the text where appropriate.

Specimen selection

Selection of the appropriate specimen is a critical component of any toxicological investigation. Circumstances surrounding the case, the availability of specimens, the nature of the investigation and even legal or statutory issues may dictate which specimens are selected, and for what purpose. Timing is an important factor in specimen collection, particularly in antemortem cases where some drugs have short detection times and therefore limited detection windows; examples include detection of an elevated concentration of Δ^9-tetrahydrocannabinol (THC) in blood from an impaired driver, or of γ-hydroxybutyric acid (GHB) following an alleged drug-facilitated sexual assault.

Postmortem specimens pose additional challenges owing to autolytic and putrefactive changes. Timing is also important in death investigations because it becomes increasingly difficult to obtain good-quality specimens as the time between death and sampling (postmortem interval) increases. Factors such as embalming of the body, decomposition or burial can further complicate interpretation if tissues have been preserved, if specimens are putrefied, or if exhumation is necessary. In order to be able to select the appropriate specimen(s) the toxicologist should have access to the case history, autopsy records/pathologist's report and all other relevant documents.

Some of the important specimen selection considerations are listed in Table 28.1.

Collection and sampling

Specimen containers

It is important that the specimen container is appropriate for the intended use and does not compromise the analytical findings. Container size should be appropriate for the volume or weight of the specimen so that headspace is minimised. Typical specimen collection quantities are given in Table 28.2. Excessive headspace in the container can increase the chance of oxidative loss, volatilisation of analyte (e.g. ethanol and other low-boiling-point compounds) or salting out, which may occur if preservatives are present. Some analytes have a tendency to adhere to plastic or glass surfaces depending on their physicochemical properties. Silanisation of glassware can reduce adsorptive losses for drugs that are present at trace levels (10 μg/L or less). Although glass containers are preferred by many, disposable plastic containers are used routinely for a wide variety of postmortem tissues and antemortem samples, particularly urine.

If glass containers are used, it is important to make use of appropriate racks for storage and transportation. One of the major disadvantages of glass is the possibility of breakage, particularly during storage at low temperatures. In order to minimise sample loss, glass containers are preferred if volatile analytes such as solvents or anaesthetic gases are suspected. Plastic containers are more susceptible to interferences by plasticisers such as phthalates that might interfere with the analysis. The use of an inert plastic such as Nalgene decreases the likelihood of chemical interference, but it is good laboratory practice to evaluate all new specimen containers prior to routine use in the laboratory. If plastic containers are chosen, their integrity at low temperatures should be evaluated. Polystyrene is more susceptible to cracking at frozen temperatures than polypropylene vessels. Rubber septa or liners in screw-cap containers should be avoided and replaced with inert liners (e.g. polytetrafluoroethylene (PTFE), or Teflon) to reduce leakage and minimise drug adsorption.

Antemortem blood samples are generally collected into evacuated glass tubes such as Vacutainer or Venoject for forensic toxicology purposes. Collection of blood into similar glass collection vessels is also good practice in postmortem blood sampling. These tubes allow the sample to be collected into a vessel that already contains necessary additives to stabilise and preserve the matrix. Proper mixing is necessary when sodium fluoride or other additives are used to ensure that dissolution is complete.

Blood

Blood is one of the most important specimens of toxicological interest as it provides unique advantages over other matrices in terms of the wide variety of analytical methodologies available, the vast amount of published reference data for both antemortem and postmortem drug concentrations, and the interpretive value of the matrix from a pharmacological standpoint. However, antemortem and postmortem blood samples are notably different, and the site of the postmortem blood draw (central or peripheral) can be of critical importance. Determination of parent drug and metabolite concentrations (and their ratios) may also yield useful information pertaining to acute or chronic use. A summary of the common advantages and disadvantages of various specimens is given in Table 28.3.

Antemortem blood

Antemortem blood is collected by venepuncture, typically from the antecubital region of the arm, using a syringe or evacuated container (e.g. Vacutainer, Venoject). Prior to collection, an antiseptic wipe is often used to clean the collection site. Non-alcohol-containing antiseptic wipes such as Betadine (povidone–iodine) are preferred to avoid any contamination that could interfere with alcohol analysis (see Chapter 4). Although evacuated blood tubes are typically glass, plastic tubes have also been evaluated (Karinen *et al.* 2010).

Postmortem blood

Postmortem blood collected at autopsy is quite different from antemortem blood collected by venepuncture from both qualitative and quantitative standpoints. Postmortem blood may be more viscous, may contain numerous small clots or sedimented cells, has a lower pH (as low as 5.5 owing to protein degradation), may contain 60–90% water, and is subject to varying degrees of haemolysis. The site of blood

collection should be clearly identified on postmortem specimens and blood from different sources should never be combined.

Central blood

Cardiac blood samples are ideally collected following opening of the pericardial sac, removal of the pericardium, and removal of the blood from the left or right chamber after the heart has been dried. Collection of central blood by insertion of a needle through the chest wall ('blind stick') is practised but is discouraged. Although central blood collected in this manner may be identified to the laboratory as 'heart blood', it may be contaminated with pericardial fluid, fluid from the pleural cavity, or blood that has drained from the pulmonary vein or artery or the inferior vena cava (Jones 2007). Blood collected in this manner is considered non-homogeneous. Central blood may contain elevated drug concentrations as a result of postmortem redistribution or contamination (diffusion) from other body compartments (Prouty, Anderson 1990; Yarema, Becker 2005), especially following blunt force trauma. Passive drug release from reservoirs such as the gastrointestinal tract, liver, lungs and myocardium may occur immediately after death; later, cell autolysis and the putrefactive process participate in redistribution (Pelissier-Alicot *et al.* 2003). Drug properties such as volume of distribution, lipophilicity, protein binding and pK_a play a role in the site- and time-dependent mechanisms responsible for postmortem redistribution. Drugs with high volumes of distribution and basic character appear particularly susceptible to postmortem redistribution and their cardiac blood concentrations should be interpreted accordingly. Postmortem redistribution can account for central/peripheral blood drug concentrations that differ by 10-fold or more. Redistribution is time and concentration dependent and is very difficult to predict. Cardiac blood is typically more plentiful than peripheral blood. Although cardiac blood can be a very useful specimen for screening purposes, the relationship between cardiac blood drug concentrations and antemortem blood drug concentrations is complex. Many toxicologists therefore advise against the use of cardiac blood for quantitative and interpretative work.

Peripheral blood

Femoral blood is the best specimen for use in postmortem testing (Chapter 10) and should be sampled wherever possible. Blood collection from a ligated vein that has been 'tied off' is least likely to be contaminated by other sources of blood or a result of release of drug from tissues and organs. Typically, however, a 'femoral stick' involves the collection of femoral blood from an unligated femoral vein in the groin area. Only a small volume of blood should be collected to avoid 'milking' the vein and drawing blood from other sources. Typically 10–20 mL of femoral blood can be collected. Over-sampling of blood from the femoral vein will draw blood from the inferior vena cava, and hence the liver, and from the larger iliac vein. Although sampling from a ligated vein is generally preferred, a comparison of drug concentrations in clamped and unclamped femoral vessels showed good correlation for eight drugs including selective serotonin reuptake inhibitors, benzodiazepines, antihistamines and one opioid (Hargrove, McCutcheon 2008). If femoral blood is not available, subclavian or iliac blood may be an alternative.

Blood clots

Following a fall or blunt trauma to the head, a victim may survive with circulation intact for several hours. Owing to the decreased circulation in the damaged region of the brain, drug or alcohol concentrations in blood clots (e.g. subdural, subarachnoid and/or epidural) may be influenced by incomplete metabolism. It has been suggested that intracranial

Table 28.2 Typical specimen collection quantities

Postmortem		*Antemortem*	
Specimen	***Quantity***	***Specimen***	***Quantity***
Blood, heart	25 mL	Blood	10–20 mL
Blood, peripheral	10–20 mL	Urine	25–100 mL
Urine	All	Amniotic fluid	5–30 mL
Bile	All	Breast milk	10–20 mL
Vitreous humour	All	Meconium	All
Cerebrospinal fluid	All	Hair	Pen-size lock
Gastric contents	All	Saliva	1–5 mL
Liver (remote proximity from liver)	All	Sweat	Microlitres (insensible sweat); 1–5 mL (sensible sweat)
Kidney	50 g		
Spleen	50 g		
Brain	50 g		
Lung	50 g		
Hair	50 g Pen-size lock (150–200 hairs or 50 mg)

Table 28.3 Advantages and disadvantages of antemortem and postmortem biological specimens

Specimen	*Advantages*	*Disadvantages*
Amniotic fluid	■ Determination of prenatal drug exposure ■ Not readily adulterated ■ Minimal sample preparation ■ Relatively few interferences	■ Invasive collection ■ Risk of complications ■ Limited reference data ■ Collection by medical personnel
Bile	■ Ease of detection of certain drugs (accumulation) ■ Particularly useful for conjugated drugs	■ Complex matrix ■ Interferences due to bile salts and fats ■ Requires sample preparation/pretreatment ■ Limited reference data
Blood (AM)	■ Widely accepted matrix ■ Determines recent drug use (hours–days) ■ Related to pharmacological effect ■ Not readily adulterated ■ Extensive reference data	■ Invasive collection ■ Collection by medical personnel ■ Shorter detection time
Blood (PM)	■ See above (AM) ■ Reference data widely available ■ Central/peripheral blood drug ratios known for some drugs ■ Cardiac blood typically in plentiful supply but requires caution with interpretation	■ Susceptible to postmortem redistribution (central) ■ Susceptible to postmortem artefacts and interferences ■ Susceptible to contamination (e.g. trauma) ■ Quality of specimen highly dependent on collection protocol ■ Limited volume of peripheral blood
Brain	■ Particularly useful for lipophilic drugs, volatiles and centrally acting drugs	■ Non-homogeneous matrix ■ Drug concentrations vary by region ■ Complex matrix ■ Requires sample preparation/pretreatment ■ Limited reference data
Breast milk	■ Determination of neonatal drug exposure ■ Not readily adulterated ■ Many drugs present	■ Privacy, invasive collection ■ Limited reference data ■ Interferences due to high lipid content ■ Drug content varies with milk composition ■ Variable matrix
Cerebrospinal fluid	■ Determines recent drug use (hours–days) ■ Minimal sample preparation ■ Relatively few interferences	■ Invasive collection ■ Limited reference data
Gastric contents	■ Identification of acute ingestion/delayed absorption ■ Identification of pill fragments possible ■ Particularly useful for orally administered drugs/poisons	■ Non-homogeneous matrix ■ Complex matrix ■ Requires sample preparation/pretreatment ■ Requires total specimen collection for interpretation
Hair	■ History of drug use (months) ■ Readily available, easy collection ■ Low potential for donor manipulation ■ Useful for drug and non-drug analytes, e.g. metals	■ New technology ■ Recent drug use not detected ■ Environmental contamination ■ Potential for ethnic bias ■ Limited reference data
Kidney	■ Particularly useful for non-drug analytes, e.g. metals	■ Complex matrix ■ Requires sample preparation/pretreatment
Liver	■ Ease of detection of certain drugs (accumulation) ■ Interpretive value for some drugs ■ Reference data available	■ Complex matrix ■ Requires sample preparation/pretreatment
Lung	■ Particularly important for volatile analyses	■ Complex matrix ■ Requires sample preparation/pretreatment

table continued

Table 28.3 continued

Specimen	*Advantages*	*Disadvantages*
Meconium	■ Long-term window of drug exposure ■ Non-invasive sample collection	■ Non-homogeneous matrix ■ Complex matrix (waxy) ■ Interferences ■ Requires sample preparation/pretreatment ■ Limited reference data
Nails	■ Easy collection ■ History of drug use (months) ■ Particularly useful for metals	■ Limited data ■ New technology ■ Not yet widely accepted ■ Recent drug use not detected ■ Environmental contamination
Saliva	■ Readily available, easy collection ■ Parent drug present ■ Related to free drug concentration in plasma ■ Minimal sample preparation ■ Many drugs determined ■ Indicates recent drug use	■ New technology ■ Short drug detection time ■ Small sample volume (1–5 mL) ■ Potential for oral contamination ■ Collection method influences specimen pH and drug content
Spleen	■ Particularly useful for certain analytes if no blood is available	■ Complex matrix ■ Requires sample preparation/pretreatment ■ Limited data for most analytes
Sweat	■ History of drug use (weeks) ■ Cumulative measure of drug use ■ Parent drug present ■ Non-invasive collection ■ Less frequent drug testing required ■ Not readily adulterated	■ Newer technology ■ Potential for environmental contamination ■ High intersubject variability ■ Requires special collection device ■ Skin irritation and discomfort ■ Small sample volume ■ No pharmacological interpretation possible ■ Non-homogeneous matrix (sweat/sebum)
Urine	■ Widely accepted matrix ■ Easy collection ■ Plentiful supply ■ Amenable to automated analysis ■ Longer detection window than blood (days–weeks)	■ Potential for donor manipulation ■ Minimal parent drug ■ Not useful for quantitative analysis ■ Not related to impairment or pharmacological effect
Vitreous humour	■ Determines recent drug use (hours–days) ■ Related to pharmacological effect ■ Resistant to putrefaction ■ Interpretive value for ethanol-related investigations ■ Minimal sample preparation ■ Relatively few interferences ■ Useful for postmortem chemistry	■ Limited data compared with blood ■ Small sample volume

blood clots may serve as 'time capsules' prior to death, because they may reflect drug concentrations several hours prior to death, when an injury may have taken place.

Vitreous humour

Direct aspiration of vitreous humour using a hypodermic syringe may yield 2–3 mL of fluid per eye. The needle should be placed in the central globe and aspirated with gentle suction. Preservation with sodium fluoride is generally recommended. The eye is located within the protective environment of the orbit and, being essentially outside the body, is remote from other tissues. Vitreous fluid is therefore a particularly useful specimen owing to its anatomical isolation, affording it notable resistance in terms of microbial invasion and degradation, as well as being remote from the central organs and subsequently less susceptible to postmortem redistribution phenomena. Vitreous humour is particularly useful for cases involving digoxin or hydrophilic analytes including paracetamol (acetaminophen) and salicylates. The equilibrium that exists between blood and vitreous fluid is slower than with other extracellular fluids, which can result in a slight delay in uptake. Furthermore, only free drugs are able to leave the blood and enter the vitreous humour. Since eye fluid is sterile and less susceptible to microbial contamination and hence postmortem alcohol production, it is routinely used for ethanol determination owing to its interpretive value from the standpoint of postmortem alcohol production and the determination of the pre- or post-absorptive phase of ethanol use

(Honey *et al.* 2005). Vitreous humour is particularly useful for postmortem analysis of glucose, urea nitrogen, uric acid, creatinine, sodium and chloride. These are important analytes for the evaluation of diabetes, degree of hydration, electrolyte imbalance, postmortem interval and the state of renal function prior to death (Coe 1977, 1993). Sodium, calcium and chloride concentrations in vitreous humour during the early postmortem interval can be used to estimate antemortem serum concentrations. It is therefore important that sodium fluoride is not added to specimens requiring vitreous chemistries. For that reason, vitreous humour is frequently collected into two separate containers: one preserved (for drug and alcohol testing) and one unpreserved (for clinical purposes).

Cerebrospinal fluid

Cerebrospinal fluid (CSF) can be collected either by lumbar puncture at the base of the spine using a hypodermic syringe or by withdrawal of cisternal fluid by puncturing the base of the neck. Although there are limited published reference data for quantitative drug concentrations in CSF, this clear fluid comprising mostly water is amenable to most routine methods of toxicological analysis. CSF may be of particular importance in alcohol-related cases where no vitreous humour is available, particularly if postmortem alcohol production is suspected. Like vitreous humour, CSF is anatomically isolated and less prone to contamination and bacterial invasion. Although it is more plentiful than vitreous humour, the lack of plentiful reference data limits its usefulness. However, CSF may be particularly useful in surgical death investigations.

Bile

Bile is generally aspirated from the gallbladder using a hypodermic syringe. It may be necessary to tie off the gallbladder prior to collection if contamination appears to be an issue. Bile should be collected prior to the liver specimen to avoid contamination. Many drugs of forensic interest accumulate in the bile, particularly those that are heavily conjugated, such as opiates, benzodiazepines and cannabinoids. Bile may also be used in cases where chronic heavy-metal poisoning is implicated. However, owing to the presence of bile salts and fats, drug extraction from this matrix can be complicated and extensive extraction and clean-up procedures are often required.

Gastric contents

Gastric content is a potentially valuable specimen for analysis in postmortem and clinical cases. Unabsorbed drug or tablet fragments in the gastric contents may provide valuable information concerning ingested compounds and provide an excellent material for preliminary screening (Chapter 9) owing to the potentially large amounts of drug that may be present. The absence of a drug in the gastric contents does not necessarily preclude oral administration. Odours emanating from the gastric content can provide valuable clues about what may have been consumed, e.g. pesticides and cyanides. The entire contents of the stomach should be collected and weighed. Gastric contents are non-homogeneous and should be homogenised prior to sampling. Quantitative drug determinations should be interpreted within the context of the entire contents (total quantity, rather than concentration) and it is important to take into consideration the differing absorption rates of drugs based on their physicochemical properties as well as their formulations and coatings.

The presence of a drug in gastric contents, particularly at low concentration, does not necessarily indicate oral administration. Drugs may be absorbed into the stomach via gastric juices that are in equilibrium with blood or as a result of intranasal drug use. Basic drugs are more susceptible to this because they have a tendency to become trapped in the gastric compartment owing to the low pH. If heavy metals are suspected, gastric contents should be collected, together with intestinal contents. In cases of suspected poisoning where the patient may have survived for a few days in hospital prior to death and where drugs may have been metabolised and eliminated from the body prior to death, any stomach content collected and retained by medical staff may provide valuable information concerning drugs or poisons consumed.

Urine

In antemortem settings, a mid-stream urine sample is usually collected into a plastic container containing sodium fluoride as preservative (Chapter 9). In some settings it may be necessary to take precautions against specimen adulteration. In postmortem settings, urine is collected by insertion using a hypodermic syringe directly into the bladder under visualisation. Puncture of the abdominal wall should be avoided to reduce the possibility of contamination. Urine is a valuable specimen for both antemortem and postmortem drug testing because it is a relatively uncomplicated matrix. However, the multiplicity of factors influencing urine drug concentrations (e.g. urine volume, clearance, metabolism, pH and time of last void) generally means that, in isolation, these results have limited quantitative value. Exceptions to this rule may include ethanol determination in a second void. Care must be exercised when considering the interpretation of urine GHB concentrations as GHB is present as an endogenous compound formed as a by-product of metabolism and may also be produced as a postmortem artefact as a consequence of the breakdown of succinic acid semialdehyde.

Tissues

When tissues are sampled they should be collected quickly and placed immediately into airtight containers. This is particularly important if volatiles or inhalants are suspected. Liver, kidney, brain, lung and spleen are the most frequently collected postmortem tissues.

Liver

Liver is a particularly important organ because of the very large number of drugs that undergo hepatic metabolism and the fairly extensive published reference data that exist. To reduce the possibility of drug diffusion from the small bowel, tissue from deep within the right lobe is preferred (Drummer 2004). The concentrations of drugs and metabolites in liver are often elevated, hence this specimen has limited interpretive value. However, liver is particularly useful for highly protein-bound drugs and the comparison of liver/blood drug ratios may allow the differentiation of acute overdose from chronic drug use for some drugs.

Kidney

Most drugs pass through the kidney as a result of urinary elimination. Kidney is an important specimen in cases of suspected heavy-metal poisoning owing to accumulation in this tissue. The presence of heavy metals or ethylene glycol during toxicological tests may be accompanied by structural changes to the kidney that can be documented using histological tests.

Spleen

Spleen is an important specimen for cyanide or carbon monoxide analyses, particularly in fire-related deaths where blood may be compromised or unavailable. Lung and brain are valuable specimens in cases involving volatiles or inhalants.

Brain

Brain tissue is lipid rich and has a tendency to concentrate some drugs, particularly lipophilic analytes, narcotics and halogenated hydrocarbons (Skopp 2004). If quantitative drug brain concentrations are used, it is important to know the location of the specimen because the brain is a non-homogeneous matrix. Drug concentrations within the brain may vary several-fold from one region to another owing to its complex structure and differing composition. Brain is not widely used in routine toxicological analysis.

Muscle

Muscle is not routinely encountered, despite the fact that it frequently contains relatively high drug concentrations, particularly for substances with high volumes of distribution. Perfusion rates between sites and drug concentrations are not consistent, and drug concentrations must be interpreted accordingly. Muscle is encountered more frequently for

ethanol determination in the absence of blood, or during the investigation of a suspected injection site.

Hair

Hair has been used in a variety of antemortem toxicology settings to provide a history of drug exposure and has therefore found applications in workplace drug testing, in monitoring of persons on probation or on parole for drug use, in insurance testing to verify the truthfulness of statements made by applicants relating to whether they use drugs or are smokers, in child endangerment, in drug-facilitated sexual assault and in other types of criminal casework (Nakahara 1999; Kintz *et al.* 2006; Curtis, Greenberg 2008). Further discussion relating to the scenarios in which hair testing is employed is provided in Chapters 8, 19 and 27. One of the major advantages is the long drug detection window compared with many other specimens. Hair may allow drug exposure over several weeks or months to be determined, depending on the length of the hair. Segmenting the hair by length may allow an approximate timeline for exposure to be determined based on head hair growth rates of approximately 1 cm per month (Clauwaert *et al.* 2000). Hair should be cut as close as possible to the scalp from the posterior vertex region of the head, since this region shows least variation in growth rate. Typically a lock of hair equivalent to the thickness of a pen or pencil is collected. The colour, length, sampling site and any obvious cosmetic treatment of the hair should be recorded. The root (proximal) and tip (distal) sections of the hair should be clearly identified. Although head hair is the preferred specimen, hair from other sites (e.g. pubis, axillae) may be used, but interpretation of analytical findings may be more complex. The lock of hair is typically tied, wrapped in aluminium foil and stored under dry conditions in the dark at room temperature.

Hair is also a useful specimen in postmortem investigations where arsenic or heavy metals are suspected. Although postmortem hair analysis is not yet widespread, there is growing interest because it may provide valuable interpretive information pertaining to the chronological sequence of toxin exposure (Cirimele *et al.* 2002). Hair has also proved to be useful in cases where exhumation is necessary (Tsatsakis *et al.* 2001). If hair is collected *post mortem*, it should be sampled at the very beginning of the examination to reduce the risk of contamination.

Hair can provide complementary toxicological information. Issues with drug testing in hair include external contamination, ethnicity and pigmentation, chemical treatment and the use of appropriate cut-off concentrations. Contamination of the hair with drugs from other sources (external deposition, environmental contamination, sweat or sebum) is generally minimised by pretreatment of the sample using a variety of aqueous and organic rinses or wash steps prior to analysis.

Other keratinised specimens such as nails can also be used to determine long-term exposure to drugs or poisons, in particular heavy metals such as thallium, arsenic or lead. However, drugs are deposited into nails at a much slower rate. External decontamination procedures should be performed prior to analysis (see Chapter 19).

Injection sites

Excision of skin and tissue (muscle) may be necessary in postmortem investigation of a suspected injection site. Typically a cube of muscle and skin is removed for this purpose. However, it is important to compare the drug concentrations in the suspected injection site with those in a control specimen from the same individual where there is no evidence of injection. Injection sites are not always reliable indicators of drug administration since the presence or absence of drugs in injection site tissue is dependent on the type and depth of the injection. If the injection is made directly into a blood vessel, little drug is likely to remain in the surrounding tissue.

Entomological specimens

The potential use of insects for detecting drugs and other toxins in decomposing tissues has been demonstrated and reviewed (Introna *et al.* 2001). If insects or larvae are collected from human remains they should be frozen as soon as possible. Larvae rapidly eliminate drugs when removed from the food source. Drugs, metals and pesticides have been identified in entomological specimens including larvae and pupae. Following wash steps to remove external contamination, entomological specimens are homogenised and analysed in a manner similar to that for tissues.

Saliva

Saliva or oral fluid can be collected non-invasively by expectoration, by aspiration, by vacuum or by saturation of an absorbent swab (Kidwell *et al.* 1998). Detection times are comparable to those in blood. As much as 1.5 L of saliva per day is produced by the submandibular, parotid and sublingual glands inside the mouth. Secretions from a specific gland may be collected using a special device or by cannulation, but this is uncommon. Although specific gland secretions are advantageous from a standpoint of saliva : plasma ratio and reduced oral contamination, mixed saliva is typically collected for routine drug-testing purposes. Oral fluid can be collected non-invasively, conveniently and without invasion of privacy. Chewing an inert substance, such as Teflon tape or a rubber band, may increase salivation for the purpose of specimen collection. It should be verified that no adsorption takes place between the drug and the chewed substance. Acidic sweets or citric acid has also been used to stimulate glandular secretions. Care must be taken that residual food, drink or interfering substances inside the mouth do not interfere with the analysis. This is particularly important for drugs that are ingested orally or smoked.

Owing to the ease and non-invasive nature of specimen collection, saliva is of particular interest in workplace drug testing, for insurance testing and, more recently, for roadside impairment testing. Saliva contains serous fluid derived from plasma. This ultrafiltrate of interstitial fluid contains the unbound fraction of drug at concentrations that are typically proportional to those measured in plasma. However, the predictable relationship that theoretically exists between saliva and plasma drug concentrations is influenced by many factors such as saliva flow rate, which can complicate pharmacological interpretation (Crouch 2005). A more detailed discussion on saliva and oral fluid testing is provided in Chapter 18.

Sweat

Moisture loss via the skin and elimination of insensible (non-visible) sweat take place during normal breathing at a rate of 0.3–0.7 L/day. Sensible sweat refers to perspiration that is actively excreted during stress, exercise or extreme temperature, at rates of 2–4 L/h. About half the total volume of sweat is eliminated from the trunk of the body. The remaining fluid is lost from the legs or upper extremities and head in approximately equal amounts (Kidwell *et al.* 1998).

Sweat is usually collected using an adhesive absorbent patch that is placed on the surface of clean skin or by wiping the skin with a swab or gauze. Careful preparation of the skin is necessary prior to placement of a sweat patch to minimise external drug contamination or bacterial degradation of the drug once it has been retained. Use of a semi-permeable membrane to cover the absorbent pad prevents non-volatile components in the environment from penetrating the pad externally, but allows oxygen, water and carbon dioxide to diffuse through. Salts, solids and drugs that pass through the skin are trapped in the absorbent pad, where they are temporarily stored *in situ*, until the patch is removed.

Owing to the relatively small volume (μL) of insensible sweat secreted from a small absorbent area (typically 3×5 cm), patches are typically worn for several days on the outer portion of the upper arm or back. In practice most skin wipes or sweat patches contain a mixture of sweat and sebum, the oily secretion from the sebaceous glands. As with saliva, increased flow rates can influence the quantity of drug eliminated into sweat. This specimen is particularly useful for compliance testing or monitoring long-term exposure (weeks), which might be desirable in probation or parole settings.

Amniotic fluid

Amniotic fluid has been used to investigate prenatal drug exposure. Its collection (amniocentesis) typically takes place between weeks 16 and 20

of pregnancy. A needle is inserted through the abdomen into the uterus where there is the least chance of touching the placenta or the foetus. The collection of amniotic fluid is typically performed in conjunction with ultrasound visualisation in order to reduce the risk of damaging the developing foetus. Although complications are rare, miscarriage occurs in a very small percentage of women. Typically 5–30 mL of amniotic fluid is removed during the procedure.

Breast milk

During pregnancy, oestrogen and progesterone, secreted in the ovary and placenta, cause milk-producing glands in the fatty tissue of the breasts to develop and become active. The pituitary hormone prolactin stimulates the production of fluid (600–1000 mL/day) by the milk-secreting cells. Contraction of the myoepithelial cells surrounding the alveoli allows the milk to be expressed. For specimen collection purposes, a breast pump can be used. The matrix is somewhat non-homogeneous. Colostrum, a creamy white to yellow pre-milk fluid, may be expressed from the nipples during the last trimester of pregnancy and shortly after delivery. Many drugs are excreted into breast milk and the scientific and medical literature contains numerous citations of the presence of drugs in this matrix (Chapter 27). Drugs that are extensively protein bound may not readily pass into the milk, but emulsified fats contained in the milk may concentrate highly lipid-soluble drugs. The high lipid content and natural emulsifying agents present in breast milk mean that some sample pretreatment is often required.

Meconium

Meconium formation begins between weeks 12 and 16 of gestation. As the first faecal matter passed by the neonate, it is typically collected within 1–5 days of birth. Analysis of drugs in meconium may provide a relatively long-term history of drug exposure during pregnancy, in particular the last 20 weeks of gestation. It provides more complete and long-term information on drug exposure than neonatal urine or cord blood. The specimen is complex and non-homogeneous. All available samples should be collected and homogenised prior to analysis. Meconium and other important matrices involved in maternal–foetal medicine have been reviewed (Gray, Huestis 2007; Lozano *et al.* 2007).

Sample handling

Sample handling is an important consideration during the pre-analytical phase. Unlike a clinical setting, where the time between sample collection and testing is often very short, significant delays are common in a forensic setting. The pre-analytical phase may be considerable, spanning the time of death and/or discovery of a victim, autopsy and collection of specimens, sample storage, transport to the laboratory and subsequent storage prior to analytical testing. In antemortem toxicology settings, the time delay between an alleged offence and specimen collection may be short (e.g. minutes to hours in the case of most impaired driving cases) or long (e.g. hours to days in the case of some sexual assault cases). Following collection, antemortem specimens may be subject to similar delays due to shipping or transport of specimens, requests for testing made by the submitting agency and storage of samples prior to actual testing. Although the toxicologist must consider the time delay between the event (i.e. death, or committing or being the victim of an offence) and collection of a specimen for interpretation purposes, these delays are beyond the control of the laboratory. Measures can be taken, however, to preserve and maintain the integrity of specimens after collection. Sample quality plays an important role in the validity or usefulness of subsequent analytical determinations. Inappropriate sample preservation or storage may have a deleterious effect on qualitative and quantitative determinations.

Preservation and storage

Specimens should be stored at appropriate temperatures, with adequate preservative and in an environment accessible only to authorised personnel to ensure security and integrity. Short-term storage at refrigerated temperature (4°C) is recommended for most samples, or frozen (−20°C or lower) during long-term storage (more than 2 weeks). Exceptions to this include hair, nails or dried blood swatches on filter paper, which can be stored at ambient temperatures.

Whereas clinical specimens are typically unpreserved, the use of a chemical preservative is often warranted in forensic specimens. Preservation of blood samples with sodium fluoride (2% w/v) is routine in most laboratories. Commercial evacuated blood collection tubes (e.g. grey-top tubes) contain sodium fluoride as the preservative and potassium oxalate as the anticoagulant. These are the preferred evacuated blood tubes for antemortem forensic toxicology casework. Inhibition of microorganisms and enzymes with sodium fluoride is important for commonly encountered analytes such as ethanol, cocaine and others. Fluoride acts as an enzyme inhibitor and helps prevent glycolysis.

Commercial blood tubes may contain a wide variety of additives (citrate, heparin, EDTA, thrombin, acid citrate dextrose mixtures, clot activator, etc.). Although these tubes are designed for a variety of clinical uses, they are not the preferred specimen containers for drug-testing purposes. Laboratories frequently encounter these blood tubes when they are submitted from a hospital setting and special care must be taken when interpreting their results (LeBeau *et al.* 2000; Toennes, Kauert 2001). If an anticoagulant is to be used, potassium oxalate is preferred rather than alternatives such as EDTA, heparin or citrate. Antioxidants such as ascorbic acid (0.25% w/v) or sodium metabisulfite (1% w/v) are sometimes used to prevent oxidative losses, but these agents have the potential to act as reducing agents towards some drugs, in particular *N*-oxide metabolites, which may be transformed into the parent drug. In a similar fashion, adjustment of specimen pH is not generally favoured routinely, because, just as some drugs are alkali labile (e.g. cocaine, 6-acetylmorphine), others are acid labile. Sodium azide (0.1% w/v) is sometimes used as a preservative and antimicrobial agent in urine samples. Sodium azide should not be used if samples are to be analysed by enzyme-linked immunosorbent assay because it can interfere with horseradish peroxidase-mediated colorimetric detection.

Although the addition of preservative should be routine for most antemortem and postmortem blood samples, an aliquot of unpreserved postmortem blood is sometimes collected. For example, fluoride preservatives should not be used if organophosphorus chemicals are suspected since this accelerates chemical degradation (Skopp, Potsch 2004). Some drugs are known to be photolabile (e.g. ergot alkaloids such as lysergic acid diethylamide and the phenothiazines). Specimens known to contain photolabile drugs should be stored in amber vials or foil-covered containers, or otherwise protected from direct sources of light. Storage of tightly sealed appropriate containers at low temperature further inhibits sample loss. Short-term storage at refrigerated (4°C) and frozen (−20°C) temperatures is commonplace in most laboratories and repeated freeze–thaw cycles should be avoided.

Labelling and specimen transfer

All samples should be properly marked for identification with the case number, donor name, date and time of collection, signature or initials of the collector and specimen description. Tamper-proof containers and/or tape bearing the collector's initials and date of collection should be used. Specimens should be forwarded to the laboratory in appropriate leak-proof and tamper-proof packaging/shipping materials with all appropriate documentation (chain-of-custody forms, requisitions for testing, special requests, case information, medications list, police report, donor information/identifier such as date of birth or social security number, agency case number, pathologist/police officer name and contact information). Improperly packaged or identified materials should be returned to the submitting agency. Documentation accompanying the specimen(s) should list all of the specimens that were collected or available for testing. Once received by the laboratory, the specimens should be inspected and appropriately documented in terms of condition and quantity during the accessioning process.

Contamination

There are a variety of contamination sources for both antemortem and postmortem specimens. In addition to the potential contamination issues that may result from the use of containers and external factors, a number of important exogenous and endogenous sources of contamination should be considered.

Exogenous contaminants

Specimens collected into plastic containers are sometimes susceptible to phthalate interferences. Numerous plasticiser interferences such as dibutylphthalate may co-extract and interfere with analytical detection by gas-chromatographic or mass-spectrometric techniques, yielding characteristic phthalate ions. All plastic containers should be evaluated prior to widespread implementation. It should be noted that contamination from phthalates may occur during the analytical process through use of disposable pipette tips, solvent containers, solid-phase extraction cartridges, tubing and numerous other sources. However, environmental exposure to these substances from household items, food, beverages and other sources can produce detectable quantities of phthalate esters or their metabolites in biological specimens including blood, serum, urine and breast milk (Silva *et al.* 2005; Högberg *et al.* 2008).

Embalming fluids, which typically contain a variety of alcohols and aldehydes, are a potential source of contamination in postmortem casework. These fluids not only dilute any remaining fluid in the body, but also alter drug distribution in remaining tissues. Another potential source of contamination comes from reusable syringes and containers for postmortem specimen collection. Some cleaning fluids that are used for syringes may contain alcohols that can compromise the analysis of volatiles. This highlights the importance of analysing specimens from multiple sites and using disposable syringes wherever possible.

The principal concern with antemortem contamination arises from the intentional manipulation of the sample to mask the presence of drugs.This typically involves the substitution, dilution or adulteration of the biological specimen with a foreign substance. Donor manipulation occurs most frequently with urine samples in workplace drug-testing situations (see Chapter 3). As a result, specimen validity testing is required in some drug-testing programmes such as for federal employees under US Department of Health and Human Services (DHHS) guidelines. Initially, adulteration of urine for drug-testing purposes involved the use of crude household items such as soap, bleach, vinegar, ammonia or cleaning fluids. Although these substances met with some success, a wide variety of commercial adulteration reagents and kits is now widely available (Dasgupta 2007). A summary of in-vitro adulteration agents is provided in Table 28.4. Some of the most popular commercial products contain glutaraldehyde (fixative), pyridinium chlorochromate (PCC) or chromium(VI)-containing species (oxidant), nitrite (oxidant) or peroxide/peroxidase. In general, in-vitro adulterants can interfere with presumptive immunoassay tests, with the intention of producing false-negative results. However, some agents have the potential to interfere with confirmatory tests such as gas chromatography/mass spectrometry (GC-MS) as well. Although this is less likely, studies have shown that some reagents may produce lower than expected or negative results for some analytes. Adulteration detection products are available commercially. On-site or dipstick tests are available for nitrite, glutaraldehyde, pH, specific gravity, creatinine, bleach, PCC and oxidants.

Specimen dilution or in-vivo adulteration by ingestion of a substance to mask the presence of drugs is also encountered. This is commonly achieved by the ingestion of large quantities of fluid prior to the test or by administration of a diuretic. Examples of in-vivo adulteration agents are given in Table 28.5. Urine specimen substitution or dilution can be detected if specimen validity tests are performed. A specimen may be considered invalid if the pH is between 3 and 4.5 or between 9 and 11. It may be adulterated if the pH is less than 3 or greater than 11. The normal temperature range is 32–38°C. A specimen is considered dilute if the creatinine concentration is less than 200 mg/L and the specific gravity is less than 1.003.

Other sources of contaminants or unexpected analytes include pyrolytic breakdown products due to thermal degradation of drugs. These may be present due to pyrolysis during administration of the drug (e.g. anhydroecgonine methyl ester following crack cocaine use) or occasionally *in situ* during analysis if conditions are not properly controlled or evaluated. Other sources of contamination may arise from pharmaceutical impurities or adulterants and cutting agents that are incorporated into illicit drugs prior to sale.

Table 28.4 In-vitro adulteration agents

- Ascorbic acid
- Alcohols
- Amber-13 (hydrochloric acid)
- Ammonia
- Bleach
- Clear Choice (glutaraldehyde)
- Detergent or soap (surfactant)
- Drano
- Ethylene glycol
- Gasoline
- Glutaraldehyde
- Hydrogen peroxide
- Klear (potassium nitrite)
- Lemon juice
- Liquid soap
- Lime-A-Way
- Mary Jane Super Clean 13 (surfactant)
- Salt
- Stealth (peroxide/peroxidase)
- THC-Free (hydrochloric acid)
- UrinAid (glutaraldehyde)
- Urine Luck (chromium VI, oxidant)
- Vanish
- Vinegar
- Visine
- Water
- Whizzies (sodium nitrite)

Table 28.5 In-vivo adulteration agents

Diuretics

Prescription

- Thiazides **and** thiazide-like drugs (e.g. hydrochlorothiazide, metolazone)
- Carbonic anhydrase inhibitors (e.g. acetazolamide)
- Loop diuretics (e.g. bumetanide, furosemide, torsemide)
- Osmotic diuretics (e.g. mannitol)

Over the counter (OTC)

- Aqua-Ban
- Diurex
- Fem-1
- Midol
- Pamprin
- Premsyn PMS

Other

- Alcoholic beverages
- Xanthines (e.g. caffeine, theophylline, 8-bromotheophylline)
- Herbals **and** aquaretics (e.g. golden seal root, juniper)

Medical artefacts

Clinical therapy can sometimes produce medical artefacts that complicate toxicological findings. Medical artefacts are most common in postmortem cases where infusion pumps may continue to run after death, introducing high concentrations of drug in local body compartments. Access to hospital records and case information, and collection of peripheral blood, vitreous fluid and liver are particularly important in these types of cases. Other sources of medical artefacts may include organ harvest drugs such as the calcium-channel blocker verapamil, or papaverine, which is used to inhibit vasoconstriction during transplant surgery.

If living patients are administered fluids (e.g. saline) during clinical care, blood is only contaminated (diluted) with the infusion solution if it is collected downstream from the intravenous line. Blood circulation and equilibrium with tissues is rapid, so the administration of fluids does not usually influence drug or alcohol concentrations in blood if normal precautions are taken. If downstream collection is suspected, careful review of the medical records and/or measurement of the haematocrit to determine specimen dilution may be necessary.

Endogenous contaminants, artefacts and interferences

By their very nature, all biological specimens are subject to endogenous interferences, regardless of whether or not they are derived from living or deceased persons. More complex biological specimens such as blood, tissue or meconium will require more extensive sample preparation to remove these interferences than less complex matrices such as vitreous humour, or cerebrospinal or oral fluid. In general, however, antemortem specimens are somewhat less susceptible to endogenous artefacts or contaminants. Ethanol, GHB, carbon monoxide, cyanide and other short-chain alcohols can be metabolically produced *post mortem* (Skopp 2004). The formation of toxicologically significant concentrations of cyanide in postmortem tissue (Lokan *et al.* 1987) has been attributed to the conversion of thiocyanate to cyanide and the breakdown of protein (Curry *et al.* 1967). Although in some circumstances ethanol can be produced *in situ* in unpreserved antemortem fluids, the same is true to a far greater extent in postmortem specimens, particularly blood. Likewise, GHB is present in antemortem fluids at very low concentrations in the absence of a serious genetic disorder such as GHB-uria (Knerr *et al.* 2007). Differentiation of exogenous and endogenous GHB is complicated by specimen type, storage conditions, preservative and other factors. Many laboratories use a cut-off concentration to help differentiate the two, for example 10 mg/L in urine (Kerrigan 2002; LeBeau *et al.* 2007). Concentrations of GHB may increase in urine during storage, upon collection and storage of unpreserved blood, or in citrate-buffered antemortem blood (LeBeau *et al.* 2000). Although preserved antemortem blood GHB concentrations are typically lower than those in urine, numerous studies have shown forensically significant concentrations of GHB in postmortem blood. Postmortem urine and vitreous fluid appear to be less susceptible to this increase.

Major changes that occur after death produce autolytic changes and putrefaction by microorganisms. Invasion of microorganisms, particularly from the gastrointestinal tract into tissues and body fluids, occurs within hours at ambient temperature. Lipids, carbohydrates and proteins are hydrolysed by microbial enzymes, the pH of blood steadily increases, and the putrefactive amines, tyramine, tryptamines, phenethylamines and other endogenous substances are liberated.

Trauma is a non-preventable source of contamination in postmortem forensic toxicology. Rupture of organs or compartments within the body can compromise quantitative drug analyses owing to the mixing of fluids (e.g. of gastric contents with blood) or from the microbial action that occurs as a result. Postmortem alcohol production can also result in detectable quantities of ethanol as an artefact. Glycolysis and the presence of yeasts and microorganisms can convert a variety of postmortem substrates to ethanol. Although concentrations are typically low (<0.7 g/L), concentrations of 2 g/L and higher have been reported (Zumwalt *et al.* 1982; O'Neal, Poklis 1996). Postmortem alcohol production is influenced by many factors, including the time between death and sampling, environmental conditions (temperature, humidity, location), external factors (traumatic injury, incineration), the availability of an ethanol substrate and the extent to which microorganisms are available. Vitreous humour and urine provide complementary information that may assist with the interpretation of results. This highlights the importance of collecting a variety of specimens *post mortem*. Other short-chain alcohols can be produced by microorganisms *in situ*. Isopropanol has been documented as a postmortem artefact, particularly in drowning victims. Putrefaction can also complicate carbon monoxide determination in postmortem blood. Increases in the apparent concentration of carboxyhaemoglobin have been documented owing to the formation of methaemoglobin, a decomposition product that can interfere with spectrophotometric determination. Preservation of postmortem blood (and storage in the dark at 4°C or lower) has been recommended (Skopp 2004).

Stability

Drug stability can be influenced by many factors including the physicochemical properties of the drug, characteristics of the specimen or matrix, tendency to conjugate/deconjugate, specimen collection procedure (e.g. contamination with microorganisms), container selection (e.g. oxidation, adsorption), and the use of preservatives or other additives.

The majority of published drug stability studies focus on antemortem or non-biological matrices. Scientific findings for biological specimens are complex because drug instability is often matrix dependent and influenced by factors such as specimen pH and the presence of other substances in addition to external factors. In general, drug instability in any toxicological specimen is due to metabolic degradation, chemical transformation, or a combination of both (e.g. cocaine).

Drug stability in postmortem matrices poses an added level of complexity because conditions are less controlled and degradation of analytes may be accelerated owing to putrefactive decomposition, microbial invasion and the increased presence of bacteria, for example, the bacterial enzymatic conversion of morphine glucuronides to free morphine in blood (Carroll *et al.* 2000), and the bioconversion of nitrobenzenes by enteric bacteria (Robertson, Drummer 1998).

After a specimen has been collected, enzymes may remain active and continue to degrade or transform the drug *in vitro*. This process may take place *post mortem* inside the body, or after postmortem or antemortem specimens have been collected, during transportation to the laboratory and during storage. This is particularly important with esterases, which may further hydrolyse drugs post-collection unless they are inhibited by a preservative.

In general, drug instability arises as a result of moieties or functional groups that are susceptible to transformation, such as esters (e.g. 6-acetylmorphine, cocaine, acetylsalicylic acid), sulfur-containing drugs, photolabile drugs (e.g. phenothiazines, midazolam, lysergic acid diethylamide) or those with functional groups that are readily oxidized or reduced. Although instability typically leads to decreases in drug concentration, this is not always the case. Conjugated drugs, such as the glucuronides may deconjugate under some conditions, increasing the concentration of free drug. Depending on the collection, storage conditions, use of preservative, container type, matrix and other factors, the concentration of a drug at the time of assay may not be identical to the concentration at the time of collection. All toxicological results should be interpreted within this context.

Some drugs also exhibit a degree of thermal instability. This is a consideration for drugs that are subjected to elevated temperatures during administration (e.g. by smoking) and during analysis (e.g. by GC-MS). Pyrolysis products may be indicative of smoking if it can be shown that they are not produced during analysis, for example: anhydroecgonine methyl ester (AEME) following the use of crack cocaine; 1-phenyl-cyclohexene following phencyclidine (PCP) use; and transphenyl propene following metamfetamine use.

Ideally, drug stability should be evaluated in a number of ways: long-term stability in the specimen or matrix of interest; the effect of freeze–thaw cycles; short-term stability (typically refrigerated); and bench-top

(room temperature) stability. The kinetic variables governing instability are often matrix and temperature dependent and an understanding of any one of these (e.g. long-term stability of a particular drug in blood) does not necessarily imply predictable results under different conditions (i.e. short-term storage of the drug in urine).

It should be noted that, although there are many published studies and reviews of drug stability, these tend to focus on long- or short-term storage in common matrices such as blood, urine, serum or plasma. As the number of drugs of interest continues to grow and the variety of specimens becomes more diverse, the scientific literature becomes somewhat limited in terms of drug stability. The stability of drugs in non-traditional and non-biological matrices is beyond the scope of this discussion, but investigations in this area are ongoing. These include studies of the stability drugs in dry stains of biological origin (DuBey, Caplan 1996), in formaldehyde solutions following embalming (Tracy *et al.* 2001), and in hair fibres after exposure to cosmetic treatment such as bleaching, perming or straightening (Pötsch, Skopp 1996). Drug stability data are often confounded by the fact that a considerable number of studies report instability as an incidental or anecdotal finding, rather than as part of a formalised and well-designed investigation of stability. Guidelines for conducting stability experiments and the statistical evaluation of the results have been reviewed (Peters 2007).

Of all of the most commonly encountered drugs, cocaine is certainly the most notorious in terms of instability. Nevertheless, the vast majority of drugs are relatively stable or moderately so to the extent that one can make reasonable assumptions when interpreting the results. Stability for some of the most frequently encountered drugs is summarised below.

Amfetamines

Metamfetamine and amfetamine in urine samples preserved with sodium fluoride (1% w/v) were stable during long-term storage at −20°C for at least a year (Moody *et al.* 1999). A long-term study of whole blood stored over 5 years at room temperature showed erratic but significant decreases in metamfetamine between 3 months and 5 years of storage, ranging from 9% to 38% (Giorgi, Meeker 1995). Results suggested that amfetamine was perhaps less stable than metamfetamine. Samples were collected into 10-mL grey-top Vacutainer tubes with sodium fluoride (100 mg) and potassium oxalate (20 mg). Although both drugs are considered to be moderately stable, storage of blood samples at room temperature is not advised owing to the production of interfering substances.

The overall stability of the amfetamine class extends to many of the designer amfetamines, for example, 3,4-methylenedioxymetamfetamine (MDMA), 3,4-methylenedioxyamfetamine (MDA) and 3,4-methylenedioxyethylamfetamine (MDEA). Stability of these drugs was investigated in urine, blood and water for 21 weeks at −20°C, 4°C and 20°C (Clauwaert *et al.* 2001). Although all drugs were stable at −20°C, results were compromised in blood samples at 5 and 13 weeks when stored at 20°C and 4°C, respectively, owing to matrix degradation and interfering substances.

Cannabinoids

Decreases in cannabinoid concentrations in refrigerated and frozen samples are largely attributed to oxidative losses, temperature effects or lipophilic binding to containers. THC may decompose when exposed to air, heat or light. It can undergo hydrolysis to cannabidiol, or be oxidised to cannabinol as a result of exposure to air or acidic conditions. THC has been reported to be stable in refrigerated blood for 6 months and at room temperature for 2 months (Johnson *et al.* 1984). Binding of THC to hydrophilic surfaces, such as storage containers or rubber stoppers should be considered. For example, THC stored in blood collected in unsilanised glass tubes was stable for 4 days at room temperature and 4 weeks at −20°C. By comparison, similar samples stored in polystyrene tubes showed 60–100% decreases in concentration (Christophersen 1986). The principal metabolite shows greater stability than the parent drug. In one study, 11-nor-9-carboxy-Δ^9-tetrahydrocannabinol (THCA) was stable in frozen urine preserved with sodium fluoride (1% w/v) for a year (Moody *et al.* 1999). However, this study used silanised glassware for urine sample storage, which may not be typical of storage containers for actual casework. Loss of THCA in urine is largely attributed to adsorption, or from foaming of the sample, which can account for losses as high as 89% (Dextraze *et al.* 1989). The use of a de-foaming agent (e.g. 2-octanol) can reverse these losses, but use is not routine. It has been suggested that, although the adsorptive losses of THCA from urine stored in plastic containers take place quickly (within an hour of collection), they are not significant enough to compromise the analysis (Stout *et al.* 2000). Furthermore, adsorptive losses of THCA in urine may be pH dependent, with greater losses occurring at acidic pH (Jamerson *et al.* 2005).

Deconjugation of cannabinoids, such as THCA-glucuronide, to THCA should also be considered (Skopp, Potsch 2004). Hydrolysis of the acylglucuronide results in increased concentration of the unconjugated metabolite. THCA-glucuronide was unstable in urine at 4°C and above, and at increasing urinary pH (Skopp 2004). Studies suggest that THCA-glucuronide is less stable in plasma than in urine (Skopp, Potsch 2002). Although no significant losses in THCA-glucuronide were seen in plasma or urine stored at −20°C, instability was documented following storage of plasma and urine at refrigerated and room temperature, in some cases within 2 days (Skopp, Potsch 2002).

Opioids

6-Monoacetylmorphine (6-MAM) is a labile metabolite of diamorphine due to hydrolysis of the ester bonds. It may undergo deacetylation to morphine during storage. Buprenorphine, codeine, fentanyl, hydromorphone, methadone, morphine, oxycododone, oxymorphone and tramadol were all stable in frozen plasma stored for almost 3 months and subjected to two freeze–thaw cycles (Musshoff *et al.* 2006). Free concentrations of morphine, codeine and methadone were moderately stable in frozen urine preserved with sodium fluoride over a year (Moody *et al.* 1999). However, total morphine concentrations under similar conditions may be less stable (Moriya, Hashimoto 1997). Long-term storage in preserved whole blood stored at room temperature showed significant increases and decreases (Giorgi, Meeker 1995) over 1–5 years. These results suggest important differences in stability between free and conjugated species.

The stability of glucuronidated morphine is of importance because ratios of free and total morphine are sometimes used for interpretive purposes. Marked differences in glucuronide stability exist between antemortem and postmortem blood. Morphine-3-glucuronide was stable in refrigerated antemortem blood preserved with sodium fluoride, but unstable in postmortem blood under the same conditions (Carroll *et al.* 2000). Hydrolysis of the glucuronidated species to free morphine increases with temperature, storage time and degree of putrefaction. Other studies have confirmed the stability of morphine-3-glucuronide in refrigerated antemortem blood and plasma for up to 6 months (Skopp *et al.* 2001). Storage of postmortem specimens at −20°C prevented *in vitro* hydrolysis of the glucuronide.

Phencyclidine

Studies suggest that PCP is a relatively stable drug, even when stored in blood at room temperature for up to 18 months (Levine *et al.* 1983). However, significant decreases in concentration were measured in preserved blood at room temperature over 5 years (Giorgi, Meeker 1995).

Cocaine

Of all of the common drugs of abuse, cocaine is certainly notorious in terms of stability. Both chemical and enzymatic transformations occur to produce hydrolytic products. Spontaneous conversion of cocaine to benzoylecgonine (BE) via the ester linkage occurs at physiological and alkaline pH. At pH 5, there were no measurable decreases in cocaine concentration at 40°C after 21 days, compared with a decrease of 40–70% in urine at pH 8 (Baselt 1983). Ester linkages have a tendency

to be alkali labile, and as a result the chemical transformation of cocaine to BE is increasingly favourable as the pH of the matrix increases. Although the addition of preservative does not prevent chemical hydrolysis, the kinetics can be inhibited by storage of samples at low temperature, or by pH adjustment. The latter is not favoured in routine casework because of the possibility that acid-labile drugs might also be present. Liver methylesterases are largely responsible for the enzymatic transformation of cocaine to BE and plasma pseudocholinesterase for the conversion of cocaine to ecgonine methyl ester (EME). Addition of a cholinesterase inhibitor such as sodium fluoride and reduced temperature are important precautions. Both BE and EME undergo further transformation to ecgonine, a polar metabolite. In unpreserved blood, hydrolysis of the phenyl ester predominates, yielding EME. Addition of sodium fluoride inhibits the production of EME but does not prevent chemical hydrolysis of cocaine to BE. Cocaine in blood stored at 4°C was undetectable within 3 days in the absence of preservative, and only 40–60% of the cocaine was detected in preserved blood and plasma after 21 days (Baselt 1983). There have been numerous studies on the stability of cocaine and its metabolites in various media and comprehensive stability studies are available (Isenschmid *et al.* 1989). In unpreserved blood, cocaine is hydrolysed to EME, whereas transformation to BE predominates in preserved blood. Although BE exhibits greater stability than cocaine, decreases in concentration are largely due to further hydrolysis to ecgonine. BE was shown to be stable in preserved urine for a period of at least 1 year when stored at −20°C (Moody *et al.* 1999).

Chemical hydrolysis of cocaine during analysis should also be considered. Liquid–liquid and solid-phase extraction of cocaine and metabolites from biological specimens routinely employ alkaline conditions during extraction or elution steps. These conditions may result in chemical hydrolysis of cocaine to BE as an artefact of analysis. Minimising the duration of exposure and appropriate use of deuterated internal standards is recommended.

Antidepressants

Studies in serum have shown the tricyclic antidepressants to be moderately stable. Amitriptyline, imipramine, clomipramine and doxepin are relatively stable in serum samples stored at −25°C for 3–6 months or at 4°C for 7 days (Rao *et al.* 1994). Newer antidepressants, including reboxetine, sertraline and venlafaxine, were also stable in frozen plasma. Significant decreases in concentration were seen for sertraline, desmethylsertraline and reboxetine when stored at room temperature for more than 7 days (Heller *et al.* 2004). Atomoxetine, citalopram, fluoxetine, mirtazepine and paroxetine have also shown moderate long-term stability when frozen (Peters 2007).

Neuroleptics

Among the newer atypical neuroleptics, quetiapine and olanzapine have been shown to exhibit significant instability at room temperature (Heller *et al.* 2004). Although both were stable for a few days, quetiapine concentrations decreased by as much as 50% after 14 days and olanzapine was undetected in some samples. However, the majority of neuroleptic drugs, including olanzapine and quetiapine, were stable in frozen plasma at −20°C for 1 month after three freeze–thaw cycles (Kratzsch *et al.* 2003). Phenothiazines exhibit a pH-dependent photosensitivity. Furthermore, increases in chlorpromazine and thioridazine concentrations in patient samples have been documented and may be attributed to a conversion of the metabolite back to the parent drug during storage (Davis *et al.* 1977; Holmgren *et al.* 2004).

Benzodiazepines

Benzodiazepines including alprazolam, chlordiazepoxide, clonazepam, diazepam, flunitrazepam, flurazepam, lorazepam, midazolam, nitrazepam, nordiazepam, oxazepam, temazepam and triazolam were stable in plasma for 1 month at −20°C (Kratzsch *et al.* 2004). Diazepam was found to be stable in blood stored at room temperature or refrigerated over a period of 5 months (Levine *et al.* 1983). In contrast, diazepam and temazepam were unstable in postmortem blood under putrefying conditions. In general, benzodiazepines with a nitro group (e.g. clonazepam, nitrazepam, flunitrazepam) are among the most unstable owing to reduction of the nitro group. Additives that inhibit reduction (e.g. 2% w/v sodium metabisulfite) slow the degradation. Postmortem conversion of nitrobenzodiazepines to their respective 7-amino breakdown products may also occur as a result of anaerobic bacterial action (Robertson, Drummer 1995, 1998). Chlordiazepoxide, which contains an *N*-oxide functionality, is also unstable in whole blood. At room temperature, chlordiazepoxide rapidly decreased and was undetectable by day 8 (Levine *et al.* 1983). Sodium fluoride inhibits the degradation of chlordiazepoxide to nordiazepam and demoxepam, but does not completely prevent it. Storage at low temperatures, preferably frozen, is recommended (Drummer, Gerostamoulos 2002; Peters 2007).

Lysergide

Lysergide (LSD) is photolabile and specimens suspected of containing LSD should be protected from the light. Decreases in drug concentration have been documented in blood, serum and urine, with and without sodium fluoride. In one study, however, LSD concentrations in urine were stable for 4 weeks at room and refrigerated temperatures (Francom *et al.* 1988).

Ethanol

During storage, ethanol concentrations may increase or decrease. Ethanol losses are largely attributed to evaporation, chemical oxidation and microbial consumption, whereas increases are largely due to microbial conversion of substrates to ethanol. Although measured increases in blood ethanol concentrations have been documented under some conditions, this is inhibited by the addition of sodium fluoride as preservative and storage at refrigerated temperatures. Ethanol was stable in fluoridated blood for 2 months at room temperature (Glendening, Waugh 1965). Even after storage for 1–3 years at room temperature, average decreases at room temperature were 0.4 g/L. Average losses following storage of blood at room temperature for 3 and 6.75 years were 0.19 and 0.33 g/L, respectively (Chang *et al.* 1984). In one study, loss of ethanol was evident in blood contaminated by *Pseudomonas*. Although this was not prevented by 1% sodium fluoride, increasing the quantity of preservative to 2% did prevent ethanol loss (Dick, Stone 1987).

Urine is less susceptible than blood to *in vitro* ethanol production except in rare instances. Urine samples treated with microorganisms known to produce ethanol did not produce increases in ethanol concentration greater than 0.2 g/L, even following incubation at 37°C (Blackmore 1968). The use of preservative and refrigeration of urine samples is effective in terms of maintaining ethanol stability. Exceptions have been noted, but are rare. For example, a dramatic increase in ethanol concentration was documented in the urine from a diabetic patient found to contain *Candida albicans*. The increase in ethanol concentration was also accompanied by a significant decrease in glucose concentration (Ball, Lichtenwalner 1979).

γ-Hydroxybutyric acid

In addition to GHB being present in a variety of biological specimens as an endogenous substance, *in situ* production of GHB during storage has been documented and widely studied. In general, increases in GHB concentration are more pronounced in postmortem specimens. The concentration of GHB in an unpreserved postmortem blood sample stored under refrigerated conditions for 4 months approached 100 mg/L. GHB increases in postmortem urine are less pronounced and typically an order of magnitude lower, even in the absence of preservative (Berankova *et al.* 2006). Antemortem samples are much less susceptible to *in situ* production over time (Kerrigan 2002; LeBeau *et al.* 2007). Nevertheless, storage at refrigerated temperature, use of sodium fluoride as preservative and analysis at the earliest possible interval are recommended wherever possible.

CHAPTER

29 Extraction

T Stimpfl

Introduction

The process of extraction is the first step in the qualitative and quantitative analysis of drugs and poisons from complex biological specimens. The large group of substances that are toxicologically relevant (pharmaceuticals, herbicides, pesticides, etc.) differ greatly in their physicochemical properties. They are often potent agents that are present only in very low concentrations. Therefore, a chosen extraction procedure must not only be able to separate the target substances from interferences in the specimens (purification) but also be able to increase their concentration relative to co-extracted matrix compounds (enrichment). The extraction process is often time-consuming and labour intensive, but practical experience shows that the effort is necessary because the subsequent analytical steps are based on, and benefit from, sample preparation. In short, proper extraction increases the chance of a successful analysis of drugs and poisons (e.g. there are fewer interferences in gas chromatography–mass spectrometry (GC-MS) and there is less ion suppression in liquid chromatography–mass spectrometry (LC-MS)). Cleaner extracts also reduce the 'down-times' of sensitive and cost-intensive analytical instruments by increasing service intervals.

Because of the large number of toxicologically relevant compounds and the different questions that need to be answered in the various fields of analytical toxicology, a universal, standard extraction procedure does not exist. Optimised extraction procedures are available for many drugs and poisons and these can be found in this book or through a comprehensive review of the literature. However, the toxicologist will often be confronted with compounds for which no appropriate extraction procedure has been published, necessitating the development of a new procedure based on available data of the target compound (most of which can be found in the individual monographs of this book). In a worst-case scenario, neither the physicochemical properties of the target compounds nor the composition of the specimen is known. A challenging example from the field of postmortem forensic toxicology would be the undirected search for a 'general unknown poison' in a putrefied tissue sample from a homicide case. In such a case, a non-selective extraction procedure covering a wide variety of possible target compounds would be required.

Choosing the best extraction procedure for a particular case and, when necessary, developing a new extraction method that correctly addresses specific case challenges are essential skills of the analytical toxicologist. These will be addressed in this chapter.

The fundamental principles of extraction

In order to develop a successful extraction procedure, some fundamental principles must be considered. An overview of the principles underlying extraction techniques is presented to enable the reader to make use of the data in the individual monographs for drugs and poisons that are included in this book. Comprehensive details about these principles can be found in the literature (see Further reading at the end of this chapter).

The following fundamental principles of extraction are covered in this section: solubility, partition coefficient, dissociation constant, ion-pair extraction, adsorption mechanisms, extraction efficiency recovery and the use of internal standards.

Solubility, distribution equilibrium and partition coefficient

The ability of a substance to dissolve in a particular solvent is referred to as its solubility and approximate values for individual drugs and poisons (from very soluble to insoluble) are given in the monographs. Solubility is temperature dependent and, in most cases, the solubility of organic compounds increases with an increase of temperature.

When a low concentration of a substance is dissolved in water, its extraction into an organic solvent is based on the non-ionised substance's distribution between the aqueous phase and the solvent (which may not be water miscible). Upon reaching equilibrium (according to the Nernst equation) the concentration ratio of the substance, distributed between organic solvent and water, is constant. On this basis, an apparent partition coefficient (K_p) for a particular substance in a two-phase system (e.g. octanol/water) can be defined as:

$$K_p = C_o / C_w$$

where C_o = concentration in the organic solvent and C_w = concentration in water.

The decimal logarithm of the partition coefficient for the octanol/water system gives log P values (see monographs). For ionisable substances, these values are pH dependent.

Examples:

- Tetrahydrocannabinol: log P (octanol/water) = 7.6
- Codeine: log P (octanol/pH 7.4) = 0.6.

These log P values can be a very useful indication of the likely success of extracting a drug from an aqueous medium into an organic solvent, i.e. the greater the value of log P the more likely the solute is to be extracted into an organic solvent.

Equilibrium of electrolytic dissociation, dissociation constant and state of ionisation

In the case of direct liquid–liquid extraction from an aqueous phase, the distribution behaviour of neutral substances can be estimated on the basis of their solubility in different solvents. However, a great number of drugs are acidic, basic or amphoteric compounds (mainly weak electrolytes), resulting in pH-dependent electrolytic dissociation.

At a given pH value, an equilibrium of electrolytic dissociation will be reached in the aqueous phase, which can be described by the acid dissociation constant (K_a) for acidic compounds (HA) and a corresponding dissociation constant (K_b) for basic compounds (B):

$$K_a = [H_3O^+]\ [A^-]/[HA]$$
$$K_b = [BH^+]\ [OH^-]/[B]$$

For practical reasons, the negative decimal logarithm of the dissociation constant is calculated (as $pK_a = -\log_{10} K_a$). These pK_a values are widely used and many of them can be found in the drug monographs. The pK_a values of basic compounds can easily be calculated using their corresponding pK_b values:

$$pK_a = pK_w - pK_b$$

where pK_w = negative decimal logarithm of the dissociation constant of water, which is 14 at 25°C

Examples:

- CH_3COOH: $pK_a = 4.75$
- CH_3COO^-: $K_b = 9.25$
- NH_4^+: $pK_a = 9.25$
- NH_3: $pK_b = 4.75$.

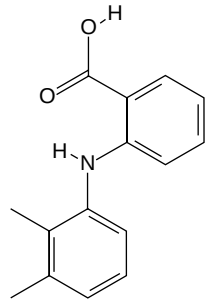
In order to estimate the distribution behaviour of acidic, basic or amphoteric substances for direct liquid–liquid extraction, their state of ionisation has to be considered. This is because only undissociated molecules are extracted into an organic phase (with the exception of ion-pair extraction, which will be discussed later).

According to the Henderson–Hasselbalch equation, an acidic or basic substance is ionised to the degree of 50% at a pH value equal to that substance's pK_a value. For acidic substances, nearly total ionisation (99%) is reached two full pH units or more above their pK_a values, and almost no ionisation (1%) is observed two full pH units or more below their pK_a values.

Conversely, for basic substances 99% ionisation is reached two full pH units or more below their pK_a values, and 1% ionisation is observed two full pH units or more above their pK_a values. Therefore, with regard to the extraction yield of weakly acidic and basic substances using direct liquid–liquid extraction it can be concluded that:

- For acidic substances, the maximum extraction yield is observed two pH units or more below their pK_a values.

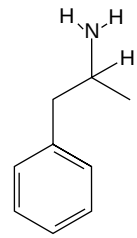
  Thus to extract mefenamic acid (pK_a 4.2) from an aqueous solution, it should be acidified with sulfuric acid to give a pH value of <1. Sulfuric acid should be preferred over hydrochloric acid when separating acidic from basic drugs as many drug hydrochlorides (e.g. methadone hydrochloride) are soluble in organic solvents.



Mefenamic acid

- For basic substances the maximum extraction yield is observed two pH units or more above their pK_a values.

  Thus to extract amfetamine (pK_a 10.1) from an aqueous solution, it should be made basic with sodium hydroxide solution to give a pH value of >13. Ammonia solution will give an aqueous solution pH of only about 10, which is not sufficiently basic for a successful extraction.



Amfetamine

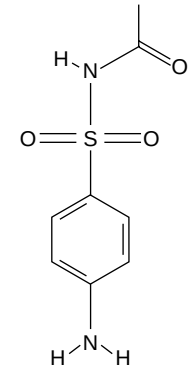
The distribution behaviour of amphoteric organic electrolytes (e.g. with one acidic and one basic function) also depends on their state of ionisation, but extraction yields are more difficult to predict.

Amphoteric substances with one weak acidic and one weak basic function ($pK_a + pK_b > 18$) can be extracted as non-ionised molecules at a pH range around their isoelectric zone, where the ionisation of the basic group has ended and the ionisation of the acidic group has not yet begun. In the special case that $pK_a + pK_b = 18$, the isoelectric zone shrinks to a particular point (isoelectric point) at which the molecule is not ionised.

Example:

- Sulfacetamide: $pK_a = 5.4$ and $pK_b = 12.2$ ($pK_a + pK_b = 17.6$).

  To a great extent the molecule is not ionised at pH = 3.6. (This value lies about two pH units above $pK_a = 1.8$, corresponding to $pK_b = 12.2$, and about two pH units below $pK_a = 5.4$.)



Sulfacetamide

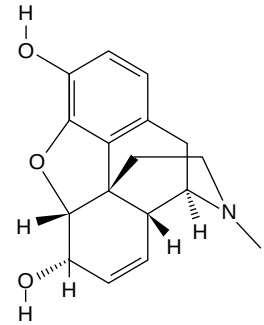
Amphoteric substances with one weaker and one stronger acidic and basic function ($pK_a + pK_b$ = between 18 and 10) can be extracted as non-ionised molecules at a pH range around their isoelectric point with a lower extraction yield because the molecule is also partly a zwitterion (i.e. the molecule has both its acidic and its basic functions ionised).

Example:

- Morphine: $pK_a = 9.9$ and $pK_b = 6.0$ ($pK_a + pK_b = 15.9$).

  The molecule is partly non-ionised at pH = 8.9 (this value lies about one pH unit above $pK_a = 8.0$, corresponding to $pK_b = 6.0$, and about one pH unit below $pK_a = 9.9$); at this pH value there also exist zwitterions that will not be extracted and which therefore reduce the overall extraction yield.

  Thus morphine is best extracted from aqueous media by using a freshly prepared, saturated sodium hydrogencarbonate solution, or similar compound, to give a pH value between 8 and 9. The high salt concentration of the saturated aqueous solution reduces the drug's aqueous solubility and therefore improves extraction efficiency.



Morphine

For amphoteric substances with one strong acidic and one strong basic function ($pK_a + pK_b = 10$ or < 10), zwitterions are to be expected, which results in a limited extraction yield.

Ion-pair extraction

Strong electrolytes (e.g. compounds with a quaternary ammonium function, such as paraquat) and very hydrophilic compounds (e.g. sulfonamides) tend to stay in the aqueous phase and will not be sufficiently extracted by organic solvents. Liquid–liquid extraction can be accomplished only by 'ion-pair' formation with appropriate counterions. These ion pairs are much more soluble in organic solvents than the drugs themselves and so assist an efficient extraction. Anionic dyes such as bromothymol blue, bromocresol green and bromophenol blue are widely used for this purpose. Moreover, solvents such as chloroform and dichloromethane can extract basic substances as hydrohalogenides, perchlorates, nitrates, phosphates, sulfates or thiocyanates. Conversely, the extraction of acidic drugs can be improved by using quaternary ammonium compounds such as cetyltrimethylammonium bromide as ion-pairing compounds.

Adsorption

Extraction of non-volatile drugs and poisons from biological specimens can also be accomplished by adsorption and the fundamental principles discussed above form the basis for adsorption methods as well. When adsorption is used, intermolecular interactions (van der Waal's forces, aromatic interaction) or electrostatic interactions will enable the isolation of target compounds from the biological matrix.

Hydrophobic interactions between neutral or non-polar substances are based on dispersion forces and are short-ranged, weak interactions between molecules or parts of molecules (bond strength 4–20 kJ/mol). They result from random fluctuations in local electron density distribution within molecules.

Hydrophilic interactions between polar functional groups or two dipoles are based either on hydrogen bonding (e.g. hydroxyls, carboxylic acids, amines), or on dipole–dipole interactions. Like dispersion forces, they too are short ranged and relatively weak forces (bond strength 10–40 kJ/mol).

Aromatic interactions are caused by attractive forces between diffuse electron clouds in π systems; their bond strength is similar to dispersion forces.

Electrostatic interactions between oppositely charged molecules have the highest bonding energies (200–1000 kJ/mol) and ionic bonding can be used for extraction via ion exchange.

Extraction efficiency, recovery and internal standards

On the basis of the fundamental principles described above, and on the data that can be found in the individual monographs of this book, extraction methods can be developed and optimised with respect to extraction efficiency. With a high extraction efficiency for the target compound, it should then be possible to create a complete analytical procedure with sufficient overall recovery (a complete procedure includes sample pre-treatment, extraction, fractionation, purification, evaporation, chromatographic separation, detection, identification and quantitative determination). The overall recovery can be calculated as the percentage of the analyte response after sample work-up compared with that of a solution containing the analyte at a concentration corresponding to 100% recovery. A low overall recovery can be tolerated only as long as the data for limit of quantification (LOQ) and limit of detection (LOD), precision and bias are acceptable (this is why recovery is not an essential part of method validation). However, it is good practice to determine recovery at high and low concentrations and ensure that it is greater than 50% to confer robustness to the analytical procedure.

For the quantitative determination of the analyte, and in order to monitor the whole procedure when biological specimens are extracted, an internal standard has to be added at the earliest possible stage. The internal standard must mimic the physicochemical properties of the analyte as closely as possible and must follow the target compound through the entire process of extraction and subsequent analytical steps in order to compensate for any loss of the target compound.

The selection of the internal standard can be a difficult task and each individual step of the whole analytical procedure should be carefully considered when making this decision. Even minor differences in the physicochemical properties between the target compound and the internal standard can result in errors, because of their different behaviour during extraction, fractionation, purification and concentration towards the applied chromatographic system, the reagents for derivatisation or their response to the detection system.

When mass spectrometry is used, stable-isotope-labelled analogues of the target compounds are the best choice as internal standards. For other analytical techniques or, if stable-isotope-labelled analogues are not available, alkyl analogues (because of their similar structure) can be used as an alternative; but it should be kept in mind that some alkyl analogues – such as morphine and codeine (methylmorphine) – can show significant differences in their physicochemical properties (the additional methyl group in codeine inactivates the phenolic function that is active in morphine). If alkyl analogues are also not available, the internal standard should be chosen on the basis of similarity in structure and functional groups (preferably from the same substance class, e.g. benzodiazepines). When glucuronides are analysed, the internal standard should also be a glucuronide. Only if there are no alternatives should active drugs be used as internal standards; in this case the presence of the active drug used as the internal standard would have to be tested for separately in the specimen. The following examples illustrate some specific considerations that should be kept in mind when choosing the internal standard: when GC is used, attention should be paid to volatility, thermal stability and reactivity with the possible derivatisation reagent; for LC, the solubility in the injection solvent (e.g. mobile phase of the LC) and the response to the detection system (e.g. UV spectrum), as well as the applicability of the ionisation technique for LC-MS should be considered. Sometimes simple problems at the beginning of the procedure can cause errors, such as the solvent used to add the internal standard to the sample (e.g. problems because of protein precipitation, or different extraction of the previously dissolved internal standard and the target compound from the sample matrix). Moreover, the added concentration of the internal standard should be similar to the expected concentration of the analyte.

In conclusion, stable-isotope-labelled analogues of the target compounds mimic the analyte very closely and therefore they should be used whenever available. But it should be kept in mind that the high separation power of modern chromatographic systems can separate stable-isotope-labelled analogues from the targeted analytes (stable-isotope-labelled analogues elute slightly earlier), leading to the possible influence of, for example, ion suppression on only one of the compounds. Moreover, stable-isotope-labelled analogues and targeted analytes can produce identical ion fragments, which can lead to problems during quantification.

To produce accurate quantitative results, the analytical procedure should be validated (see Chapter 20). If a certified reference material to validate the analytical procedure is not available (e.g. for postmortem specimens), then the 'method of standard addition' can be used, where calibration and quantification are performed directly in the sample matrix, compensating for matrix effects. In this procedure different concentrations of the target compound are spiked to aliquots of the homogeneous sample prior to work-up and the detector responses are plotted as a graph ('standard addition plot'). The initial concentration of target compound can then be calculated via extrapolation.

Practical aspects of extraction

The isolation of the compounds of interest from the biological matrix is essential for their successful detection, identification and quantification. The strategy applied and the effort invested in the development of an extraction procedure depend not only on the physicochemical properties and the expected concentration of the target compounds but also on the nature of the specimen and the available equipment in the analytical laboratory. Sometimes the physicochemical properties of the target compounds allow for their direct detection after digestion of the sample matrix (e.g. metals), or for an easy separation from the less-volatile

matrix components (e.g. gases and volatile compounds via headspace analysis). However, there is an important group of less-volatile drugs and poisons that demand more complex extraction procedures (such as liquid–liquid or solid-phase extraction) to ensure their isolation from the biological matrix.

A literature review of the *Journal of Analytical Toxicology* over the past 20 years shows that the number of publications using liquid–liquid extraction has been quite constant and has covered a wide range of analytes, whereas, for solid-phase extraction, the number of publications has continuously increased and, in recent years, the focus has switched from drugs of abuse to applications with a wider range of target analytes. It can be concluded that, although the importance of liquid–liquid extraction in analytical toxicology has already been established, solid-phase extraction is gaining increasing importance in this field.

These two important techniques for the extraction of less-volatile drugs and poisons will be discussed in more detail in this chapter. The final decision about which of these two techniques should be chosen for the particular challenge at hand is mainly based on the practical experience of the analyst and a careful consideration of the objective and the intended use of the extraction method, as well as the availability of analytical techniques.

Preconditions of extraction

Frequent problems in analytical toxicology include the lack of control over the sampling process and, sometimes, a limited availability of specimens. Such problems can result in insufficient or even inadequate samples. This challenge is partially resolved by close cooperation with the person responsible for sampling (e.g. the physician or pathologist) as well as appropriate quality control and educational measures.

In most cases, the appropriate preparation of the specimen is a fundamental precondition for successful sample extraction. Protein-free samples (such as urine) or liquid samples with low protein content (such as serum or plasma) that are frequently used in clinical toxicology are comparable to a purely aqueous phase and therefore direct extraction can be tried. If metabolites should also be detected, hydrolytic cleavage of the conjugate bond (deconjugation) with strong acids, bases or enzymes prior to extraction can increase the recovery of these metabolites from biological fluids. This approach is particularly useful for urine and essential for drugs (e.g. laxatives) that are excreted almost exclusively as conjugated metabolites. For the differentiation of the amount of conjugated and unconjugated metabolite present in the sample, either LC-MS is required or two analyses have to be performed. In the first step the unconjugated metabolite is extracted and quantified and then the sample is re-analysed after hydrolysis, resulting in 'total' metabolite concentration (conjugated plus unconjugated). To obtain reliable quantitative results, appropriate standards (also conjugated) must be carried throughout the procedure to monitor the efficiency of the hydrolysis step.

The use of an enzyme to cleave chemical bonds is the more specific of the different approaches mentioned above. It incurs additional cost and is more time intensive, but cleaner extracts can be achieved, which reduces the 'down-time' of analytical instruments. For the different preparations of purified glucuronidase and sulfatase that are available, it is crucial to pay attention to their pH and temperature optima to obtain reproducible results.

A typical procedure for the enzymatic hydrolysis of glucuronides is as follows. Mix 1 mL of blood or urine with an internal standard and 1.5 mL of appropriate buffer and then add 100 µL of β-glucuronidase obtained from *Helix pomatia*. Mix the solution and incubate it at 37°C overnight (approximately 16 h). After incubation, the pH of the solution is adjusted appropriately for solvent or solid-phase extraction of the compounds of interest (see also Chapter 10).

Acid or basic hydrolyses (Dubost, Pascal 1955), although faster and less expensive, tend to produce more artefacts due to the vigorous hydrolysis conditions and are therefore more demanding in terms of necessary clean-up procedures. Typically, strong mineral acids or alkalis are used, often with boiling or treatment in a microwave or pressure cooker. To protect the analytical instruments in subsequent analyses, the extracts must be neutralised and organic solvents have to be dried prior to injection, otherwise chromatographic performance deteriorates quickly. Moreover, care should be taken to ensure the stability of the analytes under these harsh conditions of hydrolysis. If several compounds can be hydrolysed to an identical, single compound, the accurate identification of the original substance present can be precluded. For example, both the acid and the enzymatic hydrolysis of benzodiazepines result in the cleavage of conjugates, but acid hydrolysis also converts different drugs to the same benzophenone compound (e.g. diazepam, temazepam, ketazolam, medazepam and camazepam are all converted into 2-methylamino-5-chlorobenzophenone). Although the resulting compound has good chromatographic characteristics, the approach is unsuitable for those applications (such as forensic analysis) that require absolute identification of the drug ingested (see also Chapter 40).

Biological materials that are not homogeneous, protein rich or degraded (such as tissue samples and postmortem samples) need homogenisation (e.g. with a blender to disrupt the cellular structure) and sometimes further sample preparation, such as deproteinisation, before extraction from the aqueous phase is possible.

Homogenisation can be performed directly in a buffer solution with a physiological pH of 7.4, to avoid protein precipitation. A high dilution ratio of blood (up to 1 : 10) and tissue (up to 1 : 50) results in samples that tend not to clog tightly packed extraction cartridges and are therefore suitable for direct solid-phase extraction. Automation of the extraction process will enable the analyst to handle the large sample volumes and at the same time secures a uniform and efficient extraction by providing a homogeneous flow of the sample through the extraction cartridge.

For liquid–liquid extraction of complex sample matrices, protein precipitation is generally needed before extraction. Deproteinisation can be performed with solvents such as ethanol or acetone, or with dimethylformamide, which is particularly well tolerated by most GC stationary phases. Moreover acetonitrile is frequently used for procedures where high performance liquid chromatography (HPLC) systems are applied. It is usual to use two volumes of organic phase to one volume of blood.

The following procedure of a combined protein precipitation and subsequent extraction with acetonitrile under alkaline conditions works for target analyses of neutral and basic compounds in specimens of low collagen content (such as blood or brain tissue): to 0.5 mL of blood or 0.5 g of homogeneous brain tissue, add an internal standard and a freshly prepared mixture of 1 mL acetonitrile and 0.1 mL of a saturated aqueous solution of disodium hydrogenorthophosphate. After shaking, centrifugation and evaporation of the supernatant the reconstituted residue can be extracted. For solid-phase extraction, the dilution of the supernatant (to achieve a concentration of acetonitrile below 20%) is in most cases sufficient and the resulting solution can be applied directly to the sorbent.

Protein precipitation may also be accomplished with acids (e.g. hydrochloric acid, perchloric acid, trichloroacetic acid and tungstic acid) and salts (e.g. sodium tungstate, ammonium sulfate, cupric sulfate and uranyl nitrate) (Curry 1988).

However, all of these procedures are very time-consuming and labour intensive. Protein precipitation also risks loss of the analyte from adsorption and occlusion. When perchloric, trichloroacetic or tungstic acids are applied there is a particularly high chance that the drugs being analysed may also be co-precipitated. For the extraction of trace amounts of drugs and poisons from complex matrices, dilution and homogenisation with water or buffer solutions are therefore preferred and can prevent these problems.

To prepare tissue specimens for extraction, enzymatic digestion of these samples is sometimes useful and can be achieved using pepsin, trypsin, enterokinase, lipase and β-glucuronidase. A suitable procedure is as follows: macerate 10 g of liver or other tissue with 40 mL of 1 mol/L tris(hydroxymethyl)methylamine; add 10 mg of subtilisin Carlsberg and incubate in a water bath at 50–60°C for ~1 h, with agitation. Filter the digest through a small plug of glass wool to remove undissolved connective tissue. Aliquots of this digest may be substituted for the specified biological fluid in most routine screening procedures

(Osselton 1978, 1979; Osselton *et al.* 1978). The filtered digest has a pH of 8.0–9.5 (see also Chapter 10).

The drawback of this procedure is that the resulting extracts contain undesirable by-products and artefacts, created during the process of digestion, and therefore a screening procedure will become more difficult. The presence of proteases may interfere with antibodies in immunoassay screening procedures.

Even after extensive sample preparation, a large number of matrix components are still present in the sample and these will affect the solubility and the sorption of analytes through their association with molecules as well as by their ability to change the ionic strength of a solution. Soluble matrix components are also distributed between heterogeneous phases and can influence the completeness of equilibrium adjustment as well as the overall extraction efficiency. These considerations have to be kept in mind for the subsequent extraction procedure.

Liquid–liquid extraction

Direct liquid–liquid extraction (LLE) is still predominant in many laboratories when protein-free samples (such as urine) or liquid samples with low protein content (such as serum or plasma) need to be extracted, because this technique is fast, inexpensive and efficient. LLE is based on well-defined thermodynamic relationships and has a wide dynamic range.

The extraction yield is strictly determined by:

- The distribution equilibrium (solubility)
- The equilibrium of electrolytic dissociation (pH dependent)
- The ratio of phase volumes (organic/aqueous)
- The number of extraction stages.

In practical applications, the constitution of the sample matrix has an important influence on results and appropriate sample pre-treatment (e.g. protein precipitation) is a fundamental prerequisite for successful LLE. An excess of solvent and/or repetitive extraction will simply increase the amount of co-extracted impurities. Therefore, a phase ratio (organic/aqueous) of 1 to 2 is recommended. For compounds with low extractability, it is better to switch to another solvent instead of increasing the volume of the organic phase and/or to engage in multiple extractions. In order to separate target compounds from interferences as well as from each other, their varied distribution constants and different acidic or basic properties can be used for fractionation or back extraction (see below).

Practical experience shows that, in order to achieve sufficient separation, the pK_a values of the compounds to be separated must differ by more than four units. Fractionation in more than two or three groups is therefore ineffective, because under such circumstances substances are dragged into several fractions. It should be kept in mind that neutral compounds are to be expected in the first fraction and that co-extraction of endogenous compounds is to be expected in each extract. Therefore, in every extraction scheme, sacrifices must be made when it comes to the question of the cleanliness of extracts. For the adjustment of an appropriate pH in the aqueous solution, acids or bases can be used, but in this case the stability of the analyte and the possibility of protein precipitation should be kept in mind. Thus the use of an appropriate buffer solution for the reliable adjustment of the pH is recommended.

The choice of solvent is mainly based on the solubility of the drugs and poisons that have to be extracted and follows the rule of thumb that 'like dissolves like'. Moreover, the solubility of known interferences from the sample matrix (such as lipids: fatty acids, cholesterol, etc.) that have a negative effect on the identification and/or the quantification of the analyte should also be considered in the choice of the solvent. A major criterion for the solubility of a particular substance is the solvent's polarity, which results from an unequal sharing of electrons within the molecule and depends on the electronegativity of its atoms and the asymmetry of the molecule. Polarity aside, solvents can also be chosen by their ability or inability to form hydrogen bonds (hydrogen donor or acceptor), their boiling point (solvent removal with the risk of evaporation losses), their pH stability (e.g. ester cleavage), as well as their water miscibility. A low solubility of water in the solvent facilitates drying of the extract and co-extraction of water-soluble substances (e.g. salts) can be minimised. In the case of larger amounts of water dissolved in the solvent, it is possible to put the extract in a freezer to freeze the water in order to remove it. Small amounts of water can be removed by addition of anhydrous sodium sulfate, but the possible loss of trace amounts of the analyte should be kept in mind. When choosing a solvent, the potential toxicity should also be considered (e.g. chloroform) as well as flammability and explosive potential (e.g. peroxides in diethyl ether). For practical reasons the density (top or bottom layer with water), and the solvent's UV absorbency (when spectrophotometric detection is used), as well as the grade of purity are important considerations. Before a solvent is used in a new extraction procedure, an aliquot of the solvent should be evaporated and the residue should be analysed to detect any impurities. Moreover, solvents possess different emulsifying potentials (e.g. that of chloroform is greater than that of diethyl ether), and the correct choice of solvent for LLE also includes considerations to avoid emulsion formation. The addition of neutral salts and the use of slow rotation or vortex speeds as well as using larger phase volume ratios can prevent the formation of emulsions. If emulsions are unavoidable, the phases may be separated by centrifugation, by putting the extract in a freezer and by the addition of a small amount of methanol. If emulsions are routinely obtained, the extraction method should be changed. A promising approach to avoiding emulsions, which also works well for solvents with a high density (such as dichloromethane) that are difficult to isolate from the bottom layer with water, is immobilisation of the aqueous phase (e.g. on diatomaceous earth) prior to extraction. This technique of a supported LLE can increase the extraction yield for the analyte. Some solvents can possess potential reactivity with certain analytes (e.g. some pesticides react with ethanol or acetone) and also ion-pair extraction can occur in certain solvents. This can be exploited to extract analytes (e.g. paraquat), but sometimes ion-pair extraction is an unwanted side-effect (e.g. in the case of extraction of hydrochlorides with chloroform or dichloromethane).

Finally, the analytical method applied may also influence the choice of the solvent. For example, in GC, chlorinated solvents would not be chosen if a halogen specific detector were going to be used. However, if the extract is to be evaporated to dryness and then reconstituted in another solvent before being injected into the chromatographic system (e.g. the eluent of an HPLC system), the choice of the original solvent can be wider. The boiling point and expansion volume of the solvent may also be issues (see also Table 40.6 in Chapter 40).

Adding a high concentration of neutral salts (e.g. sodium chloride) to the aqueous phase can support the extraction process (the 'salting-out effect'), depressing the mutual solubility of phases and simultaneously reducing emulsification and foaming.

The evaporation of solvents (for enrichment) demands particular care in order to avoid the loss of volatile analytes (e.g. amfetamines: b.p. 200°C). To prevent the loss of volatile analytes, a small volume of acidified methanol can be added to the extract prior to evaporation. The quality and the volume of the glassware should be chosen with care, to avoid loss of the analyte by adsorption and to enable the reconstitution of the extract in a small amount of solvent (to optimise the concentration step) for further analyses.

The appropriate solvent should extract as much of the target compound as possible while at the same time co-extracting only a minimum of interferences. To identify which solvents are frequently used in analytical toxicology, a literature review of the *Journal of Analytical Toxicology* over 5 years (2004 to 2008) was performed (Table 29.1). The most frequently used solvents were ethyl acetate, followed by 1-chlorobutane, hexane and dichloromethane. Isopropyl alcohol was mainly used as a modifier. Chloroform and diethyl ether were frequently used in the past as versatile solvents and, although the severe health risks of chloroform and the fire and explosion hazards of diethyl ether are well known today, they are still in use and have not been totally substituted by dichloromethane and methyl t-butyl ether, respectively. Finally, acetonitrile was also used on a regular basis. Other solvents (such as toluene, methanol, pentane, butyl acetate, acetone and ethanol) were used only occasionally.

Table 29.1 Number of times a solvent was used in a paper published in the *Journal of Analytical Toxicology* between 2004 and 2008 inclusive

Solvent	*Number of citations*
Ethyl acetate	38
1-Chlorobutane	28
Hexane	27
Dichloromethane	25
Isopropyl alcohol	22
Chloroform	18

Acetone	1
Cyclohexane	1
Tricholoroethanol	1
Ethanol	1
TOTAL	227

When a new extraction procedure is developed, and there are no data about an appropriate solvent available, the following solvents should be tested after adjusting the aqueous solution to an appropriate pH value (in order of increasing polarity): hexane, 1-chlorobutane, methyl *t*-butyl ether, dichloromethane, 1-butanol, ethyl acetate and acetonitrile. The basic properties of these solvents can be found in Table 29.2.

If the results are not sufficiently good using a pure solvent, then modifiers can be added, such as in chloroform–2-propanol (9 : 1; e.g. for morphine), or mixtures can be used. Although so-called all-purpose extraction solvents such as ethanol–hexane–acetone (1 : 2 : 2) or dichloromethane–2-propanol–ethyl acetate (1 : 1 : 3) are used, it should be kept in mind that, in general, the more substances with different physicochemical properties are extracted, the larger the amount of interferences from the matrix that will be co-extracted. These mixtures are therefore primarily used in the screening for a 'general unknown'. For target analysis, a toxicologist would choose a more refined procedure with a more selective solvent. If the target compound is known, data about appropriate solvent and pH value for extraction can be found in the monographs in this publication or through a literature review. A frequently used solvent that co-extracts a relatively low amount of interferences from biological samples when compared with other solvents is 1-chlorobutane. For this solvent, extraction yields of 331 toxicologically relevant compounds are available from aqueous media at pH 9.0 (Table 29.3 and in the relevant monographs). At this pH, 228 of the 331 compounds were extracted with an extraction yield equal to or higher than 80% (represented in Table 29.3 by a yield in the organic phase with a value equal to or higher than 0.8). For the remaining compounds, sufficient extraction yields could be reached by changing the pH to acidic (e.g. for phenobarbital) and/or through the addition of a modifier (e.g. for morphine). If a target compound has to be extracted, the database gives a quick overview of the extractability of the compound with 1-chlorobutane at a defined pH value. If the extraction yield from aqueous solution is good, it can be expected that the extraction is also possible from serum.

Example protocols for the extraction of various analytes can be found in various chapters of this book (e.g. Hospital Toxicology (Chapter 1), Postmortem Toxicology (Chapter 10) and High Performance Liquid Chromatography (Chapter 41)). The extraction procedure will become more complex with an increase in the complexity of the sample matrix because additional steps for purification (back extraction) have to be added.

As an example of a complete extraction scheme for the extraction of bases, neutrals and acids, and to illustrate the theoretical background discussed above, the following is reproduced from Chapter 10.

The pH of the specimen influences the extent to which acid and basic drugs are extracted. Addition of a weakly basic buffer, such as sodium borate (pH 9), favours the extraction of weakly basic drugs, as well as most neutral substances. Similarly, the addition of an acidic buffer, such as sodium dihydrogenphosphate, favours the extraction of acidic as well as neutral drugs. The majority of drugs of forensic interest are 'basic' in character, but are often present at relatively low concentrations in blood. It is, therefore, desirable to have an extraction scheme that incorporates a back-extraction step to eliminate or minimise the extraction of endogenous molecules. An example extraction scheme is shown in Fig. 29.1. The saturated sodium borate solution will force the basic drugs into the lipid-soluble un-ionised form, allowing extraction into the chlorobutane. The chlorobutane is transferred to a fresh tube and the drugs are back extracted into sulfuric acid. Neutral or acidic substances will remain in the upper chlorobutane layer, which may be pipetted or aspirated to waste. The remaining acid layer is then made basic by addition of sodium hydroxide, and the now un-ionised basic drugs are re-extracted with chlorobutane. The upper solvent layer may then be removed and concentrated under nitrogen, prior to analysis by a suitable chromatographic method. This extraction scheme will give extracts that are relatively free of interfering substances. However, it should be noted that morphine and other amphoteric drugs cannot be detected by this method since the phenolic functional group will

Table 29.2 Properties of solvents

Solvent	*Density (g/mL)*	*Boiling point (°C)*	*Solubility (g/100 mL water at 20°C)*	*Polarity index (water = 10.2)*	*Hydrogen acceptor*	*Hydrogen donor*

Extraction yield = extraction yield in the organic phase (e.g. 0.3 representing an extraction yield in 1-chlorobutane of 80%).
The database was compiled by the Committee on Extraction of the Society of Toxicological and Forensic Chemistry under the supervision of Dr U. Demme, and is reproduced here with the kind permission of the Society of Toxicological and Forensic Chemistry.

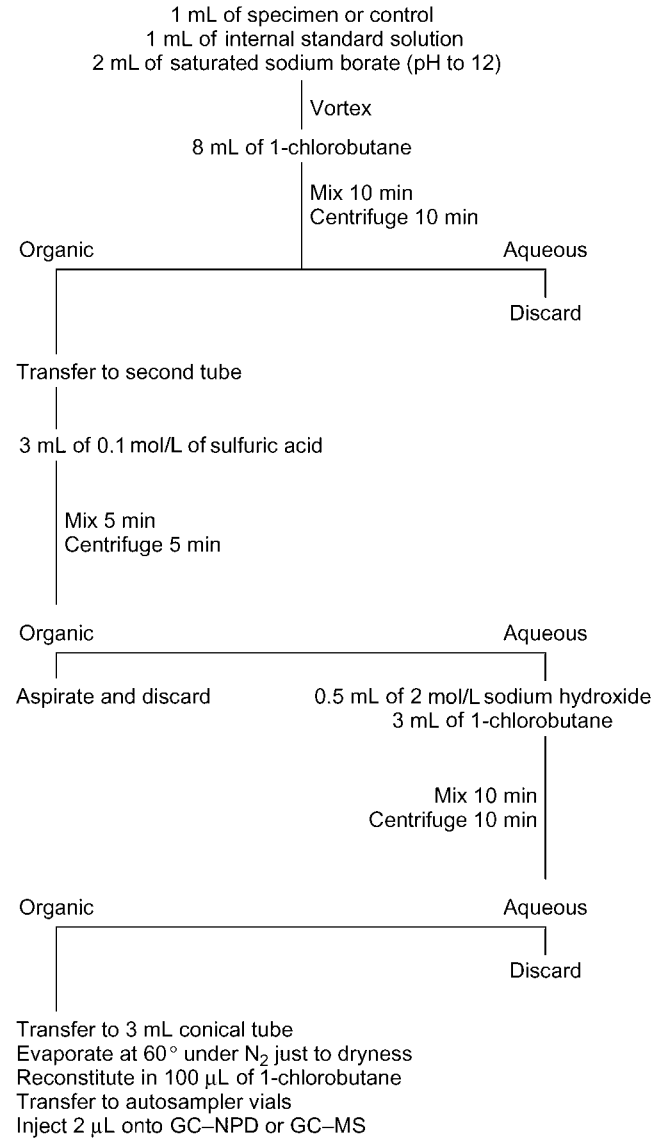

Figure 29.1 Extraction scheme for strong bases.

ionise at high pH, therefore precluding extraction into the solvent. For amphoteric drugs, the basic phase should be less than pH 9.0, and preferably pH 8.0–8.5.

Although a similar extraction scheme to that used for basic drugs (but with the additions of acid and base reversed) could be used for strongly acidic drugs, such a method does not efficiently extract weakly acidic drugs, such as the barbiturates, and neutral drugs, such as meprobamate. Conversely, simple addition of an acidic buffer to whole blood and extraction with a solvent results in the co-extraction of large amounts of endogenous lipid substances. Such extracts may be 'cleaned up' by partitioning between immiscible solvents of different polarities, such as acetonitrile and hexane, as shown in Fig. 29.2. The more polar drugs tend to partition into the acetonitrile, whereas the endogenous lipids (fatty acids, sterols) tend to partition into the hexane.

Solid-phase extraction

Although method development for solid-phase extraction (SPE) is not as straightforward as for LLE, this technique offers appealing advantages. Because of SPE's high extraction efficiency, even very small sample sizes are sufficient, thereby reducing solvent consumption. Additionally, there is no emulsion formation.

Past problems with inconsistent quality of the extraction cartridges have been overcome by manufacturers' implementation of extensive quality control measures. The increasing interest in SPE by toxicological laboratories lies mainly in its compatibility with automation. The need for automated extraction procedures is directly related to the expectation that toxicological laboratories become economically self-sufficient as well as an increased demand for quality assurance and reproducibility and, therefore, comparable results between different laboratories.

In SPE the analytes are isolated from the aqueous sample by adsorption onto a solid sorbent, followed by washing and elution steps. In each of these steps a mechanism of total retention or total release of the target compounds is desired and, as with LLE, this technique is based on the fundamental principles of extraction discussed above. Depending upon the choice of sorbent, the extraction of toxicologically relevant compounds is achieved via hydrophobic, hydrophilic, aromatic or electrostatic interactions; often a combination of several mechanisms is involved. In the field of analytical toxicology non-modified silica, surface-modified silica and polymer resins are used, and a more detailed description of these sorbents can be found in Chapter 41 (packing materials). To date, both selective procedures (for target analysis) and non-selective SPE procedures (for the screening for a 'general unknown') have been developed. Because a wide variety of different analytes can be extracted using a combination of hydrophobic and electrostatic interactions, these so-called mixed-mode sorbents (or functionalised sorbents, or hybrid extraction sorbents) are widely used in analytical toxicology. A practical

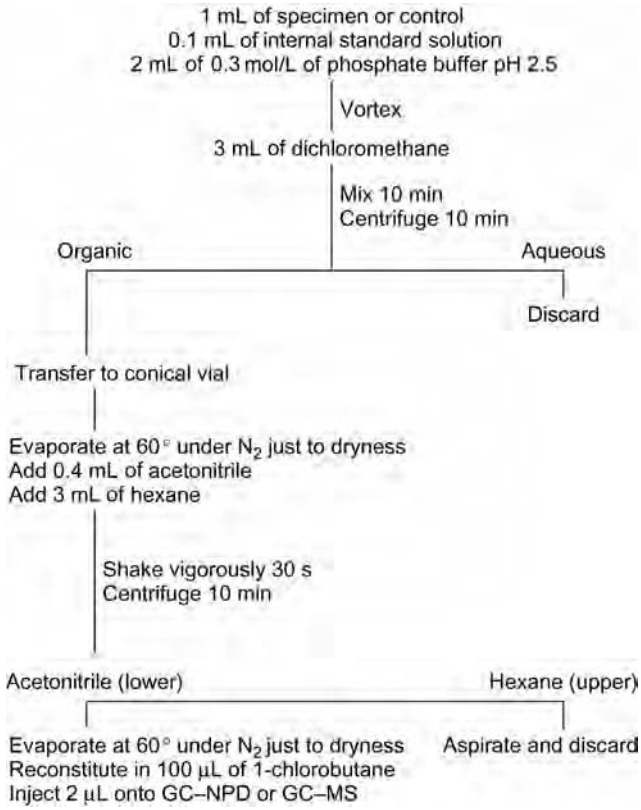

Figure 29.2 Extraction scheme for acids and neutrals.

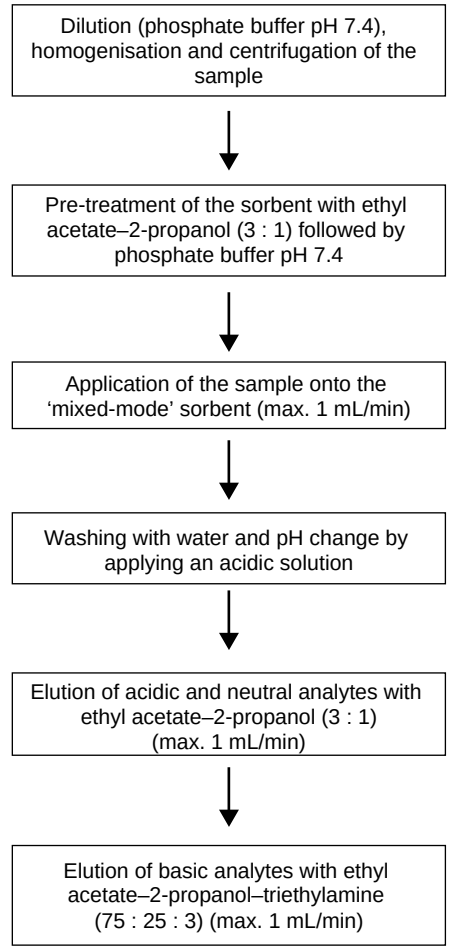

Figure 29.3 Overview of a 'mixed-mode' solid-phase extraction procedure.

example of such a procedure for the extraction and fractionation of neutral and basic metabolites of cyclizine in the urine of racehounds can be found in Chapter 7.

To illustrate the fundamental principles and possible pitfalls of SPE, the following section includes a step-by-step discussion of the development of a non-selective 'general unknown' screening procedure for a wide variety of analytes. An overview of the procedure can be found in Fig. 29.3.

The first step is the appropriate pre-treatment of viscous specimens so that the samples do not cause flow problems when passing through the tightly packed cartridges and choosing the sorbent. Tissue homogenates, especially, tend to clog the polyethylene frit (pore diameter ~20 µm) holding the sorbent in place. Practical experience has shown that diluting the specimens with ten times the amount of phosphate buffer before homogenisation provides samples that can be extracted with either negative or positive pressure. Some tissues (e.g. putrefied liver) have to be diluted even more (up to 50 times). A physiological pH of 7.4 prevents protein precipitation in biological specimens and therefore avoids an unpredictable loss of analytes. After homogenisation (e.g. with a blender), and before the sample is applied to the extraction cartridge, remaining particles and cellular structures must be removed by centrifugation (cooling can prevent the loss of volatile analytes). For the handling of the sometimes large sample volumes, automation of the whole extraction process is highly recommended. The controlled and therefore homogeneous flow of the sample through the extraction cartridge in such an extraction device secures a uniform and efficient extraction, leading to more reproducible results.

For this 'general unknown' screening procedure, a mixed-mode sorbent based on a combination of a polar modified polystyrene resin and a cationic exchanger is used. In this way analytes can be extracted by non-selective hydrophobic and aromatic interactions and, in a second step, acidic and neutral compounds can be separated from basic compounds that are retained by electrostatic interactions through their amine functionality. Polystyrene resins do not possess residual silanol groups like silica-based sorbents do (due to varying degree of endcapping) Polystyrene resins have the additional advantage of being stable across the entire pH range, in contrast to the limited stability (pH 2–8) of silica-based sorbents. Moreover, polystyrene resins offer a higher capacity than silica-based sorbents and sufficient retention of a wide variety of different analytes can be achieved at a pH of 7.4. At this pH value an equilibrium of electrolytic dissociation will be reached for acidic and basic analytes in the aqueous phase. By adsorption of the non-ionised analyte to the sorbent, equilibrium must be continuously re-established and a nearly complete extraction will be reached if sufficient contact time with the sorbent is allowed and if the capacity of the sorbent is high enough. Additionally, the porous structure of polystyrene resins can be used to exclude large molecules (e.g. proteins and lipids bound in micelles) from the extraction process. The amount of sorbent that has to be used is determined by the amount of interferences that are expected in the sample matrix analysed.

The second step is the pre-treatment of the sorbent. It should be washed with the strongest solvent applied in the procedure and then it must be conditioned – in the procedure described here, with a phosphate buffer of pH 7.4 – in order to make the sorbent compatible with the sample. Silica-based bonded sorbents should not dry out between the applications of different solutions. This is not an issue when working with polar modified polystyrene resins because of their additional hydrophilic properties.

The third step is the application of the sample. Competitive influences of matrix components displacing the analytes from the limited surface area of the sorbent have to be considered and 'overloading' the extraction cartridge must be avoided. Because the mass transfer of analyte to sorbent is determined by kinetic functions and, because the intermolecular interactions (van der Waals' forces, aromatic interactions, etc.) are short-ranged and relatively weak forces, sufficient contact

Table 29.4 Possible pitfalls in the process of developing a mixed-mode solid-phase extraction procedure

Steps of the mixed-mode procedure	*Possible pitfalls*
Specimen pre-treatment	Protein precipitation (loss of analytes), flow problems
Choice of sorbent	Capacity, undesired secondary interactions, stability
Washing and conditioning sorbent	Improper conditioning (drying of silica-based sorbents, capacity problems)
Sample application	Insufficient contact time, 'break-through', clogging
Washing and changing pH to acidic	Protein precipitation on the sorbent, insufficient acidic capacity
Elution of acidic and neutral compounds	Insufficient contact time, inappropriate solvent (solvent strength, water miscibility)
Elution of basic compounds	Insufficient contact time, inappropriate solvent (solvent strength, water miscibility), insufficient basic capacity, sorbent stability (silica-based sorbents)

time is a key factor for ensuring reproducible results. To avoid 'break-through' due to ineffective retention of analytes, the adsorption flow rate should be kept below 1 mL/min.

In the fourth step, protein and other interferences are washed away with water (to avoid protein precipitation on the sorbent when subsequently applying organic solvents) and the pH is changed by applying an acidic solution so that analytes with amino functions are protonated and establish their electrostatic interactions with the charged sorbent.

In the fifth step, because ionic interactions are relatively strong forces, acidic and neutral analytes as well as hydrophobic and polar interferences can be eluted with strong organic solvents (with different polarity and/or solvent strength; the first solvent should be miscible with water to be able to reach the 'inner surface' of the sorbent, which is loaded with water comparably to a sponge; flow rates should be kept below 1 mL/min). In the procedure described here, ethyl acetate–2-propanol (3 : 1) is used.

In the sixth and final step, all bonding mechanisms for the remaining basic analytes (ionic and hydrophobic interactions) have to be disrupted simultaneously and this can be done using an appropriate basic organic solvent (in the procedure described, ethyl acetate–2-propanol–triethylamine (75 : 25 : 3) is used). Elution will be incomplete if the basic solution is not strong enough to completely disrupt the electrostatic interaction. Again, flow rates should be kept below 1 mL/min, because ion-exchange binding kinetics are even slower than with hydrophobic and aromatic interactions. Volatile organic bases (such as triethylamine) have the advantage that they can be removed easily from the extract by evaporation.

After evaporation of the eluent from step 5, the extract can then be analysed for neutral and acidic compounds (in the case of a very complex matrix and/or a very low concentration of the analyte, a further back-extraction step might be necessary). Simultaneously, after evaporation, the extract from step 6 can be analysed for basic compounds. The aqueous phase of the sample should not be discarded in this 'general unknown' screening procedure, because strong electrolytes (e.g. quaternary ammonium compounds) will not be sufficiently extracted onto the sorbent. Extraction of these compounds can be accomplished by ion-pair formation (see Ion-pair extraction above). The possible pitfalls in using a mixed-mode SPE procedure are given in Table 29.4.

Microextraction

Miniaturisation of the extraction process simplifies the entire analytical procedure by having the extraction carried out in one vessel, eliminating the evaporation step and possible loss of volatile materials, reducing solvent use, and considerably saving in extraction time. It usually involves vigorous mixing of a small volume of solvent with a large volume of biological material (e.g. urine), centrifuging to separate the solvent layer and direct injection into a chromatograph. For example, amfetamines and related compounds may be extracted from 5 mL of urine into 100 µL of chloroform and this is injected into a GC apparatus (Ramsey, Campbell 1971).

Some microextraction methods such as hollow fibre-based liquid-phase extraction (Esrafili *et al.* 2007) and fibre-in-tube solid-phase microextraction (Yazdi *et al.* 2008) have been successfully used for the analysis of antidepressant drugs in biological fluids.

Microextraction by packed sorbent (MEPS) with on-line connection to GC or LC has been applied for the analysis of local anaesthetics in plasma samples (Abdel-Rehim 2004) and the analysis of amfetamines in hair (Miyaguchi *et al.* 2009).

Conclusions

The ongoing development of more powerful and sensitive analytical instruments can only be fully utilised after the successful isolation of the target compounds from the biological specimens. Without sufficient sample extraction, either these sensitive instruments cannot be used at all or the results are unreliable owing to interferences. Although many optimised procedures for the extraction of specific target compounds (in most cases from urine or blood) can be found in the literature, non-selective, reliable and robust procedures for the simultaneous extraction of a wide range of analytes with different physicochemical properties (e.g. for the 'general unknown' screening) are rare, especially when more complex matrices have to be extracted. Unfortunately, the greatly desired 'universal standard extraction procedure' for all possible constellations of target compounds and specimens does not (yet) exist.

The selection or development of a proper extraction procedure and the procedure's adaptation to specific cases – based on analytical data of targeted compounds, available specimens, advantages and disadvantages of the various extraction techniques, and the time and resources at hand – are key tasks of the analytical toxicologist. Special knowledge and experience are needed to meet these challenges. Analytical results usually have serious medical or legal consequences: toxicologists therefore carry a high level of responsibility. To ensure the integrity of analytical results, stringent quality control measures have been implemented in modern toxicological laboratories. But such measures should not lead to overly rigid structures that limit the toxicologist to a few strictly defined extraction methods and target analytes, as this would narrow a laboratory's flexibility to an unacceptable level.

The analytical toxicologist must stay open to new extraction technologies, improvements in sample preparation and developing trends. Among these improvements is automation, which enables the unattended, reproducible extraction of samples; advances in this application of technology are expected soon.

CHAPTER

30 Colour Tests

B Widdop

Introduction

The bulk of the material in this chapter derives from that contributed by the late HM Stevens to the second edition of this publication, which was modified and expanded by Wayne Jeffrey in the third edition. The main addition in this latest version is an appendix dealing with tests for metals and anions that are not covered by the general scheme.

Colour tests (sometimes referred to as chemical spot tests) provide toxicologists and drug analysts with one of the first tools for the presumptive identification of drugs and poisons. These colour tests are most usefully applied to pharmaceuticals and scene residues, and to a lesser extent to biological fluids such as stomach contents, urine. They are used to place the unknown into a specific class of compounds or to eliminate categories or classes of compounds. These colour tests remain popular for many reasons. They are simple to perform, use minimal reagents, are inexpensive and give results that can be viewed by the naked eye. They appeal particularly in parts of the developing world where laboratory facilities tend to be very limited. In many instances they can also be used as thin-layer chromatography (TLC) location reagents applied by spraying or dipping (see Chapters 1, 11, and 39). This chapter describes the colour tests cited in the monographs. For some substances, the colour reaction with a particular chemical reagent may be quite specific, but it is much more common for the colour to be produced by a class of compounds. Moreover, compounds that do not fall into the class may also give colours. For some of the tests, the colour reactions can be correlated with certain aspects of the chemical structure of a compound or group of compounds. However, anomalous responses often occur that cannot be explained on that basis. Some of these are noted in the colour tests described below, but it should be borne in mind that many others may be found. It follows that colour tests are only an indication of the presence of a compound or class of compounds and that all tests must be confirmed by more specific methods. This is especially important in forensic cases!

The colour tests included here range from those that rely on reactions with certain functional groups (e.g. Folin–Ciocaltaeu for phenols), those that are almost specific for a given group (e.g. FPN reagent for phenothiazines) through to those that give diagnostic colours with a wide range of compounds (e.g. Mandelin's test and the Marquis test).

Interpretation of colour tests

Colour descriptions

Colours exhibited by these tests cannot be described with any accuracy. They may vary in intensity or tincture with the concentration of compounds in the test samples and the presence of extraneous material. In addition, their assessment is always a subjective one, even in people with normal colour vision. Some of the complexes formed are unstable such that the colour changes or fades with time.

Effects of ionic form

Salts may give colours different from those of the corresponding acid or base. In general, free acids or bases that have been isolated from the test material by an extraction process give better colours than their salts. The colour of a salt may be modified by the nature of the other ions present. For example, all hydrochloride salts give a red colour in Mandelin's test and a blue colour with Koppanyi–Zwikker reagent (prior to adding pyrrolidine). Basic salts of weak acids may produce different colours because of a change in pH. Where a compound has been extracted from biological material, these factors should not create any difficulty, since it will be present in the form of the base. However, when applying the tests to pharmaceutical preparations, where the compounds are usually present as salts, this can cause problems. To overcome this, the material can be extracted in much the same way as for biological samples to derive the free base. Bromide and iodide salts can be converted into the nitrate before testing, which gives the same colour as the base, by the following method:

- To 0.5 mL of a 1% (w/v) solution of the salt in dilute acetic acid, add one drop of an 8% (w/v) solution of silver nitrate followed by one drop of a 2% (w/v) solution of sodium chloride to remove excess silver.
- Centrifuge to separate the precipitated silver halide and use the supernatant liquid, either as a solution or evaporated to dryness where necessary, for the colour tests.

The colours that are recorded in the tables and monographs are usually those obtained by testing either the free acid or the free base.

Use of the colour tests lists

The system adopted uses ten basic colours: the spectral colours (red, orange, yellow, green, blue and violet), together with pink, brown, grey and black. Where there is a variation in hue, this is indicated by combining two colours (e.g. red–brown). The second-named colour is considered to be the dominant one and is the main colour used in the lists. For example, red–brown is listed under brown, whereas brown–red is listed under red. When interpreting results, it is often necessary to search the lists given under two main colours (e.g. for red–brown, the lists under both red and brown should be consulted). This takes account of the subjective nature of colour assessment. An arrow between two colours (e.g. red→brown) indicates that the colour changes during the course of the test. In the monographs, the notation brown/red is used where there are two parts to a test that produce two colours. Occasionally, the colour displayed by a test solution in reflected light may be different from that in transmitted light, in which case the solution is described as dichroic. A combined colour may be obtained when more than one drug is present or the drug itself is coloured, which limits the value of the tests for biological samples.

Practical points

Performing the colour tests

The tests are carried out either in clear glass test-tubes or on white glazed porcelain tiles (spotting tiles), which give a uniform background against which the colours can be assessed. For drugs, the tests are designed to work on about 1 mg, either as the solid form or as a dried extract of this amount (see below), unless stated otherwise. Solutions should be made in water unless otherwise stated. Where an instruction, time, temperature, etc., appears in brackets after the drug name, such as (add water), (15 s) or (slowly at 100°C), this indicates a change in the test procedure for that particular drug.

The following recommendations are most important:

- A sample known not to contain the compound of interest should be tested at the same time as the test sample. This enables a comparison of the colours produced by the sample and by the reagent blank. Ideally, the blank sample should have the same matrix as the test sample (e.g. for urine tests use analyte-free urine), since this takes account of the effects of extraneous materials. Otherwise, water is usually adequate.
- Before making a final decision on the result of a test, the reaction of the unknown should be compared with that of a reference substance tested under exactly the same conditions.

Validation of a colour test

It is essential to validate all tests and test reagents for sensitivity and specificity; O'Neal *et al.* (2000) have outlined a suitable method for a chemical spot test.

Application of colour tests to sample extracts

Several solvent extraction schemes have been devised to fractionate compounds on the basis of their acidic, neutral or basic characteristics (see Chapters 1 and 10). The tests listed in Table 30.1 can be applied to the evaporated extracts.

Table 30.1 Tests that can be applied to the evaporated extracts

Fraction	*Test*
Strong acid	Aromaticity
	Ferric chloride
	Folin–Ciocaltaeu reagent
	Liebermann's reagent
	Millon's reagent
	Nessler's reagent
Weak acid	Aromaticity
	Coniferyl alcohol
	Diazotisation
	Ferric chloride
	Folin–Ciocaltaeu reagent
	Koppanyi–Zwikker reagent
	Liebermann's reagent
	Mercurous nitrate
	Millon's reagent
	Nessler's reagent
Neutral	Aromaticity
	Furfuraldehyde
	Koppanyi–Zwikker reagent
	Liebermann's reagent
	Mercurous nitrate
	Nessler's reagent
Basic	Amalic acid test
	p-Dimethylaminobenzaldehyde
	Ferric chloride
	Formaldehyde–sulfuric acid
	Forrest reagent
	FPN reagent
	Liebermann's reagent
	Mandelin's reagent
	Marquis reagent
	Nessler's reagent
	Sulfuric acid

Table 30.2 is formulated to give a quick lead to those tests that can be applied to detect some of the most important drug groups and other poisons.

Table 30.2 Indication of which tests can be applied to detect some of the most important drug groups and other poisons

Substance/functional group	*Useful tests*
Alcohols	Potassium dichromate
Alkaloids and nitrogenous bases	Dragendorff's reagent
Amides (aliphatic)	Nessler's reagent
Aldehydes (aliphatic)	Schiff's reagent
Amfetamines	See Appendix 30.1
	Sodium nitroprusside–acetone
Antidepressants	Marquis test
Barbiturates	Dille–Koppanyi reagent
	Koppanyi–Zwikker reagent
	Mercurous nitrate
	Vanillin reagent
	Zwikker reagent
Benzodiazepines	Formaldehyde–sulfuric acid
Cannabis	Duquenois reagent
Carbamates (non-aromatic)	Furfuraldehyde
Cocaine	Cobalt thiocyanate
	p-Dimethylaminobenzaldehyde
	Mandelin's test
	Scott's test
Chlorinated phenols	Nitric acid (fuming)
Chlorinated hydrocarbon insecticides	Nitric–sulfuric acid
Cyanide	Ferrous sulfate (B)
	Sodium picrate
Cyanide groups	Sodium picrate
Dithiocarbamates	Sodium nitroprusside
Ergot alkaloids	*p*-Dimethylaminobenzaldehyde
Halogenated hydrocarbons	Fujiwara test
Imides	Koppanyi–Zwikker test
Ketones	Sodium nitroprusside
Methadone	Cobalt thiocyanate
	Mandelin's test
	Marquis test
	Tetrabromophenolphthalein ethyl ester
Mono-substituted pyridine ring	Cyanogen bromide
Nitrates and nitrites	Ferrous sulfate
Opiates	See Appendix 30.2
Oxidising agents	Diphenylamine
Paraquat/diquat	Sodium dithionate
Phencyclidine	Cobalt thiocyanate
	p-Dimethylaminobenzaldehyde
	Tetrabromophenolphthalein ethyl ester
Phenols	*p*-Dimethylaminobenzaldehyde
	Ferric chloride
	Folin–Ciocaltaeu reagent
	Millon's reagent

Table 30.2 continued

Substance/functional group	*Useful tests*
Phenothiazines	Ferric chloride
	Formaldehyde–sulfuric acid
	Forrest reagent
	FPN reagent
Phenylpyrazolines	Nitrous acid
Primary aromatic amines	Coniferyl alcohol
	Diazotisation
Primary and secondary amines	Dragendorff's reagent
	Simon's test
Propoxyphene	Cobalt thiocyanate
	Froehde's reagent
	Liebermann's test
	Tetrabromophenolphthalein ethyl ester
Quaternary ammonium compounds	Tetrabromophenolphthalein ethyl ester
Quaternary amines	Dragendorff's reagent
Quinines	Cobalt thiocyanate
	Thalleioquin
Quinones	Methanolic potassium hydroxide
Reducing agents	Benedict's reagent
Salicylates	Ferric chloride
	Trinder's reagent
Steroids	Antimony pentachloride
	Naphthol sulfuric acid
	Sulfuric acid
Sulfonamides	Copper sulfate
	Koppanyi–Zwikker reagent
	Mercurous nitrate
	Nitrous acid
Sulfur containing	Palladium chloride
	Sodium nitroprusside
Tertiary amines	Dragendorff's reagent
	Tetrabromophenolphthalein ethyl ester

Additional information

Colour reactions given by narcotics and amfetamines with four of the so-called 'alkaloid colour reagents' (Marquis, Mecke's, Froedhe's and Mandelin's) are listed in Appendix 30.1 and Appendix 30.2. Three colour tests have been developed for gamma-hydroxybutyric acid (GHB) and its precursor gamma-butyrolactone (GBL; see Appendix 30.3).

Colour test methods

Caution: the following lists of colour tests and drugs tested are not exhaustive; the omission of a compound from a list does not indicate that no response is given, but that it may not have been tested.

Amalic acid test (test for xanthines)

Method

Add to the sample a few drops of 10 mol/L hydrochloric acid followed by a few crystals of potassium chlorate, and evaporate the mixture to dryness. Observe the colour of the residue then add 2 or 3 drops of 2 mol/L ammonium hydroxide and again observe the colour.

Table 30.3 Colours with amalic acid

Colour	*Compound*
Red (→violet)	Bufylline, caffeine
Pink (→violet)	Pentoxifylline
Orange (→violet)	Acepifylline piperazine, bamifylline, xanthinol nicotinate
Pink–orange (→violet)	Fenetylline, pentifylline
Yellow (→pink)	Etamiphylline
Yellow (→violet)	Diprophylline, proxyphylline, theobromine, theophylline

Indications

A red, pink, orange or yellow residue, which changes to pink, red or violet after the addition of ammonium hydroxide, indicates the presence of a xanthine (Table 30.3).

Ammoniacal silver nitrate

Reagent

To 20 mL of 0.1 mol/L silver nitrate add sufficient strong ammonia solution to dissolve the initial precipitate.

Method

Dissolve the sample in a minimum amount of water, with the addition of ethanol if necessary, add an equal volume of the reagent and note any colour that develops. Heat the mixture in a water-bath at 100°C for 30 s.

Indications

Red, yellow, brown or black colours (especially at room temperature) indicate potent reducing power, which occurs when adjacent carbon atoms in a ring each bear a hydroxyl group (Table 30.4). There is no response when the hydroxyl groups are *meta* to each other, but there is some restoration of reducing power when they are *para* to each other. Some colour production is also obtained with ethynyl bonds, but not with ethylenic bonds. Ethchlorvynol and ethinylestradiol both give a white precipitate that turns yellow on heating. Carbidopa gives a silver mirror on heating.

Table 30.4 Colours with ammoniacal silver nitrate

Colour at room temperature	*Compound*	*Colour at 100°C*
Red	Isoetharine	Brown–orange
	Hexoprenaline (→brown→black)	
	Isoprenaline (→red–brown)	Brown
	Rimiterol	Brown
Yellow	Ethinamate	Brown
	Levodopa (→brown)	Black
Grey–yellow	Hydroquinone	Brown
Brown		
Red–brown	Adrenaline	
	Methyldopa	Black
Orange–brown	Dopamine	Black
	Methyldopate	Orange–brown
Grey		
Red–grey	Protokylol	Brown
Black	Ascorbic acid	
	Benserazide	–
	Dobutamine	–
	Dodecyl gallate	–
	Noradrenaline	–

Antimony pentachloride

Reagent

Dry some antimony trichloride over phosphorus pentoxide, melt the dried material (m.p. 73°C), and pass dry chlorine gas into the melt until a yellow fuming liquid is obtained. Add this liquid to about 10 times its volume of chloroform, filter the solution into a dark glass-stoppered bottle and store in a desiccator.

Method

Place a drop of an ethanolic solution of the sample on a filter paper, add a drop of the reagent and dry in a current of warm air. Alternatively, the test may be carried out by adding a drop of the reagent to the sample on a white tile.

Indications

Various colours are obtained with the cardiac glycosides, their aglycones and certain oestrogens and corticosteroids (Table 30.5). No colour is obtained with beclometasone, cortisone, fluocinolone, fludroxycortide, prednisolone, prednisone, progesterone, testosterone or triamcinolone.

Aromaticity

Method 1

Place a portion of the sample in each of two ignition tubes, and to one tube add some solid sodium hydroxide. Heat both tubes carefully, allow the water vapour to escape, insert into the vapours in each tube an open capillary tube that contains Marquis reagent, and observe the colour of the reagent.

Indications

Red or orange colours indicate that the sample is aromatic in nature. The colours probably result from the liberation of traces of aromatic hydrocarbons, phenols, etc. Colours obtained after heating with sodium hydroxide generally indicate the presence of aromatic acids. Colours obtained after heating without sodium hydroxide generally indicate the presence of phenols, phenolic acids and aldehydes that contain more than one hydroxyl group.

A negative result does not necessarily imply that the substance is non-aromatic.

Method 2

Add 2 or 3 drops of concentrated nitric acid to the sample, heat in a water-bath at 100°C for 1 min, cool the mixture, dilute 3–4 times with water and make the solution alkaline by the addition of a 40% (w/v) solution of sodium hydroxide.

Table 30.5 Colours with antimony pentachloride

Colour	*Compound*
Red	Dienestrol, diethylstilbestrol
Orange	Cholesterol (→brown), desoxycortone, dydrogesterone, fludrocortisone, hydrocortisone, hydroxyprogesterone, strophanthin-K (→red)
Yellow	Alfadolone
(→brown)	Androsterone, digitoxigenin, digoxigenin
(→brown→black–violet)	Digitoxin, digoxin, lanatoside C, ouabain (very weak)
Green–yellow	Fluocortolone
Green	Betamethasone (→brown), dexamethasone, mestranol, pancuronium
Brown	Carbenoxolone, dimethisterone, estradiol, estriol, estrone, ethinylestradiol (→black), fluoxymesterone, norethandrolone, norethisterone, oxymetholone, rotenone
Orange–brown	Enoxolone (→violet)
Green–brown	Noretynodrel

Table 30.6 Colours with aromaticity test, method 2, obtained on addition of alkali to acid solution

Colour of acid solution	*Colour after addition of alkali*	*Compound*
Colourless	Red	Clobazam (heat for 3 min with acid)
	Orange	Butanilicaine, tolazoline
	Yellow	Amprolium, atropine methobromide, hyoscine butylbromide, hyoscine methobromide, ketoprofen, pipazethate, tetrahydrozoline, tetramisole, trimetaphan
	Violet	Atropine methonitrate (transient), hyoscine methonitrate (transient)
	Brown	Isopropamide
Yellow	Red	Aminacrine, benzonatate, tetracaine (amethocaine), trimethoprim
	Orange–red	Dextromethorphan, haloperidol
	Orange	Amicarbalide, carbocromen, dyclonine, glibenclamide, levallorphan, metocurine, padimate, propanidid, quinuronium, salinazid
	Brown	Dibromopropamidine, dichlorophen tubocurarine
Red	Brown–violet	Dequalinium

Indications

A change from colourless or yellow in acid solution to darker colours (e.g. orange or red–orange) after the addition of sodium hydroxide indicates the presence of a benzene ring in the molecule, probably though the production of a nitrophenol or other nitro compound.

Certain compounds (e.g. diazepam, methaqualone) give a negative result. Orange colours are given by certain non-aromatic corticosteroids (e.g. cortisone), by substances that contain sulfur and by compounds that already contain an aromatic nitro group (e.g. nifursol).

Colour changes are given in Table 30.6.

Certain substances give distinct colours with cold nitric acid, but the colours fade on heating; these are listed in Table 30.7.

Benedict's reagent

Reagent

Dissolve 1.73 g of copper sulfate in 10 mL of water. Dissolve 17.3 g of trisodium citrate and 10 g of anhydrous sodium carbonate in 80 mL of water with the aid of heat; pour this solution into the copper sulfate solution and dilute the mixture to 100 mL.

Method

Add 0.5 mL of the reagent to the sample and heat in a water-bath at 100°C for 3 min.

Indications

The formation of red cuprous oxide occurs with strong reducing agents, such as ascorbic acid, dithionites, certain phenolic compounds that contain two hydroxyl groups *para* to each other, and compounds that contain at least four hydroxyl groups on a non-aromatic ring (e.g. glucose, tetracyclines).

Table 30.7 Colours with aromaticity test, method 2, obtained on addition of cold nitric acid to sample, which fade on heating

Colour	*Compound*
Red	Aminacrine (15 s), clozapine, dropropizine, medazepam, trimethoprim
Brown	Metocurine
Pink–brown	Diethylthiambutene (changing to green)
Black	Tubocurarine

A weak response (orange–brown or brown colours) is given by streptomycin, hydroxylamine and substituted hydrazines (e.g. phenelzine). No colour is obtained with beclometasone, cardiac glycosides and estriol (two hydroxyl groups) or clindamycin (three hydroxyl groups).

Carbon disulfide

Method

Mix the sample with 1 mL of water and 0.1 mL of a 1% (w/v) solution of sodium tetraborate, add 0.2 mL of a 10% v/v solution of carbon disulfide in ethanol and heat in a water-bath at 100°C for 3 min; cool the solution and add 3 drops of 0.1 mol/L silver nitrate.

Indications

A brown colour indicates the presence of a dithiocarbamate, which suggests that the original substance was an aliphatic or heterocyclic primary or secondary amine. The original sample should be tested to ensure that it does not give a brown colour with silver nitrate alone.

Chromotropic acid

Reagent

1. Dissolve 20 mg of chromotropic acid in 10 mL of concentrated sulfuric acid.
2. Dissolve 1 g of sodium nitrite in 10 mL of concentrated sulfuric acid.

Method 1

Add a small amount of sample, either solid or in solution, to 1 mL chromotropic acid reagent. Note any colour that may be produced, and then add the solution dropwise to 0.5 mL of water, with cooling. Substances that give a colour with cold sulfuric acid must be excluded.

Indications

See Table 30.8.

Table 30.8 Colours with chromotropic acid

Colour	*Compound*
Red (before dilution)	Formaldehyde, paraformaldehyde (reacts slowly)
Violet (after dilution)	Hydrochlorothiazide, hydroflumethiazide

Method 2 (for chlorophenoxy herbicides)

Add 1 mL of 1 mol/L hydrochloric acid to 10 mL of sample and extract with 20 mL of toluene for 5 min. Centrifuge for 5 min and remove the toluene layer. Repeat with a further 20 mL of toluene and evaporate the combined extracts to dryness. Dissolve the residue in 0.2 mL of concentrated sulfuric acid and divide between two wells of a spotting tile. Add 0.1 mL of sodium nitrite solution to one well and 0.1 mL of chromotropic acid reagent to the other. Heat the tile at 80°C and observe any colour development.

Indications

See Table 30.9.

Table 30.9 Colours with sodium nitrite and chromotropic acid

Compound	*Sodium nitrite*	*Chromotropic acid*
2,4-Dichlorophenoxyacetic acid	Brown	Purple
2,4-Dichlorophenoxypropionic acid	Dark brown	Light purple
4-Chloro-2-methylphenoxyacetic acid	Light brown	Light purple
2-(4-Chloromethylphenoxy)propionic acid	Light brown	Purple
2,4,5-Trichlorophenoxyacetic acid	No reaction	Purple
2-(2,4,5-Trichlorophenoxy)propionic acid	No reaction	Light pink/ purple

Cobalt thiocyanate (see Scott's test)

Reagent

1. A 2% (w/v) solution of cobalt thiocyanate in water
2. Phosphoric acid
3. 1 g $H_2PtCl_6 \cdot 6H_2O$ in 20 mL of H_3PO_4.

Mix 9 parts of solution 1 and 3 parts of solution 2, add 1 part of solution 3 and mix well. Add 9 parts distilled water and mix. When the solution turns pink it is ready for use.

Method

Add a few drops of the reagent to the sample to be tested.

Indications

See Table 30.10.

Limit of detection (LOD): cocaine-HCl 60 µg, methadone-HCl 15 µg.

Table 30.10 Colours with cobalt thiocyanate

Colour	*Compound*
Blue (flaky precipitate)	Cocaine
Brilliant greenish blue	Benzfetamine-HCl, brompheniramine maleate, chlordiazepoxide-HCl, chlorpromazine-HCl, doxepin-HCl, hydrocodone tartrate, methadone-HCl, methylphenidate-HCl
Strong greenish blue	Diacetylmorphine-HCl, ephedrine-HCl, phencyclidine-HCl, procaine-HCl, propoxyphene-HCl, pseudoephedrine-HCl
Strong blue	Quinine-HCl

Coniferyl alcohol (primary aromatic amines)

Reagent

Warm 0.1 g of coniferyl alcohol until it melts (m.p. 74°C), dissolve in 3 mL of ethanol and dilute to 10 mL with ethanol.

Method

Place 1 drop of a solution of the sample on a filter paper, add 1 drop of the reagent and expose the paper to hydrochloric acid fumes.

Indications

An orange colour indicates the presence of an aromatic primary amine in which the amino group is attached directly to a benzene ring.

An anomalous reaction is obtained with diphenylamine (bright orange).

Copper sulfate

Method 1

Dissolve the sample in a minimum volume of 0.1 mol/L sodium hydroxide and add a 1% (w/v) solution of copper sulfate, drop by drop, until the colour change is complete.

Indications

Green, blue or brown colours indicate the presence of a sulfonamide (Table 30.11).

Table 30.11 Colours with copper sulfate, method 1

Colour	*Compound*
Green	Phthalylsulfathiazole, succinylsulfathiazole (→violet), sulfachlorpyridazine, sulfadimethoxine, sulfadimidine (→brown), sulfadoxine, sulfaethidole, sulfamerazine (→brown), sulfamethizole, sulfamethoxazole, sulfametopyrazine, sulfapyridine (→brown–green), sulfaquinoxaline, sulfasomidine
Blue	Phthalylsulfacetamide, sulfacetamide, sulfaguanidine, sulfanilamide, sulfaphenazole, sulfaurea, sulfinpyrazone, sulthiame
Brown	Sulfafurazole
Orange–brown	Sulfasalazine
Green–brown	Sulfamethoxypyridazine, sulfamoxole
Violet–brown	Sulfadiazine, sulfamethoxydiazine, sulfathiazole

Method 2
Add 1 or 2 drops of a 1% (w/v) solution of copper sulfate to the sample on a white tile.

Indications
A blue colour indicates the presence of an alkali salt of a fatty acid, such as sodium cromoglicate (1–2 min) or valproate. The colours are not produced by a change of pH (some of the alkali salts will change the pH), as negative results are obtained with sodium bicarbonate.

Cyanogen bromide

Reagent
1. Decolorise bromine solution by the addition of solid potassium cyanide and then add more bromine solution until the solution is pale yellow.
2. Prepare a saturated solution of aniline in water.

Solutions 1 and 2 are stable for 1 week. Mix equal volumes of the two solutions immediately prior to the test.

Method
Add 1 drop of the mixed reagent to the sample on a white tile.

Indications
Red, orange or yellow colours indicate the presence of a mono-substituted pyridine ring. Increasing chain length of the substituent group weakens the response; a delayed response is obtained when the pyridine ring is substituted by nitrogen adjacent to the ring nitrogen; a weak response is obtained where there is a C=O substituent adjacent to the ring nitrogen. There is no response to the test if the pyridine ring is bound to another ring, if it is substituted in more than one position or if the nitrogen in the ring is substituted. Anomalous results are obtained with azatadine (pink), bisacodyl (no response) and tropicamide (violet–pink) (Table 30.12).

Diazotisation

Method
Dissolve the sample in 2 mol/L hydrochloric acid, and to 1 drop on a white tile add 1 drop of a 1% solution of sodium nitrite, and 1 drop of a 4% solution of naphth-2-ol in 2 mol/L sodium hydroxide.

Indications
A bright red or orange–red colour indicates the presence of a primary aromatic amine. Diphenylamine does not give a reaction; aminonitrothiazole (solid) gives a violet colour.

Dille–Koppanyi reagent modified (a general test for barbiturate-like compounds)

Reagent
1. Dissolve 0.1 g of cobalt(II) acetate dihydrate in 100 mL of methanol. Add 0.2 mL of glacial acetic acid and mix.
2. Add 5 mL of isopropylamine to 95 mL of methanol.

Table 30.12 Colours with cyanogen bromide[a]

Colour	*Compound*
Red	Zimeldine (30 s)
Pink	Azatadine
Orange–pink	Carbinoxamine, dimetindene, doxylamine, iproniazid, phenyramidol, triprolidine (1–2 min)
Violet–pink	Tropicamide
Orange	Azaperone, brompheniramine, chlorphenamine, isoniazid, metyrapone, nicametate, nicotinamide, nicotine, nicotinic acid, nifenazone, nikethamide, pheniramine, xanthinol nicotinate
Red–orange	Benzyl nicotinate
Yellow	Halopyramine, mepyramine, tripelenamine

[a]Anomalous results are obtained with azatadine (pink), bisacodyl (no response) and tropicamide (violet–pink).

Method
Add 2 drops of solution 1 to the drug, followed by 1 drop of solution 2.

Indications
A light purple (blue–violet) colour indicates the presence of a barbiturate. Other reacting compounds are hydantoins, sulfonamides, pyrimidine, piperidine, methyprylon. The LOD is 25 μg or lower.

p-Dimethylaminobenzaldehyde (Wasicky reagent or Van Urk reagent; a general test for ergot alkaloids)

Reagent
Dissolve 2.0 g of *p*-dimethylaminobenzaldehyde (p-DMAB) in 50 mL of 95% ethanol and 50 mL of concentrated hydrochloric acid. The reagent should be freshly prepared.

Method
Add the reagent to the sample in a test-tube, warming if necessary. Observe any colour produced, then carefully dilute with water or spray dried spots on filter paper and heat.

Indications
Colours are given by a number of substances, which include ergot alkaloids, dimethyltryptamine, psilocin, psilocybine (gives a violet colour), cannabinols and certain indoles in which the indole ring is not bonded to another conjugated ring (red changing to violet on dilution), and certain phenols and phenolic amines (red or orange, usually changing to violet on dilution). Some other types of compound also respond. See Table 30.13.

The LOD for lysergide (LSD) is 6 μg.

Diphenylamine test

Reagent
Mix 0.5 g of diphenylamine in 20 mL of water and dilute to 100 mL with concentrated sulfuric acid.

Method
Apply the reagent to the sample on a white tile or in a test-tube.

Indications
A blue colour indicates the presence of an oxidising agent such as bromate, chlorate, chromate, dichromate, iodate, lead(IV), manganese (III, IV, VII), nitrate, nitrite, permanganate or vanadate.

This test has been modified for use on blood samples to detect ethchlorvynol (Caughlin 1991). Blood (0.5 mL) is mixed with 1.0 mL of acetone and vortex mixed. The sample is centrifuged and 50 μL of the supernatant is added to 50 μL of diphenylamine reagent and 25 μL of chloroform. The mixture is vortex mixed and allowed to stand. A pink colour that develops in the chloroform layer indicates ethchlorvynol.

Dragendorff reagent (a general reagent for nitrogenous bases)

Reagent
Dissolve 1 g of bismuth subnitrate in 3 mL of 10 mol/L hydrochloric acid with the aid of heat. Dilute to 20 mL with water and dissolve 1 g of

Table 30.13 Colours with *p*-dimethylaminobenzaldehyde

Colour	*Compound*
Red (changing to violet on dilution)	Cannabinols, phenazone (100°C, 5 min), pindolol, psilocin, psilocybine, tryptamine
Red (no violet on dilution)	Benserazide, cocaine (100°C, 3 min), feprazone, harmine, phencyclidine (100°C, 3 min)
Orange (changing to violet on dilution)	Dobutamine, dopamine, diamorphine, morphine, orciprenaline, phenol, terbutaline, tyramine
Violet	Ergot alkaloids (dihydroergotamine, ergometrine, ergotamine, ergotoxine, lysergide, methysergide), dimethyltryptamine, psilocin, psilocybine
Yellow	Primary aromatic amines, e.g. aminosalicylic acid, anileridine, aniline, procaine, benzocaine

potassium iodide in the mixture. If black bismuth triiodide separates, add 2 mol/L hydrochloric acid and more potassium iodide to dissolve it.

Method
Dissolve the sample in 3 drops of 2 mol/L hydrochloric acid, add 2–3 mL of the reagent and dilute to 10 mL with water.

Indications
An orange, red–orange or brown–orange precipitate suggests the presence of an alkaloidal base (precipitated as the alkaloidal bismuth iodide). Primary, secondary, tertiary and quaternary amines give positive results. This reagent is commonly used as a spray or locating agent to detect alkaloids on TLC plates.

Duquenois reagent, modified

Reagent
1. Add 2.5 mL of acetaldehyde and 2.0 g of vanillin to 100 mL of 95% ethanol
2. Concentrated hydrochloric acid
3. Chloroform.

Method
Place the solid sample, or an evaporated petroleum ether (or other organic solvent) extract of the sample, in a test-tube and add 3 drops of solution 1. Shake for 1 min and add 3 drops of solution 2. Agitate gently and observe the colour produced. Add 9 drops of solution 3, vortex mix gently and note whether the colour is extracted from the mixture.

Indications
A colour change from grey to green through blue to violet–blue suggests the presence of cannabis, but differentiation from roasted coffee and patchouli oil is required. The colour change is best seen with fresh drug material. The violet colour is extracted into the chloroform layer only when cannabis is present (Table 30.14). The LOD is 350 µg of tetrahydrocannabinol (THC). No colour is obtained with other natural products, such as basil, bay leaf, eucalyptus oil, mace, marjoram, rosemary, sage, thyme or tobacco.

Ferric chloride (general reagent for phenols, e.g. salicylates)

Reagent
Dissolve 5 g of anhydrous ferric chloride, or 8.25 g of ferric chloride hexahydrate, in 100 mL of distilled water.

Method
Add ferric chloride solution to the sample or an ethanolic solution of the sample.

Indications
Red, orange, green, blue, violet or brown colours indicate the presence of a phenolic compound, fatty acid or a phenylpyrazoline. High quantities of phenothiazines can also cause this test to be positive. Salicylates give a violet colour. Many phenols give no colour with ferric chloride when water is used as a solvent, but give positive tests when anhydrous solvents such as chloroform are used. Aspirin (acetylsalicylic acid) does not give a positive result unless first hydrolysed with concentrated sodium hydroxide to give salicylate. Colours are listed in Table 30.15.

Table 30.14 Colours with modified Duquenois reagent

Compound	*Initial colour*	*Colour extracted by chloroform*
Cannabis	Violet–blue	Violet
Coffee (roasted)	Violet–brown	Nil
Nutmeg	Pale reddish purple	Nil
Patchouli oil	Violet	Nil
Tea (leaves)	Green–blue	Nil

Table 30.15 Colours with ferric chloride

Colour	*Compound*
Red	Acetates, phenazone, propionates
Brown–red	Nifenazone
Orange	Chlorpromazine, hexoprenaline, propyphenazone, valproate
Yellow	
Green–yellow	Paracetamol
Green	Adrenaline, betanaphthol, dobutamine, dopamine, etamivan, ethylnoradrenaline, hexylresorcinol, hydroquinone, hydroxyquinoline, isoetarine, isoprenaline, levodopa, methyldopa, methyldopate, noradrenaline, paraphenylenediamine, phenothiazine, protokylol, rimiterol, thioridazine
Blue–green	Chlorquinaldol
Blue	Apomorphine, dodecyl gallate, gallic acid, morphine, parachlorophenol, pethidine, phenol, tannic acid
Violet	Aminosalicylic acid, diflunisal, dipyrone, hexachlorophene (transient), labetalol, salicylaldehyde, salicylamide, salicylic acid, salicyluric acid
Blue–violet	Aminophenazone, salicylamide (after hydrolysis), salicylic acid
Brown	Aloin, carbidopa
Yellow–brown	Salinazid
Green–brown	Benserazide
Black	
Violet–black	Ethyl gallate (→blue–black)

Ferrous sulfate A (test for nitrates and nitrites)

Reagent
To 1 volume of a 10% (w/v) solution of ferrous sulfate ($FeSO_4$,$7H_2O$) add 5 volumes of concentrated sulfuric acid with cooling.

Method
Add the sample to 0.5 mL of the reagent.

Indications
A red or pink colour is given only by nitrates and nitrites (e.g. glyceryl trinitrate).

Ferrous sulfate B (test for cyanide)

Reagent
Dissolve 10 g of ferrous sulfate in 100 mL of freshly boiled and cooled water (prepare fresh).

Method
Dilute 1 mL of sample with 2 mL of 10% (w/v) sodium hydroxide solution and add 2 mL of ferrous sulfate solution. Add sufficient 10% (v/v) hydrochloric acid to dissolve the ferrous hydroxide precipitate.

Indications
A blue colour is given by cyanide. There are no common sources of interference.

Folin–Ciocaltaeu reagent (test for phenolic compounds)

Reagent
For the stock solution, dissolve 100 g of sodium tungstate and 25 g of sodium molybdate in 800 mL of water in a 1500 mL flask, add 50 mL of phosphoric acid and 100 mL of concentrated hydrochloric acid, and reflux for 10 h. Cool, add 150 g of lithium sulfate, 50 mL of water and 4–6 drops of bromine, and allow to stand for 2 h. Boil for 15 min to remove the excess bromine, cool, filter and dilute to 1000 mL with water.

This stock solution should be stored at a temperature not exceeding 4°C and used within 4 months of its preparation; it has a yellow colour and must not be used if any trace of green colour is present.

For use, dilute 1 volume of this stock solution with 2 volumes of water.

Method
Add the diluted reagent to the sample and make the mixture alkaline with 2 mol/L sodium hydroxide.

Indications
A blue colour indicates the presence of a phenolic compound. The reaction is progressively inhibited with increased halogenation of the phenol nucleus.

Formaldehyde–sulfuric acid

Reagent
To 4 volumes of concentrated sulfuric acid add 6 volumes of formaldehyde solution (using a pipette with the tip below the surface of the acid) with stirring and adequate cooling. When the reagent is warm it remains clear for about 1 h. If turbidity develops, this may be dispelled by heating in a water-bath at 100°C for about 1 min (note that this reagent is not the same as that used in the Marquis test).

Method
Mix the sample with the reagent and heat at 100°C for 1 min.

Indications
Benzodiazepines generally give an orange colour with the exception of bromazepam and clozapine (a benzodiazepine-like compound), which both give yellow, and flurazepam (pink). Other indications include phenothiazines, tetracyclines and thioxanthenes. Tryptamine (brown) and zomepirac (red) also react. Those marked with an asterisk in Table 30.16 fluoresce orange under ultraviolet (UV) light ($\lambda = 350$ nm). No response is obtained with chlordiazepoxide, dimethoxanate or proquamezine. Some of the newer benzodiazepines have not been tested.

Table 30.16 Colours with formaldehyde–sulfuric acid

Colour	*Compound*[(a)]
Red	Chlorprothixene*, clopenthixol*, flupentixol*, fluphenazine, metopimazine, pericyazine, promazine, thiothixene, trifluprom azine, zomepirac
Brown–red	Lymecycline, oxytetracycline, tolmetin
Pink	Flurazepam, thioproperazine, trifluoperazine
Orange	Clonazepam, clorazepic acid, demeclocycline (→brown–red), demoxepam, diazepam, flunitrazepam, ketazolam, lorazepam, lormetazepam, medazepam (add water), metixene, nitrazepam, nordazepam, oxazepam, prazepam, temazepam, tetrazepam
Red–orange	Methacycline
Yellow	Bromazepam, clozapine, dimethothiazine, doxycycline
Green–yellow	Rolitetracycline (→yellow–brown), tetracycline (→yellow–brown)
Green	Thiethylperazine
Blue	Carphenazine, levomepromazine, thioridazine
Violet	Mesoridazine, perphenazine
Red–violet	Alimemazine, chlorpromazine, diethazine, mequitazine, methdilazine, perazine, phenothiazine, prochlorperazine, profenamine, thiopropazate
Blue–violet	Acepromazine, acetophenazine, piperacetazine, promethazine, propiomazine
Brown–violet	Thiazinamium
Brown	Tryptamine
Orange–brown	Chlortetracycline, clomocycline

[(a)]Compounds giving colours that fluoresce under UV light ($\lambda = 350$ nm) are indicated by an asterisk.

Table 30.17 Colours with Forrest reagent

Colour	*Compound*
Red	Acepromazine, carfenazine, chlorpromazine, diethazine, dimetotiazine, mequitazine, mescaline, mesoridazine, piperacetazine, prochlorperazine, promethazine, propiomazine, thiazinamium, thiopropazate, thioproperazine, thioridazine
Violet–red	Perphenazine
Brown–red	Alimemazine
Pink	Profenamine
Orange	Fluphenazine, phenothiazine, trifluoperazine, triflupromazine
Pink–orange	Acetophenazine
Red–orange	Methdilazine
Brown–orange	Perazine, pericyazine
Green	
Blue–green	Clomipramine, desipramine, imipramine, ketamine, opipramol, thiethylperazine, thioridazine, trimipramine
Violet	Levomepromazine, proquamezine (→red→orange)
Brown	Metopimazine
Red–brown	Promazine

Forrest reagent

Reagent
Mix together equal volumes of a 0.2% (w/v) solution of potassium dichromate, a 30% (v/v) solution of sulfuric acid, a 20% (w/w) solution of perchloric acid and a 50% (v/v) solution of nitric acid.

Method
Dissolve the sample in a minimum volume of 2 mol/L hydrochloric acid and add an equal volume of the reagent. To test urine, add 1 mL of reagent to 0.5 mL of urine.

Indications
Red, pink, orange, blue or violet colours are obtained with phenothiazines. A blue colour is obtained with certain dibenzazepines. The blue colour is inhibited by the presence of phenothiazines, so an excess of reagent must be added to overcome this. Colours are listed in Table 30.17.

FPN reagent (general reagent for phenothiazines)

Reagent
Mix together 5 mL of 5 % (w/v) ferric chloride solution, 45 mL of a 20% (w/w) solution of perchloric acid and 50 mL of a 50% (v/v) solution of nitric acid.

Method
Dissolve the sample in a minimum volume of 2 mol/L hydrochloric acid (or use 1 mL of urine) and add an equal volume of the reagent.

Indications
A variety of colours, from pink, red, orange, violet to blue, indicate the presence of phenothiazines (Table 30.18).

Froehde reagent

Reagent
Dissolve 1.0 g of molybdic acid or sodium molybdate in 100 mL of hot concentrated sulfuric acid.

Method
Add a drop of the reagent to the sample on a white tile.

Indications
Colours are listed in Table 30.19.

Table 30.18 Colours with FPN reagent

Colour	*Compound*
Red	Chlorpromazine, dimetotiazine, mesoridazine, methdilazine, prochlorperazine, thiazinamium, thiopropazate
Orange–red	Mequitazine
Violet–red	Perphenazine, proquamezine (→red→orange)
Brown–red	Alimemazine
Orange	Acetophenazine, diethazine (→yellow), fluphenazine, metopimazine, morphine, pericyazine, phenothiazine, profenamine, promethazine, thioproperazine, trifluoperazine, triflupromazine
Red–orange	Carfenazine
Pink–orange	Propiomazine (→red→fades)
Brown–orange	Acepromazine, perazine, piperacetazine
Blue	Clomipramine, imipramine, thiethylperazine, thioridazine, trimipramine
Violet	Levomepromazine
Brown	
Red–brown	Promazine

Table 30.19 Colours with Froehde reagent

Colour	*Compound*
Yellow	Hydrocodone, pethidine
Blue–yellow	Oxycodone-HCl
Orange	Diphenhydramine, flurazepam, promazine, trifluoperazine, triflupromazine
Green	Chlorphentermine, codeine, mescaline, oxycodone, phenyltoloxamine
Yellow–green	Lysergide
Blue	Pentazocine
Red	Amfetamine, chlorpromazine-HCl
Grey–red	Propoxyphene-HCl
Purple–red	Alimemazine, diacetylmorphine, promethazine, propylhexadrine, salicylic acid, tetracycline, thioridazine
Brown	Ephedrine, mescaline
Red–brown	Doxepin-HCl
Black	
Brown–black	Opium
Green–black	Methylenedioxyamfetamine (MDA)-HCl

Fujiwara test (general reagent for halogenated hydrocarbons)

Reagent
Freshly prepared 20% (w/v) sodium hydroxide solution.

Method
Mix together 2 mL of the reagent and 1 mL of pyridine. Add the sample (1 mL of urine) and heat in a water-bath at 100°C for 2 min with shaking.

Indications
A red–pink colour in the pyridine layer indicates the presence of compounds that possess at least two halogen atoms bound to one carbon atom. These include chloramphenicol, chlorbutanol, chloroform, dichlorophenazone, trichloroethane, trichloroethanol, trichloroacetic acid and trichloroethylene. Chloral hydrate and dichlorophenazone do themselves react but are excreted in urine as trichloroacetic acid. No colour is given by dicophane (DDT) or carbon tetrachloride, although massive exposure to the latter solvent may lead to a positive urine test because of the presence of chloroform as a contaminant. 2,2,2-Trichloroethanol gives a yellow colour. The LOD is 1 mg/L.

Furfuraldehyde (general reagent for carbamates)

Reagent
A 10% (v/v) solution of furfuraldehyde in ethanol.

Method
Dissolve the sample in ethanol, place a drop of the solution on a filter paper, add 1 drop of the reagent and expose the paper to hydrochloric acid fumes for 2–3 min.

Indications
A black spot indicates the presence of non-aromatic carbamates. *N*-Substituted carbamates do not react. The LOD is 1 μg.

Iodine test

Method
Mix the sample with an equal volume of manganese dioxide and heat the mixture carefully to dull redness over a small flame. Repeat the test by heating the sample alone.

Indications
The appearance of violet vapour indicates the presence of iodine in the molecule. Better results are sometimes obtained when the manganese dioxide is omitted (e.g. with amiodarone).

Iodoplatinate test (general test for alkaloids and nitrogenous heterocyclic compounds)

Reagent
Add 2 mL of a 5% (w/v) solution of platinic chloride and 5 g of potassium iodide to 98 mL of water and shake until dissolved. This reagent is often used as a locating agent in TLC.

Method
Dissolve the sample in 2 drops of 2 mol/L hydrochloric acid, add 2–3 mL of the reagent and dilute to 10 mL with water.

Indications
A violet, blue–violet, brown–violet or grey–violet precipitate suggests the presence of an alkaloidal base (precipitated as the alkaloid–iodoplatinate complex). The clearest colours are obtained with tertiary and quaternary amines; primary amines give indistinct colours and amines of small relative molecular mass generally do not react.

Koppanyi–Zwikker test

Reagent
A 1% (w/v) solution of cobalt nitrate in ethanol.

Method
Dissolve the sample in 1 mL of ethanol, add 1 drop of the reagent followed by 10 μL of pyrrolidine and agitate the mixture.

Indications
A violet colour is given by substances that contain the following structures:

- Imides, in which C=O and NH are adjacent in a ring (e.g. barbiturates, glutethimide, oxyphenisatine and saccharin).
- Sulfonamides and other compounds with free $–SO_2NH_2$ on a ring (e.g. clopamide, furosemide, sulfanilamide and thiazides), or with $–SO_2NH_2$ in a side-chain (e.g. chlorpropamide), or with $–SO_2NH_2$ that links a benzene ring with another ring other than a pyrazine, pyridazine, pyridine or pyrimidine ring (e.g. sulfafurazole and sulfamethoxazole). These latter structures give pink or red–violet colours (e.g. sulfadiazine and sulfadimethoxine).

No response is obtained with compounds with other substituents on the nitrogen atom. Anomalous responses are obtained with parametha-dione and theophylline (violet), and with cycloserine, idoxuridine, mephenytoin, niridazole and riboflavin (no response). Note that hydrochlorides give a blue colour before the addition of pyrrolidine.

Liebermann's reagent

Reagent
Add 1 g of sodium or potassium nitrite to 10 mL of concentrated sulfuric acid with cooling and swirling to absorb the brown fumes.

Method
Add 2 or 3 drops of the reagent to the sample on a white tile. Occasionally it is necessary to carry out the test in a tube and heat in a water-bath at 100°C. Many substances give colours with sulfuric acid alone and the test should be repeated using sulfuric acid instead of the reagent.

Indications
This test was originally developed to give intense colours with phenols:

- Orange colours are given by substances that contain a monosubstituted benzene ring not joined to C=O, N–C(=O)– or to a ring that contains a C=N–O– group.
- Orange or brown colours are given by some substances that contain two monosubstituted benzene rings (or some disubstituted compounds in which fluorine is the second substituent) that are joined either to one carbon atom or to adjacent carbon atoms.
- A wide range of colours is given by compounds that contain –OH, O–alkyl or –O–CH_2O– groups attached to a benzene ring or to a ring in a polycyclic structure that contains a benzene ring. The benzene ring must not bear –NO_2, or be halogenated, or contain an –O– substituent *ortho* to the oxy groups. Compounds that contain ring sulfur give a similar range of colours.

Colours are listed in Table 30.20. Note that a yellow colour is given by a variety of other compounds.

Mandelin's test (useful test for amfetamines and antidepressants)

Reagent
Dissolve 1.0 g of ammonium vanadate in 1.5 mL of water and dilute to 100 mL with concentrated sulfuric acid.

Method
Add a drop of the reagent to the sample on a white tile.

Indications
When interpreting the result of this test, account should be taken of the colour given by sulfuric acid and by Liebermann's test. Hydrochlorides give a red colour with this reagent. When the colours differ from those given with sulfuric acid or Liebermann's test, this indicates an aromatic ring together with a saturated 5-, 6- or 7-membered ring that contains only one nitrogen atom. The heterocyclic ring must not contain a second nitrogen atom or an oxygen atom. It must not be substituted or bound by –CONH– to the aromatic ring. The aromatic ring must not have –CF_3 as a substituent. Colours are also produced if sulfur is in a ring, provided that the ring does not contain more than one nitrogen atom (Table 30.21).

LOD values are: codeine sulfate 5.0 μg, amphetamine-HCl 10.0 μg, diamorphine-HCl 20 μg, metamfetamine 150 μg, morphine 5 μg and strychnine 0.05 μg.

Marquis test

The Marquis test is a useful broad-spectrum test used mostly for opium alkaloids and amfetamines.

Reagent
Carefully mix 100 mL of concentrated sulfuric acid with 1 mL of 40% (v/v) formaldehyde solution (stable for several weeks if protected from light).

Method
Add a drop of the reagent to the sample on a white tile.

Indications
Various colours that represent the whole of the visible spectrum are given by a large number of compounds. Structures that tend to maintain the response to the reagent at the violet end of the spectrum are, in decreasing order of efficacy: ring sulfur (with or without aromatic ring); ring oxygen (with aromatic ring); extra-ring oxygen or sulfur (with aromatic ring); aromatic compounds that consist entirely of C, H, N. Thus, there is a tendency for the response to the Marquis reagent to move gradually towards longer wavelength (i.e. through green to orange and red) as the ratio of C, H, N to the other groups in the molecule rises (Table 30.22).

The LOD values are: 1 μg for codeine sulfate, mescaline sulfate, methadone-HCl; 5 μg for lysergide tartrate, metamfetamine-HCl and morphine; 10 μg for amphetamine-HCl and diamorphine-HCl.

McNally's test

Reagents
1. A 0.5% solution of copper sulfate in 10% acetic acid.
2. A freshly prepared 2% (w/v) solution of sodium nitrite.

Method
Dissolve the sample (1 mg) in a few drops of acetone, and add 1–2 mL of water. Add 3 drops of solution 1 and an equal volume of solution 2. Shake and heat in a water-bath at 100°C for 3 min.

Indications
A red colour indicates the presence of free salicylic acid. Aminosalicylic acid gives a brown precipitate, and diflunisal gives a violet colour. Certain acids produced during the putrefaction of tissues also give red colours in this test: *p*-hydroxyphenylacetic acid, *p*-hydroxyphenylpropionic acid and *p*-hydroxyphenyl-lactic acid.

Mecke's reagent (useful test for opium alkaloids)

Reagent
Dissolve 1.0 g of selenious acid in 100 mL of concentrated sulfuric acid.

Method
Add a drop of the reagent to the sample on a white tile.

Indications
An immediate blue or green colour is indicative of opiates (see Table 30.23).

Melzer's reagent (general reagent for hallucinogenic mushrooms)

Reagent
Dissolve 1.5 g of iodine in 100 mL of an aqueous solution that contains 5 g of potassium iodide and 100 g of chloral hydrate.

Method
Place a few drops of the reagent on the mushroom spores or mushroom tissue to be tested.

Indications
A blue, bluish-grey or black–grey colour indicates amyloid mushrooms. A slight yellow or no change indicates that the mushrooms are non-amyloid. Psilocybes are always non-amyloid.

Mercurous nitrate (general reagent for barbiturate-like compounds)

Reagent
To a saturated solution of mercurous nitrate, add solid sodium bicarbonate until effervescence ceases and the precipitate formed becomes yellow. The precipitate then changes to a biscuit colour. This reagent should be freshly prepared and should be shaken immediately before use, and should not be kept for more than 1 h.

Method
Dissolve the sample in the minimum amount of ethanol, add 1 drop of the opaque reagent, shake and examine at intervals during 2 min. A blank solution that contains only ethanol and reagent should be treated similarly at the same time.

Table 30.20 Colours with Liebermann's reagent

Colour	*Compound*
Red	Acepromazine, ajmaline, alprenolol, aminacrine (100°C), antazoline, brucine, chlorprothixene, clopenthixol, flupentixol, mestranol, oxytetracycline, prajmalium, thiazinamium, tiotixene, tolmetin (100°C), trifluoperazine, xylazine
Violet-red	Indapamide
Brown-red	Methylchlorophenoxyacetic acid
Pink	Trichlorophenoxyacetic acid (→brown)
Brown-pink	Prazosin (100°C →red-orange)
Orange	Aletamine, alverine, ampicillin, atropine methobromide, atropine methonitrate, baclofen, benactyzine (→brown), bethanidine (→brown), broxyquinoline, butanilicaine, chloroquine (100°C), clidinium (→brown), cyclandelate, cyclizine, dazomet, decoquinate (slow), diethylthiambutene (100°C), dimefline, diuron, doxapram, dyclonine (100°C), fenclofenac (100°C, →brown), fenitrothion, fenpipramide, glibenclamide (100°C, 15 s), hyoscine butylbromide, hyoscine methonitrate, linuron, loxapine (50–60°C), metindizate (→brown), methylphenidate, metolazone (→green-brown), monolinuron, nomifensine, phenazone (100°C), phenelzine, propham, salinazid, sulfinpyrazone, tolazoline, trimetaphan, tripelennamine (→brown), triprolidine, xipamide, zomepirac (100°C)
Red-orange	Acetanilide, amfetamines, aniline, atropine, bamipine, beclamide, benethamine, caramiphen, carbetapentane, chlorcyclizine, cinchophen, cycrimine, diphenylpyraline, doxylamine, dropropizine, ephedrines, famprofazone, fencamfamin, glutethimide, hyoscine, hyoscyamine, isoaminile, isocarboxazid, levamisole, meclozine, mephentermine, methoin, methyl benzoquate, methylphenobarbital, metixene, metomidate, morazone, nialamide, pentapiperide, pethidine, phenacemide, phenbutrazate, phendimetrazine, phenglutarimide, pheniramine, phenmetrazine, phenobarbital, phensuximide, phenylmethylbarbituric acid, phenytoin, prolintane, tofenacin, tranylcypromine, triamterene, triphenyltetrazolium, warfarin
Brown-orange	Ambutonium, bumetanide, diphenhydramine, fenuron, feprazone (100°C, →brown), ibuprofen, labetalol, mepivacaine, methadone, nefopam (→brown), tetrahydrozoline
Yellow	Amicarbalide (100°C), clonidine (100°C, →orange), dequalinium (100°C, →orange), diethylpropion, diloxanide, ethoxzolamide, fenfluramine (100°C), flavoxate, gliclazide, metoclopramide, nifenazone (100°C), piroxicam, propachlor, tropicamide
Brown-yellow	Amiodarone
Green	Bialamicol, chlorotrianisene, colchicine, dextromoramide (100°C), diamthazole, hydrastine, mequitazine, naphthols, phenol, phenothiazine, thiocarlide
Blue-green	Hydrochlorothiazide, hydroflumethiazide, pindolol
Brown-green	Cyclopenthiazide
Grey-green	Azapropazone
Black-green	Naproxen
Blue	Amidopyrine (100°C), bendroflumethiazide, benzonatate (100°C), chromonar (100°C, 3 min), clomipramine, diphenylamine, dipyrone (100°C), imipramine, mefenamic acid, mefruside, oxypertine, padimate (100°C), procarbazine (100°C, 15 s), propyphenazone (100°C; red with water), tetracaine (100°C), yohimbine
Green-blue	Amiphenazole (100°C)
Violet	Methocarbamol, mianserin, paracetamol, penthienate methobromide, phenacetin, propiomazine, resorcinol, timolol (100°C), trazodone (100°C; transient)
Red-violet	Chloroxuron
Black-violet	Methoxychlor
Brown	Acepromazine, acetophenazine, adiphenine, azacyclonol, barban, benzilonium, benzyl nicotinate, biperiden, clemastine, clofenotane, clomifene, cyclothiazide, dextropropoxyphene, dichlorprop, diperodon, diphemanil, difenidol, emepronium, etenzamide, fenpiprane, flurbiprofen, haloperidol, mepenzolate, methylpiperidyl benzilate, mexiletine, nadolol, penfluridol, phenaglycodol, phenylbutazone (100°C), phosalone, pimozide, pipazethate (100°C, →red), pipoxolan, pyrrobutamine, rotenone, sotalol (100°C), sulindac, veratrine, zimeldine
Red-brown	Benzthiazide, bisacodyl, carfenazine, chlorpromazine, diclofenac, dosulepin, profenamine, etisazole, fenbufen, fenoprofen, methapyrilene, perphenazine, polythiazide
Pink-brown	Metoprolol
Orange-brown	Benazolin, diphenadione, maprotiline, methiocarb, piperidolate
Green-brown	Methdilazine, norbormide, promazine, thiopropazate
Violet-brown	Bamethan, clofibrate, dichlorophen
Black-brown	Mecoprop
Grey	Isopropamide
Black	Acetomenaphthone, aloin, aminophenols, amodiaquine, apomorphine, atenolol, benorilate, benzquinamide, buprenorphine, butorphanol, carbaryl (→green), carbidopa, cephaëline, chloroxylenol, chlorphenesin, clomocycline, clorgyline, codeine, cotarnine, cresol, cyclazocine, dextromethorphan, diamorphine, dibromopropamidine, diprenorphine, doxepin, emetine, ethamivan, ethinylestradiol, estradiol, estriol, estrone, etilefrine, furosemide, glycopyrronium, guaiphenesin, hexobendine, hydroxyephedrine, hydroxystilbamidine, ibogaine, indometacin, levallorphan, mebeverine, mescaline, methylchlorophenoxyacetic acid, methylenedioxyamfetamine, morantel, morphine, naloxone, 1-naphthylacetic acid, narceine, nicergoline, normetanephrine, noscapine, noxiptiline, octafonium, oxprenolol, oxyphenisatine, papaverine, pholcodine, pizotifen, practolol, profadol, propanidid, protokylol, pyrantel, rimiterol, ritodrine, rotenone, salbutamol, terbutaline, tetrabenazine, tetracycline, thymol, trimethobenzamide, trimetozine, tubocurarine, verapamil, viloxazine

Table 30.21 Colours with Mandelin's test

Colour	*Compound*
Red	Ajmaline, amfetamine, azacyclonol, chlorprothixene, diperodon (→green), dofamium (→brown), flupentixol, gelsemine (→green), indapamide, mequitazine, methotrexate, nialamide, pericyazine, prajmalium, prolintane, sodium cromoglicate, tiotixene, xylometazoline
Brown-red	Diacetylmorphine-HCl, doxepin-HCl, nadolol, propoxyphene-HCl
Orange	Brompheniramine, dropropizine (slow), ethylnoradrenaline, hydrastinine (→green), lachesine (→green), levamisole (→grey-green), methanthelinium, metixene, methyldopa, methyldopate, methylpiperidyl benzilate (→brown→green), noradrenaline, orphenadrine, pipenzolate (→green), poldine metilsulfate (→green→violet), procaine-HCl, propantheline, proquamezine (→violet), solanidine (→violet→blue), solanine (→violet→blue), strychnine (blue→purple→violet→red→red-orange), sulindac, thenalidine (→brown)
Red-orange	Cotarnine (→brown), doxepin
Green-orange	5-Methyltryptamine
Brown-orange	Mexiletine
Yellow	Azaperone, benzatropine, broxaldine, chelidonine (→green), conessine, deptropine, desipramine (→blue), dihydralazine, diphenhydramine, difenidol, diphenylpyraline, dropropizine (→orange), halquinol, homidium, lidoflazine, methacycline (→orange-violet), paraphenylenediamine, penicillamine, protokylol (→brown), tofenacin, tylosin (→yellow-brown), veratrine (→orange→violet-brown), viprynium
Orange-yellow	Cocaine-HCl, hexoprenaline, methaqualone, methylphenidate-HCl
Green-yellow	Methoxamine, oxycodone-HCl
Yellow-brown	Mescaline-HCl
Green	Acepromazine (→red), adiphenine (→blue), amfetamine, benorilate, bephenium hydroxynaphthoate, bibenzonium, buclosamide (blue rim), bunamidine, chlorpromazine (→violet), clefamide (→brown), codeine (green→blue), colchicine, cyclazocine, cyclomethycaine (→brown), debrisoquine, diaveridine, dibenzepin, diethazine (→violet with excess reagent), diethylthiambutene (→green-blue), dimethindene, dimethoxanate (→brown), dimoxyline, dipipanone (→blue), dosulepin, doxorubicin, doxycycline (→yellow), fenpiprane, guanoxan, harman, hydroxyephedrine, isoxsuprine, metanephrine, methadone (→blue), methdilazine (→violet), methocarbamol, methoxyamfetamine, methylenedioxyamfetamine (→blue), α-methyltryptamine (→orange), metopimazine, monocrotaline, niclosamide, nitroxoline, norharman (→yellow), normetanephrine, obidoxime (→blue), oleandomycin, oxymetazoline, paracetamol, pecazine (→violet), pentazocine, perazine (→violet), phenazone, phenazopyridine, phenformin, phenindamine, phenoxybenzamine (→violet), phenyltoloxamine, pindolol, piperacetazine (→red→violet), pipoxolan (→brown), prenylamine, profenamine (→violet), proflavine, promazine (→violet), promethazine (→violet), propranolol, reserpine, ritodrine, salicylic acid, thenium, thenyldiamine, thiocarlide (→yellow), tranylcypromine (→violet), trifluomeprazine (→red-violet), trihexyphenidyl
Yellow-green	Benzfetamine-HCl, metamfetamine-HCl, normethadone, opipramol
Blue-green	Amfetamine-HCl, benzoctamine, berberine (→brown), edrophonium, hydroxystilbamidine, ketobemidone, methoxyphenamine, phentolamine, profadol (→green), viloxazine
Brown-green	Benzydamine, chlorphenesin
Grey-green	Alverine, azapropazone, diamphenethide, diethyltryptamine (→yellow), dihydrocodeine, guaifenesin, hordenine, levomethadyl acetate, normorphine, oxyphencyclimine, papaverine, terbutaline, trihexyphenidyl
Blue	Bamethan (→green), clomipramine, deserpidine (→green), desferrioxamine (→violet), doxapram, droperidol (→green), harmine (→green), imipramine (add water), maprotiline, mebhydrolin, metaraminol, phenaglycodol, phenyramidol, pyridoxine (→grey-green), salbutamol (blue rim→brown rim), strychnine (blue→purple→magenta→red→red-orange→orange), thioridazine (→violet), trimipramine (add water), triphenyltetrazolium (slow), xipamide, xylazine, yohimbine (→green)
Green-blue	Chlophedianol, labetalol
Violet	Alimemazine, amidefrine, benperidol, bezitramide (→orange), bisacodyl, captodiame, cefaloridine, chloropyrilene (→orange), clomifene (→orange-brown), clomocycline (→brown), denatonium, dipyridamole, guanoclor (→orange→brown-yellow), guanoxan, hexobendine, hydromorphone (→orange), mepacrine (→yellow), mepyramine, metisazone (→yellow), mianserin, morantel, naloxone (→brown), oxyclozanide (→orange), oxyphenisatine, oxytetracycline (→red→orange), penthienate, perphenazine, phenylbutazone, pizotifen (→green), prilocaine, primaquine (→orange), propiomazine, pyrantel, pyrrobutamine, rolitetracycline (→red→orange), tetracycline (→red→orange), thiethylperazine, thiopropazate, triacetyloleandomycin (slow), tridihexethyl, trimetazidine
Red-violet	Antazoline, carfenazine, dimethothiazine, histapyrrodine, thonzylamine
Blue-violet	Alcuronium, hexocyclium, levomepromazine
Brown-violet	Alprenolol, bitoscanate, butaperazine, naphazoline
Grey-violet	Methadone-HCl, methoserpidine, oxprenolol, tricyclamol
Black-violet	Methylenedioxyamfetamine-HCl, methapyrilene
Brown	Amitriptyline (→green), azapetine, bamipine, carbetapentane (slow), clidinium (→green), cyclopentolate, diphemanil, dipyrone, doxepin, embutramide, fluanisone, fluphenazine, isoetarine, isometheptene, isoprenaline, metindizate, methyl benzoquate, methysergide, metoclopramide, norpipanone (→blue), nortriptyline (→green), opium, phenelzine, phenylephrine, pimozide, piperidolate, prochlorperazine (→violet), propoxycaine, rescinnamine, salinazid, stanozolol, tetrabenazine, thioproperazine (→green→violet), tolnaftate, tolpropamine, tramazoline, tubocurarine
Red-brown	Benzthiazide, clioxanide, cycrimine, decoquinate, diclofenac, ethomoxane, hydrastine (→red), trifluoperazine, triflupromazine
Pink-brown	Metoprolol
Orange-brown	Rifampicin, spiramycin, thebaine
Yellow-brown	Clemastine, clofazimine, physostigmine, rifamycin SV, trimethoprim, tripelennamine
Green-brown	Etenzamide, harmaline, lysergic acid, mesoridazine, narceine, pentazocine, phenyltoloxamine, syrosingopine
Violet-brown	Chlortetracycline (→yellow), cyproheptadine, demeclocycline, dihydroergotamine, ergotamine, lymecycline (→yellow), methylergometrine, nicergoline (→brown), octaphonium, oxethazaine, protriptyline, trimethobenzamide
Grey-brown	Dextropropoxyphene, mephenesin carbamate

Table 30.21 continued

Colour	*Compound*
Grey	Dihydromorphine, diprenorphine, etilefrine (→green→brown), ibogaine (→violet), indometacin, lobeline, lysergide, morphine, oxypertine, propranolol, trazodone (→violet)
Blue-grey	Alphaprodine, diamorphine, morphine
Black	Procyclidine
Grey-black	Flurazepam

Table 30.22 Colours with the Marquis test

Colour	*Compound*
Red	Alprenolol, benzylmorphine (→violet), buphenine, dimethothiazine, etenzamide, etilefrine, fenclofenac (slow), fenpiprane, fluphenazine, flurbiprofen, hexoprenaline, labetalol (→brown-red), maprotiline, mephenesin carbamate, mequitazine (slow), mesoridazine (→violet), methoxyphenamine, metopimazine, mexiletine, nadolol, pentazocine (→green), pericyazine, phenazopyridine, phenoperidine, phenylephrine, piperacetazine, prenylamine, thebaine (→orange), thiethylperazine (→green), thioproperazine, tiotixene, tolpropamine, tranylcypromine (→brown), vinblastine
Orange-red	Alverine, amfetamine-HCl, bethanidine, diphemanil, flupentixol, metamfetamine-HCl
Violet-red	Thioridazine (→blue-green)
Black-red	Doxepin-HCl
Brown-red	Alphaprodine, doxepin, trihexyphenidyl
Pink	Alimemazine, fenoprofen, fluopromazine, metoprolol, promazine, promethazine, trifluoperazine
Orange	Adrenaline (→violet), aletamine, amfetamine (→red→brown), anileridine (slow), benactyzine (→green→blue), benzethonium, benzilonium (→green→blue), benzfetamine, bunamidine (→red), carbetapentane (slow), carfenazine (→red-violet), chlorphentermine, clidinium (→blue), cyclandelate (slow), cycrimine (→red), dehydroemetine, dimethyltryptamine, dipyridamole, ethacridine (→red), ethoheptazine, ethylnoradrenaline (→brown), famprofazone, fenbufen (→brown), fencamfamin, fenethylline, fentanyl, harmine, indapamide (→violet), indometacin, isothipendyl, ketobemidone, lachesine (→green→blue), lymecycline, mepenzolate (transient), mephentermine (→brown), mescaline, metamfetamine, metanephrine (→violet-brown), methacycline, methanthelinium, methindizate (→green), methylphenidate, methylpiperidyl benzilate (→green→blue), 5-methyltryptamine (→brown), α-methyltryptamine (→brown), *N*-methyltryptamine, nefopam (→brown), nomifensine (slow), normetanephrine (→violet-brown), oxeladin, oxytetracycline, pentapiperide, pethidine, phenethylamine, phenformin (→brown), phentermine, piminodine, pipenzolate (→green→blue), piperidolate, pizotifen (→red), poldine methylsulfate (→green→blue), primaquine, profadol (→red-brown), prolintane (→brown), propantheline, prothipendyl, psilocybine, rolitetracycline, spiramycin, tetracycline, trimethoprim, trimethoxyamfetamine, tryptamine, veratrine, xylometazoline
Red-orange	Chlorprothixene
Pink-orange	Diuron
Yellow-orange	Orphenadrine, pipradrol
Brown-orange	Amitriptyline
Yellow	Acriflavine (→red), amiloride, azacyclonol, benzquinamide, benzatropine, bromazine, broxaldine, broxyquinoline, caramiphen, chlordiazepoxide, chlorphenoxamine (→green), chlortetracycline (→green), chlortalidone, cinchophen, clefamide, clemastine (green rim), colchicine, conessine (→orange), cyclizine, demeclocycline (→green), deptropine, diethyltryptamine (→brown), 2,5-dimethoxy-4-methylamfetamine, diphenhydramine, diphenidol, diphenylpyraline, doxycycline, ethoxzolamide, ethylmorphine (→violet→black), furaltadone, halquinol, hydrocodone (→brown→violet), hydromorphone (→red→violet), hydroxyephedrine, isoetarine (→orange), lidoflazine, lorazepam, mepacrine, methyldopa (→violet), methyldopate (→violet), norcodeine (→violet), orciprenaline, oxycodone (→brown→violet), oxyphenbutazone, phanquone, phenbutrazate (slow), phentolamine, phenyramidol, pindolol (→brown), pramoxine (→green), proflavine (→orange), salbutamol, salinazid, sodium cromoglicate, solanine (→violet), terbutaline, tetrabenazine, thebacon (→violet), tofenacin, triamterene, trimetazidine (fades), vancomycin, viprynium embonate, zomepirac (100°C, →orange)
Orange-yellow	Methylphenidate-HCl, stanozolol
Pink-yellow	Methadone-HCl
Green	Berberine, carbaryl, chelidonine, harman, norharman, oleandomycin, propranolol, protriptyline, pseudomorphine, sulindac (slow)
Yellow-green	Acepromazine (→red), verapamil (→grey)
Blue-green	Tolnaftate
Brown-green	Harmaline
Grey-green	Cyproheptadine, deserpidine, naphazoline, oxypertine, phenindamine, protokylol, rescinnamine, reserpine (→brown)
Blue	Clofibrate, embutramide, nicergoline (→grey)
Grey-blue	Mebhydrolin, 1-naphthylacetic acid
Violet	Alimemazine, apomorphine (→black), azatadine, benorilate, bisacodyl, buprenorphine, butriptyline, captodiame, chloropyrilene, chlorpromazine, clofazimine, codeine, diamorphine, diethylthiambutene, dihydrocodeine, dimethindene (→blue), dimethoxanate, doxorubicin, doxylamine, etoxazene, guaifenesin, guanoxan, hexocyclium metilsulfate, mepyramine, 6-monoacetylmorphine, morphine, nalorphine, normorphine, oxprenolol, oxycodone-HCl, oxyphenisatine, pecazine, penthienate, pentazocine, perazine, perphenazine, phenoxybenzamine, phenyltoloxamine, pholcodine, pimozide, pipoxolan (→grey), prochlorperazine, procyclidine, profenamine, promazine, promethazine, proquamezine, solanidine, thenium, thiopropazate, tricyclamol, viloxazine
Red-violet	Acetophenazine, benzoctamine, bephenium hydroxynaphthoate, cefaloridine, chlophedianol (→brown), dihydromorphine, ethomoxane, isoxsuprine, lobeline, methdilazine, propiomazine, tramazoline, trifluomeprazine, trifluoperazine, triflupromazine, trimeperidine
Blue-violet	Methocarbamol, levomepromazine, morantel, neopine, noscapine (fades), pyrantel

Black	
Green–black	Lysergide, opium

Indications

A dark grey or black colour indicates a ring imide group or sulfonamides with an additional ring. The speed and intensity of the reaction varies between different compounds. The following ring imides react in decreasing order of intensity: barbiturates, bemegride, phenytoin > benperidol, cycloserine, pimozide > glutethimide, oxyphenisatine > saccharin, sulfinpyrazone. In the case of sulfonamides, succinylsulfathiazole, sulfamoxole, sulfanilamide, sulfasomidine and sulfathiazole react with greater intensity than all others. Chlorpropamide and tolbutamide give a moderate response. If used as a spray, the LOD is 1–5 µg for barbiturates.

Methanolic potassium hydroxide

Reagent

A 20% (w/v) solution of potassium hydroxide in methanol.

Method

Add a few drops of the reagent to a solution of the sample in methanol and heat if necessary to boiling point to develop the colour.

Indications

A change from colourless or from a pale colour to red, orange, yellow, green or blue is given by quinones, diones that possess an aromatic ring, phenols with adjacent hydroxy groups and compounds that contain nitro groups on a ring (Table 30.24). Many of these compounds are coloured already and give pale or colourless solutions in methanol.

Millon's reagent (general reagent for phenols)

Reagent

Dissolve 3 mL of mercury in 27 mL of fuming nitric acid and add an equal volume of water with stirring.

Method

Add 0.5 mL of reagent to the sample and warm the mixture.

Table 30.24 Colours with methanolic potassium hydroxide

Colour	*Compound*
Red	Benserazide, isoetarine (→orange→yellow), metronidazole, nitrofurazone, phenindione
Orange–red	Fenitrothion, quintozene, tecnazene, trifluralin
Pink	Levodopa (→red–brown)
Orange–pink	Rimiterol
Brown–pink	Dobutamine
Orange	Acinitrazole, barban, carbidopa, dinitro-orthocresol (100°C), dinobuton, dinoseb, dodecyl gallate, hexoprenaline (→brown), isoprenaline (→yellow), nifedipine, nifuratel, nifursol, obidoxime, protokylol (→yellow)
Pink–orange	Adrenaline(→brown)
Yellow–orange	Nitrofurantoin
Yellow	Acebutolol, diphenadione, methyldopa (→orange), metolazone, niclosamide, niridazole, nitroxoline, nitroxynil, phanquone (→brown–violet), sodium cromoglicate
Green–yellow	Phytomenadione (→violet→brown)
Green	Apomorphine (→red), dinitolmide
Blue	Dopamine (→orange→brown), methyldopate (→orange), noradrenaline (→orange)
Violet	Dimetridazole (when boiled)

Indications
A red or orange–red colour indicates the presence of a phenolic substance. Primary aryl amines also react. Some basic compounds that contain a phenolic group do not react to this test; a combination of this test with the Folin–Ciocaltaeu reagent is therefore advised for phenolic compounds. Phenols that contain more than one hydroxyl group do not give the typical red colour. This reagent does not react with phenols substituted with Cl, Br or I.

Naphthol-sulfuric acid

This test should be carried out in conjunction with the sulfuric acid test.

Reagent
Mix 1 g of naphth-2-ol with 40 mL of concentrated sulfuric acid and heat in a water-bath at 100°C, with occasional stirring, until the naphth-2-ol is dissolved.

Method
Mix the sample with 1 mL of the reagent, heat in a water-bath at 100°C for 2 min and note any colour produced. Cool, add 1 mL of water and note the colour again.

Indications
A range of colours is obtained with steroidal structures (Table 30.25). A positive response to this test combined with a positive response to the sulfuric acid test is indicative of the presence of a steroid.

Compounds other than steroids that give colours with this test include chloral hydrate and chloramphenicol (brown–yellow), starch and tartaric acid (green).

Nessler's reagent

Reagent
1. Dissolve 50 g of mercuric chloride and 35 g of potassium iodide in 200 mL of water and cool.
2. Dissolve 50 g of sodium hydroxide in 250 mL of water and cool.

Add the cold solution 2 to the cold solution 1 and make up to 500 mL. Allow the mixture to stand and decant the clear supernatant (stable for many months) for use. Store in dark brown bottles away from the light.

Method
Add the reagent (3 drops) to the sample (3 drops), agitate and heat the mixture to 100°C in a water-bath, examining it every minute for 10 min. A blank solution should be treated similarly at the same time.

Indications
A brown–orange colour is produced quickly by aliphatic amides and thioamides. The presence of an aromatic ring slows the reaction. The nearer the amide group is to the ring, the more the reaction is inhibited. Substituents in the ring may cause a weak reaction. An immediate black colour is produced by substances that contain *ortho*- or *para*-hydroxy groups and by substances that contain an –NH–NH– or –NH–NH_2 group in an aliphatic side-chain. Some compounds must be heated to 100°C to produce blackening. Colours are given in Table 30.26.

Ninhydrin

Reagent
Dissolve 0.5 g of ninhydrin in 40 mL of acetone.

Method
Dissolve the sample in methanol, place a drop of the solution on a filter paper, add 1 drop of the reagent and dry in a current of hot air.

Indications
A violet colour that appears rapidly indicates the presence of an aliphatic primary amine or an amino acid group. The presence of an aromatic ring inhibits the response, and the inhibition increases the nearer the amino group is to the ring, as for amfetamine (pink–orange), procainamide and proxymetacaine (both yellow). If the amino group is associated with a saturated ring, a positive but weak pink–violet colour is obtained (amantadine, rimantadine). Gentamicin gives a violet colour after heating for 4 min.

Table 30.25 Colours of steroids with naphthol-sulfuric acid

Colour with hot reagent	*Steroid*	*Colour after dilution*
Red	Mestranol	Red
Orange-red	Desoxycortone	Blue-black
	Dydrogesterone	–
	Hydroxyprogesterone	Blue, violet (dichroic)
	Noretynodrel	Brown-red
Brown-red	Ethinylestradiol	Pink
Orange	Norethisterone	Orange-brown
Orange, green (dichroic)	Norethandrolone	Red-orange
Yellow	Diethylstilbestrol	Orange
	Testosterone	Green, brown (dichroic)
Green-yellow	Fluoxymesterone	Yellow
Green	Beclometasone	Brown-yellow
	Fluocinolone	Yellow
Yellow-green	Dexamethasone	Yellow
Green, yellow (dichroic)	Estriol	Orange
	Estrone	Orange
	Triamcinolone	Yellow
Green, brown (dichroic)	Fludroxycortide	Yellow
Blue-green, yellow (dichroic)	Estradiol	Orange
Violet	Fludrocortisone	Brown
Brown	Oxymetholone	Pink-orange
	Prednisolone	Brown
	Prednisone	Orange
	Progesterone	Yellow
Red-brown	Dimethisterone	Brown-green
	Enoxolone	Orange
	Fluocortolone	Red-brown
Orange-brown	Alfadolone	Orange
	Androsterone	Orange
	Cortisone	Orange
	Dienestrol	Yellow
Yellow-brown	Carbenoxolone	Orange
	Cholesterol	Violet
	Hydrocortisone	Yellow-brown
Green-brown	Betamethasone	Orange-brown

Nitric acid, fuming

Method
Mix the sample with 3 drops of fuming nitric acid, heat at 50°C for 30 s and observe any colour produced. Cool the mixture, add 2 drops of it to 2 mL of concentrated sulfuric acid and observe the colour. To the remainder of the cooled mixture, add 2 mL of water followed by 2 mol/L sodium hydroxide, dropwise, until pH 8 is reached (use an indicator paper).

Indications
Chlorinated phenols give a series of colours in the three parts of this test (Table 30.27).

Nitric acid-sulfuric acid (Erdmann's reagent)

Mix 1 mL of concentrated nitric acid with 30 mL of concentrated sulfuric acid.

Table 30.26 Colours with Nessler's reagent

Colour	*Compound*
Orange	Acebutolol (slow), carbidopa (→black), methotrexate
Brown–orange	Acetylcarbromal (slow), bromvaletone, carbromal, chloramphenicol, dinitolmide, etenzamide (weak), ethionamide, fluoroacetamide, nicotinamide, phenacemide (slow), pheneturide (slow), protionamide, pyrazinamide, salicylamide (weak), urea
Yellow	Dihydrostreptomycin (→brown), penicillamine
Brown	Demeclocycline, mebutamate (slow), nadolol, paracetamol (slow)
Yellow–brown	Atenolol (slow)
Black (immediate)	Adrenaline, apomorphine, ascorbic acid, benserazide, dihydralazine, dobutamine, dodecyl gallate, dopamine, ethylnoradrenaline, hexoprenaline, hydralazine, iproniazid, isocarboxazid, isoetarine, isoniazid, isoprenaline, levodopa, mebanazine, methyldopa, methyldopate, nialamide, noradrenaline, phenelzine, procarbazine, protokylol, rimiterol
Black (at 100°C)	Cimetidine, gentamicin, labetalol, meprobamate (grey–black), methallibure, salinazid, thiacetazone

Table 30.27 Colours with fuming nitric acid

Colour			
Part 1	*Part 2*	*Part 3*	*Compound*
Orange–red	Orange	Orange–brown	Hexachlorophene
Red	Red	Brown–violet	Pentachlorophenol

Method

Dissolve the sample in 1 mL of ethanol, add a pellet of potassium hydroxide and evaporate to dryness (100°C in a water-bath). To the residue add 0.5 mL of water and 1 mL of carbon tetrachloride, shake and allow to separate. Decant the lower carbon tetrachloride layer and shake it with 1 mL of the reagent.

Indications

A red colour in the acid layer suggests the presence of clofenotane or its metabolite, dichlorodiphenyldichloroethylene (DDE). The red colour changes to orange and then to green. Weak pink colours are given by aldrin, dieldrin and endrin. A red colour is also given by dichlorodiphenyldichloroethane (DDD, mitotane), but the colour does not change.

Note that the substance should be tested to ensure that it does not give a colour with sulfuric acid alone.

Nitrous acid

Method

Dissolve the sample in a minimum volume of water, and add an amount of solid sodium nitrite equal in volume to the sample followed by a few drops of 2 mol/L hydrochloric acid.

Indications

Orange or yellow colours are given by certain sulfonamides, and green, blue or violet colours by certain phenylpyrazolines (Table 30.28).

No response is obtained with succinylsulfathiazole, sulfacetamide, sulfadiazine, sulfadimethoxine, sulfaguanidine, sulfamerazine, sulfaquinoxaline, sulthiame or propyphenazone.

Palladium chloride

Reagent

Dissolve, with the aid of heat, 0.1 g of palladium chloride in 5 mL of 2 mol/L hydrochloric acid and dilute the solution to 100 mL with water. Mix together equal volumes of this solution and 2 mol/L sodium hydroxide. The mixed reagent is stable for several weeks.

Table 30.28 Colours with nitrous acid

Colour	*Compound*
Orange	Sulfafurazole
Yellow	Sulfadoxine, sulfachlorpyridazine, sulfadimidine, sulfaethidole, sulfamethizole, sulfamethoxazole, sulfamethoxydiazine, sulfamethoxypyridazine, sulfametopyrazine, sulfamoxole, sulfaphenazole, sulfapyridine, sulfasomidine, sulfathiazole, sulfinpyrazone
Green	Phenazone
Blue	Dipyrone (transient)
Violet	Amidopyrine (transient)

Method

Mix the sample with 1 mL of the reagent and heat at 100°C in a water-bath for 2 min. A blank solution should be treated similarly at the same time.

Indications

Red, orange, yellow, brown or black colours are given by aliphatic compounds that have a sulfur atom in the chain, and by aromatic compounds that have a sulfur atom in the side-chain. However, no colour is given when an *S*-alkyl chain is present, unless the chain is terminated by an halogenated group.

No response is obtained if the sulfur is in a group that links two rings. Reducing agents such as ascorbic acid, chloral hydrate, chloroform and glucose, and compounds that contain a chain with a hydrazine link (–NH–NH–, –NH–NH_2), give a translucent dark-grey or black colour, but do not give the gradual yellow to orange to brown colour seen with sulfur-containing compounds. Compounds that contain adjacent hydroxyl groups on an aromatic ring give orange colours that turn brown (Table 30.29).

Phosphorus test

Method

To the sample add 0.5 mL of concentrated nitric acid and 0.2 mL of concentrated sulfuric acid and heat at 100°C in a water-bath for 30 min. Cool, add 1 mL of a 10% (w/v) solution of ammonium molybdate and replace in the water-bath at 100°C for 5 min. A blank solution should be

Table 30.29 Colours with palladium chloride

Colour	*Compound*
Red	Gloxazone
Orange	Adrenaline (→brown), benserazide (→brown), bitoscanate, captopril, carbidopa (→brown), carbimazole, disulfiram, dobutamine (→brown), ecothiopate, isoetarine (→brown), levodopa (→brown), methallibure, thiamazole, polythiazide, rimiterol, thiacetazone, thiopental
Brown–orange	Demeton-S
Yellow	Clindamycin, dazomet, dimercaprol, dimethoate, methisazone (→orange→brown), penicillamine
Orange–yellow	Thialbarbital
Brown	Ambazone, azinphos-methyl, dihydrostreptomycin (slow), ethionamide, malathion, noxythiolin, parathion, phosalone, protionamide, spironolactone, thiram
Orange–brown	Chlorthiamid, diazinon, disulfoton, fenitrothion, formothion, phorate, vamidothion
Black–brown	Di-allate, dichlofluanid, tri-allate
Grey	Chlorfenvinphos
Black	Ascorbic acid, captan, chloroform, cloral hydrate, mebanazine, nifuratel, phenelzine, procarbazine, sulfasalazine, sulfaurea, trichlorfon

Table 30.30 Colours with potassium dichromate

Colour	*Compound*
Red	Carbidopa
Yellow (→brown)	Phenol (2 min)
Green (→brown)	Adrenaline, dopamine, hexoprenaline, isoetharine, isoprenaline, levodopa, methyldopa, methyldopate, noradrenaline, rimiterol
Blue–green	Aniline (2 min)
Brown	Benserazide, *o*-cresol (30 s), *m*-cresol (2 min), orciprenaline (slow), protokylol (→red–brown on warming), terbutaline (slow)
Green–brown	Dobutamine

treated at the same time. For some compounds, the reaction may occur after shorter heating times than those stated above.

Indications
A bright yellow solution or precipitate indicates the presence of phosphorus and suggests an organophosphorus pesticide, especially if the sample is a water-immiscible liquid. Cyclophosphamide and triclofos also react.

Potassium dichromate

Method 1
Dissolve the sample by shaking in 0.5 mL of 2 mol/L hydrochloric acid and add a few crystals of potassium dichromate.

Indications
An immediate brown colour, or a green colour that changes to brown, indicates the presence of an aminophenol or of a phenol that has two or more hydroxyl groups in adjacent positions on the ring (Table 30.30). Monophenols, halogenated phenols and phenols with hydroxyl groups *meta* to each other react more slowly or not at all.

Method 2
If the sample is a liquid, add 1–2 drops to 1 mL of water followed by 1 mL of a saturated solution of potassium dichromate in 50% v/v sulfuric acid.

Indications
A green colour is given by acetaldehyde, ethanol, methanol, propan-1-ol and propan-2-ol.

Schiff's reagent

Reagent
Dissolve 0.2 g of basic magenta (fuchsin, CI 42510) in 120 mL of hot water, cool, add 20 mL of a 10% (w/v) solution of sodium hydrogen-sulfite and 2 mL of concentrated hydrochloric acid, and dilute to 200 mL. Store at 4°C and protect from light.

Method
Add the sample to 1 mL of the reagent.

Indications
A violet colour indicates the presence of an aliphatic aldehyde. The longer the carbon chain, especially if it is branched, the weaker the response to the test.

Scott's test (see also Cobalt thiocyanate)

Reagent
1. Cobalt thiocyanate dissolved in water (2% w/v) and then diluted 1 : 1 with glycerine
2. Concentrated hydrochloric acid
3. Chloroform.

Method
Add a small amount of the sample to be tested to a test-tube, add 5 drops of solution 1 and shake. If cocaine is present a blue colour develops at once. Add 1 drop of solution 2 and shake (the blue colour disappears and a clear pink solution develops). Add several drops of solution 3.

Indications
The chloroform layer develops an intense blue colour if cocaine is present. Methadone also reacts.

The LOD is 60 µg cocaine-HCl and 15 µg methadone-HCl.

Simon's test (modified sodium nitroprusside test)

Reagent
1. Dissolve 1 g of sodium nitroprusside in 100 mL of water and add 2 mL of acetaldehyde to the solution with thorough mixing.
2. Freshly prepared 2% sodium carbonate in distilled water.

Method
Add 1 drop of solution 1 to the sample, followed by 2 drops of solution 2.

Indications
A dark-blue colour indicates a secondary amine (e.g. metamfetamine, ephedrine, 3,4-methylenedioxymetamfetamine (MDMA)) or an unsubstituted heterocyclic amine as its free base. A deep blue colour indicates the presence of metamfetamine. Primary amines (e.g. amfetamine, methylenedioxyamfetamine (MDA)) yield a slow pink to cherry-red colour.

Sodium dithionite

Reagent
A 5% (w/v) solution of sodium dithionite in a 10% (w/v) solution of sodium hydroxide.

Method
Apply the reagent to the sample, either on a white tile or as a solution in a test-tube. A blank solution should be treated similarly at the same time.

Indications
Colours are produced by bis(pyridyl) compounds (Table 30.31). Dark colours are likely to be given by certain metallic solutions because of reduction.

Sodium hypobromite test (for carbamazepine)

Reagent
Dissolve 0.5 mL of bromine in 5 mL of a 40% w/v solution of sodium hydroxide with shaking and cooling. (this should be freshly prepared).

Method
Add 1 mL of 2 mol/L hydrochloric acid to 5 mL of sample and 5 mL of chloroform. Vortex mix for 1 min and centrifuge for 5 min. Remove the upper layer, add 1 mL of the chloroform extract to 0.2 mL of sodium hypobromite reagent and mix for 30 s.

Indications
Carbamazepine forms a blue to violet colour in the chloroform layer. The test has a sensitivity of 250 mg/L.

Sodium nitroprusside

Reagent
A 1% (w/v) solution of sodium nitroprusside.

Method 1
Add the sample to 2 mL of the reagent followed by a drop of 2 mol/L sodium hydroxide.

Indications
Orange colours are given by ketones and red colours by acetaldehyde.

Table 30.31 Colours with sodium dithionate

Colour	*Compound*
Green	Diquat
Blue	Paraquat

Method 2
Mix the sample with a minimum volume of 2 mol/L sodium hydroxide, evaporate to dryness, dissolve the residue in 2 drops of water and add 0.5 mL of the reagent.

Indications
A violet colour is given by substances that contain labile sulfur in the molecule and by unsubstituted dithiocarbamates.

Method 3
Carry out Method 2 above, but after evaporation to dryness heat the residue until it is yellow or orange in colour before proceeding.

Indications
A violet colour is given by certain substances that contain labile sulfur and do not react to method 2 (e.g. clomethiazole, lincomycin and monosulfiram).

Sodium nitroprusside–acetone

Reagents
1. Dissolve 2 g of sodium nitroprusside in 5 mL of water and add 45 mL of methanol
2. 2% (w/v) sodium carbonate
3. Acetone
4. 10% acetaldehyde.

Method 1
Add a drop of solution 1 followed by a drop of solution 2 to 3–4 mg of sample dissolved in solution 3 on a spot plate. A purple colour is indicative of amfetamine. The LOD is 30 μg.

Method 2
Add a drop of solution 1 followed by a drop of solution 4 to 1–2 mg of sample dissolved in solution 3. An immediate blue colour is indicative of metamfetamine. The LOD is 5 μg.

Sodium picrate (Steyn test)

Reagent
Prepare a solution of 5 g sodium bicarbonate and 0.5 g picric acid in 100 mL of water.

Method
Mix the sample with a few drops of chloroform and concentrated sulfuric acid to hasten the reaction while holding a piece of filter paper, impregnated with the reagent, in the vapours that issue from the tube, and heating the contents to 30°C.

Indications
The yellow colour of the filter paper changes from orange to brown–orange and then to orange–red or red in the presence of cyanide. Positive results are given by compounds that contain cyanide groups (e.g. cimetidine, diphenoxylate and isoaminile).

Sulfuric acid

Method
Apply concentrated sulfuric acid directly to the sample on a white tile or in a test-tube.

Indications
A range of colours is obtained with compounds of various types. Steroids give orange or yellow colours, many of which fluoresce under UV light ($\lambda = 350$ nm) either immediately or after dilution (Table 30.32). Thioxanthenes give red or orange colours that fluoresce under UV light ($\lambda = 350$ nm) (Table 30.33).

Sulfuric acid–fuming sulfuric acid

Reagent
Mix together 7 mL of concentrated sulfuric acid and 3 mL of fuming sulfuric acid.

Method
Dissolve the sample in a minimum volume of toluene and add 1 or 2 drops of the reagent.

Indications
A red colour that appears in the lower acid layer indicates the presence of dieldrin (colour develops quickly) or aldrin (colour develops slowly). A pink–orange colour is obtained with endrin.

Tetrabromophenolphthalein ethyl ester

Reagent
Dissolve 50 mg tetrabromophenolphthalein ethyl ester (TBPE) in 100 mL chloroform, shake the solution for 2 min with 1 mL of 10% (v/v) hydrochloric acid and discard the aqueous phase. Dry the organic layer with anhydrous sodium sulfate. Separate the drying agent by filtration. Store the reagent in an amber bottle at 4°C.

Method
Place 0.5 mL of sample to be tested in a conical test tube, add 100 μL phosphate buffer (10 mmol/L, pH 8.0) and vortex mix. Add 50 μL of the TBPE reagent and vortex mix. After 2–3 min note the colour of the chloroform layer. If the sample to be tested is a solid, dissolve 1–2 mg of the material in 0.5 mL of buffer and proceed.

Indications
A deep blue colour indicates quaternary ammonium compounds. An orange, brown, red or purple colour indicates the presence of basic drugs. This test is most sensitive to tertiary amines (e.g. tricyclics, propoxyphene, phenothiazines, diphenhydramine, phencyclidine, methadone, pethidine). Its LOD is 1 mg/L.

Thalleioquin test

Method
Dissolve the sample in a minimum volume of 2 mol/L hydrochloric acid, add 2 drops of bromine solution, place 1 drop of the mixture on a piece of filter paper and expose the paper to ammonia fumes.

Indications
A green colour indicates the presence of a quinine-type structure (e.g. hydroquinidine, hydroquinine, quinidine, quinine). Cinchonidine and cinchonine do not respond.

Trinder's reagent (see Ferric chloride)

Reagent
The solution is prepared as follows: 40 g of mercuric chloride and 40 g of ferric nitrate are dissolved in 850 mL of distilled water; 10 mL of concentrated HCl is added and the solution is diluted to 1 L. This solution is stable for 1 year.

Method
A few drops of the reagent are added to a few drops of urine. A purple colour indicates the presence of a salicylate. This test was devised for the quantitative assay of salicylates in serum, with the mercuric chloride serving as a protein precipitant. The ferric chloride test has been modified for use on blood samples (Asselin, Caughlin 1990). Blood (0.5 mL) is mixed with 1.0 mL of acetone and vortex mixed. The sample is centrifuged, and 50 μL of the supernatant is added to 50 μL of ferric chloride. A purple colour at the interface indicates salicylates.

Vanillin reagent

Reagent
Dissolve 1 g of vanillin in 20 mL of concentrated sulfuric acid, warming if necessary.

Method
Add 2 drops of the reagent to the sample, heat in a water-bath at 100°C for 30 s and note any colour that is produced. Dilute the cooled mixture by adding a few drops of water and note any change of colour.

Indications
Many compounds of different chemical structure react with this reagent. However, for barbiturates, the reaction appears to be a steric

Table 30.32 Reactions of steroids with sulfuric acid

Initial colour	*Compound*	*Fluorescence at 350 nm*	*Fluorescence after dilution*
Red			
Orange–red	Dienestrol	Nil	Nil

Green–yellow	Estrone	Green	Green–yellow (orange in daylight)
No colour	Estriol	Yellow–green	Quenched (orange in daylight)
	Testosterone	Green	Nil

phenomenon that depends on the structure of the side-chain at the 5-position. Dark colours, which are either dispelled or changed to violet, blue or green by dilution, are produced when either side-chain is greater than two carbon atoms in length or contains a cycloalkene ring. Branching can be proximal to the pyrimidine ring, but not distal. No colour is obtained if both side-chains are less than three carbon atoms in length or if either is branched distally or contains an aryl nucleus. Long, straight, saturated chains also appear to hinder reaction.

Hydroxybarbiturates give positive responses (Table 30.34), but bemegride, glutethimide, phenytoin and primidone do not respond. No response is obtained with amobarbital, aprobarbital, barbital, butobarbital, enallylpropymal, hexethal, ibomal, idobutal, metharbital, methylphenobarbital, nealbarbital, phenobarbital or phenylmethylbarbituric acid. With cold reagent, an orange colour is produced by pentobarbital, secobarbital and thiopental, and a brown colour by cyclopentobarbital.

Zwicker reagent (alkaline cobalt test)

This is a general test for barbiturate-like compounds.

Reagent

1. Dissolve 0.5 g of copper(II) sulfate pentahydrate in 100 mL of distilled water.
2. Add 0.5 mL of pyridine to 95 mL of chloroform.

Method

Add a few drops of solution 1 to the sample to be tested, followed by a few drops of solution 2 and then heat.

Indications

The presence of a violet–blue colour indicates barbiturates (Table 30.35). The LOD is 1000 μg for phenobarbital.

Table 30.33 Colours of thioxanthenes with sulfuric acid

Colour	*Compound*[(a)]
Purple	Oxytetracycline, tetracycline
Red	Caramiphen (when warmed), dantron, fenitrothion, methenamine (when warmed), mequitazine (slowly at 100°C), methacycline, methylprednisolone (after 1 min), metopimazine, nuarimol, ouabin, phenothiazines, prednisolone (after 1 min), pipoxolan
Orange–red	Oxprenolol*, quinomethionate
Violet–red	Morantel, oxytetracycline
Pink	Doxylamine, indapamide (slow)
Orange	Alprenolol, amitriptyline, benactyzine, benzilonium, benzquinamide, benzyl nicotinate, chlorprothixine*, clidinium, clopenthixol*, cyclothiazide (→red–brown), diethylthiambutene, diphemanil, diphenhydramine, diphenidol, doxepin, flupentixol*, indometacin, mazindol, mebanazine, mecoprop, methapyrilene, methindizate, methixene*, methyclothiazide, methylpiperidyl benzilate, naproxen, nefopam, nifedipine, nortriptyline, orphenadrine, penthienate methobromide, polythiazide, pyrantel (→violet), rotenone, tiotixene*, tofenacin
Yellow	Acebutolol, amiloride, amiodarone, benzthiazide, broxaldine, broxyquinoline, cinchophen, clefamide, clemastine (green rim), cyclopenthiazide, diphenadione, doxycycline, enoxolone, fenbufen, furosemide, halquinol, hydroquinidine*, hydroquinine*, lorazepam, methyl benzoquate, 5-methyltryptamine, α-methyltryptamine, *N*-methyltryptamine, metolazone, minocycline, piperacetazine (→red), procyclidine, quinidine*, quinine*, rimiterol, salbutamol, salinazid, sodium cromoglicate, trichlormethiazide, veratrine (→violet), zomepirac
Orange–yellow	Ethyl biscoumacetate, hexoprenaline, pizotifen (→violet)
Green	Bromodiphenhydramine, cyclizine, diphenhydramine, diphenylpyraline, phenothiazine, protriptyline
Blue	
Brown–blue	Chlortetracycline, demeclocycline, thioridazine
Violet	Bendroflumethiazide, chlorotrianisene, chromonar*, clofazimine, cyproheptadine, dosulepin, mesoridazine (→blue), methylenedioxyamfetamine, nicergoline, perazine, phenindione, rolitetracycline, tetracycline
Red–violet	Trifluomeprazine
Brown	Chelidonine, sulindac
Red–brown	Lymecycline
Orange–brown	Biperiden, ouabain (slow)
Yellow–brown	Tylosin (slow)
Grey–brown	Octaphonium
Black	
Blue–black	Clomocycline

[(a)]Compounds giving colours that fluoresce under UV light (λ = 350 nm) are indicated by an asterisk.

Basic tests for drug substances and products

The WHO has published texts *Basic Tests for Drugs* (WHO 1998), which includes pharmaceutical substances, medicinal plant materials and dosage forms, and *Basic Tests for Pharmaceutical Substances* (WHO 1986). The basic tests described, which are designed to verify the identity of drug substances and medicinal products and to detect gross contamination, use a limited number of readily available reagents and equipment. Overall, the combined texts offer compound-specific tests for approximately 500–600 products that are based on a combination of organoleptic checks and simple physicochemical tests, such as colour reactions and melting-point determinations.

Table 30.34 Reactions of barbiturates with vanillin reagent

Colour after heating	*Compound*	*Colour after dilution*
Red	3′-Hydroxybutobarbital	Violet (transient)
Violet–red	Heptabarbital	Colourless
	3′-Hydroxyamylobarbital	Colourless
Brown–red	Cyclobarbital	Green
	Cyclopentobarbital	Green
	Pentobarbital	Violet
	Secobarbital	Violet
	Thiopental	Violet
Orange	Butalbital (weak)	Colourless
	Secbutobarbital (weak)	Violet
Brown–orange	Allobarbital	Violet (transient)
	Brallobarbital	Brown–orange
	Talbutal	Violet
	Thialbarbital	Violet (transient)
Brown	Hexobarbital	Violet
Violet–brown	Methohexital	Colourless
	Vinbarbital	Colourless
	3′-Hydroxypentobarbitone	Colourless

Table 30.35 Colours with Zwicker reagent

Colour	*Compound*
Blue	Diphenylhydantoin
Green	Diacetylmorphine, pseudoephedrine
Yellow	Tetracycline

Semi-quantitative TLC methods have been developed as basic tests using a limited number of solvent systems and detection systems. References to these tests are given in (WHO 1998).

It should be remembered that basic tests are not, in any circumstances, intended to replace pharmacopoeial requirements, but should be used as a rapid, inexpensive means to verify identity and strength of drugs and medicinal products, and possibly to detect poor-quality counterfeit and other substandard products. In the event that suspect products are detected, these should be tested for compliance against pharmacopoeial requirements.

Colour reagents and thin-layer chromatography

Many common colour-test reagents are used routinely as spray locating reagents in TLC (e.g. acidified iodoplatinate solution, Dragendorff's reagent, Marquis reagent, Van Urk's reagent). It is worth noting that the preparation of the spray equivalent of a colour reagent may differ slightly from that of the colour reagent preparation itself (see Chapters 1 and 11 and Index of Reagents).

It is also true that the reaction and resultant colour that marks the presence of a certain substance obtained from spraying a reagent on TLC plates may differ from that obtained from a direct colour test and, in some cases, will not yield any results. This is because of pH effects – that is, whether the TLC plate has been dipped in 0.1 mol/L sodium hydroxide and the substance tested is acidic in character (i.e. the free acid of a salt post extraction). However, this aspect of colour reagents and their use in TLC as sprays can often give clues as to the drug or substance's chemistry.

A list of substances and their colour reactions to various TLC spray reagents is given in the Index of Analytical Data.

Appendix 30.3. Chemical test for gamma-hydroxybutyric acid (GHB) and gamma-butyrolactone (GBL)

Reagents

Chlorophenol red
0.04 g chlorophenol red in 100 mL water, adjust to pH 7 with 0.01 mol/L sodium hydroxide.

Modified Schweppes
1. 2 g of dextrose in 20 mL of water
2. 2.4 g of aniline hydrochloride in 20 mL of ethanol.

Mix solutions 1 and 2 together and dilute to 80 mL with methanol.

Bromocresol purple
0.04 g bromocresol purple in 100 mL of water. Adjust to pH 7 with 0.01 mol/L sodium hydroxide.

Bromothymol blue
0.04 g bromothymol blue in 100 mL of water. Adjust to pH 7 with 0.01 mol/L sodium hydroxide.

Bromocresol green
0.03 g bromocresol green in 100 mL of methanol–water 4 : 1. Adjust to pH 7 with sodium hydroxide 0.01 mol/L.

Methyl orange
0.01 g methyl orange in 100 mL of methanol. Adjust to pH 7 with sodium hydroxide 0.01 mol/L.

Colour test 1

Reagent
Mix chlorophenol red and modified Schweppes reagent in a 3 : 1 ratio.

Method
Place 0.5 mL of a liquid sample in a test tube. Adjust to pH 5–8 with 0.01 mol/L sodium hydroxide. Add 2 drops of the test reagent and swirl. An immediate colour change (orange–red to dark red) indicates GHB. GBL gives a yellow colour.

Colour test 2

Reagent
Mix bromocresol purple and bromothymol blue in a 1 : 1 ratio and mix the combined reagent with modified Schweppes reagent in a 7 : 1 ratio.

Method
Same procedure as for colour test 1. GHB gives a purple colour and GBL gives a yellow colour.

Colour test 3

Reagent
Mix bromocresol green and methyl orange in a 1 : 1 ratio and mix the combined reagent with modified Schweppes reagent in a 3 : 1 ratio.

Method
Adjust the pH of the test solution to neutral if necessary and add 2 drops of test reagent. A dark-green colour indicates GHB; GBL gives a yellow–orange colour.

Colour test 4

Reagent
1% cobalt nitrate solution.

Method
Place 0.5 mL of a liquid sample in a test tube. Add a few drops of the test reagent. A pink-to-violet colour indicates GHB.

Appendix 30.4. Tests for metals and anions not covered by the general scheme

Metals

Reinsch test (for antimony, arsenic, bismuth and mercury)

Method
Use a 5 × 5 mm piece of copper foil or mesh. Clean the copper in 50% (v/v) nitric acid until it develops a shiny surface, rinse with water and proceed as follows:

1. Place 20 mL of sample and 10 mL of concentrated hydrochloric acid in a 100 mL conical flask and add the copper foil or mesh.
2. Heat on a boiling water-bath for 1 h and add as necessary dilute hydrochloric acid to maintain the volume of the solution.
3. Cool, remove the copper, wash gently with water and examine the surface.

Indications
- A purple–black stain indicates antimony.
- A dull black stain indicates arsenic.
- A shiny black stain indicates bismuth.
- A silvery deposit suggests mercury.

Note that other elements, (e.g. selenium and tellurium) also give black deposits and sulfur compounds may give a speckled discoloration.

Confirmatory test
This is applied to the stained copper foil or mesh derived as described above.

Reagents
1. Aqueous potassium cyanide solution (100 g/L)
2. Freshly prepared aqueous sodium sulfite solution (50 g/L)
3. 3 mol/L nitric acid
4. Quinine/potassium iodide reagent. Dissolve 1 g of quinine in 100 mL of water containing 0.5 mL of concentrated nitric acid. When the quinine has dissolved add 2 g of potassium iodide.

Method
1. Leave the copper in potassium cyanide solution for 10 min.
2. Wash any undissolved stain with water and add 1 mL of sodium sulfite solution followed by 1 mL of 3 mol/L nitric acid.
3. Shake the mixture frequently for 5 min and add 1 mL of water and 1 mL of potassium iodide reagent.

Indications Stains caused by the presence of arsenic dissolve in potassium cyanide solution whereas stains due to antimony and bismuth remain. The slow formation of an orange–brown suspension is seen with the quinine/potassium iodide reagent if a stain due to bismuth is present. The LOD for arsenic is about 5 mg/L and for antimony and bismuth is 2 mg/L. A more specific test for arsenic, the 'Gutzeit test', involves the conversion of arsenic to arsine and subsequent reaction of the gas with reagents such as silver diethyldithiocarbamate to give a coloured product. A modified version of the Gutzeit apparatus is available from Fischer Scientific which allows quantitative measurement of arsenic in stomach contents, food, water and other materials.

Confirmatory test for mercury
This is applied to the silver stained foil or mesh from the Reinsch test.

Reagent Cuprous iodide suspension. Dissolve 5 g of copper sulfate and 3 g of ferrous sulfate in 10 mL of water with continuous stirring and add 7 g of potassium iodide dissolved in 50 mL of water. Allow the cuprous iodide precipitate to form, filter, and wash with water. Transfer the precipitate as a suspension in water to a brown glass bottle.

Method Add 0.1 mL of copper(I) iodide suspension to a filter paper, place the foil on the suspension, cover and leave for 1–12 h.

Indications A salmon-pink colour due to the formation of cuprous mercuric iodide suggests the presence of mercury and positive results may appear within 1 h, but with low concentrations colour development may take up to 12 h. The LOD for mercury is about 5 mg/L.

Barium

Reagents
1. Concentrated hydrochloric acid
2. Platinum wire.

Method
1. Dip the end of the platinum wire into the hydrochloric acid and then into the test material.
2. Insert the wire into the hot area of a micro-burner flame and observe any changes in the flame colours.

Indications
Barium salts impart a green flame; copper and thallium salts also give a green flame in this test.

Confirmatory test

Reagents
1. 1 mol/L sulfuric acid
2. 100 g/L aqueous lead acetate solution
3. 50 mL/L aqueous acetic acid
4. Solid ammonium acetate.

Method
1. To a mixture of 2 mL of lead acetate solution and 2 mL of dilute sulfuric acid add enough ammonium acetate to dissolve the lead acetate precipitate.
2. Add 0.1 mL of dilute acetic acid to 1 mL of sample followed by 1 mL of the lead sulfo-acetate solution (from step 1) and vortex mix for 5 s.
3. Centrifuge for 2 min and observe the tube against a dark background.

Indications Barium salts yield either a white turbidity or white precipitate. Calcium and strontium salts interfere. The LOD for barium is approximately 100 mg/L.

Copper

Reagents
1. 10 g/L solution of dithiooxamide in methanol
2. Concentrated ammonium hydroxide.

Method
Place 0.1 mL of sample onto a filter paper to give a spot of around 1 cm in diameter. Expose the paper to ammonia fumes and add 0.1 mL of the dithiooxamide reagent to the spot.

Indications
An olive green stain is seen with copper salts. A green stain due to chromium is usually visible before addition of the dithiooximide reagent. Yellow–brown or yellow–red colours are given by several other metals. The LOD for copper is approximately 1 mg/L.

Iron

Reagents
1. 2 mol/L hydrochloric acid
2. 10 g/L aqueous potassium ferricyanide solution
3. 10 g/L aqueous potassium ferrocyanide solution.

Method
1. Add 0.1 mL of 2 mol/L hydrochloric acid and 0.05 mL of potassium ferricyanide solution to 0.1 mL of sample.
2. Add 0.1 mL of 2 mol/L hydrochloric acid and 0.05 mL of potassium ferrocyanide solution to a further 0.1 mL of sample.
3. Agitate both mixtures for 5 s, leave for 5 min at room temperature and centrifuge for 5 min.

Indications
Ferrous salts give a deep blue precipitate with potassium ferricyanide and ferric salts give a deep blue precipitate with potassium ferrocyanide. The LOD for both ferrous and ferric salts is about 10 mg/L.

Thallium

Test 1

Reagents
1. Cyanide reagent: dissolve 1.6 g of sodium hydroxide, 1.2 g of potassium sodium tartrate and 1.36 g of potassium cyanide in 10 mL of water.
2. Prepare a fresh solution of dithizone (250 mg/L) in chloroform.

Method Add 1 mL of cyanide reagent to 5 mL of urine in a stoppered glass test-tube and vortex mix for 20 s. Then add 2 mL of dithizone solution, vortex mix for 1 min and centrifuge (5 min).

Indications The presence of thallium is indicated by a pink–red colour in the chloroform layer. The test will detect thallium at 0.1 mg/L. A number of other metal ions give colours with this test.

Test 2

Reagents
1. Bromine water (saturated)
2. 6 mol/L hydrochloric acid
3. 20% (w/v) aqueous sulfosalicylic acid solution
4. 0.1% (w/v) aqueous methyl violet solution
5. Toluene.

Method To 1 mL of urine carefully add 2 drops of hydrochloric acid and 5 drops of bromine water. Leave to stand for 5 min, add 5 drops of sulfosalicylic acid solution and 0.5 mL of toluene, and shake gently.

Indications A transient blue–green colour in the toluene layer suggests the presence of thallium. The LOD for thallium is 1 mg/L.

Anions

Borate

Reagents
1. 10 g/L solution of turmeric in methanol
2. 1 mol/L hydrochloric acid
3. 4 mol/L ammonium hydroxide.

Method
1. Prepare turmeric test papers by soaking strips of filter paper (1×5 cm) in the turmeric solution and drying at room temperature.
2. Acidify a portion of the sample with the dilute hydrochloric acid and apply to a strip of turmeric paper.
3. When the paper is dry moisten it with dilute ammonium hydroxide.

Indications
A positive sample will impart a red–brown colour to the turmeric paper which strengthens as the paper dries. When the paper is moistened with dilute ammonium hydroxide a green–black colour is produced. Oxidising agents that bleach turmeric (e.g. bromates, chlorates, iodates and nitrites) interfere with the test. The LOD for borate is 50 mg/L.

Confirmatory test

Reagent 0.5 g/L solution of carminic acid in concentrated sulfuric acid.

Method Add 0.5 mL of filtered stomach contents or scene residue to a 10 mL glass tube and slowly pour 0.5 mL of carminic acid solution down the inside of the tube so that a layer is formed underneath the sample.

Indications Borate is indicated by the formation of a blue–violet ring at the junction of the two layers. Note that strong oxidising agents (e.g. bromates, chlorates, iodates and nitrites) also give positive results.

Bromides

Reagents
1. 2 mol/L nitric acid
2. 10 g/L solution of silver nitrate
3. Concentrated ammonium hydroxide.

Method
1. To 1 mL of clear tests sample add 0.5 mL of 2 mol/L nitric acid and mix for 5 s.

2. Add 0.1 mL of silver nitrate solution.
3. Centrifuge any precipitate and decant off the supernatant.
4. Add 0.1 mL of concentrated ammonium hydroxide.

Indications

Bromide gives an off-white precipitate that is slightly soluble in ammonium hydroxide. A white precipitate that dissolves in ammonium hydroxide indicates chloride and a yellowish precipitate insoluble in ammonium hydroxide suggests iodide. The LOD for bromide is 50 mg/L.

Confirmatory test

Reagents

1. Saturated solution of fluorescein in aqueous acetic acid (600 mL/L)
2. Concentrated sulfuric acid
3. Solid potassium permanganate.

Method

1. Soak a strip of filter paper in fluorescein solution.
2. Transfer 2 mL of test solution to a 10 mL glass tube and add about 2 mg of potassium permanganate.
3. Add 0.2 mL of concentrated sulfuric acid and hold the fluorescein paper at the mouth of the tube.

Indications Any bromide is oxidised to free bromine, which then reacts with the fluorescein dye (yellow) to give tetrabromofluorescein (eosin) which has a pink–red colour. The LOD for bromide is 50 mg/L.

Chlorate

Chlorates and other oxidising agents can be detected by the diphenylamine test described previously. The following tests can also be applied.

Test 1

Reagents

1. 6 mol/L sulfuric acid
2. 1% w/v aqueous solution of indigo carmine
3. Solid sodium sulfite.

Method To 1 mL of sample add 4 mL of 6 mol/L sulfuric acid followed by 1 mL of indigo carmine reagent.

Indications A deep blue colour indicates the presence of chlorates. The colour fades after adding several crystals of sodium sulfite. The same reactions are given by bromates and hypochlorites.

Test 2

Reagents

1. Manganous sulfate reagent: a 1 : 1 mixture of saturated aqueous manganous sulfate and orthophosphoric acid
2. A 10 g/L solution of diphenylcarbazide in methanol.

Method

1. Add 0.2 mL of manganous sulfate reagent to 0.1 mL of test sample and warm the mixture gently over a burner.
2. Cool and add 0.1 mL of diphenylcarbazide solution.

Indications Chlorate yields a purple colour that intensifies after cooling and adding diphenylcarbazide. A similar reaction is given by persulfates and periodates.

Note: after ingestion of chlorate the blood turns brown owing to the formation of methaemoglobin by oxidation of the ferrous ion of haemoglobin. Add 0.2 mL of a 10% (w/v) of aqueous potassium cyanide solution to 1 mL of blood and an immediate red colour confirms the presence of methaemoglobin. Exposure to a wide range of other substances (e.g. aniline, nitrites, nitrates, aniline, dapsone, benzocaine, urea herbicides) causes methaemoglobinaemia.

Fluoride

Test 1

Reagents

1. A 50 g/L aqueous solution of sodium chloride
2. Concentrated sulfuric acid
3. Calcium chloride (solid)
4. Powdered silica.

Method

1. To 5 mL of sample in a porcelain crucible add 100 mg of calcium chloride and gently evaporate to dryness over a burner.
2. Destroy the organic material by strong heating to leave a white ash.
3. Mix the residue with 200 mg of powdered silica.
4. Apply a drop of sodium chloride solution to a microscope slide, add 1 mL of concentrated sulfuric acid to the contents of the crucible and immediately position the slide such that the sodium chloride drop is suspended over the crucible.
5. Rest a small beaker of ice on the slide and heat the crucible gently for 5 min over a burner.
6. Remove the slide after 5 min and examine the sodium chloride solution under a microscope.

Indications In the presence of fluorine-containing compounds, silicon tetrachloride is produced, which dissolves in the sodium chloride solution to form sodium silicon tetrafluoride. This forms small hexagonal crystals as the water evaporates from the slide, which sometimes have a pink hue. The crystals are seen at the edge of the drop and appear before the larger cubic crystals of sodium chloride.

Test 2

Reagents

1. Concentrated sulfuric acid
2. Calcium hydroxide (solid)
3. Paraffin wax.

Method

1. Repeat steps (1) and (2) described for test 1.
2. Smear a film of paraffin wax on one side of a glass microscope slide and expose part of the surface by making an identifiable sign on the paraffin film.
3. Add 5 mL of concentrated sulfuric acid to the crucible and cover it with the slide, with the paraffin film on the inside.
4. Heat the crucible gently for 20 min and then remove the slide.
5. Remove the paraffin film with toluene and examine the slide.

Indications Hydrogen fluoride is generated from fluorine-containing compounds and etches the glass to give a mark corresponding to that made in the paraffin film.

Both tests have a LOD of approximately 100 mg/L of fluoride.

Hypochlorite

Test 1

Reagents

1. Glacial acetic acid
2. 50 g/L aqueous lead acetate solution.

Method

1. To 1 mL of test solution add acetic acid dropwise to reach a pH of approximately 6 (test with universal indicator paper).
2. Add 0.5 mL of lead acetate solution and boil for 3 min.

Indications Hypochlorite forms a brown precipitate. An immediate brown to black precipitate is given by sulfides with lead acetate.

Test 2

Reagents

1. 100 g/L aqueous potassium iodide solution
2. Glacial acetic acid
3. Solid starch.

Method

1. To 0.1 mL of test solution add 0.1 mL of acetic acid followed by 0.1 mL of potassium iodide solution.
2. Mix and add about 20 mg of starch.

Indications Hypochlorite gives a blue colour. (*Note:* hypochlorite also gives a positive reaction in the diphenylamine test for oxidising agents described above.)

Iodides

Reagents
1. 10 g/L aqueous silver nitrate solution
2. 2 mol/L nitric acid
3. Concentrated ammonium hydroxide.

Method
1. To 1 mL of clear test solution add 0.1 mL of nitric acid and 0.1 mL of silver nitrate solution.
2. Centrifuge down any precipitate, remove the supernatant and add to it 0.1 mL of ammonium hydroxide.

Indications
A curdy yellow precipitate that is insoluble in ammonium hydroxide is given by iodides. Chlorides give a white precipitate that dissolves in ammonium hydroxide, and an off-white precipitate that is sparingly soluble in ammonium hydroxide suggests bromides.

Confirmatory test

Reagents
1. 2 mol/L hydrochloric acid
2. 100 g/L freshly prepared sodium nitrite solution
3. Solid starch.

Method Mix thoroughly about 20 mg of starch with 0.1 mL of test solution, 0.1 mL of hydrochloric acid and 0.1 mL of sodium nitrite solution in a test-tube.

Indications A blue colour confirms the presence of iodide.

Oxalates

Reagents
1. 100 g/L aqueous calcium chloride solution
2. 30% (v/v) solution of acetic acid
3. 2 mol/L hydrochloric acid.

Method
1. Add 1 mL of calcium chloride solution to 2 mL of test solution and mix.
2. If a precipitate forms, add 1 mL of acetic acid.
3. If the precipitate does not dissolve, separate it by centrifugation and add 1 mL of dilute hydrochloric acid.

Indications
A white precipitate that is insoluble in acetic acid but dissolves in hydrochloric acid indicates the presence of oxalates.

Confirmatory test

Reagents
1. Thiobarbituric acid
2. Concentrated ammonium hydroxide.

Method
1. Add 50 µL of test solution to 100 µL of ammonium hydroxide in a micro test-tube and mix thoroughly.
2. Gently evaporate the mixture to dryness over a micro-burner.
3. Add about 200 mg of thiobarbituric acid and reheat gently to about 150°C.

Indications Oxalates give a bright red product that is soluble in methanol. The LOD for oxalate is 250 mg/L.

Sulfides

Reagents
1. 10% (v/v) aqueous solution of sulfuric acid
2. 10% (w/v) solution of lead acetate in boiled and purified water
3. 2 mol/L acetic acid.

Method
1. Immerse a strip of white filter paper in a mixture of 10 volumes of lead acetate solution and 1 volume of acetic acid and allow to dry.
2. To 1 mL of test sample in a test-tube add 3 mL of sulfuric acid and insert the lead acetate paper into the neck of the tube.
3. Heat the tube in a boiling water-bath for 5–10 min.

Indications
Hydrogen sulfide fumes that turn lead acetate paper black are produced by sulfides. The LOD for sulfide is 50 mg/L.

Thiocyanates

Reagent
A 50 g/L aqueous solution of ferric chloride.

Method
Mix 0.5 mL of ferric chloride solution with 0.5 mL of sample.

Indications
A deep red colour is given by thiocyanates. The LOD for thiocyanate is 50 mg/L.

CHAPTER

31 Immunoassays

RS Niedbala and JM Gonzalez

Introduction

The first immunoassay principles were published decades ago (Yalow, Berson 1959). Since that time immunoassays have become a routine part of day-to-day life for scientists in various disciplines as well as for general consumers. For example, every over-the-counter pregnancy and fertility test is based upon immunoassay results. The impact has been even greater in broader fields where analysts use immunoassays for the routine screening of samples for a host of target analytes. Fields such as veterinary medicine, environmental testing, anti-terrorism and human clinical diagnostics all use various types of immunoassays (Huckle, Wild 2005).

For instance, all the applications that exist, immunoassays have limitations that are generally created by the antibodies used. Antibodies may have poor specificity that results in cross-reactivity with structurally similar compounds, creating false results. Antibodies may also be affected by the matrix used. For example, hair testing for drugs of abuse is challenged by the treatments that consumers use on their hair and scalp. It is also difficult to generate antibodies reliably against target compounds. It requires a 'make it and test it' scenario that can take years.

Nevertheless, immunoassays have become an integral part of routine clinical testing. When developed carefully, immunoassays can detect minute amounts of target analyte in complex samples. They can be robust and capable of working in harsh conditions along the roadside or in remote areas. Immunoassays will remain an important tool for anyone who needs to detect analytes reliably in a cost-effective and rapid manner.

The focus of this chapter will be to explain the principles of immunoassays and practical considerations in applying them in the field of toxicology.

Immunoassays can generally be constructed for target molecules with molecular weights as low as 250, as well as for large, complex proteins and cellular components. Each immunoassay is formatted to the usage situation and its analytical requirements. Some are designed to be highly sensitive in detecting and quantifying extremely small amounts of target analyte. Others are designed only for qualitative analysis to detect the presence or absence of analytes. Thus, researchers and developers have refined immunoassays to become reliable, robust, accurate tests that can be manufactured on a large scale.

Parallel to its development, and in response to it, societies have embraced the use of immunoassay technologies. For example, many countries have enacted legislation defining cut-offs as well as specific targets for immunoassays aimed at the detection of drugs of abuse in various situations where individuals or the general public may be at risk (US Department of Health and Human Services 2006; US Department of Transportation 2000). These legislated assay parameters regulate the implementation of millions of tests that use urine, saliva, hair or blood as matrices. The results from an immunoassay test followed by confirmation using alternative technologies can be used as forensic evidence in a court of law. In several countries individuals are tested for drug use prior to starting a new job, for suspicion of use during employment (Chapter 3) or following treatment or incarceration. Other countries are seeking to allow police to perform roadside testing of suspected drivers who may be under the influence of drugs of abuse (Parliament of Victoria, Australia 2003) (Chapter 5). Efforts are under way to develop and validate robust on-site immunoassays that can meet specific requirements of law and technical performance. Although they are not yet available for all desired target drugs, much progress has been made (Maes *et al.* 1999; Moeller *et al.* 1999; Samyn *et al.* 1999b; Verstraete, Puddu 2000; Walsh *et al.* 2004).

Immunoassays may take a variety of formats, although they all contain common elements regardless of design (Table 31.1)

The first element is an antibody that has been targeted against a specific analyte. A target analyte can be a large molecule, an infectious agent or a small molecule that can elicit an immune response. The quality of the antibody will ultimately determine the potential performance of any immunoassay. The antibody is relied upon to be specific for the desired target analyte, insensitive to the test matrix being used, and stable over long periods of storage when packaged into an immunoassay test kit. The second element in an immunoassay is the reporter that will generate a signal that can be used to determine the immunoassay results. A variety of systems based on radioactive, enzymatic and chemiluminescent labels as well as colloidal particles are available for this task (Table 31.2). Each has advantages and disadvantages in immunoassay design and use. These strengths and weaknesses will be discussed later in this chapter.

Once a quality antibody and a reporter have been identified, the platform for performing the immunoassay may be selected. There are many commercial platforms that are proprietary to corporations. However, basic researchers can utilise microtitre plates or rapid test formats such as lateral flow (Peace 2000; Niedbala *et al.* 2000; Perrigo, Joynt 1995; The Walsh Group 2002; Verheijen 2002; Volkov *et al.* 2009).

Finally, the buffers and packaging for any immunoassay must meet the requirements for stability and storage of the test. Buffers also serve another key purpose, which is to prepare the sample matrix to be tested for compatibility with the antibody and test format being used.

Various issues confront an immunoassay test developer when trying to use samples as diverse as urine or saliva. Each matrix has unique characteristics that can interfere with an immunoassay causing false-negative or false-positive results. Immunoassay developers have the challenge first of developing and then of thoroughly validating any test before it is used by collaborative researchers or the general public.

When specifically evaluating the performance of a toxicology assay it is worth examining what makes a good immunoassay test. First of all the purpose of the test should be considered. For instance, is the test to be used for qualitative screening or for monitoring concentrations of a particular drug in biological fluids? The difference in analytical requirements between, for example, a test for therapeutic drug monitoring (TDM) purposes and a qualitative screening test can be substantial. A TDM test is performed to optimise the level of drug therapy and therefore the immunoassay test result must be very accurate. In some cases, changing the dose of the drug incorrectly can result in serious or fatal outcomes (Baselt 2005; Hardman *et al.* 2001; Porter 2006; Uhlenhuth *et al.* 1990) (Chapter 2)

Conversely, a screening test must simply detect the presence or absence of a target compound or a class of compounds reliably above or below a designated cut-off concentration. In such tests the cut-off concentration is specified; however, the actual performance of the test will have some variation around the cut-off. It is worth discussing two aspects of immunoassay design and performance. The terms sensitivity and specificity are often used and require some explanation. These terms relate to analytical sensitivity/specificity or clinical sensitivity/specificity. The term 'analytical sensitivity' is used to describe the assay's ability

Table 31.1 Elements of an immunoassay

Element	*Purpose*	*Representation*
Antibody	Targets analyte	
Reporter	Amplifies result	
Hapten derivative	Drug derivative to link to reporter	
Analyte	Target for assay	
Buffers	Conditions, pH Sample	
Solid phase	Location to immobilise antibody	
Matrix	Describes type of sample being analysed	

to detect the lowest level of target drug while 'analytical specificity' describes how precise it is at targeting a compound. 'Clinical sensitivity' describes how reliably a test identifies positives among a tested population, while 'clinical specificity' is a measure of whether or not identified positives are truly positive. For example, in the case of a screening test for drugs of abuse, a test that was clinically 100% sensitive and specific would have correctly identified all presumptive positives and all of them would have been confirmed positive for the target drug by an alternative and completely specific technique.

The reality is that no screening immunoassay test is 100% accurate in identifying positives or negatives. In the case of drugs of abuse assays, positives are confirmed by other techniques such as gas chromatography–mass spectrometry (GC-MS). This is often expensive, but necessary, since antibody-based immunoassays are often subject to interferences or lack target analyte specificity. A well-designed screening immunoassay will therefore have a high degree of clinical specificity, meaning that positive immunoassay results are likely to be confirmed quickly and cheaply by GC-MS, thereby minimising costs by identifying samples that do not contain the analyte of interest. A final consideration before exploring the specifics of immunoassay is the metabolism and disposition of any target analyte drug and the matrix in which it is to be detected or quantified. Toxicological assays are increasingly performed on a variety of matrices including hair, saliva, blood or urine. The reason for choice of matrix may be ease of collection (saliva), a long window of detection (hair), compliance with regulations (urine) or forensics (stool or blood). Prior to developing an assay, it is critical to know which metabolites are the most prevalent and reliable as target analytes in a given type of sample. References are available to help any immunoassay developer outline their strategy for development (Baselt 2005).

As immunoassay use has expanded, so have the tools and the understanding of the principles for developing them. Application of the principles described below should allow researchers to achieve optimal performance for any immunoassay they may develop or evaluate.

Table 31.2 Various reporters used in immunoassays

Basic principles and issues of immunoassays

Antibody development and production

The development of an immunoassay for opiates (diamorphine, morphine, etc.) serves as a good example with which to describe in detail the principles and issues of immunoassay development. Diamorphine, morphine and related opiates are used throughout the world and their benefits and deleterious effects on health are well known (Baselt 2005; Hermes 1993). However, developing an immunoassay to identify specific opiates can be tedious and requires an appropriate strategy.

The first step when developing such an assay is to consider the target molecule and the human matrix that will be tested. Diamorphine and morphine have been thoroughly studied and their pharmacokinetics are well understood (Moore *et al.* 1984). Figure 31.1 shows the metabolism of diamorphine and the major metabolites formed. It can be seen that morphine is a primary metabolite in urine, saliva and blood. It also has a relatively long half-life and is known to be stable in biological matrices. Therefore, morphine becomes the target analyte against which antibodies will be needed.

Antibodies are proteins in mammals with a primary purpose to fight infection. They are generated by beta-lymphocytes following exposure to an immunogen. Immunogens are materials such as foreign proteins or cells that trigger the immune response. There are several antibody subtypes including IgG, IgA, IgM, IgE and IgD. Each functions within various compartments of the human body and may act to attack new infections or as sentinels if an infection reappears. For our purpose, antibodies are deliberately generated by introducing a designed immunogen (or antigen) into a host cell or animal. Beta cells within the host respond to the antigen by producing antibodies with affinity for the target antigen.

Antibodies may be generated using a number of methods. The two major techniques produce monoclonal or polyclonal antibodies (Howard, Kaser 2007; Levine 2003). Polyclonal antibodies are often produced in rabbits, sheep, chickens and even llamas (Frenken *et al.* 2000). Each species has particular characteristics. Sheep, for example, may be bled to yield substantial quantities of blood for large-scale needs. Chickens are easy to use since antibodies may be isolated from eggs. No matter what the choice of species, the disadvantage of polyclonal antibodies is that there may be a mixture of antibody subtypes isolated with varying performance. In contrast to polyclonal antibodies, monoclonals are produced following fusion of a polyclonal cell with bacterial cell lines (Kohler, Milstein 1975). The fused line will produce a highly specific antibody that is immortalised in the cell line. Thus, supply is never an issue as long as the cell line is carefully maintained.

Newer methods that are alternatives to traditional polyclonal and monoclonal antibody production include phage display as well as targeted engineering of protein domains with antibody-like attributes (Binz *et al.* 2005; Chiswell, McCafferty 1992; Ryan 2003). These newer techniques have primarily been used against large proteins and have not yet been developed sufficiently for use against small drug molecules.

Following the example of morphine, an immunogen must first be developed that will be used to trigger production of antibodies. Morphine is a small molecule and, by itself, is not immunogenic. Usually a compound must have a molecular weight greater than 2000 before it will trigger an immune response. To solve the problem of immunogenicity, a morphine derivative is first linked to a carrier protein by a process known as haptenisation. The aim of this haptenisation process is to conjugate multiple, chemically modified, or derivatised, drug molecules (the hapten) to the carrier protein.

Figure 31.2 shows the structure of morphine. Examining the chemical structure, it can be seen that morphine has amino or hydroxyl groups that can be used as sites for conjugation. The specificity of the antibodies generated can be determined by the position on the molecule used for conjugation. The site of conjugation is usually hidden from the immune system, so that changes made to the molecule at this position will have no effect on antibody binding. In the case of morphine, if an

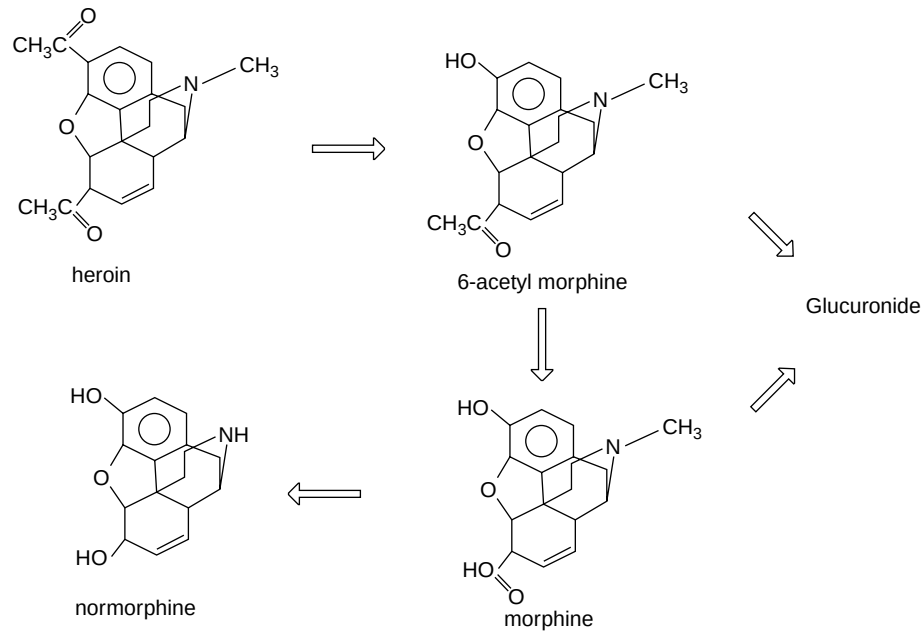

Figure 31.1 Structure of diamorphine (heroin) and its major metabolites.

immunogen is produced via conjugation with the hydroxyl group at position 3, this ceases to be a determinant against which antibodies are generated. As a result, the antibodies are likely to have cross-reactivity towards the major urinary metabolite of both diamorphine and morphine, morphine-3-glucuronide, and they will also recognise codeine (3-*O*-methylmorphine). Urine screening immunoassays to detect abuse of diamorphine or morphine usually employ antibodies raised by this means. Conversely, conjugation via the hydroxyl group at position 6 will yield antibodies that have a greater specificity towards morphine relative to morphine-3-glucuronide and that also display good cross-reactivity towards 6-monoacetylmorphine and morphine-6-glucuronide. These antibodies are well suited to formulating saliva assays for detecting diamorphine abuse, since this sample contains large amounts of 6-monoacetylmorphine as well as of morphine itself. Various methods are available to covalently couple through these groups or to add an extension linker prior to linking it to a carrier protein (Van Regenmortel *et al.* 1988). Carriers include large proteins such as bovine serum albumin (BSA), bovine gamma globulin or keyhole lymphocyte cyanin. A plethora of other possible carrier proteins exists, but in general the selected carrier proteins are dissimilar in structure to the reporter to be used in the assay and large enough to trigger the immune response.

Once antibodies are generated they are usually purified using simple precipitation techniques or by isolation using protein-A. Protein-A is a lectin that specifically binds to antibodies and allows rapid isolation of the purified proteins (Hober *et al.* 2007).

Immunoassay design

The antibody is a key element in the construction of any immunoassay and requires detailed consideration. Once an antibody is available it must be evaluated in the format in which it will be used. Assay formats are generally divided into two categories. The first is called a heterogeneous immunoassay, in which the differentiating characteristic is the requirement of a step to separate bound from free material. The alternative is called a homogeneous immunoassay and is distinguished from heterogeneous assays by the fact that it does not require a separation step. Figure 31.3 shows the basic elements of a heterogeneous immunoassay.

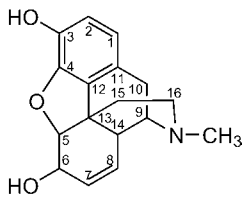

Figure 31.2 Structure of morphine.

Heterogeneous immunoassay/examples

The simplest form of heterogeneous immunoassay involves a competitive assay using a solid phase. Most commonly, a microtitre plate coated with immobilised antibodies against the target drug can be used. In this assay format, sample, buffer and a hapten–drug–reporter conjugate are added to a microtitre well. The mixture is incubated for some time during which the conjugate and free drug compete to bind to the solid phase. The solid phase is then washed to remove unbound material. Substrate is added, after which the signal is measured in each reaction well. The signal generated is inversely proportional to the concentration of free drug in the sample.

Enzyme-linked immunosorbent assay (ELISA) is the most common format used for the detection of large molecules or proteins, but it has also been adapted to detect small-molecule drugs.

These types of heterogeneous assay are sometimes called 'sandwich' assays because the target analyte is captured between two antibodies.

Figure 31.4 shows a diagram of a typical heterogeneous sandwich assay.

In the first step, an aliquot of sample or calibrator is mixed with buffer and incubated with the capture antibody that has been conjugated or adsorbed onto a solid surface such as a microtitre plate. After

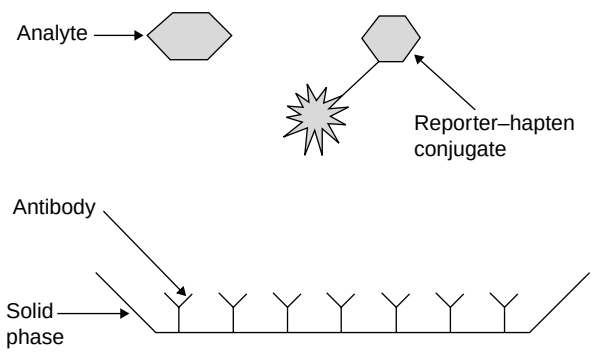

Figure 31.3 Basics of an immunoassay.

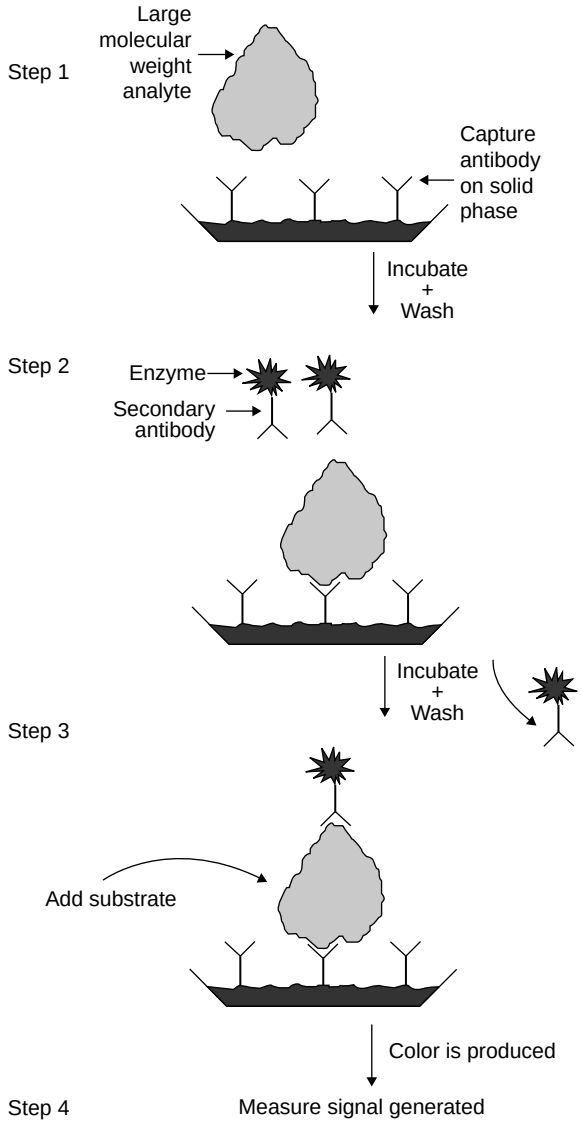

Figure 31.4 The basic scheme for an ELISA assay. Note the wash between steps. This is the distinctive feature of a heterogeneous assay.

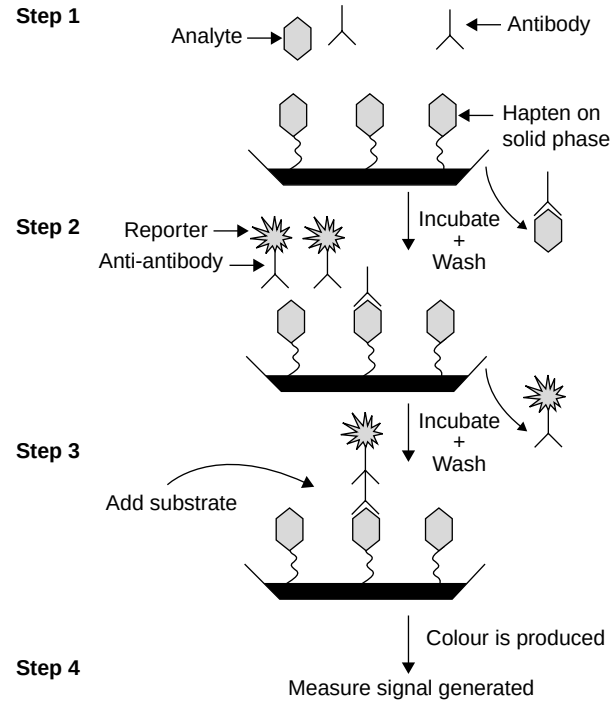

Figure 31.5 The scheme shows a typical competitive solid-phase immunoassay commonly used to detect drugs of abuse. It is a heterogeneous format using washing steps to remove materials that did not bind immunologically. Signal is inversely proportional to the concentration of free drug in the sample.

incubation, the surface is washed to remove whatever material did not specifically bind to the antibodies on the solid surface. In the second step, another solution is added that contains a secondary antibody, often labelled with a reporter. Following this incubation, the surface is again washed to remove unbound material. Next, a substrate solution or developer solution is added to generate a signal. Once sufficient signal has been generated, the reaction is stopped and the signal is measured.

The amount of signal generated is proportional to the amount of target material that was captured on the surface. Heterogeneous assays are often extremely sensitive and may be titred by adjusting the concentration of reagents and sample. The disadvantages of heterogeneous assays include the long incubation periods and multiple wash steps.

In the field of toxicology a number of heterogeneous assay techniques have become available and are in routine use. These techniques include ELISA, radioimmunoassay (RIA), chemiluminescent immunoassay (CIA), fluorescent immunoassay (FIA) and finally lateral flow assay (LFA).

Figure 31.5 shows a scheme for a typical heterogeneous assay targeting a small-molecule drug. In the first step, sample and buffer are mixed with anti-drug antibodies. If target drug is absent, the antibody will bind to the drug linked to the solid phase. The solid phase can be a microtitre plate, bead or membrane made of nitrocellulose, polymers or glass. Once this initial incubation is complete, the surface is washed and a second reagent is added containing reporter-labelled antibodies against the first antibody targeting the drug of interest. A sandwich is formed between the drug conjugate on the solid phase and the secondary antibody–reporter conjugate. After incubation, unbound secondary antibody is washed away and substrate or signal is measured in the reaction mix. The signal detected is inversely proportional to the concentration of drug in the sample.

There are a number of variations on the two assay schemes described above. In most cases the differences are in either the reporter used or the solid surface (see Table 31.2). Various reporters used include radioactive (RIA), fluorescent (FIA) and chemiluminescent (CIA) labels. The key to each heterogeneous assay is the wash step that removes excess reagent and lowers the background signal from the sample or other interferents. In this way heterogeneous assays achieve maximum analytical sensitivity.

Lateral flow is a type of heterogeneous assay that has become prevalent in emergency rooms and laboratories and in law enforcement to test on-site for drugs of abuse (Ulti-Med 2002). These tests are capable of multiplexed detection of a panel of drugs of abuse from a single aliquot of urine, blood or saliva (Inoue, Seta 1992; The Walsh Group 2002).

The basic scheme for a multiplexed lateral flow assay is shown in Fig. 31.6. A lateral flow assay is constructed from various materials that are assembled to form a test strip. A sample pad is the first component and is where a small aliquot, usually 50–100 µL, of sample is placed onto the strip. The sample pad often contains buffer salts to condition the sample to the correct pH and sometimes to remove cells or debris. These pads are often glass fibre or cellulose (Verheijen 2002; Volkov *et al.* 2009). The next material beyond the sample pad is the conjugate pad. It will usually hold the reporter–antibody conjugate targeting each drug of interest. The reporter most commonly used is colloidal gold. Gold particles are small, usually 10–100 nm in size, but are easily seen with the naked eye as they accumulate in a detection zone on a strip. Purified antibodies can easily be adsorbed onto the surface (Verheijen 2002; Volkov *et al.* 2009). Once a sample is added to a test strip it flows through the sample pad, the conjugate pad and then onto a nitrocellulose strip. Nitrocellulose as a raw material acts to bind capture

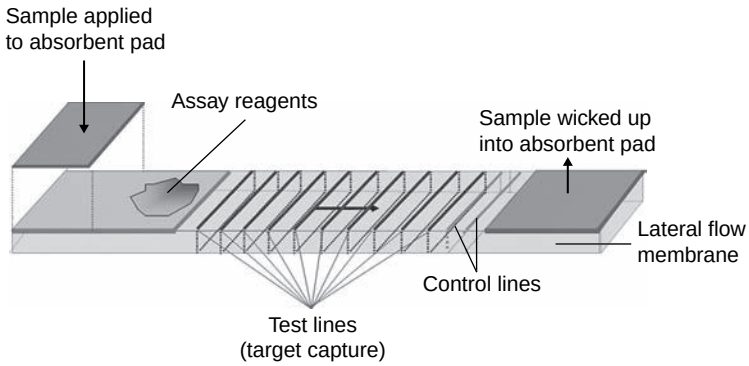

Figure 31.6 The figure shows the basic design of a lateral flow assay. It contains a series of material in linear order designed to contain reagents that flow along with the sample past capture zones. The immunological result is read in each capture zone usually by visual interpretation.

reagents and to allow liquids to flow by capillary action along a test strip. The nitrocellulose strip can vary in length according to the desired goals of the test. For example, a longer strip will allow multiple analyte test lines (see Fig. 31.6). However, it will take longer for fluids to move along the strip, thus increasing the time of the assay. The nitrocellulose is also where the immunological reaction takes place. Capture zones at the control line and test lines are created by spraying a solution of the capture protein derivative onto the nitrocellulose. The proteins then adsorb onto the nitrocellulose and become immobilised (see Fig. 31.6). The usual capture zone material is target hapten derivatised and conjugated to a carrier protein such as BSA. As the buffered sample and reporter antibody reach the reaction zone there is competition between drug in the sample and hapten conjugate on the strip to bind the reporter antibody. If there is a large concentration of drug, there will be little reporter conjugate available to bind to the reaction zone and the line will have no colour. If the sample is negative for drug, the line at the capture zone will be intense and easily seen with the naked eye. Use of lateral flow assays has grown exponentially in the last decade.

Once the basic chemistry has been developed, the system must be packaged into a housing (Fig. 31.7). The housing may be integrated into a urine cup, dip stick or a saliva collector (Draeger Safety UK Ltd 2008; Orasure Technologies 2008).

The challenge for lateral flow assays used in toxicology is that they must reliably detect a panel of drug targets using dynamic flow, and binding of reagents all moving through a series of striped materials is governed solely by capillary forces. From a purely analytical perspective, lateral flow assays are often imprecise and insensitive. It is not uncommon for lateral flow assays to have relative standard deviations (RSDs) of 15–30% when testing replicates of sample or calibrator. Also, numerous field evaluations have highlighted performance shortcomings (Peace 2000; The Walsh Group 2002). Even so, lateral flow is an accepted method used by those performing on-site testing of drugs of abuse. It is expected that, as commercial use continues to grow, new instrument-interpreted methods will improve the performance of lateral flow assays (Alverix Inc. 2010; Faulstich *et al.* 2007).

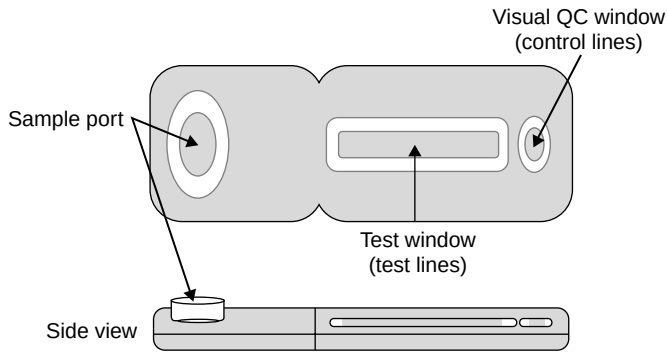

Figure 31.7 Lateral flow assay in a housing.

Homogeneous immunoassay/examples

Homogeneous immunoassays, by definition, do not require a step to separate bound from free target analytes and reagents. In most cases, homogeneous assays are used on automated platforms that require little operator interaction. This is something of a disadvantage since such equipment is not easily portable. Thus, homogeneous assays are used routinely on large laboratory-based instrument platforms capable of analysing hundreds or thousands of samples per day. The availability of these assays at a very low cost has revolutionised immunoassay-based drugs of abuse testing.

Homogeneous drug assays are often competitive assays where free drug in a calibrator or sample competes with a reporter conjugate to bind to a specific antibody on the target. After a brief incubation, the change in signal is measured spectrophotometrically, fluorescently or through chemiluminescence. The following are descriptions for some homogeneous assay methods available for drugs of abuse testing.

The EMIT (enzyme-multiplied immunoassay technique) has been a staple in drug testing since the 1970s when the method was first developed (Kabakoff, Greenwood 1981; Rubenstein *et al.* 1972; Ullman 1994; Ullman, Maggio 1980). An EMIT assay is a competitive format wherein hapten-labelled glucose-6-phosphate dehydrogenase (G6PDH) competes with free drug in a sample or calibrator to bind to a specific antibody raised against the hapten target. If the hapten-G6PDH binds to the antibody, there is a conformational change in the enzyme that leads to a decrease in activity (Fig. 31.8). This change in activity is proportional to the concentration of free drug present in the sample.

EMIT assays have been developed for a large number of drugs of abuse and TDM analytes. Over time a wide variety of instrumentation has also been made available to laboratory workers, allowing EMIT to quickly become a method of choice. However, it is worth noting that, as with all immunoassays, EMIT assay performance is dependent upon the antibody used. In addition, EMIT assays are subject to interference from sample adulteration and non-specific cross-reactivity (Colbert 1994; Rollins *et al.* 1990; Rossi *et al.* 2006).

Somewhat comparable in operating principles, CEDIA (cloned enzyme donor immunoassay) relies on the modulated activity of mutant beta-galactosidase. (Henderson *et al.* 1986) developed a genetically engineered form of beta-galactosidase which exists as two components. One fragment is called the enzyme acceptor (EA) and the other is called the enzyme donor (ED). The mutant enzyme becomes enzymatically active when both the ED and the EA are present. A homogeneous assay can be developed by conjugating a hapten to the ED. The hapten-ED will compete with free drug in the presence of antibody against the hapten (Fig. 31.9). When high concentrations of target hapten-drug are present, the hapten-ED is available to bind to the EA and an increase in beta-galactosidase will be detected. Thus, like EMIT, the amount of enzymatic activity is proportional to the concentration of free drug in the sample. Additionally, CEDIA assays can be run on the same automated spectrophotometric equipment that also runs EMIT assays.

Other types of homogeneous assays exist and are based upon reporters that are non-colorimetric. In this category, fluorescence

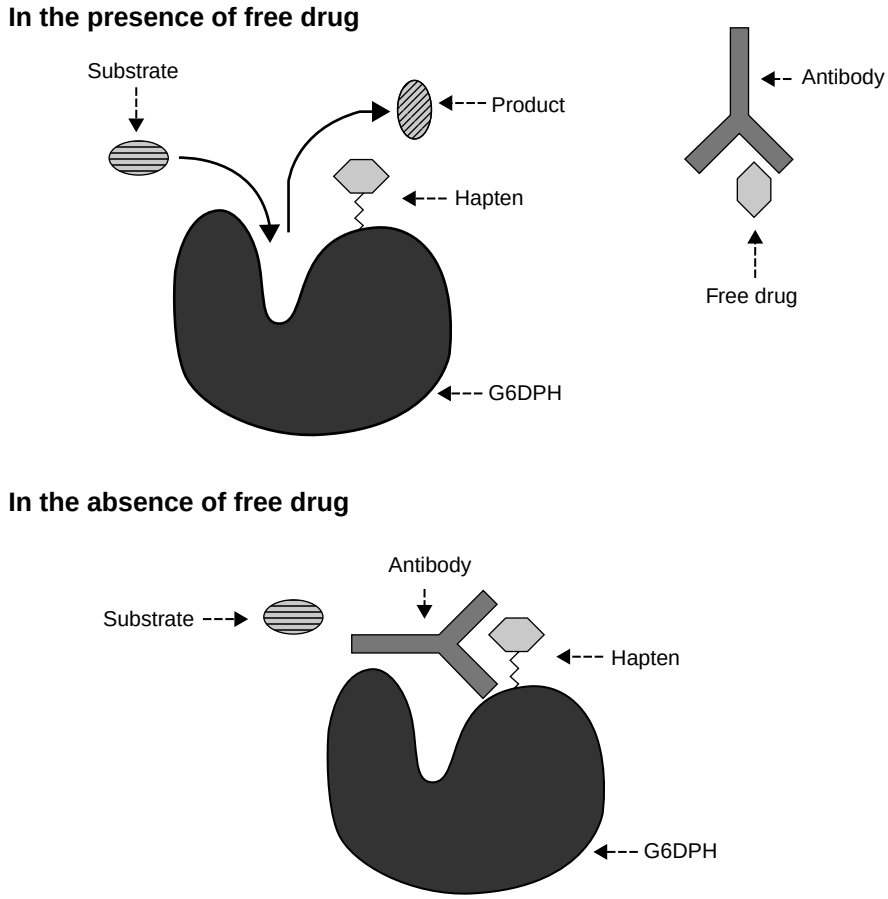

Figure 31.8 EMIT assay scheme; signal is directly proportional to the concentration of analyte.

polarisation, microparticle agglutination and new techniques such as LOCI (luminescent oxygen channelling immunoassays) (Ullman 2005) have all been demonstrated and used routinely in commercial laboratories.

Fluorescence polarisation is a relatively simple technique that utilises the competitive binding to antibodies between a hapten–fluoroscein conjugate and free drug (hapten; Fig. 31.10) (Abbott Laboratories 2005; Colbert *et al.* 1985; Dandliker *et al.* 1973). The hapten–fluorescein conjugate rotates rapidly when not bound to an antibody. When it is bound to the antibody, the rotation is slowed dramatically compared with the unbound molecule. To generate the assay signal, a fluorimeter shines light at the excitation wavelength for fluorescein through a vertical polarising filter. Rapidly rotating unbound hapten–fluorescein molecules emit light in a different plane to the incident light. The

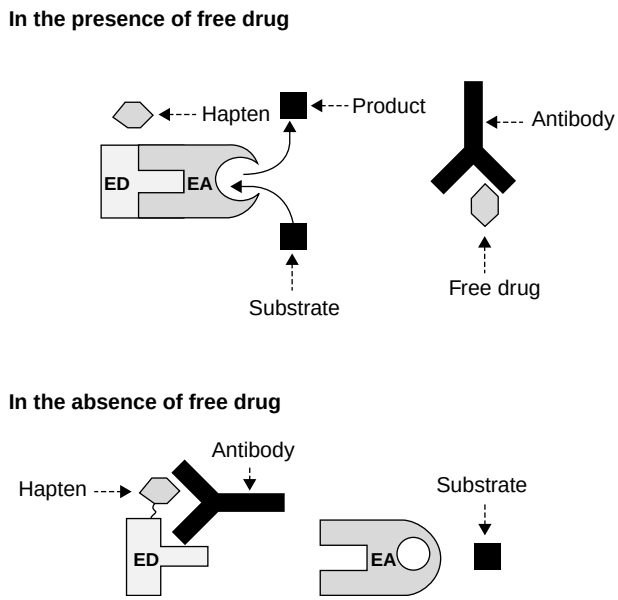

Figure 31.9 CEDIA assay scheme; signal is directly proportional to the concentration of analyte.

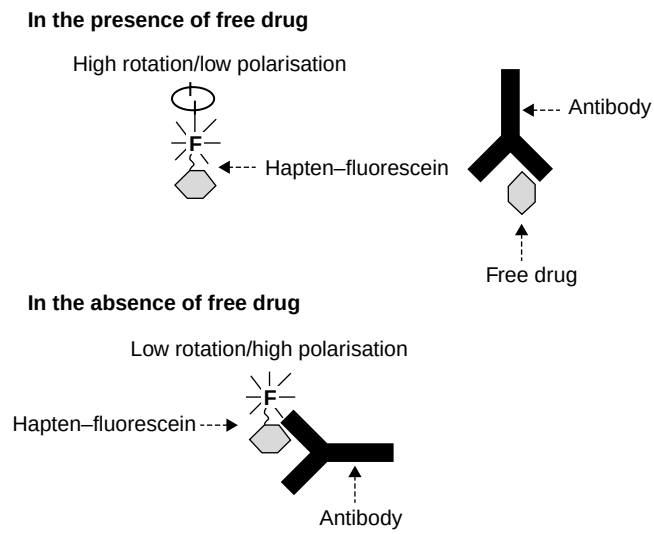

Figure 31.10 Fluorescence polarisation immunoassay assay scheme; signal is inversely proportional to the concentration of analyte.

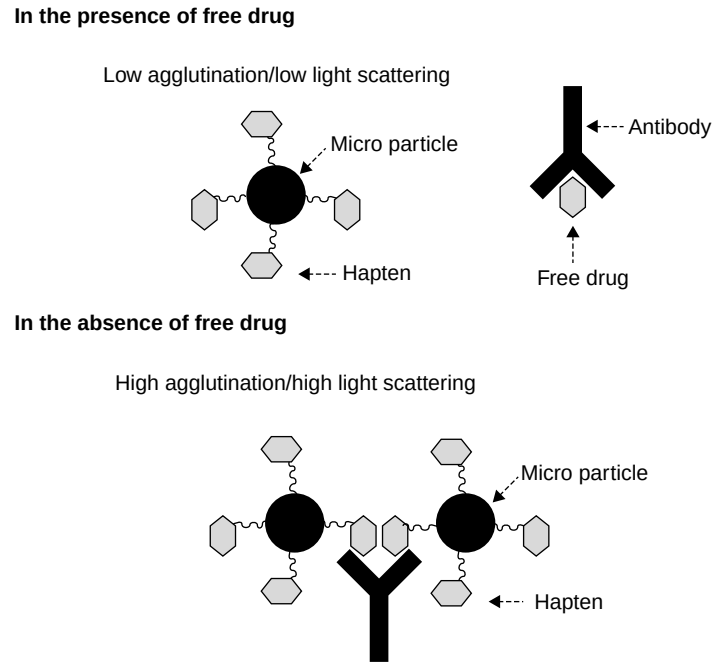

Figure 31.11 KIMS assay scheme signal is inversely proportional to the concentration of analyte.

relatively stationary antibody-bound hapten–fluorescein molecules, however, return light in a similar plane. This is detected via the polarising filter. Drug added via the sample competes for binding to the antibody with the fluorescein-labelled hapten, thereby reducing the amount of fluorescein bound to the antibody, resulting in less emitted fluorescence being detected via the polarised filter. Fluorescence polarisation assays require specialised equipment and are the basis of the Abbott ADx system. The background fluorescence found with many biological samples means that it is necessary to take a blank reading of the sample and reagents before the addition of the fluorescent tracer to the mixture.

Another popular homogeneous technique used for drugs of abuse assays is based upon microparticle agglutination. The KIMS assay (kinetic interaction of microparticles in solution) relies on the old but reliable principles of latex particle agglutination (Fig. 31.11) (De Giovanni, Fucci 2006; Feldman *et al.* 2004). In the KIMS technology, polystyrene latex microparticles have been coated with a drug-conjugate. These particles are dispersed in solution, after which sample and antibodies to the drug (hapten)-conjugate are added. In the presence of high drug concentrations, the antibody-binding sites are occupied by free drug and a low amount of agglutination takes place. In the presence of low target drug concentrations, the antibodies bridge between the particles and begin to agglutinate particles into large clusters. These clusters scatter light. Therefore, the change in signal is inversely proportional to the concentration of free target drug in the sample. KIMS is the basis of the Roche Abuscreen Online system, which involves monitoring the rate of agglutination by spectrophotometric means.

The challenge to any homogeneous assay technique is sensitivity. These assays usually take seconds to minutes to perform and are often limited by kinetics or antibody quality. LOCI is a chemiluminescent system that overcomes many limitations of other assay reporters (Ullman 2005). The reagents used to produce a signal in the assay are encapsulated in latex spheres which prevent interference from sample matrices. One population of latex spheres contains a chemiluminescer and the second a photosensitiser capable of exciting oxygen when exposed to 680 nm light. When the two beads are in close proximity, excited oxygen diffuses out of the bead and into the chemiluminescer bead, producing detectable photons. The LOCI assay has been tested with a variety of analytes and each one has shown superior sensitivity to other competing technologies (Ullman 2005).

Immunoassay optimisation

Earlier in this chapter the methods used to develop an antibody against a chosen hapten drug target were reviewed. Assuming that a viable candidate antibody has been generated and an assay format chosen, the next step is to begin developing and optimising the immunoassay. The goal of this section is to outline some of the key experiments followed by an explanation of important assay parameters that should be considered.

Again the target analyte to be used as an example in this section will be morphine. The structure for morphine is shown in Fig. 31.1. Morphine is one of a large class of opiate compounds that are often abused. Therefore, the goal of this hypothetical assay is to detect a broad class of compounds in a single sample. The format for the assay to be developed is lateral flow and the sample matrix will be saliva. Studies of the metabolism of opiates have shown that both the parent drug and its major conjugated metabolites appear in oral fluids and these have previously been shown to be detectable using a laboratory-based immunoassay (Niedbala, Kardos 2005). This suggests that a lateral flow assay is plausible.

To start developing the lateral flow assay, morphine is derivatised through the hydroxyl group before being conjugated to BSA (Verheijen 2002; Volkov *et al.* 2009).

Using a Kinematic Linomat striper, the morphine–BSA conjugate can be adsorbed onto the surface of a 10 µm pore size nitrocellulose sheet by sequentially dispensing small amounts of conjugate to form a capture zone (Verheijen 2002; Volkov *et al.* 2009). Additionally, a reporter such as colloidal gold, fluorescent latex particles or upconverting phosphors can be labelled with purified anti-morphine as described elsewhere (Niedbala *et al.* 2000, 2001). Finally, phosphate-buffered saline, *N*-(2-hydroxyethyl)piperazine-*N*′-2-ethanesulfonic acid (Hepes), or an alternative buffer may be chosen as long as it adequately controls the pH of the final assay mixture without negatively affecting the assay.

Once all the reagents are prepared and a standard curve showing a response over various concentrations of morphine has been run, experiments can be conducted to optimise the concentration of each assay component. Usually the components that are varied are the loading of reagents onto the capture zone, the level of reporter conjugate to control detectable signal, and finally the sample volume to obtain the best precision and optimal dynamic range.

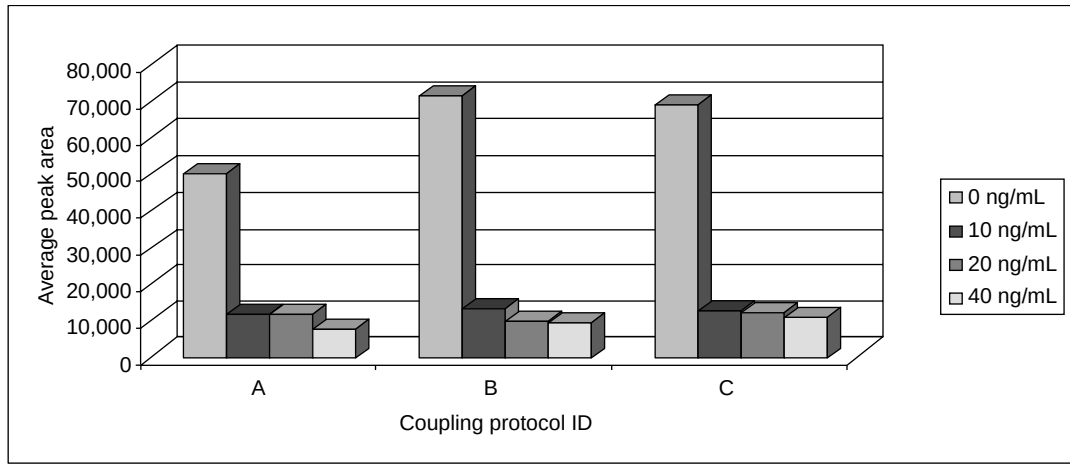

Figure 31.12 This graph shows the results from three experiments loading various amounts of morphine-BSA onto a lateral flow strip. The optimum level was reached when the signal at zero concentration of morphine was highest.

For example, Fig. 31.12 shows the effect of three different line striping protocols for the capture zone on the nitrocellulose strip. As the loading of morphine-BSA increased there was a maximum amount of signal that could be generated. Note, however, that the overall displacement between zero and the various concentration of free drug remained about the same.

Next, the concentration of reporter conjugate may be optimised. Figure 31.13 shows an example of a lateral flow assay utilising up-converting phosphor conjugates as the reporter. Note that, as the level of reporter increased, so did the signal at 0 ng/mL free morphine. This large separation helps to ensure discrimination between negative and positive samples.

Finally, the assay sample size was adjusted and the assay was tested for precision by running replicates at a number of morphine levels. As shown in Fig. 31.14, the assay developed was capable of easily discriminating between 0 and 40 ng/mL morphine, the target concentrations appropriate for an oral fluid-based test.

Immunoassay performance parameters

Having discussed the major aspects of test reagents and development, it is appropriate now to turn to parameters used to evaluate immunoassay performance. It is important to note that there are a number of ways to determine each of the parameters considered. Those discussed here are relevant to scientists developing or evaluating commercial immunoassays for toxicological investigations (Green, Isenchmid 1995; Kwong *et al.* 1988; Linnet, Brandt 1986).

Parameter 1: Precision

Precision is a measure of the variation that occurs either when replicate samples are tested in a single run (intra-assay precision) or when replicate samples are tested and compared between runs (inter-assay precision). Whether intra- or inter-assay precision, the value is always reported as the RSD. It is important to plot the RSDs of any test and look for the deviation around each point tested. In the author's laboratory it is usual to plot the mean plus 2 standard deviations above and below each assay point on the curve. If it overlaps the standard deviation from the calibrator above, optimisation of the assay is continued to improve performance. It is important that precision data should be examined as either the precision of the signal generated in an assay or transformed numbers on a standard curve. Most toxicology assays are qualitative and therefore use signal only. However, transformed numbers are more stringent and are an excellent way to show robust assay performance.

Parameter 2: Limit of detection

Many toxicology screening assays require cut-off levels that challenge the development of any immunoassay. Analytes such as LSD, buprenorphine or tetrahydrocannabinol (THC) must be detected at extremely low concentrations in oral fluids. The assay parameter that indicates the lowest level detectable is the limit of detection (LOD). The LOD for an

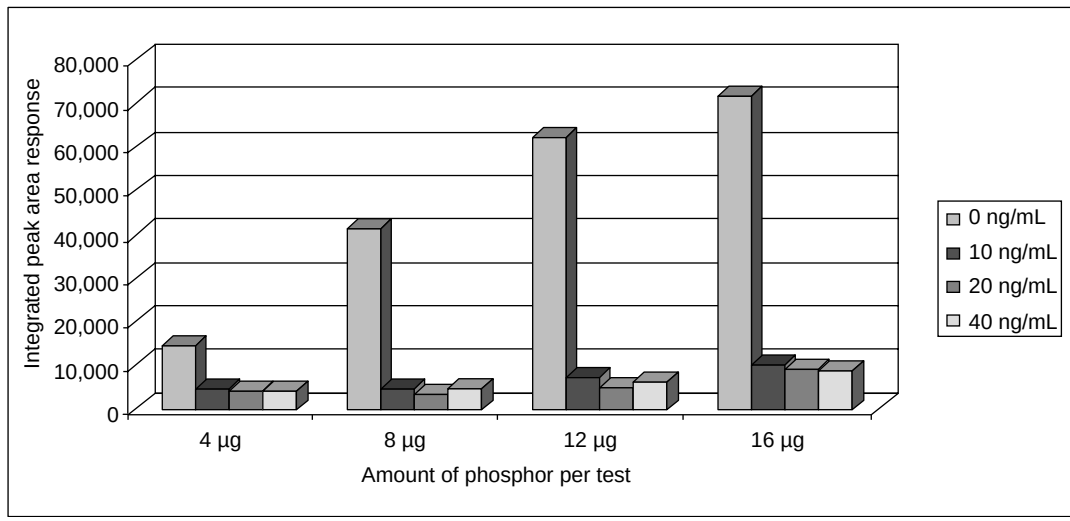

Figure 31.13 This graph shows results of varying the conjugate reporter in the lateral flow assay being designed to detect morphine. Signal increased as more conjugate was added. This produced a steeper curve and improved the performance of the assay.

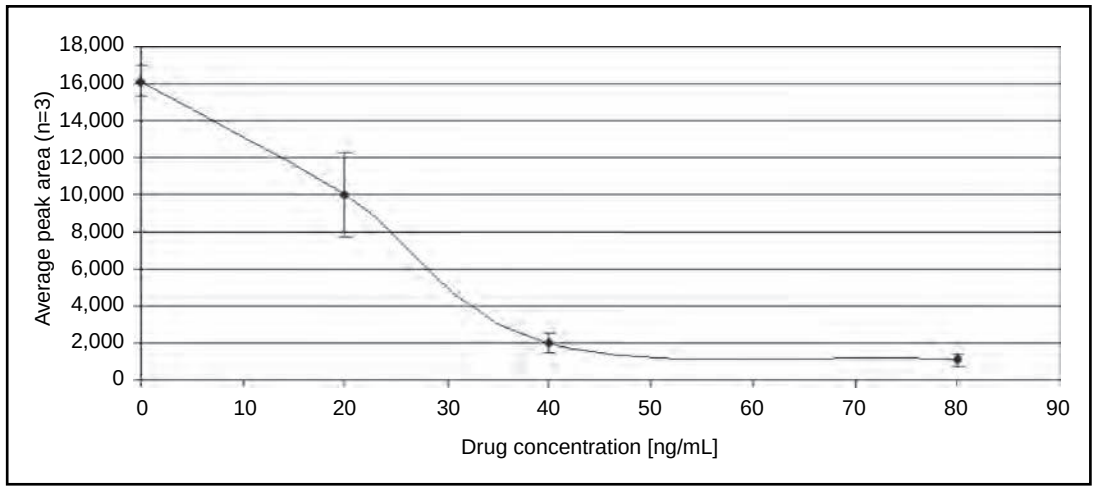

Figure 31.14 Once optimised, the morphine lateral flow assay was tested for precision. This graph shows that the optimised assay had little variation around each calibrator concentration. There was also a large separation in signal between calibrators.

immunoassay is often determined in one of two ways. The first approach is to run replicates of the zero calibrator in an assay and then take the mean plus 2 or 3 standard deviations and plot it onto the assay standard curve. This concentration is then assigned as the LOD. The second method, which is more robust, is to run replicates of a variety of concentrations along the assay curve and, similarly to determining precision, plot 2 standard deviations above and below each point. The lowest concentration that can separate 2 standard deviations above zero and 2 standard deviations below the replicate concentration is then denoted the LOD.

Parameter 3: Specificity/cross-reactivity

This parameter is extremely important for toxicology assays. As stated earlier, some assays are targeted for certain compounds, such as THC, while others will ideally detect a broad class of compounds, such as benzodiazepines. In addition, assays should also be free from interference from more common over-the-counter medications. Using the example of a morphine assay, Table 31.3 lists a number of opiates of interest along with their cross-reactivities in an immunoassay. In addition to cross-reactivity, the table also shows calculations for morphine equivalents and the concentration that may produce a positive result. Each of these values for cross-reactivity, equivalents and concentration that may produce a positive result is derived by running various concentrations of potential cross-reactants in the assay of interest and comparing the results against the cut-off calibrator, which, in this case, is morphine. Each of the parameters can be determined by comparing concentrations against the cut-off.

Parameter 4: Interferences/adulteration

Even if an immunoassay is performed correctly, it can provide an incorrect result if the sample was somehow adulterated or contained an interfering substance. The literature or product package inserts for assays that use blood or urine will frequently warn that haemolysis, lipaemia or high levels of protein in a sample can interfere with homogeneous immunoassays. More recently, orally based diagnostic tests have looked at the food or drinks that can interfere with assays, while hair testing has considered the effects of various treatments, soaps or hair colorants. In all of these cases the assay designers must be prepared to realistically evaluate such interferences. At a minimum, immunoassay developers should document and inform users of their assays about potential interferents.

Adulterants are related to, but different from, interfering compounds. Interferents are defined as normal day-to-day materials used by individuals that can cause aberrant results. Adulterants are materials wilfully added to a sample in order to disrupt a toxicology immunoassay. Such materials have been used in recent years to target many of the homogeneous assays used to initially screen urine samples for drugs of abuse (Wu *et al.* 1999). Materials such as bleach (sodium hypochlorite), salts or detergents have been reported to be very effective and their potential for disruption should be evaluated in any newly developed assay.

Parameter 5: Stability

Any immunoassay is expected to perform over a relatively long period. Commercial immunoassay kits are usually stable from 6 months to

Table 31.3 Morphine immunoassay cross-reactants

Compound	*Concentration (ng/mL)*	*Morphine equivalents (ng/mL)*	*Percentage cross-reactivity (%CV)*	*Concentration that may produce a positive result (ng/mL)*
6-Acetyl morphine	40	34.8	87.0	46
Codeine	40	24.1	60.3	66
Diacetylmorphine	100	>73.7	>73.7	54
Hydrocodone	100	60.5	60.5	66
Hydromorphone	100	>55.9	55.9	72
Meperidine	10 000	68.8	0.7	5,714
β-Morphine-3-glucuronide	100	80.0	80.0	50
Nalorphine	1	36.8	>100	1
Normorphine	100	34.3	34.3	117
Oxycodone	100	43.1	43.1	93
Oxymorphone	100	36.3	36.3	110

several years. Laboratory-based tests are somewhat easier to maintain and control, since cold-room storage is not a problem. Point-of-care tests that are used in remote locations without room temperature control or perhaps no facilities at all face some of the greatest challenges to stability. In these cases the stability of a test must always be related to the functional temperature range that can be tolerated. Any immunoassay developer should field test their immunoassay under various conditions of humidity, temperature and even altitude. Limitations can then be reported to potential users of the test. Such studies are difficult and often highlight the limitations of an immunoassay. However, they are essential so that the incidence of false results is minimised in the field or in the laboratory.

Parameter 6: Quality control

There are various ways to approach quality control for any immunoassay. Some laboratory methods look at the precision of controls from one run to another. Other immunoassays use the standard curve generated to see whether the spread between calibration points is appropriate. These internal assay controls are all good measures that ensure that the final result is correct.

Additional quality control steps should include external controls. Some vendors sell urine, blood or saliva samples that have been spiked at various concentrations.

Proficiency testing programmes are a very useful means by which an individual laboratory can ensure that its assays are performing correctly and for detecting any problems with a particular method. These schemes regularly send samples to a large number of participant laboratories to be tested on a blind basis. A number of organisations exist that can supply urine, saliva, hair or sweat proficiency samples. Examples include RTI International, the College of American Pathologists or Cardiff Bioanalytical Services Ltd. Once tested, the results for each proficiency sample are returned to the co-coordinators of the scheme and each participant laboratory receives a report showing how its findings have compared with those of the others (Cone 1992).

Immunoassay automation

Great strides have been made over the last few decades in the automation of immunoassays. The use of homogeneous assays such as EMIT, CEDIA or KIMS for the rapid analysis of large numbers of samples for drugs of abuse has been described above. In addition, specialised instrumentation has been developed by commercial companies to utilise reporters such as fluorescence, radiolabels and chemiluminesence. In every case these immunoassay platform instruments allow for precise pipetting and incubation of samples. This degree of control is essential in assuring consistent and reliable results. It is interesting to see the overall sensitivity of each system (see Table 31.2). Future systems will be required not only to perform rapid analyses on large numbers of specimens but also to test different specimen types. This is an enormous challenge for immunoassay design and matching instrumentation. Future systems may be as much as 1000 times more sensitive than current techniques.

Alternative fluids for toxicology immunoassays

The latest area of drug immunoassay innovation has been concerned primarily with applications to alternative matrices. Traditionally, toxicological assays for drugs of abuse have been developed for use with urine, whereas TDM assays almost always utilise blood, serum or plasma. Urine testing remains the dominant matrix for drugs-of-abuse screening, although it is now recognised that this sample can be easily adulterated, requires private collection facilities, and is affected by overhydration (Cone *et al.* 2003). In recent years, more assays are being performed using fluids or matrices such as hair, sweat and oral fluid. Although considered several years ago, it is only recently that interest in using alternative fluids for routine screening of drugs of abuse has arisen (Cone 1992; Malamud, Niedbala 2007; Samyn *et al.* 1999a; Schramm *et al.* 1992; Wong 2008) There are several reasons behind this trend and they vary for different countries. For some there is a desire to allow law enforcement to screen for drugs of abuse at the roadside (Parliament of Victoria, Australia 2003). This is not practical with any specimen except an oral sample (Verstraete *et al.* 1999c). In other situations, the drug concentration in the sample collected must have some correlation with that in blood so that some idea of impairment can be demonstrated. Again, this has led to the increased use of saliva testing (Cone *et al.* 2002; Thompson *et al.* 1987; Toennes *et al.* 2005) (Chapter 18). Where the goal is to have the longest window of detection to identify drug abuse, hair is the specimen of choice (Chapter 19).

Conclusions

Immunoassays for the detection or measurement of drugs and their metabolites are routinely used in commercial laboratories worldwide. Automated immunoassay instrumentation capable of analysing thousands of samples per hour has now become routine. Although there are ways in which immunoassays can be flawed, the great majority perform reliably when used correctly. Future directions in immunoassay development are expected to improve upon methods to develop antibodies and format assays. However, these improvements will still utilise the basic principles outlined in this chapter.

CHAPTER

32 Ultraviolet, Visible and Fluorescence Spectrophotometry

J Cordonnier and J Schaep

Introduction and theoretical background

General introduction

Analytical absorption spectroscopy in the ultraviolet (UV) and visible regions of the electromagnetic spectrum has been widely used in pharmaceutical and biomedical analysis for quantitative purposes and, with certain limitations, for the characterisation of drugs, impurities, metabolites and related substances. By contrast, luminescence methods, and fluorescence spectroscopy in particular, have been less widely exploited, despite the undoubted advantages of greater specificity and sensitivity commonly observed for fluorescent species. However, the wider availability of spectrofluorimeters able to present corrected excitation and emission spectra, coupled with the fact that reliable fluorogenic reactions permit non-fluorescent species to be examined fluorimetrically, has led to a renaissance of interest in fluorimetric methods in biomedical analysis.

UV and visible spectrophotometry: theoretical background

General considerations

Molecular absorption in the UV and visible regions arises from energy transitions that involve the outer orbital or valence electrons. Spectra in liquid media are usually broad, relatively featureless bands, a result of the large number of closely spaced vibrational and rotational transitions. The fundamental band shape approximates Gaussian or log-normal Gaussian curves. Given the broad, overlapping profiles commonly encountered, the shape and precise location of individual bands are of limited usefulness in qualitative analysis. However, any fine structure detected in the spectra, coupled with solvent and pH effects, can be of diagnostic value. More informative spectra can be obtained for some volatile molecules of toxicological interest, such as benzene and polynuclear aromatic hydrocarbons; when examined in the vapour phase, vibrational and rotational fine structure can readily be seen superimposed on the broad spectral profiles. This is illustrated in Fig. 32.1 for 1,2,4,5-tetrazine. However, most drugs, metabolites and related compounds are relatively non-volatile; their spectra are observed necessarily in solution, or possibly in the solid phase by reflectance, or by compression to form a KBr disc, as used in infrared spectrophotometry.

UV and visible spectrophotometry find their primary application in quantitative analysis. The scope of absorption spectroscopy can be extended significantly by the use of colour reactions, often with a concomitant increase in sensitivity and/or selectivity. Such reactions are used to modify the spectrum of an absorbing molecule so that it can be detected in the visible region, well separated from other interfering components in the UV spectrum. Moreover, chemical modification can be used to transform an otherwise non-absorbing molecule into a stable derivative that possesses significant absorption.

Spectral selectivity can be enhanced further by a number of chemical or instrumental techniques, which include difference, higher-derivative and dual-wavelength spectrophotometry. Such methods, and certain graphic techniques such as the Morton–Stubbs method, can contribute in different ways to reducing the general problem of spectral interference in quantitative spectroscopy. Spectral interference can arise from so-called 'irrelevant' non-specific absorption, and also from absorption by other materials and impurities that may be present. When interference arises specifically from the spectral overlap of two or more well-defined components, a number of methods can be applied to measure the individual concentrations. These methods include the Vierordt multi-wavelength technique, least-squares deconvolution and second- or higher-derivative spectrophotometry.

Spectral selectivity, and in some cases detection sensitivity, can be enhanced significantly by the various chemical and instrumental techniques outlined above. Such methods should, of course, be validated by applying the conventional analytical criteria of accuracy (against a reference method), linearity, precision and independence from interfering substances.

The scope of UV and visible spectrophotometry can be further extended when combined with a chromatographic separation step, such as high performance liquid chromatography (HPLC). The development of rapid-scanning detectors based on the linear photodiode array permits spectra to be acquired during the elution of peaks. Computer-aided manipulation of these spectra has led to new strategies for the examination of chromatographic peak homogeneity, based on classic techniques in spectroscopy. The use of microcomputers enables the development of archive-retrieval methods for spectral characterisation (Fell *et al.* 1984).

Nomenclature

In the UV and visible spectrum, the energy of photons associated with electronic transitions lies in the range 147–630 kJ/mol. This energy (ΔE) can be expressed in terms of the principal parameters that define electromagnetic radiation, namely frequency μ (Hz), wavelength λ (nm) and wavenumber $\overline{\nu}$ (cm^{-1}):

$$\Delta E = h\mu = \frac{hc}{\lambda} = hc\overline{\nu} \tag{32.1}$$

where h is Planck's constant and c is the velocity of radiation *in vacuo*.

The positions of peaks are sometimes described in terms of wavenumber, which has the advantage of being a linear function of energy, but this term is much more frequently used in infrared spectrophotometry. The practical unit most often used in UV and visible spectrophotometry is wavelength, usually expressed in nanometres (nm). The units that have previously been used for wavelength – millimicron (mμ) and ångström (Å) – are not recommended terms. The position of maximum absorbance of a peak is designated λ_{max}.

The wavelength span is conventionally divided into two ranges: the UV extends from 200 nm to about 400 nm; the visible range extends from about 400 nm to 800 nm. Outside these limits, the 'far UV' or 'vacuum UV' extends from 100 nm to 200 nm, and the 'near infrared' from 1 μm to about 3 μm.

A molecular grouping specifically responsible for absorption is described as a chromophore, and is usually a conjugated system with extensive delocalisation of electron density. Any saturated group with little or no intrinsic absorption of its own, but that modifies the absorption spectrum when attached directly to a chromophore, is described as an auxochrome, examples being –OR, $–NR_2$, –SR. Auxochromes are considered to exert their effect through partial conjugation of their polarisable lone-pair electrons with those of the adjacent chromophore. If, however, the lone pair of electrons is involved in bonding as, for example, in the case of a protonated quaternary ammonium group, the

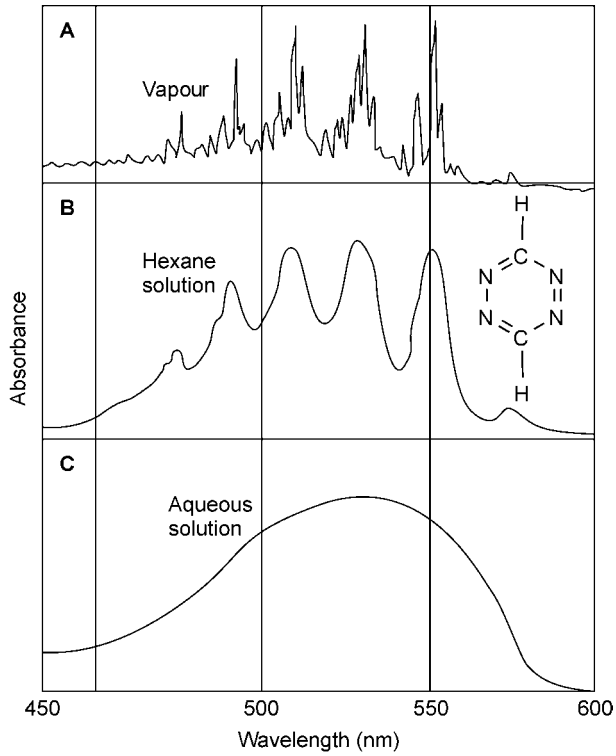

Figure 32.1 UV absorption spectra of 1,2,4,5-tetrazine.

auxochromic effect vanishes. This property can be used for molecular characterisation, as discussed below.

Laws of absorption spectrophotometry

The extent of absorption of radiation by an absorbing system at a given monochromatic wavelength is described by the two classic laws of absorptiometry, which relate the intensity of radiation incident on the absorbing system (I_0) to the transmitted intensity (I) (Fig. 32.2). Lambert's (or Bouguer's) law concerns instrumental factors, and states that, at a given concentration (c) of a homogeneous absorbing system, the transmitted intensity (I) decreases exponentially with increase in path length (b). The complementary Beer's law deals with concentration and states that, for a layer of defined path length (b), the transmitted intensity (I) decreases exponentially with the increase in concentration (c) of a homogeneous absorbing system. Combination of these observations gives the familiar Beer–Lambert law:

$$\log \frac{I_0}{I} = cb \tag{32.2}$$

where ε is the molar absorptivity or molar extinction coefficient of the system, defined as 'the absorbance of a one molar solution in a cell of 1 cm path length'. The concentration c is here expressed in mol/L.

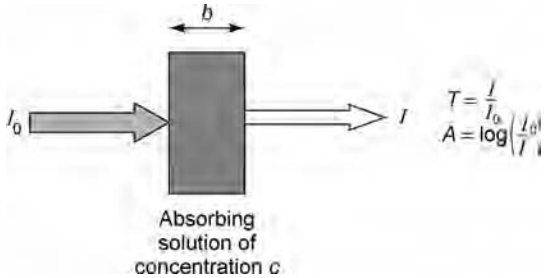

Figure 32.2 Attenuation of a beam of radiation by an absorbing solution.

The logarithmic term is linearly related to concentration and path length, and is referred to as absorbance (A). The older terms extinction (E) and optical density (OD) are not recommended, although they are often found in the literature. Transmittance ($T = I/I_0$) and percentage transmittance ($\%T = 100(I/)_0$) are not linear functions of concentration and path length, and can be related readily to absorbance:

$$A = \log \frac{I_o}{I} = \log \frac{1}{T} = 2 - \log(\%T) \tag{32.3}$$

The molar absorptivity, ε, is a fundamental property of a molecule that tells how much light is absorbed at a particular wavelength. It has two connotations in European usage, and a third according to American convention. If the concentration is expressed in g/L, ε is described as the absorptivity (k, L/g per cm).

When concentration is expressed in g/100 mL, k is described as the specific absorbance and given the symbol $A_{1\ \mathrm{cm}}^{1\%}$ or A(1%, 1 cm), defined as 'the absorbance of a 1% w/v solution in a cell of 1 cm path length'. It is usually written in the shortened form A_1^1 and is widely used in analytical chemistry. It was formerly known as the 'specific extinction coefficient', symbol $E_{1\ \mathrm{cm}}^{1\%}$ or E(1%, 1 cm).

American convention recognises the constant k as 'absorptivity' (a, L/g/cm) defined as 'the absorbance of a 1 g/L solution in a cell of 1 cm path length'. These terms for absorptivity can readily be interconverted:

$$a = \frac{A_1^1}{10} = \frac{\varepsilon}{M_r} \tag{32.4}$$

where M_r is the relative molecular mass. Thus, a compound with an M_r of 100 and absorptivity a of 20 at wavelength λ in a particular solvent at a defined pH (if aqueous) and at a specified temperature, has a corresponding specific absorbance A_1^1 of 200 and a molar absorptivity ε of 2000.

Absorbance and absorptivity are often expressed in logarithmic form in cases where spectra are to be compared. The logarithmic form of the Beer–Lambert law expresses the effects of the molar extinction coefficient (ε), concentration (c) and path length (b) as additive terms

$$\log A = \log\varepsilon + \log c + \log b \tag{32.5}$$

The value for $\log\varepsilon$ is typically in the range 1–5. Since only the molar extinction coefficient (ε) is a function of λ, the shape of a logarithmic absorption curve is independent of concentration and path length. Their only effect is to shift the $\log A$ spectrum along the $\log A$ axis. A disadvantage of the $\log A$ plot is that fine structure near the top of the peak is compressed.

Validity of the Beer–Lambert law

The validity of the Beer–Lambert law is affected by a number of factors. If the radiation is non-monochromatic, i.e. if its spectral bandwidth is greater than about 10% of the drug absorption bandwidth at half-height, the observed absorbance will be lower than the 'true' limiting value for monochromatic radiation. Thus, sharp bands are more susceptible than broad bands to absorbance error on this account. Moreover, if the absorbing species is non-homogeneous, or if it undergoes association, dissociation, photodegradation, solvation, complexation or adsorption, or if it emits fluorescence, then positive or negative deviations from the Beer–Lambert law may be observed. Stray-light effects and the type of solvent used may also lead to non-compliance with the Beer–Lambert law.

Stray-light effects

Stray light is radiation at wavelengths different from those desired. It may arise from light scattering or other defects within the instrument, or it may be caused by external radiation. If the stray light is not absorbed, the observed absorbance tends to a constant value as the concentration of drug is increased, yielding a negative deviation from the Beer–Lambert law.

Stray-light errors are more likely to be observed near the wavelength limits of an instrument, at which the radiation intensity of the source and the efficiency of the optical system are reduced, especially below 220 nm and at the crossover point between the UV and the visible lamps (about 320–400 nm). Errors may become serious if the solvent absorbs strongly or if a strongly absorbing sample is measured by difference spectrophotometry.

Solvent effects

The solvent often exerts a profound influence on the quality and shape of the spectrum. For example, many aromatic chromophores display vibrational fine structure in non-polar solvents, whereas in more polar solvents this fine structure is absent because of solute–solvent interaction effects (see also Fig. 32.1). A classic case is phenol and related compounds, which have different spectra in cyclohexane and in neutral aqueous solution. In aqueous solutions, the pH exerts a profound effect on ionisable chromophores because of the differing extent of conjugation in the ionised and the non-ionised chromophore.

The quality of spectral measurement is affected directly by the type and purity of the solvent used. Each solvent has a cut-off wavelength (which corresponds to about 10% transmittance) and this varies with solvent purity (Table 32.1). A solvent should not be used below its cut-off wavelength, even though reference-cell compensation is employed, because of the greater risk of stray-light effects. The UV spectra of some solvents are illustrated in Fig. 32.3.

Some cautionary comments may be appropriate at this point. It is better to use single- or double-distilled water, and to avoid deionised water, which can be contaminated with absorptive fragments of ion-exchange resin or contain bacterial metabolites; these can contribute significantly to non-specific absorption at low wavelengths. Ethanol is normally used as the 96% v/v strength, since dehydrated alcohol is usually contaminated with traces of benzene added to form the azeotropic mixture for distillation. Acetonitrile can vary noticeably in quality, depending on the supplier; the grade supplied for use in HPLC is usually to be recommended. Acetone, sometimes used to clean cells, is highly absorptive and not always easily removed, despite its volatility and aqueous solubility. Chloroform and carbon tetrachloride absorb strongly at about 250 nm and should therefore be used only for measurements at wavelengths above about 280 nm. Given the safety considerations of chlorinated solvents, use of these is best avoided if possible. Ether, although transparent down to 220 nm, presents particular problems because of its volatility (unstable standard solutions) and inflammability. Although absorptivity is considered to be relatively insensitive to temperature changes, organic solvents in general suffer from high temperature coefficients of expansion, so that for ultimate precision a cell provided with a thermostat may be required.

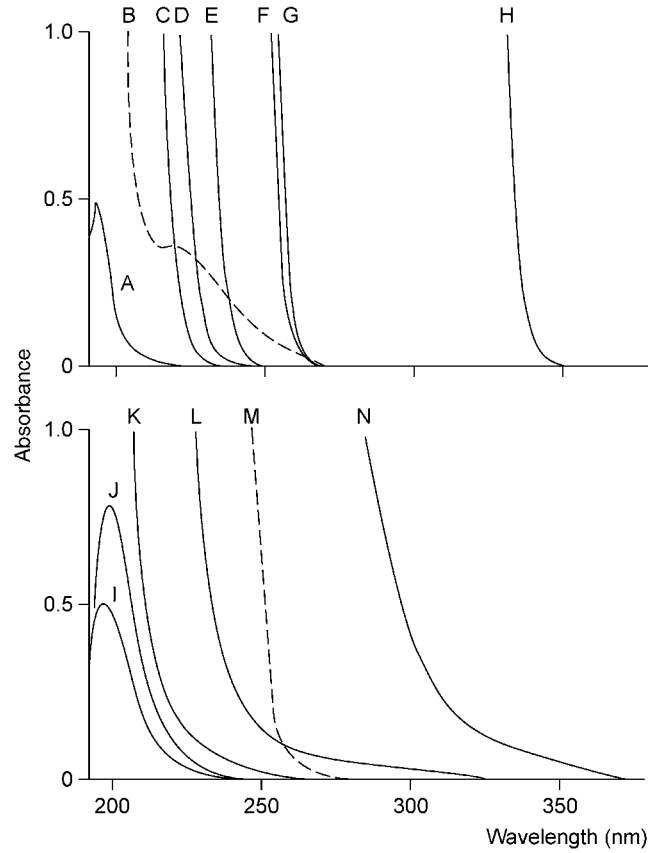

Figure 32.3 UV absorption of solvents (HPLC grade unless otherwise stated): A, acetonitrile (far-UV grade); B, methyl *t*-butyl ether; C, acetonitrile; D, 1-chlorobutane; E, methylene chloride; F, acetic acid (AR grade); G, ethyl acetate; H, acetone; I, hexane; J, iso-octane; K, methanol; L, tetrahydrofuran; M, chloroform; N, diethylamine (AR grade).

Table 32.1 Cut-off points equivalent to 10% transmittance for spectroscopic solvents

Solvent	*Wavelength (nm)*
Water (distilled) or dilute inorganic acid	190
Acetonitrile (HPLC, far-UV grade)	200
Acetonitrile	210
Butyl alcohol	210
Cyclohexane	210
Ethanol (96% v/v)	210
Heptane	210
Hexane	210
Isopropyl alcohol	210
Methanol	210
Ether	220
Sodium hydroxide (0.2 mol/L)	225
Ethylene dichloride	230
Methylene chloride	235
Chloroform (stabilised with ethanol)	245
Carbon tetrachloride	265
N,*N*-Dimethylformamide	270
Benzene	280
Pyridine	305
Acetone	330

Fluorescence spectrophotometry: theoretical background

General considerations

Molecular fluorescence is an emission process in which molecules are excited by the absorption of electromagnetic radiation. The excited species then relax to the ground state, giving up their excess energy as photons.

There are several ways in which an excited molecule can give up its excess energy and relax to its ground state. Two of the most important of these mechanisms are non-radiative relaxation and fluorescent relaxation.

Non-radiative relaxation can occur through collisions between excited molecules and molecules of the solvent, giving excess energy to solvent molecules. When relaxation takes place by fluorescence, bands of radiation are produced as the excited molecules relax to several energy states, which are very close in energy level and thus in wavelength (Fig. 32.4). Fluorescence occurs only from the lowest vibrational level of an excited electronic state.

Note that molecular fluorescence bands are made up largely of lines that are longer in wavelength (lower in energy) than the band of absorbed radiation responsible for their excitation. This shift to

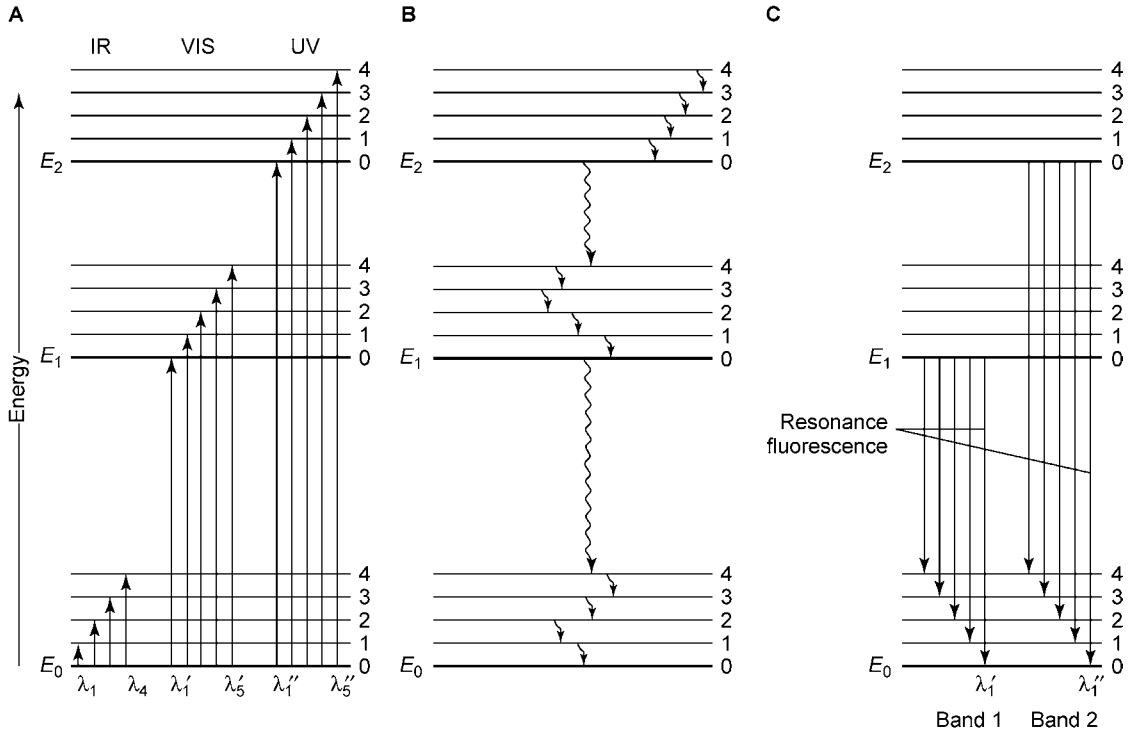

Figure 32.4 Energy-level diagram showing some of the energy changes that occur during (A) absorption, (B) non-radiative relaxation and (C) fluorescence by a molecular species.

longer wavelength is sometimes called the Stokes shift. For that reason, the absorption or excitation spectrum and the fluorescence spectrum for a compound often appear as approximate mirror images of each other. The most useful region for the fluorescence technique is 200–800 nm.

Fluorescence spectrophotometry is usually the method of choice for quantitative analytical purposes if applicable. It has assumed a major role in analysis, particularly the determination of trace contaminants in our environment, industries and bodies, because for applicable compounds fluorescence spectrometry gives high sensitivity and high specificity. The selectivity of fluorescence methods is greater than that of absorption methods, as fewer substances fluoresce than absorb radiation in the UV or visible region. Furthermore, fluorescence is more selective because both the emission and the absorption spectra can be obtained. Fluorescence is usually also more sensitive than absorption methods, as it is always easier to measure a small signal against a very small zero background than to measure a small difference between large signals. However, the phenomenon of fluorescence itself is subject to more rigorous constraints on molecular structure than is absorption.

Nomenclature

The term quantum efficiency used in fluorescence is quantified by the quantum yield (i.e. the ratio of the number of molecules that fluoresce to the total number of excited molecules). Highly fluorescent molecules can have quantum efficiencies that approach unity. Many drugs possess rather high quantum efficiencies for fluorescence, such as quinine and lysergic acid diethylamide (LSD).

All absorbing molecules have the potential to fluoresce. They do so if fluorescent emission occurs at a greater rate than relaxation by non-radiative pathways. The kind of relaxation process is highly dependent on the molecular structure. Compounds that contain aromatic rings give the most intense and most useful fluorescence emission. Substitution on an aromatic ring causes shifts in the excitation wavelength spectrum and in fluorescence efficiency. Substituents such as $-NH_2$, –OH, $-OCH_3$ and $-NHCH_3$ groups often enhance fluorescence, while –Cl, –Br, –I, $-NO_2$ or –COOH are electron-withdrawing groups that can lead to reduction or absence of fluorescence (e.g. aniline fluoresces whereas nitrobenzene does not). The molecular grouping responsible for fluorescence is sometimes described as a fluorophore.

Fluorescence is particularly favoured in rigid molecules, as molecular rigidity reduces deactivation by non-radiative processes (there being fewer internal vibrations). This is also why certain organic chelating agents are more fluorescent when complexed with a metal ion.

Laws of fluorescence spectrophotometry

The power of fluorescent radiation I_f is proportional to the radiant power of the excitation beam absorbed by the system:

$$I_f = K'(I_0 - I) \tag{32.6}$$

The constant K' depends upon the quantum efficiency of the fluorescence. Beer's law can be used to relate I_f to the molar concentration c of the fluorescing molecule:

$$\frac{I}{I_0} = 10^{-bc} \tag{32.7}$$

Substituting equation (32.7) into (32.6) we obtain:

$$I_f = K' I_0 \left(1 - 10^{-bc}\right) \tag{32.8}$$

After expansion of the exponential term, and provided that $\varepsilon bc < 0.05$, we can write:

$$I_f = 2.3K' bcI_0 \tag{32.9}$$

or at constant I_0, with the factor K composed of all constants:

$$I_f = Kc \tag{32.10}$$

Thus, a plot of the fluorescence power of a solution versus the concentration of the emitting species should be linear at low concentrations. Limiting factors for linearity are not only the concentration of the solute

but also factors such as the blank fluorescence, quenching and absorption of exciting radiation by the solvent.

Quenching and other special effects

When the fluorescence of a species is attenuated as a result of its reaction with an analyte, the signal decreases. This effect is called quenching and can be used for quantification purposes, primarily for the determination of anions. Quenching can also be an unwanted effect in the case of dissolved oxygen (see later).

Also, if the analyte is too concentrated, self-quenching may occur when fluorescing molecules collide and lose their excitation energy by radiationless transfer. The fluorescence versus concentration curve may have a maximum and then actually show a decrease in fluorescent power with increasing concentration. It is imperative in quantitative determinations to be aware of this problem, since a given fluorescent power can correspond to two values of concentration.

Instrumentation

General considerations

The basic components of analytical instruments for absorption and fluorescence spectroscopy are alike in function and general performance requirements. Most spectroscopic instruments are made up of five components:

- Stable source of radiant energy
- Wavelength selector that permits the isolation of a restricted wavelength region
- Sample container
- Radiation detector, which converts radiant energy to a measurable signal (usually electrical)
- Signal processor and readout.

Ultraviolet and visible spectrophotometry

Colorimeters

Colorimeters usually employ a single tungsten radiation source in combination with broad-band (~30 nm) optical filters of nominal wavelength, or narrow-bandwidth interference filters with a defined wavelength for use in the visible range. The range of linearity of the colorimeter may be constrained by the relatively broad spectral bandwidths employed, and therefore should be checked carefully for each type of assay.

Single-beam spectrophotometers

These differ from the colorimeter in using a prism or a high-quality diffraction grating monochromator, together with an additional intense source of UV radiation, usually a deuterium (or hydrogen) lamp. They are capable of high precision, particularly in the optimum absorbance range (0.3–0.6 absorbance units). The reference and sample cells must be moved manually in and out of the radiation beam at each wavelength, so it is not practicable to scan a spectrum using such a device.

Double-beam spectrophotometers

Double-beam spectrophotometers use similar high-quality optical components to those in the single-beam instrument. However, the radiation from the monochromator is split into two identical beams by a rotating mirror. One beam passes through the sample and the other through the reference cell, before being recombined to focus on the detector. Each signal is processed appropriately by the detector electronics to measure the absorbance 10–20 times per second, which gives full compensation for cell and solvent absorption. A scan motor drives the monochromator to give a constant wavelength change per second, which is synchronised with a recorder or digital plotter to present the spectrum. For broad bands, scan speeds up to 2 nm/s can be employed. However, some computer-controlled spectrophotometers with fast data-processing capabilities can scan at rates approaching 20 nm/s and still maintain spectral fidelity even for sharp peaks.

A relatively new type of energy source is the xenon lamp. This lamp is used as a pulsed lamp source as the lamp emits light in a discontinuous fashion (i.e. the lamp emits light only at the time of light measurement). The xenon lamp covers a wavelength range of 200–1100 nm. Advantages of a xenon lamp include the following:

- There is no transition region between UV and visible range.
- There is no need for a warming-up period to ensure stabilisation.
- The lamp has a substantially longer lifetime than a conventional lamp source.

Diode-array spectrophotometers

Diode-array spectrophotometers employ multichannel detectors. The most commonly encountered detector of this type is the linear photodiode array. The reversed-optics mode is employed, so that radiation is passed through the sample or reference cell, then dispersed by a diffraction grating polychromator and detected by a device that comprises several hundred diodes. Each photodiode registers the integrated intensity of radiation incident on it, which is determined by the spectral dispersion : photodiode ratio. For example, if a 200 nm bandwidth of radiation is dispersed across 256 photodiodes, the nominal resolution per photodiode is 0.78 nm.

A spectrum in a specified range is acquired within 20 ms. The analogue signals from each photodiode are digitised and transferred to a computer, where they are corrected for dark-current response and transformed to absorbance. A number of digital techniques are available to increase sensitivity, extending the use of rapid-scanning detectors to multicomponent analysis, reaction kinetics, tablet dissolution tests, process control and detection in HPLC (Fell *et al.* 1982).

Microplate readers

Microplate readers make no use of conventional cuvettes in which light runs through the walls of the cuvette containing the sample. Microplates are transmissible to light and typically have 96 wells (8×12) containing small sample volumes. The light is conducted from under the plate and the detector is mounted above the plate. As the plate moves, the absorbance of all 96 well positions can be read.

By making use of optical fibres the light from the source can be divided over eight samples, thus speeding up the reading process.

Automatic thin-layer chromatography

UV-visible spectrophotometry can also be applied to quantify organic toxic substances, separated by thin-layer chromatography (TLC). By moving the TLC plate, the absorbance of each spot can be scanned to give a two-dimensional absorption spectrum. For fluorescing molecules this technique can also be applied to obtain a fluorescence spectrum.

Fluorimetry

Single-beam fluorimeters

A single-beam spectrofluorimeter consists of a radiation source (usually a mercury or xenon lamp), a primary filter (excitation), a sample cell, a secondary filter (emission) and a fluorescence detection system. In most such fluorimeters the detector is placed on an axis at 90° from that of the exciting beam. This right-angle geometry permits the exciting radiation to pass through the test specimen and not contaminate the output signal received by the fluorescence detector. However, the detector unavoidably receives some of the exciting radiation as a result of the inherent scattering properties of the solutions themselves, or if dust or other solids are present. Filters are used to eliminate this residual scatter. The primary filter selects the short-wavelength radiation able to excite the test specimen, while the secondary filter is normally a sharp cut-off filter that allows the longer-wavelength fluorescence to be transmitted but blocks the scattered excitation. Most fluorimeters use photomultiplier tubes as detectors. The photocurrent is amplified and read out on a meter or recorder.

Scanning spectrofluorimeters

When at least one monochromator (grating or prism) is used instead of a filter, the instrument is called a spectrofluorimeter. The use of gratings instead of filters makes the instrument superior in wavelength selectivity, flexibility and convenience. More complex spectrofluorimeters employ two diffraction gratings (or prisms) to select the fixed excitation

wavelength (λ_{ex}) and the fixed wavelength (λ_f), together with a high-intensity xenon source, scanning motors and electronic compensation for variations in source intensity as the wavelength is varied.

Coupled techniques

Where large numbers of samples must be analysed quickly, the use of automatic instruments becomes viable. One path is to use the automated sample handling in the flow injection analysis technique.

Flow injection analysis (FIA) is an example of a continuous flow system: the sample becomes part of a flowing stream in which the unit operations of the analysis take place as the sample is carried from the injection point to a flow-through measuring device (such as a photometer) and finally to waste.

The intensity of the radiation that reaches the detector is recorded continuously; when an absorbing species is passing through, a sharp peak is generated, with the height of the peak proportional to the analyte concentration. Sample sizes are mostly in the range 10–30 μL.

Instruments are available with the ability to carry out manipulations such as in-line heating, in-line distillation, in-line UV digestion or in-line extraction, so that UV and/or visible spectroscopy can be used for a wide variety of compounds.

In multicomponent systems, the limited specificity for spectroscopic methods can be an important drawback and a restriction for analysis. With the technique of liquid chromatography, a wide variety of macromolecules and ionic species in complex mixtures can be separated. Detection systems depend upon the nature of the component of interest, but the most widely used detectors in liquid chromatography are based upon UV or visible radiation. Photometers often make use of the 254 nm and 280 nm lines from a mercury source, because many organic functional groups absorb in this region. However, to achieve an adequate specificity, often diode arrays are used, which are able to display an entire spectrum as an analyte exits the column (liquid chromatography with diode array detector (LC-DAD)). Compared with single-wavelength detection, which provides no information about peak purity, the diode array's full spectral comparison provides results with a far greater confidence level.

Generally, the LC-DAD technique is applied for toxicological screening. Substances are identified on the basis of both retention time and UV spectrum (Bogusz, Wu 1991; Elliott, Hale 1998; Lambert *et al.* 1995; Tracqui *et al.* 1995). The diode array can also be connected to a mass spectrometer (LC-DAD-MS), which increases the sensitivity and gives an extra confirmation of the component's identity.

For components of interest that fluoresce, the chromatographic system can be equipped with a fluorimetric detector (LC-FL). In the case of weakly fluorescent or non-fluorescent drugs, a number of well-characterised derivatisation reactions are available. These include dansyl chloride (5-dimethylaminonaphthalene-1-sulfonyl chloride) for primary and secondary amines and phenolic hydroxyl groups, and fluorescamine (4-phenylspiro-[furan-2(3*H*),1′-isobenzofuran]-3,3′-dione), and *o*-phthalaldehyde for primary amines. Derivatisation reactions of this type have extended the scope of fluorescence detection in HPLC significantly.

The same type of detectors (DAD/fluorescence) can be coupled with capillary electrophoresis (CE-DAD or CE-FL) or ion chromatography to determine charged components in complex mixtures.

Data processing and presentation of results

Ultraviolet and visible spectrophotometry

Single-component systems

Where only one component in the sample absorbs significantly, the wavelength is chosen to coincide with the centre of a broad maximum in the spectrum to minimise wavelength-setting errors. If the spectrum has no suitable maximum, a flat absorption minimum can be used, provided that the consequent loss of sensitivity is acceptable. Wavelengths near the extremities of the UV and visible ranges must be avoided, because of the effects of stray-light errors.

Accurate measurements of a drug in solution may be difficult because of non-specific absorption. In these circumstances, the geometric correction devised by Morton and Stubbs is sometimes applied. This assumes that the non-specific absorption varies linearly with wavelength over the range measured. Taking a solution of pure drug, two equi-absorptive points are selected, one at a lower wavelength (λ_1) and the other at a higher wavelength (λ_3) than that of the peak maximum (λ_2). Any irrelevant absorption in the sample increases the observed absorbance of one equi-absorptive point (usually λ_1) more than the other (λ_3). A simple geometrical calculation involving absorbances at λ_1 and λ_3 enables the absorbance at λ_2 to be corrected for the non-specific absorption (Donbrow 1967). The assumption of linearity of the irrelevant absorption can be tested by subtracting the theoretical curve for the calculated quantity of pure material and inspecting the residual difference spectrum.

The classic example of a pharmacopoeial assay based on the Morton–Stubbs correction is that for vitamin A alcohol and the ester (The Stationery Office 2002). Other techniques proposed for the correction of non-specific absorption include difference spectrophotometry, second-derivative spectrophotometry, the use of orthogonal polynomials, and chemical or physical transformation of the drug to give absorption at a longer wavelength.

Multicomponent systems

The absorption spectra of two or more drugs of interest often overlap. Subject to certain conditions, the Vierordt method of simultaneous equations can be employed to obtain the individual concentrations (Glenn 1960). If each of n drugs obeys the Beer–Lambert law over the concentration range of interest, and if the law of additivity of absorbances applies, then the total absorbance, A_T^λ, observed at any wavelength λ is given by the sum:

$$A_T^\lambda = \sum_{i=1}^{n} A_i^\lambda = \sum_{i=1}^{n} k_i^\lambda c_i b \qquad (32.11)$$

where the subscript i denotes each component in the system. The term k_i^λ represents the absorptivity a (L/g/cm), the specific absorbance ($A_{1\ cm}^{1\%}$), or the molar absorptivity ε (L/mol/cm), as determined by the units selected for concentration c_i.

For a two-component system, two wavelengths λ_1 and λ_2 are selected (as discussed below) and two corresponding simultaneous equations are set up:

$$A_T^\lambda / b = k_1^{\lambda_1} c_1 + k_2^{\lambda_1} c_2 \qquad (32.12)$$

$$A_T^{\lambda_2} / b = k_1^{\lambda_2} c_1 + k_2^{\lambda_2} c_2 \qquad (32.13)$$

Equations 32.12 and 32.13 readily yield the concentration of each component, c_1 and c_2, by conventional algebra.

The selection of appropriate wavelengths and the use of accurate absorptivity values are clearly crucial. Generally, λ_1 is the λ_{max} for component 1, while λ_2 is the λ_{max} for component 2, provided that at these wavelengths the absorptivity of the overlapping component is small. If the spectra of both components are very similar, the errors of the method increase appreciably as the difference between the absorptivity ratios tends to zero.

Although this method should apply to the analysis of three or more components, in practice it is often difficult to select wavelengths that fulfil all the requisite conditions. However, computer-aided spectrophotometers exploit the 'principle of overdetermination', in which the number (m) of observation wavelengths exceeds the number (n) of components known to be present. This gives an $n \times m$ matrix of data that can be solved readily by standard matrix algebra.

The limit test for amphotericin A (a tetraene, λ_{max} 300 nm) in the antifungal antibiotic amphotericin (consisting primarily of amphotericin B, a heptaene, λ_{max} 380 nm) is an example of such a two-component analysis (The Stationery Office 2002).

Difference spectrophotometry

Difference spectrophotometry is a method of compensating for the presence of extraneous materials in a sample that would otherwise interfere with the spectrum of the drug being determined. It involves the measurement of the absorbance difference, at a defined wavelength, between two samples in one of which a physical or chemical property of the drug has been changed. It is assumed that the spectrum of the drug can be changed without affecting the spectrum of the interfering material. Alternatively, the absorbance difference may be measured between the sample and an equivalent solution without the drug. Difference spectrophotometry is sometimes described as 'differential spectrophotometry', but this term is not recommended because of its possible confusion with derivative spectrophotometry.

Many suitable methods for physical and chemical modification of the drug absorbance have been reported. For example, the bathochromic effect (also discussed later) is used in the difference spectrophotometric assay of barbiturates. The absorbance of the sample at about pH 10 (A_{10}), to which the mono-anionic species contributes (A_M), is used to compensate for the absorption of interfering endogenous materials (A_{EM}) that have been carried through the extraction procedure. The sample absorbance at pH 13 (A_{13}), to which the di-anionic species (A_D) contributes, is measured at about 260 nm with reference to the sample absorbance at pH 10 (A_{10}), so that

$$A_{13} = A_D + A_{EM} \tag{32.14}$$

$$A_{10} = A_M + A_{EM} \tag{32.15}$$

Thus,

$$\Delta A = A_{13} - A_{10} = A_D - A_M \tag{32.16}$$

If

$$\Delta = (_D - _B) \tag{32.17}$$

then

$$\Delta A = \Delta bc \tag{32.18}$$

Thus, the difference absorbance can be related readily to concentration by prior calibration of the constant $\Delta\varepsilon$, or the concentration may be found by simple proportion:

$$\frac{\Delta A_{test}}{\Delta A_{standard}} = \frac{c_{test}}{c_{standard}} \tag{32.19}$$

It should, however, be established that ΔA is a linear function of concentration (c) over the range required. It is convenient to select for the analytical wavelength a value that corresponds to a maximum in the difference spectrum, obtained by scanning the sample and reference solution over an appropriate wavelength range.

Difference spectrophotometry can be used for quality control in cases where the interfering material is well defined, because an appropriate dilution of a suitable reference solution can be used in the reference cell. The difference absorbance is, however, susceptible to systematic error when there is uncertainty in the concentration of interfering materials in the samples to be assayed. This error increases in proportion to the ratio of the molar absorptivity of the interference to that of the drug.

A further technique to correct for absorptive interferences by difference measurement is based on *dual-wavelength spectrophotometry*. In this method, two monochromatic beams at different wavelengths are passed through the same sample. One wavelength (λ_1) is generally characteristic of the drug, while the other (λ_2) is selected carefully so that the absorbance is equivalent to the level of absorptive interference (A_m^{λ}) anticipated at the analytical wavelength (λ_1). Thus, the second radiation beam is analogous to the reference cell employed in conventional difference spectrophotometry, and the difference in absorbance at the two wavelengths (ΔA) represents the absorption of drug (A_m^{λ}) corrected for interference:

$$A^{\lambda_2} = A_n^{\lambda_1} + A_m^{\lambda_2} \tag{32.20}$$

and since

$$A^{\lambda_2} = A_m^{\lambda_1} \tag{32.21}$$

then

$$\Delta A = A^{\lambda_1} - A^{\lambda 2} = A_n^{\lambda_1} \tag{32.22}$$

A classic application of this method is the correction of Rayleigh scattering in samples of biological origin.

Derivative spectrophotometry

In derivative spectrophotometry, the absorbance (A) of a sample is differentiated with respect to wavelength (λ) to generate the first-, second- or higher-order derivatives:

$A = f(\lambda)$ zero order

$dA/d\lambda = f'(\lambda)$ first derivative

$d^2A/d\lambda^2 = f''(\lambda)$ second derivative

and so on.

Derivative spectra often yield a characteristic profile, in which subtle changes of gradient and curvature in the normal (zero order) spectrum are observed as distinctive bipolar features (Fig. 32.5). The first derivative of an absorption spectrum represents the gradient at all points of the spectrum and can be used to locate 'hidden' peaks, since $dA/d\lambda = 0$ at peak maxima (Fig. 32.5). However, second- and higher-even-order derivatives are potentially more useful in analysis.

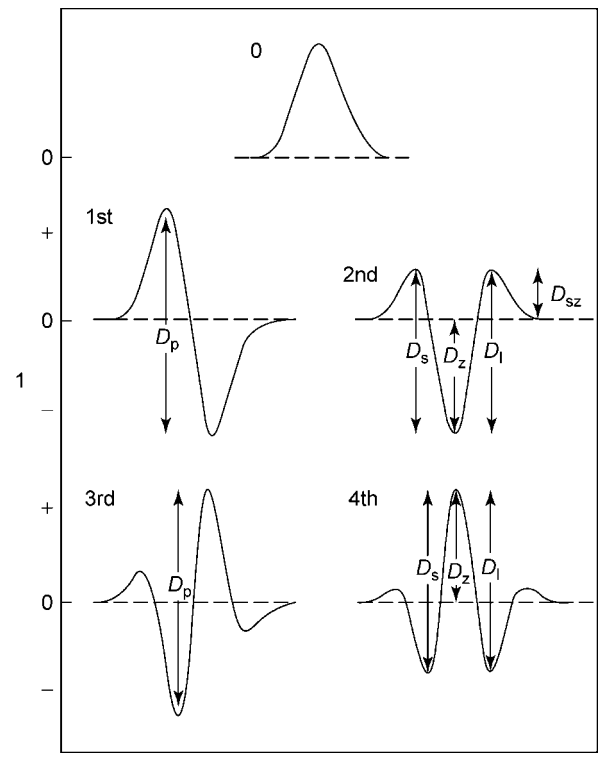

Figure 32.5 First to fourth derivatives of a Gaussian peak, and some graphic measures of derivative amplitude (D). D_p, peak-to-peak; D_s, peak-to-satellite at short wavelength; D_z, peak-to-derivative zero; D_l, peak-to-satellite at long wavelength; D_{sz}, satellite peak-to-derivative zero.

The even-order derivatives are bipolar functions of alternating sign at the centroid (i.e. negative for second, positive for fourth, etc.), whose position coincides with that of the original peak maximum (Fig. 32.5). To this extent, even-derivative spectra bear a similarity to the original spectrum, although the presence of satellite peaks that flank the centroid adds a degree of complexity to the derivative profile. A key feature is that the derivative centroid peak width of a Gaussian peak decreases to 53%, 41% and 34% of the original peak width in the second, fourth and sixth orders, respectively. This feature can increase the resolution of overlapping peaks. However, the increasingly complex satellite patterns detract from resolution enhancement in higher-derivative spectra.

An important property of the derivative process is that broad bands are suppressed relative to sharp bands. This effect increases with increasing order of the derivative, since the amplitude (D_n) of a Gaussian peak in the nth derivative is inversely related to the original peak width (W), raised to the nth power:

$$D_n \sim W^{-n} \tag{32.23}$$

Thus, for two coincident peaks of equal intensity, the nth derivative amplitude of the sharper peak (X) is greater than that of the broader peak (Y) by a factor that increases with derivative order:

$$\frac{D_{n,\,\mathrm{X}}}{D_{n,\,\mathrm{Y}}} = \left[\frac{W_\mathrm{Y}}{W_\mathrm{X}}\right]^n \tag{32.24}$$

This property leads to the selective rejection of broad, additive spectral interferences, such as Rayleigh scattering.

If the Beer–Lambert law is obeyed, that is:

$$A = bc \tag{32.25}$$

then:

$$\frac{\mathrm{d}A}{\mathrm{d}\lambda} = \frac{\mathrm{d}}{\mathrm{d}\lambda} bc \tag{32.26}$$

$$\frac{\mathrm{d}^2A}{\mathrm{d}\lambda^2} = \frac{\mathrm{d}^2}{\mathrm{d}\lambda^2} bc \tag{32.27}$$

and similarly for higher derivatives, where ε is the molar absorptivity (L/mol per cm), b is the cell path length (cm) and c is the concentration (mol/L).

For quantitative work, the amplitude of a derivative peak can be measured in various ways (Fig. 32.5). Although the true derivative amplitude is that measured with respect to the derivative zero, the most common practice is to record the amplitude with respect to a satellite in the spectrum, which affords an extra degree of suppression of interference from extraneous substances. It is essential to run standards in bracketing sequence with the samples, and thus subject both to the same experimental conditions. It should be established that the graphic derivative adopted fulfils the analytical criteria of linear response with concentration, regression through or close to the origin, independence from interfering substances and optimum precision.

In general, methods for generating derivative spectra fall into two classes. These are optical methods, which operate on the radiation beam itself, and electronic or digital methods, which operate on the photometric detector output. The electronic analogue device generates the required derivative as a function of time as the spectrum is scanned at constant speed ($\mathrm{d}\lambda/\mathrm{d}t$), and therefore the derivative amplitude varies with the scan speed, slit width and gain. Moreover, the signal-to-noise ratio has been reported to decrease by approximately a factor of 2 in each successive derivative order.

Alternatively, a microcomputer, employing one of a number of digital algorithms, can be used to produce smoothed derivative spectra. This is carried out in real time or by post-run processing of the digitised spectrum. The digital approach is employed commonly in contemporary spectrophotometers, because of the widespread adoption of microprocessors for instrument control and data handling, coupled with the addition of powerful software for further data processing.

Although transformation of a spectrum to its second- or higher-order derivative often yields a more highly characteristic profile than the zero-order spectrum, the intrinsic information content of the data is not increased; indeed, some data, such as constant 'offset' factors, are lost. However, the derivative method tends to emphasise subtle spectral features by presenting them in a new and visually more accessible way. The method is generally applicable in analytical chemistry and can be used equally for resolution enhancement of electrochemical, chromatographic or thermal analysis data.

Derivative spectrophotometry has found significant application in clinical, forensic and biomedical analysis (Gill *et al.* 1982). In forensic toxicology, the suppression of the absorbance from interfering substances by second-derivative spectrophotometry is well demonstrated in studies on amfetamine in a homogenised liver extract (Fig. 32.6).

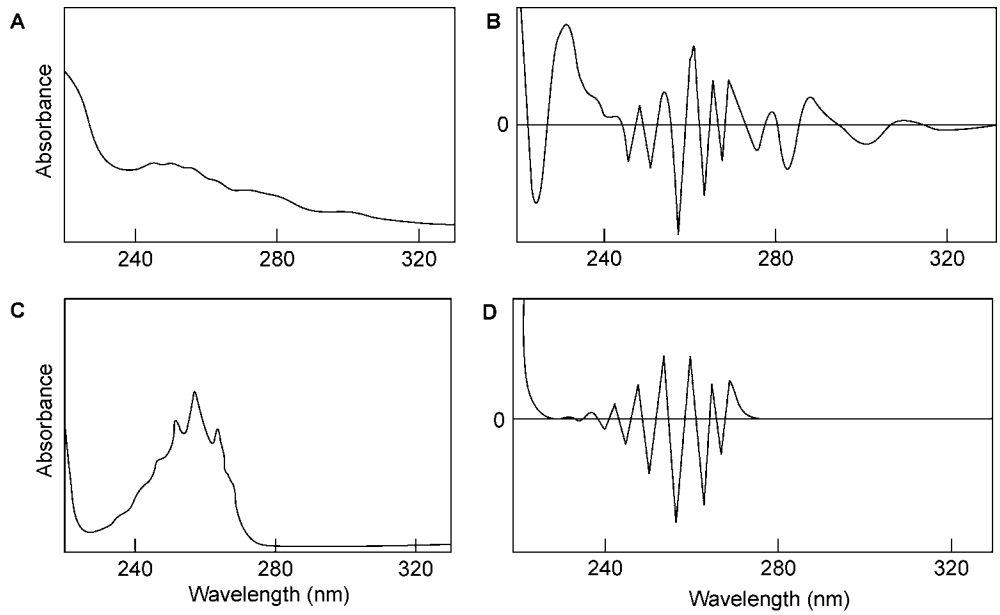

Figure 32.6 Detection of amfetamine in homogenised liver extract. Standard zero-order (A) and second-derivative (B) spectra of the liver extract, compared with the standard zero-order (C) and second-derivative (D) spectra of amfetamine; solutions were in 0.1 mol/L sulfuric acid. (From Gill *et al.* 1982].)

Transformation of the zero-order spectrum (A) to its second derivative (B) using a rapid-scanning multichannel spectrophotometer permits the characteristically sharp benzenoid peaks of amfetamine to be detected and compared with an authentic standard (D), while the interfering background absorption is reduced substantially. The second- and fourth-derivative method for biological background correction can give a tenfold increase in the detection limit of serum paraquat in cases of poisoning (Fell *et al.* 1981). The derivative method can be combined successfully with difference spectrophotometry to give second-derivative difference spectra, in which enhanced discrimination against interfering substances and sharpened fine structural features are observed.

Analytical fluorimetry

The fluorescence properties of a compound are characterised by two spectra. An excitation spectrum is obtained by monitoring the fluorescence at a convenient fixed wavelength λ_f, while scanning the excitation monochromator at a fixed speed up to a wavelength no higher than λ_f. The excitation spectrum should, in principle, be comparable with the absorption spectrum. The fluorescence spectrum is obtained by illuminating the sample at a convenient fixed excitation wavelength λ_{ex} and scanning the emission monochromator at a fixed speed over a wavelength range no lower than λ_{ex}. For interlaboratory comparisons, corrected fluorescence and excitation spectra should be obtained using one of the generally available digital or instrumental techniques.

Some spectrofluorimeters are able to scan the excitation and emission monochromators synchronously to yield fluorescence spectra that are generally simpler and considerably sharper than the conventional fluorescence spectrum. With computer-aided spectrofluorimetry, the acquisition and digital storage of fluorescence spectra are possible. These can then be manipulated in various ways to give the derivative spectrum in which fine structure is accentuated, the difference spectrum or multiwavelength spectral deconvolution, to calculate the concentration of known overlapping components (Winfield, Williams 1984).

In another digital technique, a series of fluorescence spectra is acquired while sequentially stepping up the excitation wavelength. When these spectra are combined to give a matrix of (I_f, λ_f, λ_{ex}), a three-dimensional isometric projection is presented. This type of graphic presentation is described as an 'emission–excitation matrix' or 'fluorogram' (Fig. 32.7). The data can also be plotted as the equivalent two-dimensional plot of isointensity contours in the (λ_f, λ_{ex}) plane (Fig. 32.8). Three-dimensional graphics are increasingly used for the qualitative comparison of fluorescent molecules, as in the example of promethazine and its principal degradation product, promethazine sulfoxide (Figs 32.7 and 32.8).

Instrument performance checks

Although instruments with conventional optics may require frequent calibration because they have many moving parts, diode array spectrophotometers with no moving parts are extremely reproducible and stable, in both the short and the long term.

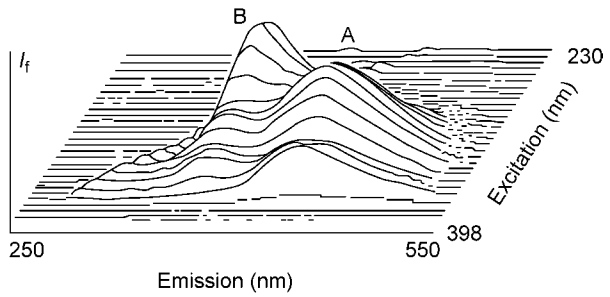

Figure 32.7 Isometric projection of the emission–excitation matrix of fluorescence intensity (I_f) for promethazine hydrochloride (A) and promethazine sulfoxide (B) in buffer at pH 3.0. (From Fell *et al.* 1981.)

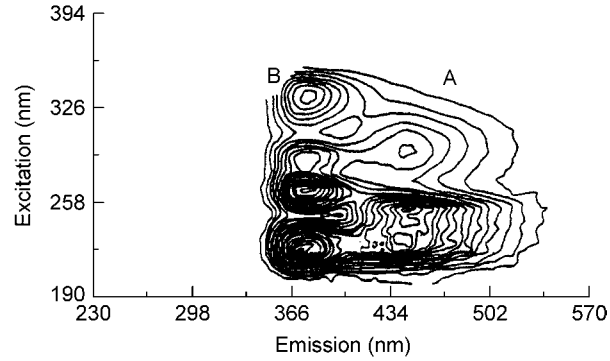

Figure 32.8 Contour plot of emission–excitation matrix of promethazine hydrochloride (A) and promethazine sulfoxide (B) in buffer at pH 3.0. (From Clark *et al.* 1985.)

Following the recommendations of the European Pharmacopeia (Council of Europe 2007) for UV and visible spectrophotometry, the wavelength and the absorbance must be calibrated. The wavelength scale must be verified using the absorption maxima of holmium perchlorate solution, the line of a hydrogen or deuterium discharge lamp, or the lines of a mercury vapour lamp. The permitted tolerance is ±1 nm for the UV range and ±3 nm for the visible range. The absorbance should be checked using suitable filters or a solution of potassium dichromate of 60 mg/L in 0.005 mol/L sulfuric acid at the wavelengths indicated in Table 32.2.

The level of stray light should be assessed, since it increases with instrument age. It may be detected at a given wavelength with suitable filters or a 1.2% w/v potassium chloride solution. The European Pharmacopeia (Council of Europe 2007) requires that the absorbance be greater than 2 at a wavelength between 198 and 202 nm when compared with water as compensation liquid.

In some assays it is necessary to specify the minimum desirable resolution, since changes in the spectral bandwidth (or monochromator slit width) can seriously affect the observed absorbance of sharp peaks. The European Pharmacopoeia requires that the spectral bandwidth employed should be such that further reduction does not lead to an increase in measured absorbance. This is particularly important for drugs that have aromatic or strongly conjugated systems (e.g. diphenhydramine, phenoxymethylpenicillin, and amphotericin A and B). In such cases, a spectral bandwidth of more than 1 nm leads to a reduction in observed absorbance at the peak maximum (and conversely an increase in absorbance at a peak minimum), since the recorded absorbance is the mean of that over the whole bandwidth at that wavelength. Although increasing the slit width gives a better signal-to-noise ratio, a slit width of 2 nm is adequate for most bands, with 1 or 0.5 nm being used for very sharp peaks.

For qualitative analysis the resolution can be measured by recording the spectrum of a 0.02% solution of toluene in hexane. The minimum ratio of the absorbance at the maximum at 269 nm to that at the minimum at 266 nm is stated in the monographs of the European Pharmacopoeia (Council of Europe 2007).

According to the principles of good laboratory practice (GLP), the apparatus should be periodically inspected, cleaned, maintained and calibrated according to the laboratory's standard operating

Table 32.2 Wavelengths at which absorbance should be checked

Wavelength (nm)	*Specific absorbance* (A_1^1)	*Maximum tolerance*
235	124.5	122.9–126.2
257	144.5	142.8–146.2
313	48.6	47.0–50.3
350	107.3	105.6–109.0

procedures. Records of procedures should be maintained. Calibration should, where appropriate, be traceable to national or international standards of measurements.

Examples of interesting options on the system are a logbook database in which lamp changes and defects are registered. Also, a key-lock function is now a common part of a quality system to avoid effects from unwanted keystrokes.

In fluorescence the calibration of excitation and emission monochromator wavelengths should be checked regularly by the use of sharp lines from the instrument's own radiation source (e.g. xenon lines at 450.1, 462.4, 467.1 and 473.4 nm) or the use of sharp fluorescence peaks in solutions or glasses of trivalent lanthanide ions (tellurium, europium). Other fluorescence standards in common use are ovulene and other polycyclic aromatic hydrocarbons with fine vibrational structures such as naphthalene and anthracene. In practice, it is necessary only to calibrate one monochromator, since the other can then be calibrated by the Rayleigh scattered radiation using a sample of colloidal silica in the sample position. The use of an auxiliary light source, such as a mercury light pen, is the least satisfactory method for wavelength calibration.

It is recommended that the performance of each computerised system be verified for the proper functioning of data acquisition, method-related calibration and reporting. Usually, test packages are commercially available from the supplier.

Sample preparation and sample presentation

The most frequent mode of sample presentation is as a dilute solution, although gases and solid surfaces can also be examined. Combinations of UV and visible spectrophotometry or spectrofluorimetry with HPLC are particularly advantageous for sensitive and selective detection of chromophores and/or fluorophores.

Ultraviolet and visible spectrophotometry

Cells

In the visible region, a matched pair of glass cells can be used, but these are inappropriate for the UV region because of the poor transmission properties of glass in this range (Fig. 32.9). Fused-silica or quartz cells have high transmittance from 190 nm to 1000 nm, and are therefore the cells of choice. The path length employed is usually 1.00 cm; cells with longer path length are used for poorly absorptive drugs and/or where the concentration is low. Flow cells designed to minimise turbulent flow through the cell are used to monitor changes in absorbance during a reaction, for tablet dissolution studies or for HPLC; care should be taken that the cell walls do not block the radiation beam, otherwise variable errors are introduced. Cells provided with a thermostat are used for studies on enzymatic and other processes in which temperature is a key parameter.

The meticulous handling and care of cells is a necessary condition for precise and accurate measurement. Cells should be cleaned carefully, filled with an appropriate solvent and matched for absorbance to less than 1%. Each pair of cells should be marked on the base in soft pencil to identify the set and its normal orientation. The tolerance on the path length of the cells used is ± 0.005 cm (Council of Europe 2007).

When filled with the same solvent, the cells intended to contain the solution to be examined and the compensation liquid must have the same transmittance. If this is not the case, an appropriate correction must be applied. It is convenient to designate the more strongly absorbing cell as the 'sample' cell, the other cell being coded as 'reference'. In this way the cell constant (i.e. the difference in absorbance at the measurement wavelength when filled with solvent) will be positive and can thus be subtracted from each absorbance reading. Moreover, the possibility of 'oscillating error' introduced by randomly changing the cell orientation during a series of measurements is eliminated. The 'cell constant' should be checked regularly at the measurement wavelength when filled with an appropriate solvent, or by scanning the baseline over the wavelength range.

Cells should be cleaned scrupulously after use. If they have contained aqueous solutions, they can be cleaned readily by repeated rinsing with distilled water or by soaking overnight in a very dilute solution of detergent; special detergents should be used to clean cells contaminated with biological material. Periodically, it is good practice to soak cells and stoppers thoroughly in a fresh solution of chromic acid, followed by copious rinsing with distilled water, to restore their matched performance. Cells that have been used with organic solvents require special care, with a sequence of solvents ending in spectroscopic ether being convenient to obtain dry, clean cells. In all cases, the manufacturer's instructions should be followed, when available. Sharp glass or metal objects should not be introduced into a cell, lest the internal surface be scratched. The outside optical surfaces should be polished before use with a soft cloth or photographic lens tissue. Cells should be stored in pairs, dry and in a protective container.

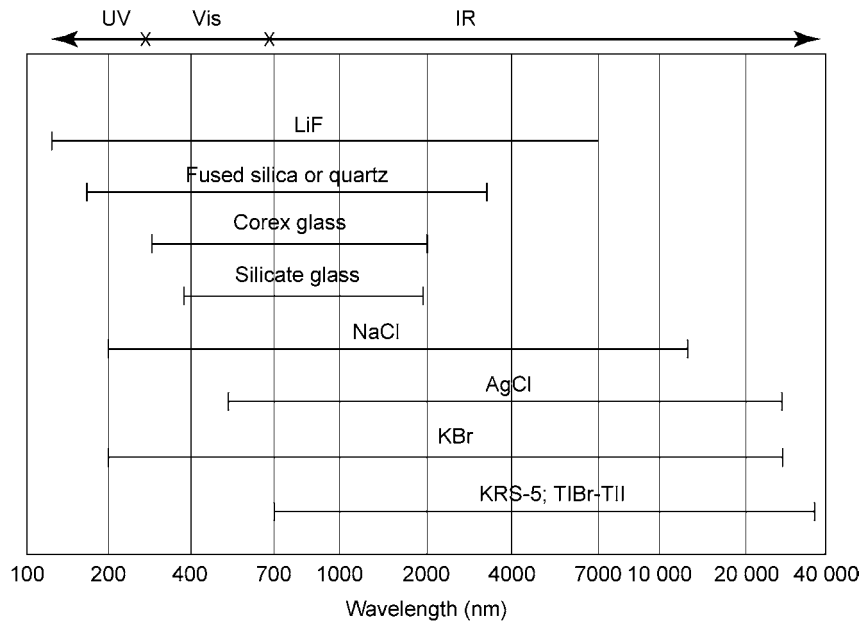

Figure 32.9 Transmittance ranges for various optical materials. (From Skoog *et al*. 1996, p. 529.)

Solvents

Solvents used in spectrophotometry must meet certain requirements to ensure successful and accurate results. The solvent chosen must dissolve the sample, yet be compatible with cuvette materials. The solvent must also be relatively transparent in the spectral region of interest. To avoid poor resolution and difficulties in spectrum interpretation, a solvent should not be used for measurements near or below its UV cut-off (i.e. the wavelength at which absorbance for the solvent alone approaches one absorbance unit). The cut-offs of common solvents are listed in Table 32.1.

Once a solvent is selected on the basis of its physical and spectral characteristics, its purity must be considered. The absorbance curve of a solvent, as supplied, should be smooth (i.e. have no extraneous impurity peaks in the spectral region of interest). Solvents specially purified and certified for spectrophotometric use are available from suppliers.

Good laboratory practice

According to GLP, chemicals, reagents and solutions should be labelled to indicate identity (with concentration if appropriate), expiry date and specific storage instructions. Information concerning source, preparation date and stability should be available. The expiry date may be extended on the basis of documented evaluation or analysis.

Records, including test-item and reference-item characterisation, date of receipt, expiry date, and quantities received and used in studies should be maintained. Handling, sampling and storage procedures should be identified in order that the homogeneity and stability are assured to the degree possible, and that contamination and mix-up are precluded. Storage containers should carry information on identity, expiry date and specific storage instructions. The stability of test and reference items under storage and test conditions should be known for all studies.

Fluorimetry and spectrofluorimetry

Cells

Specimen cells used in fluorescence measurements may be round tubes or rectangular cells similar to those used in absorption spectrophotometry, except that they are polished on all four vertical sides. A convenient test specimen size is 2–3 mL, but some instruments can be fitted with small cells holding 100–300 µL or with a capillary holder that requires an even smaller amount of specimen.

Temperature regulation is often important in fluorescence spectrophotometry. For some substances, fluorescence efficiency may be reduced by as much as 1–2% per degree of temperature rise. In such cases, if maximum precision is desired, temperature-controlled sample cells are useful. For routine analysis, it may be sufficient to make measurements rapidly enough that the specimen does not heat up appreciably from exposure to the intense light source (US Pharmacopeial Convention 2002).

Solvents

Change of solvent may markedly affect the intensity and spectral distribution of fluorescence. It is inadvisable, therefore, to alter the solvent specified in established methods without careful preliminary investigation. Many compounds are fluorescent in organic solvents, but virtually non-fluorescent in water; thus, a number of solvents should be tried before it is decided whether or not a compound is fluorescent. In many organic solvents, the intensity of fluorescence is increased by elimination of dissolved oxygen, which has a strong quenching effect. Oxygen may be removed by bubbling an inert gas, such as nitrogen or helium, through the test specimen.

Interpretation of spectra and qualitative analysis

Ultraviolet and visible spectrophotometry

Spectrophotometric measurements with UV or visible radiation are useful for detecting components that contain unsaturated groups or atoms such as sulfur or halogens. A drug, its impurity or a metabolite can also be transformed selectively so that the spectrum is shifted to the visible region and away from interference caused by another drug, formulation components or biological substances, and thereby confer a further degree of specificity.

However, specific identification of a compound can rarely be made on the basis of UV spectral evidence alone. Often, the spectrum serves as confirmatory evidence of identity, in support of other analytical data. The general approach usually followed in qualitative applications is first to establish by independent means (e.g. chromatography) that the material consists substantially of one absorbing component. Spectra are then recorded in aqueous acidic, basic, and ethanolic or methanolic solution. The wavelengths of the principal peaks and the corresponding absorptivity values are noted for each solvent system. By comparison with data tabulated in ascending wavelength order (see Ultraviolet Absorption Maxima in Indexes of Analytical Data), a number of compounds with absorbing properties similar to the test substance are selected (using a wavelength window of ± 2 nm). One must be aware that, in general, the spectrum of metabolites of a component matches closely the spectrum of the component itself.

Further evidence can be deduced from the absorptivity ratios of peaks within a spectrum; moreover, the change in these ratios together with the shift in peak positions as the pH is changed can be diagnostic. If a drug molecule ionises reversibly (i.e. without degradation), the family of curves for a constant concentration in acidic and basic solvents displays one or more isosbestic points at characteristic wavelengths, at which the absorbance is constant at all values of pH.

Spectral shifts are among the most useful diagnostic features in drug molecules that possess ionisable groups. A marked *bathochromic shift* (or 'red' shift) to longer wavelengths in alkaline solution is observed not only for most of the phenolic drugs, such as the phenolic oestrogens, but also in the case of hydroxypyridines, ketones, benzodiazepines, pyridones and nitro-compounds. The bathochromic shift is often large ($<$10 nm) and accompanied by an increase in molar absorptivity (*hyperchromic effect*) and loss of any fine structure.

This effect has been exploited, both for qualitative and for quantitative purposes, for the analysis of barbiturates. In acidic or neutral solution, barbiturates show little absorption above 230 nm (Fig. 32.10), but in 0.05 mol/L borax buffer (pH 9.2) ionisation yields an intense conjugated chromophore (Figs 32.10 and 32.11) with a well-defined maximum near 240 nm ($A^{1}_{1} = 400$–450). In sodium hydroxide solution (pH 13), a second stage of ionisation occurs (except in *N*-substituted derivatives) to extend further the conjugation and give a peak maximum near 255 nm (Figs. 32.10 and 32.11). However, solutions in alkali are unstable through ring opening, so that measurements must be made rapidly.

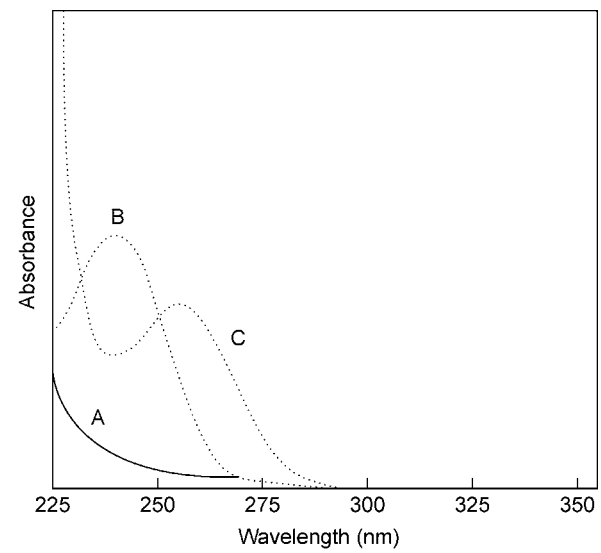

Figure 32.10 Effect of pH on the UV spectrum of phenobarbital: A, non-ionised barbiturate in 0.1 mol/L hydrochloric acid; B, mono-anion in 0.05 mol/L borax buffer pH 9.2; C, di-anion in 0.5 mol/L sodium hydroxide pH 13.

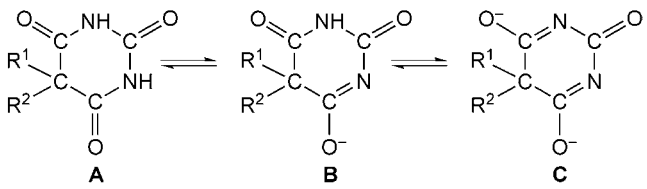

Figure 32.11 Dissociation of C5-substituted barbituric acids: (A) undissociated free acid; (B) mono-anion; (C) di-anion.

The *hypochromic* or 'blue' shift to shorter wavelengths is shown by aromatic amines in acid solution and is highly characteristic for many drugs. On acidification, the protonated quaternary ammonium group no longer participates in the chromophore so that the spectrum is shifted to lower wavelengths, sometimes by as much as 30 nm, with a sharp fall in absorptivity (*hypochromic effect*).

In addition to their use in characterising a chromophore, pH-induced shifts can also be exploited to shift a spectrum along the wavelength scale to obtain an interference-free window for measurement of an ionisable species in a mixture.

Solvent effects

A solvent for UV and visible spectroscopy must be transparent throughout the region of interest and should dissolve a sufficient quantity of the sample to give well-defined peaks. Moreover, consideration must be given to possible interactions with the absorbing species. For example, polar solvents, such as water, alcohols, esters and ketones, tend to suppress vibrational fine structure and should thus be avoided when spectral detail is desired. Non-polar solvents, such as cyclohexane, often provide spectra that more closely approach those of a gas (see also Fig. 32.1). In addition, the polarity of the solvent often influences the position of absorption maxima. Consequently, a common solvent must be employed when comparing spectra for the purpose of identification.

When using an HPLC-UV system, any effects on the spectral characteristics of a substance brought about by various mobile phases must be considered when comparing spectra generated in this manner with those recorded from acidic, neutral and alkaline solutions. Moreover, potential effects brought about during gradient elution HPLC, in which the composition of the mobile phases is constantly changing, should be borne in mind. With acetonitrile, methanol, ethanol, isopropanol and other water-miscible solvents, no essential changes in the spectra may occur and direct comparison with other databases is feasible. However, changes in pH can have a significant effect on the UV spectra of compounds involved in an acid–base equilibrium (e.g. carboxylic acids, phenols, thiophenols) and compounds with basic nitrogen atoms. Direct comparison of spectra with other compendia of data, including those listed in this volume, is valid only when the mobile phases have the same pH.

Spectrofluorimetry

For compounds with appropriate fluorescence properties, this technique gives high sensitivity and high specificity. High sensitivity results from the difference in wavelengths between the exciting and fluorescence radiation. This results in a signal contrasted with an essentially zero background; it is always easier to measure a small signal directly than a small difference between two large signals, as is done in absorption spectrophotometry. High specificity results from dependence on two spectra, the excitation and emission spectra, and the possibility of measuring the lifetimes of the fluorescent state. Although in biological samples the fluorescence intensity of interfering substances may be relatively high, the sensitivity and selectivity of the method are generally such that fluorescent drugs and their metabolites can be analysed more readily than by conventional spectrophotometry. Two compounds that are excited at the same wavelength, but emit at different wavelengths, are readily differentiated without the use of chemical separation techniques. Likewise, two compounds may fluoresce at the same wavelength but require different excitation wavelengths. Also, a fluorescent compound in the presence of one or more non-fluorescent compounds is readily analysed fluorimetrically, even when the compounds have overlapping absorption spectra. Non-fluorescent or weakly fluorescent compounds can often be reacted with strong fluorophores, which enables them to be determined quantitatively.

Many fluorescent species contain ionisable groups with fluorescent properties sensitive to pH. In some cases only one of the ionised species may be fluorescent. Examples are the barbiturates, which fluoresce only at an elevated pH in the di-anionic form. Phenol fluoresces at pH 7, but at pH 12, when it is converted into its anion, there is no fluorescence. Therefore, the relationship of fluorescence intensity with pH should always be examined as part of the method development.

Fluorescence intensity and wavelength often vary with the solvent. In most molecules, fluorescence decreases with a decrease in solvent viscosity as the probability of intermolecular energy transfer tends to be enhanced. The same effect occurs with an increase in temperature.

Quantitative analysis: ultraviolet and visible spectrophotometry

Fundamental basis

The basic principle of most spectrophotometric measurements involves comparing, under well-defined conditions, the absorption of radiation by the substance in an unknown amount with the same absorption of radiation by a known amount of the material being determined. In general, to obtain the maximum sensitivity it is best to work with radiation of a wavelength that is approximately equal to that for which the solution exhibits a maximum selective absorption.

Assuming that the linear range for compliance with the Beer–Lambert law has been established and that the drug concentration has been adjusted within the optimum range for the type of instrument concerned, two approaches to quantification may be employed. If an acceptable reference standard of the drug is available, and if the calibration graph passes through zero, measurement of replicates of the standard (at a comparable concentration) and of the tests are performed in bracketing sequence (i.e. each group of samples is preceded and followed by the standard), under identical conditions of solvent and temperature and using the same pair of matched cells. Each result should be corrected for the cell constant; the concentration of the test sample is then found by reference to the results from the standards.

Alternatively, the specific absorbance is used to calculate the sample concentration, using the absorbance measured in the specified solvent. A check on the accuracy of the absorbance scale is clearly essential. Wavelength accuracy is not so important.

The practical usefulness of reference-specific absorbance values (A_1^1) clearly depends on a number of factors. These include the state of purity of the substance, the solvent conditions originally used to establish the reference data, the precise conditions employed in the reference instrument and the extent to which they correspond with those of a particular test laboratory. It is therefore wise to ascertain the status of any absorptivity data in the literature. In the monographs in Volume 2, the reliability of all A_1^1 values has been assessed and indicated (see General Notices). However, if a sample of the drug concerned is available in pure form, it is good practice to establish periodically a 'local' value of the absorptivity and to use this in calculating sample concentrations.

Linearity issues

The validity of the Beer–Lambert law should be established for each drug under the measurement conditions to be used over an appropriate concentration range. For single-beam instruments, the absorbance range for precise measurements is between about 0.3 and 0.6 absorbance units, the optimum being at 0.43 absorbance units. For double-beam spectrophotometers, the optimum range lies between 0.6 and 1.2 absorbance units. Five or more standard solutions, with absorbances that span the working range, should be measured in duplicate in a matched pair of cells against the solvent as reference;

the residual absorbance difference between the cells when filled with solvent (the cell constant) should be subtracted from each individual measurement and checked regularly.

The linearity of an analytical method is determined by mathematical treatment of the absorbance data of the standard solutions across the claimed range of the method. The treatment is normally a calculation of a regression line $y = ax + b$, with y being the absorbance and x the concentration, by the method of least squares. The linearity is usually expressed by means of a correlation coefficient r, where

$$r = \frac{\sum_i (c_i - \bar{c})(A_i - \bar{A})}{\sqrt{\left(\sum_i (c_i - \bar{c})^2\right)\left(\sum_i (A_i - \bar{A})^2\right)}} \quad (32.28)$$

for all n points with i from unity to n. When $r = 1$, there is perfect correlation. Usually, r values better than 0.995 can be obtained.

The intercept should not differ significantly from zero. If a significant non-zero intercept is obtained, it should be demonstrated that there is no effect on the accuracy of the method.

Frequently, the linearity is evaluated graphically in addition or alternatively to a mathematical evaluation. The evaluation is made by visual inspection of a plot of absorbance A as a function of analyte concentration c. If any systematic positive or negative deviation is found, additional points should be inserted and the linear working range established.

Deviations from linearity are sometimes difficult to detect, and two additional graphic procedures can be used. The first is to plot the deviations from the regression line against the concentration, or the logarithm of the concentration if the concentration range covers several decades. For linear ranges the deviation should be distributed equally between positive and negative values.

Another approach is to plot the function A/bc (the absorptivity) on the y-axis and the corresponding concentrations on the x-axis. The line obtained should be horizontal over the full linear range. Parallel horizontal lines are drawn on the graph that correspond to, for example, 95% and 105% of the plotted line. The method is then linear up to the point where the plotted relative response line intersects one of these two lines.

International Conference on Harmonisation validation criteria

The main objective of validation of an analytical procedure is to demonstrate that the procedure is suitable for its intended purpose. The objective of an analytical procedure should be understood clearly, since this will govern the validation characteristics that need to be evaluated. Typical validation characteristics that should be considered according to the International Conference on Harmonisation of Technical Requirements for Registration of Pharmaceuticals for Human Use (ICH) are accuracy, precision (repeatability and intermediate precision), specificity, detection limit, quantification limit, linearity and range. All these characteristics are also listed and explained in the USP 25 (US Pharmacopeial Convention 2002). For the quantitative determination of impurities, all these criteria should be evaluated, while for limit tests the specificity and detection limit are most relevant. For assays, all characteristics except detection limit and quantification limit are normally evaluated.

For linearity, the ICH recommends a minimum of five concentrations to be measured. The range is allocated the following limits:

- For the assay of a drug substance or a finished (drug) product – normally from 80% to 120% of the test concentration.
- For content uniformity – covering a minimum of 70–130% of the test concentration, unless a wider more appropriate range, based on the nature of the dosage form (e.g. metered-dose inhalers), is justified.
- For dissolution testing – ±20% over the specified range.
- For the determination of an impurity – from the reporting level of an impurity to 120% of the specification.
- If assay and purity are performed together as one test and only a 100% standard is used, linearity should cover the range from the reporting level of the impurities to 120% of the assay specification.

To determine the accuracy, use of a minimum of nine determinations over a minimum of three concentration levels that cover the specified range is recommended.

Repeatability should be assessed using a minimum of nine determinations that cover the specified range for the procedure (e.g. three concentrations with three replicates each) or a minimum of six determinations at 100% of the test concentration.

To determine the detection limit, the ICH recommendations correspond with the USP 25 and can be determined, for example, on the basis of signal-to-noise ratios, where 2 : 1 or 3 : 1 is generally accepted, or on the standard deviation of the blank.

To calculate the quantification limit, both ICH and USP 25 recommend a signal-to-noise ratio of 10 : 1. Both USP 25 and the ICH recommend explicitly validation of the quantification limit by the analysis of a suitable number of samples known to be near or prepared at the quantification limit.

Quantitative analysis: fluorimetry

Fundamental basis

Excitation spectra are usually used to confirm the identity of components and to select an optimum excitation wavelength for quantitative analysis. The emission spectrum is then used for analytical applications.

Spectrofluorimetry differs from absorption spectrophotometry in not yielding an absolute scale of values, as it depends on the number of excited molecules and their method of relaxation. For this reason it is essential to employ a reference standard for quantitative measurements.

The linear relationship between the power of fluorescence and the concentration of the fluorescing solute forms the basis for quantification, the linearity constant for which may be established by calibration with standards. A plot of fluorescence readings against the concentration of the reference solutions furnishes the calibration curve. Glass reference filters are also suitable as a calibration standard.

Linearity and baseline issues

In dilute solution, the fluorescence intensity (I_f) for defined values of λ_{ex} and λ_f is related linearly to molar concentration (c), according to the approximate relationship:

$$I_f = Kc \text{ at } \lambda_{ex},\ \lambda_f$$

under constant instrumental conditions.

Sensitivity can be increased by working at high excitation powers to give larger signal-to-noise ratios. Since the source intensity can change from time to time, fluorescence signals are not measured as absolute parameters. They are expressed rather in terms of relative fluorescence. All measurements are made relative to reference standards of known concentration. All readings must be corrected for background fluorescence.

A necessary condition is that the total absorbance ($=\varepsilon bc$) of the system should not exceed 0.05 absorbance units, otherwise progressively greater negative deviations from linearity are observed. At high drug concentrations, fluorescence intensity reaches a plateau. Beyond this, fluorescence intensity actually decreases with increasing concentration, because of inner-filter effects, in which ground-state molecules absorb the fluorescence emitted by excited molecules.

It is essential to establish the range of linearity of the calibration curve *of* I_f versus c, using at least five standard solutions, for which the condition holds that absorbance at the wavelength of maximum excitation is <0.05 absorbance units. Samples are usually analysed by single-point bracketing, taking a standard conveniently close to the anticipated sample value and calculating the result by simple proportion.

The sequence of standard measurements before and after measuring the sample permits any baseline drift to be compensated. For additional assay security, two-point bracketing can be employed, in which two standard solutions, one higher and the other lower than the concentration observed for the sample, are used in bracketing sequence.

Instrumental limitations caused by instability of the radiative source can be overcome by the ratio mode operation. A small fraction of the exciting radiation is directed to a reference photodetector, which is chosen primarily for wide wavelength response. The output signal is used as a monitor and, as the excitation radiation increases or decreases in power because of fluctuations in the source, there is a corresponding increase or decrease in relative fluorescence.

CHAPTER

33 Infrared Spectroscopy

RD Jee

Introduction

The absorption of infrared (IR) radiation is a very characteristic property of a substance and is widely used for identification purposes. Infrared spectroscopy is the study of the scattering, reflection, absorption or transmission of IR radiation in the spectral range 800–1000 000 nm (0.8–1000 μm). In older literature (pre-1970), IR radiation was referred to in terms of its wavelength in units of microns (micrometres, μm). Nowadays, the wavenumber ($\tilde{\nu}$) is used almost exclusively. The relationship between wavenumber in units of reciprocal centimetres (cm^{-1}) and wavelength (λ) in micrometres (μm) is given by:

$$\tilde{\nu} = \frac{10^4}{\lambda}$$

The IR spectrum can be divided into three subregions: 12 500–4000 cm^{-1} (0.8–2.5 μm; near IR), 4000–400 cm^{-1} (2.5–25 μm; mid-IR) and 400–10 cm^{-1} (25–1000 μm; far IR). Only the mid-IR region (often referred to simply as infrared) is considered here because it is the region widely used in the analysis of drugs and pesticides. However, some modern instruments can scan from 15 000 cm^{-1} to about 50 cm^{-1}; the extension to the far IR is useful for halogenated compounds and for inorganic substances.

The energy associated with electromagnetic radiation is given by Planck's equation:

$$E = \frac{hc}{\lambda}$$

where E is the energy, h is Planck's constant, c is the speed of light and λ is the wavelength of light.

IR radiation can excite molecular vibrations (and associated molecular rotations). At room temperature, a molecule is generally in its ground electronic state and lowest vibrational state. Provided that the incoming IR radiation has the appropriate energy (wavelength, wavenumber), resonant absorption occurs to excite the molecule to a particular higher vibrational state. Vibrational transitions give rise to an absorption spectrum characteristic of the compound. Several factors characterise this absorption spectrum: the number of absorption features and their associated wavenumbers, the strength (intensity) of the absorption features and the sharpness of these features.

Energy and wavenumber of infrared absorption by molecular vibration

Molecules can undergo two types of vibrations, namely stretching vibrations that involve changes in bond length and bending vibrations that involve changes in bond angles. The vibrational modes associated with the methylene CH_2 group are illustrated in Fig. 33.1.

Theoretically, a non-linear molecule has $(3N-5)$ such modes of vibration, where N is the number of atoms in the molecule. A linear molecule has $3N-6$ modes of vibration. These are called fundamental modes and require IR energy in the range 4000–400 cm^{-1} (mid-IR) to become excited. Not all vibrations in a molecule are assignable; generally, only the most prominent are readily assigned to a given vibrational mode. These characteristic vibrations are a good way to detect the existence of functional groups in a chemical compound. The precise wavenumber at which a particular vibration absorbs light is associated with bond strength and the atomic masses of the atoms in the bond. The wavenumbers required for the excitation of typical vibrations are given in Table 33.1.

In addition, there are overtones (the excitation of a vibration to a double or higher frequency) and combinations that are the sum or difference of two or more fundamental bands. No fundamental vibrations require energy greater than 4000 cm^{-1} to become excited. All vibrations in the near IR are therefore overtones or combination bands. The reader is referred to spectroscopic texts for a more detailed explanation of the origin of IR bands (e.g. Williams, Fleming 2007, and others listed in the Further reading).

Changes in the wavenumber of a band can be related to changes in either the structural environment or the physical state of the molecule. However, many bands in the complex region from 1800 cm^{-1} to 400 cm^{-1}, which is usually referred to as the 'fingerprint region', remain of unconfirmed origin. Many of the bands are characteristic of the molecule as a whole and cannot be assigned directly to particular bonds. Nevertheless, inspection of IR spectra can form the basis of qualitative analytical work in IR spectroscopy to confirm the identity of a sample. A complete molecular structure cannot be deduced directly from an IR spectrum. Rather, functional groups are identified and total molecular identity is confirmed by comparison with IR spectra in a spectral library.

Strength of molecular vibration absorption

Traditionally, an IR spectrum is reported as a plot of percentage transmittance ($T\%$) against wavenumber $\tilde{\nu}$. Increasingly, spectra are reported as a plot of absorbance against wavenumber. The IR transmission spectrum of a polystyrene film used to calibrate the wavenumber scale is given in Fig. 33.2.

The absorption of light in Fig. 33.2 is registered as the transmission of light. The simple ratio of the transmitted intensity to the incident intensity is known as the transmittance. The percentage transmittance is 100 times the transmittance (Fig. 33.3).

The absorption of light is quantified through Beer's law as:

$$A = \log(I_0/I_t) = cl$$

where A is the absorbance, c is the molar concentration (mol/L), l is the path length (m) of the sample and ε is the molar extinction coefficient (L/mol per cm). Absorbance is the log of the inverse of transmittance:

$$A = \log(I_0/I_t) = \log(1/T) = -\log T = 2 - \log T\%$$

Not all vibrational modes are 'active' in the IR region. For absorption of radiation, the act of vibration must cause the dipole moment to change. The carbonyl (C=O) stretch at around 1650 cm^{-1} has a particularly strong transition electric dipole moment (i.e. large change in dipole moment), and therefore ε is large for a vibration (approximately 100 mol/L per cm) and the carbonyl absorption is a very prominent feature. The C=O stretch is said to be allowed spectroscopically. The C–H stretching mode generates a lower transition electric dipole

moment and the ε value is smaller at approximately 10 mol/L per cm. However, there are usually many C–H bonds in a molecule and the additive absorption of these makes the C–H vibration a prominent feature.

The stretches of symmetrical bonds, such as H–H (hydrogen gas), –C–C– (ethane), O–O (oxygen) and N–N (nitrogen), do not have a transition dipole moment and therefore ε→0 mol/L per cm and these stretches are not observed and are said to be forbidden. Similar vibrations in complex molecules do absorb, but extremely weakly. On the other hand, gases such as NO, NO_2, CO, CO_2, SO_2, CH_4 and H_2O (water vapour) do have IR-active vibrations that can be measured to monitor environmental levels. The low value of ε and low concentrations of these gases mean that gas cells for IR spectroscopy are very long (up to 1 m or more). Water vapour and CO_2 present in the normal atmosphere produce absorption effects in an IR spectrometer in the absence or presence of a sample. High-precision work therefore benefits from flushing with dry air or nitrogen. The water vibrations centred at 3782 cm^{-1} and 1587 cm^{-1} show a fine structure associated with the rotations of the water molecule.

The actual movement of charge during a vibration is in practice very small and a value of ε of approximately 200 mol/L per cm is a practical upper limit. In tables of IR data, the intensity of vibrational bands is designated as 'vs' (very strong), 's' (strong), 'm' (medium) and 'w' (weak) to reflect the variation in extinction coefficient (intensity of spectral feature). For older designs of instrument the measurement of IR intensity was unreliable, which made quantitative work in the IR unreliable. This is not true for modern instruments.

The spectroscopic character of overtones and combinations is less well defined. Accordingly, ε in the near IR is low and absorption is detected only for concentrated solutions with an absorption that may be too strong for spectral regions in which ε is larger. The molar extinction coefficient, ε, is largely responsible for setting the sensitivity of an analysis.

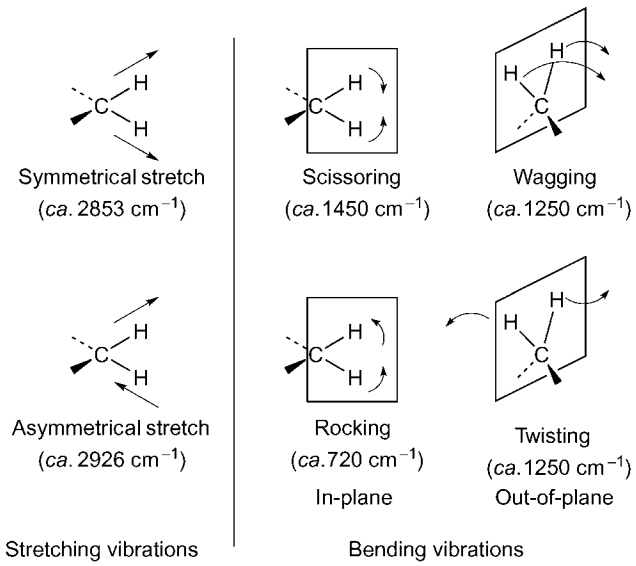

Figure 33.1 Molecular vibrations of the methylene CH_2 group (courtesy of Pavia *et al*. 1996).

Table 33.1 Important vibrations and IR frequencies	
Wavenumber (cm^{-1})	***Vibration***
3600–2500	O–H stretch, broad, strong (prominent)
3400	N–H stretch, broad, strong (prominent)
3000	C–H aromatic stretch
2900	C–H aliphatic stretch
1800–1650	C=O stretch strong (prominent)
	Ester R–O–C=O, ca. 1740 cm^{-1}
	Ketone C=O, ca. 1715 cm^{-1}
	Carboxylic acid HO–C=O, ca. 1705 cm^{-1}
	Amide H_2N–C=O, ca. 1650 cm^{-1}
1300–1000	C–O stretch, strong
1800–400	Forest of vibrations – fingerprint region

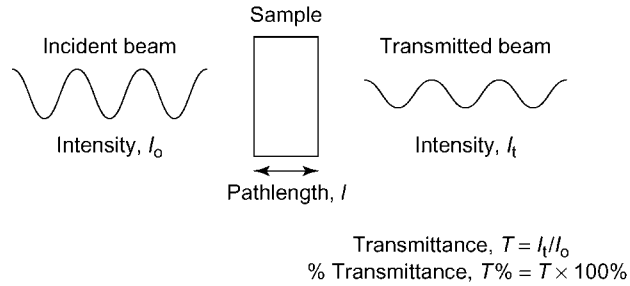

Figure 33.3 Transmission of light by a sample.

Width of an infrared absorption band

In ultraviolet (UV) and visible electronic absorption spectroscopy, absorption is limited to the excitation of a single electron in a chromophore, albeit to one of several excited states. An electronic spectrum is rarely composed of more than three prominent spectral features. However, the energy required to excite an electron is enough also to excite associated vibrational and rotational states, and the absorption profile is broad. The UV-visible spectrum is characterised by only a few broad features. A typical half-height width of a UV-visible absorption is between 2000 and 5000 cm^{-1}.

The IR spectrometer sees the excitation of bond vibrations and associated rotational motions. The IR spectrum comprises many relatively sharp features that provide an excellent fingerprint for identification. A typical half-height width of an IR absorption band is 10–20 cm^{-1}.

Instrumentation

IR spectrometers consist of three basic components: radiation source, monochromator or interferometer, and detector. Fourier transform IR (FTIR) spectrometers are the most widely used and no major instrument manufacturer provides dispersive instruments any longer.

Dispersive spectrometers

Conventional spectrometers start with an appropriate light source focused onto the entrance slit of a monochromator that splits the light up into its wavelength components. The monochromator exit slit selects a particular emerging wavelength. The monochromatic light passes through a sample, where it may or may not be absorbed before being detected by a light detector (photomultiplier or photodiode). This type of spectrometer is known as a dispersive instrument. To measure transmittance or absorbance, both the incident intensity I_0 and the transmitted intensity I_t need to be measured at every wavelength.

Single-beam dispersive spectrometers

With a single-beam instrument, the I_0 spectrum is measured first with air (or solvent) as a reference in the light beam. In a separate measurement the I_t spectrum of the sample is recorded. Interfacing with a computer allows data to be stored and processed automatically. To ensure accuracy and precision, all components in the instrument (light source, detector and electronics) need to be very stable to ensure that I_0 does not drift.

Nowadays, single-beam dispersive IR spectrometers are likely to be found only in monitoring processes (e.g. environmental pollution). The FTIR spectrometer described below normally operates as a single-beam instrument.

Double-beam spectrometer

Double-beam spectrometers are designed to compensate for instrument drifts and the need to determine I_0 and I_t in separate measurements. The layout of a typical double-beam spectrometer is illustrated in Fig. 33.4. Dispersive instruments in the infrared have the sample located next to the light source before the monochromator, unlike their UV-visible counterparts.

IR light from the source, typically an electrically conducting element such as a Globar maintained at about 1300 K, illuminates equally two mirrors M_1 and M_2. The light from mirror M_1 acts as the reference beam; the light from M_2 is the sample beam. Mirrors M_3 and M_4 send the light beams to mirrors on a mechanical chopper. The mechanical chopper is a rotating disc carrying mirrors that alternately reflect the reference and sample beams into the monochromator. After passage through the monochromator, monochromatic light from the sample and reference beams is detected alternately by the single detector as the wavelength drive changes the wavelength that passes through the system. In the reference-beam chopper period the detector registers I_0 and in the sample-beam chopper period I_t is measured. The alternating signals are amplified and their ratio is calculated to give $I_t/I_0 = T$ or $\log(I_0/I_t) = A$. The preferred detector, certainly by the 1980s, was deuterated triglycine sulfate (TGS). This is a pyroelectric detector with an electrical resistance very sensitive to heat (IR intensity).

All measurements can be made simply with air in the reference beam. Placing a cell with solvent in the reference beam enables compensation for unwanted absorption (e.g. from solvents). The measurement cell path lengths in the reference and sample beams must be identical. A computer interfaced with the spectrometer enables post-measurement subtraction of a reference spectrum from the sample spectrum.

The amount of polychromatic IR light that hits the detector from the natural room-temperature black-body radiation of the cell compartment walls can be 10-fold or more than the desired monochromatic IR radiation from the reference or the sample. This background radiation is stray light that severely affects the accuracy of the I_0/I_t value. Locating the sample before the monochromator ensures that the 'chopped' signal selected by the detector system is related almost exclusively to light derived from either the sample or the reference beams. Artificial reduction of absorbance values is thereby greatly reduced. However, locating a sample close to an IR source can cause deleterious heating effects.

Interferometric spectrophotometers

FTIR spectrometers have the sample next to the detector after wavelength selection. This reduces heat effects from having a sample in proximity to an IR source. Locking into the mirror oscillation frequency coupled with the signal filtering associated with the Fourier transform and the improvements in optics and detectors makes this preferred sample position viable.

The FTIR spectrometer incorporates an interferometer in place of a monochromator. The way a FTIR spectrometer operates is presented here with reference to Fig. 33.5.

If the mirror M_1 is set to oscillate along the optic axis, the distance travelled by beam (B + D) varies, while the distance travelled by (C + E) remains unchanged.

Identical (B + D) and (C + E) distances means that D and E are in phase and recombination is fully constructive. As mirror M_1 moves towards the beam splitter, the beam D arrives 'ahead' of beam E;

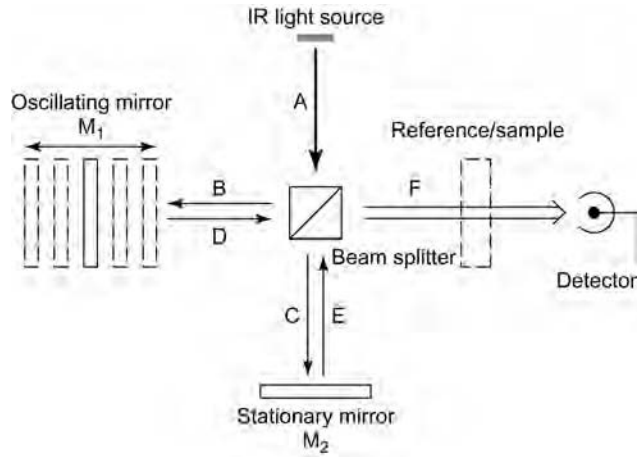

Figure 33.5 Layout of an IR interferometer (FTIR spectrometer).

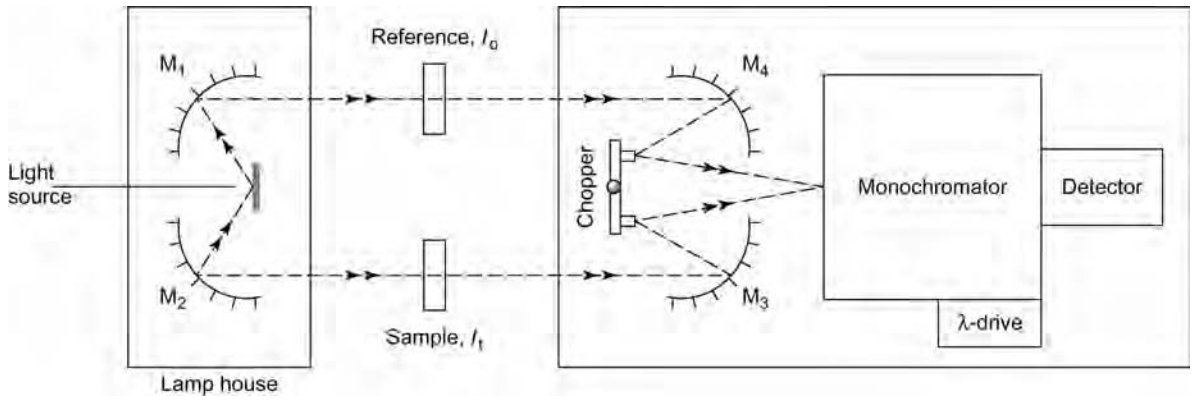

Figure 33.4 Double-beam dispersive IR spectrometer.

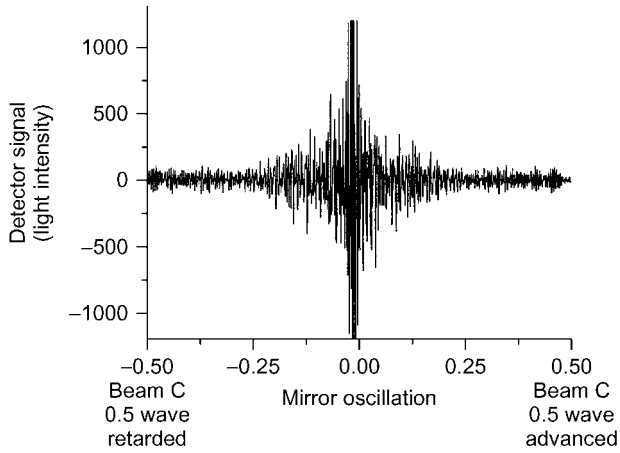

Figure 33.6 Interferogram produced by a single mirror oscillation.

recombination is not fully constructive and the intensity of beam F is reduced and its phase changes. Eventually the mirror movement of M_1 leads to beam D being a half-wave ahead of beam E. The recombination is now fully destructive and the intensity of beam F becomes zero. At this point, the movement of M_1 is reversed past the oscillation mid-point to eventually make D retarded compared with E to give zero intensity at half-wave retardation before returning to the mid-point of the oscillation.

- As the mirror moves back and forth through a single mirror oscillation period, the intensity of a single wavelength of IR light varies considerably. In practice, all wavelengths are passing through the system simultaneously. Accordingly, the total IR light intensity registered as falling on the detector during a single mirror oscillation period is very complicated and takes the form illustrated in Fig. 33.6.
- The signal illustrated in Fig. 33.6 is now subjected to a mathematical procedure called a Fourier transform. This extracts the light intensity versus wavelength (wavenumber) information.
- With no reference or sample in the beam, this measurement is the background or I_0 spectrum, which is stored in the computer to be used as the I_0 for all subsequent transmittance (I_t/I_0) or absorbance [$\log(I_0/I_t)$] measurements during the working session.
- A measurement is now made with the sample in place. A similar interferogram is created. This is also subjected to a Fourier transformation to produce a sample light-intensity throughput spectrum.
- Subsequent data manipulation in the computer produces the transmission or absorption spectrum of the sample.

Technical details

The IR source is a Globar or similar proprietary 'hot' element that operates at approximately 1300 K. The detector needs to have a fast response and low inherent noise. The TGS detector remains the most widely employed for routine use. Pyroelectric devices based upon lithium tantalate are becoming popular as they are less expensive, have greater ordinate linearity and present better temperature stability (TGS linearity falls off above approximately 32°C). For high-precision work with lower noise, liquid-nitrogen-cooled semiconductor detectors are available based on indium–antimonide (In–Sb), indium–gallium–arsenide (In–Ga–As) or mercury–cadmium–telluride (Hg–Cd–Te).

FTIR spectrometers have advantages over dispersive instruments. The interferometer offers greater light collection and throughput. More light means less noise and greater sensitivity. The multiplex advantage concerns the very nature of the interferometric measurement. All wavelengths are observed for a single scan at the same time. In a dispersive instrument, only one wavelength is detected at any one time. In the interferometer, more time is spent effectively measuring each wavelength, even though the total scan time may be the same. More time to measure each wavelength means lower noise and greater sensitivity.

Two options are available to the FT technique: either a spectrum can be scanned much faster than with a dispersive instrument or the same time as for the dispersive instrument can be spent measuring a spectrum to present lower noise results. In practice, a single mirror oscillation in the interferometer produces a spectrum scan in a fraction of a second. A dispersive instrument scan can take up to 10 min. Taking 10 min over an FTIR measurement allows the averaging of very many scans. The signal-to-noise (S/N) ratio in an IR spectrometer is proportional to the square root of the number of scans. Accumulating and averaging 1, 4, 16, 64, 256 or 1024 scans produces a signal-to-noise improvement of 1-, 2-, 4-, 8-, 16- or 32- fold, respectively.

- The level of stray light associated with FTIR spectroscopy is low, typically less than 0.02%, because the technique is devoid of imperfect gratings and the signals selected are associated only with the oscillating mirror movement. Absorbance values remain linear up to two absorbance units, which in turn leads to more accurate quantitative measurements, even with strongly absorbing bands.
- Resolution is generally excellent over the whole spectrum, with an effective measurement spectral bandwidth (SBW) of 1 cm^{-1} being achieved readily.

Data processing

All modern IR spectrometers are computer controlled, with measured data stored digitally. Computer control simplifies the process of running instruments and allows the easy implementation of standard operating procedures (SOPs). Although software is usually manufacturer specific, companies such as Galactic Industries among others have produced software (GRAMS/AI from Thermo Galactic, 395 Main Street, Salem, NH 03079, USA) that operates many instruments and certainly accepts data from effectively all spectrometers on the market.

Computers readily allow changes between spectral units. In the early days, the IR spectrum of a compound was reported as percentage transmittance as a function of wavelength in microns; by the 1970s percentage transmittance as a function of wavenumber became the preferred form. The computer allows the ready conversion between transmittance and absorbance and between microns and wavenumber. Presentation in terms of absorbance/wavenumber is likely to become increasingly more familiar.

Computers readily allow accumulation of spectra. The spectrum of a weak sample can be scanned repeatedly to give an averaged spectrum with appreciably reduced noise and an improvement in sensitivity. For example, there is little difference between the spectra of carbon disulfide and of benzocaine in carbon disulfide (Fig. 33.7), but with spectrum manipulation, a good spectrum of benzocaine is obtained readily

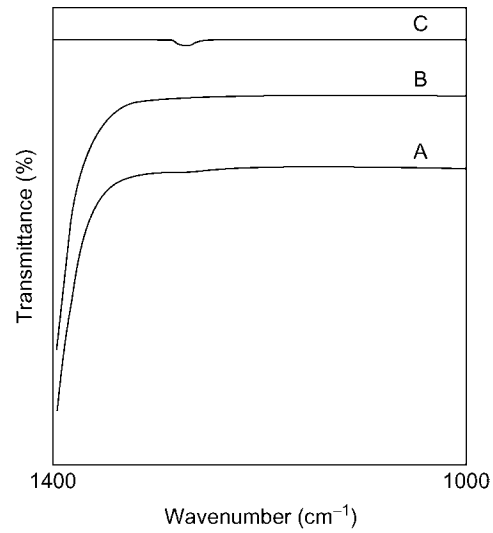

Figure 33.7 IR spectra of benzocaine in carbon disulfide (A) and of carbon disulfide (B). (C) is the the difference spectrum (A – B). (Courtesy of Perkin-Elmer Ltd.)

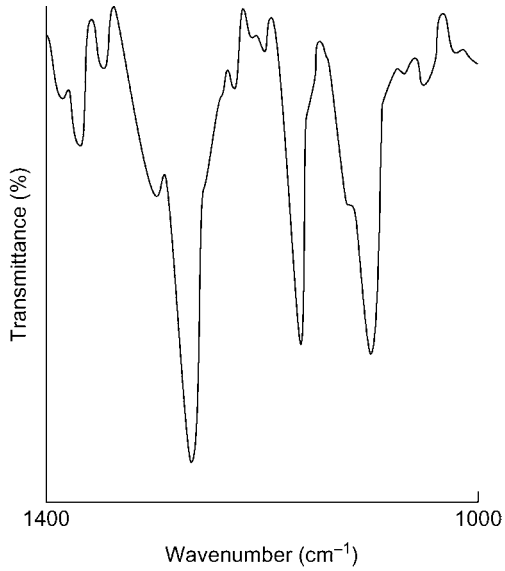

Figure 33.8 The difference spectrum of benzocaine shown in Fig. 33.7 smoothed, corrected for baseline contribution and with percentage transmittance scale expanded 200 times. (Courtesy of Perkin-Elmer Ltd.)

(Fig. 33.8). The amount of benzocaine in the cell was approximately 4 μg but only about a quarter of this was in the IR beam. Each spectrum was recorded in less than 30 s.

Digitised spectra can be corrected easily for solvent absorption or the presence of impurities. Various mathematical procedures can be applied, which include baseline corrections and levelling, smoothing, the determination of peak bandwidths and the calculation of absorption band areas. Derivative spectra can be produced to help distinguish the contributions of overlapping components in an absorption band.

The identification and interpretation of spectra are assisted greatly by computer analysis. Spectra can be readily overlaid for comparison. The spectrum of a sample can be compared with a library of spectra (database) and a list of the compounds of best fit can be either displayed on a screen or printed out. The presence of certain functional groups can also be confirmed.

Six factors need to be considered when calibrating an IR spectrometer:

- Wavelength (wavenumber) scale
- Absorbance scale
- Stray light
- Spectral resolution
- Data resolution
- Time scale of measurement (time constant).

Wavenumber (wavelength) scale

A card carrying an accredited transparent polystyrene film approximately 35 μm in thickness is used to calibrate the wavenumber (wavelength) scale, which should have the form illustrated in Fig. 33.2 and Fig. 33.9. Peak locations and tolerances recommended in the *British Pharmacopoeia* (2008) are given in the inset in Fig. 33.9.

Absorbance scale

Unfortunately, there are no internationally recognised standards for IR spectra. The absorbance scale is set in the factory with the aid of complicated optics. Filters are available in the 4000–2000 cm^{-1} range. The high background black-body radiation that falls on the detector from sources other than the sample means that the ideal absorbance for good signal-to-noise ratio is approximately 0.4.

Stray light

Stray light can be tested by introducing a neat solvent or very high-concentration sample into the sample beam so that at the wavelength (wavenumber) of interest the expected absorbance is in excess of $A = 5$. Effectively all the relevant light at this wavelength (wavenumber) has been absorbed.

Spectral resolution (spectral bandwidth)

In dispersive instruments, the SBW is set by the entrance and exit slits of the monochromator. In the FTIR spectrometer, the 'depth' of the Fourier transformation sets SBW with typical values of 1 cm^{-1}, 2 cm^{-1} and 4 cm^{-1} available in the spectrometer control software. The narrower the SBW the more faithfully are sharp absorption bands registered; however, the noisier the spectrum (less light), the more time (number of accumulations) is required to keep the noise level down.

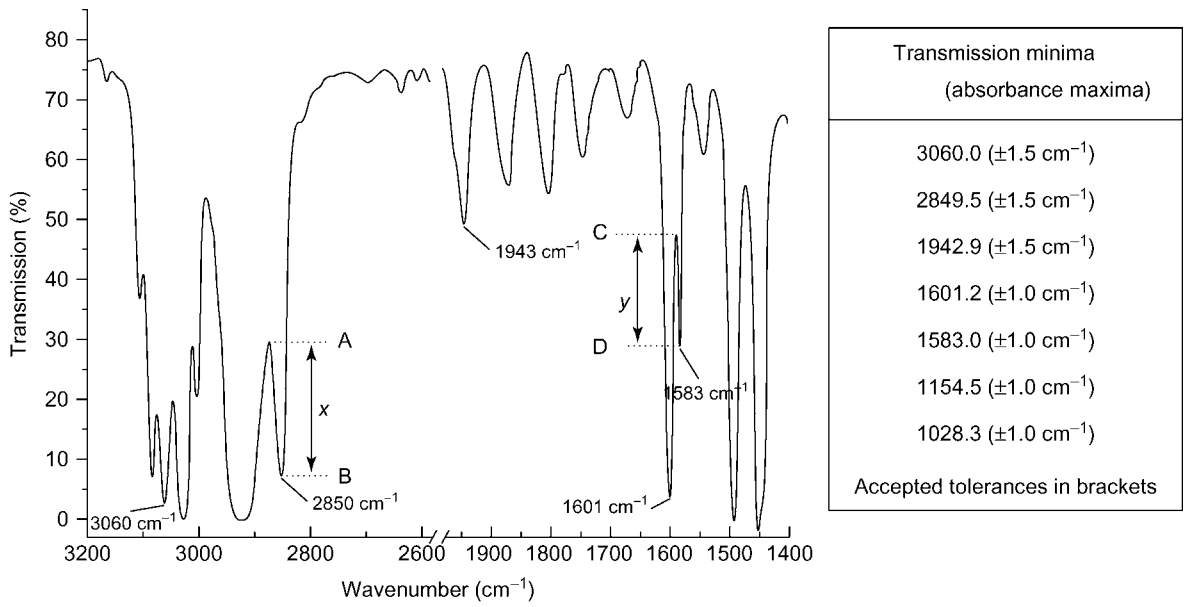

Figure 33.9 Zoomed-in regions of the IR spectrum of a 40 μm thick polystyrene film indicating the location of critical parameters. A whole spectrum is illustrated in Fig. 33.2.

The *British Pharmacopoeia* (2008) recommends the following to ensure good spectral resolution:

> For instruments having a monochromator, record the spectrum of a polystyrene film approximately 35 µm in thickness. The difference x [Fig. 33.9] between the percentage transmittance at the transmission maximum A at 2870 cm^{-1} and that at the transmission minimum B at 2849.5 cm^{-1} must be greater than 18. The difference y between the percentage transmittance at the transmission maximum C at 1589 cm^{-1} and that at the transmission minimum D at 1583 cm^{-1} must be greater than 10.
>
> For Fourier-transform instruments, use suitable instrument resolution with appropriate apodisation prescribed by the manufacturer. The resolution is checked by suitable means, for example by recording the spectrum of a polystyrene film approximately 35 µm in thickness. The difference between the absorbances at the absorption minimum at 2870 cm^{-1} and the absorption maximum at 2849.5 cm^{-1} is greater than 0.33. The difference between the absorbances at the absorption minimum at 1589 cm^{-1} and the absorption maximum at 1583 cm^{-1} is greater than 0.08.

This recommendation is very specific for a 35 µm thick film of polystyrene.

Data resolution

In a computer, spectra are stored as lists of wavenumber and transmittance (absorbance) data pairs. These X,Y data pairs are plotted on demand. A sufficient number of data points are required to give an undistorted picture. Too many points may be unnecessary and require excessive memory allocations. Figure 33.10 illustrates the effects of spectral and data resolution on the spectral integrity of the IR spectrum of a 40 µm thick polystyrene film.

The terms spectral resolution and data resolution are often confused. Some instruments, in modifying the Fourier transform mathematics to reduce the SBW, also produce a change in the data resolution of the spectra computed. The 1154 cm^{-1} band of polystyrene is reproduced in Fig. 33.10 measured with different SBW and data resolutions. Inspection of the spectra presented in Fig. 33.10 indicates that data resolution can be a more important issue than spectral resolution. In general, for typical drug molecules, a SBW of 4 cm^{-1} is probably sufficient to describe faithfully the natural bandwidth of a vibrational absorption band. However, a data resolution of 1 cm^{-1} is preferred to ensure that the measured data are a faithful representation of the capability of the spectrometer. Increasing SBW, reducing data resolution, or both, can reduce noise.

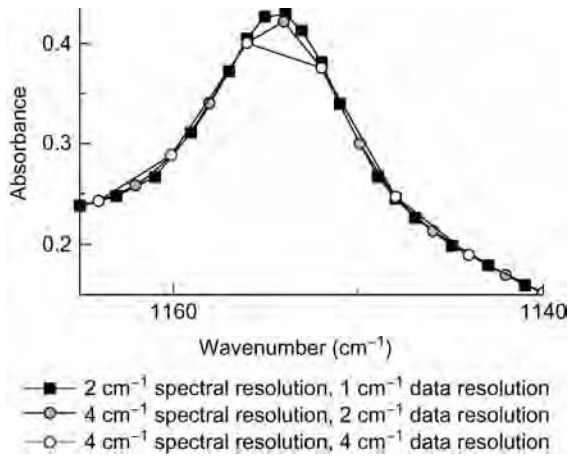

Figure 33.10 Zoomed-in region of the IR spectrum of a 40 µm thick polystyrene film illustrating the effect of SBW and data resolution.

Time scale of measurement (time constant, averaged scans)

In analogue dispersive instruments, the scan speed refers to the rate of rotation of the monochromator diffraction grating, which in turn controls the rate of change of the wavelength (wavenumber) that comes from the monochromator exit slit. The instrument has an inherent controllable response time (time constant). Scanning too fast means that measured peaks are distorted and flattened (reduced intensity); the instrument is being run too fast for the electronics to cope with the changing signal from the detector. A scan should be fast enough to avoid time wastage, yet slow enough to leave the spectrum undistorted. The lower the response time (time constant), the lower the noise but the longer the time required to measure spectra. The choice of time response versus scan speed is sample dependent and needs to be selected on the basis of experience.

In an FTIR spectrometer, the scan speed is set by the oscillation rate of the moving mirror and the computer Fourier transformation speed. A typical spectrum can be accumulated in a second or so. The instrument operator has no control of this. The time to measure an FTIR spectrum is set by the number of scans accumulated and averaged, and the speed of the computer (see Technical details earlier).

Sample preparation

A major advantage of IR spectroscopy is the ability to measure relatively heterogeneous materials and poorly characterised samples, particularly in condensed phases (e.g. creams, powders, crystalline materials). By their nature, these samples are often not chemically pure and IR spectroscopy can identify or confirm the existence of major constituents. IR spectroscopy is often used to demonstrate that a sample is concordant with expectation.

Nevertheless, it is essential to have pure samples to act as standards for IR spectroscopy. A major difficulty can be that of purifying and handling a few micrograms of material without substantial losses, although these problems have largely been overcome by using fractional crystallisation or chromatography as a prelude to IR spectroscopy. On-line FTIR spectroscopy is possible, but is largely a research tool. Nowadays, the identification of samples in minute amounts is achieved by other techniques, such as nuclear magnetic resonance (NMR) spectrometry (see Chapter 36) and mass spectrometry (MS) (see Chapter 37). This is particularly the case with 'hyphenated' techniques, which involve the use of spectrometric methods on-line with a chromatographic process. Nevertheless, IR spectroscopy has an important role to play in identifying functional groups.

However, the isolation of pure samples of an analyte for IR spectroscopy can still be an important issue. When the starting material is a residue from the evaporation of a solvent extract of urine, blood, tissue or other material, the most suitable method of purification is some form of chromatography.

Thin-layer chromatography

Suitable systems for thin-layer chromatography (TLC) are described in Chapter 39. Any of these systems is potentially useful when it is required to elute a spot, but reversed-phase systems should be avoided because it is difficult to remove the spot without the stationary phase, which would interfere with the IR spectrum. Furthermore, location reagents must be chosen with care, and a destructive reagent, such as the Marquis reagent for alkaloids, should not be used. Non-destructive reagents, such as iodoplatinate solution, can be used because the coloured complex is decomposable to yield the original compound. However, even this procedure may introduce extraneous peaks into the spectrum and, ideally, location reagents are best avoided. If the compound cannot be detected under UV light, it could be applied to the thin-layer plate twice and only a portion of the chromatogram sprayed, which thus allows the unsprayed portion to be eluted.

The use of aqueous acid or alkali to elute the compound from the thin-layer plate, followed by solvent extraction of the aqueous solution, is more efficient than direct solvent extraction of the adsorbent. In one

method of direct extraction, the adsorbent is scraped from around the spot, the glass adjacent to the spot is carefully cleaned and the adsorbent is eluted *in situ* directly onto a wall of potassium bromide (KBr) built around the tip of the spot. The KBr is then pressed into a disc. This technique is suitable only for well-resolved spots. Elution of the spot sideways reduces contamination from compounds that are not resolved as well. The recovery of material from chromatograms varies from nil to over 70%. Compounds that contain hydroxyl and carboxyl groups, which can readily form hydrogen bonds with the solid support, tend to be recovered in low yield. Considerable interference in the 1100 cm^{-1} region is found with some adsorbents and compounds.

In a variation of this method, the thin-layer adsorbent is placed in the bottom of a glass vessel together with a triangular 'wick' of compressed KBr. Solvent is added and it rises up the wick and evaporates from the upper region. The compound is conveyed up the wick by the solvent and accumulates at the tip of the triangle, which is then cut off, dried and used to prepare a disc. About 10 μg of compound is required to produce a satisfactory spectrum. The advantage of this technique is that the lower part of the KBr wick acts as a filter and removes finely divided adsorbent, which can give rise to spurious peaks.

In a further method, the thin-layer adsorbent is scraped onto a small amount of KBr powder in the hub of an 18-gauge metal hypodermic needle. A 1 mL glass syringe is filled with pure solvent and connected to the needle, and the compound is eluted dropwise onto a mound (10 mg) of dry KBr powder. Each drop of solvent is allowed to evaporate completely before the elution of the next drop. The powder and solute are then mixed and pressed into a disc.

Eluted material almost always includes unwanted extraneous matter co-extracted from the thin-layer chromatogram. Thus it is advisable to use the eluent from a 'blank' area as a reference solution. Contamination from plasticisers, solvents and dirty glassware can also be a serious problem when a spectrum has to be obtained from a few micrograms of a compound. Even momentary contact of dry adsorbent with plastic tubing can remove appreciable quantities of plasticisers. Hence the following precautions should be taken:

- Use the minimum amount of the purest adsorbent available.
- Elute with less than 1 mL of a solvent that contains <0.0001% (1 ppm) of non-volatile residue.
- Keep sample handling to a minimum.
- Clean all glassware with an efficient detergent in an ultrasonic bath.
- Avoid contact of materials and samples with plastics.

Gas chromatography

Gas chromatography (Chapter 40) can provide a very convenient method of obtaining pure samples for IR spectroscopy. However, the sample can still be contaminated with impurities eluted from the stationary phase. The effluent from the chromatograph is a hot vapour and the problem is to obtain small quantities in a form suitable for presentation to the spectrometer. The spectrum of the vapour can be recorded directly or the compound can be trapped and then its spectrum recorded. Unfortunately, there is no entirely satisfactory method for the direct coupling of a gas chromatograph to a standard dispersive IR spectrometer. The outlet of the gas chromatograph can be split and one part connected to a heated cell (or light pipe) placed in the beam of an IR spectrometer. The gas flow is then stopped, trapping the sample in the cell, and the spectrum is recorded in the vapour phase. This technique can provide acceptable spectra of volatile compounds such as butyl acetate, which has a strong carbonyl band, but spectra of less-volatile compounds such as caffeine and phenylbutazone are more difficult to obtain. The temperatures of the connecting pipe and cell are clearly of great importance to keep the compounds as vapours. The coupling of a gas chromatograph to an FTIR instrument is much more satisfactory because the speed of scanning is sufficiently rapid to enable the spectrum of a compound to be recorded as it is eluted. Nevertheless, the temperatures of the cell and pipework are still of critical importance.

The method used to trap a compound depends on whether it is a solid or a liquid and, if the latter, on its volatility. Ways in which small samples can be obtained from a gas chromatograph in a form suitable to present to the spectrometer are given below. The main difficulty, common to all these methods of collecting fractions, is to determine the optimum temperature of the outlet tube from the chromatograph and the temperature of the collecting device. This problem can be resolved only by trial and error.

Cooled tubes

Most techniques for collecting the effluent employ cooled tubes of glass or metal, but it is difficult to obtain good recoveries of a few micrograms of compounds of different volatilities by any one technique. Drugs such as the barbiturates and phenothiazines can be recovered in 50–70% yields in glass or metal capillary tubes held at room temperature, whereas more volatile drugs, such as the amfetamines, need to be cooled in liquid nitrogen or solid carbon dioxide (Curry *et al.* 1968; De Leenheer 1972).

Alkali halide tubes

A straight tube that contains a plug of powdered alkali halide is connected to the outlet of the chromatograph. The effluent condenses on the halide, which can then be pressed into a disc. This technique is most useful for compounds that are solid at room temperature.

High performance liquid chromatography

High performance liquid chromatography (Chapter 41) provides a very convenient method of purification, particularly if gas chromatography is inapplicable or derivatisation of the compound is necessary. Unlike gas chromatographs, liquid chromatographs are usually operated at or slightly above ambient temperature, and most types of detector are non-destructive. Thus, the appropriate fraction of eluate can be collected by holding a test-tube under the exit port.

The method used to retrieve the sample from the eluate for presentation to the spectrometer depends upon whether the compound is a solid or a liquid and, if the latter, on its volatility and the quantity present. All the common solvents absorb in the IR region. However, with the data-processing facilities of modern IR spectrometers, this is not a great disadvantage. The spectrum of the solvent can be recorded and then subtracted from the combined spectra of the compound and solvent to give a difference spectrum. If the concentration of the sample is low, the difference spectrum can be enhanced either by repetitive scanning and signal averaging or by expansion of the ordinate scale. In many cases, however, the amount of material is too small to enable the compound to be collected and transferred to standard cells.

Alternatively, the compound can be recovered by evaporation of the solvent. However, evaporation also concentrates any non-volatile impurities in the solvent, so the use of pure solvents is essential. Another possible source of contamination is the packing material used in liquid chromatography columns. Many of these materials are based on silica gel and appreciable amounts of silica may be dissolved by certain solvents.

Microsublimation

This simple technique can be highly effective in purifying certain compounds (Fig. 33.11). Drugs may be sublimed from an evaporated solvent extract in the tube onto the cold finger of the apparatus, and the sublimate transferred by grinding the KBr powder gently with the cold finger.

Sample presentation

IR spectra can be measured in the gas, liquid or solid phase. However, most compounds of interest are solids at room temperature. In principle, an IR spectrum can be obtained from as little as 1 μg of a compound. From a practical point of view, quantities of the order of 200–1000 μg are much easier to handle. Very small quantities require greater sensitivity to be achieved with micro-cells, placing as much material as possible in the IR beam. Micro-cells require beam-condensing optics to focus as much light as possible through the microcell assembly.

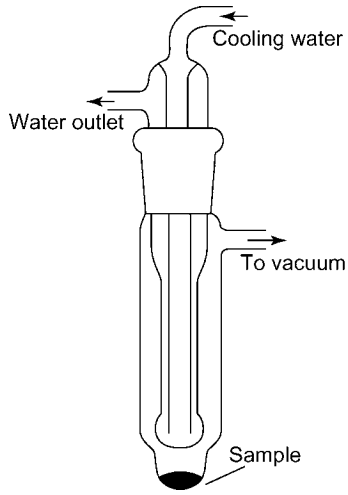

Figure 33.11 Apparatus for microsublimation.

Glass and silica contain SiO–H and Si–O bonds that can vibrate and strongly absorb IR radiation. Therefore, cell windows need to be fabricated from ionic materials with bonds that do not have vibrations. Crystal lattice vibrations cause absorption in the far IR. Barium fluoride (and calcium fluoride) are excellent for aqueous media, although window absorption prevents measurements below 1000 cm^{-1}. Silver chloride windows are water resistant and will allow transmission down to 400 cm^{-1}, but are friable. The most popular IR window material is sodium chloride, which is water soluble but transparent down to 600 cm^{-1}.

Gases

In normal laboratory experiments, IR spectroscopy is used only rarely for analysis in the gas phase. Gases are likely to be at a very low concentration and special long-path, airtight gas cells are required. These cells normally have sodium chloride windows, and mirrors may be used to reflect the light through the gas cell several times to achieve a very long path length. The detection of environmental gases is a typical application of gas-phase IR spectroscopy.

Liquids and solutions

Liquids have a very high molarity. Thus chloroform, with a relative molecular mass of 119.4 and density of 1.48 g/mL, can be said to be 12.4 mol/L. According to Beer's law, to detect the C–H stretch ($\varepsilon \approx 10$ L/mol per cm) with absorption $A = 0.4$, the path length required, given by $l = A/(\varepsilon c)$, is approximately 3×10^{-3} cm.

Non-volatile, neat liquids can be measured simply by placing a drop between two IR transparent plates and pressing the plates together to ensure a narrow (<0.1 mm) measurement path length (Fig. 33.12). Volatile liquids may need proper sealed liquid cells.

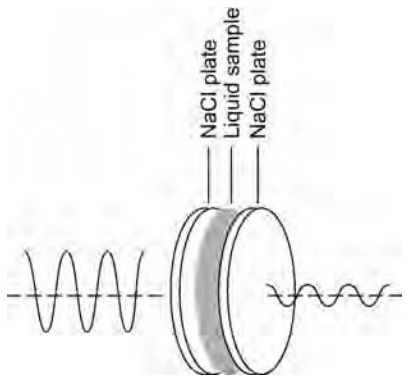

Figure 33.12 Liquid sample or Nujol mull sandwiched between two NaCl plates.

Liquid cells usually consist of two parallel transparent windows (0.1–0.01 mm apart) separated by a precise gasket made of Teflon or lead and fitted with inlet and outlet ports. Cells with variable path lengths are also available, in which one window is retained on a screw that can be finely adjusted to give a precise path length in the 0.1–0.01 mm range. These cells are particularly useful to vary path length to accommodate for solvent absorption and variations in concentration ranges. Solvent absorption can be accounted for in a computer by comparison of the solution and solvent spectra.

The number of solvents suitable for IR spectroscopy is limited. The measurement of the IR absorption of a solute is possible only in a spectral range for which the solvent is relatively transparent. Carbon tetrachloride and carbon disulfide, which lack hydrogen and contain a minimal number of bond types, are often suggested as the most useful solvents because they have relatively few absorption bands in the IR region. However, they have poor solubilisation characteristics. In practice, solvent choice is based upon solubility and IR transparency at the wavenumber of interest. Deuterated solvents can help open regions for analysis. Chloroform–deuterochloroform, acetonitrile, water–deuterated water, toluene and dioxane are good solvents to consider.

To overcome the inherent absorption of solvents and the relatively low extinction coefficient of a vibration, path lengths are short and concentrations are high. The concentration of the test compound is usually about 5–10%, but concentrations up to 20% (w/v) can be employed. With these high concentrations, hydroxyl and amino compounds often exhibit bands caused by intermolecular hydrogen bonding. Interactions between the compound and the solvent can occur, which may result in changes in the intensity and wavenumber of bands in different solvents and the breakdown of Beer's law.

IR solvents are often volatile and require very short path lengths. This combination can lead to solvent evaporation, which produces large concentration changes. In the older-style IR spectrometers, the heat of IR radiation could cause evaporation – this is less of a problem with FT systems with the sample placed after the interferometer. An example is presented here of the determination of the amount of dimeticone in a cream formulation.

Dimeticone can be extracted from creams with 4% (w/w) liquid paraffin in toluene and quantified by reference to standard solutions based upon the Si–O stretching vibration at 1260 cm^{-1} in a 0.1 mm sodium chloride liquid cell (Fig. 33.13).

Solids

Solids are generally examined either as thin films or as dispersions in either liquids or solids. The ideal sample for IR transmission measurements is clear, visually transparent and homogeneous. This can be difficult to achieve with solids. Heterogeneous samples that are optically poor with large sample particles can introduce light scattering and the Christansen effect. Light scattering becomes significant when the particle size is more than 1/20 of the wavelength of the incident light. Light scattering produces a spectrum offset that is curved, with high light scattering at shorter wavelengths/higher wavenumbers and lower light scattering at longer wavelengths/lower wavenumbers. Samples must be ground until particle sizes are less than 1 μm. The Christansen effect, which results from severe refractive index changes at the sample surface, leads to distorted band shapes. Peaks take on an S-shape with an apparent reduced (or even negative) absorption at the longer wavenumber edge. As a result, asymmetrical bands may be observed that vary in position and intensity from true values. For transmission measurements, the sample must ideally have the appearance of a 'perfect glass'. To reduce the light scattering and the Christansen effect, all components of the sample must have a very small particle size ($\leq$1 μm) and they must be dry.

The polymorphic form of a solid sample can affect the IR spectrum. This is an important issue in the pharmaceutical industry, as the rate of dissolution of a solid drug can depend upon its crystal morphology. Success has been achieved by simply crushing the sample between two diamond windows in a device known as a diamond anvil (Fig. 33.14).

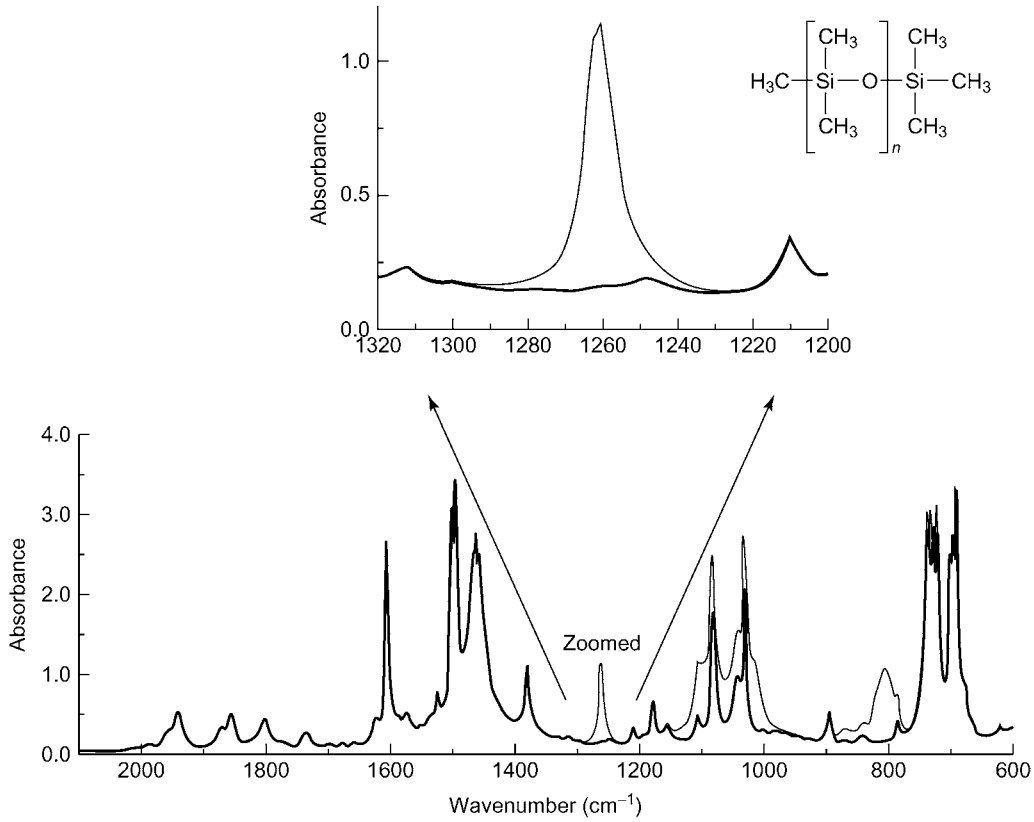

Figure 33.13 The IR spectrum of dimeticone dissolved in 4% (w/w) liquid paraffin in toluene: (heavy line) 4% (w/w) liquid paraffin in toluene; (light line) 1.5% (w/v) dimeticone dissolved in 4% (w/w) liquid paraffin in toluene.

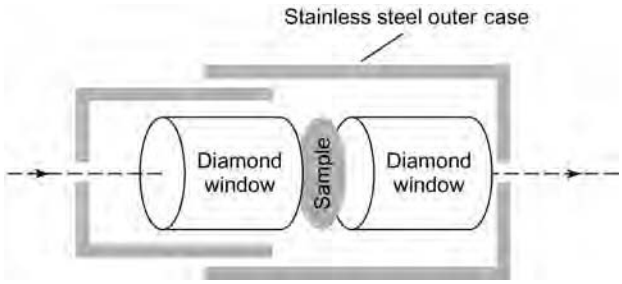

Figure 33.14 A diamond anvil.

Mulls

Solid compounds are dispersed in a liquid, such as liquid paraffin (Nujol). The finely powdered compound (about 1–10 mg) is mixed with one drop of the liquid and ground in an agate mortar. The test sample must have the constituency of a smooth, thin cream. The mull is spread onto an alkali halide plate, usually sodium chloride or KBr, and another plate is placed on top, taking care to exclude air bubbles. The plates are pressed together strongly. A disadvantage of this method is that the spectrum of the mulling agent is superimposed upon that of the sample. Consequently, liquid paraffin cannot be used if the C–H stretching vibrations are to be examined, and a halogenated liquid, such as 'Fluorolube' (a fluorinated hydrocarbon) or hexachlorobutadiene, must be employed.

Alkali halide discs

The technique of dispersing the compound in an alkali halide has been used widely in the identification of drugs. Originally, KBr was used and the technique is still often referred to as the 'KBr technique'. However, potassium chloride (KCl) is superior to KBr because it is less hygroscopic. Storage of the alkali halide in an 80°C oven helps to ensure anhydrous conditions.

The finely powdered, dry, test compound (about 1 mg) is mixed with the alkali halide (about 250 mg) and ground either mechanically in an agate ball mill or by hand in an agate mortar. A texture approaching that of talcum powder is a good consistency. The mixture is pressed under approximately 10 tons pressure in a purpose-designed press to produce an optically good, thin disc (Fig. 33.15). A vacuum helps to retain dry conditions and smooth disc formation. The pressure is applied for 10 min.

If only small quantities of the compound are available (about 200 μg), a thin cardboard mask with a slot in the centre can be used. The mask is placed in the die and the slot is filled with the mixture before pressing. A mask is often employed routinely because it provides a support for the alkali halide and so enables the disc to be handled more easily. Microdiscs of diameter down to 0.5 mm can be prepared by using

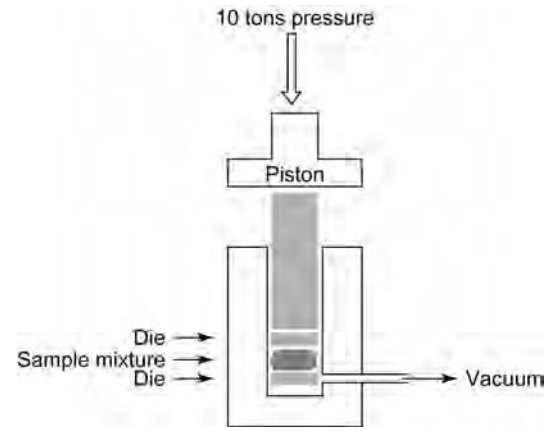

Figure 33.15 A KBr disc press.

metal (lead or stainless steel) discs of 13 mm diameter with a hole of the appropriate size in the centre. The hole is filled with KBr (about 1 mg) that contains from 0.05% to 0.2% of the sample, which is then pressed in the usual way. The metal discs should be washed before use in both polar and non-polar solvents and finally in good-quality acetone to remove traces of oil and grease, which may produce artefacts in the C–H region of the spectrum. The method may fail if excessive pressure is used, as this causes deformation of the lead disc.

Another useful technique consists of dissolving the compound in a small volume of chloroform and drawing it into a Hamilton-type syringe held in a repeater holder. A small cluster of fine KBr particles is picked up on the end of the needle by a trace of chloroform expressed from the needle. The solvent is evaporated gently and the rest of the solution is fed into the KBr from the syringe as it evaporates. A disc is then made from the powder. It is important that the end of the needle be cut at right angles to the shaft and ground flat; needles supplied for use with liquid chromatographs are suitable. For bases one must decide whether to evaporate solvents without the addition of hydrochloric acid, and accept the consequent loss of certain amines by volatilisation, or to add hydrochloric acid and accept the reduced solubility of the amine hydrochlorides in chloroform. Considerable losses of the sample by evaporation may occur for other types of compound (e.g. phenols), particularly when dilute solutions are used.

KBr is hygroscopic, which means that it is sometimes difficult to remove the last trace of water, and so AgCl may be used instead. An indentation about 0.8 mm deep and slightly wider is made in the centre of a small piece of silver chloride sheet, and a solution (about 0.1 μL) that contains as little as 500 ng of substance is placed in the indentation and gently warmed to evaporate the solvent. The sheet is then placed in a die, which produces a cone of silver chloride with the sample embedded in it. A similar cone of plain silver chloride is mounted in the reference beam. Excellent spectra can be obtained with this technique.

The alkali halide discs can be stored in a dry environment and give good spectra several years after preparation. A well-prepared disc should have over 80% transmittance in regions where the sample does not absorb, although it will not necessarily be visually clear. It is not always easy to obtain a good disc when a very small amount of a recovered drug is available. In these circumstances, attenuation of the reference beam can 'sharpen' the spectrum. Another technique is to heat the alkali halide disc to about 80°C for 30–60 min with an IR lamp to evaporate any absorbed water. However, the high temperature accentuates the disadvantages of the alkali halide disc technique. In addition, the following artefacts have been observed:

- Formation of anhydrides from carboxylic acids
- Reversion of ketals and cyanohydrins to the parent ketone
- Loss of water from secondary alcohols.

Several disadvantages are inherent in the alkali halide disc technique. The alkali halides that are generally used are hygroscopic, and it is very difficult to exclude all traces of water. This often results in an O–H band in the spectrum. A number of compounds that contain O–H groups either form hydrogen bonds with the alkali halide or are adsorbed on its surface, so the method is unsuitable if the O–H band is to be examined. In such cases, polytetrafluoroethylene (PTFE) powder can sometimes be used in place of the alkali halide. Polymorphism occurs in many compounds and the grinding and pressing can alter the crystal form and consequently the spectrum. Splitting of bands also frequently occurs. Another disadvantage is the possibility that chemical changes will occur during the preparation of the disc. For example, double decomposition can occur:

$$\text{Base HCl} + \text{KBr} \rightarrow \text{Base HBr} + \text{KCl}$$

Hence, preferably hydrochlorides should be examined in KCl. Bromide may be oxidised to bromine by some compounds, particularly strong oxidising agents, which may result in a disc becoming either discoloured or having yellow–brown spots. If the sample is a potential oxidising agent, other techniques of sample preparation should also be used to check the reliability of the spectra obtained from the alkali disc.

Organic compounds that contain nitrogen in a functional group should not be used with plates that are made of thallium bromide and thallium iodide as they appear to react with the plates.

Despite these disadvantages, the technique is still very useful for solid drugs. The advantages are that, besides being easy to use, the absorption of the alkali halide is very low and the quantity of compound required is small. The discs can easily be stored for reference purposes or the compound can be recovered if required.

Thin films

This method is of use if it is necessary to obtain spectra free from the dispersing media. The film can be prepared either by melting the solid and pouring it onto a suitable plate or by evaporation of a solution on an IR transparent plate.

Measurement of strongly absorbing or strongly light-scattering samples

IR light incident on solids, powders or other materials such as creams is transmitted only poorly, if at all, because of the long path lengths and light scattering. Neat liquids and solutions need very narrow path lengths to overcome solvent absorption. However, scattered light or reflected light can be monitored in these cases and these techniques can be used to examine intact pharmaceutical preparations.

Light scattering

IR light falling on a powder can be reflected in two ways. The light can be reflected truly in the sense of mirror reflection (angle of incidence equals the angle of reflectance); this is known as specular reflectance. Alternatively, the IR light can be scattered, in the Rayleigh scattering sense, over all angles with a scattering intensity related to particle size; this is often referred to as diffuse reflectance. Specular reflectance is related to the refractive index of the sample, and intensity versus wavenumber data are difficult to interpret. Diffuse reflectance, on the other hand, is more simply related to light intensity; if the light is absorbed at the surface, it cannot be scattered back. A typical accessory, often given the acronym DRIFT (diffuse reflectance IR Fourier transform spectroscopy), is illustrated in Fig. 33.16. The sample is placed on a sample tray located beneath two ellipsoidal mirrors M_3 and M_4. Heterogeneous powders and fibres often benefit from being ground and 'diluted' with

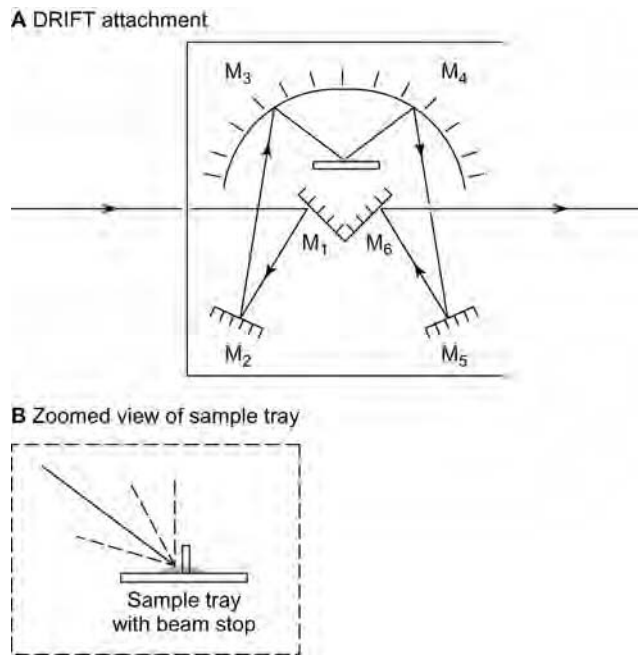

Figure 33.16 DRIFT attachment: IR light from the interferometer strikes mirror M_1 and is directed onto the sample tray by mirrors M_2 and M_3. In (A) the pure reflection path is highlighted. In practice, a beam stop as in (B) blocks the specular reflectance and only the diffuse reflected (scattered) beam is collected by mirrors M_3 and M_4 and directed towards the detector by mirrors M_5 and M_6.

KBr. Pure KBr can be used as the reference material in a separate measurement for the reference spectrum. A good sample can be produced by rubbing a solid sample with silicon carbide abrasive paper (68 μm) to produce a sample of approximately 150 μg over a 35 mm^2 area.

Diffuse reflectance is a measure of intensity versus wavenumber data, normally in a single-beam configuration. To ensure that measurements are at least approximately proportional to concentration, a Kubelka–Munk $f(R)$ transformation can be applied (Kubelka, Munk 1931):

$$f(R) = \frac{(1-R)^2}{2R}$$

where R is the reflectance of the sample. This transformation may be applied at an individual wavenumber or across the complete spectrum.

Alternatively, data can be presented as $-\log(R)$ versus wavenumber.

Attenuated total reflectance

Light that arrives at an appropriate angle to the boundary between two media (or materials) with appropriate refractive indices n_1 and n_2 can be reflected back into the first medium (Fig. 33.17A). This is known as internal reflectance. For this to happen the light beam must have at least sampled the second medium, if only to a depth of approximately 10 μm. The light in this fine slice of the second medium is referred to as an evanescent wave. If the second medium has absorption properties, this is sensed by the evanescent wave and the reflected beam has a reduced (attenuated) intensity, the attenuated total reflectance (ATR). The detected beam now provides intensity versus wavenumber characteristics that are effectively the absorption spectrum of the second medium.

Several proprietary attachments on the market are based upon a single rhomboid prism, of which an example is illustrated in Fig. 33.17. Suitable optical materials for medium 1 are zinc selenide (ZnSe), germanium and diamond. A sample well is created on the side of the rhomboid optical block. A typical ZnSe block is 50 mm × 1 or 2 mm, which gives 15–45 reflections, depending on rhomboid angles. In this case, 5–10 μm sections of medium 2 are sampled 7 to 22 times, which results in an effective optical path length of the order of 35–220 μm. The path length is reproducible and samples are easy to change in comparison with the equivalent simple transmission spacer cell, although the latter may be preferred for simple solutions. Any material that forms a good optical contact with the prism can, in principle, be measured (solutions, oils, waxes, creams, pastes, powders and films).

More sophisticated devices exist, such as such the DuraSamplIR attachment (Fig. 33.18) supplied by SensIR Technologies, (Warrington, UK). The IR radiation from the interferometer is directed into a ZnSe prism by mirror M_1. Subsequent internal refection directs the IR radiation through a diamond prism, where the evanescent wave is reflected back through the ZnSe prism and then onto the detector via mirror M_2. In principle, a powder sample, with no sample preparation, is placed on the diamond prism surfaces where it is compacted by a plunger. Powders, films, solutions, etc., can all be measured with equal ease and no sample pre-treatment. This device produces excellent results; baselines are flat as the technique is not dependent on light scattering.

Interpretation of spectra

A non-linear molecule has $(3N-5)$ fundamental (normal) modes of vibration (this excludes overtones and combinations). Thus a molecule such as paracetamol (see Fig. 33.21) with the formula $C_8H_9NO_2$ has $(3 \times 20 - 5) = 55$ fundamental (normal) modes of vibration. Assigning 55 peaks in an IR spectrum is a daunting task at the very least. Therefore, the total molecular structure of a drug is unlikely to be determined directly from IR spectral information alone.

There are three aspects to identifying a chemical entity. In the first instance, the properties (biological, chemical and spectroscopic) of a

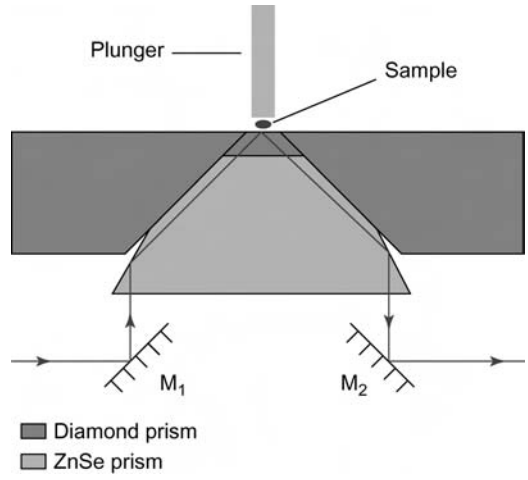

Figure 33.18 The DuraSamplIR attachment.

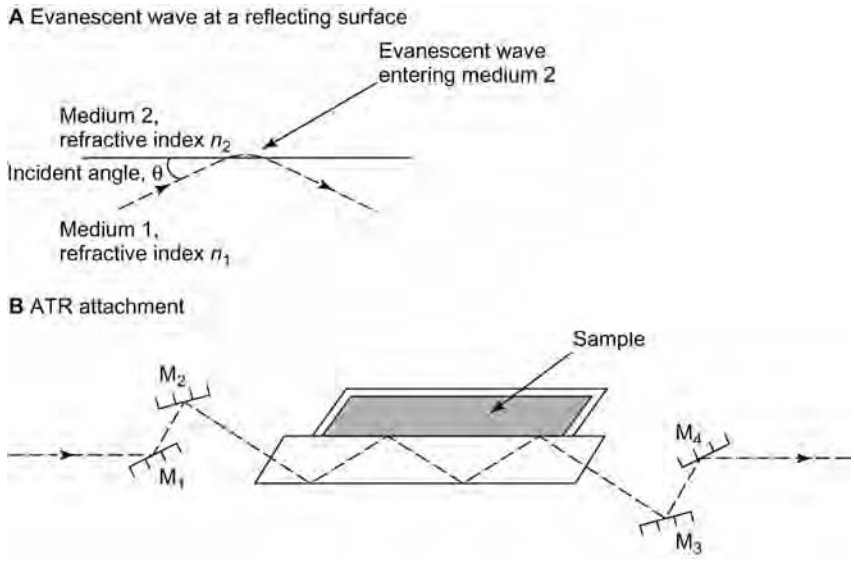

Figure 33.17 (A) The evanescent wave senses medium 2. (B) The ATR attachment, with light directed by mirrors M_1 and M_2, enters the rhomboid prism at 90°. Here the sample is measured twice (two internal reflections) before the light exits the prism at 90°, and directed to the detector by mirrors M_3 and M_4. In practice, there can be as many as 45 reflections.

drug are assessed and the drug is classified according to its type (e.g. non-steroidal anti-inflammatory drug, barbiturate, steroid). The analyte may be a previously characterised compound, in which case a comparison of data from the unknown with reference data, often termed fingerprint identification, confirms the identity of the compound. This may be possible through computer matching of the spectra. The molecular structure of a new chemical entity will most likely need to be determined by NMR spectroscopy, perhaps in combination with MS. However, information such as the existence of specific functional groups or the elimination of putative structures is of great help in processing the NMR information.

Functional group identification

Table 33.1 lists the important IR vibration frequencies. The precise location of a band often gives an indication of the structural environment of the group (e.g. the C=O group in cyclohexanone and cyclopentanone, the amide bond in an α-helix or β-sheet polypeptide chain). More substantial lists of peak assignments are found in the standard texts on IR spectroscopy (see Further reading).

Qualitative analysis

Infrared spectra matching and fingerprint identification

In the simplest case, two spectral printouts – one of the reference and the other of the analyte – can be overlaid on a light box and the spectral features related by eye. Overlaying spectra on the computer screen achieves the same objective.

When the spectrum of a substance being examined is compared with a reference spectrum, such as those in the *British Pharmacopoeia*, the positions and relative intensities of the absorption bands of the spectrum of the substance being examined should conform to those of the reference spectrum. The sample spectrum must be recorded under the same operating conditions that were used to obtain the reference spectrum, i.e. dispersive or FT instrument, and same resolution (*British Pharmacopoeia* 2008).

When a chemical reference substance is available, the substance being examined and the chemical reference substance should be prepared by the same procedure before recording the spectra (see later under Polymorphism). The transmission minima in the spectrum obtained with the substance being examined should correspond in position and relative size to those in the spectrum obtained with the reference substance (*British Pharmacopoeia* 2008).

In recent years, IR spectral databases have been created and stored electronically in databases and/or libraries. The spectrum of the analyte is presented to the database and the computer attempts to match the spectrum with one already held in the database. A report is made of the best matches. The computer program lists the most likely hits in order of a closeness of fit. Many compilations of spectra (databases) are private collections, held typically by individual pharmaceutical companies; some can be purchased and a few are in the public domain.

The number of compounds for which IR spectra have been measured is now massive. Potentially, the greater the number of spectra in a database, the greater is the probability of making a good match for the unknown sample. However, the probability of making a mismatch is also greater, as more spectra with fine differences are available for comparison. The computer is simply matching 'pictures' by the number of peaks, their positions and their relative intensities. The best that the computer fitting can do is to indicate a mathematical similarity. It is important to qualify a computer search:

- A visual overlay of the test compound spectrum and the hit spectrum ensures that the search has not chosen a match that is mathematically acceptable, but chemically not acceptable.
- Knowledge of the class of a compound can help restrict the search to a more refined reference set (database).
- Other properties of the sample and the reference compound should match, such as chromatographic retention times, chemical and colour reactions and functional group assignments.
- The computer can select only spectra that are in its library and, if the spectrum of the compound under investigation is absent, then it will select those that give the next-best fit.
- Different forms of the same compound give different IR spectra (different polymorphs, racemate and/or enantiomer, ionisation status, cations and anions).
- If the spectra have been recorded on different instruments, they may, superficially at least, appear very different. In this case a more detailed study of band frequencies and relative intensities must be undertaken.

If the matching procedure fails, and in cases where the type of compound is unknown or can be allocated only to a certain class (e.g. a phenothiazine or a barbiturate), reference may be made to the index of IR peaks in the Indexes of Analytical Data and to the information in the individual monographs. Comparison of the spectrum of the unknown with that of the suspected compound should either confirm or disprove the tentative identification. If the two spectra were recorded under similar conditions on the same type of instrument, they should be very similar in appearance. Some examples of the identification of drugs are given below.

Infrared spectra of amfetamines

The IR spectra of amfetamine base and the hydrochloride have many similarities, but the hydrochloride spectrum shows much finer detail (Fig. 33.19A and B). The IR spectra of the hydrochloride and mandelate salts show differences (Fig. 33.19B and C) because of the absorption of the mandelic acid. However, the spectra of the hydrochloride and sulfate salts (Fig. 33.19B and D) are very similar since they both have inorganic anions. The only major difference is the absorption band caused by the sulfate at 1110 cm^{-1}.

Infrared spectra of barbiturates

Important derivatives of malonylurea (barbituric acid) have two substituents at position 5. Others are also substituted at position 1 and in others the oxygen atom attached to position 2 is replaced by sulfur to form thiobarbiturates (Fig. 33.20).

The barbiturates can be classified chemically into three classes: 5,5-disubstituted barbituric acids, 1,5,5-trisubstituted barbituric acids and 5,5-disubstituted thiobarbituric acids. These classes can be further divided depending on whether the substituents in position 5 are alkyl, alkenyl, aryl or cycloalkenyl. In most common barbiturates, one of the 5-substituents is either ethyl or allyl and the other is either a straight- or a branched-chain alkyl or alkenyl group with five or fewer carbon atoms. Some barbiturates are available as sodium salts. The IR spectrum of a barbiturate therefore depends on the class of compound, the nature of the substituents and whether it is the free acid or the sodium salt.

With the exception of phenobarbital and barbituric acid, the free barbiturates do not absorb appreciably above 3300 cm^{-1} (e.g. barbital, Fig. 33.20A), a feature that distinguishes them from the ureides; a weak band of unknown origin sometimes occurs between 3500 and 3400 cm^{-1}. All the barbiturates have two bands that occur near 3200 and 3100 cm^{-1} and are caused by N–H stretching vibrations. In the 5,5-disubstituted compounds, the relative intensities of the two bands are similar, although that at 3100 cm^{-1} is usually slightly less intense. In compounds substituted on the nitrogen atom at position 1, the intensity of the band at 3100 cm^{-1} may be greatly reduced and is often present only as a shoulder on the band at 3200 cm^{-1}, e.g. metharbital. Methylphenobarbital appears to be an exception in that the band at 3100 cm^{-1} is the most intense one in the region. A similar phenomenon occurs with the sodium salts, since here again one of the hydrogen atoms in either position 1 or 3 has been replaced.

A series of up to four medium-to-intense bands occurs in the region 3000–2800 cm^{-1} and is caused by alkyl C–H stretching vibrations of the substituents in positions 1 and 5. The intensity of the bands gives a very approximate indication of the number of C–H bonds and hence the number of carbon atoms in the chain. This does not appear to apply to the sodium salts, in which the band that occurs at 3000–2950 cm^{-1} is usually increased in intensity, compared with that of the free acid, and

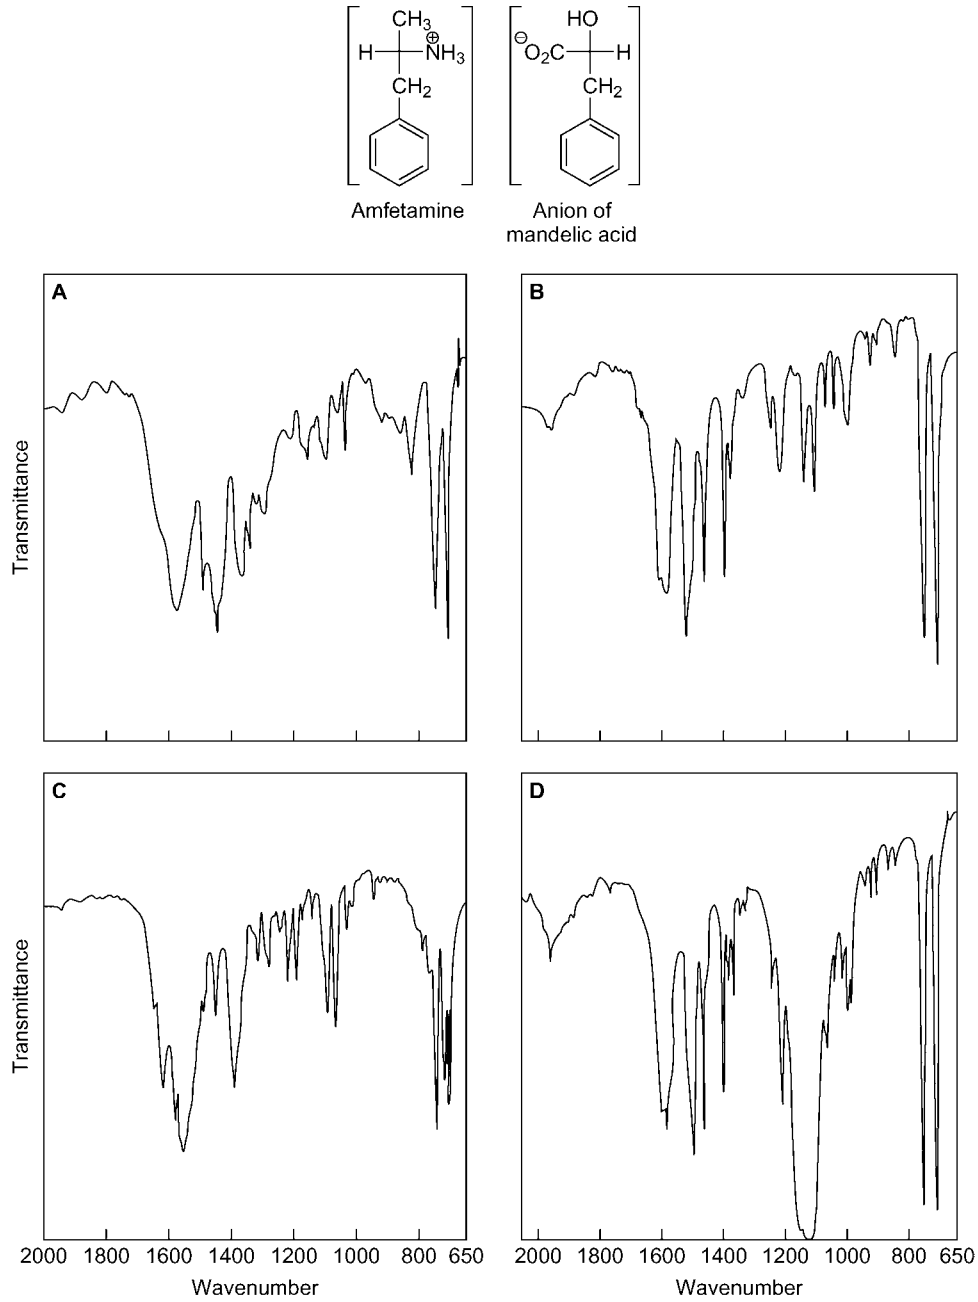

Figure 33.19 IR spectra of (A) amfetamine base; (B) amfetamine hydrochloride; (C) amfetamine mandelate; (D) amfetamine sulfate.

becomes the strongest band. Compare, for example, the spectra of barbital (Fig. 33.20A) and barbital sodium (Fig. 33.20B).

The barbiturates have up to three strong bands in the region 1765–1670 cm^{-1}, which result from C=O stretching vibrations. Knowledge of the origin of these bands helps to understand the differences in the spectra of the various types of barbiturate.

In symmetrical molecules, the three bands are all of similar intensity. In asymmetrical molecules, the band at the highest frequency is often less intense than the other two, particularly so when the molecule is substituted in position 1. The sodium salts of the barbiturates have only two bands in this region, since the molecule is no longer symmetrical, and these occur at a lower frequency, between 1700 and 1650 cm^{-1}. In addition, a broad strong band occurs between 1600 and 1550 cm^{-1}; the free barbiturates show practically no absorption in this region. The sodium salts of the thiobarbiturates exhibit only the lowest of the three C=O vibrations in the region 1700–1680 cm^{-1}. They do, however, exhibit the broad, strong band that occurs between 1650 and 1600 cm^{-1}. Therefore, the number, position and intensity of the bands between 1800 and 1500 cm^{-1} give a very good indication of whether the barbiturate is the free acid, the salt or a thiobarbiturate.

Most barbiturates have a number of strong bands between 1460 and 1250 cm^{-1}, and some of these result from C–H deformation and C–N stretching vibrations. The sodium salts of the thiobarbiturates have a broad strong band between 1500 and 1480 cm^{-1}, which is believed to be caused by C–N stretching vibrations of the carbon atom attached to sulfur. This band is not present in the ordinary barbiturates and therefore provides another way to distinguish those that contain sulfur. Many barbiturates exhibit a few weak-to-medium intensity bands in the region 1150–900 cm^{-1}. The 1-substituted barbiturates exhibit a greater number of sharp bands of medium intensity. Those compounds that contain an allyl group exhibit bands at about 1000 to 960 cm^{-1}, which probably result from C–H deformation vibrations. The sodium salts of the thiobarbiturates show a band of medium intensity between 1020 and 1000 cm^{-1}. Finally, many barbiturates, but not the thiobarbiturates,

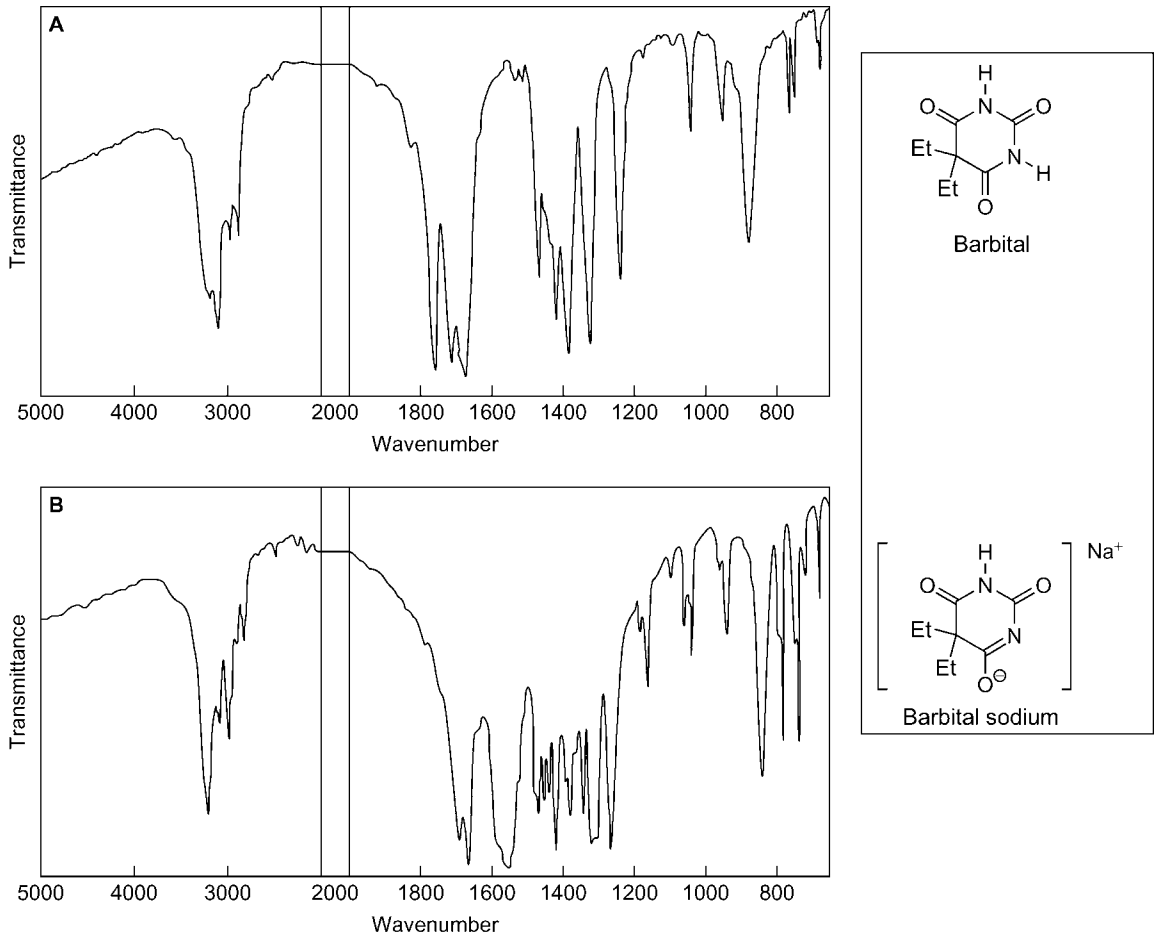

Figure 33.20 IR spectra of (A) barbital; (B) barbital sodium.

exhibit a broad band of medium-to-strong intensity between 900 and 800 cm^{-1}.

Infrared spectra of aspirin, Nujol and paracetamol

The spectra of aspirin, Nujol and paracetamol are given in Fig. 33.21, which illustrates the differentiation of N–H, O–H, ester, carboxylic acid and amide groups. In particular, the effect of Nujol on the drug spectra is apparent.

Polymorphism

Many drugs exist in polymorphic forms and have different IR spectra for each different crystalline form. IR spectroscopy can therefore be used to distinguish between different polymorphic forms, to identify them and also to measure quantitatively the proportions of each in a mixture.

If a test compound gives a different spectrum to the corresponding chemical reference substance, and polymorphism is suspected, both should be treated in the same manner so that they crystallise or are produced in the same form. This can often be achieved by dissolving them in a suitable solvent and evaporating to dryness.

The barbiturates are notable for the extent to which they exhibit polymorphism, including many metastable forms found only in mixtures. Spectral differences between polymorphs are associated with different types of hydrogen bonding, and there is a correlation between hydrogen bond strength and duration of action of the barbiturates on the central nervous system. The crystalline structure of barbiturates can be affected by grinding with an alkali halide or in preparing a mull, but, if precautions are taken to ensure reproducibility, the spectra of the barbiturates are sufficiently different to be used for identification purposes.

Interferences

Spurious bands can occur readily in IR spectra, particularly when a biological sample has undergone several purification procedures. Traces of plasticisers, surfactants and oils left on glassware can all give rise to spurious IR bands. A useful list has been compiled by Szymanski (1971), part of which is given in Table 33.2.

Infrared data in monographs

Modern spectral identification by reference to computer databases involves sophisticated chemometric algorithms to compare all the digitised points in a test spectrum with a set of reference spectra. Spectra that are judged to be most similar are said to be a match, which allows the identity of the test spectrum to be established. This type of work requires specialised database reference sets and computer programs. Much of it is proprietary and related to the software of the spectrometer being used.

However, it has been shown (Curry *et al.* 1969; Ingle, Mathieson 1976) that an IR spectrum of a particular substance can be retrieved from a collection, with some degree of confidence, by reference to its six major absorption bands. This forms the basis for a system of identification.

Data that consist of six major absorption bands have been selected from the recorded spectrum over the range 2000–650 cm^{-1} (5–15 μm) and are included in the monographs in Part 2 in Volume 2. In many cases, the spectrum is also reproduced in a reduced size. The selected peaks are the six most intense peaks, except those in the region where Nujol absorbs (1490–1320 cm^{-1}, 6.7–7.6 μm) have been omitted. The peaks are arranged in descending order of amplitude. It should be noted that, because of variations in instruments and conditions, other determinations of the spectrum might not give peaks with the same relative intensities.

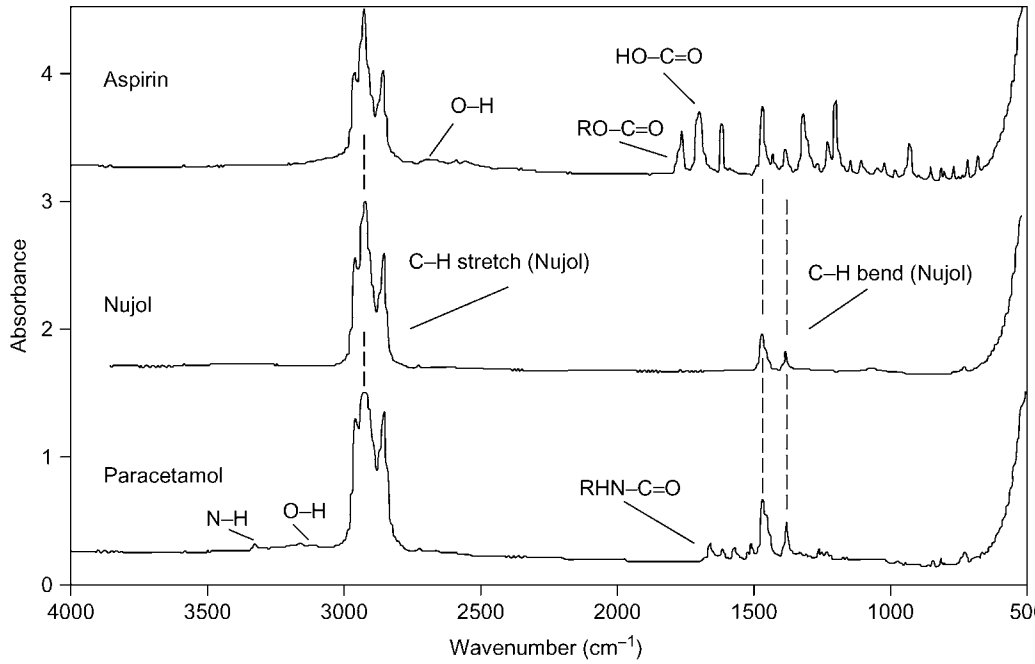

Figure 33.21 The IR spectra of aspirin, Nujol and paracetamol. The drug spectra were measured as Nujol mulls.

The principal peaks are listed in descending order of amplitude and details of how to use the data are given in the Indexes of Analytical Data.

Quantitative analysis

Concentration of molecular species

FTIR spectrometers are now very stable instruments and, coupled with computer control and data manipulation, should be as easy to operate as UV-visible spectrophotometers. They can operate routinely in the absorbance mode, which is required for concentration determinations. However, relatively high concentrations are required given the restriction of solvent absorption, the need for narrow path lengths and the low extinction coefficients of vibrations. Assuming that Beer's law is obeyed, absolute concentrations can be determined in solution from specific bands in windows of solvent transparency. In the solid state, the relative amounts of two components can be estimated readily from the relative intensities of two specific absorption bands:

$$A_{1\lambda_1} = {}_{1\lambda_1}c_1 l$$

$$A_{2\lambda_2} = {}_{2\lambda_2}c_2 l$$

$$\frac{A_{1\lambda_1}}{A_{2\lambda_2}} \propto \frac{c_1}{c_2}$$

where $A_{1\lambda_1}$, $A_{2\lambda_2}$, ${}_{1\lambda_1}$ and ${}_{2\lambda_2}$ are, respectively, the absorbances and extinction coefficients of species 1 and 2 at the corresponding wavelengths λ_1 and λ_2. The concentrations of species 1 and 2 are c_1 and c_2, and the path length is l.

Collections of data

General collections

Compilations of IR spectral data are available in two forms, either as pictures or as digital absorbance/wavenumber data in electronic databases. Pictures are available in book or computer form and are suitable for visual inspection. Spectral characteristics can be determined with the aid of a ruler. Electronic databases are available in computer memory for data manipulation and spectral matching. Third-party software for the computer manipulation of IR spectral data include:

- GRAMS/AI version 8 and Spectral ID available from Thermo Galactic, 395 Main Street, Salem, NH 03079, USA.
- Aldrich Spectral Viewer available from Sigma-Aldrich Company Ltd, The Old Brickyard, New Road, Gillingham, Dorset SP8 4XT, UK, or via their web site www.sigmaaldrich.com.
- Thermo Nicolet OMNIC FTIR available from Thermo Fisher Scientific Inc., 81 Wyman Street, Waltham, MA 02454, USA.

Table 33.2 Spurious peaks in IR spectroscopy (after Szymanski 1971)

Wavenumber (cm^{-1})	*Assignment*	*Comments on sources*
3800–2500	H_2O	Bound or unbound water in a molecule can give rise to sharp or broad bands. In alkali halide discs a water band at 3350 cm^{-1} may appear
3300–3000	NH_3^+	Lens tissues
1810–1600	C=O	Impurities that contain the carbonyl group, e.g. phosgene in chloroform, plasticisers
1750–1500	H_2O	Bound or unbound water can give rise to sharp or broad bands
1610–1515	COO^-	Alkali salts (which also have a weaker band at 1425 cm^{-1}) can be produced from alkali halides
1400	NH_3^+	Lens tissues
1265	$Si–CH_3$	Stopcock grease or silicone oil
1110–1050	Si–O–Si	Glass or hydrolysed Si compounds
730, 720	Polyethylene	Polyethylene laboratory ware
700	Polystyrene	Polystyrene laboratory ware

Other instrument manufactures can provide suitable software.

The most comprehensive collection of published spectra is that of the Sadtler Research Laboratories. This is available through Bio-Rad, Informatics/Sadtler Group, 3316 Spring Garden Street, Philadelphia, PA 19104–2596, USA. The total database covers 220 000 spectra, which are divided into over 100 spectral databases. Subgroups are preferred to ensure more secure compound matching. Bio-Rad also supplies appropriate database software.

A collection of 3000 FTIR spectra of standard chemical compounds is available from E. Merck, Darmstadt (Pachler KGR *et al.* (1988). *Merck FTIR Atlas: Eine Sammlung von FTIR-Spektren Teil I/II (A Collection of FTIR Spectra Part I/II)*. Wiley, 1988). In this:

- Absorbance spectra are presented, breaking with tradition, with the advantage that band intensities are directly proportional to concentration.
- Spectra of solid compounds are recorded in a KBr matrix. Hence, no interfering peaks from the matrix are included.
- All spectra are augmented with the following data: list of nine strongest bands, structure, molecular formula, relative molecular mass, melting and boiling points, CAS registry numbers, sample preparation and Merck–Schuchardt catalogue number.

The Sigma-Aldrich Company offers several collections of IR spectral data from printed books to computer-based systems. Details of Sigma-Aldrich products are available from Sigma-Aldrich Company Ltd, The Old Brickyard, New Road, Gillingham, Dorset SP8 4XT, UK, or their website www.sigmaaldrich.com. Their products include:

- The *Aldrich Library of FTIR Spectra*, 2nd edn, three-volume set, 1997; contains over 18 000 IR spectra. (See also: Pouchert CJ (2008). *Aldrich Library of FT-IR Spectra*, 3 volumes, 2nd edn. Wiley Blackwell.)
- Pouchert CJ (1989). *Aldrich Library of FTIR Spectra: Vapor Phase*, Vol. 3. Milwaukee: Aldrich Chemical Co.; contains 6550 vapour-phase spectra.
- Pouchert CJ (1981). *Aldrich Library of Infrared Spectra*, 3rd edn, Milwaukee, Aldrich Chemical Co., 1981; contains more than 12 000 spectra classified by functional group and structural presentation.
- A set of over 10 400 FT-IR spectra of biochemicals and related organics is given in: Keller RJ (1986). *Sigma Library of FTIR Spectra*, Vols 1 and 2. St Louis: Sigma Chemical Co.
- The computer-based system *Aldrich Spectral Viewer*, includes an IR collection of over 11 000 spectra (Product Number Z540285) and an ATR-IR library of over 18 000 compounds (Product number Z547492).
- 667 spectra of commercial materials with fragrance or flavour-enhancing properties are included in the *Nicolet/Aldrich Flavor & Fragrances Vapor Phase Library*, Product number Z273031.
- 5010 gas-phase spectra collected by Aldrich using a GC interface to ensure chromatographically pure samples: *Nicolet/Aldrich Vapor Phase Library*, Product number Z27296-5.
- A spectral collection of 10 411 of the most common chemicals found in the Sigma Chemical catalogue represents a wide range of chemical classes of particular interest to those in biochemical research or quality control: *Nicolet/Sigma Biochemical Condensed Phase Library*, Product Number Z272973.

Other sources include:

- The Coblentz Society Special Collection of over 9500 IR spectra: *The Coblentz Society Infrared Spectra Collection for ACD/Labs*. www.coblentz.org/
- A collection of nearly 400 spectra in the *British Pharmacopoeia Collection*, Vol. IV of the *British Pharmacopoeia*. London: The Stationery Office, 2008.
- Fiveash Data Management Inc. offers software and reference spectra databases through their web site www.fdmspectra.com. The databases include the FTIR Spectra of Drugs/Canadian Forensic Spectra (3750 spectra).
- The spectra of 1044 organic compounds are presented as pictures in: Schrader B (1989). *Raman/Infrared Atlas of Organic Compounds*, 2nd edn, New York: Wiley.
- Lin-Vien D *et al.* (1991). *Handbook of Infrared and Raman Characteristic Frequencies of Organic Molecules*. London: Academic Press.
- Nyquist RA *et al.* (1997). *The Handbook of Infrared and Raman Spectra of Inorganic Compounds and Organic Salts*, 4 volumes. London: Academic Press. (Also a CD-ROM version.)
- NIR, IR, Raman and UV-visible spectra of organic compounds, polymers and surfactants are presented in: Workman J Jr (2000). *Handbook of Organic Compounds*, 3 volumes. New York: Academic Press.
- Tables and charts of IR spectra can be obtained from: Socrates G (2001). *Infrared and Raman Characteristic Group Frequencies: Tables and Charts*, 3rd edn. New York: Wiley.
- NICODOM Ltd, Hlavni 2727, CZ-14100 Prague 4, Czech Republic (www.ir-spectra.com). FTIR spectra Database of over 140 000 infrared spectra.

Specialised collections

Drugs

Collection of spectra (includes IR, UV, NMR, mass spectra, etc.) of 1750 illicit and prescription drugs: Mills T *et al.* (2005). *Instrumental Data for Drug Analysis*, Vols 1–6, 3rd edn. Boca Raton, FL: CRC Press.

Alkaloids

1000 spectra with other physical data: Holubek J, Strouf O (1965–1973). *Spectral Data and Physical Constants of Alkaloids*. London: Heyden.

Antibiotics

A comprehensive collection published by the International Centre of Information on Antibiotics: Lenzen C, Delcambe L *ICIA Inf Bull* 1972, *10:* 78–160; 1973, *11*: 1–157; 1975, 12: 1–178; 1976, 13: 1–178; 1977, 15: 1–208; 1977, 16: 1–212; 1978, 17: 1–248; 1979, 18: 1–268.

Barbiturates

Solution spectra of 41 barbiturates: Sucharda-Sobczyk A (1970). *Roczn Chem* 44: 1435–1445. Also Mesley RJ (1970). *Spectrochim Acta* 26A: 1427–1448.

Carbohydrates

Spectra of 79 carbohydrates: Kuhn LP (1950). *Anal Chem* 22: 276–283.

Excipients

Spectra of 300 commonly used excipients: Bugay DE, Findlay WP (1999). *Pharmaceutical Excipients Characterization by IR, Raman, and NMR Spectroscopy*. New York: Marcel Dekker.

Narcotics and related bases

Levi L *et al.* (1955). *Bull Narcot* 7: 42–84.

Farmilo CG, Genest K (1963). Narcotics and related bases. In: Stolman A, ed. *Progress in Chemical Toxicology*, Vol. 1. London: Academic Press, 199–295.

Natural products

Spectra of alkaloids, amino acids, carbohydrates, carotenoids, steroids and terpenes: Yamaguchi K (1970). *Spectral Data of Natural Products*, Vol. 1. Amsterdam: Elsevier.

Organophosphorus compounds

Shagidullin RR *et al.* (1990). *Atlas of IR Spectra of Organophosphorus Compounds*. Moscow: Nauka.

Pesticides and related compounds

Spectra of 76 pesticides: Gore RC *et al.* (1971). *J Assoc Off Anal Chem* 54: 1040–1082.

Spectra of 478 pesticides, disinfectants, fumigants, fungicides, etc.: Giang P (1977). Spectroscopic methods of analysis. In: Zweig G, ed. *Analytical Methods for Pesticides and Plant Growth Regulators*, Vol. 9. London: Academic Press, 153–290.

Spectra for 68 substances which may occur as impurities, residues or adjuvants in commercial pesticides: Collerson RR *et al.* (1976). *NPL Report Chem*. 48, National Physical Laboratory, Division of Chemical Standards.

Pharmaceutical spectra of 335 substances: Sammul OR *et al*. (1964). *J Assoc Off Agric Chem* 47: 918–991.

Over 400 FTIR spectra of commonly used pesticides and related metabolites: Visser T (1993) *Infrared Spectra of Pesticides*. London: Taylor and Francis (CRC).

Phenothiazines

Spectra of 19 phenothiazines: Scapini G, Gardini GP (1964). *Ateneo Parmense* 35: 328–334.

Phenothiazines and their sulfoxides: Kreyenbuhl B *et al*. (1979). *Pharm Acta Helv* 54: 197–205.

Turner LK (1963). *J Forensic Sci Soc* 4: 39–49.

Plasticisers

Spectra of 284 plasticisers and additives: Craver CD, ed. (1977). *Plasticisers and Other Additives*. Kirkwood: The Coblentz Society.

Steroids

Spectra of 900 steroids: Neudert W, Roepke H (1965). *Atlas of Steroid Spectra*. Berlin: Springer-Verlag.

Also: Arzamastsev AP, Yashkina DS (1975). *Ultraviolet and Infrared Spectra of Drugs*, No. 1, Steroids. Moscow: Meditsina.

CHAPTER

34 Near-infrared Spectroscopy

RD Jee

Introduction

The near-infrared (NIR) region of the electromagnetic spectrum extends from about 780 nm to 2500 nm (or 12800 to 4000 cm^{-1}). It is therefore the part of the spectrum that exists between the red end of the visible spectrum and the beginning of the mid-infrared (IR) region. Its discovery by Herschel in 1800 was the first indication that radiation other than visible radiation existed.

The region is subdivided into two regions: 780–1100 nm and 1100–2500 nm, the first of which is named the Herschel region. Although discovered some 200 years ago, it is only in the past 35 years with the advent of computers and chemometrics that its analytical potential has been exploited. For the qualitative analysis of solid samples, invariably NIR spectra are measured by reflectance. Spectra are often complex with many overlapping peaks (Fig. 34.1A). As a result of this, the technique was viewed originally with some scepticism until the easy application of chemometric methods became possible. Although the reflectance spectrum of a material is complex, its second-derivative spectrum is very suitable for identification purposes (Fig. 34.1B).

NIR spectra are associated with molecular vibrations and consequently provide information similar to that obtained by mid-IR spectrophotometry. Although NIR spectra are much more difficult to interpret than mid-IR spectra, it is their fingerprint nature that makes the technique useful for identification purposes.

NIR spectroscopy is not a trace analytical technique nor is it generally suited to the identification of individual substances in multicomponent mixtures. Its strength lies in its ability to identify relatively pure samples rapidly or to identify a matrix of nearly fixed composition, such as tablets. Although it is used for the quantitative assay of solids in the pharmaceutical industry, setting up a calibration model is usually a time-consuming and expensive process that precludes its use for 'one-off' quantitative determinations. Spectra are particularly simple to measure, and the technique is non-destructive and generally requires no sample preparation. A further advantage of NIR spectra is that they contain information about the physical properties of the sample, such as particle size, compaction density, polymorphs, etc., which often makes it possible to differentiate between samples of the same chemical identity but of different grades or from different sources.

Theory

NIR absorbances correspond to overtones and combinations of molecular vibrations that have their fundamentals in the mid-IR region of the spectrum. Figure 34.2 illustrates the potential energy curve for a simple diatomic molecule.

The allowed energy levels, E, for such an anharmonic oscillator are given by:

$$E \approx (v+0.5)hf - (v+0.5)^2 hfx$$

where h is Planck's constant, v is the vibrational quantum number, f is the equilibrium frequency of oscillation and x is the anharmonicity constant. The vibrational quantum number may take values 0, 1, 2, ... The selection rules for an anharmonic oscillator are $\Delta v = \pm 1, \pm 2, \pm 3, \ldots$, and consequently transitions such as $\nu_{1\leftarrow 0}$, $\nu_{2\leftarrow 0}$, $\nu_{3\leftarrow 0}$, $\nu_{2\leftarrow 1}$, etc., are allowed (in practice, only transitions starting at $v = 0$ are important for spectra measured at room temperature). These transitions are referred to as the fundamental frequency of vibration, first overtone, second overtone, and so on. As the anharmonicity constant is typically small ($x < 0.05$), these spectroscopic transitions occur approximately at frequencies close to f, $2f$ and $3f$, and so on.

For most molecular vibrations the fundamental frequency of vibration occurs in the mid-IR region of the spectrum; however, the overtones occur in the NIR region, which is the basis of NIR spectroscopy.

Polyatomic molecules may exhibit simultaneous changes in the energies of two or more vibrational modes: the frequency observed will be the sum ($f_1 + f_2$, $2f_1 + f_2$, ...) or the difference ($f_1 - f_2$, $2f_1 - f_2$, ...) between the individual frequencies (note that $2f$ represents the first overtone and the subscripts 1 and 2 refer to different vibrational modes). This results in very weak bands called combination and subtraction bands – the latter are possible, but rarely observed in spectra measured at room temperature. Combination bands have a very low probability of occurrence unless they arise from two vibrations that involve a common atom or arise from bonds connected through multiple chemical bonds. The transition probabilities for overtones and combination bands are 10^{-1} to10^{-3} those for the fundamental frequency and, consequently, such absorbances are weak. This weakness of absorbances can be put to good advantage in that samples may be measured without any need for sample dilution or preparation.

Reflectance and transmission

NIR spectra may be measured by either reflectance, R, or transmission, T. Reflectance is the ratio of the intensity of radiation reflected by the sample, I_r, to the intensity of the radiation impinging on it, I_0; hence $R = I_r/I_0$.

Similarly, transmission is the ratio of the intensity of radiation that passes through the sample, I_t, to that impinging on it, I_0; hence $T = I_t/I_0$.

Reflected radiation is made up of two main components – specular and diffuse radiation. Specular reflection is radiation that is simply reflected directly from the surface of the sample and contains little useful information about the sample for identification purposes.

Diffuse reflection refers to radiation that has penetrated into the particles of the sample, undergone multiple reflections within the substance and re-emerged after the various characteristic absorptions of the substance have occurred.

Figure 34.3 shows a schematic illustration of diffuse reflectance, I_r. Such reflected radiation gives rise to chemical information. The path length of the radiation is dependent on numerous factors, such as particle size, particle shape and sample compaction, and therefore also contains information about the physical state of the sample. The exact path taken by the radiation is difficult to describe mathematically and consequently there is no totally satisfactory theory for diffuse reflectance. However, the Kubelka–Munk theory is a useful approximation for NIR reflectance measurements.

The Kubelka–Munk function, $f(R_a)$, relates the absolute reflectance, R_a, of the sample to its absorption coefficient, k, and scattering coefficient, s, according to:

$$f(R_a) = \frac{(1 - R_a)^2}{2R_a} = \frac{k}{s}$$

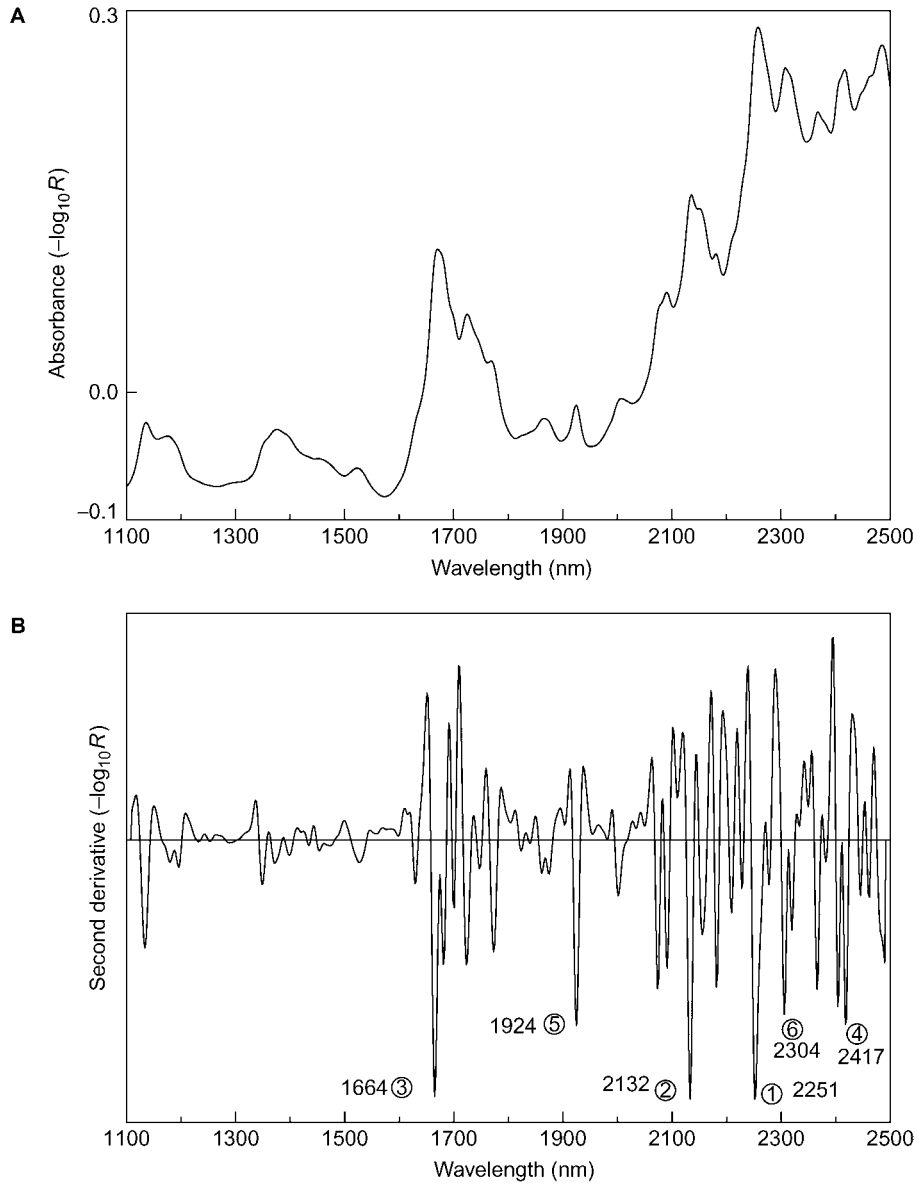

Figure 34.1 (A) Near-infrared spectrum of acetomenaphthone ((4-acetyloxy-2-methylnaphthalen-1-yl) acetate) measured by reflectance; (B) the second-derivative spectrum of (A). Circled numbers indicate the six most intense negative peaks in order of decreasing intensity.

The absorption coefficient is equal to the absorptivity, ε (as defined by the Beer–Lambert law), multiplied by the concentration, c, and hence the Kubelka–Munk function is related to concentration according to:

$$f(R_a) = \frac{\varepsilon c}{s}$$

Recently Dahm and Dahm (2007) have developed a new theory for interpreting diffuse reflectance and transmittance.

Practical reflectance measurements are made with respect to some standard reflecting material. A measure of practically measured reflectance (R_m, although R is commonly used for this function) is the ratio of the intensity of light reflected from the sample to that reflected from a background or reference surface. The dependence of reflectance on concentration is often no better described by the Kubelka–Munk function than by using the apparent absorbance ($A = -\log_{10} R$) and Beer's law:

$$A = -\log_{10} R = a' c$$

where a' is a proportionality constant.

The passage of radiation through a solid or powdered sample occurs by what is termed diffuse transmission. The radiation undergoes many internal reflections within the particles of the sample and emerges in all directions (Fig. 34.3). Because of the many internal reflections, the actual optical path length can be surprisingly large; for a 2–5 mm thick tablet it is about 20–25 cm (Johansson *et al.* 2002).

The transmission of a 2–5 mm thickness of compact powder (e.g. a tablet) when measured with respect to air will typically be 10^{-4} to 10^{-6}. Transmission measurements are commonly limited to the wavelength region below 1900 nm because of the poor signal-to-noise ratio at longer wavelengths. Compared with reflectance spectra, transmission spectra tend to lack detail and are therefore less suited for identification purposes.

Instrumentation

Spectrometers that record NIR spectra are generally based on filter, grating or interferometer designs. Instrumentation is similar to that used for ultraviolet and/or visible absorption spectroscopy and is based on fixed wavelengths, scanning or diode array systems. Tungsten–halogen lamps serve as energy sources, while lead sulfide and/or indium gallium

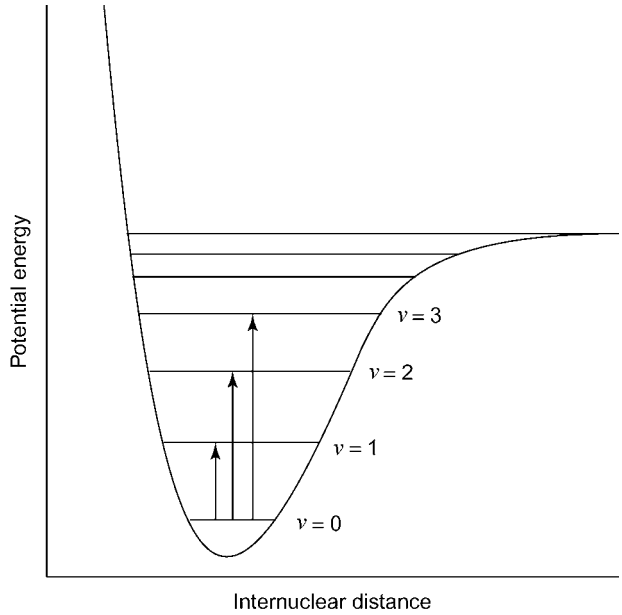

Figure 34.2 Vibrational energy levels for a diatomic molecule, illustrating the transitions that correspond to the fundamental frequency ($v = 0 \rightarrow v = 1$), the first overtone ($v = 0 \rightarrow v = 2$) and the second overtone ($v = 0 \rightarrow v = 3$).

arsenide detectors are used. Present-day instruments are computer controlled, which enables spectra to be measured in a matter of seconds and saved to a computer file.

A typical spectral file for a grating instrument consists of 700–4000 data points at 2- to 0.5-nm intervals over the wavelength range 1100–2500 nm. Fourier transform (FT) instruments normally give outputs in wavenumbers and a typical file might have 500–3000 data points at 12–2 cm^{-1} intervals over the range 4000–10 000 cm^{-1} (i.e. 2500–1000 nm). Saved spectra are generally the average of a number of scans so as to reduce noise levels. Measurements are made by reflectance or transmission. Details of sample presentation methods are given in the section Sample preparation and sample presentation.

Data processing and presentation of results

Although the original NIR reflectance spectrum of a substance is complex and often relatively featureless, its second-derivative spectrum is very suitable for identification purposes. Taking the second derivative of the spectrum largely removes the effects of baseline offsets and baseline slopes. This is illustrated in Fig. 34.4A, which shows a spectral absorption peak with:

1. Horizontal background
2. Linearly sloping background
3. A curved background plus zero offset.

Taking the first derivative with respect to wavelength removes any offset and reduces a linearly sloping background to a simple offset (Fig. 34.4B). Taking a further derivative (i.e. second derivative) removes this offset and all three spectra are now almost identical (Fig. 34.4C).

The positions of the negative peaks in the second-derivative spectrum correspond to the positions of peaks in the original spectrum. This can be seen for acetomenaphthone in Fig. 34.1A and B. Derivative spectra can be calculated by a variety of methods. The simplest is to calculate the difference between blocks of data points on either side of the wavelength at which the derivative is required. This point is replaced by the difference between the two blocks (Fig. 34.5).

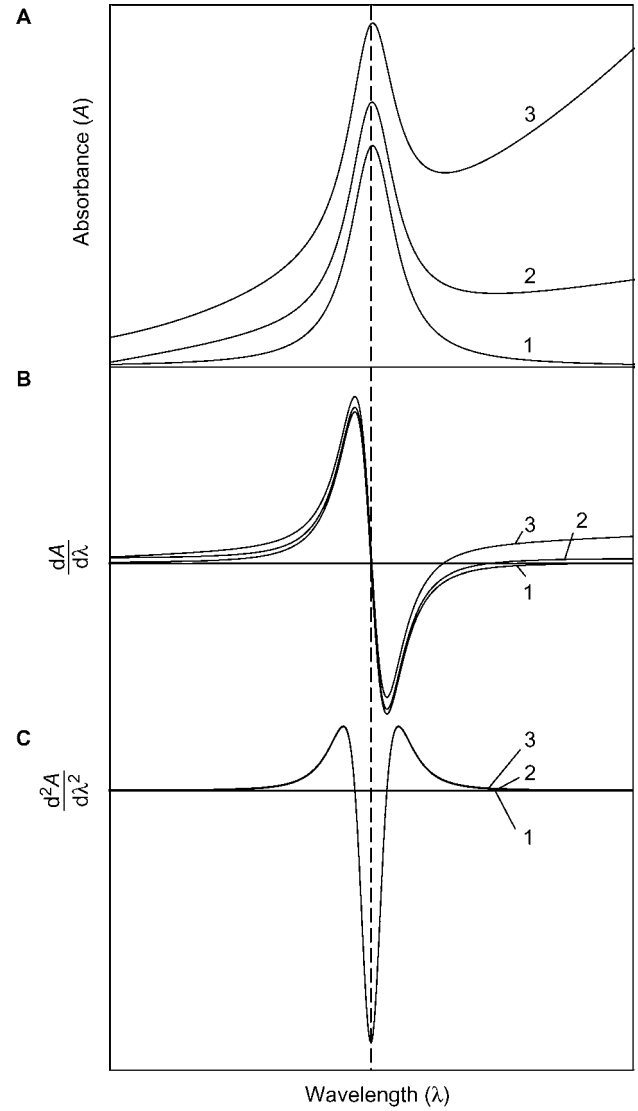

Figure 34.4 Advantages of using second-derivative spectra: (A) original spectra, (B) first-derivative spectra and (C) second-derivative spectra. 1, zero baseline; 2, linearly sloping baseline; 3, curved (quadratic) baseline with zero offset.

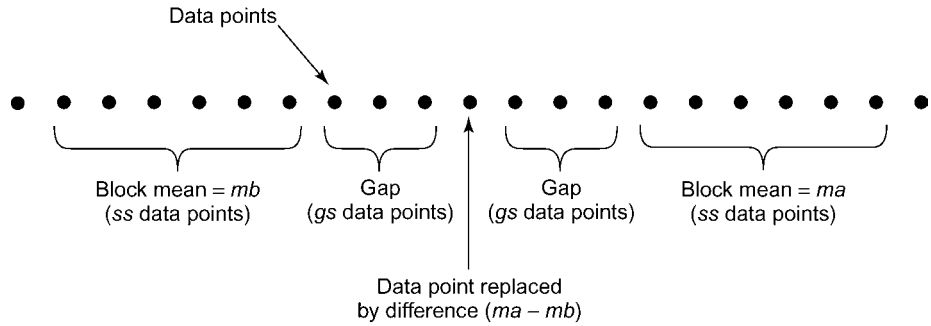

Figure 34.5 Simple difference method for calculating derivative spectra. *ss* is the number of data points in the sample block; *gs* is the number of data points in the gap block.

The process is repeated across the whole spectrum, moving along one data point each time. To calculate a second derivative, etc., the process is simply repeated the required number of times. By suitable selection of the number of data points in the sample block (*ss*) and the number of points in the gap block (*gs*), the degree of spectral smoothing can be adjusted. Values of $ss = 3$ to 10 and $gs = 0$ are commonly used. Sample spectra and reference spectra must be treated equally.

Another commonly used method is that of Savitzky and Golay (1964). In effect, a polynomial of specified order is fitted by least squares to the data using a specified number of data points before and after the point at which the derivative is required. The estimated derivative is then the derivative of the resultant fitted polynomial. The process is repeated across the whole spectrum, moving one data point each time. These many-least-squares fits could be laborious and time-consuming. However, provided that the data points are all equally spaced, they can be achieved very efficiently using a Savitzky–Golay filter. Typical parameters used are 3–10 data points with a polynomial fitting order of 2–4. The Savitzky–Golay method has the advantages that it is a published method and gives more control over the smoothing parameters (number of data points and order of polynomial).

Sample compaction and changes in particle size of samples can have a pronounced effect upon the spectrum of a sample. Figure 34.6A shows spectra for samples of lactose monohydrate of different particle sizes.

Various data pre-treatments may be applied if it is required to reduce such effects. The best one for a particular application is usually found by trial and error. The standard normal variate (SNV) transformation is one of several normalisation processes that may be used. The ordinate (absorbance, second-derivative absorbance, etc.) of a spectrum at each wavelength, i, is replaced by z_i according to:

$$z_i = \frac{(y_i - \overline{y})}{s}$$

where $\overline{y}$ is the mean spectral value over the complete spectrum, s is the standard deviation of the spectral values over the complete spectrum and y_i is the spectral value at wavelength i. Figure 34.6B shows the lactose monohydrate spectra after SNV transformation, which demonstrates that most of the effects of particle size have been removed.

Multiplicative scatter correction (MSC) is another transformation commonly applied to minimise light-scattering effects. For each spectrum in a set (e.g. calibration set) a linear regression of the ordinate values on those for the mean spectrum of the set is performed. The intercept, a, and slope, b, are then used to generate a new spectrum according to:

$$y_{\mathrm{MSC},I} = (y_i - a)/b$$

where y_i is the original ordinate value at wavelength i and $y_{\mathrm{MSC},i}$ is the corresponding corrected value. In effect, each spectrum is adjusted so that it fits the mean spectrum as closely as possible. Unlike the SNV transformation, the values of a and b calculated from the mean spectrum must be stored so that the same transformation may be applied to the spectra of test samples. An advantage with respect to SNV, however, is that the corrected spectra have an ordinate scale similar to that of the original spectra.

Systems suitability test

Most NIR instrument and/or software systems prevent sample measurements being taken until a systems suitability test has been run. Checks typically include photometric noise, wavelength accuracy, band-pass, etc., and are normally carried out once per day. The *British Pharmacopoeia* (2008) and *European Pharmacopoeia* (Council of Europe 2007) provide a number of guidelines for performance checking, as also does the Pharmaceutical Analytical Sciences Group (see Further reading). A number of independent tests for noise and wavelength accuracy, and so on, can be carried out easily.

Wavelength accuracy

Numerous wavelength standards for the NIR spectral region are available (Burgess, Hammond 2007). Standard reference materials (SRMs) are available from the United States National Institute for Standards and Technology (NIST) for wavelength accuracy measurements. The present preferred NIST standard for reflectance measurements is SRM 2036 which is a poly(tetrafluoroethylene)-backed glass made from a mixture of holmium, samarium, ytterbium and neodymium oxides in a zirconia-stabilised borate matrix (Choquette *et al.* 2005). This standard provides seven well-defined nearly symmetrical peaks in the 975–1946 nm range with a wavelength accuracy of better than 0.1 nm. Most instrument manufacturers can also supply standards that are traceable to the NIST standards. The reflectance spectrum of an equal mixture by mass of dysprosium, erbium and holmium oxides is commonly used as a standard and exhibits 37 reflectance minima in the NIR wavelength range (Weidner *et al.* 1986). Above 2000 nm there are few useful peaks in the mixed oxide standard. However, the addition of talc to the mixture provides a useful reference peak at 2313.5 nm. Figure 34.7A shows the reflectance spectrum of a mixed lanthanide oxides/talc standard over the wavelength range 1100–2500 nm, with the major minima marked. The reference wavelength values are slightly band-pass dependent and the values shown are for an instrument with a band pass of 10 nm. The reference values given by NIST for this mixed oxide standard have an uncertainty of ±1 nm. As some minima are associated with a sloping background, it is important to display the spectrum in terms of reflectance rather than absorbance ($-\log_{10} R$), this being the condition under which NIST documented the wavelength values. Pure (>99.99%) samples of the lanthanide oxides are readily available and may be used instead of expensive NIST wavelength SRMs. Examples of reflectance spectra obtained for the three separate oxides measured on a FT-NIR instrument are shown in Fig. 34.7B. As the band pass of a FT-NIR instrument varies in terms of wavelength across the spectrum, care is needed in selecting the reference values. In Fig. 34.7B, reference values for a 10 nm band pass were used in the range 4000–7000 cm^{-1} and 5 nm band-pass values for above 7000 cm^{-1}. A typical commercial grating instrument (data stored at 2 nm intervals) might have a wavelength

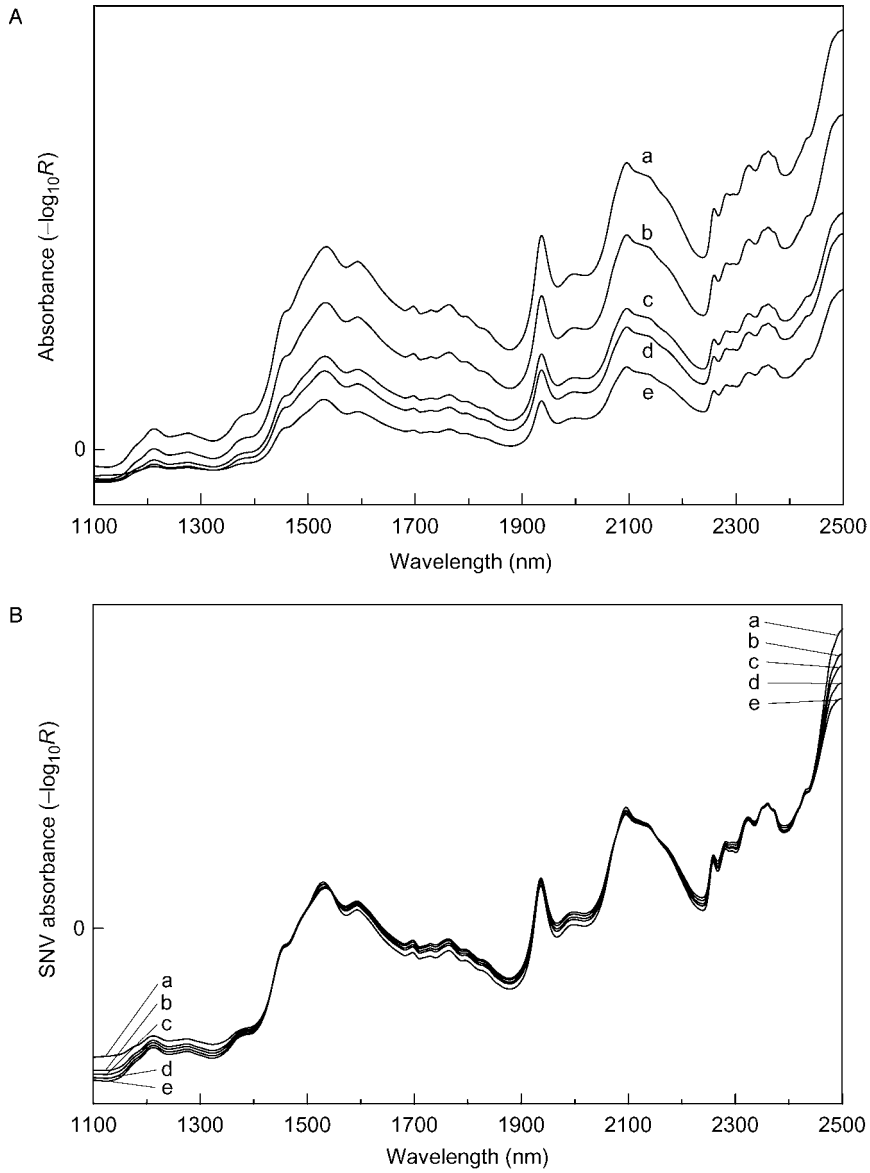

Figure 34.6 Effect of particle size on the reflectance spectrum of lactose monohydrate. Sieve fractions: (a) >150, (b) 93, (c) 63, (d) 45 and (e) 32 µm. A, original spectra; B, spectra after standard normal variate (SNV) transformation.

accuracy of ±0.3 nm, while an FT instrument (data stored at 12 cm^{-1} intervals) has an accuracy of ±2 cm^{-1}. Some form of wavelength interpolation between stored data points is essential when locating the position of minima (see Wavelength repeatability).

NIST and NIST-traceable wavelength standards for transmission measurements are also available; however, an inexpensive alternative is to use trichloromethane, which exhibits sharp absorption peaks at 1152.1, 1410.2, 1619.9 and 1861.2 nm (Busch *et al.* 2000). The *British Pharmacopoeia* recommends the use of methylene chloride (dichloromethane) as a standard. Figure 34.8 shows the spectrum of methylene chloride with the important absorption peaks labelled. For instruments in which transmittance or transflectance measurements are not possible, a spectrum may be measured by adding titanium dioxide to a few millilitres of methylene chloride and recording the diffuse reflectance spectrum.

Wavelength repeatability

Wavelength repeatability can be checked by recording a sample spectrum a number of times (e.g. more than 12 times, without moving the sample between scans) and calculating the standard deviation of the wavelengths of minima or maxima in the second-derivative absorbance spectra. Materials with well-defined narrow second-derivative peaks, such as the mixed lanthanide oxides wavelength standard (suitable for wavelengths below 2200 nm), are ideal. Alternatively, compounds such as ascorbic acid, aspartame, benzoic acid, salicylic acid, sucrose and talc may be used. Some form of wavelength interpolation between stored data points is essential when locating the position of peaks. Fitting a quadratic curve to three consecutive data points that encompass a peak and calculating the exact position from the equation works well. Let the fitted equation be $A = a + b\lambda + c\lambda^2$, where A is the second-derivative absorbance and a, b and c are the fitted coefficients; then $p_{eak} = -b/2c$. Typical standard deviations for peak wavelengths are <0.01 nm for a grating instrument that stores data points at 2 nm intervals and <0.5 cm^{-1} for a FT instrument that stores data at 12 cm^{-1} intervals.

Photometric noise

Photometric noise can be determined by measuring the absorbance of a single sample a number of times (e.g. >12) and calculating the standard deviation at each wavelength. To obtain an estimate of the instrument noise, as distinct from the repeatability of sample measurements, the

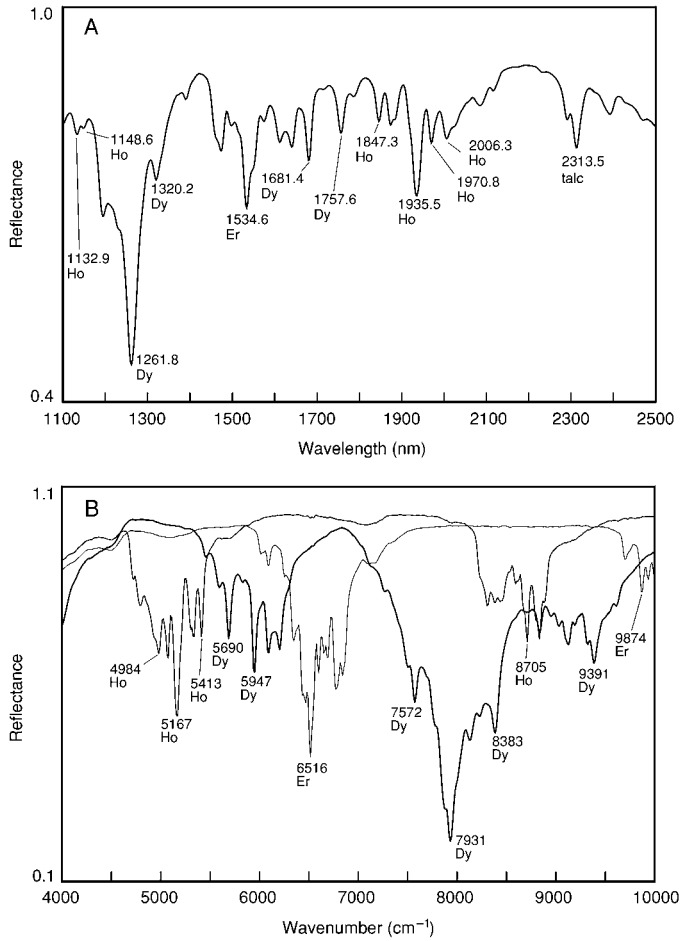

Figure 34.7 (A) Reflectance spectrum of a three lanthanide oxides (Ho_2O_3, Dy_2O_3 and Er_2O_3) and talc wavelength standard (wavelength scale); (B) reflectance spectra of holmium, dysprosium and erbium oxides (wavenumber scale).

sample should not be moved between scans. To reduce the effects of wavelength repeatability errors, the sample used should ideally have a flat spectral response. Rapid repeat scanning of a sample can result in sample heating and introduce unwanted variations in the spectra. For this reason, sintered perhalopolyethylene cake and/or carbon black reflectance standards are not recommended for this test. The noise level should be checked over the full wavelength range of the instrument and for both low and high absorbances. For low-absorbance samples the instrument reference standards, barium sulfate and titanium dioxide, are ideal. As strong absorbers, substances such as carbon black, finely ground sucrose and butylated hydroxytoluene, may be used. Although far from spectrally flat, the mixed lanthanide oxides wavelength standard is thermally stable and works well. Noise levels depend upon the number of primary scans averaged. However, under normal recommended operating conditions, the noise level is generally very low and differences between repeat spectra are not easily visible without expanding the display scale. For typical grating instruments, repeat measurements can be expected to give a standard deviation of <0.05 milli-absorbance units (mAU) across the wavelength range 1100–2500 nm and absorbance range zero to unity. The typical noise level for a FT-NIR instrument would be <0.5 mAU.

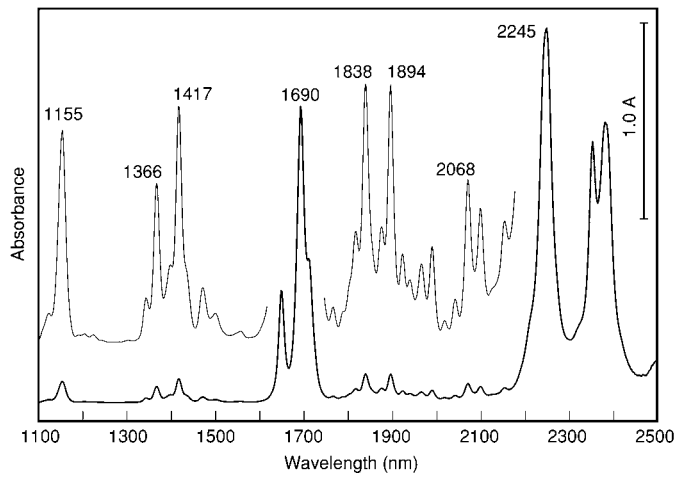

Figure 34.8 Absorbance spectrum of methylene chloride measured by transflectance with a 1 mm optical path length. The ordinate scale for the inserts has been magnified 10-fold.

Photometric accuracy, linearity and specular and/or stray radiation

All reflectance measurements made using a sample stage include specular radiation from the sample stage itself and from the sample bottle (Fig. 34.9A and B). The effect of this is to make a plot of measured absorbance ($-\log_{10} R_m$) versus true (absolute) absorbance ($-\log_{10} R_a$) curved and hence limit the photometric range. To check photometric linearity, and measure the extent of specular radiation, samples of known absolute reflectance are required. Suitable standards with absolute reflectances of 0.02–0.99 are available from NIST and various instrument manufacturers. The standards typically are carefully prepared mixtures of sintered perhalopolyethylene cake and carbon black and should regularly be sent for re-certification. Tables of actual reflectance versus wavelength are provided for each standard. The measured reflectance for a given standard (relative to the instrument standard) can be expressed as follows:

$$R_m = \frac{(I_D + I_s) + I_{ss}}{I_{oc}} = \frac{R_a(I_o - I_{ss}) + I_{ss}}{I_{oc}}$$

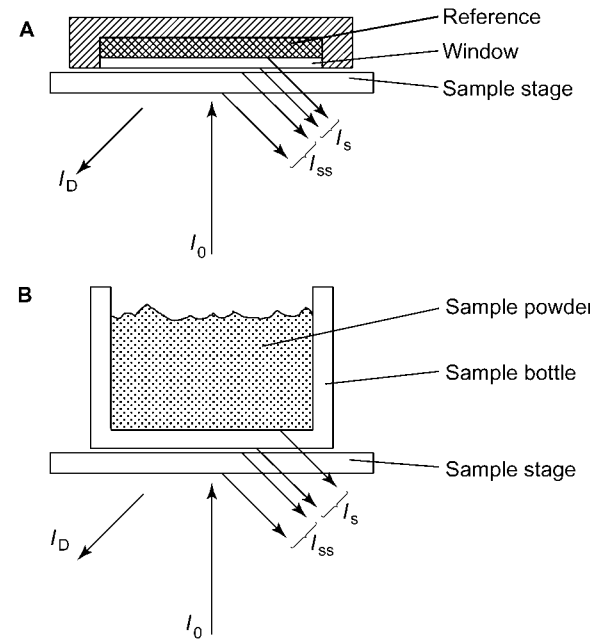

Figure 34.9 Measurement of reflectance using a sample stage: (A) reference measurement; (B) sample measurement. I_0 is the intensity of impinging radiation, I_D is the intensity of diffuse reflected radiation from the reference/sample, I_s is the intensity of specular radiation reflected by the sample bottle or reference window and I_{ss} is the intensity of specular radiation reflected by the sample stage.

or

$$R_m = R_a k + k'$$

where I_0, I_D, I_s and I_{ss} are as defined in Fig. 34.9 and k and k' are constants (and therefore $I_r = I_D + I_s + I_{ss}$). I_{0c} represents the intensity of radiation reflected by the instrument reflectance standard. The above assumes that the collection efficiency and/or geometry is the same for both the reference and the sample.

A plot of R_m versus R_a at a given wavelength should therefore give a straight line if the photometric response is linear. However, in practice, a small degree of curvature is usually observed. The value of k' represents the specular and/or stray radiation expressed as a fraction of radiation reflected by the instrument reflectance standard. Values for k' vary from one instrument to another and change with time as the surface conditions of the sample stage, etc. age ($k' < 0.01$ is typical). Measuring the signal without a sample on the stage also gives a simple method of accessing the background specular and/or stray radiation, provided that external light and internally reflected radiation can be avoided. Similarly, measuring an empty bottle (no top) gives a measure of $I_s + I_{ss}$ relative to the instrument standard.

Sample preparation and sample presentation

NIR spectra can be measured by either reflectance or transmission. Reflectance measurements are particularly easy to make. Common glasses (borosilicate, soda, etc.) are virtually transparent to NIR radiation and powdered samples may be measured in such sample bottles directly (Fig. 34.10A and B). Transmittance measurements of solids, e.g. tablets, require custom-made holders so as to minimise radiation leakage around the edge of the tablet. Absorbances for tablets by transmittance are typically 3–5 absorbance units and restricted to below 1900 nm.

The radiation reflected by the sample is measured as a function of wavelength and with respect to the reflectance of a suitable standard, such as a flat disc of ceramic or Spectralon. Spectra are clearly dependent upon the reference chosen and the reproducibility of such standards can be a problem when it comes to transferability of spectra from one instrument to another. This problem has not been completely resolved at present. Fibre-optic probes that can be inserted directly into the sample can be attached to many instruments (Fig. 34.10B). Liquids can be measured using conventional cuvettes or by transflectance, again using a fibre-optic probe fitted with a transflectance tip (Fig. 34.10C), or directly on a sample stage in a cup with a suitable reflector (Fig. 34.10D). Transflectance reflectors may be gold plated, stainless steel, PTFE, etc., and constructed with various path lengths. The optical path length for transflectance is twice the physical path length as the radiation passes through the sample twice. For most liquid samples an optical path length of 1–5 mm is suitable.

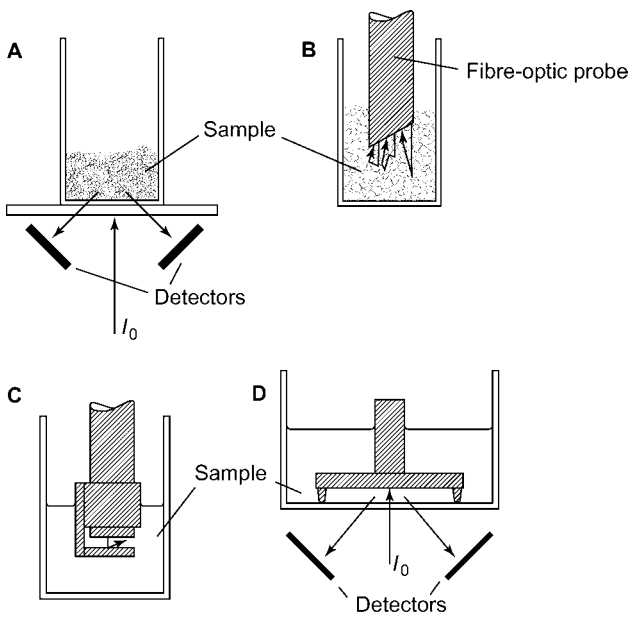

Figure 34.10 Sample presentation methods: (A) sample bottle on sample stage; (B) fibre-optic probe; (C) liquid sample using a fibre-optic probe fitted with transflectance adapter; (D) liquid sample measured by transflectance.

For the measurement of powders by reflectance, it has been recommended that sample bottles should be filled by 'pouring' the powder into the bottle without tapping (Yoon *et al.* 1998). Tapping causes compaction of the powder and was found to result in poor sample-measurement repeatability. For reflectance measurements, the sample thickness should be sufficient that any further increase in sample thickness has no effect upon the spectrum. Typically, NIR radiation penetrates 1–3 mm into a powdered sample and a sample thickness of >10 mm is recommended to give an effective 'infinite thickness'. For a compact material, such as a tablet, the reflected radiation will penetrate only 0.1–1 mm. The sample bottle diameter should exceed that of the radiation beam. For many instruments this means a bottle of diameter of about 10 mm or greater. Sample bottles should be chosen that have smooth bases, otherwise specular reflectance varies from one bottle to the next, as well as with the orientation on the sample stage. A typical sample bottle contributes 2–10% of specular radiation to the reflected signal. The same type of sample bottle should be used for both test samples and reference materials.

Sample-measurement repeatability is very dependent upon the nature of the sample. Liquids and solutions are highly reproducible because of the homogeneous nature of the sample. Crystalline powders usually show poor repeatability because of varying specular reflection from the crystal surfaces. Specular reflection distorts the 'absorbance' spectrum and limits the usable photometric range. Identification algorithms can be affected markedly by the crystallinity of samples. Careful crushing of the material to reduce the particle size can help to minimise the effects. Vibrational patterns are affected by differences in the crystal lattice and hence different polymorphs show significant differences in their NIR spectra (Blanco *et al.* 1998; Patel *et al.* 2001).

Solvents for the preparation of solutions are somewhat limited. Only carbon tetrachloride and carbon disulfide among the common solvents are transparent throughout the entire NIR region. Methylene chloride, dioxane, heptane, acetonitrile and dimethyl sulfoxide have regions below 2200 nm that can be used.

Water has a particularly strong absorbance spectrum in the NIR region and samples must be protected from uptake of water from or loss of water to the atmosphere. The presence of water can be recognised easily by the characteristic absorption peak in the range 1900–1940 nm. The exact peak position depends on the nature of the water – free water or water of crystallisation – and the extent of hydrogen bonding. The water peak in the spectrum of lactose monohydrate (see Fig. 34.6) and the residual water in the chlortetracycline hydrochloride samples (see Fig. 34.16) can be easily seen.

Intact tablets may be measured as easily as any other sample. A sample bottle that contains tablets randomly packed may be placed on the sample stage, or single tablets may be measured directly. The depth of penetration of reflected radiation from compact materials, such as tablets, is limited to only a few tenths of a millimetre. Markings on tablets can affect the spectra and a decision to measure one side or both needs to be made. With coated tablets it is possible for the reflectance spectrum to be dominated by the coating material, though some radiation will penetrate into the core. Tablets can be crushed and the powder measured in a sample bottle if required.

With grating instruments, spectra commonly exhibit a small anomalous peak known as Wood's peak at about 1520 nm. The magnitude of the peak is dependent upon the difference in diameters of the sample and reflectance standard used: the greater the difference, the larger the peak (Fig. 34.11). It can be quite pronounced in the spectra of poorly absorbing substances and care is required not to confuse Wood's peak with peaks from the material. Tablets, which generally have a small diameter, often show a prominent Wood's peak when measured by placing them directly on the sample stage.

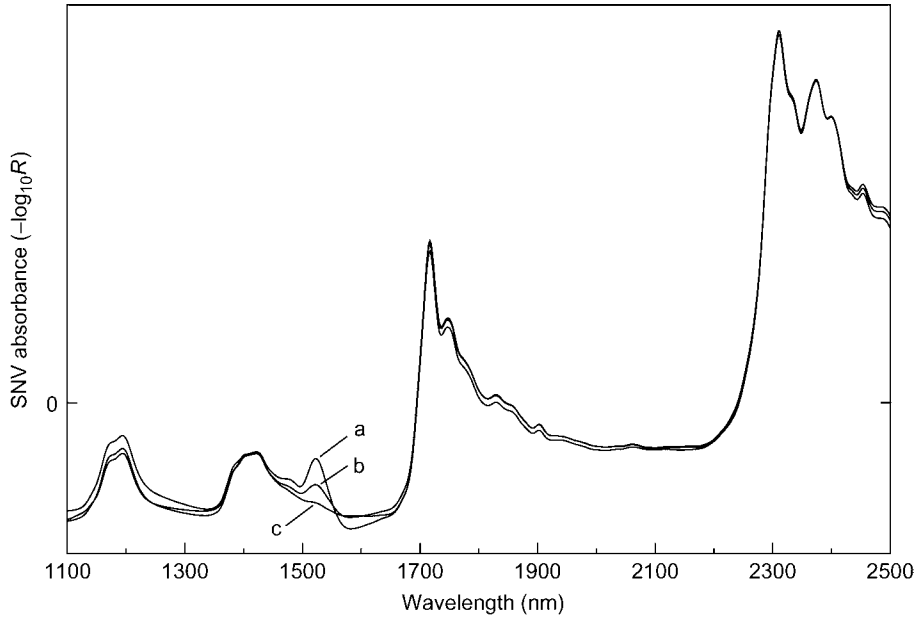

Figure 34.11 Wood's anomaly observed with grating monochromator instruments. Reflectance spectra of poly(vinyl chloride) powder measured in sample bottles of different diameter. Bottle diameter: (a) 8 mm, (b) 15 mm, (c) 25 mm. Reference diameter 50 mm.

Interpretation of spectra

Functional groups such as X–H, where X is C, N, O or S, have a small reduced mass and hence high fundamental frequency of vibration, and are particularly important for NIR spectroscopy – the first and second overtones appear in the NIR region. Groupings such as C–Cl, C–F, C=O, etc., with high reduced masses, are of less importance in NIR spectroscopy as their fundamental frequencies are low and their overtones generally also appear in the mid-IR region. For organic molecules, the C–H bond is the most important and for alkanes its fundamental stretching vibration in the mid-IR region at about 2960–2850 cm^{-1} gives rise to first and second overtones at approximately 1700–1730 and 1150–1170 nm in the NIR region. The C–H group stretching and deformation vibrational modes give rise to combination bands in the region 2000–2500 nm. Water is a particularly strong absorber in the NIR region, with the O–H first overtone of the stretching vibration occurring at 1450 nm (second and third overtones at 970 and 760 nm, respectively). Alcohols similarly show absorptions around 1450 nm. A very intense absorption occurs in the region 1900–1940 nm for water and has been assigned to the combination band between the fundamental stretching and deformation vibrations of the O–H bond; in the case of alcohols this vibration occurs at a somewhat longer wavelength. Temperature can have a marked effect on the spectra of compounds with hydrogen bonds. The spectrum of water is particularly sensitive to temperature, with changes in both the intensities and the band positions. Similar shifts are observed for different states of adsorbed water.

Although characteristic wavelengths, such as those mentioned above, can often be identified readily in the NIR spectrum of a material, the general complexity of NIR spectra precludes any easy interpretation and identifications are based on comparison with reference spectra. Figure 34.12 gives a summary of the positions of some of the more important NIR absorptions. More extensive lists of NIR vibrations are given by Osborne *et al.* (1993) and Burns and Ciurczak (2001).

Qualitative analysis

Identification of samples depends in one way or another on comparing sample spectra to spectra of known standards. Three simple classification procedures are described below.

Peak positions

The six-peak method used for mid-IR spectra (see Chapter 33) is particularly simple and can be easily applied to NIR spectra. Figure 34.1B shows the second-derivative spectrum of a sample of acetomenaphthone. The positions of the six most intense peaks (negative-going peaks) are noted and then compared with a database of peak positions of compounds. An example of part of such a database is shown in Table 34.1, in which the spectroscopic peaks of the compounds are listed in decreasing order of intensity. It is a simple matter to compare the peaks of the unknown sample with those in the database.

The peaks of the spectrum shown in Fig. 34.1B give a very good match to acetomenaphthone. Although the process of locating peak positions and finding the best match to those in a database can be carried out manually, it can also be computerised easily. Peak order is often different between sample and reference spectrum because of differences in the physical properties of the sample and those used to construct the database. Consequently, care is required when searching for the best match. An initial simple search without regard to peak intensities is preferred. To obtain maximum discrimination between different substances, numerous parameters should be optimised. Important parameters are the number of peaks, spectral range, degree of spectral smoothing, number of data points used to calculate the second-derivative spectra and the window size within which peaks are considered to match. Decreasing the window size improves the ability to distinguish between materials, but conversely tends to increase the false-negative identification rate. Increasing the number of peaks and/or calculating a score that takes the relative peak intensities into account can improve the discrimination still further. However, not relying on relative peak intensities makes the method more robust towards changes in the physical properties of the samples.

Peak positions are relatively unaffected by the physical properties of the sample. Although particle size, in particular crystallinity, can have a marked effect upon the relative peak amplitudes, there is little effect on wavelength position. Peak positions commonly vary by only a few tenths of a nanometre for different batches of pure compounds. Greater variation is observed for naturally occurring materials, but variations are still generally less than 1 or 2 nm. The position of the peak minima of the two spectra of salicylic acid (crystalline sample and solidified

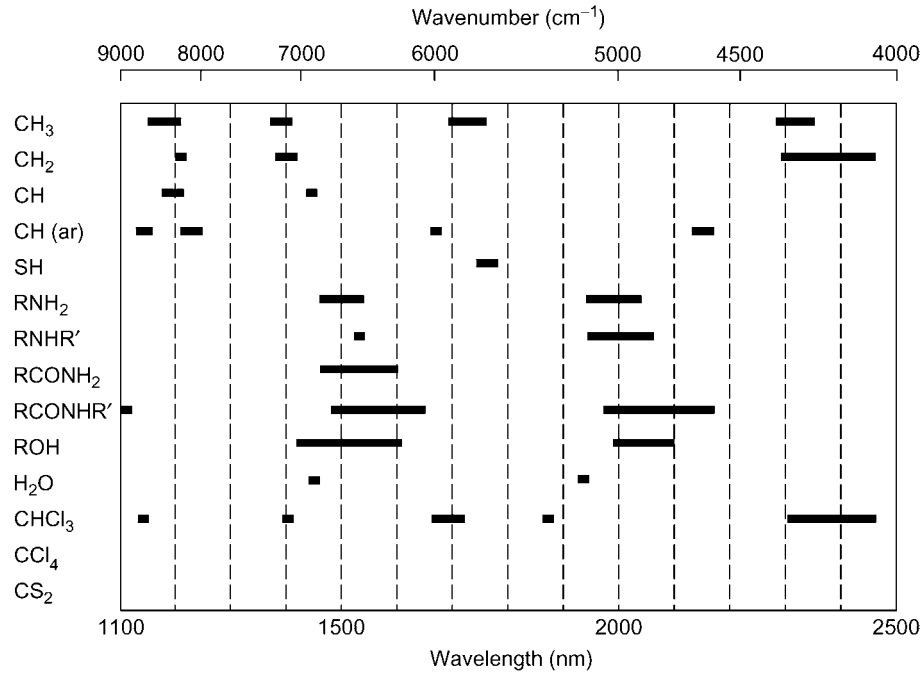

Figure 34.12 Wavelengths of important near-infrared absorbances. Black lines show regions of absorption.

sample after melting) shown in Fig. 34.13 do not deviate by more than ±0.5 nm from each other, even though there are major differences in peak intensities. A window size of ±2 nm has been found suitable for identification by peak matching.

Although increasing the number of peaks compared for each spectrum increases the ability to distinguish between substances, it is important to check that the peaks are genuine and not noise. With powders this is usually not a problem, as most second-derivative NIR spectra contain in excess of 20 usable negative peaks. Modern NIR spectrophotometers have very good signal-to-noise ratios and spectra are very reproducible. With liquids the spectra are commonly much simpler and it may not be possible to find even six peaks. When comparing such spectra with a database it is important not only to record the number of matches but also to check for missing or unaccountable peaks.

Correlation in wavelength space

In this method of identification, the sample, *S*, and reference, *R*, spectra are compared by calculating a correlation coefficient between them. If two spectra rise and fall in perfect synchronisation with each other (Fig. 34.14A), then plotting the amplitude of *S* against that of *R* at each wavelength results in a straight line (correlation plot, Fig. 34.14B).

A numerical measure of the correlation can be obtained by calculating the dot-product, r_d, or product-moment, r_p, correlation coefficient:

$$r_d = \frac{\sum S_i R_i}{\sqrt{\sum S_i^2 \sum R_i^2}}$$

$$r_p = \frac{\sum (S_i - \overline{S})(R_i - \overline{R})}{\sqrt{\sum (S_i - \overline{S})^2 \sum (R_i - \overline{R})^2}}$$

S_i and R_i are the ordinate values of the two spectra being compared at wavelength i, while $\overline{S}$ and $\overline{R}$ are the mean values across the selected wavelength range. The summations are performed over the selected wavelength range, which is usually the complete measured spectrum. An r value of unity represents a perfect match. However, in practice r is always less than unity because of noise. There is little to choose between these two correlation coefficients. For second-derivative spectra they give almost identical results as the mean value for a second-derivative spectrum is usually close to zero. When original absorbance ($-\log_{10} R$) spectra are being used, the product-moment correlation coefficient often gives better discrimination. However, because of the general increase in absorbance with increase in wavelength observed for typical NIR spectra, correlation values are all very close to unity and are of little use for discrimination purposes. The product-moment correlation coefficient is less affected by data pre-treatment than the dot-product correlation coefficient, but sample and reference spectra should always be

Table 34.1 Example of part of a database of second-derivative peak positions (negative peaks). Values in bold correspond to the best match to the peaks for the spectrum given in Fig 34.1B

Compound	*Peaks in decreasing order of intensity, left to right (nm)*

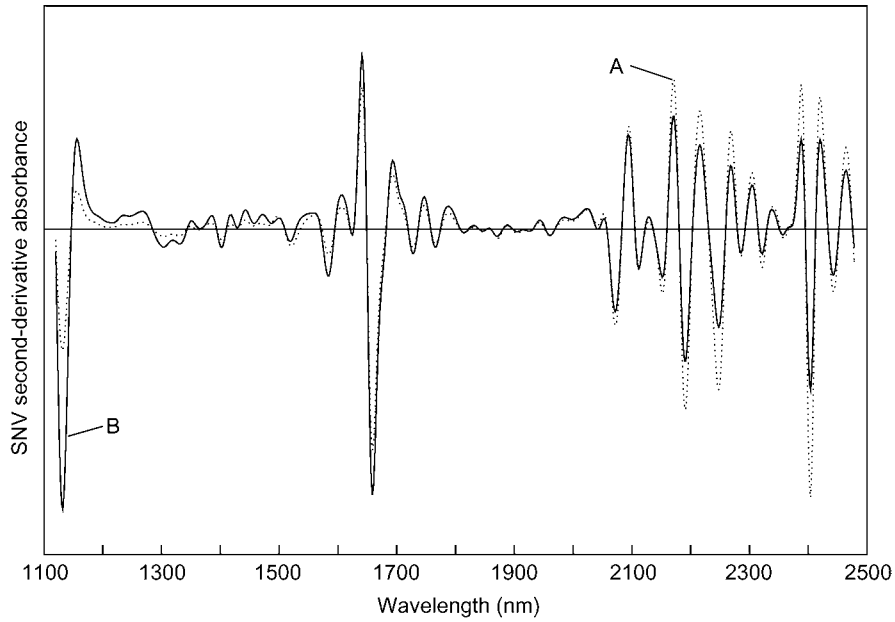

Figure 34.13 Effect of crystallinity on the NIR reflectance of salicyclic acid: (A, dotted line) original crystalline sample; (B, solid line) sample after melting and allowing to solidify. Both spectra are shown as SNV-transformed second-derivative absorbance ($-\log_{10} R$) spectra.

treated equally. A critical r value of 0.95 has commonly been used as a cut-off point; r values greater than 0.95 indicate a positive identification, and values below 0.95 indicate a mismatch. The exact value needs to be found by trial and error (see Creating a database).

Crystallinity has a marked effect on identification by correlation in wavelength space (and other identification algorithms). The relative magnitudes of peaks are very dependent upon the presence of specular radiation in the reflectance signal. Differences in crystallinity can cause r to fall to very low values and a correlation plot characteristically shows a number of intersecting straight lines rather than the ideal single line. This is illustrated for the salicylic acid sample spectra of Fig. 34.13 in the correlation plot (Fig. 34.15), which shows that different small wavelength regions of the spectra show good correlations (i.e. the individual lines), though the overall correlation coefficient is only 0.9 because the lines are not coincident. Careful visual inspection of spectra is vital when trying to identify substances.

Small shifts in wavelengths between sample and reference spectra can have a disastrous effect on identification by correlation. For a typical second-derivative spectrum, a shift of 1 nm might cause the correlation coefficient to fall to 0.97. This needs to be kept in mind if sample and reference spectra are measured on different instruments.

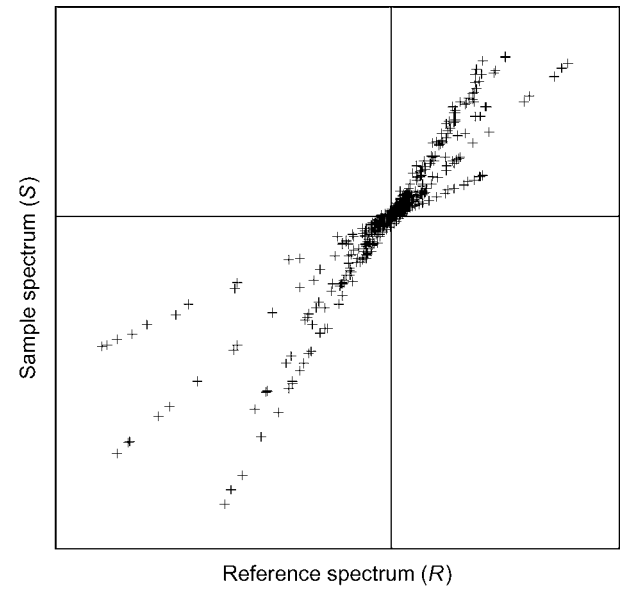

Figure 34.15 Effect of crystallinity on correlation in wavelength space. Reference spectrum, original salicylic acid sample; sample spectrum, melted and solidified sample (spectra shown in Fig. 34.13). Second-derivative spectra, correlation coefficient, $r = 0.904$.

Maximum wavelength distance

This algorithm compares spectra by testing whether the sample spectrum falls within an 'acceptance envelope' centred on a mean reference

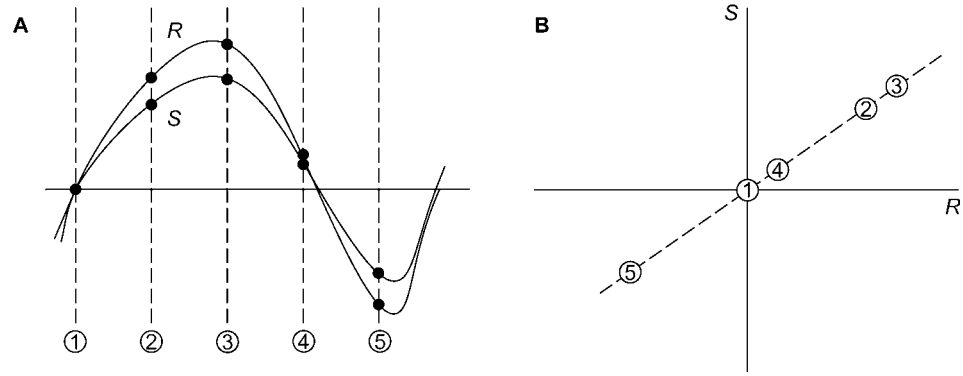

Figure 34.14 Correlation in wavelength space: (A) plot of spectra R (reference) and S (sample); (B) plot of S amplitude versus R amplitude.

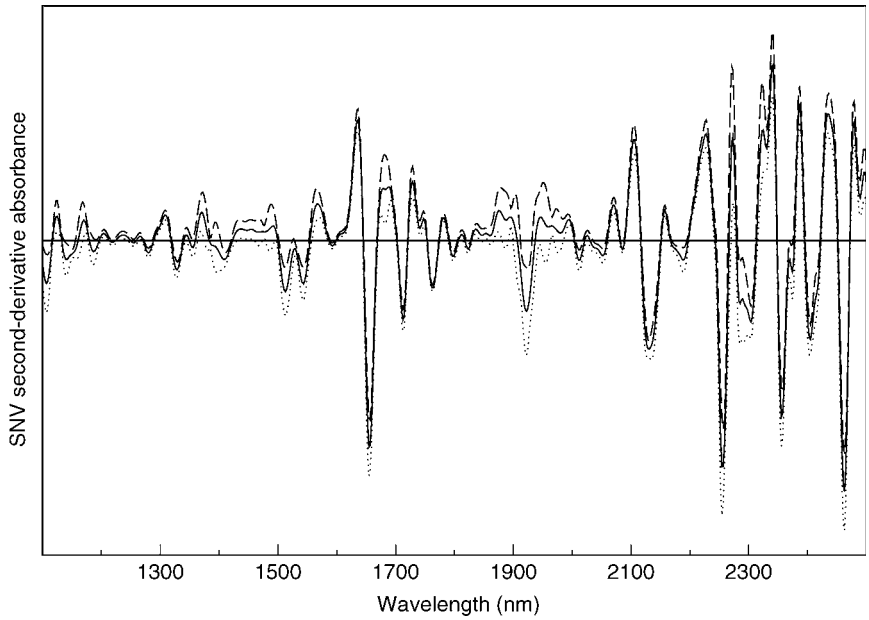

Figure 34.16 Spectra illustrating the method of maximum distance in wavelength space. Mean spectrum (solid line) with ±5.04 standard deviations envelope (dashed lines) for chlortetracycline hydrochloride (20 spectra, 690 wavelength data points). There is a 95% probability that another spectrum from the same population will fall within the envelope.

spectrum. A representative number of samples of the reference material, which should include all acceptable variations in parameters such as particle size, crystallinity, water content and purity, are measured and the mean spectral value and standard deviation at each wavelength calculated. An acceptance envelope on either side of the mean reference spectrum is then calculated, corresponding to the standard deviation multiplied by some critical value. The amplitude of the envelope changes across the spectrum, which reflects that some regions are more variable than others (Fig. 34.16). Spectral regions associated with water, for example, typically show greater variation. The size of the envelope (i.e. critical value) depends upon the number of reference spectra, number of wavelengths and the probability level required.

The mean, $\overline{X}$, and standard deviation, s_i, of the n reference spectra at each wavelength i are calculated:

$$\overline{x}_i = \frac{1}{n}\sum_{j=1}^{n} x_{ij} \quad s_i = \left[\frac{1}{n-1}\sum_{j=1}^{n}(x_{ij}-\overline{x}_i)^2\right]^{1/2}$$

The test statistic, t, is given by:

$$t = \max\left[\frac{(y_i-\overline{x}_i)}{s_i}\left\{\frac{n}{(n+1)}\right\}^{1/2}\right]_{\text{over all } i}$$

where y_i is the spectral value of the test sample spectrum at wavelength i.

The test is simply a two-sampled Student's t test carried out at each wavelength over the whole spectrum or part of the spectrum of interest. Critical values of t need to be calculated according to the number of wavelengths used as well as the reference sample size. Table 34.2 lists the critical values for some commonly used reference sample sizes, number of wavelengths and probability levels (with fewer than 10–12 reference samples, the critical t values are unreasonably large). Further details of the method and how critical values can be calculated are given in Gemperline and Boyer (1995). A sample spectrum with a t value that exceeds the critical value (i.e. outside the acceptance envelope) is considered to have come from a different population from that to which the reference spectra belong. For many purposes it is sufficient to select a critical value by trial and error.

Table 34.2 Critical Student's *t* values for maximum wavelength distance method

Number of samples in reference set, n	*Number of data points in spectrum*			
	500		*700*	
	p = *0.05*	p = *0.01*	p = *0.05*	p = *0.01*
5	15.44	23.30	16.82	25.35
8	7.85	10.09	8.28	10.62
10	6.57	8.10	6.87	8.44
12	5.90	7.09	6.14	7.36
15	5.35	6.28	5.54	6.49
20	4.89	5.62	5.04	5.78
30	4.50	5.08	4.62	5.21

Unlike correlation in wavelength space, this algorithm is sensitive not only to the shape of the spectrum but also to its magnitude; therefore, some form of data pre-treatment is commonly applied before comparing spectra. The use of derivatives and/or SNV normalisation to remove unwanted baseline shifts, etc., is typical. The algorithm is very sensitive to small spectral differences and can be used not only for identification but also to distinguish between different grades or sources of materials. The high sensitivity of the procedure makes it difficult to transfer between instruments.

Other classification procedures

There are numerous chemometric procedures that can be used for the classification of NIR spectra. Methods based on principal component analysis (PCA), such as soft independent modelling of class analogies (SIMCA) or simple visual inspection of PCA score plots, can be very useful for distinguishing between the spectra of closely related materials. Textbooks on chemometrics should be consulted for further details (Adams 1995; Martens, Næs 1991; Næs *et al.* 2002; Otto 1999). The

tutorial review by Downey (1994) is a useful guide. The software supplied with many NIR instruments commonly includes a range of chemometric algorithms. NIR spectroscopy without chemometrics is unimaginable, but its incorrect use is very common. Readers are strongly recommended to consult a number of papers describing the 'Use and abuse of chemometrics' (Pretsch, Wilkins 2006).

Creating a database

When setting up a database it is important to include all substances closely related to those of direct interest, and other likely substances, so that the optimum parameters (e.g. data pre-treatment, wavelength range) for distinguishing between the various materials can be found. As the NIR spectra of powders are sensitive to the physical characteristics of the samples, it is wise to include spectra from different batches of material to increase the probability of correct identification. The first step in validating a database is to see whether it is possible to distinguish between all the compounds within it, which is achieved most easily by comparing all possible pairs of spectra and displaying the test statistic values (e.g. number of peaks matched, *r*, *t* value) as a histogram. Ideally, a critical value can be selected below (or above) which all different pairs of compounds fall and above (or below) which all batches of the same material occur. In practice, unless the database is very small, it is unlikely that all compounds will be distinguishable and a compromise value for the test statistic must be made. To test the robustness of the identification procedure the database should be challenged with samples not used in its construction. The importance of visually inspecting spectra and not relying only on the test statistic value cannot be too strongly stressed.

Problem compounds

Compounds with long aliphatic chains, such as hydrocarbons, stearates and waxes, are difficult to distinguish as the spectrum becomes dominated by the $–CH_2$ groups. Starches and related compounds, such as maltodextrins, gums and other materials with polysaccharide groupings, are difficult to distinguish from each other reliably. With inorganic compounds, which often have little or no genuine absorbance, care is required that any apparent spectral matching is not from absorbances caused by residual moisture, Wood's peak and/or the sample bottle itself. Mid-IR and other spectroscopic techniques are most probably no better for these problem compounds – the extremely good signal-to-noise level in NIR spectra means that often the chemometric classification techniques are able to distinguish more easily between closely related compounds than they can for other spectra.

Detection of counterfeit materials

The ability of NIR spectroscopy to detect both physical and chemical differences between samples means that it can used like fingerprinting. For example, batch-to-batch variation of tablets, or of tablets manufactured at different sites, can often be distinguished. Similarly, the detection of counterfeit products is possible (Scafi, Pasquini 2001). Spectra of a representative sample of the genuine product are compared with those of the suspected counterfeit. Although spectral comparison methods, such as maximum wavelength distance, may be used, methods such as PCA are often to be preferred. A simple visual plot (two- or three-dimensional) of the principal component scores is often sufficient. Different data pre-treatments (use of derivatives, SNV, MSC, etc.) should be investigated to remove unwanted differences in spectra. Similar samples form clusters of points on the plots, while differences in scores indicate differences in samples (Fig. 34.17). More complex methods of classification (such as SIMCA, etc.) may be usefully applied and allow probability levels to be set.

Materials and/or products must be handled with care. Tablets and the like often rapidly exchange moisture with the atmosphere and an apparently suspect product might simply have a different moisture content. If moisture differences are not important, then genuine and suspect samples should be allowed to equilibrate to ambient humidity before measurement. When differences in moisture are important, measurements must be made as soon as the samples are opened (e.g. tablets must be measured immediately they are removed from a blister pack).

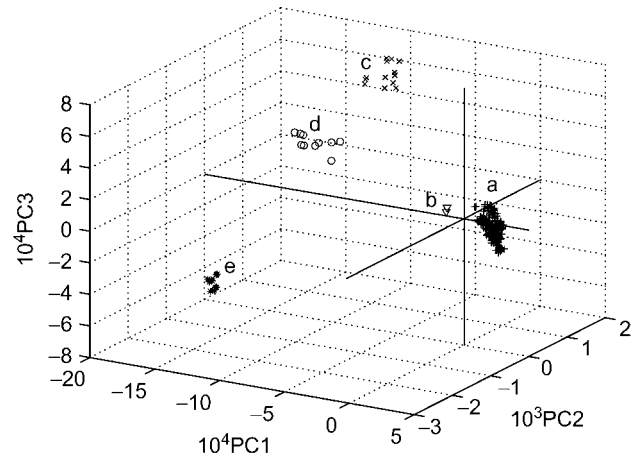

Figure 34.17 PCA score plot (first three principal components, PC1, PC2 and PC3) illustrating the detection of counterfeit tablets. (a) and (b) genuine product; (c), (d) and (e) counterfeit samples.

Examination of the principal component loadings plots can sometimes indicate possible causes for the differences between samples, especially those with just one major cause of difference. For example, when the largest difference is due to moisture content (genuine and test samples well separated along the first principal component), the loading plot resembles the spectrum of water.

Quantitative analysis

Quantitative methods of NIR analysis are generally time-consuming to set up and not suited to 'one-off' assays. However, once developed, a quantitative assay takes little more than the time to record a sample spectrum. The purpose of calibration is to construct a model that relates the sample concentration of one or more analytes to the spectral data from training samples (those samples used to create the model) and then to use the model to predict the analyte values of future new samples. NIR is best suited to measuring major components (10–90% by mass (m/m)), though with strongly absorbing substances useful calibrations as low as 1% have been achieved. The strong absorption exhibited by water often allows it to be determined at $<0.1\%$ m/m levels in solvents by transmittance. Transmittance NIR spectroscopy generally gives better results for solids than reflectance, as it is less sensitive to the inhomogeneity of the sample and gives results more representative of the bulk material.

The complex nature of NIR spectra makes it unlikely that, even for simple mixtures, a unique wavelength for the analyte (unaffected by other compounds) can be found. Some form of multivariate calibration procedure, such as multiwavelength linear regression (MLR), or whole-spectrum methods, such as principal component regression (PCR) and partial least-squares regression (PLSR), will be required. Details of these methods can be found in numerous textbooks (Adams 1995; Burns, Ciurczak 2001; Martens, Næs 1991; Næs *et al.* 2002; Otto 1999). A review of multivariate calibration has been written by Brereton (2000), while more recently Small (2006) has written about some of the pitfalls of multivariate calibration. Software provided with most spectrophotometers usually includes these calibration methods. Specialised software packages are also readily available, such as PLS-Toolbox (Eigenvector) for MATLAB (MathWorks), Pirouette (Infometrix), Unscrambler (Camo ASA) and SIMCA-P (Umetrics).

Calibration involves a number of steps:

- Selecting/preparing a set of samples
- Measuring their spectra and determining their reference values
- Developing and selecting the best model
- Validating the model.

Sample selection for constructing the model is extremely important. Methods such as PCR and PLSR are essentially statistical, and therefore it is vital that the calibration samples cover all possible sources of variation likely to be encountered in the samples that are later to be predicted. All possible chemical components and their range of concentrations, along with all variations in physical properties (e.g. particle size, powder compaction) must be included if a robust model is to be produced. Samples should be designed such that there is a minimum of correlation between all the concentrations or other properties of the components. The generation of such samples to cover a sufficiently wide range of compositions for products such as tablets, which are normally manufactured to within very tight limits, presents numerous problems. Useful guidelines are provided by the Pharmaceutical Analytical Sciences Group (2001). Blanco *et al.* (2001) investigated a number of strategies to extend the composition range. Synthetic samples, prepared by mixing weighed quantities of the pure components, and doped samples, made by adding known amounts of active component or excipients to powdered production samples, may be used. Neither approach is entirely satisfactory, though sample sets that contain production, doped and synthetic samples gave acceptable models. Reference values for the analytes of interest must be measured for the samples using a reliable analytical technique, such as HPLC, UV–visible spectrophotometry or titration. The accuracy of the model cannot be better than that for the reference values. The samples should be divided at random into ideally three sets: a calibration set, an optimisation set (a ratio of 2 : 1 or 3 : 1 is suitable) and a test set. The calibration set is used to construct the model, while the optimisation set is used to optimise the model (e.g. select the number of principal components, etc. required). Finally, the test set is used to demonstrate that the model is robust and predicts correctly for real samples. These three data sets must be independent, e.g. samples from the same batch of a product should appear in only one of the sets. Although there are no fixed recommendations for the number of calibration samples required (it depends upon the complexity of the samples and calibration model), a minimum of 30–60 is not atypical. Six to ten samples for each wavelength and/or principal component used in the model are a minimum requirement.

Before applying MLR, PCR, etc., spectra generally require some form of pre-treatment to remove baseline shifts, particle size effects, and so on. Commonly applied pre-treatments are first- or second-derivative, SNV, MSC or other normalisations. Combinations of such transformations are often applied. There are no definite rules for selecting the best pre-treatment to use, apart from trial and error. Similarly, the choice of model (MLR, PCR, PLSR, etc.) is also largely a matter of trial and error until the best is found, PLSR being the most popular.

With simple samples, such as solutions or solids in which only a single component is variable in a nearly constant matrix, it is often possible to construct a calibration model based on MLR. The concentration, c, of the analyte is modelled to an equation of the form:

$$c = b_0 + b_1 A_1 + b_2 A_2 + \cdots$$

where A_1, A_2, ... are the spectral values at wavelengths 1, 2, ..., respectively, and b_0, b_1, b_2, ... are the coefficients found by least-squares regression. The number of wavelengths required depends upon the complexity of the samples. Finding the optimum number of wavelengths and their values is not a trivial problem. Ideally, a full search of all possible combinations of wavelength values from the whole spectrum (i.e. perhaps >500 data points) should be carried out. While this is possible with two or three wavelengths, the time taken for larger numbers of wavelengths makes this impractical. For complex samples, in which many components vary, whole-spectrum techniques, such as PCR and PLSR, are preferred. Care must be taken not to over-fit the calibration data by using too many parameters in the model. The final step, validation, is the most important. The model produced is used to predict the values for the test set that can then be compared against their reference values. Only if the values predicted for this independent data set are satisfactory can the model be considered acceptable.

Plots of NIR predicted values versus reference values for both the calibration and test sets (e.g. Fig. 34.18) should be examined. Visual inspection easily reveals any problems with the data sets and model, such as outliers or curvature. Ideally, both plots should be straight lines with slope unity and intercept zero. A good calibration plot but poor validation plot suggests over-fitting of the model. Numerically, the fit can be assessed by calculating the standard error of calibration (SEC) and standard error of prediction (SEP):

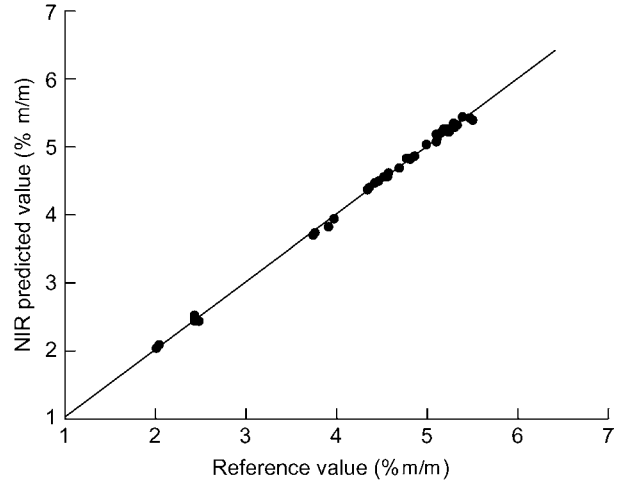

Figure 34.18 Typical validation plot of near-infrared predicted value against reference value.

$$\mathrm{SE} = \sqrt{\frac{\sum_{i=1}^{n} (X_i - \hat{X}_i)^2}{D}}$$

where X_i is the reference value and $\hat{X}$ is the NIR predicted value for the ith sample of the calibration set (for SEC) or validation set (for SEP), n is the number of samples in the data set being considered, and D is the number of degrees of freedom (for the calibration set this will be n minus the number of parameters fixed in the model, e.g. number of wavelengths used for MLR plus 1, number of components used plus 1 (if data centred) for PCR or PLSR). For the validation set, $D = n$.

For a good model, SEC and SEP should be similar and not much larger than the standard error of the reference method. SEP is a measure of the accuracy (how close the NIR predicted values are to the reference values) for the method and, of course, needs to be compatible with the intended purpose to which the procedure is to be put. Moffat *et al.* (2000) have shown how quantitative NIR can meet the requirements of the International Conference on Harmonisation's Guidelines on Validation of Analytical Procedures for the assay of an intact pharmaceutical product in terms of specificity, linearity, range, accuracy, precision and repeatability.

Near-infrared imaging

The coupling of an NIR spectrometer and scanning microscope allows spectroscopic imaging of surfaces. Not only can small samples be identified, but information about the distribution of different chemical components and their particle size can be obtained. Commercial reflectance NIR microscopy mapping systems are based on one of three data acquisition methods. In point mapping, a single detector is used to measure a spectrum at a single point on the sample surface and then the sample position is moved and the process is repeated until the complete area has been scanned. Line mapping works in a similar way except that a linear array of detectors is used so that data are more quickly acquired. In global mapping, the whole sample area is measured simultaneously using some form of tuneable filter to control the wavelength selection. Typically spectral resolution of 4–16 cm^{-1} and spatial resolution of >10 μm can be achieved. Because of the nature of NIR diffuse reflection, it is most probably not meaningful to work at spatial

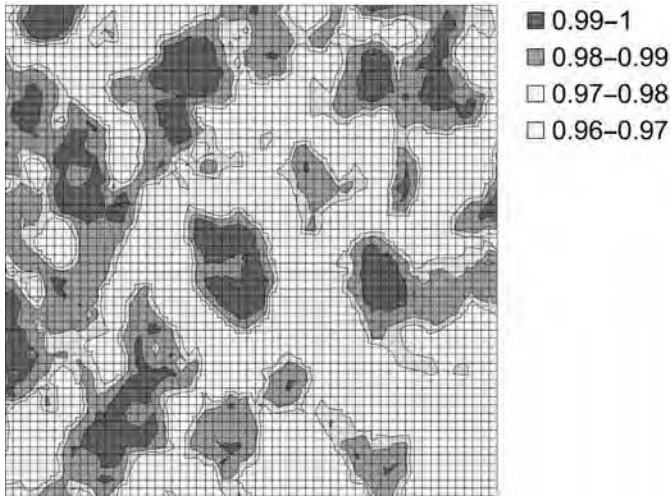

Figure 34.19 NIR image of a cross-section of a ranitidine tablet. Each pixel is $30 \times 30\,\mu m^2$. The image is 60×60 pixels (i.e. $1.8 \times 1.8\,mm^2$). The map shows the value (coded in different shades of grey) of the correlation coefficient of the NIR spectrum at each pixel when compared with that of a pure sample of ranitidine. (Reproduced with permission of RA Watt and A Duszyńska.)

resolutions of $<20\,\mu m$. A surface area of 1–10 mm^2 of the sample is commonly analysed by recording a spectrum for, say, each $20 \times 20\,\mu m^2$ area of sample, which allows a 'grid' of spectral information to be constructed – this gives many thousands of spectra. Spectral information comes from the top surface layers down to a depth of approximately 30–100 μm and represents 10–100 ng of sample. With use of suitable chemometrics the spectra may be processed to determine the chemical identity at each 'grid' position. Chemical image plots to show the distribution of the various chemical species may then be created for the whole surface. Clarke *et al.* (2001) have described such a system using both NIR and Raman spectroscopic data to give a chemical image of pharmaceutical formulations.

Figure 34.19 shows an image of a $1.8 \times 1.8\,mm^2$ cross-section of a ranitidine tablet (∼40% m/m active). The image is 60×60 pixels (each pixel is $30 \times 30\,\mu m$). The NIR spectrum from each pixel has been correlated against the NIR spectrum of a pure sample of ranitidine and the different correlation ranges are assigned different colours to give the map shown. Images are useful for comparison purposes, comparing genuine and counterfeit samples, good and bad blends, etc. However, any attempted physical interpretation of what the image represents needs to be carried out with considerable care.

Collections of data

Several commercially available NIR spectral libraries have been developed. NICODOM Ltd have a library containing 696 spectra of actives and excipients used in the pharmaceutical industry as well as a library of 660 NIR polymer spectra. Thermo Scientific have a FT-NIR spectral library collection of 385 active and inactive pharmaceutical substances. Fiveash Data Management, Inc. can provide 330 NIR spectra of food and agricultural materials. A small selection of printed NIR spectra is found in the *Handbook of Organic Compounds, NIR, IR Raman, and UV-Vis Spectra Featuring Polymers and Surfactants* (Workman 2001). The third edition of *Infrared and Raman Characteristic Group Frequencies – Tables and Charts* (Socrates 2001) has a section on NIR. The *Handbook of Pharmaceutical Excipients* (Rowe, Shesky 2009) has NIR spectra for many excipients.

CHAPTER

35 Raman Spectroscopy

DE Bugay, PA Martoglio Smith and FC Thorley

Vibrational spectroscopy has been an integral tool for the identification and characterisation of drugs. When one typically thinks of vibrational spectroscopy, infrared (IR) techniques come to mind, not Raman spectroscopy. However, over the last 25 years a renaissance of the Raman technique has been seen, mainly due to development of instrumentation. These developments have led to unique applications in the pharmaceutical and forensic industries where drug identification and characterisation are necessary. This chapter presents to the reader the theory, instrumentation, sampling techniques and applications of Raman spectroscopy as applied to drugs.

Introduction and theory

Raman spectroscopy is a form of vibrational spectroscopy that has widespread use in pharmaceutical investigations. Applications include chemical structure elucidation, routine chemical identification and solid-state characterisation such as that of polymorphism. Raman spectroscopy is also applicable to drug product characterisation including solid form analysis of the drug incorporated into the formulation, contaminant analysis, drug–excipient interaction and problem-solving. A distinct advantage of pharmaceutical analysis by Raman spectroscopy is the ease of the technique and its broad range of applicability. Analysis can be performed on virtually any type of sample such as single crystals, bulk materials, slurries, creams, particulates, films, solutions (aqueous and organic), oils and on-process streams (the last through the use of fibre-optic probes). Additionally, Raman spectroscopy is typically non-destructive in nature, allowing recovery of the material for further characterisation. Since Raman spectroscopy measures the vibrational motions associated with a molecule, it is complementary to IR spectroscopy as well as other characterisation techniques. Finally, under proper sampling conditions, Raman spectroscopy is a quantitative technique.

When a compound is irradiated with monochromatic radiation, the radiation is transmitted, absorbed or scattered by the molecule. Of the scattered radiation, a majority of the photons are scattered at the same frequency as the incident radiation frequency. This form of scattering has been termed *elastic* or *Rayleigh scattering*. If the scattered radiation is passed into a spectrometer, a strong Rayleigh line is detected at the unmodified frequency of radiation used to excite the sample. Additionally, a very small percentage of photons (about one per million) is scattered at frequencies arrayed above and below the frequency of the Rayleigh line. The *differences* between the incident frequency of radiation and arrayed frequencies correspond to the frequency of molecular vibrations present in the molecules of the sample. These wavelength-shifted frequencies are termed *inelastic scattering* and a collection of these wavelength-shifted frequencies is termed a Raman spectrum. For example, a Raman line at $\pm 2980\ cm^{-1}$ may be obtained on either side of the Rayleigh line and thus the sample possesses a vibrational mode at this frequency. The frequencies of molecular vibrations are typically 10^{12}–10^{14} Hz. A more convenient unit, which is proportional to frequency, is wavenumber (cm^{-1}) since fundamental vibrational modes lie between 3600 and 50 cm^{-1}.

As shown in Fig. 35.1, when a molecule is irradiated with monochromatic radiation, a number of different transitions may occur. If the radiation is of sufficient energy, an absorption process may occur representing an electronic transition ($S_o \rightarrow S_1$, UV/visible spectroscopy). If a slightly less energetic source is used, the molecule will be promoted to a *virtual state*. The virtual state represents a distortion of the electron distribution of a covalent bond within the molecule. After promotion to the virtual state, the molecule will immediately relax back to the original ground electronic state by emitting a photon. If the molecule relaxes back to the original vibrational state, the emitted photon is of the same frequency as the incident radiation. This represents Rayleigh or elastic scattering. If the molecule relaxes back to a higher vibrational energy state, the emitted photon represents less energy than the incident radiation. The inelastically scattered photon will have a longer wavelength (lower frequency) than the incident radiation. This energy transition represents Stokes Raman scattering. Conversely, if the molecule relaxes back to a lower vibrational energy state, the emitted photon represents greater energy than the incident radiation. The inelastically scattered photon will have a shorter wavelength (higher frequency) than the incident radiation. This energy transition represents anti-Stokes Raman scattering. Generally, the anti-Stokes lines are less intense than the Stokes lines because these transitions arise from higher vibrational energy levels containing fewer molecules, as described by the Boltzmann distribution. Hence, the Stokes portion of the spectrum is generally used.

A Raman spectrum is normally represented as a plot of Raman scattering intensity (ordinate) versus wavelength (abscissa). Normally, the abscissa of the spectrum is labelled as wavenumber shift or Raman shift (cm^{-1}) and the negative sign (for Stokes shift) is omitted (Fig. 35.2). The wavenumber or Raman shift represents the shift in frequency of a photon from the exciting wavelength.

Pharmaceutically relevant molecules are typically covalently bound organic molecules. The chemical bonds within these molecules consist of an electron cloud. In a Raman experiment, the electromagnetic radiation incident on the molecule consists of oscillating electric and magnetic fields. Interaction of the electromagnetic radiation with the chemical bond causes the electron cloud to oscillate. The oscillation in turn causes a photon to be emitted. This is called scattering. In Rayleigh scattering, the energy from the incident electromagnetic radiation causes electron oscillation and the emitted photon is observed at the same frequency. In Raman scattering, an additional energy transition occurs. The polarisability of the electron cloud may change as the positions of the atoms making up the chemical bond change. In other words, a vibrational mode may cause atoms to be displaced, in turn affecting the polarisability of the electron cloud of the chemical bond. In this case, the incident radiation causes the electron cloud to oscillate, but the electron cloud oscillation is also affected by the change in polarisability caused by a change in the position of the atoms during the molecular vibration. Oscillation causes a photon to be emitted, but the frequency is perturbed by the change in polarisability of the chemical bond. For a vibrational mode to be Raman active, a change in polarisability must take place during the vibration. This condition is termed the Raman selection rule. Since the polarisability of a chemical bond is dependent upon the atoms making up that bond, as well as atoms in close proximity, Raman spectroscopy is a probe into the chemical or physical structure of a molecule. This is why Raman spectroscopy is an important tool for pharmaceutical analysis.

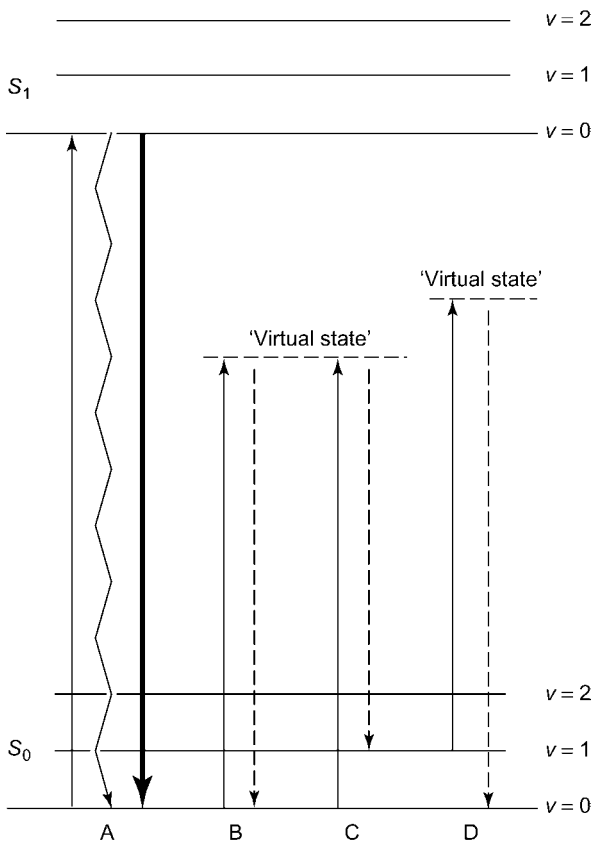

Figure 35.1 Jablonski energy level diagram illustrating possible transitions; solid lines represent absorption processes and dotted lines represent scattering processes. A, electronic transition with non-radiative decay (heat: ↯) or radiative decay (fluorescence: ⇓); B, Rayleigh scattering; C, Stokes Raman transition; D, anti-Stokes Raman transition. S_0 is the singlet ground state, S_1 the lowest singlet excited state and *v* represents vibrational energy levels within each electronic state.

Instrumentation

Although the Raman effect was discovered in 1928, the first commercial Raman instruments did not start to appear until the early 1950s. These instruments did not use laser sources, but used elemental sources and arc lamps. In 1962, laser sources started to become available for Raman instruments and the first commercial laser Raman instruments appeared in 1964–65. The first commercial Fourier transform (FT) Raman instruments were available starting in 1988 and, by the next year, FT-Raman microscopy was possible.

Dispersive spectrometers

The basic configuration and components of a dispersive spectrometer are shown in Fig. 35.3. The source of monochromatic radiation is a laser. Typically helium–cadmium (325, 354 or 442 nm), air-cooled argon-ion (488 or 514 nm), doubled continuous-wave neodymium–yttrium –aluminium garnet (Nd : YAG or Nd : $Y_3Al_5O_{12}$; 532 nm), helium–neon (633 nm) or stabilised diode (785 nm) lasers are used for dispersive Raman spectrometers. The stability of the emitted radiation from a laser is one of the key attributes of a good spectrometer. Frequency stabilisation of the laser under standard laboratory conditions (slight temperature fluctuations, vibrational effects, etc.) is required. Laser lifetimes and cost are also considerations for the choice of the laser to be used. One additional consideration for laser selection in dispersive Raman systems is the generation of fluorescence. As stated previously, the Raman signal is fairly weak. For many organic systems, fluorescence may occur when the helium–neon laser frequency of 632.8 nm is used and, instead of promoting the molecule of interest to a virtual state, an electronic transition occurs with subsequent radiative decay (fluorescence, see Fig. 35.1). The fluorescence background signal can be so intense as to mask the Raman scattered photons. Fluorescence is also wavelength dependent, so a sample that fluoresces with one laser source may not with another. If fluorescence does not pose a problem, lower-frequency lasers can be used (532, 514 nm) for enhanced sensitivity, as the efficiency of Raman scattering is proportional to $1/(\lambda)^4$, where λ is wavelength of excitation.

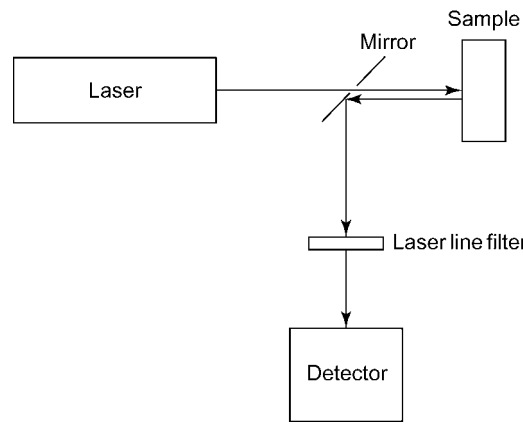

Figure 35.3 Schematic representation of a dispersive Raman spectrometer.

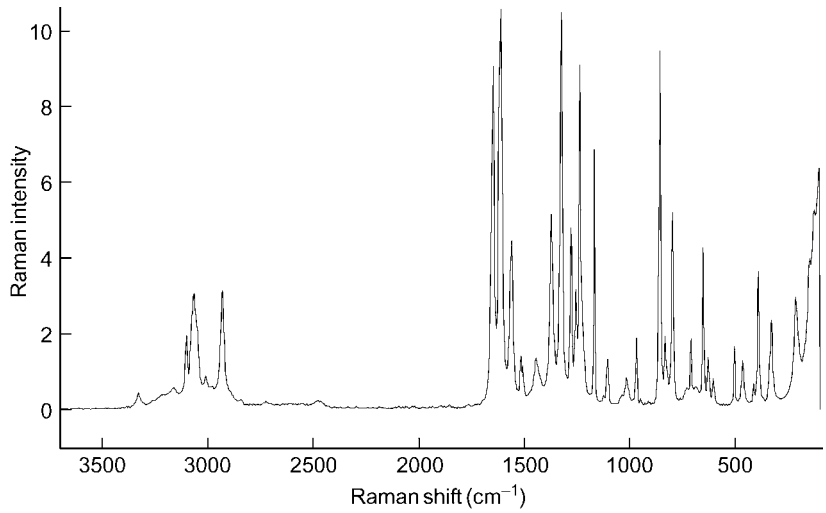

Figure 35.2 FT-Raman spectrum of paracetamol (acetaminophen).

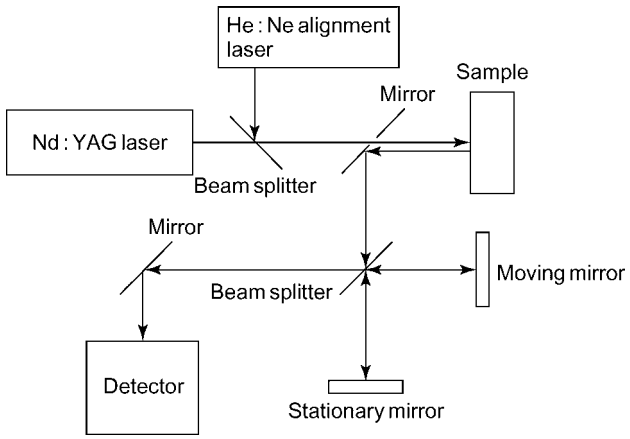

Figure 35.4 Schematic representation of an FT-based Raman spectrometer.

If fluorescence is a problem when using these high-energy sources, then lower-energy sources, such as those used in FT-based Raman spectroscopy, can be used to minimise the fluorescence effects (see below).

In a dispersive Raman spectrometer, the sample is positioned in the laser beam and the scattering radiation is collected in either a 180° backscattering or a 90° right-angle scattering configuration (see Fig. 35.3). Recent developments also offer transmission Raman geometries, which can be useful for analysing bulk tablets or capsules, as well as on-line process monitoring (Matousek, Parker 2007). After irradiation of the sample, a laser-line rejection filter is put in place to filter out the Rayleigh scattering. Finally, a detector is positioned in the spectrometer. For dispersive systems, typically a charge-coupled device (CCD) is utilised. Silicon CCD detectors are normally used for Raman spectrometers in which visible wavelength lasers are used. Previously, photomultiplier tubes (PMTs) were used for detection, but, since the advent of CCDs and their inherently better performance, PMTs are not normally used today. All commercial spectrometers are controlled digitally by a computer system.

Interferometric spectrometers

Figure 35.4 displays the configuration of an FT-based Raman spectrometer. Advantages of an FT-Raman spectrometer are wavelength accuracy and the use of a near-infrared laser which typically eliminates fluorescence. In the FT-based system, a $Nd:YVO_4$ laser, 1064 nm, is used to irradiate the sample. Analogous to the dispersive system, the sample is positioned in the laser beam and the scattering radiation is collected in either a 180° backscattering or a 90° right-angle scattering configuration. The scattered photons are then passed into an interferometer with laser line filtering. Detection of the scattered photons from systems that utilise lasers emitting light with wavelengths greater than 1000 nm are of the single-element type, either high-purity p-type germanium or indium/gallium/arsenic (InGaAs) detectors. These detectors are noisier than CCDs or PMTs, but do exhibit high quantum efficiencies. By cooling the germanium (Ge) detector to 77 K, the frequency response is extended to $\sim 3500\,cm^{-1}$.

By utilising the longer-wavelength $Nd:YVO_4$ laser in an FT-Raman spectrometer, fluorescence is minimised. The reason for fluorescence minimisation is that the longer-wavelength excitation has less likelihood of inducing an electronic transition with subsequent fluorescence than the relaxation mechanism.

Coupled techniques

Microscopy

Raman spectra can be acquired on small amounts of material through the use of a Raman microprobe. Utilising the microscope, the Raman scattered photons are collected in a 180° backscattering configuration that allows the operator to optically view the sample, focus the incident radiation and subsequently collect the Raman spectrum. Most commercial Raman microscope systems utilise confocal microscopy to increase axial resolution (*z*-axis). Confocal points are defined as the point source, the in-focus sample location and the focused image of the sample point. Axial resolution, defined as the distance away from the focal plane in which the Raman intensity from the sample decreases to 50% of the in-focus intensity, can be approximated from the numerical aperture (NA) used in the microscope. When utilising a 0.95 NA objective on a confocal microscope system, the axial resolution is proportional to the square of the NA, in this case 0.9025 μm.

An additional advantage of Raman microscopy is spatial resolution as opposed to axial resolution. The spatial resolution (*xy*-plane) is dependent upon the NA of the collecting objective and the wavelength of the laser radiation. Larger NA values and shorter wavelengths provide higher spatial resolution, often down to 1 μm. Since a high-intensity of monochromatic radiation from the laser is focused upon a small amount of sample, sample degradation by the laser must be monitored. Otherwise, the Raman microprobe is ideal for investigating polymorphism (single crystals), particulate contamination and small amounts of samples. Using an apparatus similar to those used for IR microspectroscopy, variable temperature and humidity studies can also be performed with a Raman microprobe.

Fibre-optics

Fibre-optics have been used in Raman spectroscopy since the early 1980s. Solids and liquids can be analysed with an arrangement of optical fibres on the end of a probe. Today, much of the research in the use of fibre-optics in FT-Raman spectroscopy centres around fibre and fibre bundle design, as well as collection angle. The number, type and arrangement of the fibres in a fibre bundle are all factors that are varied to produce fibre bundles for different applications. Fibre systems include single fibre, where the laser excitation and collected scattered radiation travel along the same fibre, and multi-fibre, where laser excitation is transmitted along one (or multiple) fibres and the scatter is transmitted to the detector along different fibres. The arrangements of the fibres in a multi-fibre system can also vary. Two examples include an arrangement in which one excitation fibre is surrounded by several collection fibres, or an arrangement in which several excitation and collection fibres are randomly mixed in a bundle. The collection process can occur via traditional backscatter, spatially offset Raman spectroscopy (SORS) or transmission. The greatest single advantage of the use of fibre-optics in Raman spectroscopy is the ability to sample remotely. No longer does the spectrometer have to be brought to the sample or vice versa. Fibre-optics can link the spectrometer to the sample, typically at distances of tens of metres. Common applications include monitoring of process streams or hazardous reactions.

Data processing and presentation of results

All contemporary dispersive and FT-based Raman spectrometers are controlled through a digital computer that handles instrument control, data collection, data processing and presentation of the spectral results. Utilisation of a FT-Raman spectrometer requires one extra step of data processing that is not required for dispersive-based Raman spectrometers. In the FT system, the original data are collected on a time scale and are subsequently Fourier transformed to obtain a frequency-domain spectrum. After this point, data processing for both systems is analogous.

Since the Raman spectrum of a particular sample is represented digitally, various additional processing applications can be performed. Spectral subtraction is one commonly used data processing technique as well as spectral smoothing, spectral searching and resolution enhancement. Figure 35.5 displays some of these processing techniques on one original data file. Since Raman spectroscopy can be utilised for quantitative measurements, digital representation of the spectrum allows for numerous means of measuring the analytical response of an analyte's signal and relating it to concentration. Electronic integration of

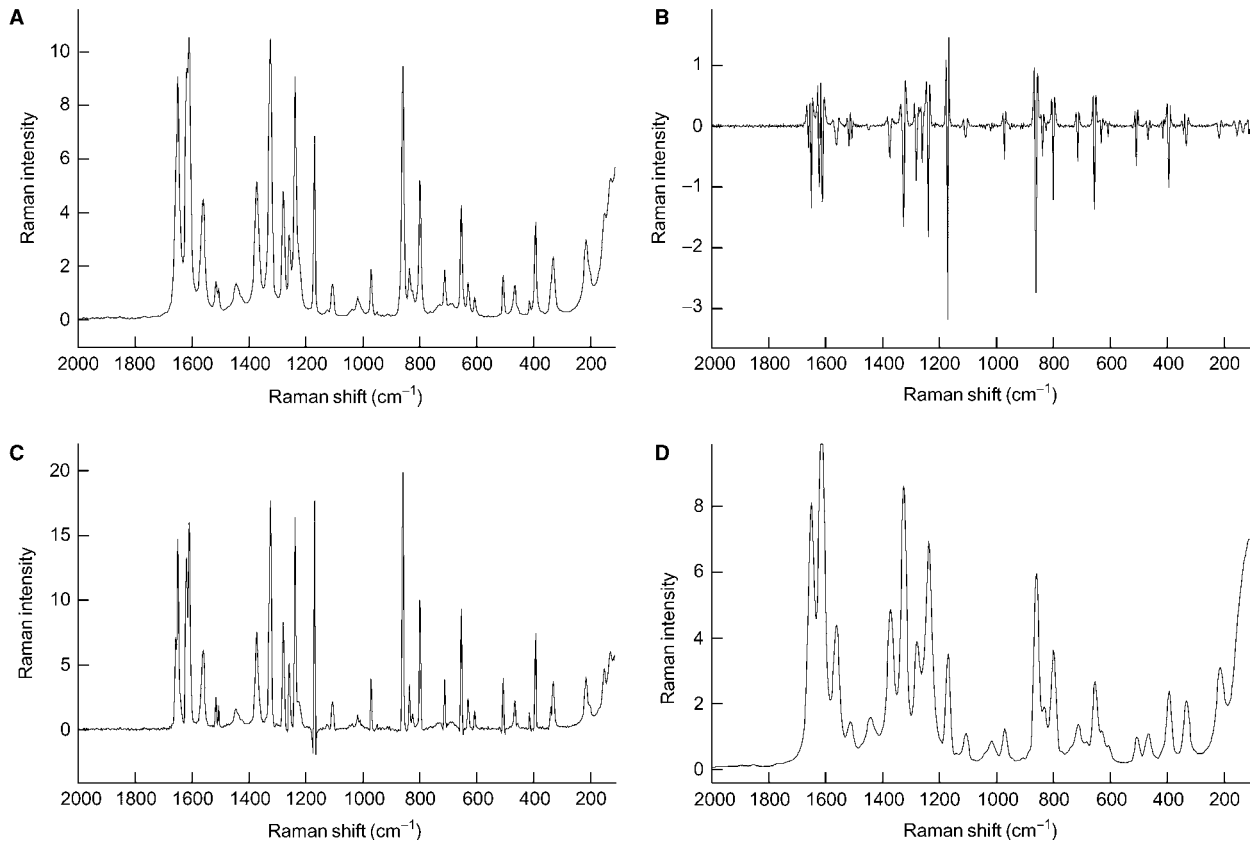

Figure 35.5 Examples of digitally processed spectral files: (A) original Raman spectrum; (B) spectral result after calculating the second derivative of the original Raman spectrum; (C) spectral result after resolution enhancement by Fourier deconvolution of the original Raman spectrum; (D) spectral result after Fourier smoothing the original Raman spectrum by 80%.

the peak area, curve fitting of the Raman spectrum and chemometric approaches can be utilised (Fig. 35.5).

System suitability tests

In a current good manufacturing practices (cGMP) environment, all laboratory instrumentation must be adequately inspected, cleaned and maintained. Additionally, instruments used for the generation, measurement or assessment of data must be adequately tested, calibrated and/or standardised. Based upon these regulatory agency requirements, the accuracy of Raman spectrometers needs to be assessed before usage via performance qualification (PQ). Typically, for the calibration testing of any instrument regulatory agencies require the use of a recognised standard material distributed by an official agency. In 2007, the American Society for Testing and Materials (ASTM) established a series of Raman shift frequency standards (ASTM E 1840) for calibration use. An attractive feature of using shift standards as opposed to wavelength standards (such as atomic emission lines) is that they are not dependent on laser wavelength. Standard Raman shifts for eight different materials are included in the ASTM standard. Included within these eight options are cyclohexane and sulfur, both of which have been recognised by the spectroscopy community for years as appropriate calibration standards. The Raman spectrum of sulfur displays vibration bands at 153, 219 and 472 cm^{-1}, whereas the spectrum of cyclohexane displays bands at 802, 1267, 1444, 2853, 2924 and 2938 cm^{-1} (Fig. 35.6). Silicon is another possible sample recognised by the spectroscopic community, and has a very strong peak at 520 cm^{-1}. A Raman intensity standard is still under consideration by the ASTM. One possible approach was proposed by Ray and McCreery (1997). Their approach uses the known luminescence of standards that fluoresce in response to laser irradiation to correct for the instrumental response function. An example of this type of correction can be found with Thermo Electron's background correction software function, which uses the white light source for the correction function. By collecting the fluorescence or white light source in the same configurations as the Raman sample of interest, sensitivities that vary across the Raman spectrum can be normalised.

System suitability has a deeper meaning than simply PQ when considered for solid-state method development and validation. In this context, system suitability testing ensures that the system (e.g. the Raman spectrometer) is working properly at the time of analysis. A good system suitability test ensures that the instrument is capable of providing appropriate data according to the developed method. For example, consider a solid-state Raman limit test or quantitative method for polymorphic analysis. Maintenance of the limit of detection (LOD) or minimal quantifiable limit (MQL) is essential if the method is to provide reliable data. Therefore, in addition to wavenumber accuracy, the signal-to-noise ratio (SNR) is also important. Because the Raman signal can be affected by sample focus and density, a reliable SNR measurement is best obtained from a solid (not powdered) material. A polystyrene puck is a useful material to use for system suitability in this regard. Polystyrene is also listed in the ASTM document noted above as a Raman shift standard.

Sample preparation and sample presentation

Sampling techniques for Raman spectroscopy are relatively simple since the only requirements are that the monochromatic laser beam irradiates the sample of interest and the scattered radiation is focused upon the detector.

Raman spectroscopy may be performed on very small samples (e.g. a few nanograms). Powders do not need pressing into discs or diluting with KBr as, in IR spectroscopy, the material simply needs to be irradiated by the laser beam. Solid samples are often examined in stainless-steel or glass sample holders generally requiring ~25–50 mg of material. Typically, liquid samples are analysed in quartz or glass cuvettes, which may have mirrored rear surfaces to improve the signal intensity. Glass is

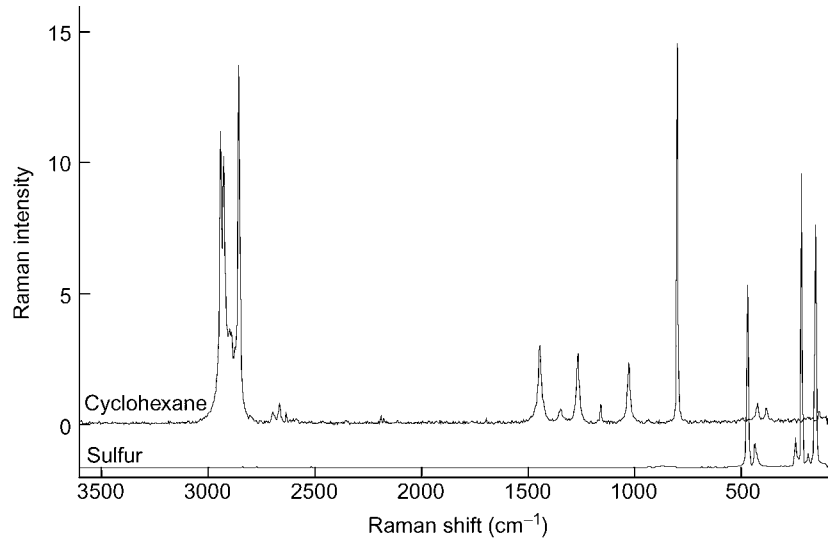

Figure 35.6 FT-Raman spectra of wavelength calibration standards cyclohexane and sulfur.

a very weak Raman scatterer, so many samples (liquid and solid) can be simply analysed in a bottle or, for example, in a nuclear magnetic resonance (NMR) tube, although fluorescence from some glasses can be problematic. Capillary tubes are also possible sample holders, but these should be used only when the sample is limited as the SNR on spectra obtained from capillary tubes can be poor. Water is a good solvent for Raman studies since the Raman spectrum of water is essentially one broad, weak band at 3500 cm^{-1}. One type of sample that may pose a problem is any material that is darkly coloured. Often, these samples absorb excessive heat and burn, causing sample and spectral degradation. Amorphous materials also have a tendency to absorb heat in the laser beam. To avoid sample burning, it may be necessary to dissipate the heat. This dissipation can be accomplished by reducing the laser power or by using an accessory that spins the sample, avoiding the irradiation of a single point in the sample. Further reduction of the laser power can also be accomplished through a neutral density filter. Sometimes, the sample can be diluted in KBr to help reduce sample burning.

The complete Stokes Raman spectrum covering shifts in the range 100 to ~3500 cm^{-1} can be obtained and the intensity of Raman scattering is directly proportional to the concentration of the scattering species, an important factor for quantitative analysis. However, the Raman effect is relatively weak and hence a material needs to be present at a concentration of at least about 1% for accurate assessments, whereas IR can be used to detect materials down to a concentration of approximately 0.01%. Fluorescence can also be problematic in Raman studies, but is typically due to additives in the glass sample tubes, or impurities within the sample of interest. Data massaging techniques can sometimes blank out Raman spectral contributions due to fluorescent materials. Photobleaching is another means of suppressing fluorescence. This technique involves irradiating the sample for a prolonged period of time (seconds to hours) with the laser. During this time the fluorescence may decrease due to the destruction of the fluorescing component as a result of the prolonged exposure to the laser irradiation. The spectrum is then acquired after photobleaching is complete. Of course, it is also possible that the laser radiation may change the component of interest. For example, a solvated crystalline material may desolvate with exposure to laser radiation. It would be wise to establish sample integrity by comparing spectra acquired with short acquisition times and those acquired with long acquisition times. Additionally, another technique, such as IR spectroscopy or X-ray powder diffraction (XRPD) could be used to check for sample changes after Raman analysis.

Variable-temperature studies in Raman spectroscopy provide a wealth of information. Because a Raman spectrum typically covers a wavelength range that extends beyond the range normally associated with mid-infrared spectroscopy (typically 4000–400 cm^{-1}), information about lattice vibrations of organic compounds is readily available. Varying the temperature of a sample changes the lattice energies of the compound, allowing for interpretation of the nature of the crystal lattice. In addition, information similar to that obtained in IR variable-temperature studies (crystal form changes and the nature of solvate association) can be achieved through variable-temperature Raman investigations.

Interpretation of spectra

The number of fundamental vibrational modes of a molecule is equal to the number of degrees of vibrational freedom. For a non-linear molecule of n atoms, $3n - 6$ degrees of vibrational freedom exist. Hence, there are $3n - 6$ fundamental vibrational modes. Six degrees of freedom are subtracted from a non-linear molecule since (a) three coordinates are required to locate the molecule in space and (b) an additional three coordinates are required to describe the orientation of the molecule based upon the three coordinates defining the position of the molecule in space. For a linear molecule, $3n - 5$ fundamental vibrational modes are possible since only 2 degrees of rotational freedom exist. Thus, in a total vibrational analysis of a molecule by complementary IR and Raman techniques, $3n - 6$ or $3n - 5$ vibrational frequencies should be observed. It should be noted that in complex molecules (such as pharmaceuticals) it may not be possible to observe every vibration due to overlap and relative intensity differences.

Regarding spectral interpretation, two of the best textbook sources are *Introduction to Infrared and Raman Spectroscopy* (Colthup *et al.* 1990) and *The Handbook of Infrared and Raman Characteristic Frequencies of Organic Molecules* (Lin-Vien *et al.* 1991). Both of these texts contain chapters dedicated to functional groups (e.g. methyl and methylene groups) and chemical compound types (e.g. ethers, alcohols and phenols). By the examination of peak location and intensity in Raman spectra, functional groups (and chemical compound types) can be determined. Discussed below are some guidelines for interpreting a Raman spectrum. It should be emphasised that this section is to serve as general background information. Any complete spectral interpretations should be made with the guidance of one of the referenced texts.

Raman spectroscopy provides information about the molecular bonding of a molecule. Certain functional groups will give rise to fundamental vibrational modes. For example, the C=C stretch in ethylenes will occur near 1650 cm^{-1}. The C–N stretch (amide III peak) for primary amides occurs between 1430 and 1390 cm^{-1}. A C–S stretch usually appears strongly in the 735–590 cm^{-1} region. There are many other functional groups that give rise to Raman peaks in specific spectral regions. Infrared bands will also occur in the same spectral regions, but because of selection rules the band intensities will differ, often dramatically. In the most basic terms, a vibrational mode is Raman

active when there is a change in polarisability during the vibration. Conversely, a vibrational mode is infrared active when there is a change in the molecular dipole moment during the vibration. Hence, vibrational modes that give rise to strong Raman peaks often give weak infrared bands and vice versa. It is because of this characteristic that infrared and Raman spectroscopy used together to examine the molecular bonds in a compound are described as 'complementary'. Some of the strongest Raman peaks will come from functional groups such as C=C, N=N, S–S, C–H, S–H, C=N, C=S and C–S, which have low polarity and high polarisability. These functional groups tend to occur in rather constant frequency ranges, although some shifts can occur based on other substituents in the molecule.

Vibrational modes can be separated into two classes: those in which the molecular bond is stretching and those in which it is bending. It takes a specific amount of energy for each of these actions to occur. The energy required depends on the atoms involved and the strength of the bond. In the theory section of this chapter, the nature of Raman excitation of a molecule was discussed. The location of the vibrational mode (its peak wavelength position in the spectrum) is related to the frequency of the excitation source (the laser) and the frequency of the scattered light. The equation defining this relationship is $h\nu = h\nu' + \Delta E_{\text{vibration}}$, where h is Planck's constant, ν is the excitation frequency, ν' is the scattered light frequency and ΔE is the vibrational energy. The vibrational energy is directly related to the strength of the bond and the amount of energy required to make that bond stretch or bend. These actions are elaborated below.

A stretching vibration is the motion that a molecular bond undergoes when the two atoms involved in the bond move apart and then contract. The stretch can be a simple contraction/expansion between two atoms such as the C=C stretch of ethylene. This type of motion occurs as a peak in the Raman spectrum at approximately 1650 cm^{-1}. When three atoms are involved, there are two types of possible stretches: symmetrical and antisymmetrical. Using a methylene group as an example, a symmetrical CH_2 stretch would occur when the two hydrogen atoms move apart from the carbon atom at the same time. This type of stretch occurs near 2853 cm^{-1}. The antisymmetrical CH_2 stretch occurs when one hydrogen atom is moving away from the carbon atom while the other hydrogen atom is moving closer to the carbon atom. This vibrational mode appears near 2926 cm^{-1}. The symmetrical stretches are typically stronger in Raman spectra (a greater change in polarisability), whereas the antisymmetrical stretches are stronger in infrared spectra. When many atoms are involved in the stretching, such as with aromatic rings, the types of stretches become more complicated. For example, a benzene ring monosubstituted with a halogen has 30 vibrational modes. Of these modes, some are strictly stretches, some are bends and some are combinations of both. Perhaps the simplest stretching mode for benzene rings is the ring-breathing mode, in which the two, four and six carbons move outwards. This mode occurs as a very strong Raman peak near 1000 cm^{-1} for mono-, *m*- and 1,3,5-trisubstituted benzenes. Clearly, many types of stretches can occur.

In a bending vibration, the molecular bond bends instead of stretching. Many types of bends can occur: antisymmetrical, symmetrical, torsion, scissor, wag, twist and rock. Using a CH_3 group as an example, antisymmetrical, symmetrical, rock and torsion bends are possible (Fig. 35.7). In the antisymmetrical bend, two of the CH bonds bend towards each other in a pinching motion while the third bends outwards and away from the pyramid. This mode occurs between 1470 cm^{-1} and 1430 cm^{-1}. In the symmetrical bend, the three CH bonds all bend inwards, similar to a grasping type of action. This mode occurs from 1395 cm^{-1} to 1365 cm^{-1}. In the CH_3 rock, the three CH bonds all bend in one direction in a sort of 'sweeping' mode. Finally, the CH_3 torsion involves the three CH bonds all bending in a clockwise direction in a twisting motion.

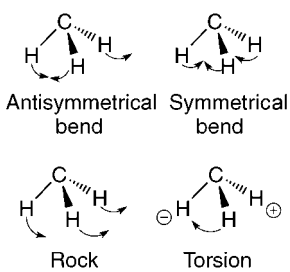

Figure 35.7 Bending vibrational motions associated with CH_3 (⊕ represents movement above the plane, ⊖ represents movement below the plane).

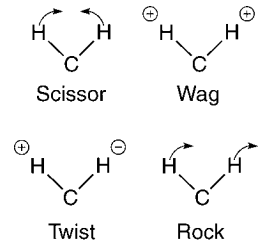

Figure 35.8 Bending vibrational motions associated with CH_2 (⊕ represents movement above the plane, ⊖ represents movement below the plane).

The CH_2 group can bend in slightly different ways (Fig. 35.8). A CH_2 scissor bend occurs when the two hydrogen atoms move towards each other in a scissoring motion. For a CH_2 wag, the two hydrogen atoms are bent towards the carbon atom. If the two hydrogen atoms alternately twist around one another, this is a CH_2 twist. Finally, if the two hydrogen atoms move back and forth, in line with the carbon atom, this is a CH_2 rock. As was seen with the CH_3 modes, each of these different types of motions will appear in different portions of the spectrum because they each require a different and unique amount of energy to occur. The scissor mode appears near 1465 cm^{-1}. The rocking, wagging and twisting modes are more complicated, falling in the range 1422–719 cm^{-1}. Depending on the substituents in the molecule, these modes can each be narrowed down to tighter ranges. It is this dependence of certain modes on substituents that gives rise to correlation tables. These are discussed in the next section.

Although the general location for a certain type of mode, for example a C=C stretch, can be listed, the exact location of the peak will vary slightly with the type of substituent present. For example, a vinyl C=C stretch (monoalkyl) will occur from 1650 cm^{-1} to 1638 cm^{-1}. A vinylidine C=C stretch (1,1-dialkyl) will occur from 1660 cm^{-1} to 1640 cm^{-1}. A *cis*-dialkyl substituted C=C stretch will occur from 1662 cm^{-1} to 1631 cm^{-1}, whereas a *trans*-dialkyl substituted C=C stretch will occur from 1676 cm^{-1} to 1665 cm^{-1}. Finally, trialkyl and tetraalkyl substituted C=C stretches appear from 1680 cm^{-1} to 1665 cm^{-1}. Some modes are very substituent sensitive, whereas others appear relatively consistently near a certain wavenumber.

Over the years, many types of compounds have been studied in great detail. When a spectrum of a single compound is interpreted such that every peak or band is assigned to a type of motion, this is called vibrational assignment. Through the examination of many vibrational assignments it was possible to draw correlations between types of vibrational modes and types of substituents. The culmination of this work is detailed in correlation tables that an investigator can use to aid in spectral interpretation (Colthup *et al.* 1990; Dollish *et al.* 1974; Lin-Vien *et al.* 1991).

The most efficient way to use correlation tables is to look for certain peaks that will quickly narrow down the type of compound. For example, if peaks are found at 3000 cm^{-1} or slightly higher, the compound is aromatic or olefinic. However, if the CH_2 stretches appear below 3000 cm^{-1}, the compound is aliphatic. Once that determination is made, then the correlation tables can be consulted to look for other confirmatory modes, such as CH wags for aromatic compounds. This type of process is continued until a compound class can be either verified or discounted.

It should be noted that for complex molecules it may not be possible to determine the structure from the Raman spectrum alone, or even if the infrared spectrum is available as well. Other techniques such as

nuclear magnetic resonance and mass spectrometry provide important information to aid in structure elucidation.

Qualitative analysis

Chemical identity testing of compounds is one role of the pharmaceutical spectroscopy laboratory. Testing can be accomplished with methods utilising Raman spectroscopy. An FT-Raman method has been developed to identify the two active components (tegafur and uracil) in formulated capsules (Petty *et al.* 1996). The Raman spectrum of the formulated product displayed a spectral region in which Raman bands unique to uracil and tegafur are observed. The presence of these bands allowed the analyst to confirm that both components were present in the formulated product. Owing in part to the ease of use and chemical specificity inherent with Raman spectroscopy, it has become an essential chemical and physical identification tool for the pharmaceutical spectroscopist.

Polymorphism (the ability of a molecule to crystallise in different three-dimensional structures) is a very important aspect of the drug development process. Raman spectroscopy is also used for the qualitative and quantitative characterisation of polymorphic compounds of pharmaceutical interest. For the sake of brevity, the term 'polymorphs' will encompass polymorphs, pseudopolymorphs, hydrates and solvates throughout the remainder of this chapter. The term 'polymorphs' is more commonly used and defined as the collection of different crystal structures that can exist for a chemical entity. The terms 'hydrates' and 'solvates', sometimes referred to as 'pseudopolymorphs', refer to the collection of different crystal structures that result from varying degrees of solvation. These materials differ chemically only by the degree of solvate incorporation (monohydrate, dihydrate) into the crystalline lattice, but physically they display different crystal structures. Since solid-state vibrational spectroscopy (Raman and IR) can be used to probe the nature of polymorphism on the molecular level, these methods are particularly useful in instances where full crystallographic characterisation of polymorphism is not found to be possible. An example is shown in Fig. 35.9, where spectra of different polymorphs of carbamazepine are displayed. An added advantage of using Raman spectroscopy for polymorphic investigations is the ease of the technique and the ability to measure low-frequency vibrations (500–50 cm^{-1}) that are attributed to lattice modes. In many cases, two different solid-state forms of a pharmaceutical entity will display spectral differences in the low-frequency region of the Raman spectrum. These spectral differences are also noted in the spectral comparison of crystalline versus amorphous material, a significant advantage for amorphous/crystalline characterisation of the drug. In addition, no sample preparation is required, providing a significant advantage over other techniques.

Raman microspectroscopy is well suited for *in situ* analysis of contaminants found in pharmaceutical processes. Owing to the non-destructive nature of the analysis, further experiments such as energy dispersive X-ray analysis or IR microspectroscopy may be performed on the same sample. A consideration for contaminant analysis by Raman spectroscopy is the axial and spatial resolution of the technique compared with IR microspectroscopy. In general, IR microspectroscopy is diffraction limited to investigating samples typically larger in size than 5 μm. As previously discussed, with a 0.95 NA objective, 1 μm spatial resolution can be achieved with a Raman microscope, permitting the analysis of very small contaminants.

Real-time monitoring of pharmaceutically relevant processes is an exciting application for Raman spectroscopy. Real-time monitoring by Raman spectroscopy has been utilised to examine synthetic organic reaction schemes to investigate kinetics, as well as to identify non-isolated reaction intermediates. Distinct advantages for Raman spectroscopy in this area are: (1) the ability to work with aqueous-based systems with little spectral interference from water, (2) utilisation of a fibre-optic probe for direct and/or remote sampling, (3) collection of the Raman spectrum directly through the glass vessel with little or no spectral interference, and (4) the ability to quantitatively analyse the spectrum. Other recent applications of real-time process monitoring by Raman spectroscopy include polymorphic interconversion under slurry conditions and crystallisation monitoring (Findlay, Bugay 1998).

Another exciting application of Raman spectroscopy is chemical mapping and imaging. With the incorporation of a microscope into a Raman spectrometer it is possible to investigate the spatial distribution of different compounds or polymorphic forms within a sample. By using a mapping stage, a sample such as a microtomed tablet can be moved in the *x* and *y* directions, obtaining spectra at each step. If the sample requires refocusing at different locations, the *z* direction can be automated as well. When the stage is moved to collect each individual spectrum, the resulting data set is referred to as a map. Spectral imaging occurs when spectra from the field of view are collected simultaneously by using an array detector.

In Raman mapping applications, multiple spectra can be collected at user-defined step sizes (as small as 1 μm) at several discrete points (a point map), along a line (a line map) or over an area (an area map)

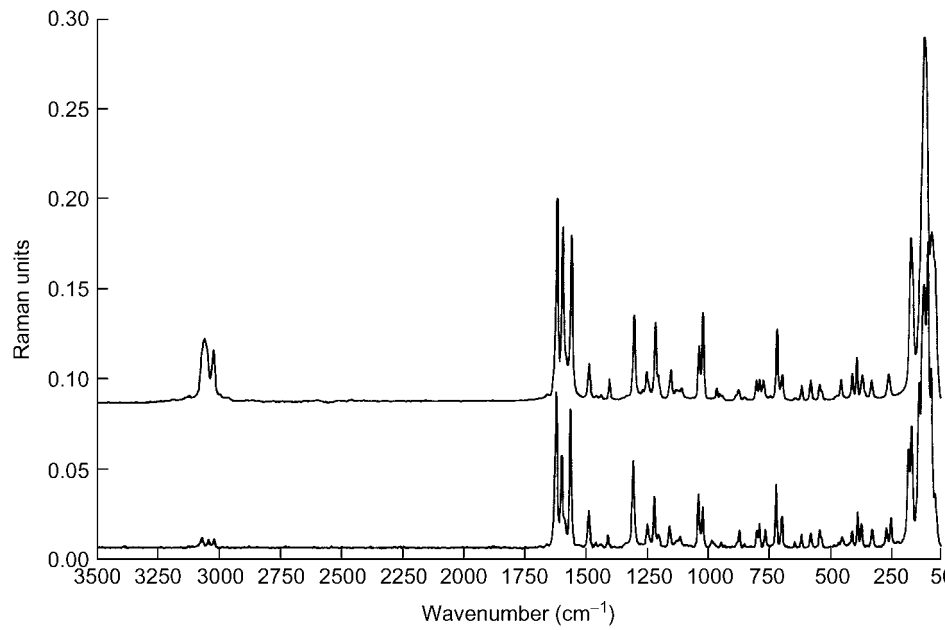

Figure 35.9 FT-Raman spectra of the polymorphs of carbamazepine (*top*, polymorph I; *bottom*, polymorph III).

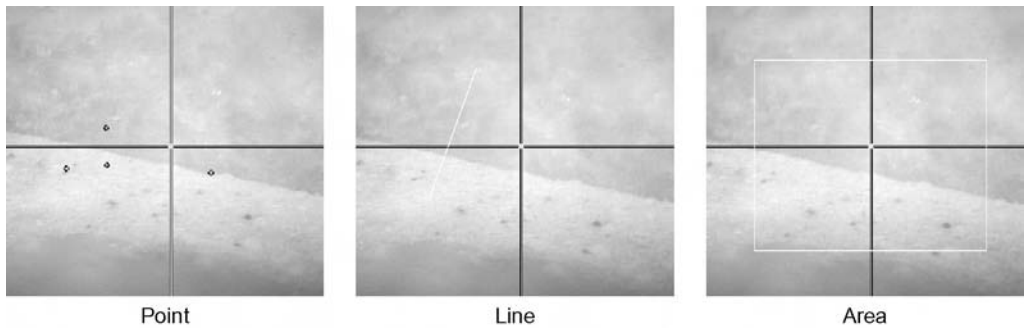

Figure 35.10 Examples of defined point, line and area maps.

(Fig. 35.10). A point map provides several different areas of a sample to be analysed consecutively, but the spectra are not related to each other spatially. A point map can be considered as a type of autosampler. An example of a point map application is a 96-well plate that contains combinatorial beads in each well. The second map type (the line map) defines a series of spectra to be obtained along one dimension. In line maps, chemical changes that occur along this dimension are investigated. An example of a line map sample is a cross-sectioned pharmaceutical beadlet that has several different layers exposed. One of the more practical reasons that line maps are so popular is that they can provide detailed information regarding the chemical changes that occur across a sample without the need to collect as many spectra as are required for area maps. The final map type (the area map) defines a series of spectra to be collected in two dimensions (i.e. over an entire region). This type of map provides a Raman image that can be directly compared with the visual image, often allowing features that are not visible to the eye to be identified. A tablet is common area map sample. The tablet can be mapped and the various ingredients can be monitored as to content uniformity, for example.

A series of images demonstrating the dispersion of several excipients in a tablet is displayed in Fig. 35.11. This particular area map was obtained with a step size of 4 μm in both the x and y directions, a sampling spot size of approximately 1 μm, and a total sampling area of 87×52 μm. The time required to collect this map was approximately 26 h. It should be noted that not all Raman mapping experiments require this amount of time. For example, if a map is being performed to search for a particular component, the step size need only be of the order of the particle size of that substance. A good approach would be to first obtain a larger area map on the sample with larger step sizes and shorter sampling times per point. Once an area of interest is defined by analysing the data from the first map, a smaller, higher-resolution map can then be defined. Another approach would be to use a separate technique to determine the area of interest and then collect a Raman map from that area. For example, near-infrared imaging (NIR) would be a good starting technique. Instrumental advances have also increased the speed of map acquisition. The instances of high-powered diode lasers required optics in order to spread the power across a line rather than onto a spot on the sample to avoid burning or heating of the sample. The line allows for several spectra to be collected simultaneously, reducing the number of times that the stage has to be moved to cover the area required and thereby reducing experimental time. Additional progress has been made over recent years in this approach (Hutchings *et al.* 2008). This improvement allows for the collection of many spectra across a whole sample in a shorter time by using larger CCDs in conjunction with a faster readout of the CCD. This configuration obviously reduces the time required to analyse samples without forgoing spatial and spectral resolution.

Raman imaging, as opposed to Raman mapping, involves the simultaneous collection of multiple responses from a larger area on a sample using CCD array cameras and liquid crystal tuneable filter (LCTF) technology. This approach greatly reduces the amount of time required to collect a chemical image (Zugates, Treado 1999). In one case, the time required to collect a chemical image decreased by approximately 4 h after switching from a CCD camera (>5 h experiment) to LCTF technology (<1 h). During an imaging experiment, the LCTF (or another form of bandpass filter) is tuned to a specific wavelength. The choice of wavelength is normally based on the spectrum of the component of interest. The laser, which has been defocused onto the sample to illuminate a greater area, irradiates the sample. The signal obtained is based on the intensity response at the given wavelength. The response also contains spatial information obtainable through mapping. A complete spectrum of a given area of the sample may be obtained by collecting an image, retuning the bandpass filter to the next wavelength and collecting a subsequent image until the whole spectral range has been obtained. This, however, would be a long process and is not typically used. If a complete spectrum is required, a fast mapping set-up is preferable.

There are instruments available nowadays that have the capability of mapping and imaging using one system. This allows the user to

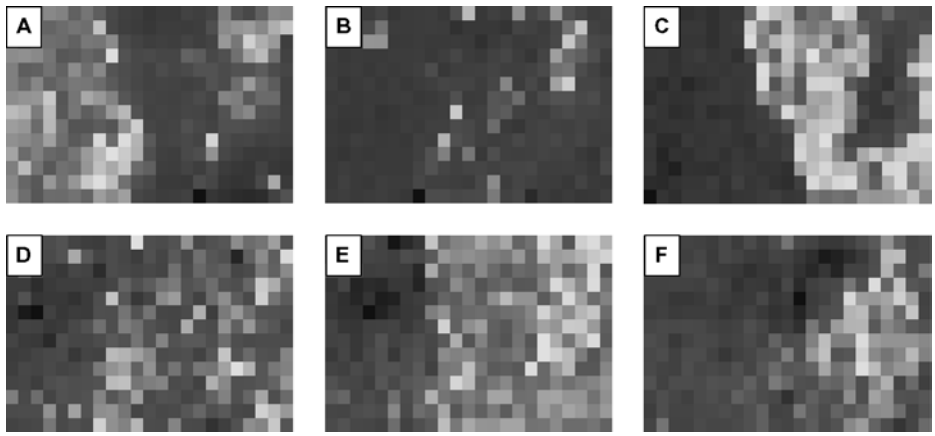

Figure 35.11 Peak area profiles (images) representing (A) mannitol, (B) aspartame, (C) cellulose, (D) magnesium stearate, (E) corn starch and (F) monoammonium glycyrrhizinate.

determine which set-up is preferable depending on the sample and data required. There are also instruments that may be interfaced with an atomic force microscope (AFM) tip that enables yet another dimension of the sample to be probed (Schmidt *et al.* 2005).

Once line or area mapping experiments have been performed, profiles are created that enable certain spectral features to be monitored spatially on the sample. The data sets generated by mapping can consist of hundreds or even thousands of spectra, and viewing all of these spectra concurrently is unrealistic. Profiles can aid in this task by reducing the data set into a more easily viewed format (an image). A profile is a representation of map data in which a measurement of spectral intensity or some other characteristic is shown for each sample point. A profile will verify the presence, location and extent of a defined spectroscopic feature in the sample. There are many types of profiles. Some profiles, such as chemigram or component profiles, compare an entire reference spectrum with every spectrum in the map, with the resulting image showing spectral similarity across the mapping region. Other images can be created based on profiling a specific peak area, peak height, peak area ratio or peak height ratio. Profiles can also be performed based on a group of peaks specific for certain functional groups (e.g. alkanes) or even on a quantitative method.

Literature references of other mapping applications of relevance to the pharmaceutical industry include some of the following: solid dispersions of ibuprofen in PVP (polyvinylpyrrolidone) (Breitenbach *et al.* 1999), crystal formation in hormone replacement therapy patches (Armstrong *et al.* 1996), particle size analysis in mixtures (Theophilus, Lancaster 2000), pharmaceutical matrix determination of dosage formulations (Clarke *et al.* 2000) and characterisation of drug substances in low dosages (Henson, Zhang 2006). An overview of examples is also given by Clark *et al.* (2007).

Quantitative analysis

The ability to perform quantitative analysis by Raman spectroscopy is a significant advantage of the technique. Through mathematical treatments, it has been shown that the Raman scattering intensity is proportional to the number of molecules being irradiated. The intensity of scattered radiation is also proportional to the intensity of the incident radiation and the fourth power of the difference in frequencies between the laser frequency and the molecular vibrational frequency. Thus, increased Raman scattering intensity, and potentially lower limits of detection, can be achieved by increasing the intensity of the laser radiation and/or increasing the frequency of the laser irradiation. This quantitative relationship between Raman scattered intensity and concentration can be expressed as:

$$I_R = (I_L \sigma K) PC$$

where

I_R = measured Raman intensity, in photons per second
I_L = laser intensity, in photons per second
σ = absolute Raman cross-section, in cm^2 per molecule
K = measurement parameters
P = sample pathlength, in cm
C = concentration, in molecules per cm^3.

The constant K represents lumped measurement parameters such as utilising the same spectrometer (collection optics efficiency), sample positioning and overall efficiency of the Raman spectrometer.

In the past, quantitative analysis was not often performed with Raman spectroscopy because of problems inherent to dispersive systems. When FT-Raman spectrometers became popular, the feasibility of quantitative applications greatly improved (Walder, Smith 1991). Some of the advantages of FT that lend themselves well to quantitative applications are Jacquinot's advantage, Fellgett's advantage and Connes' advantage. Jacquinot's advantage, also known as the throughput advantage, depends on the fact that the entrance aperture of the interferometer is large. The larger aperture makes the sampling geometry less sensitive to absolute repositioning of the sample cell. Fellgett's advantage, otherwise known as the multiplex advantage, concerns the increased speed with which spectra can be collected because all wavelengths of the spectrum are collected simultaneously. This rapid collection implies that FT-Raman spectroscopy may be less sensitive to instrument drift. Finally, Connes' advantage, also called the precision advantage, arises because there is only one moving part in an FT system (one mirror in the interferometer). An FT system is therefore very rugged, allowing excellent day-to-day wavelength precision.

Although FT-Raman spectroscopy is more applicable to quantitative applications than dispersive Raman spectroscopy, there are still some issues. These mainly concern the optimisation of sampling conditions. FT-Raman spectroscopy typically samples a relatively small area (e.g. a 1–2 mm spot) of the total sample. As such, it is important that any spectra collected are truly representative of the bulk sample. For solution studies, homogeneity of the multicomponent samples presented for quantitative analysis is not an issue. In contrast, solid-phase analysis can present significant inhomogeneity issues for quantitative analysis. One way to improve sample uniformity is to prepare all solid mixtures by geometric mixing. Slurry mixing is another good technique if the sample can withstand contact with the slurry solvent. For spectral acquisition, sample-spinning accessories should be used to spin the sample cup containing the mixture during spectral acquisition. Use of this type of accessory results in the collection of a more representative sample spectrum (a ring of data is collected, instead of data just at a single point). To effectively minimise any sample heterogeneity concerns, different rings of data can be collected for each sample cup. The individual spectra from each sampled area can then be co-averaged into groups to create representative spectra for the sample in the cup.

Another factor to consider when using Raman spectroscopy quantitatively is that the power output of the Raman laser can vary from day to day, thereby affecting the intensity of spectral peaks. It is advisable to normalise any data before using it in a quantitative manner. One possible method for normalising spectra is to ratio the spectral response of the analyte against a peak response for a non-changing component (e.g. an excipient in a drug product or an internal standard). Owing to difficulties with sample homogeneity, the use of an internal standard is usually discouraged. Alternatively, a ratio can be measured using a peak response of a component changing in an opposite direction to that of the component being monitored. For example, in a quantitative method used to monitor the amount of crystalline drug substance in the presence of the amorphous form, a crystalline peak response (e.g. peak area or peak height) can be normalised by dividing it by an amorphous peak response.

An excellent reference for Raman quantitative analysis was published in 2003 by MJ Pelletier (Pelletier 2003). This article first discusses the fundamental basis for quantitative analysis using Raman spectra, and then follows with in-depth discussions about the value and utilisation of noise, useful preprocessing operations, the use of both peak position and peak shape for method development, and univariate and multivariate calibrations. The reader is referred to this publication for more in-depth discussions beyond the scope of this chapter.

When developing a quantitative method, it is very important to follow regulatory agency guidelines. Important quantitative issues include:

- *System suitability* – an overall test of system function
- *Specificity* – the ability of Raman spectroscopy to differentiate the analyte from the matrix
- *Working range* – the concentration range over which the method is validated
- *Linearity* – demonstration of a direct relationship between a measured analytical response and concentration over the working range of the method
- *Precision* – the repeatability with which a number can be represented
- *Accuracy* – degree of conformity of a measurement to a standard or true value
- *Limit of detection* – the lowest concentration that an analyte can be detected
- *Minimum quantifiable limit* – lowest concentration at which an analyte can be quantified with acceptable accuracy and precision

- *Robustness* – demonstration of the reliability of an analysis with respect to deliberate variations in method parameters.

One literature example of quantitative Raman analysis addresses the question of amorphous/crystalline content of indometacin samples (Taylor, Zografi 1998). The paper highlights the quantitative nature of Raman spectroscopy, the need to produce homogeneous calibration/validation samples, and difficulties associated with collecting a Raman spectrum that is truly representative of the concentration. A linear correlation curve was constructed in which low concentrations of both amorphous and crystalline material could be detected and predicted in mixtures. The authors felt that the largest source of error in the measurements arose from inhomogeneous mixing of the amorphous and crystalline components in the blends. For solid-state analysis, this conclusion points out the need for a sampling device that collects a Raman spectrum that is truly representative of the sample, in this case a mixture.

Chemometrics

In the above literature example of quantitative analysis, a univariate approach (a single peak response) was used to create the calibration curve or predictive model. Chemometrics represents a multivariate approach to creating a predictive model for quantitative analysis. Chemometrics may be defined as the 'use of statistical and mathematical techniques to make either quantitative or qualitative measurements on chemical data'.

A chemometric approach is useful when there are very few spectroscopic differences between the compounds in a mixture, which is often the case for polymorphic studies. Partial least-squares and discriminant analysis are examples of two types of chemometric approaches that can be taken for quantitative and semiquantitative work. These methods are capable of identifying one or more regions of complex overlapping spectra and monitoring their differences by looking at peak position, peak shape, and first-derivative and second-derivative spectra. They represent the differences between the calibration spectra as linear combinations (factors). These factors account for the differences between the spectra, with the first factor representing the strongest differences and subsequent factors representing more subtle differences. Eventually, a point is reached where the factor simply represents changes in random noise between the spectra.

Partial least squares

In the article 'Quantitative analysis of vitamin A using Fourier transform Raman spectroscopy' the authors used partial least squares (PLS) to obtain a method quantified to a concentration of 0.005% w/w (Hancewicz, Petty 1995). One of the concerns that they addressed is that Raman spectra need to be standardised to account for changes in the overall intensity of the spectrum. Possible sources of error include changes in sample positioning, laser power fluctuations and sample wall thickness variations. It was mentioned above that forming peak response ratios with an internal or external standard could normalise the data, but these authors took another approach. They used multiplicative scatter correction (MSC) to compensate for the random multiplicative and additive contribution to the spectra caused by sampling. MSC is traditionally used for diffuse reflectance, but can be used on any data that are collected with unknown or changing pathlengths.

Discriminant analysis

Discriminant analysis is a chemometric technique that allows it to be stated that an unknown sample most resembles a certain class, where each class represents sample 'X', 'Y' or 'Z'. For example, X could be 0% crystalline material in amorphous material, Y could be 5% crystalline material and Z could be 15% crystalline material. In this example, a discriminant analysis method is a pattern recognition model that can be semiquantitative.

There are three main parts to developing a discriminant analysis method. First, decisions must be made regarding the number of spectra (or standards) needed for each class. Once all of the spectra have been collected, some are used to create a calibration (training) model. This training model is 'tweaked' with regard to the spectral regions examined, the number of factors (or principal component (PC) scores) used, baseline treatments, and so on. Once the training model is defined such that it correctly predicts all of the spectra within it (i.e. it is calibrated), the model is tested by internal cross-validation. This validation consists of omitting one standard at a time from the data set, using the depleted set to obtain a new calibration model, and applying this new model to the omitted standard. This process is repeated for each standard. If each spectrum is accurately predicted, then the method is validated. The internal cross-validation also aids in determining whether the model is over-fitted. All these steps may be performed automatically by a given software package.

Overall, chemometrics provides an excellent approach to quantitative method development by enhancing method accuracy and precision, and allowing lower limits of detection and quantification. The reader is referred to Further reading for further publications regarding chemometrics.

Collections of data

By far the quickest method for identifying unknown materials is to search the spectrum against spectral libraries. Often an answer can be found within seconds. However, care must be taken when performing spectral searching.

Computer search programs determine the difference between a sample spectrum and the reference spectra in a library. There are several possible algorithms that can be used to compare spectra, some based on intensity and others based on peak position. For example, difference algorithms accentuate peak intensity over location. The *absolute difference* algorithm puts more weight on the small differences between the unknown spectrum and library spectra, meaning that impurities will have a larger effect on the search results. The *squared difference* algorithm emphasises the large peaks in the unknown spectrum, making it useful when searching a noisy spectrum. *Derivative* algorithms accentuate peak position over intensity. The *absolute derivative* algorithm gives small peaks and peak shifts an increased effect in the search results. This algorithm removes any differences between the unknown and library spectra caused by an offset in the unknown spectrum and so it is useful for analysing spectra with distorted baselines. The *squared derivative* algorithm emphasises large peaks as well as peak shape and works best for noisy spectra with distorted baselines. Perhaps the most versatile search algorithm is *correlation*, which balances the contributions of both intensity and peak position. This algorithm normally gives the best results and is recommended for most applications.

When a search is performed, a hit list is produced. The reference spectra are ranked in order of match quality. Some programs assign a value of 100 to a perfect match, others use 0. In either case, a good hit would obviously be one that is closest to perfection. In the best-case scenario, the top hit (if 100 is perfect) is above 90 and all other hits are significantly lower. In cases of spectral mixtures, however, the best hit may not even be 50. In those cases, the best reference spectra are compared with the sample spectrum to determine whether they could represent a portion of the sample. If so, a spectral subtraction may be performed to remove the reference component from the sample spectrum and the resulting spectral subtraction can be searched again to look for additional components. Often, if strong peaks are being subtracted from each other, regions of over- or under-subtraction will occur, producing derivative-shaped peaks in the subtraction spectrum. In these cases, it may be advantageous to 'blank-out' these regions before searching for lesser components. The process of spectral searching and subtraction can be repeated until the S/N ratio of the subtraction spectrum yields unusable results and no more components can be identified.

There are several commercial libraries that are useful for drug analysis (see Further reading). Aldrich has a comprehensive library containing over 14 000 FT-Raman spectra. Thermo Scientific markets two useful libraries. One is a Raman forensic library containing 175 spectra of drug compounds, excipients, precursors and metabolites. The other is a pharmaceutical excipients library that contains 300 reference spectra.

For this second library, there is also a matched set of corresponding FT-IR spectra. Galactic Industries and Bio-Rad are two other popular suppliers of spectral libraries. Of course, sometimes the most useful libraries are ones that analysts create themselves.

A final note on the use of spectral libraries: the results from a hit list should always be verified by (1) comparing the reference spectrum with the sample spectrum, (2) ensuring that the reference spectrum is accurately named in the library (no library is perfect), and (3) determining that the suggested hit is a logical component to be expected in that particular sample.

CHAPTER

36 Nuclear Magnetic Resonance Spectroscopy

JC Lindon and JK Nicholson

Introduction

Since its first observation in bulk phases in 1945, nuclear magnetic resonance (NMR) spectroscopy has become one of the foremost methods for molecular identification, for evaluating detailed molecular structures, for understanding conformations and for probing molecular dynamics, such as molecular tumbling and diffusion in solution. If the measurements are carried out under appropriate conditions, NMR spectroscopy can also be used for quantitative analysis. Although powerful in its own right, NMR spectroscopy can be regarded as complementary to other analytical chemical techniques. For example, it can provide information on substances with no ultraviolet (UV) chromophores, such as carbohydrates. It is a universal detector in that, if the molecule under study contains NMR-active nuclei, these should be detectable. However, it is only possible to infer details of parts of the molecule that do not contain NMR-active nuclei, such as the presence of a sulfate conjugate of a drug metabolite, in which case the definitive loss of mass 80 seen in mass spectrometry (MS) is complementary.

The vast majority of NMR spectroscopic experiments are carried out in solution to identify the structures of small chemical molecules, including natural products, but a wealth of high-resolution applications is found in other areas, such as determination of the three-dimensional structures of proteins and nucleic acids and the analyses of complex biological mixtures. This last application has seen a dramatic expansion since 2001, and is now known as metabonomics or metabolomics, with diverse studies covering drug toxicity, disease diagnosis, drug therapeutic effects, and nutrition and lifestyle effects. In addition, much effort has been devoted to solid-state NMR spectroscopy in which special techniques have to be used to overcome very broad NMR peaks and to recover useful chemical information. One application in this area of interest to pharmaceutical scientists is the determination of polymorphic forms of drugs in the solid state.

Finally, NMR spectra can be obtained from living humans and animals and *in vivo* NMR or magnetic resonance spectroscopy (MRS) has found a use in disease diagnosis. The same technology and principles lie behind magnetic resonance imaging (MRI), which is now widely available in hospitals for clinical diagnosis.

Theory

Atomic nuclei in a magnetic field

The phenomenon of nuclear magnetic resonance arises because the positively charged nuclei of certain atoms possess a quantised property called spin, denoted by a spin quantum number I. This spin is associated with a nuclear magnetic moment, also quantised, such that in a magnetic field it is possible for the nuclear magnetic moment to take up various orientations with respect to the field. Each orientation is associated with a discrete energy state and in the presence of the magnetic field these states have different energies. I can have half-integer or integer values, including zero. For nuclei with $I = 0$, there is no magnetic moment, which is the case when both the atomic number and the atomic weight are even, such as in ^{12}C and ^{16}O. In general, there are $2I + 1$ energy states or levels and so for the simplest magnetic nuclei, with $I = {}^1/_2$, there are just two levels. As a consequence of the differing energies of the states, and because of the Boltzmann distribution, the populations of spins in the two states are not equal and an excess of nuclear spins will occur in the lower energy level. It is possible to induce transitions of nuclear spins between these levels by applying an oscillating magnetic field; for commercially available NMR magnets, these transitions are in the radiofrequency region of the electromagnetic spectrum. There is a linear relationship between the magnitude of the nuclear magnetic moment and the observation frequency of the NMR phenomenon for a given applied magnetic field strength. There is also a linear relationship between observation frequency and applied magnetic field strength for a given nucleus. Because of electron shielding effects in molecules, not all nuclei of a given atomic isotope have the same resonance frequency (known as the Larmor frequency), depending on their chemical environment, and hence the NMR phenomenon gives rise to a range of resonance frequencies that correspond to peaks in an NMR spectrum.

Many good textbooks describe the theory of NMR spectroscopy in more detail, a selection of which are listed in Further reading at the end of this chapter.

Important NMR-active nuclei

Although all nuclei have at least one isotope that is, in principle, NMR active, most NMR spectra are based on just a few nuclear types. There are several reasons for this. One is that nuclei with $I > {}^1/_2$ have a property called a nuclear quadrupole moment that, in general, results in short lifetimes in the excited spin states and a rapid return to the low-energy state, and this gives very broad NMR lines. Second, many NMR-responsive nuclei exist at low natural abundances and so are difficult to detect without isotopic enrichment. Third, the strength of the NMR response is related to the size of the nuclear magnetic moment; many nuclei have rather small values of the magnetic moment and so have low detectability. Finally, some nuclei, once excited to the upper level, are slow to relax back to the ground state, which must occur before another scan can be added. This then incurs a time penalty for acquiring the summed scans necessary to improve detection limits. Sometimes these difficulties of low sensitivity, low natural abundance and long relaxation times come together.

The principal nuclei of interest for pharmaceutical and biochemical studies are given in Table 36.1, together with their NMR properties. The common isotopes of carbon and oxygen, ^{12}C and ^{16}O, do not have magnetic moments and so do not give rise to NMR spectra. The ubiquitous ^1H nucleus, or proton, has one of the highest relative sensitivities, surpassed only by its radioactive isotope tritium, ^3H. The ^{13}C isotope is useful for characterising the carbon skeleton of organic molecules and, with a natural abundance of about 1.1%, the chance of finding two ^{13}C nuclei in a given molecule is only about 0.01%, which simplifies the spectra considerably because of the absence of spin–spin interactions between carbon atoms. Many spectroscopic methods have been developed to allow the routine observation of ^{13}C NMR spectra of organic molecules. The ^{19}F nucleus is almost as sensitive as the ^1H nucleus (about 83%) in NMR terms, and ^{19}F NMR spectroscopy is used extensively in studies of the metabolism of fluorine-containing drugs. More limited use is made of other nuclei in pharmaceutical and biochemical research, and nuclei such as ^{15}N have been used extensively for protein-structure determination after isotope enrichment. The use of ^{31}P NMR spectroscopy is widespread in biochemistry and medicine as a means of investigating the various phosphorylated molecules

Table 36.1 NMR properties of some nuclei of interest for pharmaceutical studies

Nucleus	Spin quantum number	Natural abundance (%)	NMR Larmor frequency (MHz)	Relative sensitivity
^{12}C	0	98.89	—	—
^{16}O	0	>99	—	—
^{1}H	1/2	99.98	600.00	1.00
^{3}H	1/2	0.0	639.98	1.21
^{13}C	1/2	1.11	150.86	1.59×10^{-2}
^{15}N	1/2	0.37	60.80	1.04×10^{-3}
^{19}F	1/2	100.0	564.46	8.30×10^{-1}
^{29}Si	1/2	4.7	119.19	7.84×10^{-3}
^{31}P	1/2	100.0	242.88	6.63×10^{-2}
^{2}H	1	0.015	92.10	9.65×10^{-4}
^{14}N	1	99.63	43.34	1.01×10^{-1}
^{23}Na	3/2	100.0	158.71	9.25×10^{-2}
^{35}Cl	3/2	75.53	58.79	4.70×10^{-3}
^{17}O	5/2	0.037	81.34	2.91×10^{-2}

important in biology, including many studies *in vivo*. Many other spin-$^1/_2$ nuclei, such as ^{29}Si, ^{119}Sn, ^{129}Xe, ^{195}Pt and ^{199}Hg, have found much use in specialist applications. Nuclei with $I > {}^1/_2$ are quadrupolar and, in general, give broad NMR lines, but in some cases useful information can be gleaned. Examples include ^2H NMR in liquid crystals, ^{14}N NMR in heterocyclic chemistry, and ^{23}Na NMR studies of intra- and extracellular sodium ions.

Parameters from an NMR spectrum

Chemical shifts

As mentioned earlier, not all nuclei of a given isotope resonate at exactly the same frequency. This is because, in a molecule, a given atomic nucleus is surrounded by electrons which also possess a magnetic moment, and these provide a fluctuating magnetic field that opposes the main field of the NMR magnet. As a consequence, the nuclei are shielded from the main magnetic field and require a higher field to bring them to resonance and thus they can be considered to have higher Larmor frequencies. The degree of shielding depends on the electron distribution around the nucleus and hence on the chemical environment. The different degrees of shielding are known as chemical shifts. Thus, interpretation of chemical shift values allows identification of molecular structural fragments. Chemical shifts are measured relative to that of a reference substance usually placed into the sample. For ^1H and ^{13}C shifts in organic solvents, this is tetramethylsilane (TMS). The chemical shift is then defined as $\delta(H) = (\text{difference in the resonance frequency in hertz between the analyte and TMS}) \times 10^6/(\text{operating frequency of the spectrometer})$. Chemical shifts are thus quoted in parts per million (ppm) and are independent of the operating frequency of the spectrometer, which allows comparisons irrespective of magnetic field strength. For aqueous samples, an alternative reference compound is used, of which trimethylsilyl [2,2,3,3-$^2H_4$]propionic acid sodium salt (TSP) is the most common example. The chemical shifts for TMS and TSP are set arbitrarily to zero. Typical ^1H and ^{13}C NMR chemical shifts of a variety of important molecular fragments are shown in Tables 36.2 and 36.3, respectively.

Indirect (J) spin–spin coupling

The resonance lines of individual nuclei can show further splitting because of indirect spin–spin coupling. Given the symbol *J*, this is measured in hertz and is independent of the observation frequency. Such spin coupling arises from a magnetic interaction between NMR-active nuclei and is transmitted via the intervening electrons, hence the term 'indirect'. Coupling is observed only within a molecule. Thus for two spin-$^1/_2$ nuclei, such as protons, the resonance line for each proton is split into a doublet, the two lines corresponding to the two possible orientations of the adjacent proton relative to the magnetic field. For extended coupling chains, each component of a doublet can be split further into doublets of doublets and so on. If a given proton is adjacent to two equivalent other protons (as in a CH_2 group) then, of the four possible spin orientations of the two protons, two of them are identical and a 1 : 2:1 triplet results. For such 'first-order' systems, the multiplicity can be deduced on the basis of Pascal's triangle according to the number of equivalent coupled nuclei. In situations where the chemical shift difference between the protons is large compared with the *J*-coupling, this simple rule applies. For situations where the chemical shift in hertz between coupled partners is not large compared with the magnitude of the coupling constant ($\delta/J <$ ca. 10), or in symmetrical molecules, more complex rules have to be applied and sometimes the only way to

Table 36.2 The range of ^1H NMR chemical shifts for protons in various molecular fragments

Fragment	$\delta(^1H)$
Cyclopropyl CH_2	−0.2–0.8
C·CH_2·C	0.4–2.4
CH_3·C	0.5–2.0
C·NH	0.5–3.0
C·OH	0.5–5.0
CH_3·C=C	1.5–2.3
C·CH_2·C=C	1.6–2.0
CH_3S; CH_3CO	1.7–2.7
CH_3·Ph	2.0–3.0
CH_3N	2.2–3.1
C·CH_2·S	2.3–3.0
C=C·CH_2·C=C	2.3–3.0
C·CH_2·CO	2.3–3.5
C·CH(Ph)·C	2.5–3.0
C·CH_2·Ph	2.5–3.2
C·CH_2·N	2.5–3.3
C=C·CH_2·CO	2.8–3.7
C=C·CH_2·Ph	3.0–3.8
CH_3O	3.2–4.1

(a) Designated carbon is shown in bold face.
(b) X = C, O, N.
(c) Indicates peak multiplicity in a ^{1}H-coupled spectrum; s, singlet; d, doublet; t, triplet; q, quartet.

interpret a spectrum is via a computer simulation. For ^{1}H–^{1}H interactions, the coupling does not normally extend beyond three bonds, with four-bond couplings being quite small, if resolvable. Three-bond ^{1}H–^{1}H couplings provide valuable information on the dihedral angles between C–H vectors in aliphatic compounds through an empirical equation known as the Karplus equation. Typically, for CH–CH fragments, if the CH vectors have a dihedral angle of 180°, the coupling is of the order of 10 Hz, for 90° it is close to zero and for 0° it is about 6 Hz. In olefinic systems, the three-bond coupling across a C=C double bond is about 6–10 Hz for a *cis* arrangement and 12–16 Hz for a *trans* arrangement. All of these values are modified by the presence of substituents with varying electronegativities. Hence the *J*-coupling is a valuable parameter for distinguishing between isomers and for measuring molecular conformations. Compilations of coupling constants have been made and empirical models for calculating them in various conformations have been proposed (Pretsch *et al.* 1989).

Peak areas

If the NMR data are acquired under conditions in which each scan is acquired on a fully relaxed spin system in which the state populations are those given by the Boltzmann distribution, the areas under the NMR peaks are directly proportional to the number of nuclei contributing to that peak and to the concentration of the molecule in the sample. If an internal standard of known concentration is added to the sample, absolute concentrations can be determined.

Relaxation times

Two 'times' define how fast a nuclear spin interacts with the rest of the sample as a whole (known as the lattice) and how nuclear spins interact with each other in a pair-wise fashion. These are designated T_1 and T_2. T_1 is known as the spin–lattice or longitudinal relaxation time, and is the characteristic time for the exponential process of nuclear spins to reach equilibrium populations in the spin states. For small molecules in mobile solutions, ^{1}H T_1 values are usually in the range 1–10 s. The other relaxation time is known as T_2, the spin–spin or transverse relaxation time, and is related to the rate of magnetisation loss caused by spin–spin flips. For small molecules in free solution $T_1 = T_2$. However, macromolecules and exchanging species have short T_2 times, typically in the range 10–100 ms, even though T_1 may be much longer. Determined values of T_1 and T_2 can be used to deduce information on molecular dynamics in solution and the shorter T_2 values of macromolecules can be exploited to edit NMR spectra so as to attenuate their peak intensities, better revealing small-molecule NMR resonances.

Diffusion coefficients

The molecular self-diffusion coefficient is a whole-molecule property that does not normally appear in NMR spectra. However, it is a valuable measure of molecular mobility and in free solution is related directly to molecular size. It is possible to measure diffusion coefficients using a specially designed NMR experiment, which includes the application of magnetic field gradients.

Direct (dipolar) spin–spin coupling

Another important interaction in NMR spectroscopy is called the dipolar coupling. This is a direct magnetic interaction between nuclei through space, not through bonds, as for *J*-coupling; it is proportional to the inverse cube of the internuclear distance. This dipolar coupling can be several orders of magnitude larger than *J* couplings. However, because it depends on the angle that the internuclear vector makes with the magnetic field, it is averaged to zero by fast isotropic molecular tumbling in liquids, but in solids is largely responsible for the observed very broad resonance bands. In semi-solids, such as tissues, the dipolar couplings between nuclei are partially averaged out by the considerable molecular freedom and the residual couplings, and hence the line broadening can be removed by the technique of magic-angle spinning (MAS). However, for molecules tumbling in solution, the fluctuating dipolar interaction is an important relaxation mechanism and, even though its average value is zero, it can be used to interpret nuclear Overhauser enhancements (NOEs). These are peak intensity changes caused by selective perturbation of the spectrum, or a two-dimensional experiment (see later), and the sign and magnitude of NOEs can be related to internuclear distances and hence molecular structural information.

Instrumentation

Practical aspects of ^{1}H NMR spectroscopy

NMR spectroscopy is used mostly to identify molecular structures, usually as pure compounds, although, because it is such a high-resolution technique, it is possible to characterise individual components in chemical and biological mixtures. Of course, it is increasingly difficult to identify minor components (e.g. less than 5 mol%) in mixtures, in which case concentration by solid-phase extraction may improve detection. It is also possible to couple high performance liquid chromatography (HPLC) directly to NMR spectrometers (see below). Nevertheless, it is possible to quantify lower levels of impurities given a clearly resolved NMR resonance for the impurity. Each of the two natural-abundance ^{13}C satellite signals of the main component (ca. 0.55 mol%) can provide a useful quantification standard, if resolved. Thus, impurity detection limits depend on the resolution of a suitable NMR resonance, but a detection level of 0.1 mol% is not unreasonable.

Almost all spectrometers used for chemical structural studies are now based on a superconducting magnet with an operating frequency for ^{1}H observation that ranges from 300 MHz to 1000 MHz. Both resolution and detection are improved with increased magnetic field strength. For routine chemical studies in which compound availability is not limited,

300 MHz and 400 MHz observation is quite usual, but 500 MHz and 600 MHz systems are now common (in 2010). Higher observation frequencies are available (700, 750, 800, 900, 950 and 1000 MHz) and are used for specialised research studies, mainly in the field of protein-structure investigation and for complex biological mixtures such as biofluids. Historically, and still generally, a sample for high-resolution NMR spectroscopy is placed in an expensive, precision-machined, 5 mm glass tube sealed with a plastic cap, which is inserted into the detector (known as the probe) of an NMR spectrometer. Other tube diameters are also used, including 10 mm for larger samples and 3 mm when sample quantity is limited. More recently, robotic systems for injecting samples directly into a flow probe using about 500 μL from individual sample vials or 96-well plates have been developed. A wide range of capillary flow probes is also available from the main manufacturers and from accessory suppliers that allow sample volumes typically down to 10 μL, and, if the sample can be concentrated down to small volumes, this represents a way of producing the best sensitivity and hence lowest detection limits.

The development of cryogenic probes with the detector coil and preamplifier (but not the samples) cooled to around 20 K has provided a marked improvement in spectral signal-to-noise ratio (SNR) by reducing the thermal noise in the electronics of the spectrometer. An improvement of up to 500% can be obtained for samples in organic solvents, but, for strongly ionic solutions such as biofluids, the improvement is less dramatic. Conversely, because the NMR SNR is proportional to the square root of the number of co-added scans, data acquisition times shorter by up to a factor of 25 become possible for the same amount of sample, broadening the feasibility of chemical kinetics studies.

Tissue studies use a technique called high-resolution ^{1}H MAS NMR spectroscopy, employing small (∼10–20 mg) pieces of intact tissues with no pre-treatment. Rapid spinning of the sample (typically at ∼4–6 kHz) at an angle of 54.7° relative to the applied magnetic field serves to reduce the loss of information caused by line broadening effects seen in non-liquid samples such as tissues (caused by sample heterogeneity, and residual anisotropic NMR parameters that are normally averaged out in free solution where molecules can tumble isotropically and rapidly). MAS NMR spectroscopy has straightforward, but manual, sample preparation. NMR spectroscopy on a tissue sample in an MAS experiment is the same as solution-state NMR and all common pulse techniques can be employed in order to study metabolic changes and to perform molecular structure elucidation and molecular dynamics studies.

Sample preparation

As spectrometers have become more sensitive, it is now possible to provide high-quality ^{1}H NMR spectra for small organic molecules on less than 1 mg of sample using widely available 400 MHz instruments. For organic chemical samples, a dilute solution in a fully deuterated solvent is usually used. Typical solvents are chloroform-*d* and dimethylsulfoxide-d_6, but occasionally more expensive alternatives have to be used, such as dimethylformamide-d_7, cyclohexane-d_{12} or acetone-d_6. A small amount of the volatile TMS is added as a chemical-shift reference. It is also possible to use D_2O as a solvent for water-soluble materials, in which case TSP is usually used for a chemical-shift reference. For biological samples, such as biofluids, which largely comprise H_2O, it is possible to freeze-dry these and reconstitute them into D_2O, but this risks the loss of volatile components. Alternatively, it is possible simply to add a small amount of D_2O and suppress the huge water NMR resonance by using one of a number of solvent-suppression NMR pulse sequences. These either suppress the water signal selectively or have the effect of exciting the whole of the NMR spectrum except for the water peak. The deuterated solvent, or the added D_2O, provides a ^{2}H NMR signal for the spectrometer to use as a field-frequency lock signal, so that all scans are co-registered exactly.

Acquisition of NMR data

The radiofrequency circuits of the spectrometer are tuned and matched to the sample so that the reflected power is minimised and then the magnetic field homogeneity is optimised by adjusting currents in small ancillary coils around the sample, either manually or under computer control. This process is known as 'shimming' and yields the best peak heights and hence the sharpest NMR peaks. The historical method of acquiring an NMR spectrum by slowly sweeping either the magnetic field or the radiofrequency (the continuous wave or CW method) is now obsolete and all spectra are obtained using the pulse-Fourier transform (FT) approach. In this method, all nuclei are excited simultaneously using a short, powerful radiofrequency pulse that covers all frequencies of interest. A typical pulse width is ∼10 μs and, if it has sufficient power to equalise the populations of the two spin states, it is termed a 90° pulse. As the nuclei relax back to equilibrium, an oscillating, decaying voltage known as a free-induction decay (FID) is induced in the receiver coil. This signal is converted into a digital form using an analogue-to-digital converter (ADC) and stored in computer memory as many thousands of data points. The total data-acquisition time for a single scan is typically in the range 0.1–4 s.

Data processing

This amplitude-against-time signal is treated as a series of decaying cosine waves and is converted into an amplitude-against-frequency spectrum by the mathematical process of Fourier transformation. Multiple scans are usually co-added to improve the SNR, since this is proportional to the square root of the number of scans. The resultant FID is usually multiplied by some function to improve SNR or reduce the spectral line widths, and hence increase resolution. For example, it is possible to enhance SNR by multiplying the FID by a negative exponential, $\exp(-At)$, where t is the acquisition time and A is a positive constant, but this also has the effect of increasing line widths. Alternatively, it is possible to enhance resolution by multiplying by a positive exponential, $\exp(+At)$, but this has a large deleterious impact on SNR. In addition, if the acquisition time is too short, the FID is truncated before it has decayed into the noise, and artefacts are seen as oscillations on each side of the NMR peaks. A good compromise to overcome truncation artefacts and to improve resolution without too large a compromise on SNR is to carry out a Lorentzian–Gaussian transformation. This is achieved by multiplying by a positive exponential and a negative exponential squared, $\exp(+At - Bt^2)$. The value of A is chosen to match the experimental line width and B is selected to give a Gaussian line shape of the desired reduced width and acceptable SNR. Since the delays in the electronics are frequency dependent, not all peaks will appear phased (upright). This has to be corrected either manually or automatically.

System tests

A number of standard system tests are used to define the performance of NMR spectrometers to meet the specifications guaranteed by the manufacturers.

A good line shape is an important requirement of modern NMR spectroscopy. The line-shape test is often called the 'hump' test and comprises an examination of the ^{1}H NMR peak from 1% chloroform in acetone-d_6, degassed and sealed. In addition to an acceptable value for the peak width at half height (50%), a good line shape is also defined by the width at the height of the ^{13}C satellites (0.55%) and at one-fifth of this height (0.11%). NMR peaks should have a Lorentzian line shape and therefore the widths at 0.55% height and 0.11% height should be 13.5 and 30 times the width at 50% height; deviations from these values should be avoided and typical values for a 500 MHz spectrometer might be 3.5 Hz and 8.5 Hz. The spectrum is measured in both spinning and non-spinning conditions. The standard resolution test for ^{1}H NMR spectroscopy now usually uses the same sample, giving a typical value of about 0.3 Hz full width at half height.

The sensitivity test for ^{1}H NMR spectroscopy is based on a degassed and sealed sample of 0.1% ethylbenzene in $CDCl_3$. A single 90° pulse is used with a spectral width of 10 ppm and a 1 Hz line-broadening function is applied to the FID. The region of the spectrum between δ4 and δ6 is expanded vertically, typically by a factor of 16, to show the full

extent of the noise band, and this is compared with the height of the peak from the methylene group. The SNR is defined as the peak height multiplied by 2.5 divided by the peak-to-peak noise value in that specified region. A typical value for a 500 MHz spectrometer could be about 700 : 1, while for a cryoprobe on an 800 MHz spectrometer the value could be in the region of 6000 : 1.

There are two main tests of ^{13}C NMR performance. The American Society for Testing and Materials (ASTM) approach uses a solution of 60% benzene-d_6 in 1,4-dioxane, degassed and sealed, and tests only the ^{13}C performance. The other test uses a solution of 10% ethylbenzene in $CDCl_3$, degassed and sealed, and tests both the ^{13}C sensitivity and the ^1H decoupling efficiency since ^{13}C NMR spectra are usually acquired with all $J(^{13}C–^1H)$ splittings removed by secondary irradiation at the ^1H frequency. For the ASTM test, a single 90° pulse is applied to the sample with the ^1H decoupler switched off. The FID is zero-filled to 65 536 (64k) points, weighted by a line-broadening function of 3.5 Hz, and the full spectrum is plotted. The region between δ_C80 and δ_C120 is expanded vertically by a factor of 4 to allow good visualisation of the noise band, and this height is compared with that from the triplet signal from the C_6D_6. A typical value for a 500 MHz spectrometer might be 120 : 1. When using the ethylbenzene test sample, a single 90° pulse is applied to the sample, the FID is zero-filled to 65 536 (64k) points, a line broadening of 0.3 Hz is applied and the full spectrum is plotted. The noise height is taken, as before, from the region between δ_C80 and δ_C120 and compared with the peak height of the aromatic CH ^{13}C NMR signals, with a typical value of ~80 : 1 for a 500 MHz spectrometer. A similar test is used for ^{31}P NMR sensitivity and comprises 0.0485 mol/L triphenylphosphate in acetone-d_6. Another test covers water peak suppression efficiency in aqueous samples, and this uses 2 mmol/L sucrose in 10% D_2O–90% H_2O.

Two-dimensional NMR spectroscopy

One-dimensional NMR spectroscopy gives rise to one frequency axis and this is achieved by Fourier transformation of an FID obtained as the response after a radiofrequency pulse or pulse sequence. By incorporating a second incremented time period into an NMR pulse sequence, it is possible to carry out Fourier transformation with respect to both time periods to give two frequency axes that result in two-dimensional NMR spectra. This spreads out the NMR spectrum in a variety of ways, and so makes interpretation simpler. Extension to the use of three or more time periods leads to the concept of three (or more)-dimensional FT-NMR spectroscopy.

All two-dimensional NMR experiments can be considered to have a preparation period, which might simply be a relaxation delay or could be some way of preparing the spin system for further manipulation. Next, the evolution period contains the first variable time period, t_1, which is incremented in equal time steps. Then it is possible to include a mixing period to allow the various spins to interact in some non-equilibrium condition. However, not all pulse sequences use this period. This is followed by the detection of the FID during the second time period, t_2.

To see how this works in practice, it is possible to consider one of the simplest two-dimensional pulse sequences. This is correlation spectroscopy (or COSY), which uses two, typically 90°, radiofrequency pulses with an incrementable time delay between them. The time-domain data comprise a series of FIDs for a range of inter-pulse delays. After the first Fourier transformation with respect to t_2, the data consist of an array of spectra on a frequency axis, each of which corresponds to a given inter-pulse delay, but with the phase of the peaks modulated as a result of the various values of t_1. After a second Fourier transformation with respect to t_1, the data array comprises NMR intensity as a function of two frequency axes and is shown as a three-dimensional plot. This is quite difficult to interpret, especially if it is complicated by many signals. The data are visualised more easily as a contour plot 'looking down' on the peaks. In the COSY spectrum the peaks of the normal spectrum appear along the diagonal and the presence of off-diagonal cross-peaks indicates two nuclei that have a common indirect spin–spin (J) coupling. Hence, this experiment correlates nuclei that are spin-coupled together and are thus close together in bond terms. The frequency axes are labelled F1 and F2, deriving from t_1 and t_2, respectively.

There are many two-dimensional NMR pulse sequences in the literature, most of which are for very specialised applications but a few very useful experiments are used widely for molecular structural studies (Croasmun, Carlson 1994). Two-dimensional NMR experiments can be classified into two types – resolved and correlation. The former resolve a particular type of NMR parameter into the second dimension. For high-resolution solution-state studies, this type is restricted largely to the J-resolved experiment (JRES), which separates the chemical shifts and spin-coupling multiplets into the two dimensions. This can be carried out in a homonuclear mode for ^1H chemical shifts resolved from $^1H–^1H$ couplings and in a heteronuclear mode in which, usually, ^{13}C chemical shifts are resolved from $^1H–^{13}C$ couplings.

Most two-dimensional NMR experiments are of the correlation type, which includes the COSY experiment that provides a correlation between ^1H chemical shifts that have a direct J coupling. The total correlation spectroscopy (TOCSY) pulse sequence provides a correlation as off-diagonal peaks, also based on the J coupling, but now along an unbroken chain of couplings. The nuclear Overhauser enhancement spectroscopy (NOESY) experiment provides a correlation between ^1H chemical shifts connected by an NOE. This experiment can also be used to investigate spin systems of molecules undergoing chemical exchange.

It is possible to obtain heteronuclear correlation two-dimensional NMR experiments, usually the correlation of ^{13}C and ^1H chemical shifts, although the use of other nuclei such as ^{15}N or ^{31}P is possible. Direct detection of the heteronucleus is possible and historically was the main approach. However, this is usually a low-sensitivity experiment because of the lower inherent sensitivity, or natural abundance, or both, of most heteronuclei compared with ^1H. To overcome this problem, experiments have been devised that use indirect detection of the heteronuclei attached to the protons (see ^{13}C NMR spectroscopy below).

A summary of the principal, useful, two-dimensional, NMR pulse sequences is given in Table 36.4. This also lists the typical length of time required for data acquisition and the quantity of material required for each experiment.

^{13}C NMR spectroscopy

Much molecular structural information is available by measuring the ^{13}C NMR spectrum of organic molecules at natural abundance. As this nucleus is less abundant and inherently less sensitive than ^1H, larger amounts of sample are needed (typically 10 mg for a material of molecular weight 250 at a ^{13}C observation frequency of 125 MHz, which corresponds to 400 MHz for ^1H measurement) and usually more FIDs need to be accumulated to build up the SNR. However, some factors alleviate these difficulties. These include the broadband decoupling of all $^1H–^{13}C$ coupling patterns using special pulse sequences, so that each carbon signal is a singlet. This also has the effect of boosting the SNR through the NOE from the ^1H spins, this being most effective for CH, CH_2 and CH_3 carbons. One disadvantage of ^{13}C NMR spectroscopy is that some carbons, particularly quaternary carbons (which have at best only weak NOEs), also have long relaxation times and are saturated easily and thus give weak peaks. For these reasons, quantitative studies based on ^{13}C resonances are more prone to error than those based on ^1H resonances. The undesirably long ^{13}C relaxation times can be shortened by the addition of a paramagnetic agent, such as the acetylacetonate complex of chromium, $Cr(acac)_3$. The identification of the carbon resonances as C, CH, CH_2 or CH_3 can be achieved through off-resonance decoupling of the protons, which leaves a residual characteristic coupling pattern of singlet, doublet, triplet and quartet, respectively (see Table 36.3). Alternatively, a number of NMR pulse sequences, such as the attached proton test (APT) or the distortionless enhancement by polarisation transfer (DEPT) approach, can be applied to give the same information.

Directly observed ^{13}C NMR spectra have now been surpassed largely by a technique that involves indirect ^{13}C detection through ^1H NMR spectroscopy. This has come about through the advent of inverse-geometry NMR probes and the development of NMR pulse sequences that

Table 36.4 Two-dimensional NMR experiments useful for small molecules

allow transfer of magnetisation between ^{13}C and ^{1}H. In an inverse experiment, usually conducted in the two-dimensional mode: ^{1}H magnetisation is generated and then transferred to ^{13}C; the ^{1}H and ^{13}C spins are allowed to interact for a variable time based upon the one-bond ^{1}H–^{13}C coupling constant of about 125–160 Hz; and then the magnetisation is transferred back to ^{1}H for detection. The resultant two-dimensional NMR spectrum has ^{1}H chemical shifts on the detection axis (F2), ^{13}C chemical shifts on the indirect axis (F1), and a peak at the intersection of the ^{1}H and ^{13}C chemical shifts for CH, CH_2 and CH_3 groups. In addition, all ^{1}H NMR signals from hydrogens bonded to^{12}C also have to be suppressed by the pulse sequence. A number of pulse sequences achieve this correlation, the two best known being heteronuclear multiple quantum coherence (HMQC) and heteronuclear single quantum coherence (HSQC). Quaternary carbons do not appear in such a spectrum and have to be detected in a separate experiment based on a longer-range ^{1}H–^{13}C spin coupling, usually that over three bonds with a typical value of 6–10 Hz. For long-range coupling correlation, the experiment usually used is heteronuclear multiple bond correlation (HMBC). Full details of these methods are given by Croasmun and Carlson (1994), in particular, and in the books listed in Further reading. Such inverse-detected correlations have rendered obsolete the conventional ^{13}C-detected two-dimensional methods such as HETCOR.

The ^{13}C isotope has a natural abundance of only around 1.1%, so ^{13}C–^{13}C correlation spectroscopy has to rely on the observation of only 0.01% of the sample, and at the same time suppress the ^{13}C resonances of all singly labelled molecules that are 100 times larger. However, such a method does exist, given the rather ridiculous acronym INADEQUATE, and provides a correlation between carbons separated by one bond, the ^{13}C–^{13}C coupling constant in this case being around 40 Hz. Typical sample requirements for two-dimensional NMR studies that involve ^{13}C are given in Table 36.4.

Quantitative analysis

Quantification is possible using NMR spectroscopy (Holzgrabe *et al.* 2005). In this case, it is necessary to ensure that, for the summation of successive scans, the spin system is fully relaxed at the start of each scan. This is achieved by waiting between scans five times the longest T_1 for the signals of interest. This ensures that 99.3% of the signal is recovered. This is reasonable for ^{1}H NMR spectroscopy, in which T_1 values are usually less than 4–5 s, but for ^{13}C NMR spectroscopy (see above) T_1 can be much longer. As shown for ^{13}C NMR spectroscopy, the peak areas are, in general, not related quantitatively to concentration, and steps have to be taken to overcome this. This can be achieved by adding a relaxation agent and/or by modifying the pulse sequence to remove the NOE, which can affect signal intensity.

Quantification is done by measuring peak areas in the usual fashion, either by adding a known amount of a pure internal standard or by the method of standard addition. For a peak from an analyte with relative molecular mass M_{rA}, arising from N_A equivalent nuclei having an area I_A, and for a corresponding peak from an internal standard with relative molecular mass M_{rS}, from N_S nuclei with area I_S, the mass of the analyte in the sample is given by:

$$\frac{m_A}{m_S} = \frac{I_A M_{rA} N_S}{I_S M_{rS} N_A}$$

where m_S is the mass of the standard in the sample. Peak areas can be measured by integration, i.e. by summing the intensity of data points over a defined region of a peak or by curve fitting to the peak shape.

The two enantiomers of a chiral compound give identical NMR spectra in a non-chiral solvent because the magnetic environments of the nuclei are identical in both isomers. However, addition of a chiral paramagnetic shift reagent or use of a chiral solvent allows resolution of the NMR spectra of the two forms and hence integration of peak areas and measurement of the enantiomer proportions. Several applications of quantitative NMR spectroscopy to substances in international pharmacopoeias are given later.

An example of molecular structure determination: ibuprofen

The various types of NMR spectra often used to confirm a molecular structure are illustrated by the example of the non-steroidal anti-inflammatory drug ibuprofen dissolved in dimethyl sulfoxide-d_6 (DMSO-d_6). Figure 36.1 shows the 600 MHz ^{1}H NMR spectrum of this substance; the molecular structure and numbering system are also shown, along with the assignments of the various NMR signals.

Thus, the two doublets at δ0.85 and δ1.33 arise from the methyl groups with typical chemical shifts, that from CH_3(12,13) being of double intensity, with both showing spin coupling to a single proton. The resonance at δ1.80 comprises nine lines in a binomial intensity pattern because it arises from CH(11), which is coupled to eight adjacent hydrogens. The 1 : 3:3 : 1 quartet at δ3.61 is from CH(7). The doublet at δ2.40 is the resonance from CH_2(10) and arises from coupling to CH(11) exclusively. The small multiplet at δ2.49 is from the residual DMSO-d_5 in the DMSO-d_6 solvent and comprises a 1 : 2:3 : 2:1 quintet because the residual CHD_2 proton is coupled to two deuterium nuclei that have a spin quantum number of unity, each giving rise to a 1 : 1:1 splitting, and the two splittings overlap to give the resultant multiplet. Finally, the aromatic protons give rise to the multiplets at δ7.09 and δ7.17. These are not simple doublets, as can be seen by the partially

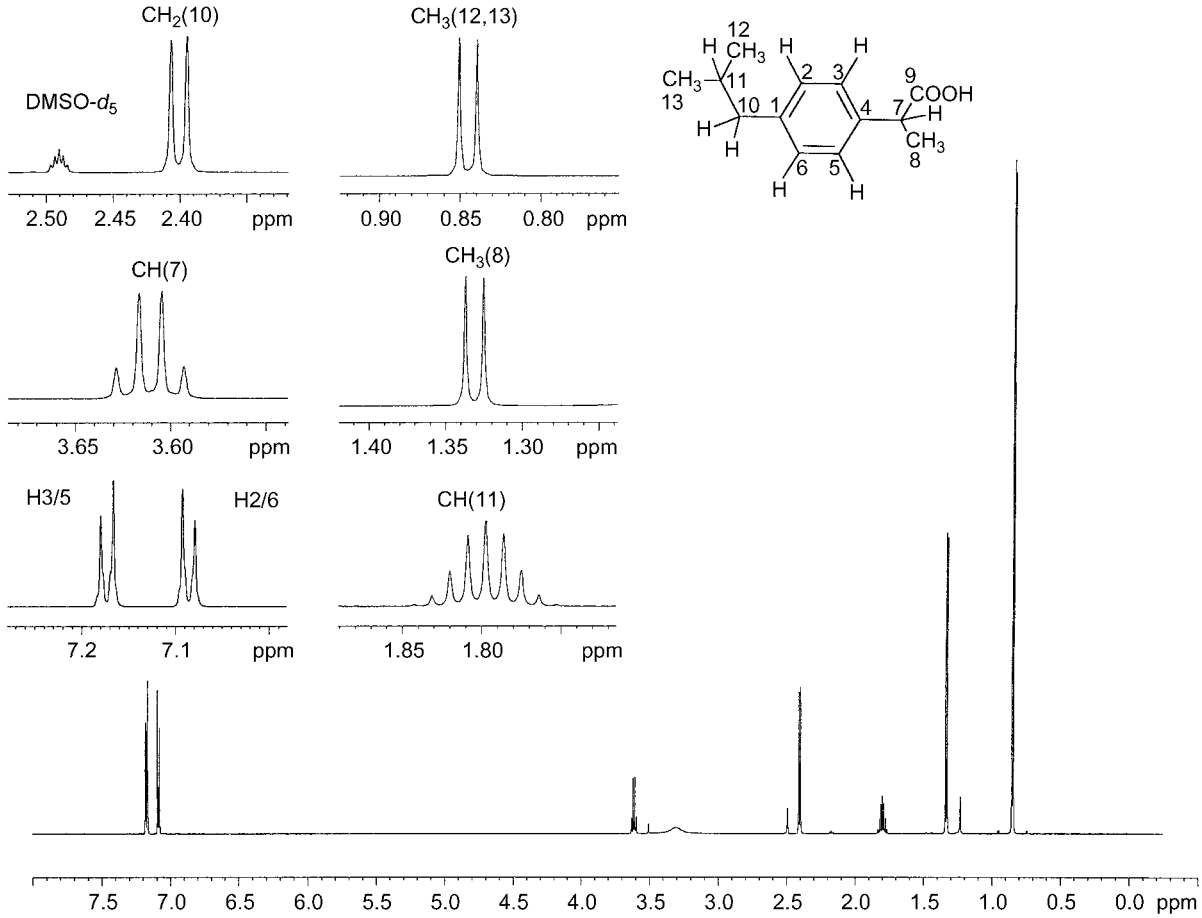

Figure 36.1 600 MHz ^{1}H NMR spectrum and molecular structure with numbering system of the non-steroidal anti-inflammatory drug ibuprofen dissolved in DMSO-d_6. Assignments are as marked. Expansions of the various resonances are shown.

resolved lines in the wings of the main peaks. These patterns arise as a consequence of the symmetry of the aromatic ring, with H2/H6 being chemically equivalent, but not magnetically equivalent (e.g. H2 will have a different spin coupling from H3 and H5). The broad peak near δ3.3 arises from the residual water in the sample and solvent.

The 600 MHz ^{1}H–^{1}H COSY spectrum of ibuprofen is shown in Fig. 36.2. Dotted lines are used to indicate the off-diagonal peaks that connect two chemical shifts arising from spin–spin-coupled protons. For example, the peak at δ0.85 from CH_3(12,13) is connected by an off-diagonal peak to the chemical shift at δ1.80 arising from CH(11), which in turn is connected to the peak at the chemical shift of δ2.40 corresponding to CH_2(10).

The 125 MHz ^{13}C NMR spectrum of ibuprofen in DMSO-d_6 is given in Fig. 36.3. Since all spin–spin couplings between protons and ^{13}C are removed by decoupling, each non-equivalent carbon gives a single resonance peak. The assignments of the peaks are also given on Fig. 36.3. Thus, the carboxyl carbon appears at 175.3 ppm and the two quaternary aromatic carbons are at 139.6 and 138.4 ppm; the assignments to C1 and C4, respectively, are based on a two-dimensional experiment, known as HMBC. This correlates ^{13}C and ^{1}H peaks via long-range spin–spin couplings (see ^{13}C NMR spectroscopy). Next come the other aromatic carbons, C2/6 at 129.0 ppm and C3/C5 at 127.0 ppm. These peaks are more intense because each arises from two equivalent carbons, and also, because of the decoupling of the ^{1}H–^{13}C spin–spin interactions, each carbon experiences an NOE that boosts the intensity of its NMR resonance. The resonances from CH(7) and CH_2(10) appear very close together, the assignments again being based on an HMBC spectrum. The 1 : 3:6 : 7:6 : 3:1 septet at 39.5 ppm arises from the carbons in the solvent DMSO-d_6 and the splitting is caused by ^{13}C–^{2}H spin–spin coupling, which is not affected by decoupling the ^{13}C–^{1}H interactions. The resonance for CH(11) is at 29.6 ppm and the methyl carbons appear at 22.1 ppm (CH_3(12,13)) and 18.4 ppm (CH_3(8)), one being twice as large as the other, as expected.

To illustrate the use of indirectly detected ^{1}H–^{13}C two-dimensional NMR spectroscopy, the ^{1}H–^{13}C HSQC spectrum of ibuprofen is shown in Fig. 36.4. This provides the connectivity between ^{13}C nuclei and directly attached ^{1}H nuclei. Hence, given the partial assignment of both the ^{1}H and ^{13}C NMR spectra based on inspection, it is often possible to complete the assignment of both spectra using this type of data. The two-dimensional contour plot shows a number of peaks, each of which occurs at the intersection of the ^{1}H and ^{13}C NMR chemical shifts of a given CH, CH_2 or CH_3 group. Quaternary carbons do not appear in this spectrum because they have no directly attached hydrogens to provide the one-bond ^{1}H–^{13}C spin–spin coupling used for the correlation. For ease of interpretation, the ^{1}H and ^{13}C one-dimensional NMR spectra, assigned earlier in Figs 36.1 and 36.3, are plotted along the appropriate axes.

Thus, in summary, all of the acquired NMR data are consistent with the known chemical structure of ibuprofen. To assign the proportions of the two enantiomers that may be present, it would be necessary to add a chiral chemical shift reagent, as described above. Even then, the absolute stereochemistry of the two forms could not be determined from such a spectrum, and recourse would need to be made to other techniques, such as circular dichroism.

Directly coupled HPLC-NMR-MS

The identification of components in complex mixtures has been rendered much more efficient by the ability to couple HPLC directly with NMR spectroscopy. The on-line coupling of HPLC with MS has already

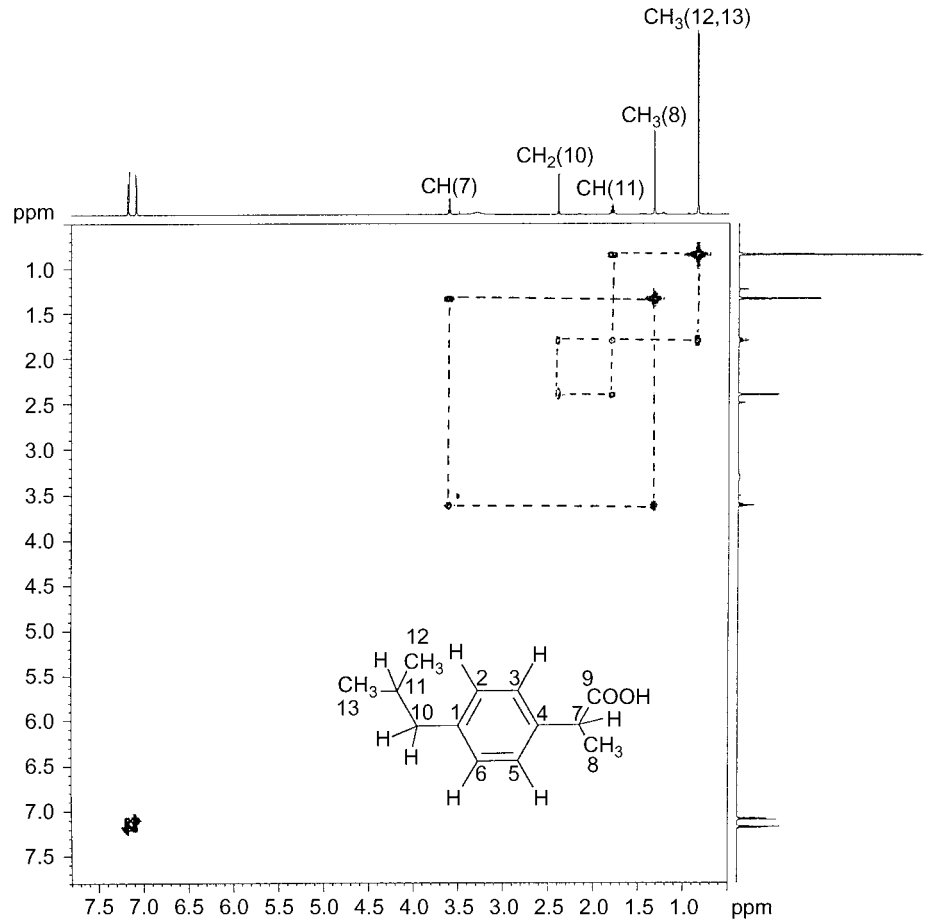

Figure 36.2 Two-dimensional 600 MHz ^{1}H–^{1}H COSY NMR spectrum and molecular structure of the non-steroidal anti-inflammatory drug ibuprofen dissolved in DMSO-d_6. The spin–spin coupling connectivities for the $CH_2(10)$–$CH(11)$–$CH_3(12,13)$ and $CH(7)$–$CH_3(8)$ spin systems are shown as dotted lines. Assignments are as marked.

proved to be of immense value, and the complementary structural capability of NMR spectroscopy has meant that complete molecular identification can now be very fast. Most applications to date have focused on the identification of drug metabolites in biofluids and similar matrices, but there are also applications in drug impurity analysis and drug degradation profiles (Lindon *et al.* 2000). The general scheme for HPLC–NMR–MS is shown in Fig. 36.5, which indicates that the typical configuration is to have the HPLC apparatus situated on the bench as normal. After the column and UV (possibly diode-array) detection the eluate is split, usually in the ratio 95 : 5, to the NMR and mass spectrometers, respectively. The length of the capillary lines to these spectrometers can be adjusted so that either the NMR spectrometer or MS detects the eluate first. For example, the MS could occur first to identify characteristic ions, such as those relating to the isotope patterns of chlorine or bromine. Alternatively, the NMR spectrometry could occur first, e.g. to pick up the presence of a ^{19}F NMR signal.

Currently, five main options can be employed for HPLC–NMR, using either isocratic or gradient elution. The simplest of these is continuous-flow detection, in which NMR spectra are collected in real time as chromatographic peaks elute, but this is only practical when using ^{1}H or ^{19}F NMR for detection, unless isotopically enriched compounds are available. Where continuous-flow NMR detection is used for gradient elution, the NMR resonance positions of the solvent peaks shift with the changing solvent composition and, for effective solvent suppression, these solvent resonance frequencies must be determined as the chromatographic run proceeds.

If there is a method for detecting retention time on-line (UV, MS or radioactivity), stop–flow HPLC–NMR can be carried out using all the usual techniques available for high-resolution NMR spectroscopy. In particular, these include two-dimensional NMR experiments. In practice, it is possible to acquire NMR data on a number of peaks in a chromatogram using a series of stops during elution without on-column diffusion causing an unacceptable loss of chromatographic resolution.

There are two further categories of stop-flow experiment. First, in an increasingly popular approach, fractions eluted from the column can be stored in capillary loops for later off-line NMR study ('peak picking'). Second, the flow can be halted at short intervals during the passage of the eluting peak through the NMR flow cell ('time-slicing'), in a manner analogous to the use of a diode-array UV detector, to obtain spectra from various portions of the peak. This allows chromatographic peak purity to be estimated. Time slicing is most useful if the separation is poor, or if the compounds under study have weak or no UV chromophores, which makes it difficult to determine the retention times.

Fully automated analysis is now possible and, in this mode, automatic detection of UV peaks in the chromatogram based on predetermined time-windows or peak intensities is allowed under software control. The successful detection of each UV peak triggers the system to stop the flow at an appropriate time to isolate the peak in the NMR flow probe. This automatic NMR operation includes field homogeneity optimisation, setting and optimisation of all NMR acquisition parameters, and the pre-definition of the resultant SNR required in the spectrum. Two-dimensional NMR spectra can also be measured. With

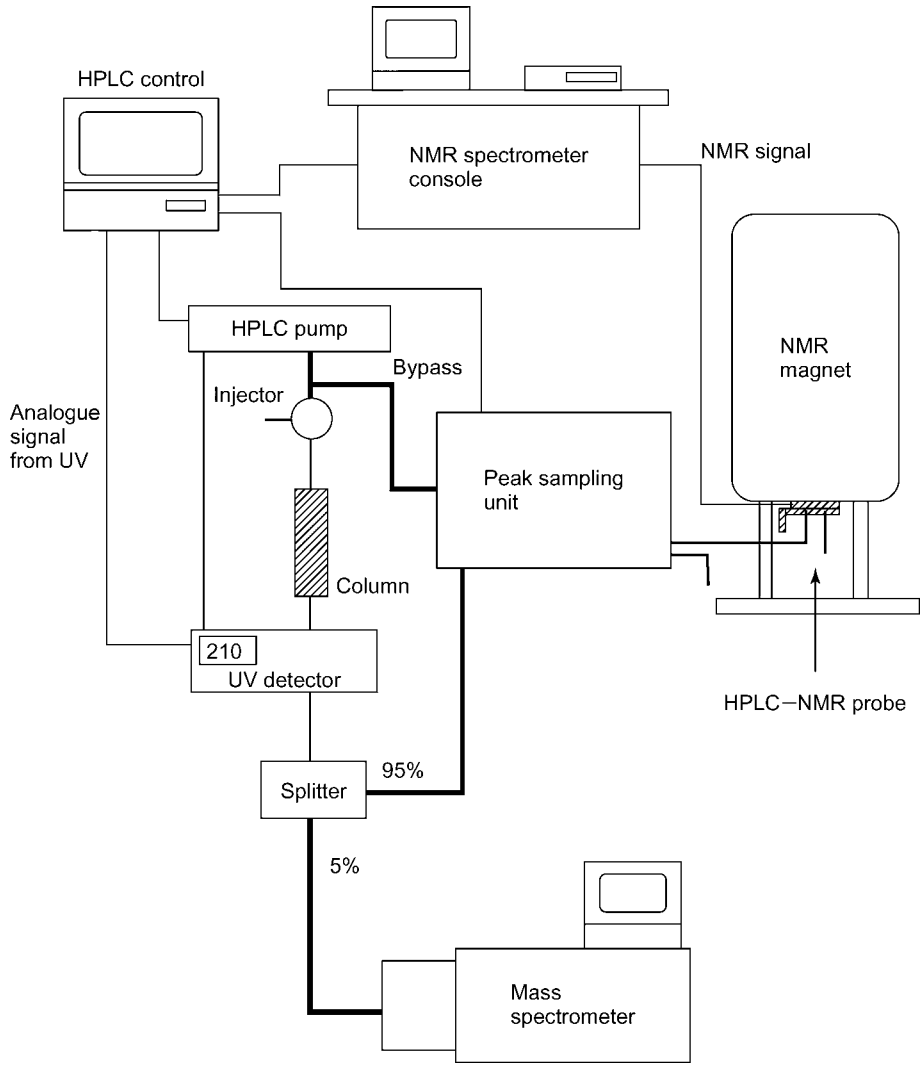

Figure 36.5 The experimental arrangement for directly coupled HPLC–NMR–MS. The bold lines indicate sample flow and the thinner lines are the electronic control and data signals.

currently available commercial software, the automated run can be halted at any time with reversion to manual control if desired.

Usually, for reversed-phase HPLC separations, a gradient eluent system of acetonitrile–water is used. To reduce the solvent suppression demands, the aqueous phase is made up of D_2O, but to save on cost any organic solvents are used in their conventional protio forms. In some cases, it is preferable to use deuterated acetonitrile, for example, as this aids the detection of NMR peaks near the methyl peak of the solvent. The increase in cost is outweighed easily by the time saving in carrying out the study and the improvement in the chance of success. Apart from this, it is not usually necessary to make any compromises in a desired chromatographic procedure to accommodate the various types of HPLC–NMR experiment. The powerful structural elucidation capabilities of NMR spectroscopy often ensure that complete chromatographic separation is not necessary for full characterisation of the peak.

In the case of HPLC–NMR–MS experiments, there are some additional considerations. So far, the principal MS ionisation method used has been electrospray in either positive- or negative-ion mode (using either single quadrupole or ion-trap mass spectrometers), which places further constraints on the chromatographic solvent systems. It is also possible to mix the eluent just prior to the mass spectrometer with a non-deuterated solvent to back exchange any deuterium atoms in exchangeable situations (e.g. NH and OH groups) for hydrogens. Comparison of the MS data with and without D_2O present enables the number of exchangeable hydrogens in any compound to be determined. In addition, MS can be used to search for particular diagnostic groups or fragments, such as an increase in m/z 16 for phase I hydroxylated drug metabolites or an increase of m/z 196 for a glucuronide.

The use of an ion-trap design allows fragmentation of the initial ions to be carried out in tandem experiments, such as MS–MS, MS–MS–MS, ... (denoted MS^n), etc. The use of time-of-flight or FT mass spectrometers provides very high resolution that allows good predictions of empirical molecular formulae from accurate ion masses, including those from MS^n experiments. Finally, some studies using inductively coupled plasma MS have been carried out. This technique provides no molecular information, as the sample is reduced to atomic form in the plasma, but it yields atom-specific chromatographic detection, which can be valuable for identifying the retention times of molecules of interest, such as those that contain heavy atoms or halogens such as chlorine and bromine.

By far the largest body of work to date using HPLC–NMR and HPLC–NMR–MS is in the field of drug metabolism, in which the methodology has been used extensively to identify metabolites in studies from clinical trials that involve human subjects, in the investigation of model drugs in animals *in vivo*, and also in *in vitro* systems such as liver microsome incubations.

Many marketed drugs are either natural products or modifications of such substances. Hence considerable effort has been spent in isolating and characterising chemicals from natural sources so that they can be tested in a variety of biological screens. Often it is necessary to carry out laborious extraction and purification steps, so the advent of directly coupled HPLC–NMR–MS has been explored as an alternative technique for natural product identification (Wolfender *et al*. 1998).

The use of NMR spectroscopy in the *British Pharmacopoeia*

NMR spectroscopy has been incorporated into a number of tests in the *British Pharmacopoeia* (BP) 2010, *European Pharmacopoeia* and *US Pharmacopoeia*.

These include assays for the peptide analogues buserelin and goserelin, in which the ^{1}H and ^{13}C NMR spectra, respectively, are compared with corresponding spectra of reference standards. Low-molecular-weight heparin samples can also be characterised by comparison with a reference sample using ^{1}H NMR spectroscopy. Medronic acid, used for radiopharmaceutical preparations, is assayed for two known impurities using the same method by comparison of an ^{1}H NMR spectrum of the material with those from reference impurity materials. In a similar fashion, an impurity in tetra-*O*-acetyl-mannose triflate is assayed using ^{19}F NMR spectroscopy.

The test for the degree in the quantification approach, the test for the degree of molar substitution (MS) in a modified cyclodextrin (hydroxypropylbetadex) is based on the relative integrals of the ^{1}H NMR peaks of the methyl groups (A1) (part of hydroxypropyl group modification) and the glycosidic protons (A2). MS = A1/(3 × A2) and the number of hydroxypropyl groups per molecule of β-cyclodextrin is 7 × MS.

Similarly, poloxamers are synthetic block copolymers of ethylene oxide and propylene oxide and thus contain oxyethylene (–O–CH_2–CH_2–O–) units and oxypropylene (–O–CH·CH_3–CH_2–O–) units. The characterisation of poloxamers includes the use of ^{1}H NMR spectroscopy to determine the ratio of the two types of subunit, based on integration of the ^{1}H NMR resonances at δ1.08 from the methyl group of the oxypropylene units and at δ3.2 from methylene groups from both types of subunit.

An assay for the positional distribution (β(2)-acyl) of different types of fatty acid in farmed salmon and cod liver oils has been developed based on a ^{1}H-decoupled ^{13}C NMR spectrum of a sample dissolved in $CDCl_3$. The main components are $C_{22:6}$, $C_{20:5}$ and $C_{18:4}$ fatty acids. By comparison with peaks from a reference sample, and by integration of the peaks in the region δC 171.5–173.5 from TMS (carbonyl carbons), it is possible to determine the overall proportions of α to β fatty acids.

Solid-state NMR spectroscopy of polymorphs

Polymorphism occurs widely in solid molecular systems, and polymorphs can differ in many of their properties, for example in the rate of dissolution and solubility of pharmaceuticals, and this can affect bioavailability. Similarly, the presence of solvates (also called pseudo-polymorphs), especially hydrates, can cause problems in pharmaceutical development. MAS NMR spectroscopy is now a useful technique for understanding the structure of polymorphs and solvates of pharmaceutical significance. The principal technique used is ^{13}C NMR spectroscopy, but other nuclei are also important, especially ^{19}F. Many drug-related studies are now in the literature since NMR spectroscopy can address problems involving amorphous systems, dynamics and non-stoichiometry that cannot readily be solved by diffraction techniques (Harris 2006). Solid-state NMR spectroscopy can provide quantitative information down to the level of ~1%.

NMR spectroscopy in metabonomics

Metabonomics encompasses the comprehensive and simultaneous profiling of metabolite levels in whole organisms through the study of biofluids and tissues. Metabolite levels undergo systematic and temporal changes, with factors such as diet, lifestyle, environment, genetic effects and pharmaceutical effects (both beneficial and adverse) having impact (Lindon *et al*. 2007). The principal analytical techniques used are NMR spectroscopy and mass spectrometry. Metabonomic studies generally use biofluids or cell or tissue extracts. Urine and plasma are obtained essentially non-invasively, and hence can be used more easily for disease diagnosis and in a clinical trials setting for monitoring drug therapy. However, a wide range of fluids have been studied, including seminal fluids, amniotic fluid, cerebrospinal fluid, synovial fluid, digestive fluids, blister and cyst fluids, lung aspirates and dialysis fluids. In addition, a number of metabonomic studies have used analysis of tissue biopsy samples and their lipid and aqueous extracts, as well as *in vitro* cell systems. Tissue studies use high-resolution ^{1}H MAS NMR spectroscopy.

In the post-genomic era, there is much emphasis on the study of the consequences of changes in gene expression (functional genomics), by examination of either the protein complement (proteomics) or the small-molecule metabolite composition of a biological system (metabonomics). There is a need to integrate information at the transcriptomic, proteomic and metabonomic levels to provide a full systems biology understanding, and this is at best only partially fulfilled.

In all cases the problem involves the detection and identification of low amounts of analytes in a very complex matrix with many potential interferences, all obscured by inter-subject biological variation. High-resolution ^{1}H NMR spectroscopy is particularly appropriate for investigating abnormal body fluid compositions, as a wide range of metabolites can be quantified simultaneously with no sample preparation and without preselection. However, high-resolution one-dimensional and multidimensional NMR spectra measured on biofluids can be extremely complex, and contain many thousands of resonances. In many cases, visual inspection of such spectra releases only a small percentage of the information available in the data. For this reason, the use of computer-based methods to extract the maximum information from such complex spectra is the general approach used. One recent development that has already proved popular is the use of correlation techniques to monitor peak changes across large cohorts of spectra. This has proved to be very useful for biomarker identification. Because it gives molecular fragment connectivity information somewhat analogous to the two-dimensional TOCSY experiment described earlier, it has been termed statistical TOCSY or STOCSY (Cloarec *et al*. 2005).

To illustrate the complexity of biofluid NMR spectra, Fig. 36.6 shows the 800 MHz ^{1}H NMR spectrum of a control human urine sample, with successive horizontal and vertical expansions. It has been shown that each biofluid has its own characteristic fingerprint.

A number of studies have used metabonomics to characterise normal metabolic variation in experimental animals such as mice and rats, caused by a range of inherent and external factors. Such differences may help explain differential toxicity of drugs between strains and inter-animal variation within a study. Many effects can be distinguished, including male/female differences, wild-type and genetically modified animal models, age-related changes, oestrus cycle effects in females, diet, diurnal effects, and interspecies differences and similarities. Analogous studies have also been undertaken in humans. The importance of the symbiotic relationship between mammals and their gut microfloral populations has been studied extensively.

The minimisation of the occurrence of drug adverse effects is one of the most important aims of pharmaceutical research and development, and metabonomic classification of the target organ or region of toxicity, the biochemical mechanism of that toxin, the identification of combination biomarkers of toxic effect and evaluation of the time-course of the effect, e.g. the onset, evolution and regression of toxicity, can all be determined.

Many examples exist in the literature on the use of NMR-based metabolic profiling to aid human disease diagnosis. A promising use of NMR spectroscopy of urine and plasma, as evidenced by the number of publications on the subject, is in the diagnosis of inborn errors of metabolism in children.

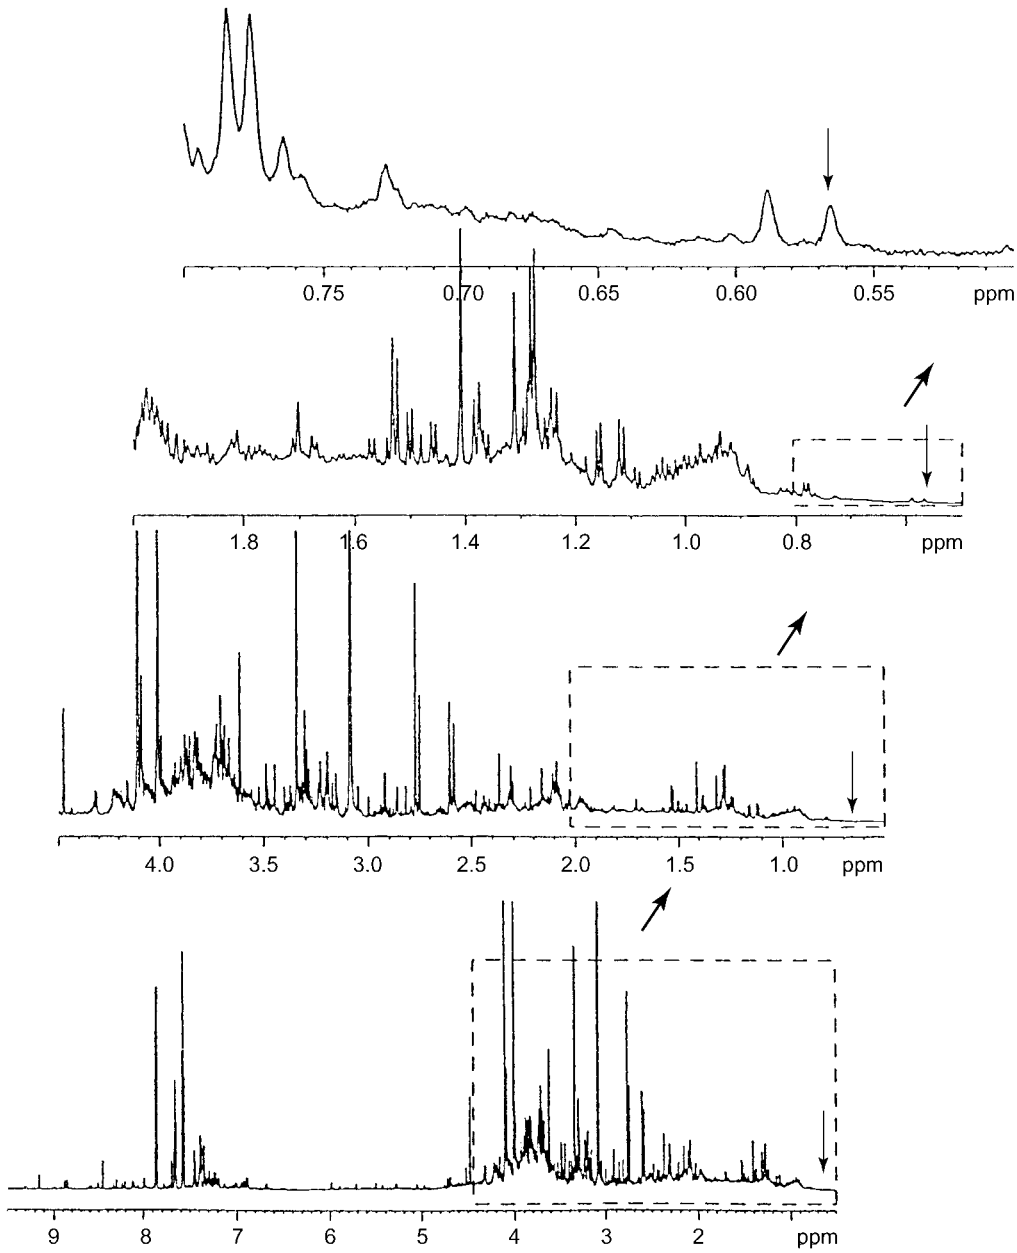

Figure 36.6 800 MHz ^{1}H NMR spectra of a typical control human urine sample showing successive horizontal and vertical expansions, and illustrating the complexity of the biochemical profile. The vertical arrow points to a very minor peak from the axial methyl group of a bile acid, a substance known to be elevated in certain types of hepatotoxicity. This demonstrates the ability of ^{1}H NMR spectroscopy of biofluids to detect very subtle changes in minor components.

An alternative approach to understanding inter-subject variability in response to drug treatment has been developed using a combination of multivariate metabolic profiling and chemometrics to predict the metabolism and toxicity of a dosed substance, based solely on the analysis and modeling of a pre-dose metabolic profile. This approach, termed pharmacometabonomics, is sensitive to both the genetic and environmental influences that determine the basal metabolic fingerprint of an individual, since these will also influence the outcome of a chemical intervention.

Integration of metabonomic data with that from other multivariate techniques in molecular biology, such as from gene array experiments or proteomics, is also feasible. It is now clear that characterising the relationships between genomic and phenotypic variation is an essential step in understanding disease processes and, to this end, the first real transcriptomic–metabonomic cross-correlations have been achieved.

Other areas where major expansion is expected are nutritional studies, sports medicine and lifestyle studies, including the effects of diet, exercise and stress, and evaluation of the effects of interactions between drugs, and between drugs and diet.

CHAPTER

37 Mass Spectrometry

D Watson

Introduction

A mass spectrometer works by generating charged molecules or molecular fragments either in a high vacuum or immediately before the sample enters the high-vacuum region. Instruments typically maintain vacuums of about 10^{-6} mmHg (1.33×10^{-4} Pa), since ionised molecules have to be generated in the gas phase to enable them to be manipulated using magnetic or electrostatic fields. In classic mass spectrometry (MS) only one method could produce the charged gaseous molecules, but now quite a number of alternatives are available. Once the molecules are charged and in the gas phase, they can be manipulated by the application of either electric or magnetic fields to enable the determination of their relative molecular mass and the relative molecular mass of any fragments produced by the molecules breaking up. A number of useful introductory texts that describe mass spectrometers and mass spectral interpretation are available (Dass 2007; de Hoffman, Stroobant 2007; Gross 2004; McLafferty, Turecek 1993; Smith, Busch 1999; Throck Watson, Sparkman 2007; Williams, Fleming 1995).

Theory

Magnetic sector mass spectrometers

A magnetic sector mass spectrometer is illustrated in Fig. 37.1. For MS that follows chromatographic separation, other methods of ion separation are generally preferred on the basis of the cost of separation in a magnetic field.

One method of introducing a sample into a mass spectrometer is to insert it on the end of a heated probe so that it is volatilised with assistance from the high vacuum in the instrument. Once the analyte molecules are in the vapour phase, the source provides energy to cause them to ionise. The original method for producing ionisation, which is still used for routine analyses, is to bombard the analyte with electrons produced by a rhenium or tungsten filament. The electrons produced by the filament are accelerated towards a positive target with an energy of, most commonly, 70 eV. The analyte vapour is introduced into the instrument between the filament and the target. Since the electrons used to promote ionisation are of much higher energy than the strength of the bonds within the analyte (which are of the order of 4–7 eV), extensive fragmentation of the analyte usually occurs. In magnetic sector mass spectrometers the ions are separated by application of an electrostatic field followed by a magnetic one, or the reverse in reverse-geometry instruments.

In a straight geometry magnetic sector mass spectrometer the ions generated in the source are pushed out of the source by a repeller potential, which has the same charge as the ions. These ions are then accelerated and focused into a beam using a series of electrostatic lenses, which can be tuned to give optimum sensitivity. As the ions leave the ion source they have a range of kinetic energies because they were formed at different points in the source. The kinetic energies of the ions are focused into a narrow range using an electrostatic field applied at right angles to their direction of travel. As a result they take a circular path through the electrostatic analyser. Only ions with a narrow range of velocities then pass through the slit into the magnetic analyser. The width of the slits in the instrument can be varied to control its resolving power. Having focused the ion beam, the ions are then separated in the magnetic analyser according to equation (37.1). By varying the magnetic field B, ions with a range of mass/charge (m/z) values can be collected and detected using either an electron-multiplier or photomultiplier. A typical sweep time for the magnetic field across a mass range of 50–800 atomic mass units (amu) would be 1 s, but faster speeds are required if high-resolution chromatography is being used.

$$\frac{m}{z} = \frac{B^2 r^2 2}{2V} \tag{37.1}$$

where B is the magnetic field strength, r is the radius of the path through the magnet and V is the accelerating velocity. It is also possible to vary the potential of the electrostatic field and keep B constant. In this case, the mass range is limited by the range of kinetic energies of the ions generated in the source and scans may be only over a mass range of 5–10% of the mass of the ion being measured. However, the electrostatic region is not subject to hysteresis in the same way as the magnetic field and better high-resolution measurements can result from varying the electrostatic field. Although magnetic sector instruments are still widely used to determine the elemental compositions of ions, they may be superseded eventually by time-of-flight (TOF) instruments.

Relative molecular masses and elemental composition

The nitrogen rule

Most relative molecular masses of analytes are even numbers, unless the molecule contains a nitrogen atom. Compounds that contain a single nitrogen atom have odd-number relative molecular masses; two nitrogen atoms in a structure produce an even relative molecular mass, three an odd relative molecular mass and so on. Other elements (e.g. boron) can produce odd-number relative molecular masses, but nitrogen is the most common within the structures of drug molecules.

Isotopes

Table 37.1 summarises the isotope abundances of some elements commonly found in drug molecules. Chlorine and bromine have abundant isotopes; the presence of ^{35}Cl and ^{37}Cl or ^{79}Br and ^{81}Br produces characteristic 3 : 1 or 1 : 1 molecular ion patterns, respectively. These isotope patterns are very distinctive and are particularly so if a molecule contains more than one chlorine or bromine atom. The ^{13}C isotope has quite a high abundance, 1.1% of the abundance of the ^{12}C isotope. For instance, androstenedione has a molecular ion at m/z 286 (Fig. 37.2) and, since the molecule contains 19 carbon atoms, it has an isotope peak at m/z 287 that is about 21% ($19 \times 1.1\%$) of the ion at m/z 286, which is the probability of the occurrence of one ^{13}C atom in its structure. By the same logic, there is an ion at m/z 288 that is about 4% of the m/z 286 ion and results from two ^{13}C atoms in androstenedione. Androstenedione also contains 26 hydrogen atoms, so its mass will be higher by about 0.2 amu from its nominal mass, based on hydrogen having an exact mass of 1.0078 (Table 37.2). These two effects have to be taken into account when dealing with molecules of very high relative molecular mass, such as proteins. The deviation of the mass of hydrogen from unity makes a significant difference to the exact mass of a protein, and the abundance of ^{13}C in protein molecules makes the isotope patterns of protein spectra complex. The ^{15}N isotope and the ^{34}S isotope also add to the complexity of the isotope pattern of protein spectra. Often, the average mass of a molecule is quoted; this is the average of the contribution of all the

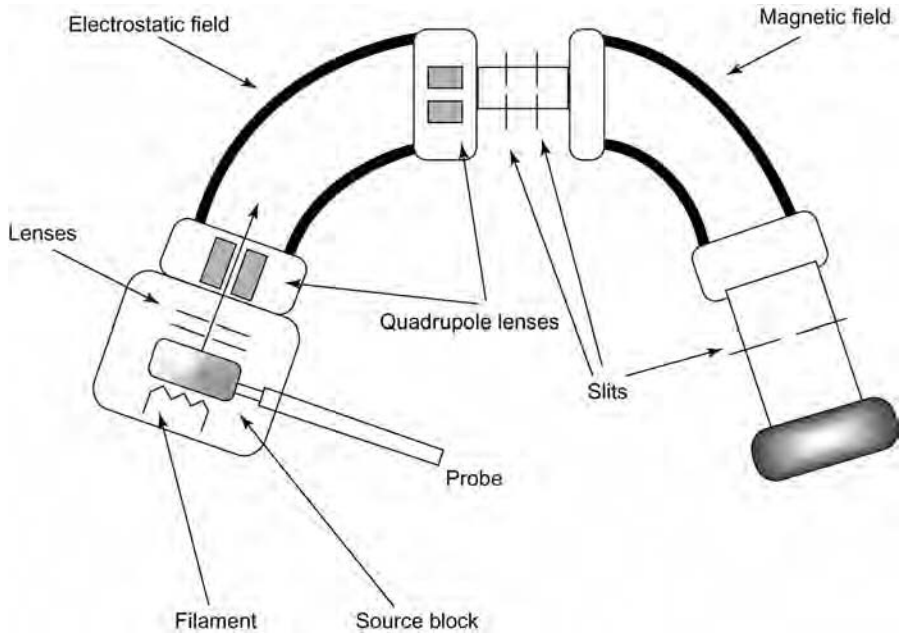

Figure 37.1 Schematic diagram of a double-focusing magnetic sector mass spectrometer.

isotopes towards its mass. Thus, HCl has an average mass of 36.5, since it contains 75% of ^{35}Cl and 25% of ^{37}Cl.

The relatively new technique of gas chromatography–combustion–isotope ratio MS (IRMS) to evaluate the content of ^{13}C or ^{15}N has potential for forensic toxicology, such as in the differentiation of endogenous and exogenous testosterone in sports drug testing. Figure 37.3

Table 37.1 Abundancee of isotopes commonly found in drug molecules

Isotope	*Relative atomic mass*	*Natural abundance (%)*
^{1}H	1.0078	99.985
^{2}H	2.014	0.015
^{12}C	12.000000	98.9
^{13}C	13.003	1.1
^{14}N	14.003	99.64
^{15}N	15.0001	0.36
^{16}O	15.995	99.8
^{17}O	16.999	0.04
^{18}O	17.999	0.2
^{19}F	18.998	100

^{14}N	14.0031
^{16}O	15.9949
CO	27.9949
CH_2 CH_2	28.0313
N_2	28.0061

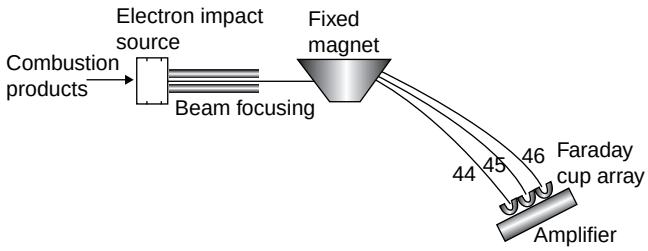

Figure 37.3 Schematic diagram of an isotope ratio mass spectrometer.

shows a schematic diagram of an isotope ratio mass spectrometer. The sample is burnt before being introduced into the mass spectrometer, generating gases such as CO_2, N_2, H_2O and SO_2 along with small amounts of these compounds incorporating stable isotopes – ^{15}N, ^{13}C, ^{2}H, ^{18}O and ^{34}S. The gaseous compounds are ionised by the electron impact mass spectrometry, and the ions are focused and then separated by a fixed magnet, i.e. without scanning. Thus ions are collected over a narrow range, e.g. CO_2 and its isotopomers. The ions are collected by an array of Faraday cups so that ion collection is continuous. Such a system produces high sensitivity and precision in the determination of isotopomers. The use of IRMS in forensic science has been reviewed by Benson *et al.* (2006) and applications include determination of geographical or synthetic origin or illegal narcotics, doping in sport, origin of explosives and flammable liquids.

Accurate mass measurement

Magnetic sector instruments can be used to determine the mass of a molecule to several decimal places. Based on the convention that carbon (^{12}C) has an exact mass of 12, the atoms of other elements do not have exact masses, as seen in Table 37.1. Thus, a high-resolution mass spectrometer would be able to distinguish CO, CH_2CH_2 and N_2, which all have a rounded mass of 28 amu The difference in mass between CH_2CH_2 and N_2 is 0.0252 amu, which relative to a mass of 28 is 900 parts per million (ppm; 1 ppm relative to 28 = 0.000028). Most double-focusing magnetic sector instruments should be able to measure masses to 1 ppm accuracy. To carry out accurate mass measurements, the instrument usually has to be calibrated at the same time as the sample is being measured.

Figure 37.4 shows the mass spectrum of chloroquine phosphate obtained using fast atom bombardment (FAB) ionisation. FAB is a soft ionisation technique, so that the spectrum is quite simple and the molecular ion for chloroquine (+H) is seen at *m/z* 320 for the chlorine-35 isotope and *m/z* 322 for the chlorine-37 isotope. A feature of FAB is that matrix peaks are usually also present in the spectrum. Two clear peaks can be seen at *m/z* 277 and *m/z* 369; these result from the formation of cluster ions from the glycerol matrix in which the sample is dissolved. These two peaks, and other glycerol cluster ions, have a known elemental composition/exact mass ratio and can be used to calibrate the mass axis of the instrument with high precision, so that an elemental composition for the two molecular ions of chloroquine can be obtained. Other commonly used calibrants are volatile ones used in heated probe work (perfluorokerosene (PFK) and perfluorotributylamine (PFTBA)) and poly(ethylene glycol) and Ultramark (used in calibrating the masses of high-molecular-weight compounds).

Resolution

Resolution in MS is rather analogous to the separation of peaks in chromatography and is of similar importance when quantitative measurements are being made, since overlap can produce quantitative inaccuracies. Unit resolution implies that two masses are completely separated (0% peak/valley ratio). For example, if 100 is separated completely from 101, this is termed 100 resolution. Magnetic sector instruments can effect resolution of up to 20 000 at 50% peak/valley, i.e. they can resolve masses of 20 000 and 20 001, so there is a valley of

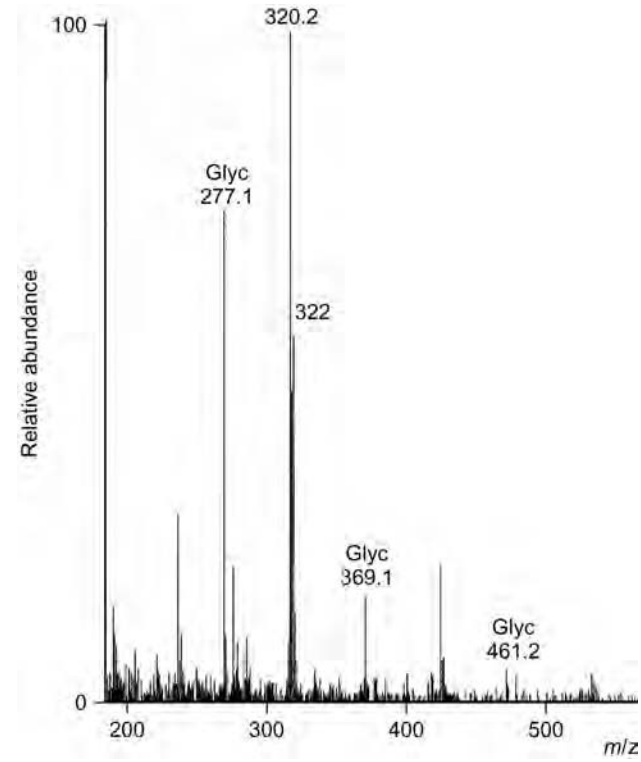

Figure 37.4 Fast-atom bombardment mass spectrum of chloroquine in a glycerol matrix.

50% of the peak height between them. However, greater resolution is achieved by narrowing the slits in the instrument, which means lower sensitivity because fewer ions pass through. Quadrupole instruments provide resolution of only about 500. Time-of-flight instruments are now beginning to approach the level of the resolving power of magnetic sector instruments. Fourier transform instruments afford the highest resolution with resolutions of up to 100 000.

Instrumentation

A prominent feature of MS is the range of instrumentation available, a range that is still rapidly expanding.

Magnetic sector instruments

The magnetic sector instrument is discussed above under Theory (and see Fig. 37.1).

Quadrupole instruments

Figure 37.5 illustrates a quadrupole mass spectrometer. For many years, quadrupoles were the only alternative to magnetic sector instruments. The principal features of quadrupole instruments are summarized below:

- Two varying electrostatic fields, one direct current (DC) and one at varying radiofrequency, are applied at right angles to each other via the four rods of the quadrupole. This creates a resonance frequency for each *m/z* value in a mass spectrum. The full mass range is scanned by varying the resonant frequency of the quadrupole.
- A simple quadrupole mass spectrometer gives only about 500 resolution and thus masses of ions separated by a quadrupole are only measured to one decimal place.
- Quadrupole instruments are of higher sensitivity than magnetic sector instruments, as they do not require all the ions that enter the quadrupole to have the same kinetic energy, and thus ion transmission is not reduced by slits.

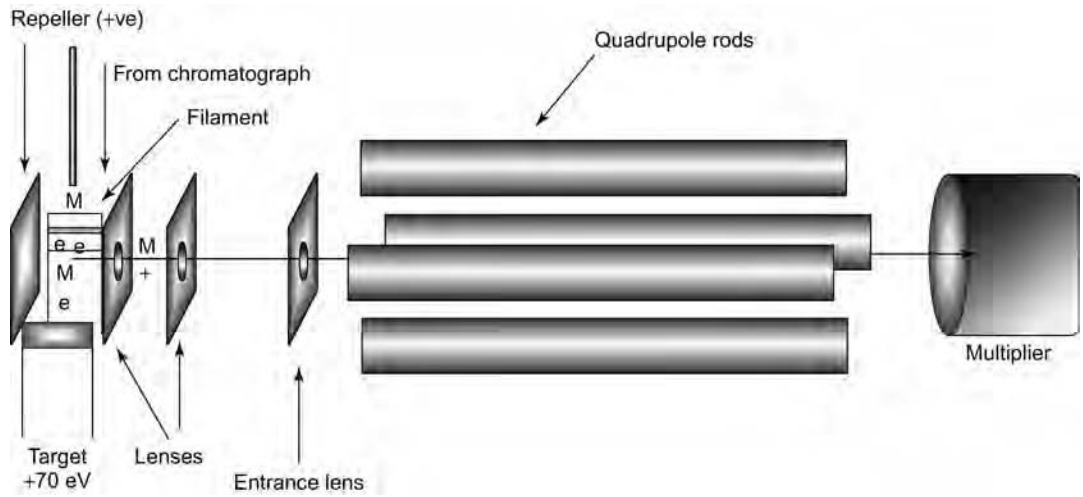

Figure 37.5 Schematic diagram of a quadrupole mass spectrometer.

- Since quadrupoles do not suffer from hysteresis, as magnetic sector instruments do, they are ideal for the rapid switching between ions required in selected-ion monitoring mode. In this mode a few significant ions in the mass spectrum of an analyte are monitored to achieve high sensitivity by ignoring background ions not derived from the analyte of interest.
- In a quadrupole instrument, larger-diameter rods produce increased sensitivity. Narrower or longer rods increase the resolving power.

Tandem mass spectrometry

The most common form of tandem MS started with three quadrupole mass spectrometers linked together. It a powerful mass spectrometric technique because it enables analytes to be separated rapidly by using a mass spectrometer rather than chromatography. It is particularly valuable in conjunction with electrospray ionisation, the most commonly used ionisation technique used in liquid chromatography-MS, since this soft ionisation technique produces few diagnostic fragments. In a triple quadrupole instrument, three quadrupoles are linked in series. Q1 (Fig. 37.6) separates the ions in a mass spectrum in the usual way. Then a selected ion (or ions) may be transferred to the second quadrupole Q2, which simply acts as an ion guide rather than producing separations, in which they are allowed to collide with atoms of a heavy gas, such as argon or nitrogen, to produce additional fragmentation. The fragmentation pattern produced is analysed using Q3. In Fig. 37.6 the MS spectrum of chlorpromazine is shown on the left and the spectrum resulting from the selection of the molecular ion at *m/z* 319 and its fragmentation in the second quadrupole is shown on the right. The fragmentation pattern obtained for chlorpromazine by tandem MS differs considerably from the spectrum of the drug obtained under electron impact conditions where the ion at *m/z* 58 dominates the spectrum.

The most common method for promoting fragmentation of an analyte is collision with an inert gas. High-energy collisions are promoted by acceleration of the ions prior to their entering the collision chamber; this is the approach used in ion-trap analyses. In this case, the gas used to promote fragmentation is usually helium and the fragmentation is fairly reproducible because the kinetic energy of the ions is controlled. Low-energy collisions rely on the inherent kinetic energy of the analyte ions and are less reproducible because the kinetic energy of the ions is variable. In this instance, either argon or nitrogen is used as collision gas and the fragmentation varies according to gas type, temperature and pressure. Photodissociation may also be used to promote ion fragmentation, the photoenergy being provided by a laser. This

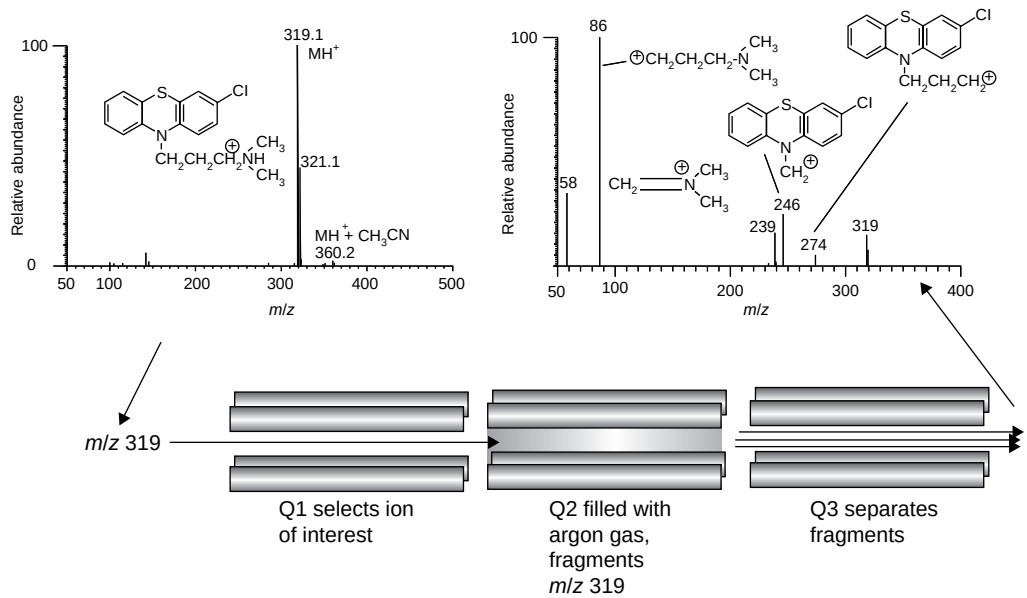

Figure 37.6 Illustration of the tandem MS process in the analysis of chlorpromazine.

technique gives very reproducible fragmentation and is particularly applicable to ion-trap analyses in which the ions can be trapped and irradiated.

Tandem mass spectrometry has become the standard method for the determination of drugs in biological fluids. The combination of high ion throughput obtainable with quadrupole ion separation and the high specificity available from selection of an ion of interest followed by quantitative analysis based on monitoring of a fragment or fragment ions of interest delivers the highest available level of sensitivity. It is important to note that monitoring of fragment ions produced by in-source fragmentation does not deliver the same level of sensitivity.

Ion-trap instruments

Ion traps (Ghosh 1995) have been developed in the past 20 years only and their performance has improved greatly in the past 5 years. The analyte is ionised using one of the available methods and the ions are transferred into the trap in which they are then confined by application of a radiofrequency voltage to the circular electrode (Fig. 37.7). The energy of the ions in the trap is quenched by helium, which is introduced into the trap to give a pressure of about 1 mmHg (133 Pa), so that they focus near the centre of the trap (i.e. their centrifugal energy is reduced). The ions can then be mass-selectively ejected by increasing a radio-frequency potential applied to the endcap electrodes (which also have a DC potential applied to them) to produce a mass spectrum as the ions are detected by the electron or photomultiplier tube. Since the ions in the trap are quenched by helium, there tends to be a greater degree of fragmentation in ion-trap spectra.

The power of the ion-trap technique resides in the amount of control that can be exerted on the ions in the trap. The ions can be confined within the trap and excited by changing the radiofrequency potential applied to the ring electrode so that their kinetic energy increases and they fragment more extensively through collision with the helium atoms in the trap. Selectivity can be introduced by ejecting all ions apart from, for instance, the molecular ion of the analyte of interest. The analyte is thus freed from any interfering peaks in the background and can be subjected to additional fragmentation by changing the radiofrequency potential of the trap. In theory, repeat fragmentation can be carried out several times on selected ions, making ion-trap mass spectrometry very useful where structure elucidation is required, such as in drug metabolism studies. Such mass spectrometric experiments are termed MS^n experiments, where n indicates the number of times that the mass spectrum has been produced. Figure 37.8 shows the MS^3 spectrum of chlorpromazine. In this case the ion at m/z 274 was selected from the initial MS^2 fragmentation and subjected to further fragmentation producing the ions at m/z 246 and 239. It can be seen that the signal-to-noise level is lower with the repeat fragmentation. Ion-trap instruments exhibit very good sensitivity in full scan mode and a wide dynamic range and can be used in quantitative work, although their ultimate sensitivity is at least an order of magnitude less than that of a top-of-the range tandem instrument.

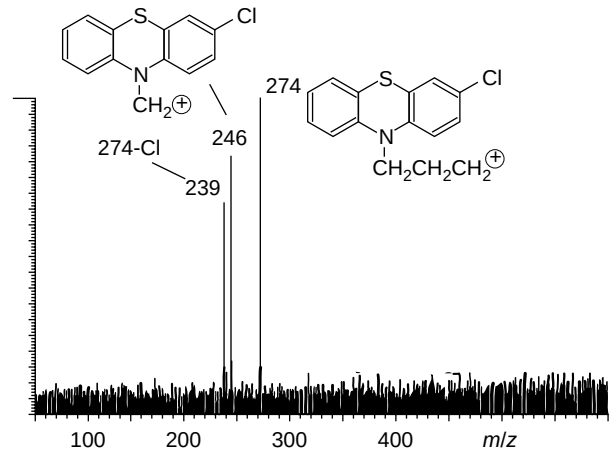

Figure 37.8 MS^3 spectrum for chlorpromazine obtained on an LCQ instrument at 30 V fragmentation energy for both stages.

Ion cyclotron resonance mass spectrometer

This instrument operates in a similar way to an ion trap. The ions are formed and then introduced into a trap and orbit within a circular magnetic field. As they circulate within the trap they pass close to two opposing electrode plates and thus induce a small alternating electric current within the circuit attached to the two plates. The amplitude of this current is proportional to the number of ions in the trap and its frequency is the same as the cyclotron frequency of the ions. The ions are

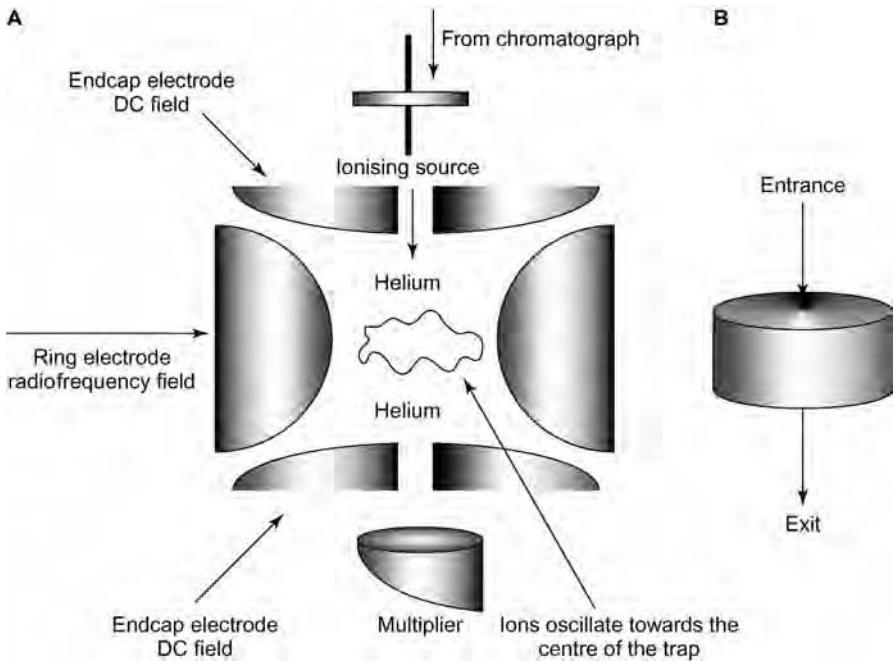

Figure 37.7 (A) Thermo Fisher LCQ ion-trap mass spectrometer. (B) View of the trap from outside.

thus detected without colliding with the detector via the current (the image current) that they induce. The ions in the trap can be excited by application of a radiofrequency pulse of radiation, which boosts the image current, which in turn falls off as the ions return to their unexcited state. The fall-off in the current can yield frequency information through the use of Fourier transformation, which leads to the construction of a mass spectrum. This process is analogous to Fourier-transform nuclear magnetic resonance spectroscopy, and can yield extremely high-resolution mass measurement, about ten times greater than the best performance of a magnetic sector instrument. The resolving power of this type of instrument is good enough to allow the accurate mass measurement of proteins. Recent developments in this field have resulted in the production of a new type of Fourier transform trap, the ThermoFinnegan Orbitrap. The design of the trap is a completely new concept but the data yielded from it are almost equivalent to that yielded by the older type of magnetic field-based FT-MS, giving accurate mass measurement to 5 decimal places and routinely mass accuracies to <2 ppm. This instrument has significant advantages over the older type of trap: it is considerably cheaper, the trap is electrostatic rather than magnetic and can be run with water cooling rather than expensive liquid helium cooling, and the instrument is more readily compatible with liquid chromatography.

Time-of-flight instruments

Time of flight (TOF) (Cotter 1997) was an early technique that produced ion separations. It is a very good technique for the analysis of compounds of high relative molecular mass such as proteins. The principle of TOF is quite simply that the larger an ion, the longer it will take for it to reach the detector of a mass spectrometer after acceleration through an electric field. For the technique to be effective, the time period during which the ions leave the ion source has to be well defined.

One ionisation process, matrix-assisted laser desorption ionisation (MALDI), uses short pulses of laser energy focused on the sample dissolved in a matrix that absorbs ultraviolet (UV) light. Alternatively, electrospray ionisation (ESI; see below) may be used in conjunction with a gating mechanism that allows ions to enter the separation field for only a very short period of time. The ions formed in the source have varying kinetic energies and, to avoid broad mass peaks, a device called a reflectron may be used to focus the kinetic energies of the ions that enter the TOF analyser. The greater the kinetic energy of an ion, the further it penetrates into the reflectron, and thus the faster ions are retarded by the reflectron, which allows the slower ions to catch up. Improvements in reflectron focusing, which include the use of double reflectron configuration and gating mechanisms, have enabled TOF to become capable of accurate mass measurement.

Hybrid quadrupole TOF (QTOF) instruments have become very popular for applications such as impurity profiling and drug metabolite identification and are a lower-cost alternative to FT-MS. In the QTOF type of instrument the third quadrupole in a tandem instrument is replaced with TOF separation. These types of instruments have tended to be used for qualitative work because of the limited quantitative dynamic range of TOF ($\sim 10^3$), although recent refinements in gating mechanisms have aimed to improve this.

MALDI-TOF has also advanced. MALDI-TOF^2 instruments have become available allowing tandem MS experiments to be conducted. Interfacing LC with MALDI is still not straightforward, however. MALDI-MS is increasingly used as an imaging technique in order, for example, to determine the distribution of a drug within a section of tissue.

Coupled techniques

Introduction

The most powerful mass spectrometric techniques involve the coupling of separation techniques with mass spectrometers. The development of ionisation techniques is linked intimately to the development of coupled techniques. Thus, in the majority of applications the ionisation technique has been developed and refined in conjunction with a separation technique. This is particularly true of the ionisation techniques used in conjunction with liquid chromatography (LC).

Gas chromatography–mass spectrometry

Gas chromatography–mass spectrometry (GC-MS; Kitson *et al.* 1996; Message 1984; Neissen 2001) was the earliest technique in which chromatography and MS were coupled. The original type of gas chromatograph had a packed GC column with a gas flow rate passing through it of about 20 mL/min, so the major problem was how to interface the GC without losing the mass spectrometer vacuum. This was solved by use of molecular separators. In one of these, known as the jet separator, the column effluent was passed across a very narrow gap between two jets and the highly diffusible gas was largely removed, whereas the heavier analyte molecules crossed the gap without being vented. This problem of how to dispose of the GC carrier gas no longer exists, since GC capillary columns provide a flow rate of 0.5–2 mL/min of gas, which can be introduced directly into the mass spectrometer without a loss of vacuum. The GC-MS interface is very simple and no special design is required. The GC effluent is simply introduced in the same way as a direct insertion probe would be introduced into the instrument. If the same carrier gas pressure and column are used when a GC method is transferred to a GC-MS one, the retention times produced by the GC-MS method are shorter because of the effect of the vacuum at the mass spectrometer end of the column. Most GC software incorporates a flow calculator that enables an estimate to be made of the effect of a mass spectrometer vacuum on the linear velocity of the GC carrier gas.

Although many analyses are now carried out by LC-MS, GC-MS is still important for many drug analyses. In the negative-ion mode, it is probably the most sensitive analytical technique available for analytes that are strongly electron capturing. The main areas of application for GC-MS are in the characterisation of volatile compounds, such as flavourings, fatty acids and unidentified residual solvents. In the forensic field many narcotics can be analysed by GC-MS with a high degree of selectivity, as can other abused drugs such as anabolic steroids. An advantage of GC-MS is that electron impact (EI) spectra can be obtained, which are correlated readily to library spectra that have been built up over many years. The disadvantage of the technique is that more sample preparation is required in comparison with LC-MS techniques.

Liquid chromatographic interfaces with mass spectrometers

The interfacing of a liquid chromatograph to a mass spectrometer proved much more difficult than for a gas chromatograph, since each mole of solvent produces 22.4 L of solvent vapour even at atmospheric pressure. The technique has made huge advances in the past ten years and many types of interface are available, the most successful of which are the electrospray and atmospheric pressure ionisation sources (Neissen 1998). The advances in technique have meant that splitting of the eluent flow from a high performance liquid chromatography (HPLC) column is now unnecessary and instruments can cope with flow rates of up to 1 mL/min, although mobile phases with a high water content may need to be introduced at flows of less than 1 mL/min.

Electrospray ionisation mass spectrometry and atmospheric pressure chemical ionisation mass spectrometry

Electrospray ionisation (ESI) (Cole 1997; Snyder 1996) and atmospheric-pressure chemical ionisation (APCI) are the most widely used interfaces between liquid chromatography and mass spectrometers. They are carried out using the same source. In the ESI mode the sample is sprayed in solution into the source via a needle held at a high potential of 3–5 kV. The formation of an aerosol from the sample is assisted by a flow of heated nitrogen, which enters the instrument along a direction co-axial with the needle. The sample enters the instrument through a narrow orifice in a metal cone, which leads to a chamber at an intermediate level of vacuum; it then passes through a second orifice into a high-vacuum region. Figure 37.9 illustrates the production of the electrospray. At the tip of the capillary, positive ions are separated from their negative counter ions, which are pulled towards the capillary. The

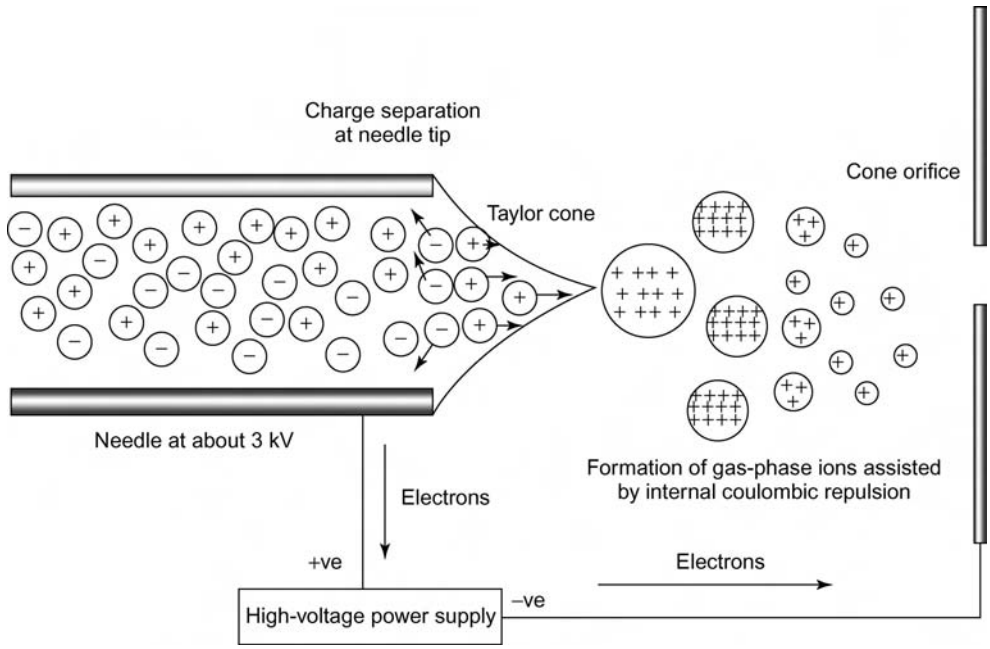

Figure 37.9 The electrospray process.

isolated positive ions generated are repelled by the capillary. This force breaks up the surface tension of the liquid in which the sample is dissolved, to generate a cone (the Taylor cone) that breaks up into charged droplets. This process is charge dependent and, since the analyte is usually of low concentration, electrolytes must also be in the liquid at a minimum concentration of 10^{-5} mol/L to assist in promoting ESI. Once the sample has formed into charged droplets, the excess of positive charges in the droplets produces repulsion, which causes the droplets to break up further. This is assisted by evaporation of solvent from the droplets, which increases their charge and thus further promotes their break up. At the final stage, the analyte is believed to abstract one or more protons from the solvent (or to donate a proton if a negative ion is formed) to give a positively charged gas-phase ion.

Figure 37.10 shows the positive ESI spectrum for morphine; it also illustrates an addition point about electrospray, which is that adducts can form with a variety of components present in the chromatographic mobile phase. Thus the ion at *m/z* 308 is due to addition of Na^+ to the molecular mass; *m/z* 327 is due to the addition of acetonitrile, which is present in the mobile phase; and *m/z* 349 is due to addition of both Na^+ and acetonitrile. Other common additions in the positive-ion mode include: K^+, NH_4^+ and methanol. In negative-ion mode the mobile phase additives acetic acid and formic acid are often added to the molecular ion.

If analytes can be protonated at multiple sites, they will carry several charges. Thus, a protein of molecular weight 10 000 amu that carries 10 charges appears to the mass analyser to have a mass of 1000 amu. Figure 37.11 shows the electrospray mass spectrum of porcine insulin. The charge on a given ion may be obtained from two adjacent ions in the mass spectrum according to equation (37.2):

$$n = \frac{M_A - 1}{M_A - M_B} \tag{37.2}$$

where n is the charge on M_B, and M_A and M_B are the masses of adjacent ions A and B with A the higher in mass. For the spectrum of porcine insulin shown in Figure 37.11:

$$n = \frac{1157 - 1}{1157 - 964} = \frac{1156}{193} = 5.99 \tag{37.3}$$

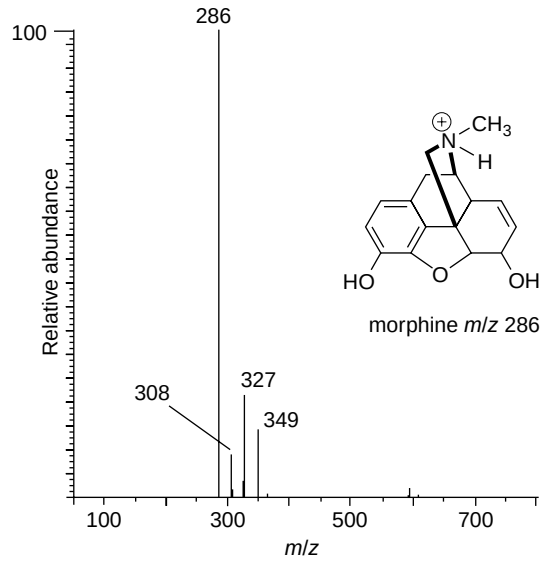

Figure 37.10 Positive-ion ESI spectrum of the MH^+ ion for morphine, *m/z* 286.

Thus the charge on the ion at *m/z* 964 is 6+, giving a relative molecular mass of 5784 for hexaprotonated porcine insulin. Insulin has six basic centres and, in this case, the predominant ion is that with all six centres protonated. Protonation of all the basic centres of a protein does not always occur.

To carry out APCI the instrument used for ESI simply has to be reconfigured to introduce a corona discharge pin at the point where the stream of solvent that contains the analyte enters the instrument. Although APCI is carried out on the same instrument as ESI, it is quite a different process. It does not depend on the production of ions by evaporation, rather it uses chemical species to promote the ionisation process in a manner analogous to the production of ions under positive-ion chemical ionisation conditions (PICI; see below). In this case the reagent ions that promote the ionisation include N_2^+ and H_3O^+. APCI tends to be less sensitive than ESI, but it is useful for molecules that will not ionise readily (e.g. neutral drugs such as steroids).

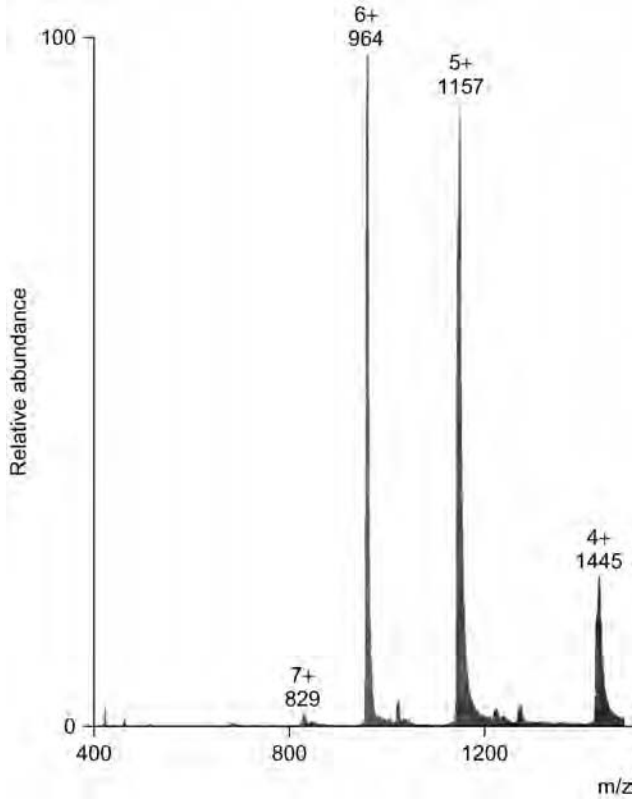

Figure 37.11 Electrospray mass spectrum of porcine insulin.

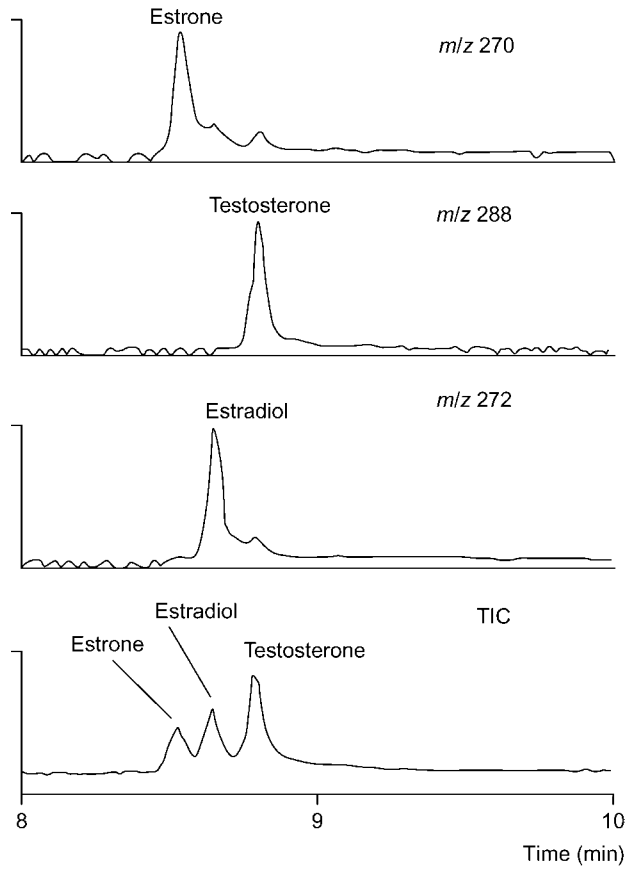

Figure 37.12 GC-MS trace of a mixture of estradiol, estrone and testosterone showing extracted ion traces for their molecular ions and the total ion current.

Capillary electrophoresis–mass spectrometry

The preferred mode of ionisation for interfacing a capillary electrophoresis (CE) instrument with a mass spectrometer is ESI. The technique has been improved by the development of a method to introduce a sheath flow of mobile phase, which augments the nanolitre per minute flows through the CE column to form a stable electrospray. During CE, a potential of 25–30 kV is applied across the capillary between the inlet and the outlet, the outlet being at ground potential. In ESI, the needle is normally held at a potential of 3–5 kV so that the potential applied across the CE has to be increased to compensate for the increase in potential at the outlet end. The CE interface is one of the most recent developments in MS and it is expected to have a wide range of applications in obtaining impurity profiles of both conventional synthetic drugs and biotechnological drugs.

Data processing

At a basic level the considerations for processing data obtained from mass spectrometers overlap those involved in the processing of chromatographic data obtained using other types of detector. Thus, from the chromatographic standpoint, the correct settings of integration parameters, such as peak width and threshold, are important to ensure that processing parameters do not confound the accuracy of the data obtained.

The difficulties of fused peaks in total ion current (TIC) chromatograms can often be circumvented by the use of selected ions that are characteristic of the compound of interest. For example, in the chromatogram shown in Figure 37.12, the peaks for testosterone, estradiol and estradione partially overlap. However, it is possible to extract the molecular ions for each individual compound and Figure 37.12 shows the extracted ion traces for the molecular ions of the three analytes, with very little interference between them. However, interference is not necessarily completely eliminated, as the testosterone peak produces some response in the selected ion trace for estrone since *m/z* 270 occurs in the mass spectrum of testosterone through the loss of water from its molecular ion at *m/z* 288.

The use of extracted ion traces is common in LC-MS data processing used for the screening of drug metabolites. The background produced by ions derived from the LC solvent in LC-MS mode means that when metabolites are present only in low amounts the molecular ions of potential metabolites can be predicted and used to generate extracted ion traces to check for their presence. However, chromatograms such as these do not show the same sensitivity as single-ion monitoring does.

Data processing in the generation of accurate mass data is a little more complex since the mass spectrum of the compound of interest may have to be calibrated against a standard, which is introduced into the mass spectrometer at the same time as the sample. For example, three of the calibrant ions are picked manually by the operator and the computer can construct a calibration curve based on the known masses of all the major calibrant ions (see Fig. 37.4). However, increasingly at the high price end of the market, instruments are capable of retaining mass accuracy after tuning for several days and thus the introduction of a calibrant at the same time as the sample is not necessary.

Beyond these basic considerations there have been extensive developments of data processing software aimed at facilitating the elucidation of drug metabolites or trace analytes in an automated fashion. Mass spectrometry manufacturers all sell versions of software that will predict the mass shifts caused by metabolic transformations for drugs and associated isotope patterns and predict fragmentation patterns. Also extensive work has been done in the proteomics field on the identification of peptide sequences produced by tryptic digestion followed by tandem MS and database matching of these sequences in order to identify the protein.

System suitability tests

Chromatographic tests

Chromatographic systems interfaced with mass spectrometers are subjected to the same system suitability tests as used in conjunction with other types of chromatographic detectors (see Chapters 39, 40, 41, 42).

Calibration of the mass axis

A test of fundamental importance in MS is calibration of the mass axis of the mass spectrometer with a suitable tuning compound or mixture. In GC-MS systems the most popular tuning compound is perfluorotributylamine (PFTBA). The use of a fluorinated tuning compound has two advantages. On the carbon-12 scale of relative atomic mass, fluorine is very close to its nominal mass of 19, whereas the mass of hydrogen is considerably greater than its nominal mass of unity. Second, since PFTBA is electron capturing, it can be used to tune in the negative-ion chemical ionisation mode. In the EI mode, PFTBA produces a number of abundant ions below a mass of *m/z* 219 and weaker ions above this value. Tuning should be carried out on a minimum of three ions that cover the mass range of interest. Typically, the ions at *m/z* 69, 219 and 502 generated by PFTBA are used to calibrate the mass axis in EI mode. These ions are also used to determine resolution between masses. There is always a trade-off between resolution and sensitivity and, if the mass window is narrowed to reduce peak width, sensitivity is lost. The PFTBA ions at *m/z* 69, 219 and 414, and 452, 595 and 633 are suitable for instrument tuning in PICI and negative-ion chemical ionisation (NICI), respectively. Instruments can be tuned automatically or manually. With quadrupole mass spectrometers and other low-resolution instruments, such as ion traps, the ions used in tuning are assigned masses to the nearest whole number. When high-resolution calibration is being carried out, masses of four or five decimal places are assigned to calibration ions; thus, for instance, the CF_3^+ ion at *m/z* 69 would be assigned its exact mass of *m/z* 68.9952. All the major ions in the spectrum of PFTBA would be used to carry out a high-resolution calibration and thus enable accurate mass assignment.

A mixture of caffeine, the tetrapeptide methionine–arginine–phenylalanine–alanine and Ultramark (a polyfluorinated fluorinated amine giving a series of ions differing by CF_2) is a popular choice for tuning electrospray instruments. Horse myoglobin is also used, as well as poly(ethylene glycol)s. In negative electrospray mode, salts of acids such as sodium dodecyl sulfate and sodium taurocholate can be used for tuning.

Sensitivity checks

There is no specific test for checking the sensitivity of a mass spectrometer. The counts provided by the tuning compound provide an indication of sensitivity, but beyond that the usual checks are of the sensitivity of the system when interfaced with chromatography. Manufacturers usually have their own favourite compounds for assessing sensitivity, such as methyl stearate to assess EI sensitivity in GC-MS mode or octafluoronaphthalene to assess NICI sensitivity in GC-MS mode. However, these particular analytes are not typical of the average drug molecule for which chromatographic factors contribute to the overall sensitivity. Sensitivity checks are usually carried out by diluting the compound of interest until it is no longer detectable by the particular system being used.

Sample preparation and presentation

The preparation of samples for GC-MS and LC-MS analysis does not differ from the types of preparation that would be carried out prior to any other chromatographic method, i.e. is, extraction to remove interferences by the sample matrix as far as possible. In the case of biological fluids, urine may not require much pre-treatment although, if it is not going to be diluted to a reasonable extent, it might be wise to precipitate out some of the salt content by dilution with acetonitrile. The most popular method for pre-treating plasma (due to its speed) is to precipitate out the protein prior to analysis by adding acetonitrile. This has been facilitated recently by the introduction of protein crash plates that allow the protein to be removed by filtration following addition of the solvent. If extraction is required, then a wide range of solid-phase extraction cartridges is available. Many drugs are bases and the cleanest extracts are produced by using strong cation exchange as the mode of extraction.

There is a tendency, because MS is a selective technique, to think that the cleanliness of the extracts and the chromatographic separation prior to introduction into the instrument is less important. In the case of ESI mode it may often be wrong to go for rapid analytical methods, since interfering ions in the matrix can often cause ion suppression of the analyte of interest. Plasma phospholipids and poly(ethylene glycol) are major culprits when it comes to ionisation suppression since they accumulate on HPLC columns and can then start to bleed off the column in subsequent runs. If the analyte is too close to the void volume of the HPLC column, this can also cause ionisation suppression. Ionisation suppression presents the greatest problem in the case of ion-trap mass spectrometers where matrix ions can cause suppression of the signal in the trap as well as during the electrospray process. It has been recommended that ionisation suppression should be checked by comparing the response factor for the analyte in water against the same amount of analyte spiked into a blank extracted matrix (Matuszewski *et al.* 2003).

Some additional considerations apply, for instance in GC-MS mode, as very often derivative formation may be necessary. For example, trimethylsilyl derivatives provide fairly abundant $[M-15]^+$ ions, which may be useful. Also, fluoroacylated derivatives may be prepared so that the sample is suitable for analysis in the negative-ion mode. If a chromatographic step is not used in conjunction with MS, it is important that the sample be relatively free of non-volatile materials, such as salts that would prevent it from evaporating from the direct insertion probe. The presence of non-volatile salts in samples may also interfere in LC-MS in the ESI or APCI mode, since the non-volatile salt will elute from the column and deposit on the cone, and so reduce instrument sensitivity quite rapidly. The cone can be continually washed to remove buffer salts, but, despite this, sensitivity tends to fall quite rapidly with time.

Data interpretation

Introduction

The interpretation of a mass spectrum (Dass 2007; de Hoffman, Stroobant 2007; Gross 2004; Lee 1998; McLafferty, Turecek 1993; Throck Watson, Sparkman 2007; Williams, Fleming 1995) is intimately bound up with the type of ionisation used to generate the mass spectrum. With EI MS, the fragmentation patterns for molecules are generally quite complex and many of the fragmentations do not fit the rules laid down by organic chemists for simpler organic molecules. Under other types of ionisation, fragmentation is less extensive and more predictable, as described below. As described above, many manufacturers of mass spectrometers now sell software that can help in the interpretation of mass spectra. In general in forensic analysis the order of importance for identification of a drug is: molecular ion, chromatographic retention time and fragmentation pattern. Identification of the fragments is of secondary importance and is required only for a particularly difficult problem.

Electron-impact mass spectrometry

EI ionisation uses high-energy electrons at 70 eV, which produce extensive fragmentation of the bonds within the analyte. It is still very commonly used in standard chemical composition analyses, but is not as readily applicable if the molecule being analysed is very non-volatile or unstable. In these cases, a range of other ionisation techniques can be applied.

Figure 37.13 shows a generalised scheme for decomposition of a molecule under EI conditions:

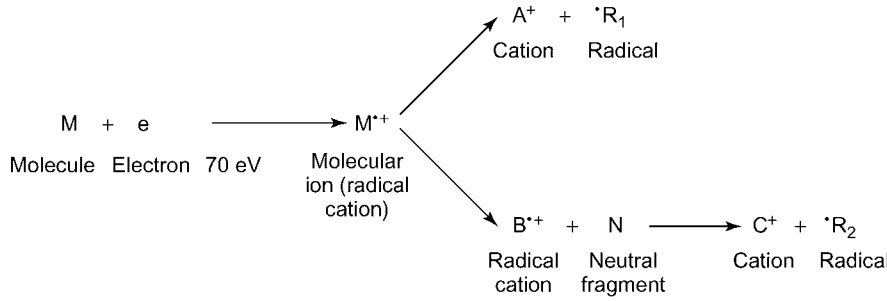

Figure 37.13 Electron-impact ionisation.

- Mrad$^+$ represents the molecular ion that bears one positive charge, since it has lost one electron, and the unpaired electron that results from the loss of one electron (represented by a dot).
- Mrad$^+$ may lose a radical that, in a straightforward fragmentation not involving rearrangement, can be produced by the breaking of any single bond in the molecule. The radical removes the unpaired electron from the molecule to leave behind a cation A$^+$.
- This cation (A$^+$) can lose any number of neutral fragments, such as H_2O or CO_2, but no further radicals.
- The same process can occur in a different order with a neutral fragment (H_2O, CO_2, etc.) being lost to produce the radical cation Brad$^+$; since this ion still has an unpaired electron, it can lose a radical to produce C$^+$, which can thereafter lose only neutral fragments.

An EI spectrum is shown for heroin in Fig. 37.14 and the fragmentation pathways that give rise to the spectrum are shown in Fig. 37.15. The molecular ion can be seen at *m/z* 369 (and therefore must contain a nitrogen atom) and the fragments at *m/z* 327 and 310 correspond to ions B and A in Fig. 37.13. The ion at *m/z* 268 corresponds to ion C in Fig. 37.13, and can also be derived via loss of acetate from ion B. The ion at *m/z* 284 results from the loss of two neutral fragments. Like many molecules the simply explained losses occur only within about 100 amu of the molecular ion, and below *m/z* 268 the fragment ions are derived from complex rearrangements of the structure of the molecule. An advantage of EI is that the complex fragmentation pattern produced can be used as a fingerprint to identify the molecule, for instance to confirm the identity of traces of heroin in a forensic sample or the identity of an anabolic steroid in a urine sample. Thus, with EI spectra there is plenty of scope to identify an unknown via interpretation. Table 37.3 shows some of the common losses from molecular ions that may be used in the interpretation of an EI mass spectrum.

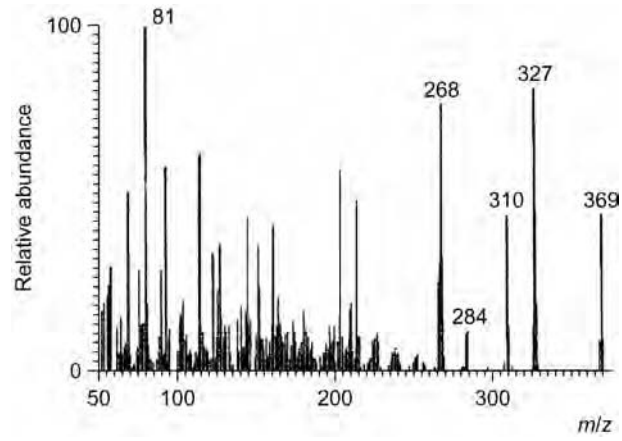

Figure 37.14 Electron-impact mass spectrum of heroin.

The fragmentation patterns of large molecules may be difficult to interpret. For instance, steroid molecules give particularly complex

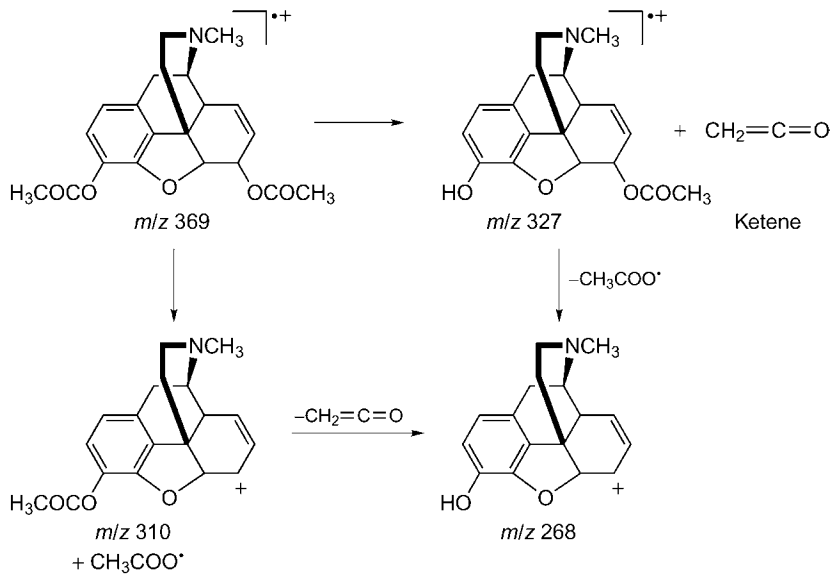

Figure 37.15 Fragmentation pathways that produce some of the ions in the EI spectrum of heroin.

Table 37.3 Some common losses from a molecular ion

Loss amu	*Radicals and/or neutral fragments lost*	*Interpretation*
1	Hrad	Often major ion in amines and aldehydes
15	CH_3rad	Most readily lost from quaternary carbon
17	OHrad or NH_3	
18	H_2O	Readily lost from secondary or tertiary alcohols
19/20	Frad/HF	Fluorides
28	CO	Ketone or acid
29	C_2H_5rad	
30	CH_2O	Aromatic methyl ether
31	CH_3Orad	Methyl ester/methoxime
31	CH_3NH_2	Secondary amine
32	CH_3OH	Methyl ester
33	$H_2O + CH_3$	
35/36	Clrad/HCl	Chloride
42	CH_2 C O	Acetate
43	C_3H_7rad	Readily lost if isopropyl group present
43	CH_3COrad	Methyl ketone or acetate
43	$CO + CH_3$rad	
44	CO_2	Ester
45	CO_2Hrad	Carboxylic acid
46	$CO + H_2O$	
57	C_4H_9rad	
60	CH_3COOH	Acetate
73	$(CH_3)_3Si$rad	Trimethylsilyl ether
90	$(CH_3)_3SiOH$	Trimethylsilyl ether

patterns. Most of the ions in the EI mass spectrum of hydrocortisone (Fig. 37.16) arise from rearrangements of the structure that involve migrations of hydrogen atoms. These types of spectra give a characteristic fingerprint and the base peak ion (most abundant ion) at *m/z* 123 occurs in many steroids. However, it may vary in mass from a hydrogen atom higher to one lower than 123. The base peak in the mass spectrum of testosterone occurs at *m/z* 124, even though it has exactly the same A and B rings as hydrocortisone. However, the mass spectrum of prednisolone, which has an additional unit of unsaturation in the A ring, is consistent with hydrocortisone and yields a base peak ion at *m/z* 121.

With many drug molecules, the use of EI ionisation results in a low abundance of the molecular ion. Thus chloroquine under EI conditions gives less than 1% abundance of molecular ion (Fig. 37.17) and its mass spectrum is dominated by an alpha cleavage fragment, which arises as shown in Fig. 37.18.

The spectra of heroin, hydrocortisone and chloroquine illustrate the three most common types of spectra observed in drug molecules. The spectra of heroin and hydrocortisone are most useful, since they are complex, provide a fingerprint, and are more open to interpretation than simple spectra such as the spectrum of chloroquine. Other dominant fragmentation modes exist, such as the formation of a tropylium ion, which occurs in benzyl compounds, but these are not as common as those mentioned above and are discussed elsewhere (Dass 2007; de Hoffman, Stroobant 2007; Gross 2004; Lee 1998; McLafferty, Turecek 1993; Williams, Fleming 1995).

If more information is required about the relative molecular mass of a drug that fragments easily, such as chloroquine, softer ionisation techniques are used. FAB ionisation is one option (the FAB spectrum of chloroquine is shown in Fig. 37.4). However, FAB combines less satisfactorily with chromatographic interfaces than other ionisation methods; quite a number of methods promote ionisation, some of which are discussed below.

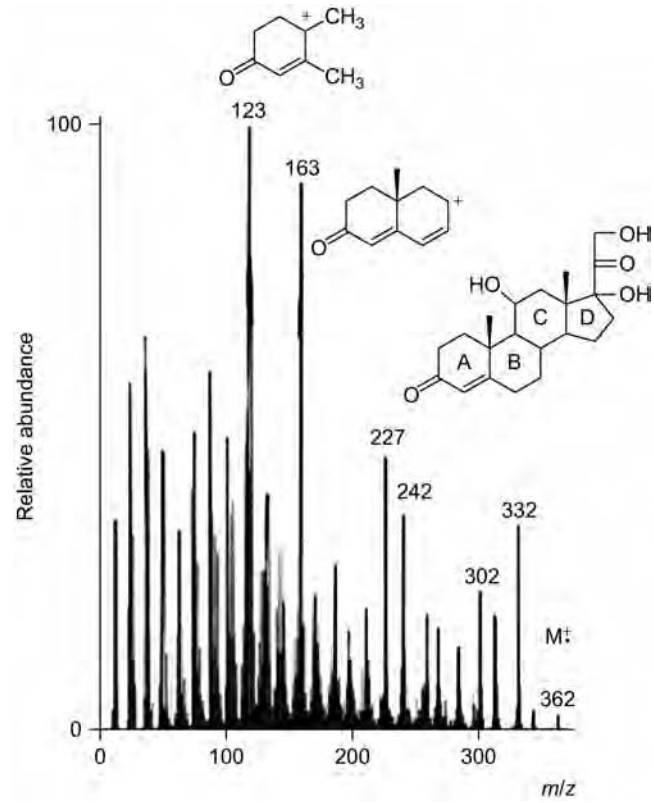

Figure 37.16 Electron-impact mass spectrum of hydrocortisone.

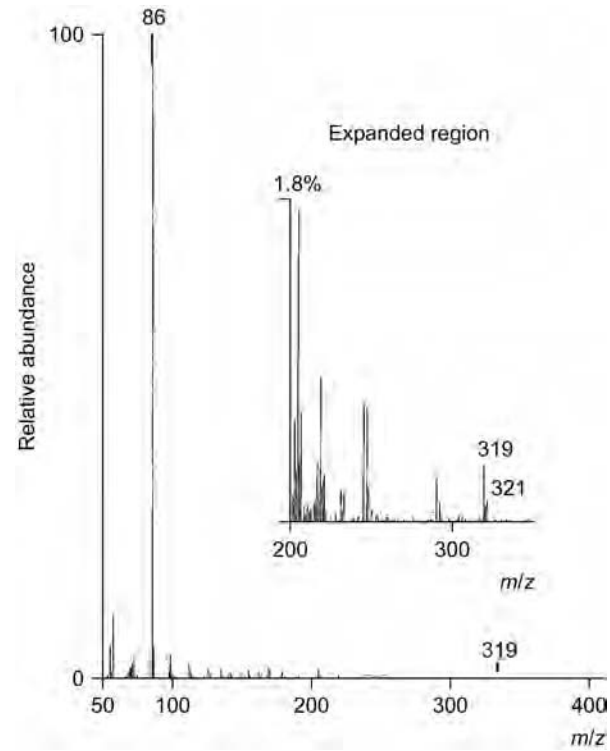

Figure 37.17 Electron-impact mass spectrum of chloroquine.

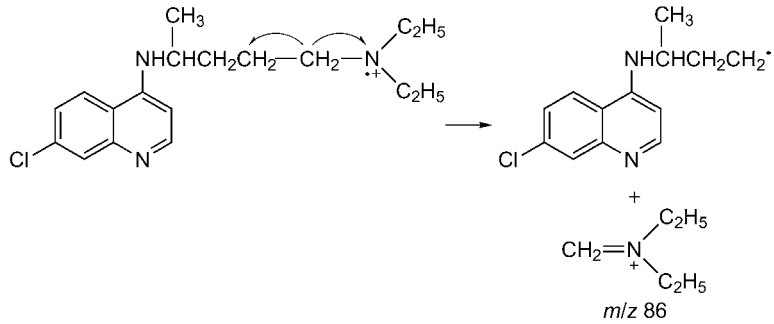

Figure 37.18 α-Homolytic cleavage of chloroquine.

Positive-ion chemical ionisation

Positive-ion chemical ionisation can be carried out with a number of reagent gases (methane, isobutene and ammonia are most commonly used), and it is most applicable in GC-MS. The gas is introduced into the source of the mass spectrometer continuously during the analysis and the source configuration is changed so that the gas is contained within a small chamber within the source. Gas is introduced to give a source pressure of about 1 mmHg (133 Pa) and bombarded with electrons produced by the same filament as used for EI ionisation at energies of about 200 eV. The electrons cause the reagent gas to ionise and further ions are produced through the gas reacting with itself. In the case of methane, three major reagent ions are produced, namely CH_5^+ (*m/z* 17), $C_2H_5^+$ (*m/z* 29) and C_3H_5 (*m/z* 41). These reagent ions can either transfer a proton to the analyte, thus ionising it, or combine with it to produce adduct ions.

When chloroquine is ionised under PICI conditions the spectrum shown in Fig. 37.19 is produced, which can be compared with the EI spectrum in Fig. 37.17. In the PICI spectrum the $[M+H]^+$ ion is the base peak and ions seen at *m/z* 348 and *m/z* 360 are from the addition of *m/z* 29 and *m/z* 41 reagent ions to chloroquine. There is also an ion at *m/z* 284, which is caused by ionisation via abstraction of the chlorine atom from chloroquine by the reagent ions. PICI is not commonly used in chromatographic analyses, since it is usually of low efficiency, but it can sometimes be a useful method to help identify impurities in drugs; it is also a useful way to generate an abundant molecular ion for elemental composition determination when using high-resolution MS.

Negative-ion chemical ionisation

Negative-ion chemical ionisation spectra are generated in the same way as PICI spectra, except that the instrument is set to focus and detect negative ions. Most negative-ion spectra are not true chemical ionisation spectra, but are rather electron-capture spectra. Molecules that contain electronegative and/or electron-rich groups, such as halogens, oxygens or conjugated double bond systems, have a high affinity for electrons and thus capture the low-energy electrons produced by collision with methane. Thus, NICI is suitable only for molecules that contain electron-capturing groups, but for this type of molecule it is an extremely efficient and selective mode of ionisation. The NICI spectrum of chloroquine is shown in Fig. 37.20. As in PICI, the spectrum is dominated by the molecular ion, in this case at *m/z* 319.

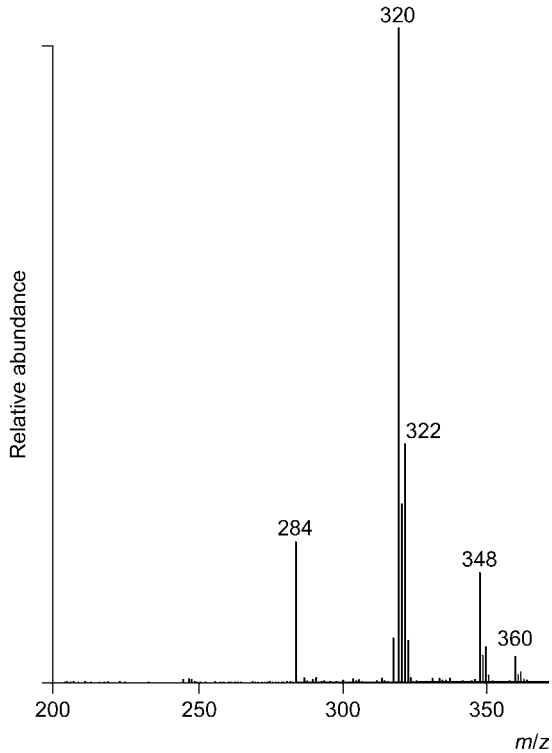

Figure 37.19 Positive-ion chemical ionisation spectrum of chloroquine.

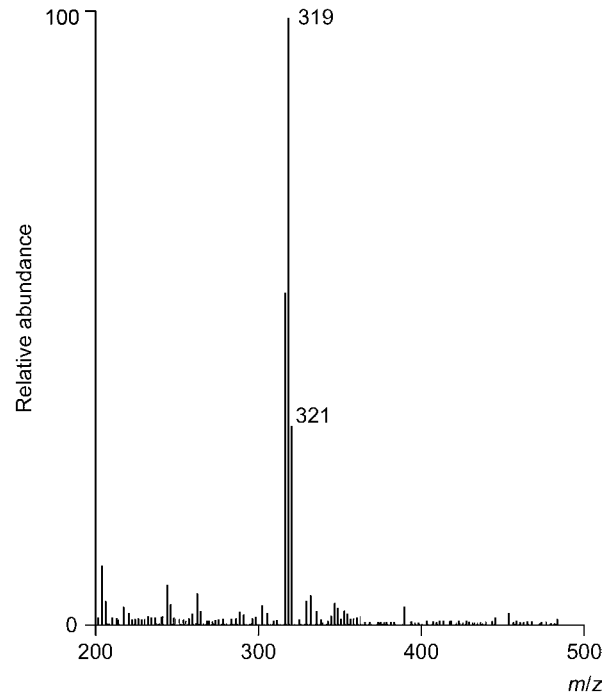

Figure 37.20 Negative-ion chemical ionisation spectrum of chloroquine.

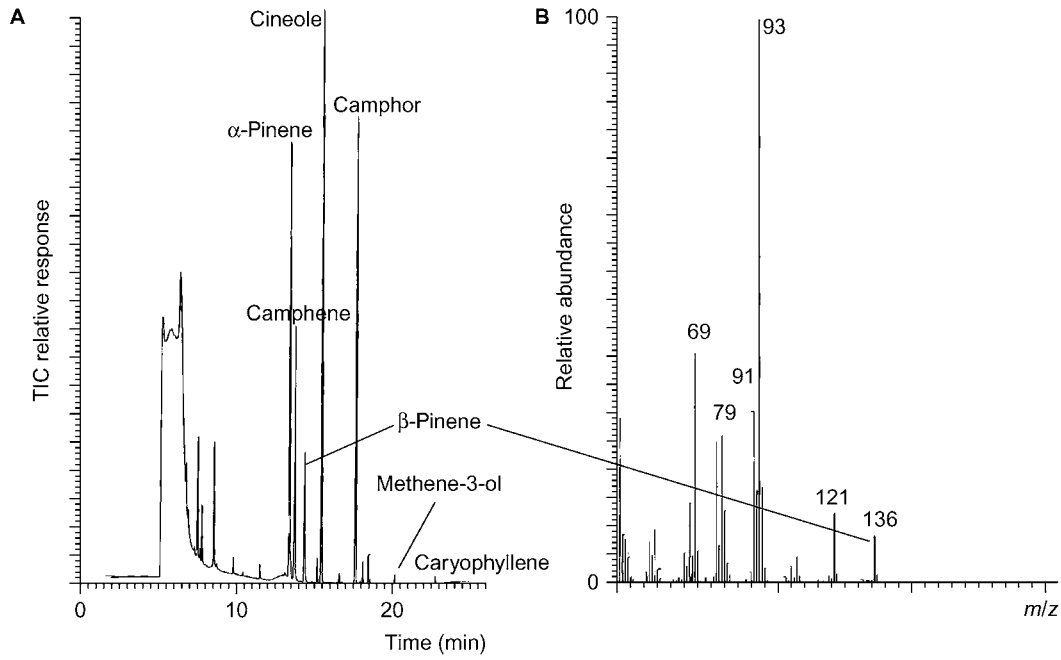

Figure 37.21 (A) Total ion current (TIC) chromatogram of rosemary oil by GC-MS. Conditions: ZB-1 column (60 m × 0.32 mm i.d., 0.5 µm film). Head pressure 130 kPa. Temperature programme: 50°C for 1 min to 80°C at 5°/min to 270°C at 10°/min. (B) The mass spectrum of the peak at 14.37 min (β-pinene).

Mass spectrometry in qualitative analysis

Some applications of GC-MS in qualitative analysis

Analysis of rosemary oil

Figure 37.21A shows the chromatogram obtained from the analysis of a sample of rosemary oil by GC-MS. The mass spectrum shown (B) is for the peak at 14.37 min. This spectrum was computer matched against the NIST library spectrum (details from www.hdscience.com) and gave two match figures of 932 and 941. Spectra are matched with the library by comparing the intensities of ions across the mass range scanned and a correlation coefficient is obtained. Any match of between 900 and 1000 is regarded as excellent. The higher second match figure in this case was obtained by matching the library spectrum to the unknown, omitting any peaks in the unknown that did not occur in the library spectrum, which is why the correlation number is slightly higher.

Library search matches are very useful for identifying unknown volatile materials; another area in which GC-MS is useful is in the identification of unknown residual solvents. Even though solvents are relatively simple molecules, there is quite a wide range of possibilities when an unknown is picked up, so library matching is very useful in such cases. In addition to solvents, many manufacturing intermediates have a relatively low molecular weight and are volatile and thus suitable for GC-MS analysis.

Impurity profiling

The Food and Drug Administration (FDA) now require that impurities of greater than 0.1% be identified in pharmaceuticals, in which MS with chromatography can assist. Such impurities can arise either from the manufacturing process or from degradation of the drug. Figure 37.22A shows a GC-MS trace for a commercial sample of the beta-blocker

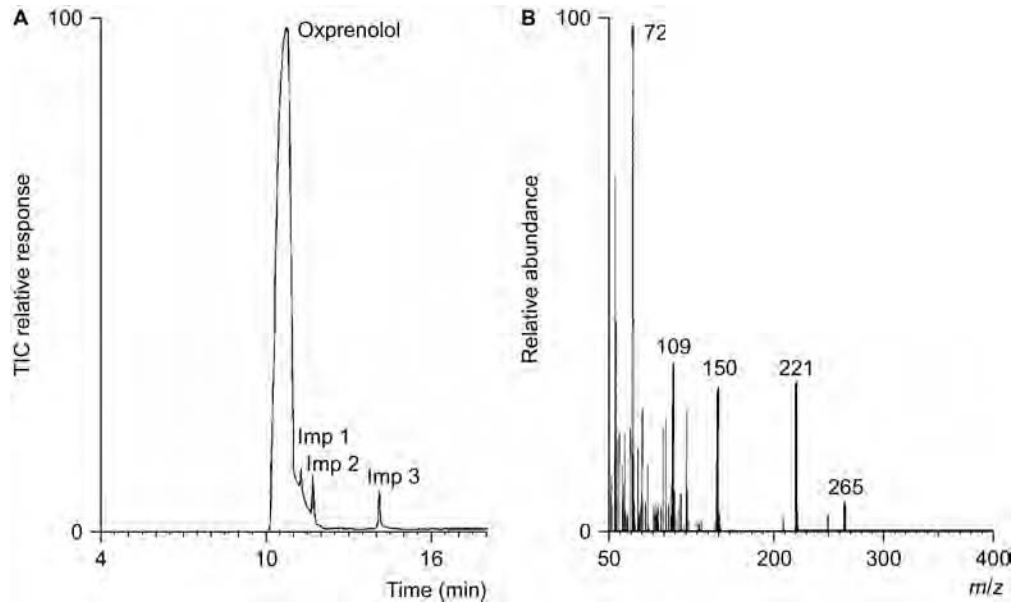

Figure 37.22 (A) GC-MS TIC trace of a commercial sample of oxprenolol and (B) the EI mass spectrum of oxprenolol.

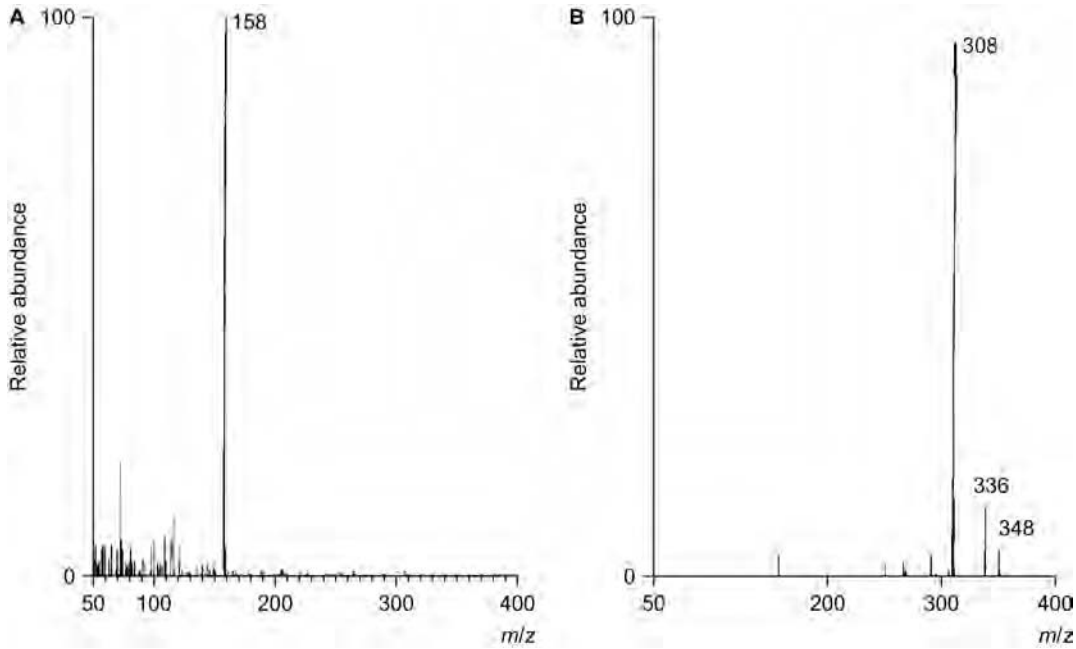

Figure 37.23 (A) EI and (B) PICI spectra of impurity 3.

oxprenolol. The compound contains three major impurities, one of which is resolved poorly from the very large peak obtained for the drug. The manufacture of beta-blockers is by fairly standard routes, which helps the identification of manufacturing impurities. The mass spectrum of oxprenolol is shown in Fig. 37.22B. Under EI conditions it gives a relatively weak molecular ion at *m/z* 265 and the spectrum is dominated by the fragment that arises from α-homolytic cleavage next to the amine in the side chain, which is typical of many amines (as in chloroquine).

Let us take, as an example, the impurity peak 3. The EI spectrum of this impurity (Fig. 37.23) shows only two major ions at *m/z* 158 and *m/z* 72. Its GC retention time is longer than that of oxprenolol and, on the non-polar GC column used, this suggests that the impurity has a higher molecular weight than oxprenolol. Under PICI conditions, the base peak of the mass spectrum of the impurity is an ion at *m/z* 308; the ion at 158 is still present, although much weaker. Taking into account the final step in the synthetic route to oxprenolol, the product possibly arises from the presence of a small amount of diisopropylamine in the isopropylamine used in the final step of the synthesis. Impurities 1 and 2 are isomers of oxprenolol; impurity 1 could arise via opening of the epoxide ring in the final step of the synthesis to form a primary alcohol, but both might also arise from isomers of the dihydroxybenzene present in the starting material for the synthesis.

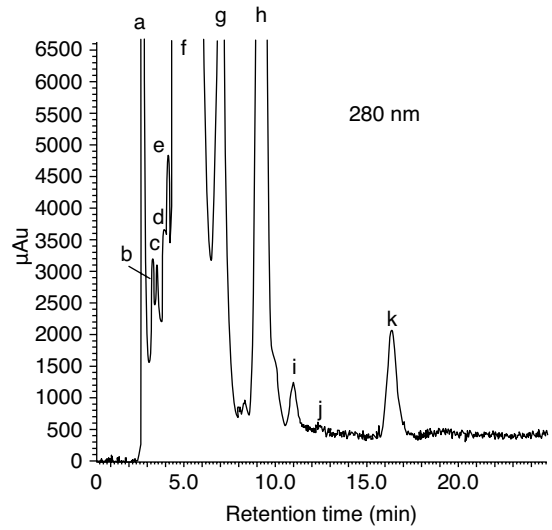

Figure 37.24 HPLC-UV chromatogram obtained from the analysis of poppy straw extract (1 g/L). Phenylhexyl column (150 × 4.6 mm); mobile phase 0.02 mol/L ammonium acetate–methanol (55 : 45), flow rate 0.4 ml/min.

Application of LC-MS in qualitative analysis

Determination of minor alkaloids in poppy straw extract

In the forensic field of analysis the most important goal in an analysis is first of all identification. The most powerful LC-MS technique available for identification is high-resolution FT-MS, whereby very precise elemental compositions can be assigned to unknown substances. Figure 37.24 shows a HPLC-UV chromatogram of morphine and co-occurring alkaloids in a poppy straw extract. Such minor congeners could be invaluable in determining the geographical origin of a sample of morphine. In the example shown the congeners are at relatively high levels (between 0.1 and 7% w/w) since the crude extract is less refined than purified morphine. However, the dynamic range of most LC-MS systems is at least 10^5 and very minor amounts of these congeners could be detected in a more refined sample. Table 37.4 shows the elemental compositions, with their deviations from the exact mass for the assigned composition, obtained on an LTQ Orbitrap, for morphine and its minor congeners and the probable identities where the elemental composition fits with known congeners. Figure 37.25 indicates the orthogonal selectivity of high-resolution mass spectrometry and compares the extracted ion traces for morphine and normorphine which occurs within the sample at ~0.08% w/w with respect to morphine itself. It can be seen that even a very low percentage of normorphine in the sample can be readily detected. Introducing patterns of congeners into chemometric software would enable forensic analysts to pinpoint geographical origin and identify factors such as time of harvesting. The presence of *N*-oxides could also give some indication of the age of the sample.

Identification of drug metabolites

Metabolism is an important component in the drug discovery and development process, and LC-MS has an important role in identifying drug metabolites (Oliveira, Watson 2000). The pathways of phase 1 and

i	344.18558	$C_{20}H_{26}NO_4$	0.20	Tetrahydropapaverine
j	354.13345	$C_{20}H_{20}NO_5$	−0.40	
k	312.15948	$C_{19}H_{22}NO_3$	0.20	Thebaine

phase 2 drug metabolism are well known, and it is possible to derive useful information even from a single quadrupole instrument by using extracted ion chromatograms to search for predicted metabolites. For example, formation of a monoglucuronide of a drug results in a shift of 176 amu from the molecular ion of the parent. However, the process of searching for metabolites is easier if tandem MS is available. The preferred mode of metabolite profiling in the preliminary analysis of metabolites is to use product-ion scanning. The predicted ion for a metabolite is selected by the first quadrupole and subjected to fragmentation in the collision cell and the fragments are analysed by the third quadrupole. This enables acquisition of clean metabolite spectra that are free from any interfering solvent background. If a quantitative analysis is required, selected-reaction monitoring may be carried out, in which a critical transition is monitored. For example, the transition produced by loss of a glucuronide moiety from a glucuronide metabolite might be monitored if it gives a very specific response for that particular metabolite. Constant neutral-loss scanning is especially useful for searching for a particular class of metabolite, since it can readily detect metabolites resulting from both phase 1 and phase 2 metabolism. For example, glucuronide metabolites for which the loss of the glucuronide moiety (−177 amu) is a major fragmentation pathway might be monitored. If the masses of the metabolites fall in a range (e.g. between 400 and 700 amu), the first quadrupole is set to scan between 400 and 700 amu and the second quadrupole to scan in the range 400–177 amu to 700–177 amu. In this way, any metabolites that are, for example, methylated or undergo additional hydroxylation followed by glucuronidation are picked out, as well as simple glucuronides.

Ion-trap instruments can also be used to good effect in drug-metabolism studies and have approximately ten times the sensitivity of triple-sector quadrupole instruments when used to examine full-scan spectra. This is advantageous in the first phase of metabolite identification when the metabolites are unknown. Another advantage of trap instruments is that fragmentation of selected ions can be carried out several times with all the ions, apart from the molecular ion of the metabolite of interest, being ejected from the trap before the next fragmentation. This process produces clean spectra for the metabolite.

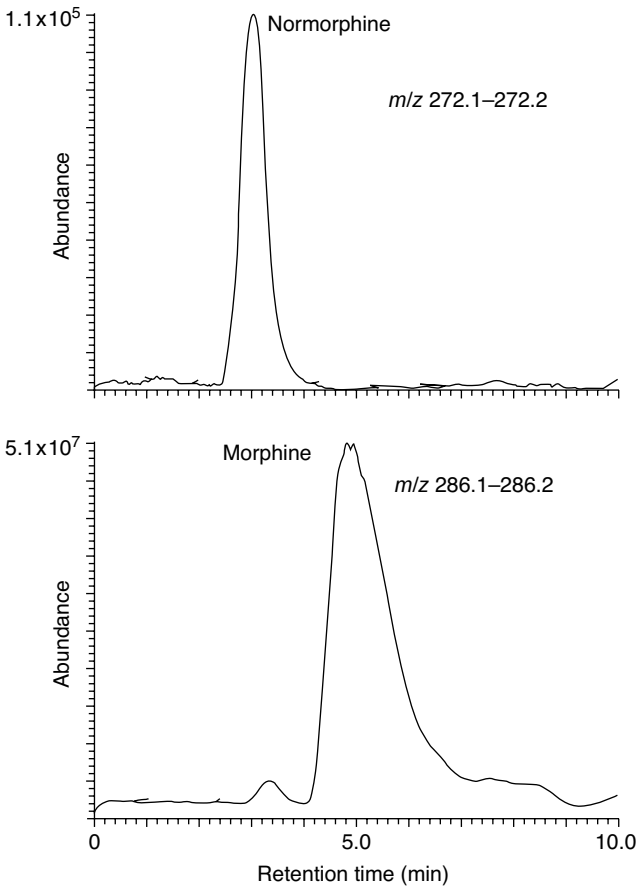

Figure 37.25 Extracted ion traces for morphine and normorphine in poppy straw extract.

Some applications of mass spectrometry in quantitative analysis

Mass spectrometric detectors are able to carry out precise and accurate quantification of analytes. However, it is generally necessary to use an internal standard in analyses, since the instrumentation is more subject to sensitivity fluctuations than simpler detectors, such as the UV-visible detectors used in HPLC analyses. The selection of an internal standard has to be made carefully so that its mass spectrometric behaviour is reproducible and closely similar to that of the analyte. The internal standards labelled with stable isotope (described below) are ideal, since they mimic the analyte very closely, but often a close structural analogue of the analyte will suffice.

The most common application of MS to quantitative analysis of biomedical samples is in the quantitative determination of drugs and their metabolites in biological fluids and tissues. The advantage of MS in this area is that its selectivity means that it is less subject to interference by other compounds extracted from the biological matrix along with the compound of interest. The greatest accuracy in such analyses is afforded by using as internal standards analogues of the compound being measured that are labelled with stable isotopes. An isotopomeric internal standard of a drug co-elutes with it from a chromatographic column (sometimes deuterated compounds elute very slightly earlier than the unlabelled compound) and should have an almost identical response factor. Figure 37.26 shows the NICI mass spectra of the trimethylsilyl oxime derivative of prednisolone and its tetradeuterated analogue. The deuterated analogue of prednisolone can be used as an internal standard in the determination of prednisolone in a biological matrix. On the basis of the mass spectra shown the ions at *m/z* 457 and 472 are monitored for prednisolone and those at *m/z* 461 and 476 for the tetradeuterated internal standard.

Since isotopomeric internal standards co-elute with the analyte, they aid in the recovery of the analyte from the chromatographic system (carrier effect). Figure 37.27 shows a selected-ion chromatogram of prednisolone methyl oxime/trimethylsilyl (MO/TMS) derivative (Knapp 1990) (monitored as the sum of the ions *m/z* 457 and 472, Fig. 37.26), which was extracted from aqueous humour after addition of 10 ng of tetradeuterated prednisolone (the MO/TMS derivative was monitored as the sum of the ions *m/z* 461 and 476, Fig. 37.26); the

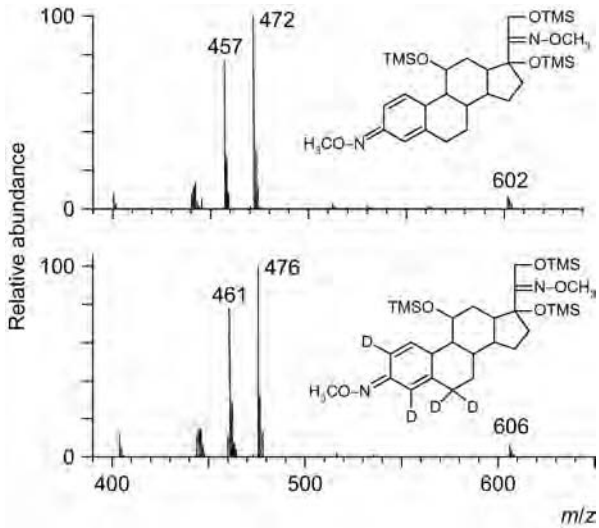

Figure 37.26 NICI spectra of trimethylsilyl prednisolone oxime and its tetradeuterated isotopomer.

analysis was carried out using GC-MS. Similar types of approaches can be taken in LC-MS analysis.

Collections of data

Electron-impact libraries

The most comprehensive collections of mass spectral data are based on EI mass spectra that have been acquired over many years and are used most commonly in conjunction with GC-MS analysis. The most popular libraries are the NIST library (details from www.hdscience.com), which contains the mass spectra of 130 000 compounds, and the Wiley Registry of Mass Spectral Data (www.wileyregistry.com), which contains 390 000 reference spectra. The mass spectrum of a molecule in the library may be called up by using either its CAS number, its name or its relative molecular mass. These libraries use peak-based matching to compare the mass spectrum of an unknown against the library spectrum. Spectra are matched in a manner analogous to the way two UV spectra are matched, except that in this case the *m/z* values and the intensity of the ions of the library spectrum and the unknown are matched. To simplify matching, a threshold can be set to eliminate, for example, ions of less than 1% intensity from the mass spectra being compared. A perfect match to a library spectrum has a value of 1000 and a value above 900 is regarded as a good match; a poor match has a value below 600. Other sources of EI mass spectra, such as the Eight Peak Index (Mass Spectrometry Data Centre 1991), and a collection of mass spectra of drugs and poisons (Pfleger *et al.* 2000) are available in book form, but the computer-based libraries offer a greater degree of convenience in most cases.

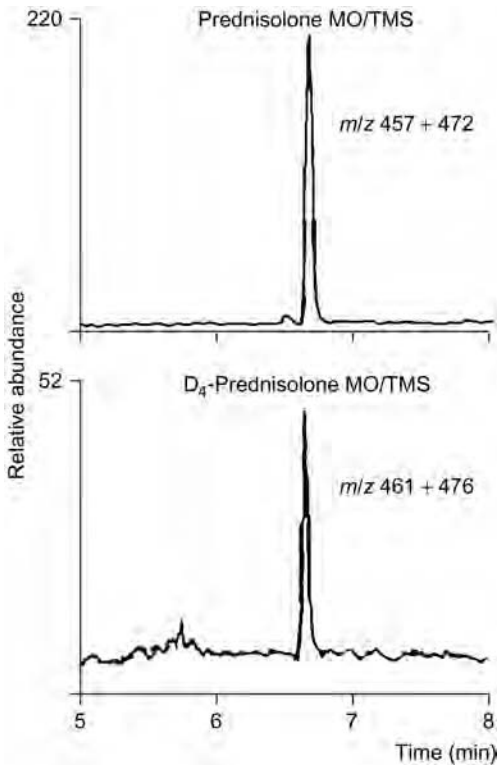

Figure 37.27 Prednisolone extracted from aqueous humour in comparison with D_4-prednisolone (10 ng) added as an internal standard (both as their trimethylsilyl oximes).

Libraries associated with LC-MS ionisation methods

Mass spectra obtained under the ionisation conditions used in LC-MS, such as electrospray, show little fragmentation, and the established libraries of EI spectra are of little use in searching such spectra. The use of tandem techniques increases the degree of fragmentation of molecules, but these do not reproduce exactly the EI spectrum of a molecule. Currently no comprehensive libraries have been developed for methods, such as ESI and APCI, used to ionise compounds after LC separation; generally, these types of library are user generated for a specific purpose.

There is one area in which comprehensive databases based on MALDI TOF or electrospray–ion-trap spectra have been built up, and this is in the field of proteomics (James 2000; Kinter, Sherman 2000). The databases built up from MALDI TOF data have been in operation longer than those based on ion-trap data. The standard approach used in conjunction with MALDI TOF is to separate proteins on gel electrophoresis, and thus obtain an approximate p*I* value (the pH of the isoelectric point of the protein), which can also be used in identification. The protein is cut from the gel, a proteolytic digest (most often using trypsin) is carried out and the peptide fragments generated are analysed using MALDI TOF. The pattern of peptides obtained can be matched against one of a number of databases by using a linking program, such as ProteinProspector (www.prospector.ucst.edu). The linking program searches one of the large protein-sequence databases, such as SwissProt, for the proteins that contain amino acid sequences most closely matching those of the unknown. Additional information can be obtained by varying the laser power during the ionisation step or by post-source decay using the reflector to produce additional fragmentation of the peptides in the digest, and this information can be used to further refine the database search. A similar process is used for the ion-trap instruments using ESI. In this case the peptide digest can be separated by HPLC prior to its introduction into the mass spectrometer. A program such as TurboSEQUEST can be used to search protein sequence databases and MS-MS spectra can be obtained from the peptides in the digest to refine the search.

CHAPTER

38 Liquid Chromatography–Mass Spectrometry

HH Maurer

Introduction

In the 1980s, hyphenation of gas chromatography with mass spectrometry (GC-MS) had become the gold standard in all fields of analytical toxicology owing to its high identification and separation power combined with high sensitivity. It took more than 30 years to hyphenate liquid chromatography with mass spectrometry (LC-MS) for routine application. LC-MS techniques are indispensable for determination of thermolabile, polar and/or higher-molecular-weight compounds such as phase II metabolites, peptides or proteins. In contrast to GC, LC provides more flexibility in selection of stationary and mobile phases, resulting in better separation for particular analyte types. In the early 1990s, several groups started working with LC-MS in analytical toxicology. Some of them began with the transfer of existing LC–ultraviolet (LC-UV) or GC-MS procedures so that the scientific and/or practical progress was rather limited owing to problems with the new technique at that time such as rather poor spectral information (in a single-stage apparatus), the poor reproducibility of the ionisation and the susceptibility to matrix effects (ion suppression or enhancements).

In recent years, the apparatus has been improved and analysts have learned to more or less overcome the disadvantages and challenges of LC-MS analysis (Maurer 2006, 2007, 2009, 2010). For example, interfering matrix effects can often be avoided by suitable specimen clean-up, chromatographic changes, reagent modifications and effective internal standardisation. However, possible matrix effects must always be looked for during method development and validation. Furthermore, overlapping compounds such as isotope-labelled internal standards (Remane *et al.* 2010c) or analytes in multi-analyte procedures (Remane *et al.* 2010b) may lead to ion suppression or enhancement. After 15 years, single-stage or tandem LC-MS (LC-MS(-MS)) with electrospray ionisation (ESI) or atmospheric-pressure chemical ionisation (APCI) have now definitively left the development stage and are becoming increasingly standard techniques in routine toxicological analysis, especially for quantification of identified analytes (Maurer 2004, 2006, 2009, 2010). They have even opened the door to new fields of toxicological interpretation and expertise such as in the sensitive detection of chemical agents in hair in the case of drug-facilitated crimes (Kintz 2007) or the determination of chronic alcohol consumption by the analysis of ethanol conjugates in plasma, urine, or hair (see Chapter 19).

When searching for LC-MS(-MS) procedures relevant to clinical and forensic toxicology, case reports are often found with a more or less detailed description of more or less validated procedures. Here, the case information is often more useful than the analytical data. Furthermore, many toxicologists or pharmaceutical companies have published single-analyte procedures for a particular purpose, e.g. a pharmacokinetic study. However, in routine toxicological work, multi-analyte procedures for screening and/or quantification are the most useful because they allow analysis of several important compounds with a single injection, saving time and resources. Even if single analytes only have to be determined, as is often the case in clinical and forensic toxicology, such procedures provide a reliable quantification.

Sample preparation for LC-MS

At the beginning of the LC-MS era, it was thought that (extensive) sample preparation would no longer be necessary for bioanalysis by LC-MS, since LC would allow aqueous biofluids to be injected either directly or after simple deproteinisation. A series of papers describing matrix effects as a cause of invalid LC-MS analysis led to the conclusion that sample preparation was essential. With the increasing sensitivity and robustness of the apparatus, direct injection, e.g. of diluted urine for testing for drugs of abuse (Andersson *et al.* 2008) or for monitoring of psychotropic drugs in plasma after deproteinisation (Kirchherr, Kuhn-Velten 2006), was described. Such approaches enable a very high throughput of samples.

Nevertheless, for most of the currently used LC-MS procedures, a comprehensive preparative work-up of samples is needed to increase analytical sensitivity or to reduce matrix effects. All types of common sample preparation methods such as liquid-liquid extraction (LLE), solid-phase extraction (SPE) or solid-phase microextraction (SPME) are used (Maurer 2007, 2009; Wille, Lambert 2007). Simple and fast LLE procedures are a good compromise between protein precipitation and laborious SPE and are used, for example, in multi-analyte quantification procedures (Wille, Lambert 2007; Maurer 2007, 2009; Remane *et al.* 2010a). Derivatisations that are often mandatory for GC-MS analyses are only needed in LC-MS if a particular functional group, e.g. in a metabolite, has to be confirmed. For example, Philipp and co-workers could distinguish between a carboxy and a phenol group in paynantheine metabolites by selective methylation (Philipp *et al.* 2010).

Separation systems for LC-MS

One major advantage of high performance liquid chromatography (HPLC) over GC was the flexibility in separation systems. All types of analyte (non-polar/polar, small/large molecular weight) can be separated using different stationary phases (e.g. C_{2-18} reversed phase, normal or chiral phases) and mobile phases with different buffers, solvents and modifiers in isocratic or gradient elution (for details see Chapter 41) For LC-MS using atmospheric-pressure ionisation techniques (e.g. ESI, APCI), only a limited selection of mobile phases, namely volatile phases, is suitable. In most cases, water, methanol, acetonitrile and the volatile buffers ammonium acetate or formate are used (Maurer 2007, 2009). With regard to stationary phases, a much better separation can be achieved using monolithic columns with porous channels rather than beads or so-called ultra-high pressure LC (UHPLC) systems using smaller particles and higher pressures. UHPLC is particularly advantageous for multi-analyte procedures with numerous analytes (e.g. Remane *et al.* 2010a).

Ionisation and detection modes for LC-MS

At the moment, the electrospray techniques ESI or APCI are most often used in routine applications. The principles of the ionisation and detection modes are described in Chapter 37. The question of whether ESI or APCI is more suitable for developing a new procedure cannot be answered in general terms and each must be tried for any application. APCI is more appropriate for apolar analytes. The sensitivity depends on the analyte structure and the apparatus type used and should always be evaluated. Dams and co-workers found that both ESI and APCI exhibited matrix effects, with ESI being much more susceptible than APCI (Dams *et al.* 2003). Remane and co-workers confirmed this result when studying the influence of co-eluting standards or analytes (Remane *et al.* 2010b, 2010c). Finally, it was shown that the accuracy and precision data of a plasma quantification method for toxic alkaloids were very similar when using LC-APCI-MS or LC-ESI-MS(-MS) (Beyer *et al.* 2007).

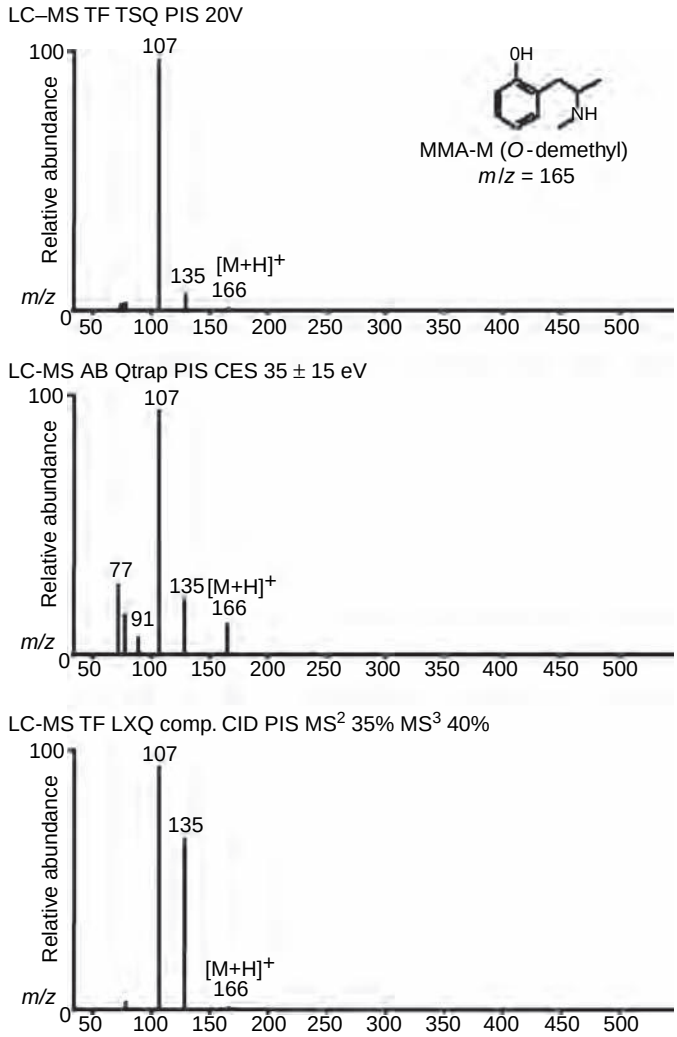

Figure 38.1 Product ion spectra of the *O*-demethyl metabolite of 2-methoxymetamfetamine (MMA) recorded using a QQQ (upper part), a QTrap (middle) and an LIT (lower part). Apparatus used: ThermoFisher (TF) TSQ; Applied Biosystems (AB) QTrap with given collision energy spread (CES); TF LXQ; composite spectrum (comp. CID) of 35% MS^2 plus 40% MS^3.

In contrast to the well-established ionisation techniques, the development of mass analysers such as the quadrupole (Q), ion trap (IT), or the high resolution (HR) time-of-flight (TOF) or Orbitrap (OT) analysers is still active. Besides single quadrupoles or TOF instruments, equipment is available that allows fragmentation to 2 (tandem MS) or *n* stages, such as triple quadrupoles (QQQ), TOFs (QTOF), IT or hybrids of quadrupoles with ITs (QTrap). They provide differing powers for quantification or for screening and identification. On the one hand, such variability is advantageous but, on the other, selection of the best apparatus for a particular application or even for all possible applications may be difficult if only one or two apparatus types can be purchased or are available. If the intention is to use LC-MS for library-based screening and identification, the major problem is the dependency of the reference spectra on the type of apparatus. In the beginning, the reproducibility of spectra was poor between different types of apparatus. Moreover, reproducibility was poor within the same type of apparatus owing to variations in the collision-induced dissociation that occurred in single-stage equipment. Only strict standardisation permitted the use of such libraries, which were mostly in-house. The reproducibility of product ion spectra in tandem MS is much better within the same apparatus family, but is still not sufficient between different analyser types (e.g. QQQ vs linear IT (LIT)).

The only ways of overcoming this limitation in future will be strict standardisation of the parameters (Hopley *et al.* 2008) and the use of sophisticated search algorithms (Mylonas *et al.* 2009). In principle, this should be possible because all fragmentation types break the molecules more or less at the same unstable bonds, but with different abundances. Figure 38.1 shows, for example, product ion spectra (PIS) of the *O*-demethyl metabolite of the doping agent 2-methoxymetamfetamine (MMA) recorded using a QQQ (ThermoFisher, TF, TSQ; upper part), a QTrap (Applied Biosystems, AB; collision energy spread, CES; middle) and an LIT (TF LXQ; composite spectrum of MS^2 and MS^3; lower part). As can be seen, the abundance varies, but most ions are present in all spectra. Similar effects are depicted in Figure 38.2 for the corresponding glucuronide. However, we are still far away from one spectral format for all types of LC-MS apparatus, as established 30 years ago for electron ionisation GC-MS spectra that can be used for Q, IT and TOF analysers coupled to GC (NIST/EPA/NIH 2008; Maurer, Peters 2006; Maurer *et al.* 2011) and are given in the monographs for individual drugs in this book.

The identification power of the different LC-MS screening and identification approaches should always be borne in mind because false-positive or false-negative results may lead to severe consequences. According to the European Union Commission Decision concerning the performance of analytical methods and the interpretation of results (European Communities 2002), identification points (IPs) are a useful criterion for assessing the identification power. Thus, single stage GC-MS or LC-MS provides a single IP per monitored ion, MS-MS methods provide 4 IPs for one precursor and two daughter ions and 5 points for two precursors and one daughter ion each, and MS-MS-MS provides 5.5

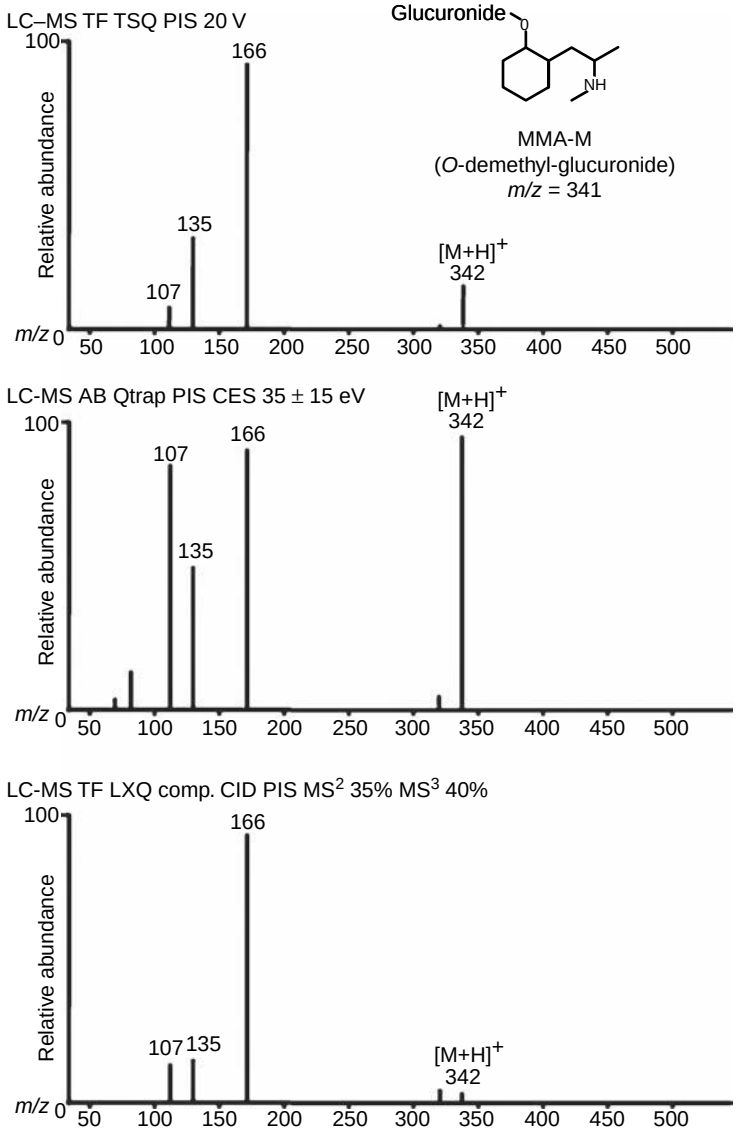

Figure 38.2 Production spectra of the glucuronide of *O*-demethyl 2-methoxymetamfetamine (MMA) recorded using a QQQ (upper part), a QTrap (middle) and an LIT (lower part). Apparatus: see Figure 38.1.

points for one precursor, one daughter and two granddaughter ions. High-resolution analysers provide double the points. Considering this recommendation, screening approaches using selected-ion monitoring (SIM) and multiple-reaction monitoring (MRM) modes are of less selectivity and are thus less reliable, as demonstrated, for example, by Allen (2006). Best identification power provides comparison of full scan spectra or full production ion spectra. The number of IPs depend on the number of ions per spectrum and on the spectral reproducibility.

Screening by LC-MS^n

Most screening procedures focus on multi-target screening rather than on systematic toxicological analysis (STA). This means that they allow a certain number of analytes to be screened for in the SIM or MRM modes, whereas analytes that are not included at the start cannot be detected. Further disadvantages, such as limited identification power, have already been discussed above. For STA, the best GC-MS strategies are based on full-scan MS, reconstructed mass chromatography and identification via library searches, while the best LC-MS strategies are based on tandem MS with a survey scan (MRM) and an enhanced product ion (EPI) scan in an information-dependent acquisition (IDA) mode and identification of the product ion spectra by library search using the authors' EPI spectra libraries (Sauvage *et al.* 2006; Dresen *et al.* 2009). LC-MS(-MS) screening procedures for drugs using a hybrid triple–quadrupole linear ion-trap mass spectrometer (QTrap), were described by the working groups of Marquet and of Weinmann. A survey scan (full scan or MRM) and an EPI scan were recorded in an IDA experiment followed by library-assisted identification using the authors' EPI spectra library. In contrast to reference libraries used for comprehensive GC-MS screening procedures (Maurer *et al.* 2011), not all currently available libraries for LC-MS screening are focused on metabolite spectra. Thus, their applicability for urine screening is limited because most toxicologically relevant compounds are excreted into urine more or less exclusively as phase I and/or II metabolites. Detection of (several) metabolites increases the selectivity, provides confirmation that the substance has passed through the body and, finally, minimises the risk of false-negative LC-MS results that might be caused by ion suppression of the target analyte. Even the risk of false-positive results can be reduced by considering the metabolite patterns. With this in mind the author's group developed a full-scan, metabolite-based screening procedure focused on urine analysis as a complement to other general unknown screening procedures (Wissenbach *et al.* 2010). Other screening procedures have recently been compared (Lynch *et al.* 2010) and reviewed (Maurer 2007, 2009; Peters 2010).

For screening of urine samples, several LC-MS strategies have been developed such as the use of classic MS-MS after extraction or direct

injection of samples or the use of accurate mass measurement with TOF mass analysers. A few years ago, Ojanpera and his colleagues started the development of urine screening procedures based on the enzymatic cleavage of conjugates and mixed-mode SPE; this used a TOF mass analyser based on measurement of the accurate mass and retention times and their comparison with reference data. They relied on a large target database of exact masses of reference drugs and their metabolites. Using liquid chromatography–Fourier transform mass spectrometry (LC-FTMS), they were able to confirm the findings with higher mass accuracy than that provided by the LC-TOF. Mass spectral identification was based on matching the measured accurate mass and isotopic pattern of a sample component with those in the database using newly developed software for automated reporting of findings in an easily interpretable form. However, it must be remembered that there are several drugs with the same empirical formula and molecular mass (e.g. morphine and hydromorphone) and that their metabolites (e.g. *N*- or *O*-demethyl metabolites) also have the same masses. This means that, in many cases, other procedures are needed for confirmation. This limitation can also be reduced by using collision-induced dissociation, which could result in some fragments that may have distinguishing isomers (Lee *et al.* 2009; Tyrkko *et al.* 2010).

A strategy for rapid and selective testing for drugs of abuse in urine as an alternative to immunoassay prescreening has been developed by the working group of Beck (e.g. Andersson *et al.* 2008). They reported multi-analyte screening methods for directly injected, diluted urine samples that were based on classic triple–quadrupole LC-MS(-MS) operated in the MRM mode. However, as such methods initially require a selection of precursor ions, the methods are limited to the target analytes. Positive screening results are considered as preliminary and are subjected to confirmation analysis. A major drawback of LC-MS procedures with direct injection of urine is the susceptibility to matrix effects. Meanwhile, corresponding studies have been performed that showed no serious matrix effects if the analytes were separated from the solvent front. Therefore, it can be concluded that this strategy may in future replace the common immunoassay prescreening approach for drugs of abuse in urine, at least in specialised laboratories with a high sample throughput where screening by LC-MS may be cost-effective.

Quantification by LC-MS^n

In analytical toxicology, quantification of compounds in urine is of less importance than in blood, because the concentrations may vary considerably depending on the hydration status of the body and the urinary pH. Moreover, compounds in urine have already been eliminated from the body, so their concentrations are of little relevance with respect to any toxic effects. Nevertheless, detection procedures are frequently developed as quantitative assays, particularly for confirmation of immunoassay results and/or for determinations that must meet designated cut-off values.

Numerous papers have been published over recent years describing the single- or multi-analyte quantification of therapeutic substances, drugs of abuse or pesticides in blood and other biosamples, mostly using QQQ in the MRM mode. Details of these developments can be found in recent review articles (Kraemer, Paul 2007; Maurer 2007, 2009; Peters 2010). The majority of these methods have targeted classic drugs of abuse and therapeutic drugs that have abuse potential or are relevant in the context of driving under the influence of drugs. Others have covered diuretics, β-blockers, stimulants, opioids, steroids, HIV medication, β-adrenergic drugs, calcium-channel antagonists, angiotensin II-receptor antagonists, antiarrhythmic drugs, muscle relaxants, antidepressants (including selective serotonin reuptake inhibitors), low-dose antipsychotics, organophosphorus pesticides and toxic plant alkaloids.

In the following section only general aspects of method development are discussed. Principles of method development and validation are described in detail in Chapter 20. An important point in early method development is the choice of appropriate internal standards (ISs). These can compensate for variability arising from sample preparation (e.g. because of differences between batches of SPE columns, chromatography, or even ion suppression/enhancement) and thus improve accuracy and precision data. As in any MS-based analytical method, a stable-isotope-labelled analogue of the analyte is an ideal IS. However, mutual ion suppression/enhancement of analytes and their stable-isotope-labelled IS has been reported. Even though this phenomenon does not affect quantification, at least as long as certain conditions are fulfilled, additional matrix effects may lead to a change of response ratios (analyte vs IS) and thus affect quantification negatively. More serious problems have to be expected when no stable-isotope-labelled analyte is available as IS, because, in such cases, ion-suppression effects on analytes and alternative IS might differ considerably. At this point it must be stressed that, if no stable-isotope-labelled IS of the analyte is available and an alternative IS must be selected, it is essential to avoid choosing a therapeutic drug for this purpose, not least in analytical toxicology. In this field, it is never possible to exclude that the patient or defendant to be monitored has taken the chosen drug. In such cases, the peak area of the IS would be overestimated, leading to underestimation of the actual analyte concentration. Therefore, if no deuterated analogue of a specific drug is available, the author recommends selecting a suitable IS from the pool of available deuterated compounds. Nowadays deuterated substances are available with a large variety of structures and with different physicochemical properties. This strategy has been used successfully in the author's laboratory for a number of GC-MS and LC-MS assays for various classes of drugs, all of which employed trimipramine-d_3 as IS. The effects of non-deuterated analytes on their respective deuterated analogues were studied with respect to concentration of the non-deuterated compounds and ionisation mode (Remane *et al.* 2010c). Again, APCI was less affected than ESI. While this may not be a problem when using the deuterated compound as IS for the respective non-deuterated analyte, it may cause serious quantification bias when the deuterated compound is also used as IS for compounds other than the non-deuterated analyte. Therefore, such ion suppression/enhancement studies are essential in such situations and the use of APCI is recommended unless there are other reasons against this, such as a large variability of ionisation.

Another important point in routine toxicological work concerns the quantification of analytes not in a large series of samples but in single cases, particularly in emergency hospital toxicology. The multi-analyte procedure concept enables the laboratory to have validated methods for a large variety of drugs. However, full calibration for a single analysis is very laborious, time-consuming and expensive. Therefore, one-point (linear through zero) calibration is often used as a compromise. Theoretically, this is applicable when the concentration–response function is linear and the y intercept is negligibly small. Considering its widespread use, surprisingly few studies have been dedicated to systematic evaluation of its applicability and performance in comparison with other calibration approaches. The most common approach is to measure the response of a single calibrator and then to calculate the concentrations of unknown samples via their responses in relation to that of the calibrator. Another strategy is very similar, but involves adjusting the absolute amount of analyte in the sample to closely match that in the calibrator by varying the amount of sample analysed. A third strategy involves transformation of exponential concentration–response functions to linear through zero functions allowing one-point calibration. To assess the feasibility of one-point calibration in multi-analyte procedures, Peters and Maurer (2007) used retrospective analysis to evaluate the validation data from six bioanalytical multi-analyte procedures. The results showed that the best one-point calibration results were obtained with the calibrator close to the centre of the full calibration range with which acceptance criteria for bias and precision were fulfilled for the majority of analytes. This study showed that, after full validation of a new approach, the one-point calibration performance should be tested statistically. If acceptable, one-point calibration can be a feasible alternative to full calibration.

Validation of LC-MS methods

Despite the maturity of the technique itself, individual LC-MS procedures must be validated before use to ensure their reliability and applicability for the intended purpose. This is of particular importance in

forensic and clinical toxicology and doping control, because reliable analytical data are a prerequisite for the correct interpretation of toxicological findings. Unreliable results might not only be contested in court but could also lead to unjustified legal consequences for the defendant or to inappropriate treatment of the patient. The importance of validation, at least for routine analytical methods, can never, therefore, be overestimated. This is especially true in the context of quality management and accreditation, which have become matters of increasing importance in analytical toxicology in recent years. At the very least the following parameters should be evaluated: selectivity, calibration model (linearity), stability, accuracy (bias), precision (repeatability, intermediate precision) and the lower limit of quantification. Additional parameters that may be relevant include limit of detection, recovery, reproducibility and ruggedness (robustness). Details can be found in Chapter 20.

Pitfalls and quality control

As mentioned previously, several pitfalls of the technique must be considered, such as matrix effects, analyte carryover via LC injection systems, poor reproducibility of spectra and limited selectivity in MRM approaches. Prevention strategies have been described for LC-tandem-MS using the selected reaction monitoring (SRM) mode (Sauvage *et al.* 2008). In this context it is important to recognise that even extensive matrix effects may be acceptable as long as they are reproducible between matrix batches and as long as the sensitivity of the method remains acceptable.

Besides suitable method validation, quality control procedures are essential in routine work. This is especially true in the context of quality management and accreditation, which have become matters of increasing relevance in analytical toxicology in recent years. A daily performance check is obligatory and should consist first of the analysis of a standard drug solution to check both the chromatographic and the MS components of the system. Figure 38.3 shows typical linear ion-trap mass analyser-merged mass chromatograms (for the chromatographic conditions see Wissenbach *et al.* 2010) with the given ions of a methanolic solution of a mixture of drugs with different retention times, polarities and molecular weights (morphine, nalorphine, codeine, strychnine, quinine, diphenhydramine, haloperidol, methaqualone and diazepam). For the system's performance to be acceptable, chromatographic separation should be obtained for compounds 3 and 4, and for compounds 8 and 9. Furthermore, symmetrical peak shapes should be obtained for at least compounds 7 and 9. Additionally, compound 1 should be clearly separated from the injection peak. This test mixture has proved suitable over the years in the author's laboratory for both GC-MS and LC-MS. Further checks are recommended by analysing blank samples between any analysis and control samples within all quantitative runs.

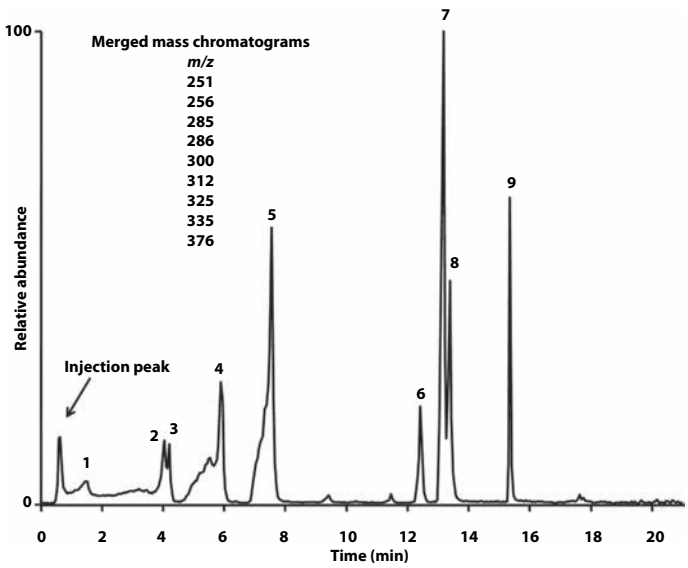

Figure 38.3 Typical linear ion-trap mass analyser-merged mass chromatograms with the given ions of a methanolic solution of drugs with different retention times, polarities and molecular weights: 1, morphine; 2, nalorphine; 3, codeine; 4, strychnine; 5, quinine; 6, diphenhydramine; 7, haloperidol; 8, methaqualone; 9, diazepam. (For chromatographic conditions see Wissenbach *et al.* (2010).)

Conclusions and perspectives

Liquid chromatography coupled with low- or high-resolution mass spectrometry is now an indispensable tool in analytical toxicology. It provides the high selectivity, sensitivity and universality needed for screening, identification and quantification of drugs, poisons and/or their metabolites in biological samples. LC-MS is a must when determining thermolabile (e.g. antiretroviral drugs (Koal *et al.* 2005)), polar (e.g. risperidone (Kratzsch *et al.* 2003)) or phase II metabolites (Ketola, Hakala 2010)) and/or higher-molecular-weight compounds such as peptides or proteins (e.g. insulins (Thomas *et al.* 2009)). Some limitations and pitfalls still exist and should always be considered when applying the technique, although it is likely that future developments will help to overcome them. While LC-MS(-MS) is the method of choice for target screening and quantification, low- and high-resolution linear ion traps are the most powerful technique for more comprehensive screening. High-resolution TOF analysers can also be useful if supplementary fragmentation increases the identification power. Finally, matrix-assisted laser desorption ionisation (MALDI, see Chapter 37) looks promising for increasing sample throughput in the routine analysis of small molecules such as most drugs or in postmortem toxicology by using direct analysis of tissues.

CHAPTER

39 Thin-layer Chromatography

CF Poole

Thin-layer chromatography (TLC) is a widely used technique for the separation and identification of drugs. It is equally applicable to drugs in their pure state, to those extracted from pharmaceutical formulations, to illicitly manufactured materials, and to biological samples. TLC as we know it today was established in the 1950s with the introduction of standardised procedures that led to improved separation performance and reproducibility, and paved the way for its commercialisation and an increase in the number of published applications. The 1970s saw the introduction of fine-particle layers and associated instrumentation required for their correct use. In this form, TLC became known as high performance TLC, instrumental TLC or modern TLC to distinguish it from its parent, now generally referred to as conventional TLC. High performance TLC has not displaced conventional TLC from laboratory studies and the two approaches coexist today because of their complementary features (Table 39.1). Conventional TLC provides a quick, inexpensive and portable method for qualitative analysis. It requires minimal and readily available instrumentation and uses easily learned experimental techniques. High performance TLC is characterised by the use of kinetically optimised layers for faster and more efficient separations, takes advantage of a wider range of sorbent chemistries to optimise selectivity and requires the use of instrumentation for convenient (automated) sample application, development and detection. High performance TLC provides accurate and precise quantitative results based on *in situ* measurements and a record of the separation in the form of a chromatogram, such as the example in Fig. 39.1. While all modern laboratories are capable of drug analysis by conventional TLC, only those laboratories equipped with the necessary instrumentation for high performance TLC have that option.

In the basic TLC experiment, the sample is applied to the layer as a spot or band near the bottom edge of the layer. The separation is carried out in a closed chamber either by contacting the bottom edge of the layer with the mobile phase, which advances through the layer by capillary forces, or by the mobile phase being forced to move through the layer at a controlled velocity by an external pressure source or centrifugal force. A separation of the sample results from the different rates of migration of the sample components in the direction travelled by the mobile phase. After development and evaporation of the mobile phase, the sample components are separated in space, their position and quantity being determined by visual evaluation or *in situ* scanning densitometry aided by the formation of easily detected derivatives by post-chromatographic chemical reactions, as required.

Separations by column liquid chromatography (HPLC) and TLC occur by essentially the same physical process. The two techniques are frequently considered as competitors, when it would be more realistic to consider them as complementary. The attributes of TLC that support its coexistence as a complementary technique to HPLC are summarised in Table 39.2. On the basis of these attributes, TLC methods are most effective for the low-cost analysis of a large number of samples (e.g. drug screening in biological fluids and tissues, determination of the botanical origin and potency of traditional herbal medicines, stability testing and content uniformity testing), for the rapid analysis of samples that require minimal sample clean-up, or where TLC allows a reduction in the number of sample preparation steps (e.g. analysis of samples containing components that remain sorbed to the stationary phase or contain suspended microparticles). TLC is also preferred for the analysis of substances with poor detection characteristics that require post-chromatographic chemical treatment for detection. In other cases, HPLC methods are generally preferred, particularly if a large number of theoretical plates are necessary for a separation, for separations by size-exclusion and ion-exchange chromatography, and for trace analysis using selective detectors unavailable for TLC.

Stationary phases

Conventional TLC plates can be prepared in the laboratory by standardised methods, but reproducible layer preparation is easier to achieve in a manufacturing setting and few laboratories prepare their own plates today. Precoated plates for high performance, conventional and preparative TLC are available in a range of sizes and different layer thickness, supported on glass, aluminium or plastic backing sheets. To impart the desired mechanical stability and abrasion resistance to the layer a binder, such as poly(vinyl alcohol), poly(vinyl pyrrolidone), gypsum or starch in amounts from 0.1% to 10% (w/w) is incorporated into the layer. An ultraviolet (UV) indicator, such as manganese-activated zinc silicate of a similar particle size to the sorbent, may be added to the layer to visualise separated samples by fluorescence quenching. TLC plates with a narrow preadsorbent zone located along one edge of the layer are available to aid manual sample application.

Silica gel is the most important stationary phase for TLC, with other inorganic oxide adsorbents, such as alumina, kieselguhr (a silica gel of low surface area) and Florisil (a synthetic magnesium silicate), of minor importance. Most silica gel sorbents have an average pore size of 6 nm and are designed for the separation of small molecules (relative molecular mass <700). The chromatographic properties of the inorganic oxide adsorbents depend on their surface chemistry and specific surface area. For silica gel, silanol groups are the dominant adsorption sites. The complementary sample properties that govern retention are the number and type of functional groups and their spatial location (Fig. 39.2). The influence of functional group properties on selectivity is illustrated in Fig. 39.1 for the separation of ethynyl steroids. The steroids with phenolic groups are the most strongly retained, followed by hydroxyl groups, and then ketone and ester groups. Subtle separation differences through steric hindrance at a functional group and differences in ring conformations are also seen, which allow the separation of steroids with very similar chemical properties.

Chemically bonded layers are prepared from silica gel by reaction with various organosilane reagents to form siloxane bonds, with some of the silanol groups present on the silica surface (Table 39.3). Reversed-phase alkylsiloxane-bonded layers with a high level of surface bonding cannot be used with mobile phases that contain a significant amount of water ($>30\%$ v/v) because of the inadequate mobile phase velocity generated by capillary forces. Water compatibility for alkylsiloxane-bonded layers is achieved by increasing the particle size, using a reproducible although lower degree of silanisation, and by using modified binders. These layers are referred to as water wettable and are used for all types of reversed-phase separations, while layers with a high degree of silanisation are used predominantly with non-aqueous mobile phases. Alkylsiloxane-bonded phases are used primarily (but not exclusively) for the separation of water-soluble polar drugs and weak acids and bases after ion suppression (buffered mobile phase) or ion-pair formation. Water compatibility is not a problem for polar chemically bonded phases, which can be used for both normal and reversed-phase

Table 39.1 Characteristic properties of silica gel precoated TLC layers

Parameter	*High performance TLC*	*TLC*
Plate dimensions (cm^2)	10×10	20×20
Layer thickness (mm)	0.1 or 0.2	0.1–0.25
Starting spot diameter (mm)	1–2	3–6
Diameter of separated spots (mm)	2–6	6–15
Solvent front migration distance (cm)	3–6	10–15
Time for development (capillary flow) (min)	3–20	20–200
Detection limits[a]		
Absorption (ng)	0.1–0.5	1–5
Fluorescence (pg)	5–10	50–100
Nominal particle size range (μm)	3–7	5–20
Apparent particle size (μm)[b]	5–7	8–10
Minimum plate height (μm)	22–25	35–45
Optimum velocity (mm/s)	0.3–0.5	0.2–0.5
Porosity		
Total	0.65–0.70	0.65–0.75
Inter-particle	0.35–0.45	0.35–0.45
Intra-particle	0.28	0.28

[a]For drugs with favourable detection properties.
[b]Determined by chromatographic measurements. Precoated TLC layers are prepared from silica gel with a narrower particle size range than typical bulk materials available for self-made layers.

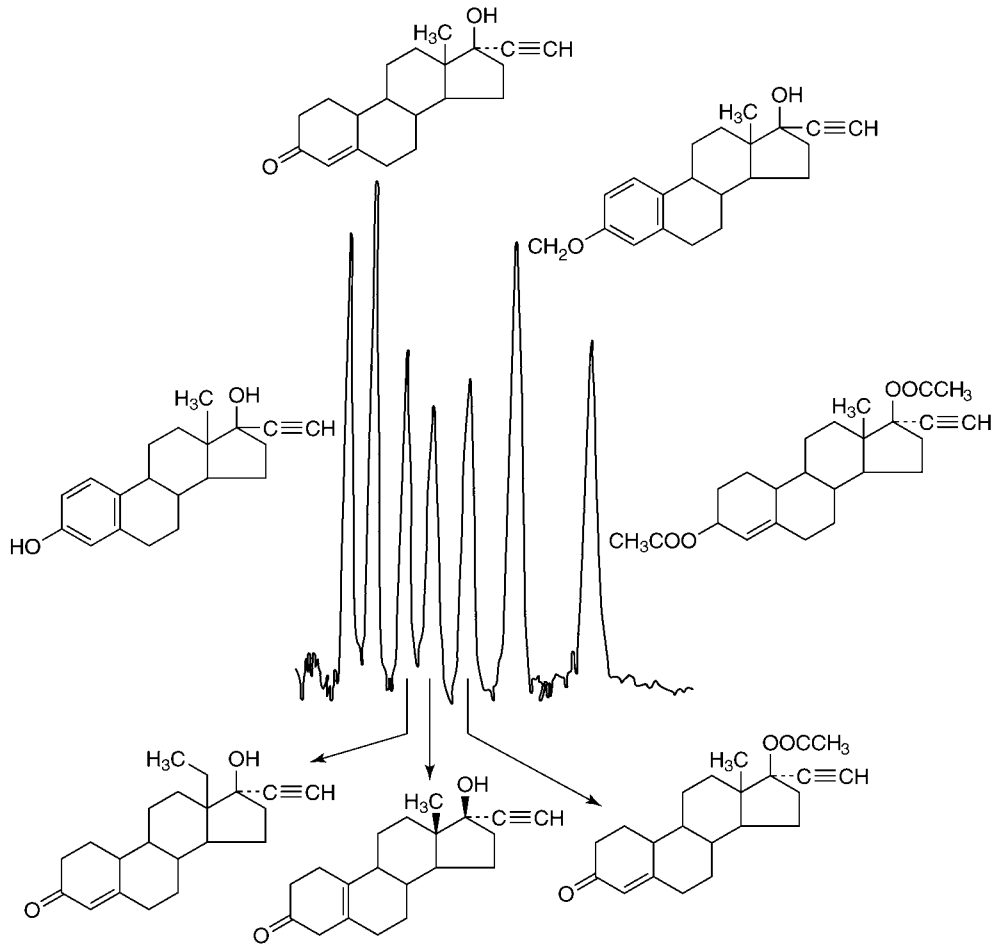

Figure 39.1 Separation of ethynyl steroids (birth-control pill components) by high performance TLC. Two 15 min developments with the mobile phase hexane–chloroform–carbon tetrachloride–ethanol (7 : 18 : 22 : 1) on a silica gel 60 high performance TLC plate. The chromatogram was recorded by scanning densitometry at 220 nm.

Table 39.2 Attributes of TLC providing the link to contemporary applications in drug analysis

Attribute	*Application*
Separation of samples in parallel	Low-cost analysis and high-throughput screening of samples requiring minimal sample preparation
Disposable stationary phase	Analysis of crude samples (minimising sample preparation requirements)
	Analysis of a single or small number of samples when their composition and/or matrix properties are unknown
	Analysis of samples containing components that remain sorbed to the separation medium or contain suspended microparticles
Static detection	Samples that require post-chromatographic treatment for detection
	Samples that require sequential detection techniques (free of time constraints) for identification or confirmation
Storage device	Separations can be archived
	Separations can be evaluated in different locations or at different times
	Convenient fraction collection for coupled column–layer chromatography
Sample integrity	Total sample occupies the chromatogram, not just that portion of the sample that elutes from the column

separations. For separations that cannot be achieved on silica gel, the polar chemically bonded phases are the most widely used stationary phases. The 3-aminopropylsiloxane-bonded layers can function as a weak anion exchanger for the separation of polyanions with a buffered mobile phase. Cellulose layers provide only weak retention of common drug substances and are used primarily to separate very polar compounds in biochemistry.

TLC has found limited use for the separation of enantiomers. The most widely used approach employs ligand-exchange chromatography on reversed-phase layers impregnated with a solution of copper acetate and (2*S*,4*R*,2*RS*)-*N*-(2-hydroxydodecyl)-4-hydroxyproline. Separations result from stability differences in diastereomeric complexes formed between the drug, copper and the proline selector. Suitable drugs for this application require an amino acid or α-hydroxycarboxylic acid group for complex formation. A more versatile approach to the separation of enantiomeric drug substances by reversed-phase TLC involves the use of chiral selectors, such as cyclodextrins or bovine serum albumin, as mobile phase additives.

Technique

The technique of TLC involves a number of separate steps: preparing the layer; applying the sample; developing the plate; and detecting the separated zones. These steps are described below.

Layer pretreatments

Prior to chromatography it is common practice to prepare the layers for use by any or all of the following steps: washing, conditioning and equilibration. Layers may also be cut to preferred sizes using scissors for plastic- or aluminium-backed plates and diamond or carbide glass-cutting tools for glass-backed plates. Newly consigned precoated layers are invariably contaminated, or quickly become so, because of residual contaminants from the manufacturing process, contact with packaging materials and adsorption of materials from the atmosphere. To remove contaminants, single or double immersion in a polar solvent, such as methanol or propan-2-ol, for about 5 minutes is generally superior to predevelopment with the mobile phase. For trace analysis, sequential immersion and predevelopment may be required to obtain the best results.

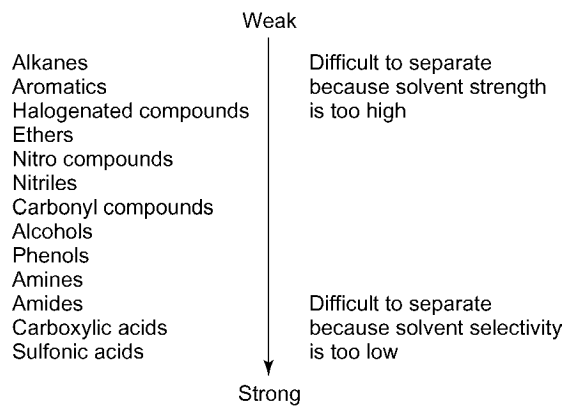

Figure 39.2 General adsorption scale for separations by silica gel TLC.

For inorganic oxide adsorbents the absolute R_f (see later) value and the reproducibility of R_f values depend on the layer activity. The latter is controlled by the adsorption of reagents, most notably water, through the gas phase. Physically adsorbed water can be removed from silica gel layers by heating at about 120°C for 30 min. Afterwards, the plates are stored in a grease-free desiccator over blue silica gel. Heat activation is not normally required for chemically bonded layers. Equilibration of activated layers by exposure to the atmosphere is extremely rapid and the step of layer activation is at times unnecessary. In modern air-conditioned laboratories, layers achieve a consistent level of activity that should provide sufficient reproducibility for most separations. Inorganic oxide layers can be adjusted to a defined activity by exposure to a defined gas phase in an enclosed chamber. Since manipulation in the atmosphere almost certainly readjusts this activity, it is best performed after application of the sample zones in a developing chamber that allows both layer conditioning and development in the same chamber (e.g. a twin-trough or automated development chamber). Atmospheres of different constant relative humidity can be obtained by using solutions of concentrated sulfuric acid or saturated solutions of various salts. Acid or base deactivation can be carried out in a similar manner by exposure to, for example, ammonia or hydrochloric acid fumes.

Sample application

Drugs are applied to TLC plates as spots or bands of minimum size with a homogeneous distribution of material within the starting zone. For high performance layers, with desirable starting spot diameters of about 1.0–2.0 mm, this corresponds to a sample volume of 100–200 nL if applied by a dosimeter (micropipette) or several microlitres if applied by a spray-on device. For conventional TLC plates, sample volumes 5- to 10-fold greater are acceptable. Desirable properties of the sample solution are summarised in Table 39.4. If scanning densitometry is used for detection, manual sample application with hand-held devices is inadequate. For densitometry, the starting position of each spot must be known accurately, which is achieved easily with mechanical devices that operate to a precise grid mechanism. Also, the sample must be applied to the layer without disturbing the surface, something that is nearly impossible to achieve using manual application.

Sample application devices for TLC encompass a wide range of sophistication and automation. The most popular devices for quantitative TLC use the spray-on technique. A controlled nitrogen-atomiser sprays the sample from a syringe or capillary, to form narrow, homogeneous bands on the plate surface. The plate is moved back and forth under the atomiser on a translational stage to apply bands of any length

Table 39.3 Retention properties of silica-based chemically bonded layers

Type of modification	*Functional group*	*Application*[a]
Alkylsiloxane	Si–CH_3	For reversed-phase separations generally, but not exclusively
	Si–C_2H_5	Separation of water-soluble polar organic compounds (RPC)
	Si–C_8H_{17}	Weak acids and bases after ion suppression (RPC)
	Si–$C_{18}H_{37}$	Strong acids and bases by ion-pair mechanism (RPC)
Phenylsiloxane	Si–C_6H_5	Of limited use for drug analysis
Cyanopropylsiloxane	Si–$(CH_2)_3CN$	Useful for both RPC and NPC
		In NPC it exhibits properties similar to a low-capacity silica gel
		In RPC it exhibits properties similar to short-chain alkylsiloxane-bonded layers (it has no selectivity for dipole-type interactions)
Aminopropylsiloxane	Si–$(CH_2)_3NH_2$	Used mainly in NPC and IEC; limited retention in RPC
		Selectively retains compounds by hydrogen-bond interactions in NPC; separation order generally different to that in silica gel
		Functions as a weak anion exchanger in acidic mobile phases (IEC)
Spacer-bonded propanediol	Si–$(CH_2)_3OCH_2$ $CH(OH)CH_2OH$	Used in NPC and RPC, but more useful for NPC because of low retention in RPC
		Polar drugs selectively retained by hydrogen bond and dipole-type interactions in NPC; more hydrogen-bond acidic and less hydrogen-bond basic than aminopropylsiloxane-bonded layers in NPC; more retentive than aminopropylsiloxane-bonded layers in RPC
		Similar retention to short-chain alkylsiloxane-bonded layers, but different selectivity for hydrogen-bonding drugs

[a]IEC, ion-exchange chromatography; NPC, normal-phase chromatography; RPC, reversed-phase chromatography.

between zero (spots) and the maximum transit length of the spray head. For analytical applications, bands are typically 0.5 or 1.0 cm in length. For preparative-scale separations, the band is usually applied for almost the complete length of the plate, leaving a 1 cm section at each edge unused. The rate of sample deposition is also adjustable to accommodate sample solutions of different volatility and viscosity. An advantage of spray-on devices is that different volumes of a single standard solution can be applied for calibration purposes and the standard addition method of quantification is carried out easily by overspraying the sample already applied to the layer with a solution of the standard. Fully automated sample applicators can be programmed to select samples from a rack of vials and deposit fixed volumes of the sample, at a controlled rate, to selected positions on the plate. The applicator automatically rinses itself between sample applications and can spot or band a whole plate with different samples and standards without operator intervention.

Glass microcapillaries for conventional TLC and fixed-volume dosimeters (which consist of a 100 or 200 nL platinum–iridium capillary sealed into a glass support capillary) for high performance TLC are also commonly used for sample application and require less sophisticated instrumentation. The capillary tip is brought into contact with the plate surface using a mechanical device to discharge its volume. A click-stop grid mechanism is used to provide an even spacing of the samples on the layer and a frame of reference for sample location during scanning densitometry.

Layers with a preadsorbent zone (a narrow zone prepared from a silica gel of low surface area with weak retention) simplify some aspects of sample application. This allows relatively large sample volumes or dirty samples to be applied to the preadsorption zone and their reconcentration to a narrow band at the interface between the preadsorbent and separation zones by a short development prior to chromatography. However, since the distribution of the sample may not be even

Table 39.4 Solution requirements for sample application

Property	*Requirements*
Sample solvent	Good solvent for the sample to promote quantitative transfer from the sample application device to the layer
	Low viscosity and sufficiently volatile to be easily evaporated from the layer (dilute viscous samples if possible with a volatile solvent of low viscosity)
	Wet the sorbent layer to provide adequate penetration of the layer by the sample (a potential problem for alkylsiloxane-bonded layers and aqueous sample solutions)
	Weak chromatographic solvent to minimise predevelopment during sample application (ideally, if used as a chromatographic solvent the least-retained sample component should have $R_f < 0.1$)
Aqueous solutions	Dilute if possible with a water-miscible solvent that forms a lower-boiling-point azeotrope
	Apply in small increments or, if spray-on techniques are used, with a slow application rate
	Use layers with a preadsorption zone and refocus the sample prior to development
Suspensions	Filter before attempting sample application
	Otherwise use layers with a preadsorption zone and an extraction solvent that mobilises the components of interest for refocusing

within the band, the quantitative accuracy of densitometric measurements may be lowered using this approach.

Development

The principal development techniques in TLC are linear, circular and anticircular, with the velocity of the mobile phase controlled by capillary forces or forced-flow conditions. In any of these modes continuous or multiple development can be used to extend the application range. Radial development is used rarely for drug analysis and is not considered further. Forced-flow development is not widely used in analytical laboratories and uses sophisticated equipment only recently available as a user-friendly system.

For linear (or normal) development, samples are applied along one edge of the plate and the separation developed for a fixed distance in the direction of the opposite edge. Viewed in the direction of development, the chromatogram consists of a series of compact symmetrical spots of increasing diameter or, if samples are applied as bands, in rectangular zones of increasing width.

In continuous development the mobile phase is allowed to traverse the layer under the influence of capillary forces until it reaches some predetermined position on the plate, at which point it is evaporated continuously. Evaporation of the mobile phase usually occurs at the plate atmospheric boundary using either natural or forced evaporation. Continuous development is used primarily to separate simple mixtures with a short development length and a weaker (more selective solvent) than employed for normal development.

In unidimensional multiple development, the TLC plate is developed for some selected distance, then either the layer or the mobile phase is withdrawn from the developing chamber, and adsorbed solvent evaporated from the layer before repeating the development process. The principal methods of unidimensional multiple development are summarised in Table 39.5. Multiple development provides a very versatile strategy for separating complex mixtures, since the primary experimental variables of development distance and composition of the mobile phase can be changed at any development step, and the number of steps varied to obtain the desired separation. Multiple development provides a higher resolution of complex mixtures than does normal or continuous development, can easily handle samples of a wide polarity range (stepwise gradient development) and, because the separated zones are usually more compact, leads to lower detection limits. Equipment for automated multiple development is commercially available.

For drug mixtures that span a wide retention range, some form of gradient development is required to separate all the components either in a single chromatogram or in separate chromatograms for successive developments. Continuous solvent-composition gradients, as commonly employed in HPLC, are used only rarely in TLC. These require experimental conditions that are less convenient than those for step mobile phase gradients. In addition, step gradients can be constructed easily to mimic a continuous linear gradient, with the added advantage that the zone-refocusing effect can be employed to minimise zone broadening. Gradients of increasing solvent strength are used to fractionate complex mixtures by separating just a few components in each step. Individual drugs are usually identified and quantified at the intermediate steps at which the drugs of interest are separated. In this way, the zone capacity can be made much larger than predicted for a complete separation recorded as a single chromatogram. However, this approach is tedious when many components are of interest and it is difficult to automate. Alternatively, if incremental multiple development is used, the sample can be separated for the shortest distance in the strongest mobile phase, with each subsequent, longer development using mobile phases of decreasing solvent strength. This strategy is most useful when the final separation is to be recorded as a single chromatogram, but it is limited in zone capacity because all the components must be located between the sample origin and the final solvent front. The two approaches for exploiting solvent-strength gradients are thus complementary and selection is made based on the properties of the sample. The decreasing solvent-strength gradient approach is the operating basis of automated multiple-development chambers.

In two-dimensional TLC the sample is spotted at the corner of the layer and developed along one edge of the plate. The solvent is then evaporated, and the plate is rotated through 90° and redeveloped in the orthogonal direction. If the same solvent is used for both developments, the sample is redistributed along a line from the corner at which the plate was spotted to the corner diagonally opposite. In this case, only a small increase in resolution can be anticipated. The realisation of a more

Table 39.5 Multiple development techniques

Method	*Features*
Multiple chromatography	Fixed development length
	Same mobile phase for each development
	The number of developments can be varied
	Drugs that are difficult to separate should be repeatedly developed with solvents that produce low R_f values corresponding to the most selective mobile phase for the separation
	The maximum zone centre separation for two drugs of similar migration properties occurs when the zones have migrated 0.63 of the solvent front migration distance
Incremental multiple development	Variable development length: (a) first development is the shortest (b) each subsequent development is increased by a fixed distance (c) last development length corresponds to the maximum useful development distance
	Same mobile phase for each development
	The number of developments can be varied
	Provides better separations than multiple chromatography
Increasing solvent-strength gradients	Uses incremental multiple development
	Fractionates sample into manageable subsets
	Optimises separation of each subset
	Complete separation of all components is not achieved at any segment in the development sequence
Decreasing solvent-strength gradients	Uses incremental multiple development
	First development employs the strongest solvent with a weaker solvent for each subsequent step
	Final separation recorded as a single chromatogram

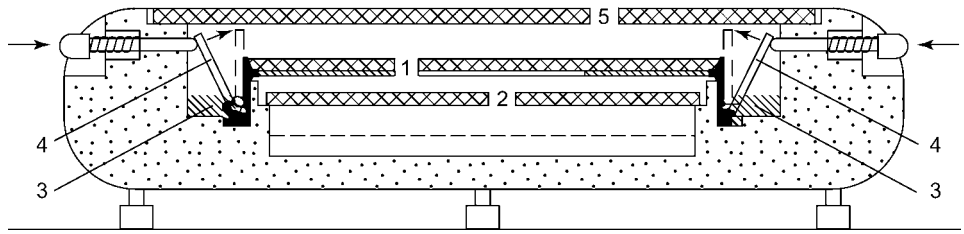

Figure 39.3 Illustration of a horizontal developing chamber (1, TLC plate; 2, removable counter plate to convert the chamber from normal to sandwich configuration; 3, mobile phase reservoirs; 4, glass slide to direct mobile phase flow; 5, glass cover plate). Raising the glass slide (4) to contact the edge of the layer (1) causes the mobile phase to flow through the layer from the solvent reservoir (3). If both glass slides are raised simultaneously, development occurs from both sides to the middle, which allows the simultaneous development of samples applied along the two edges of the layer.

efficient separation system implies that the resolved sample should be distributed over the entire plate surface. This can be achieved only if the selectivity of the separation mechanism is complementary in the orthogonal directions. Using two solvent systems with complementary selectivity is the simplest approach to implement in practice, but it is often only partially successful. In many cases the two solvent systems differ only in their intensity for a given set of properties and are not truly orthogonal. Chemically bonded layers can be used in the reversed-phase and normal-phase modes, and they enable the use of additives and buffers as a further way to adjust selectivity. Two-dimensional TLC remains a largely qualitative method, but advances in imaging analysis techniques permit quantitative evaluation of chromatograms with some restrictions.

Development chambers

The development process in TLC can be carried out in a variety of vessels that differ significantly in design and sophistication. For convenience these are often categorised under the headings of normal (N-chamber) and sandwich (S-chamber), and further subdivided according to whether the internal atmosphere is saturated (N_S or S_S) or unsaturated (N_U or S_U). Sandwich chambers have a depth of gas phase in front of the layer of less than 3 mm, with other chamber designs indicated as normal chambers. Saturation of the vapour phase is achieved by using solvent-saturated pads or filter papers as a chamber lining.

The twin-trough chamber is the most popular of the simplest TLC developing chambers. It consists of a standard rectangular developing tank with a raised, wedge-shaped bottom. The wedged bottom divides the tank into two compartments, so that it is possible either to develop two plates simultaneously or to use one compartment to condition the layer prior to development. The horizontal developing chamber (Fig. 39.3) can be used in either the normal or the sandwich configuration for either conventional edge-to-edge or simultaneous edge-to-centre development. Starting the development simultaneously from opposite edges allows the number of samples separated to be doubled in the same time. The sandwich configuration of the horizontal developing chamber is not suitable for mobile phases that contain volatile acids or bases or large amounts of volatile polar solvents, such as methanol or acetonitrile, because of the restricted access of the saturated vapour phase to the dry portion of the separation layer.

The automated developing chamber increases laboratory productivity and improves the reproducibility of separations by providing precise control of layer conditioning, mobile phase composition, solvent-front migration distance and drying conditions. This chamber can be used in the normal or sandwich configuration with all the operational features preselected on a microprocessor-based control unit and monitored by sensor technology.

The automated multiple-development chamber (Fig. 39.4) provides the necessary conditions and control for automated separations by incremental multiple development with a decreasing solvent-strength gradient. The operating parameters of layer conditioning, solvent-front migration distance, mobile phase composition and drying time for each development, and the total number of developments for the separation, are entered into the computer-based control unit. The complete separation sequence is carried out without further intervention. Each development is typically 3–5 mm longer than the previous one and, depending on the complexity of the desired mobile phase gradient, a total of 10–30 developments is used, which requires 1.5–4.5 hours for completion.

Detection

About 1–10 μg of coloured substances with a quantitative reproducibility rarely better than 10–30% can be detected by visual inspection of a TLC plate. This may be adequate for qualitative methods, but for reliable quantification *in situ* spectrophotometric methods are preferred, as their use is more accurate and far less tedious and time-consuming than excising zones from the layer for determination by conventional solution spectrophotometry. The fluorescence-quenching technique enables

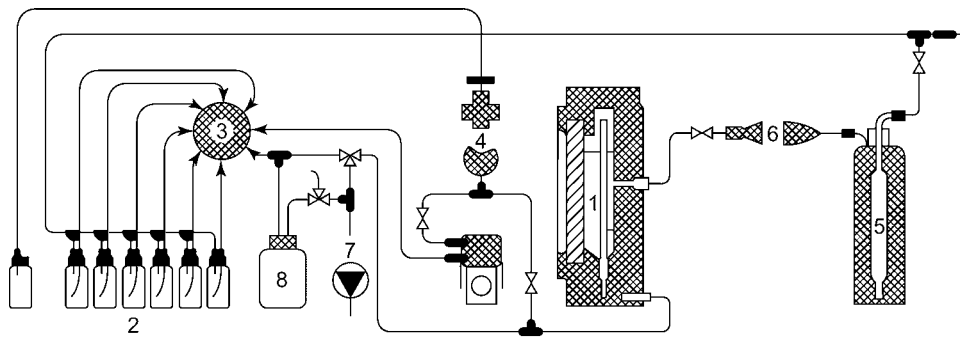

Figure 39.4 Illustration of the automated multiple-development chamber (1, developing chamber; 2, solvent reservoirs; 3, solvent-selection valve; 4, solvent mixer; 5, wash bottle for preparation of the gas phase for layer conditioning; 6, gas phase reservoir; 7, vacuum pump; 8, solvent waste reservoir). All operations of this chamber are managed by a programmable control unit and initiated as time sequences. A sequence starts with a conditioning step in which the vapour phase stored in reservoir (5) is pumped into the developing chamber (1). During conditioning the mobile phase composition is mixed by withdrawing the desired solvents from their storage bottles (2) and transferring the desired volumes to the mixer. At the selected time the mobile phase is pumped into the developing chamber and ascends the layer to the desired height, determined by an optical position monitor. The solvent is then drained from the chamber to waste (8) and the vacuum pump (7) is engaged to remove solvent vapours from the chamber. The next segment of the sequence is then commenced according to the program entered into the control unit, until all the segments are complete and the separation is finished.

visualisation of UV-absorbing drugs on TLC plates that incorporate a fluorescent indicator. The zones of UV-absorbing substance appear dark against the brightly fluorescing background of a lighter colour when the plate is exposed to UV light of short wavelength. The method is not universal, since it requires overlap between the absorption bands of the indicator ($\gamma_{max} \approx 280$ nm with virtually no absorption below 240 nm) and of the drug, but in favourable cases it is a valuable and non-destructive method for zone location.

All optical methods for the quantitative *in situ* evaluation of TLC chromatograms are based upon measuring the difference in optical response between a sample-free region of the layer and regions of the layer in which separated substances are present. Reflectance measurements can be made at any wavelength from the UV to the near infrared (185–2500 nm). The relationship between signal and sample amount in the absorption mode is non-linear, and does not conform to any simple equation. The principal method of quantification in TLC is by calibration using a series of standards that span the concentration range of the drug to be determined. The calibration curve is usually based on a second-order polynomial fit for the calibration standards, with individual samples quantified by interpolation only.

The determination of drugs that fluoresce on TLC plates is fundamentally different from absorption measurements. At low sample concentrations the fluorescence signal F is described adequately by $F = \Phi I_0 \varepsilon b C$, where Φ is the quantum yield, I_0 is the intensity of the excitation source, ε is the molar absorption coefficient, b is the thickness of the TLC layer and C is the sample amount. With the exception of the sample amount, all terms in this expression are constant, or fixed by the experiment, and therefore the fluorescence emission is linearly dependent on the sample amount over two or three orders of magnitude.

Derivatisation reactions

There is a long history of the use of derivatisation reactions in TLC to visualise colourless compounds. Many of these reactions are of a qualitative nature, which was not a problem when TLC was used rarely for quantification. Some of these reactions have been adapted to the demands of quantitative scanning densitometry, as either pre- or post-chromatographic treatments, and new reagents and methods have been added specifically for quantitative measurements in TLC.

In post-chromatographic reactions the reagents can be applied to the layer through the gas phase or by evenly coating the layer with a solution of the reagents. Gas-phase methods are fast and convenient but are restricted by the number of useful reagents. Examples include iodine, ammonia and hydrogen chloride, which are applied by inserting the layer into a tank that contains a saturated atmosphere of the reactive vapour. Spraying or dipping is used to apply reagents in solution to the layer. Spray techniques that use simple atomisers have long been used in TLC, but reagent application by this method is quite difficult to perform well. The homogeneity of the reagent distribution over the layer depends on many factors, such as the droplet size, distance between the spray device and layer, direction of spraying and discharge rate of the reagent. If ventilation of the workspace is inadequate, spray techniques can be a potential health hazard. For quantitative analysis, immersion of the layer into a solution of the reagents in a controlled manner (referred to as dipping) or the use of fully automated spray devices is the preferred technique, since neither relies on manual dexterity and produces superior results in scanning densitometry. Some spray reagents do not make good dipping solutions because they contain solvents that are too aggressive or viscous for convenient application (aqueous concentrated acids and bases, for example). Dipping solutions are usually less concentrated than spray reagents and water is often replaced by an alcohol for adequate permeation of reversed-phase layers. In general, it is necessary to reformulate dipping solutions from earlier recipes for spray solutions and, possibly, to change the reaction conditions. Automated low-volume dipping chambers provide a uniform speed and dwell time for the immersion process, which typically requires only a few seconds, and is long enough to impregnate the layer with solution but not long enough to wash sample components off the layer.

Post-chromatographic derivatisation reactions can be classified as reversible or destructive, depending on the type of interaction between the reagents and separated drugs, and as selective or universal, based on the specificity of the reaction. The most common reversible methods employ iodine vapour, water, fluorescein or pH indicators as visualising reagents. In the iodine vapour method, the dried plate is enclosed in a chamber that contains a few crystals of iodine; components on the chromatogram are stained more rapidly than the background and appear as yellow–brown spots on a light yellow background. Simple removal of the plate from the visualisation chamber to allow the iodine to evaporate can reverse the reaction. Spraying a TLC plate with water reveals hydrophobic compounds as white spots on a translucent background when the water-moistened plate is held against the light. Solutions of pH indicators (e.g. bromocresol green, bromophenol blue) are widely used to detect acidic and basic drugs.

Irreversible methods are more common for quantification and comprise hundreds of reagents based on selective chemistries reduced to standard operations over several decades of use. Some typical examples used in drug identification are summarised in Table 39.6. Reagents that are specific to functional groups or selective for compound classes can be applied to determine low levels of substances in complex matrices such as biological fluids and plant extracts.

Sometimes the fluorescence response for drugs and their derivatives on TLC layers is less than that expected from solution measurements, is observed at different excitation and emission wavelengths than in solution, and may decrease with time. Adsorption onto the sorbent layer provides additional non-radiative pathways for the dissipation of the excitation energy, which is most probably lost as heat to the surroundings and reduces the observed fluorescence signal. The extent of fluorescence quenching often depends on the sorbent used for the separation and is generally more severe for silica gel than for chemically bonded sorbents. In most cases, impregnating the layer with a viscous liquid, such as liquid paraffin or Triton X-100, before evaluating the separation enhances the emission signal (in favourable cases 10- to 200-fold). The general mechanism of fluorescence enhancement is assumed to be dissolution of the sorbed solute with enhancement in response due to the fraction of solute that is transferred to the liquid phase, where fluorescence quenching is less severe. Viscous solvents are employed to minimise zone broadening from diffusion in the liquid phase during the measurement process.

Ready accessibility of the immobilised sample after separation facilitates the application of biological reagents for detection. The inhibition of bioluminescence of the bacterium *Vibrio fischeri* is widely used to identify toxic compounds in complex mixtures. All materials necessary for the assay are available in kit form, so laboratories lacking experience in culture techniques can perform this assay as simply as any other post-chromatographic derivatisation procedure. Image analysers employed for TLC detection are suitable for monitoring the inhibition of bioluminescence. Alternative test species based on immunochemical and cellular reporting probes are in development and this aspect of biological-specific detection in TLC is expected to grow in importance and applications.

Slit-scanning densitometers

Commercial instruments for scanning densitometry usually allow measurements in the reflectance mode by absorbance or fluorescence. Most instruments employ grating monochromators for wavelength selection and spectrum recording in the absorption mode. For fluorescence measurements a filter that transmits the emission wavelength envelope but attenuates the excitation wavelength is placed between the detector and the plate. The separations are scanned at selectable speeds up to about 10 cm/s by mounting the plate on a movable stage controlled by stepping motors. A fixed sample beam is shaped into a rectangular area on the plate surface, through which the plate is transported in the direction of development. Each scan, therefore, represents a lane of length defined by the solvent-front migration distance and width defined by the slit dimensions of the source. Distorted chromatograms can be corrected by track optimisation, in which the sample zones are integrated as if the slit had moved along an optimum track from peak maximum to peak maximum. In modern TLC the relative standard deviation from all errors, instrumental and chromatographic, can be maintained below 2–3%, which makes it a very reliable quantitative tool.

Table 39.6 Some common visualisation reagents for drug identification in TLC

Name	*Reagent*	*Application*
Bratton–Marshall	Dissolve 1 g *N*-(1-naphthyl)ethylenediamine dihydrochloride in 50 mL DMB and 50 mL concentrated HCl	Aromatic and primary amines, sulfonamides, benzodiazepines
Tillman	Dissolve 0.1 g sodium salt of 2,6-dichlorophenol indophenol in 100 mL ethanol	Organic acids
Dragendorff	(a) 17% (w/v) bismuth nitrate in 20% aqueous acetic acid (b) 40% (w/v) potassium iodide in water Mix 4 parts of (a) with 1 part of (b) and 14 parts of water	Alkaloids, miscellaneous, drugs
Fast Black K	0.5% (w/v) aqueous solution of Fast Black K salt	Aliphatic primary and secondary amines, amphetamines and phenols, and heterocyclics
Fluorescamine	(a) 25 mg fluorescamine in 100 mL acetone	Primary amines, sulfonamides
FPN	(a) 0.05 mol/L ferric chloride solution (b) 5% (w/v) perchloric acid Mix 1 part (a) with 50 parts (b)	Phenothiazines, dibenzazepines
Platinic chloride	(a) 5% (w/v) aqueous platinic chloride solution (b) 10% (w/v) aqueous potassium iodide Mix 5 mL of (a) with 45 mL of (b) and dilute to 100 mL with water	Quaternary ammonium compounds, alkaloids
Mandelin	Dissolve 1.2 g ammonium monovandate in 95 mL water and carefully add 5 mL concentrated sulfuric acid	Acid drugs
Marquis	Add 0.2–1.0 mL of 37% formaldehyde solution carefully to 10 mL concentrated sulfuric acid	Alkaloids, β-blockers, amfetamines, phenothiazines
Van Urk	Dissolve 1 g *p*-dimethylaminobenzaldehyde in 100 mL ethanol and add 10 mL concentrated HCl	Indoles, amines, sulfonamides, pesticides

Image analysers

For image analysers, scanning takes place electronically using a combination of a computer with video digitiser, light source, monochromators and appropriate optics to illuminate the plate and focus the image onto a charged-coupled device video camera. The captured images are initialised, stored and transformed by the computer into chromatographic data. Background subtraction and thresholding are common data-transformation processes. Image analysers provide fast data acquisition, simple instrument design and convenient software tools that search and compare sample images. Current instruments lack the sensitivity, wavelength operating range and resolution of mechanical scanners, but the robust market for digital cameras has reduced their cost significantly. They have proved popular for less-demanding tasks, for the development of field-portable instruments and as a replacement for photographic documentation of TLC separations. A major application is in the fingerprinting of herbal drug products for quality control applications.

Other instrumental detection methods

Radioisotope-labelled drugs and their metabolites can be detected selectively with good sensitivity by imaging detectors that use windowless gas-flow proportional counters as detectors. The proportional counter is filled with a mixture of argon and methane gas, which is ionised locally by collision with beta or gamma rays produced by radioactive decay in the sample zones that contain radioisotopes. The local bursts of ionised gas molecules are sensed by a position-sensitive detector and stored in computer memory. These signals are accumulated for quantitative measurements.

Flame ionisation has been used to detect samples of low volatility that lack a chromophore for optical detection. The separation is performed on specially prepared, thin, quartz rods with a surface coating of sorbent attached by sintering. The rods are developed in the normal way, usually held in a support frame that also serves as the scan stage after the rods have been removed from the developing chamber and dried. The rods are moved at a controlled speed through a hydrogen flame and the signal processed in a similar manner to the flame ionisation detector used in gas chromatography. The linear working range of the detector is about 3–30 μg for most substances. There are few reported applications in drug analysis.

Spectroscopic detection of separated zones has moved out of the research laboratory and commercial interfaces are available for infrared, Raman and mass spectrometry. These methods offer the possibility of identification or confirmation of identity for samples in the nanogram to microgram range. These techniques are generally considered semi-quantitative since quantification often requires special calibration procedures – for example, the use of stable isotope standards in mass spectrometry. The most widely used interfaces for mass spectrometry are based on electrospray or atmospheric pressure chemical ionisation with tandem mass spectrometry or matrix-adsorption laser desorption and ionisation (MALDI) with time-of-flight mass spectrometry. Direct sampling interfaces for electrospray ionisation are based on three principles: liquid junction extraction (surface sampling probe); plunger-based extraction devices; and desorption electrospray ionisation (DESI). They differ primarily in extraction efficiency for different combinations of sample and sorbents and whether scanning of the chromatogram is possible while simultaneously recording mass spectra. The recently introduced direct analysis in real time (DART) interface has been shown to be suitable for recording mass spectra directly from TLC layers at atmospheric pressure.

Method development

Selection of the development technique is based on the number of detectable components in the mixture and their polarity range

Table 39.7 Zone capacity calculated or predicted for different conditions in TLC

Development method	*Dimensions*	*Zone capacity*
Predictions from theory		
Capillary-controlled flow	1	<25
Forced flow	1	<80 (up to 150 depending on pressure limit)
Capillary-controlled flow	2	<400
Forced flow	2	Several thousand
Based on experimental observations		
Capillary-controlled flow	1	12–14
Forced flow	1	30–40
Capillary-controlled flow (AMD)	1	30–40
Capillary-controlled flow	2	About 100

(Table 39.7). A single development with capillary-controlled flow may be too difficult or impossible for mixtures that contain more than eight to ten components of interest. In addition, if the range of polarities is too wide, multiple development techniques using mobile-phase gradients are necessary. It is only necessary to separate the components of major interest from each other and from the less important components, which need not be separated individually. Method development is easier if standards for the relevant compounds are available. Standards simplify zone tracking and enable detection characteristics and the possibility of spectroscopic resolution of incompletely separated zones to be established. Standards are also required for calibration, if quantification is required, and to construct spectral libraries for identification purposes. The expected concentration range of relevant compounds may indicate the need for derivatisation to obtain the required detection limits and to increase zone separation of neighbouring compounds if one compound is a minor component with similar migration properties to a major component.

A general guide to the selection of stationary phases for TLC separations is summarised in Fig. 39.5. Silica gel is generally the first choice to separate drugs of low molecular weight that are soluble in moderately polar organic solvents. Reversed-phase chromatography on chemically bonded layers is generally used to separate drugs that are difficult to separate on silica gel because of inadequate retention, inadequate selectivity or zone asymmetry. Ionic compounds and easily ionised compounds are frequently separated by reversed-phase chromatography using buffered mobile phases (weak acids and bases) or ion-pair reagents (strong acids and bases). Only a limited number of stationary phases are available for ion-exchange chromatography, which is not a widely used separation mechanism in TLC.

Since the solvent used for the separation is evaporated prior to detection, a wider range of UV-absorbing solvents is commonly used in TLC than is the case for HPLC. Solvents must be of high purity, since involatile impurities and stabilisers remain sorbed to the layer, which causes problems in the detection step. Multicomponent mobile phases can produce a mobile-phase gradient in the direction of development through demixing. If demixing is complete, zones with sharp boundaries are formed, which separate the chromatogram into sections of different solvent composition and, therefore, selectivity. Demixing effects are less apparent when saturated developing chambers are used. These considerations hinder optimisation strategies based on the composition of the mobile phases as popularised in HPLC.

The selection of a mobile phase to separate simple mixtures need not be difficult and can be arrived at quickly by guided trial-and-error methods. A solvent of the correct strength for a unidimensional development migrates the sample components into the R_f range 0.2–0.8, or thereabouts and, if of the correct selectivity, distributes the sample components evenly throughout this range. Solvent systems can be screened in parallel using several development chambers, as prescribed in the PRISMA model. To select suitable mobile phases, the first experiments are carried out on TLC plates in unsaturated chambers with ten solvents, chosen from the different selectivity groups, indicated by bold type in Table 39.8. After these screening experiments with single solvents, the solvent strength is either reduced or increased so that the substance zones are distributed in the R_f range 0.2–0.8. If the substances migrate into the upper third of the plate, the solvent strength is reduced by dilution with hexane (the strength-adjusting solvent). If the substances remain in the lower third of the plate with the single solvents, the solvent strength is increased by the addition of a strong solvent, such as water or acetic acid. A similar procedure is followed in the reversed-phase mode, except that solvent selection is limited to water-miscible solvents and water is used as the strength-adjusting solvent. From these trial experiments, those solvents that show the best separation are selected for further optimisation in the second part of the model.

Table 39.8 Solvent-strength parameters and selectivity groups for solvents used for separations on silica gel

Selectivity group	*Solvent*
I	*n*-Butyl ether, diisopropyl ether, methyl *t*-butyl ether, **diethyl ether**
II	*n*-Butanol, **propan-2-ol**, propanol, **ethanol**, methanol
III	**Tetrahydrofuran**, pyridine, methoxyethanol, dimethylformamide
IV	**Acetic acid**, formamide
V	**Dichloromethane**, 1,1-dichloroethane
VI	**Ethyl acetate**, methyl ethyl ketone, **dioxane**, acetone, acetonitrile
VII	**Toluene**, benzene, nitrobenzene
VIII	**Chloroform**, dodecafluoroheptanol, water

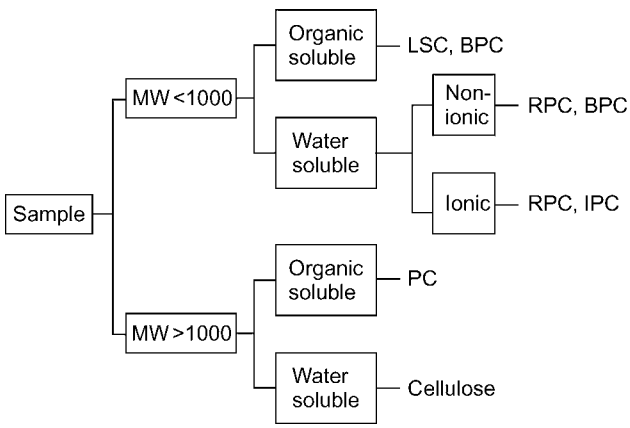

Figure 39.5 Mode selection guide for TLC. LSC, liquid–solid chromatography on an inorganic oxide layer; BPC, liquid–solid chromatography on a chemically bonded layer; RPC, reversed-phase chromatography with a chemically bonded layer and an aqueous organic mobile phase; IPC, ion-pair chromatography with reversed-phase separation conditions; PC, precipitation chromatography used to separate polymers based on solubility differences in a mobile phase solvent gradient.

Between two and five solvents can be selected to construct the PRISMA model for solvent optimisation. Modifiers required to maintain an acceptable zone shape, such as acids and ion-pair reagents, can be added in a low and constant concentration, so that their influence on solvent strength can be neglected. The PRISMA model (Fig. 39.6) is a three-dimensional geometrical design that correlates solvent strength with selectivity of the mobile phase. The model consists of three parts: the base or platform (which represents the modifier), the regular part of the prism with congruent base and top surfaces, and the irregular truncated top prism (frustum). The lengths of the edges of the prism (S_A, S_B, S_C) correspond to the solvent strengths of the neat solvents (A, B, C). Since the selected solvents usually have different solvent strengths, the lengths of the edges of the prism are generally unequal and the top plane of the prism is not parallel and congruous with its base. If the prism is cut parallel to its base at the height of the lowest edge (determined by the solvent strength of the weakest solvent, solvent C in Fig. 39.6), the lower part gives a regular prism, and the top and any planes, which represent weaker solvents diluted with a strength-adjusting solvent, are parallel equilateral triangles. The upper frustum of the model is used for mobile phase optimisation of polar drugs in normal-phase TLC, while the regular part is used to separate moderately polar drugs in normal-phase TLC and all separations by reversed-phase TLC.

For polar compounds, optimisation is always started on the top irregular triangle of the model, either within the triangle, when three solvents are selected, or along one side, for binary mobile phases. Any solvent composition on the face of the triangle can be represented by a three-coordinate selectivity point (P_S), each coordinate corresponding to the volume fraction of the solvent at that position on the triangle (Fig. 39.6). Optimisation is commenced by selecting solvent

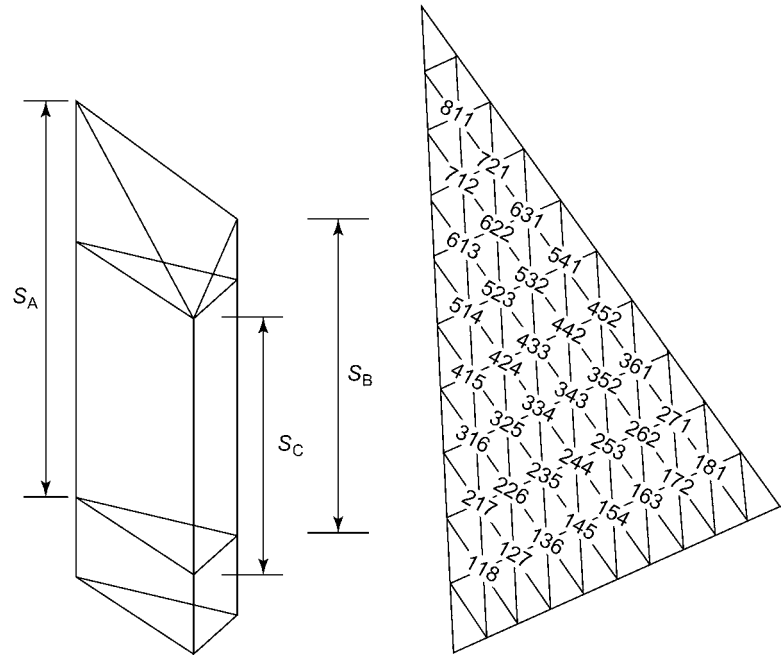

Figure 39.6 The PRISMA mobile phase optimisation model, showing the construction of the prism and the arrangement of selectivity points on the top face or horizontal plane cut through the prism.

combinations that correspond to the centre point $P_S = 333$ and three other points close to the apexes of the triangle $P_S = 811$, 181 and 118. If the separation obtained is insufficient, other selectivity points are tested around the solvent combination that gave the best separation. On changing the selectivity points on the top triangle, the solvent strength changes as well, especially when the solvent strengths of the solvents used to construct the prism are significantly different. The solvent strength should be adjusted with the strength-adjusting solvent as required to maintain the separation in the optimum R_f range. Failure to obtain the beginning of a separation requires that a new prism be constructed, using a different solvent for at least one of the edges.

For reversed-phase TLC, the solvation-parameter model provides a convenient computer-aided approach to method development. Suitable water-miscible solvents with a range of selectivity include methanol, propan-2-ol, 2,2,2-trifluoroethanol, acetonitrile (or dioxane), acetone (or tetrahydrofuran) and dimethylformamide (or pyridine). For optimisation of systems (stationary phases and binary mobile phases), preliminary results in the form of system maps (a continuous plot of the system constants against mobile-phase composition) are required. System maps are a permanent record of the system properties used in all calculations and are available for most common layers and indicated solvents for selectivity optimisation. For each computer-simulated separation a retention map is calculated from the system map and displays the computed R_f values as a continuous function of the binary mobile phase composition. A typical retention map for the computer-predicted separation of analgesics on an octadecylsiloxane-bonded layer with 2,2,2-trifluoroethanol–water mixtures as the mobile phase is shown in Fig. 39.7. Solvent compositions that result in an acceptable zone separation are identified easily by visual inspection. Computer simulation of retention maps allows those systems (defined as a combination of stationary and mobile phases) likely to provide an acceptable separation to be identified before experimental work commences. The agreement between model predicted and experimental R_f values is generally good, typically better than 0.05 R_f units. A mixture-design approach is used to extend this method to ternary solvent mixtures.

For drug mixtures of a wide polarity range, stepwise changes in solvent composition are required to achieve a satisfactory TLC separation. Models to calculate migration distances using incremental multiple development with increasing and decreasing solvent-strength gradients have been described, but are complicated and not widely used. Optimised gradients for automated multiple development are usually arrived at by more pragmatic means. Methods based on a universal gradient commence with methanol, end with hexane, and use either dichloromethane or methyl *t*-butyl ether as the intermediate solvent for separations on silica gel. By scaling and superimposing the chromatogram of the separation above the theoretical gradient profile, those regions of the chromatogram that affect the separation are identified easily. The solvent composition for the initial and final development steps is adjusted to eliminate those portions of the gradient that do not contribute to the separation. The gradient shape is modified to enhance resolution in those regions of the chromatogram that are separated poorly or to minimise regions devoid of sample zones. For moderately complex mixtures this approach is often satisfactory. If, after the above adjustments, the separation is inadequate, it is necessary to identify a

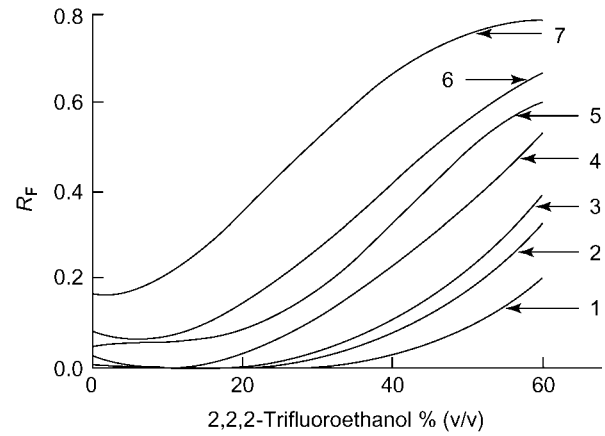

Figure 39.7 Retention map for the simulation of the separation of analgesics by reversed-phase TLC on an octadecylsiloxane-bonded layer with 2,2,2-trifluoroethanol–water as the mobile phase: 1, chlorphenamine (chlorpheniramine); 2, ibuprofen; 3, naproxen; 4, phenacetin; 5, aspirin; 6, caffeine; 7, paracetamol.

more selective solvent for problem regions in the gradient. The PRISMA model can be used at this point to identify more selective solvents to incorporate into the gradient as a replacement for the initial, terminal or base solvent.

Preparative thin-layer chromatography

Preparative TLC is used mainly to purify drugs or to isolate drug metabolites and impurities in amounts of about 1–100 mg for subsequent use as reference materials, structural elucidation, biological activity evaluation and other purposes. Scale up from analytical TLC is achieved by increasing the thickness of the layer (loading capacity increases with the square root of the layer thickness) and by increasing the plate length used for sample application. Pre-coated TLC plates for preparative chromatography vary in size from 20 × 20 cm to 20 × 40 cm and are coated with 0.5–10 mm thick layers, with the most popular thickness being 1.0–2.0 mm. As the average particle size (~25 μm) and size distribution (5–40 μm) are larger for preparative layers, and as sample overload conditions are used commonly in preparative chromatography, invariably inferior separations in a longer time (~1–2 h) are obtained compared with analytical separations. Resolution can be increased significantly by using wedge-shaped, gradient-thickness layers. These layers have a uniform increase in thickness from 0.3 mm at the bottom to 1.7 mm at the top. Sample bands are focused during migration by the negative mobile-phase velocity gradient created by the layer geometry.

Sample application is a critical step in preparative TLC, and if performed improperly can destroy all or part of the separation. The sample, usually as a 5–10% (w/v) solution in a volatile solvent, is applied as a band along one edge of the layer to give a maximum sample load of about 5 mg/cm for each millimetre of layer thickness. Sample loads are usually lower for difficult separations and for cellulose and chemically bonded layers. Any of the automated band applicators for analytical TLC are suitable for sample application in preparative TLC. Manual sample application by syringe or glass pipette must be performed carefully to avoid damaging the layer and producing irregularly shaped migrating zones. A short predevelopment, of about 1 cm with a strong solvent, is often useful to refocus manually applied bands. Preparative layers with a preadsorbent zone are useful for manual sample application, since the focusing mechanism can be used to correct for poor sample-application technique. In all cases, it is important that the sample solvent be evaporated fully from the layer prior to the start of the separation to avoid the formation of distorted separation zones. It is usual to leave a blank margin of 2–3 cm at each vertical edge of the layer to avoid uneven development.

Most of the changes in preparative TLC over the past decade have occurred in the method of development. Conventionally, ascending development in large-volume tanks that hold a number of preparative layers in a rack is used commonly. In laboratories that perform preparative TLC on a regular basis, higher resolution and shorter development times are achieved by using forced-flow development or rotation planar chromatography (accelerated development using centrifugal force). These methods allow conventional development and elution with on-line detection and automated fraction collection to be used.

After development, physical methods of zone detection are used to identify the sample bands of interest. Layers that contain a UV indicator for fluorescence quenching or the adsorption of iodine vapours are useful for this purpose. If a reactive spray reagent is used for visualisation, it should be sprayed on a small strip of the chromatogram only, so as not to contaminate the remainder of the material. Once the bands of interest are located, the zones are scraped off the plate carefully with a spatula or similar tool. A number of devices based on the vacuum-suction principle for removing the marked zones from the plate are also available. Soxhlet extraction, liquid extraction or solvent elution with a polar solvent is used to recover drugs from the sorbent. For solvent extraction, water is often added to dampen the silica gel prior to extraction with a water-immiscible organic solvent. Chloroform and ethanol (methanol is less suitable because of its higher silica solubility) are widely used for solvent elution. Colloidal silica can be removed by membrane filtration prior to vacuum stripping of the solvent.

Retardation factor

The retardation factor, or R_f value, is the fundamental parameter used to characterise the position of a sample zone in a TLC chromatogram. For linear development it represents the ratio of the distance migrated by the sample compared with the distance travelled by the solvent front:

$$R_f = Z_X/(Z_f - Z_o)$$

where Z_X is the distance travelled by the sample from its origin, $(Z_f - Z_0)$ is the distance travelled by the mobile phase from the sample origin, Z_f is the distance travelled by the mobile phase measured from the mobile phase level at the start of the separation and Z_0 is the distance from the sample origin to the mobile phase level at the start of the separation. The boundary conditions for R_f values are $1 \geq R_f \geq 0$. The R_f value is generally calculated to two decimal places. Some authors prefer to tabulate values as whole numbers, as hR_f values equivalent to $100R_f$.

Drug identification

The R_f value is affected too adversely by measurement difficulties and by variations in experimental and environmental conditions to be a useful identification parameter on its own. When standard substances are available, it is common practice to run standards and samples in the same system for improved confidence in identification based on R_f values. If scanning densitometry is used, an acceptable agreement in R_f values is generally supported by the automated matching of specific absorbance ratios or full spectra for the samples and standards.

In drug-screening programs, in which simultaneous separation of standards and samples is impractical, the certainty of drug identification is improved by simultaneous separation of a series of related standard substances that allow the experimental R_f values to be corrected to standardised R_f values for automated library searches:

$$hR_f(X)^c = hR_f(A)^c + [\Delta^c/\Delta][hR_f(X) - hR_f(A)]$$

$$\Delta^c = hR_f(B)^c - hR_f(A)^c$$

$$\Delta = hR_f(B) - hR_f(A)$$

where $hR_f(X)$ is the R_f value for substance X, $hR_f(A)$ and $hR_f(B)$ are the R_f values for the standard substances that bracket $hR_f(X)$, and the superscript c indicates the corrected value for X and the accepted values for A and B. Alternatively, a calibration curve of experimental R_f values against the accepted R_f values for the standards can be prepared and used to convert experimental R_f values to corrected R_f values. Typically, four evenly spaced standard substances with the sample origin ($hR_f = 0$) and solvent front ($hR_f = 100$) are included as additional reference points.

Database searches

Database searches are used in systematic toxicological analysis to identify suspect substances in biological fluids and postmortem tissue samples. Extracted samples are separated in one or more standard TLC systems. The corrected R_f values, often combined with the results of sequential post-chromatographic colour reactions, are then entered into the search program. The input data are automatically compared against a database of reference drugs, common metabolites, natural contaminants, etc., for identification. A number of chemometric procedures can be used for data analysis, but the most common approach is based on the mean list method.

It is assumed that the errors in individual measurements are random and can be described by a standard deviation. The precision of the separation system can then be described as the mean of the standard deviation of all substances separated in the system, called the system mean standard deviation. This allows a confidence interval or window to be assigned to the system as some multiple (typically three) of the system mean standard deviation. Each R_f value in the system database that appears in the window could be confused with the original substance. The number of substances identified as above is called the list length. Repeating the process for all R_f values in that system and averaging the individual list lengths provides the mean list length for that system. The

mean list length indicates, on average, the number of substances in the database that qualify as candidates for the identification of a single drug. The shorter the mean list length, the greater the information potential of the system. Combining the results from additional retention parameters in complementary standard separation systems, colour reactions, spectroscopic data, etc., minimises the mean list length to the point that only a small number of candidate compounds for the unknown are indicated. More specific tests can then be used to identify the unknown from among the small number of indicated possibilities. For systematic drug identification in forensic toxicology, commonly two or more

[(a)]Concentration of reference standards, 2 mg/mL of each substance.
[(b)]Error window defined as three times the mean standard deviation.
TIAFT, the International Association of Forensic Toxicologists

complementary TLC systems combined with the results from several *in situ* sequential colour reactions, are used. For drugs of toxicological interest, a mean list length from two to ten is possible.

Systematic drug identification

Systematic toxicological analysis takes advantage of the separation of an unknown substance in standard TLC systems (or other chromatographic systems) to establish the probable identity of the substance by reference to a database of candidate compounds using a statistical comparison approach, such as the mean list method. Suitable chromatographic techniques for systematic toxicological analysis must meet the following criteria:

1. The drugs must exhibit acceptable chromatographic properties in the separation system.
2. The R_f values for the drugs must be distributed evenly over the full R_f range.
3. The R_f values are standardised in such a way that good inter-laboratory reproducibility is obtained.
4. When more than one separation system is used, there must be a low correlation of R_f values in the selected systems.

TLC systems that meet these requirements are described below.

Since pH-dependent extractions are customarily used in drug extraction and work-up procedures, generally different TLC systems are used to separate acidic and basic drugs, with neutral drugs likely to occur in both fractions. The Committee for Systematic Toxicological Analysis of the International Association of Forensic Toxicologists (TIAFT) recommended 11 separation systems for drug identification (Table 39.9). Four systems (1 to 4a) are to separate neutral and acidic drugs and seven systems (4b to 10) are to separate neutral and basic drugs. Reference data are presented for about 1600 toxicologically relevant substances. For general drug screens, the use of two separation systems with a low correlation is recommended: systems 2 and 4a for neutral and acidic drugs and systems 5 and 8 for neutral and basic drugs (systems 7 and 8 are nearly as good). Combining colour reactions with the TLC data improves the certainty of identification significantly. Four colour reactions are carried out on the same plate in sequence. After each step the colour is noted and encoded by means of a colour chart (1, yellow; 2, orange; 3, brown; 4, red; 5, purple; 6, black; 7, blue; 8, green; 0, no spot observed). The sequence consists of formaldehyde vapour and Mandelin's reagent, water, fluorescence under 366 nm irradiation and modified Dragendorff's reagent. Other sequential colour reactions can be encoded and utilised in the same way. The Merck Tox Screening System (MTSS) contains the TIAFT TLC database and several other useful tools for searches using other chromatographic and spectroscopic databases and user-created databases.

Romano *et al.* (1994) presented data for 443 drugs in four TLC systems using high performance silica gel TLC plates (Table 39.10). These systems use slight modifications of the mobile phase compositions recommended by TIAFT. The UniTox system uses three TLC systems (Table 39.11). System 1 is designed to separate neutral and acidic drugs and systems 2 and 3 to separate basic, amphoteric and quaternary drugs. Two of the separation systems are based on reversed-phase separations designed to complement the more familiar silica gel separations. The database contains over 375 drugs of general toxicological interest, including a large number of amfetamines.

The Toxi-Lab system is a TLC kit for toxicological drug screening; it contains equipment for extraction, development, detection and identification. Separations are performed on unsupported, particle-embedded, glass-fibre sheets with holes punched in them to receive samples and standards as extraction or reference discs. A combination of silica gel and reversed-phase separations together with sequential colour reactions is used for identification and confirmation purposes. The database is designed for computer searches, with results entered in a standard format.

Pesticides are a further class of toxic substances of interest to systematic toxicological analysis because of their general availability, toxicity and potential confusion with drugs. Erdmann *et al.* (1990) developed a database for 170 commonly used pesticides separated in three standardised TLC systems (Table 39.12). The systems in Table 39.12 supplement those in Table 39.9, in which many common pesticides migrate with the solvent front. Systems 1 and 2 are recommended for general screening and system 3 for the identification of special compounds not distinguished in the first two systems.

General applications

Thousands of general and validated methods are available for the determination of drugs as pharmaceutical products and in biological fluids. Since the zone capacity of TLC systems is small, there are no general methods for drugs as a class, but there are a large number of methods for individual drugs defined by therapeutic or chemical categories. These

Table 39.10 The separation systems recommended by Romano *et al.* (1994) for systematic toxicological analysis by TLC (drug database Romano *et al.* 1994)

No.	TLC system			Reference compounds	$hR_f^{c(a)}$

still represent substantial diversity driven by the need to optimise selectivity for each group of substances taken for analysis. This information can provide a useful starting point for system selection but it is no general substitute for systematic method development. For these reasons, universal methods for general drug analysis do not exist and earlier attempts at systematised approaches for different drug categories have failed to keep pace with the growth in number of drugs in those categories. In addition, systems recommended for the separation of individual drug categories rarely prove optimal for the separation of individual drugs and their impurities or metabolites.

Systems for thin-layer chromatography

The TLC systems given below are general screening methods for nitrogenous bases (systems TA, TB, TC, TL, TAE and TAF), for acids and neutral compounds (systems TD, TE, TF and TAD) with a further three general screening methods (systems TAJ, TAK and TAL). Furthermore, seven systems specific for pesticides (systems TW, TX, TY, TZ, TAA, TAB and TAC) and another 19 systems covering specific groups of drugs are also listed. The drugs are divided into chemical or pharmacological groups, but some other drugs are included with certain groups if they are chemically similar and would be extracted with that group.

There may not be one best system for a particular separation and a number of systems can be applied from those suggested. However, each of the systems described has been selected because it gives a good spread of R_f values, has high reproducibility and has low correlation with the other systems selected for that group of drugs. These systems have proved useful for a large number of groups of drugs over the years and are robust and dependable. At least three systems are given for each group, where possible. The hR_f values of the reference compounds suggested for the general screening systems have been derived using solutions of approximately 2 mg/mL of each substance.

Fluorescent plates should always be used and the absorption or fluorescence of the drug under ultraviolet light (both 254 and 350 nm) should be used as a location procedure. The suggested locating agents include general ones to visualise any drug that might be present as well as more specific ones to pick out individual classes of drugs.

Note In the tables of hR_f values, a dash indicates that no value is available for the compound.

Systems described in Table 39.9 have been assigned the following codes:

Code	Number in Table 39.9
TA	7
TB	8
TC	9
TD	1
TE	4
TF	2

Screening systems

Basic nitrogenous drugs

Stead AH *et al.* (). *Analyst* 107: 1106–1168.
de Zeeuw RA *et al.* (1992) *Thin-layer Chromatographic R_f Values of Toxicologically Relevant Substances on Standardized Systems*. Report XVII of the DFG Commission for Clinical-Toxicological Analysis, 2nd edn. Wienheim: VCH.

System TA

- *Plates*: Silica gel G, 250 µm thick, dipped in, or sprayed with, 0.1 mol/L potassium hydroxide in methanol, and dried.
- *Mobile phase*: Methanol–strong ammonia solution (100 : 1.5).
- *Reference compounds*: Atropine hR_f 18, codeine hR_f 33, chlorprothixene hR_f 56, diazepam hR_f 75.

System TB

- *Plates*: Silica gel G, 250 µm thick, dipped in, or sprayed with, 0.1 mol/L potassium hydroxide in methanol, and dried.
- *Mobile phase*: Cyclohexane–toluene–diethylamine (75 : 15 : 10).
- *Reference compounds*: Codeine hR_f 06, desipramine hR_f 20, prazepam hR_f 36, trimipramine hR_f 62.

System TC

- *Plates*: Silica gel G, 250 µm thick, dipped in, or sprayed with, 0.1 mol/L potassium hydroxide in methanol, and dried.
- *Mobile phase*: Chloroform–methanol (90 : 10).
- *Reference compounds*: Desipramine hR_f 11, physostigmine hR_f 36, trimipramine hR_f 54, lidocaine hR_f 71.

System TL

- *Plates*: Silica gel G, 250 µm thick, dipped in, or sprayed with, 0.1 mol/L potassium hydroxide in methanol, and dried.
- *Mobile phase*: Acetone.
- *Reference compounds*: Amitriptyline hR_f 15, procaine hR_f 30, papaverine hR_f 47, cinnarizine hR_f 65.

System TAE

- *Plates*: Silica gel G, 250 µm thick.
- *Mobile phase*: Methanol.
- *Reference compounds*: Codeine hR_f 20, trimipramine hR_f 36, hydroxyzine hR_f 56, diazepam hR_f 82.

System TAF

- *Plates*: Silica gel G, 250 µm thick.
- *Mobile phase*: Methanol–*n*-butanol (60 : 40) and 0.1 mol/L NaBr.
- *Reference compounds*: Codeine hR_f 22, diphenhydramine hR_f 48, quinine hR_f 65, diazepam hR_f 85.

Location reagents for systems TA, TB and TC

Ninhydrin spray Spray the plate with the reagent and then heat in an oven at 100°C for 5 min. Violet or pink spots are given by primary amines and yellow colours by secondary amines.

FPN reagent Red or brown–red spots are given by phenothiazines and blue spots by dibenzazepines. This reagent may be used to overspray a plate that has been previously sprayed with ninhydrin spray.

Dragendorff spray Yellow, orange, red–orange or brown–orange spots are given by tertiary alkaloids. This reagent may be used to overspray a plate that has been previously sprayed with ninhydrin spray and FPN spray.

Acidified iodoplatinate solution Violet, blue–violet, grey–violet or brown–violet spots on a pink background are given by tertiary amines and quaternary ammonium compounds. Primary and secondary amines give dirtier colours. This solution may be used to overspray a plate that has previously been sprayed with ninhydrin spray, FPN reagent and Dragendorff's spray.

Mandelin's reagent This reagent is preferably poured onto the plate because of the danger of spraying concentrated acid. Many different colours are given with a variety of drugs (see Chapter 30 and the Index of Colour Tests).

Marquis reagent This reagent is preferably poured onto the plate because of the danger of spraying concentrated acid. Black or violet spots are given by alkaloids related to morphine. Many different colours are given with a variety of drugs (see Chapter 30).

Acidified potassium permanganate solution Yellow–brown spots on a violet background are given by drugs with unsaturated aliphatic bonds.

R_f values R_f values for drugs in these systems will be found in drug monographs and in the Indexes of Analytical Data in Volume 2; they are also included in the systems for specific groups of drugs that follow.

Acidic and neutral drugs

Stead AH *et al.* (). *Analyst* 107: 1106–1168.
de Zeeuw RA *et al.* (1992) *Thin-layer Chromatographic R_f Values of Toxicologically Relevant Substances on Standardized Systems. Report XVII of the DFG Commission for Clinical-Toxicological Analysis*, 2nd edn. Wienheim: VCH.

System TD

- *Plates*: Silica gel G, 250 µm thick.
- *Mobile phase*: Chloroform–acetone (80 : 20).
- *Reference compounds*: Paracetamol hR_f 15, clonazepam hR_f 35, secobarbital hR_f 55, methylphenobarbital hR_f 70.

System TE

- *Plates*: Silica gel G, 250 µm thick.
- *Mobile phase*: Ethyl acetate–methanol–strong ammonia solution (85 : 10 : 5).
- *Reference compounds*: Sulfadimidine hR_f 13, hydrochlorothiazide hR_f 34, temazepam hR_f 63, prazepam hR_f 81.

System TF

- *Plates*: Silica gel G, 250 µm thick.
- *Mobile phase*: Ethyl acetate.
- *Reference compounds*: Sulfathiazole hR_f 20, phenacetin hR_f 38, salicylamide hR_f 55, secobarbital hR_f 68.

System TAD

- *Plates*: Silica gel G, 250 µm thick.
- *Mobile phase*: Chloroform–methanol (90 : 10).
- *Reference compounds*: Hydrochlorothiazide hR_f 11, sulfafurazole hR_f 33, phenacetin hR_f 52, prazepam hR_f 72.

Location reagents for systems TD, TE and TF

Acidic drugs

Van Urk's reagent Spray the plate with the reagent and then heat in an oven at 100°C for 5 min. Yellow spots are given by sulfonamides and by meprobamate, blue spots are given by ergot alkaloids, and pink or violet spots are given by some other compounds, e.g. phenazone.

Ferric chloride solution Blue or violet spots are given by phenols. This solution may be used to overspray a plate that has been previously sprayed with Van Urk's reagent.

Mercurous nitrate spray Barbiturates give dark spots that fade slowly; with some dilute solutions the spots fade rapidly.

Acidified potassium permanganate solution Yellow–brown spots on a violet background are given by drugs with unsaturated aliphatic bonds, e.g. secobarbital. This solution may be used to overspray a plate that has been previously sprayed with mercurous nitrate spray.

Neutral drugs

Furfuraldehyde reagent Violet to blue–black spots are given by some neutral compounds, e.g. carbamates.

Acidified iodoplatinate solution This solution may be used to overspray a plate that has previously been sprayed with furfuraldehyde reagent.

R_f values R_f values for drugs in these systems will be found in drug monographs and in the Indexes of Analytical Data in Volume 2; hR_f

values are included in the systems for specific groups of drugs that follow.

Note It is worth noting that system TE can be used for acidic, neutral and basic drugs. Furthermore, systems TC and TAD use the same mobile phase so that acidic, neutral and basic drugs can be run in the same tank, although on separate plates. It should also be noted that the above systems for basic nitrogenous drugs are also able to separate neutral drugs if the latter are present in the sample or in the basic extract thereof.

Finally, the Index of Colour Tests lists colour reactions with TLC spray reagents for approximately 250 compounds and may therefore serve as an indication of colour reactions specific to certain classes of compounds.

General screening systems

The TLC systems listed below (systems TAJ, TAK and TAL) were developed primarily by Professor George Maylin, New York State Racing Wagering Board, Drug Testing Programme, as well as system TAM listed under steroids.

System TAJ

- *Plates*: Silica gel G, 250 µm thick.
- *Mobile phase*: Chloroform–ethanol (90 : 10).

System TAK

- *Plates*: Silica gel G, 250 µm thick.
- *Mobile phase*: Chloroform–cyclohexane–acetic acid (4 : 4 : 2).

System TAL

- *Plates*: Silica gel G, 250 µm thick.
- *Mobile phase*: Chloroform–methanol–propionic acid (72 : 18 : 10).

Anticonvulsants and barbiturates

The tabulated systems, previously described, together with the associated location reagents may be used or system TH, below, which gives good separations.

Systems TH

- *Plates*: Silica gel G, 250 µm thick.
- *Mobile phase*: Isopropyl alcohol–chloroform–strong ammonia solution (90 : 90 : 20).

Location reagents for systems TD, TE and TH

Mercuric chloride–diphenylcarbazone reagent White spots on a violet background are given in neutral systems, and violet spots on a pink background are given if the plate is alkaline.

Acidified potassium permanganate solution Yellow–brown spots on a violet background are given by drugs with unsaturated aliphatic bonds.

Zwikker's reagent Pink spots are given by 5,5-disubstituted barbiturates; green spots are given by thiobarbiturates; and faint pink spots are given by bromobarbiturates and by 1,5,5-trisubstituted barbiturates. The test is not very sensitive.

Fluorescein solution Spray the plates with a 10% solution of sodium hydroxide and heat at 100°C in an oven for 5 min before applying the reagent. Pink spots are given by bromobarbiturates.

Mercurous nitrate spray Barbiturates give dark spots which fade slowly; with some dilute solutions the spots fade rapidly.

Cannabinoids

The tabulated systems, previously described, may be used together with the associated location reagents or systems TI and TJ, below. These systems may be used for extracts of both cannabis and cannabis resin.

System TI

- *Plates*: Silica gel G, 250 µm thick, dipped in, or sprayed with, a 10% solution of silver nitrate, and dried.
- *Mobile phase*: Toluene, using unsaturated (open tank) conditions.

System TJ

- *Plates*: Silica gel G, 250 µm thick, sprayed with diethylamine immediately before use.
- *Mobile phase*: Xylene–hexane–diethylamine (25 : 10 : 1).

Location reagents for systems TI and TJ

Fast blue B solution Cannabidiol gives an orange colour, cannabinol gives a violet colour and Δ^9-tetrahydrocannabinol gives a red colour. The colours may be intensified by overspraying with 1 mol/L sodium hydroxide or by exposing the plate to ammonia fumes.

Duquenois reagent After spraying with the reagent, overspray the plate with hydrochloric acid. Blue to violet colours are given by cannabinoids.

Location reagents

The reagents given for systems TD, TE and TF can be used as well as that given below.

N-(1-Naphthyl)ethylenediamine solution Spray the plate with dilute sulfuric acid, expose it to nitrogen dioxide vapour for 15 min and then spray with the reagent.

Drugs of abuse

The tabulated systems, previously described, may be used together with the associated location reagents. A further three systems (TAH, TAI and TAN), described below, may be used for drugs of abuse. Refer to Chapter 11 for R_f values.

System TAH

- *Plates*: Silica gel G, 250 µm thick.
- *Mobile phase*: Hexane–diethyl ether (80 : 20).

System TAI

- *Plates*: Silica gel G, 250 µm thick.
- *Mobile phase*: Acetone.

System TAN

- *Plates*: Silica gel G, 250 μm thick.
- *Mobile phase*: Butanol–acetic acid–water (2 : 1 : 1).

Ergot alkaloids

Ardrey RE, Moffat AC (1979). *J Forensic Sci Soc* 19: 253–282.

The tabulated systems, previously described, may be used together with the associated location reagents.

System TL, previously described, may be used or system TM below. Note that these systems can be run in a single tank as they use the same mobile phase and have low correlation of hR_f values.

System TM

- *Plates*: Aluminium oxide, 250 μm thick.
- *Mobile phase*: Acetone.
- *Reference compounds*: Lysergide hR_f 70, ergotamine hR_f 48, ergometrine hR_f 26.

Location reagents for systems TL and TM

Naphthoquinone sulfonate solution Spray the plate with the reagent, then spray with a 10% v/v solution of hydrochloric acid and heat at 110°C for 20 min. Red–violet spots on a light pink background are given by ergot alkaloids.

Nitrosonaphthol solution Spray the plate with the reagent, then spray with a 10% v/v solution of hydrochloric acid and heat at 110°C for 20 min. Blue–black spots on a yellow background are given by ergot alkaloids.

Van Urk's reagent After spraying the plate, heat in an oven at 100°C for 5 min. Blue spots are given by ergot alkaloids.

Pesticides

System TW

Getz ME, Wheeler HG (1968). *J Ass Off Anal Chem* 51: 1101–1107.

- *Plates*: Silica gel, 250 µm thick.
- *Mobile phase*: Cyclohexane–acetone–chloroform (70 : 25 : 5).

Location reagent Allow the plate to dry in air, heat at 110°C for 2 h, allow to cool, spray with molybdate–antimony reagent, and then lightly overspray with ascorbic acid reagent.

System TX

- *Plates*: Silica gel G, 250 µm thick.
- *Mobile phase*: *N*-Hexane–acetone (80 : 20).
- *Reference compounds*: Triazophos hR_f 20, parathion-methyl hR_f 30, pirimiphos-methyl hR_f 49, quintozen hR_f 84.

System TY

- *Plates*: Silica gel G, 250 µm thick.
- *Mobile phase*: Toluene–acetone (95 : 5).
- *Reference compounds*: Carbofuran hR_f 20, azinphos-methyl hR_f 46, methidathion hR_f 60, parathion-ethyl hR_f 85.

System TZ

- *Plates*: Silica gel G, 250 µm thick.
- *Mobile phase*: Chloroform–acetone (90 : 10).

System TAA

- *Plates*: Silica gel G, 250 µm thick.
- *Mobile phase*: Chloroform.

System TAB

- *Plates*: Silica gel G, 250 µm thick.
- *Mobile phase*: Dichloromethane.

System TAC

- *Plates*: Silica gel G, 250 µm thick.
- *Mobile phase*: Ethyl acetate–isooctane (85 : 15).

Refer to the pesticides chapter (Chapter 16, Table 16.) for hR_f values for systems TX, TY, TZ, TAA, TAB and TAC.

Quaternary ammonium compounds

Systems TN and TO

Stevens H, Moffat AC (1974). *J Forensic Sci Soc* 14: 141–148.

System TN

- *Plates*: Cellulose, 250 μm thick.
- *Mobile phase*: Ammonium formate–formic acid–water–tetrahydrofuran (1 : 5 : 95 : 233).

System TO

- *Plates*: Silica gel (without gypsum), 250 μm thick.
- *Mobile phase*: Methanol–0.2 mol/L hydrochloric acid (80 : 20).

Location reagents for systems TN and TO

Acidified iodoplatinate solution Violet, blue–violet, grey–violet or brown–violet spots on a pink background are given by quaternary ammonium compounds.

Cobalt thiocyanate solution Blue spots are given by quaternary ammonium compounds.

	TN	TO
Acetylcholine chloride	70	60
Atropine methonitrate	95	35
Bretylium tosilate	94	40
Cetrimide	100	50
Choline	60	60
Decamethonium bromide	56	16

Steroids

The tabulated systems, previously described, may be used or systems TP, TQ, TR, TS and TAM.

Systems TP, TQ, TR and TS

Lund W, ed. (1979). *Pharmaceutical Codex*, 11th edn. London: Pharmaceutical Press: 940.

System TP

- *Plates*: Silica gel G, 250 μm thick.
- *Mobile phase*: Methylene chloride–ether–methanol–water (77 : 15 : 8 : 1.2).

System TQ

- *Plates*: Silica gel G, 250 μm thick.
- *Mobile phase*: Dichloroethane–methanol–water (95 : 5 : 0.2).

System TR

- *Plates*: Kieselguhr, 250 µm thick, impregnated with a mixture of acetone–formamide (9 : 1).
- *Mobile phase*: Toluene–chloroform (3 : 1).

System TS

- *Plates*: Kieselguhr, 250 µm thick, impregnated with a mixture of acetone–propylene glycol (9 : 1).
- *Mobile phase*: Cyclohexane–toluene (1 : 1).

System TAM

Professor George Maylin: personal communication.

- *Plates*: Silica gel G, 250 µm thick.
- *Mobile phase*: The plate is run to 5 cm in a TLC system of chloroform–ethyl acetate–methanol (50 : 45 : 5), dried and then re-run to 7 cm in the solvent composition of system TE, ethyl acetate–methanol–strong ammonia solution (85 : 10 : 5).

Location reagents for systems TP, TQ, TR, TS and TAM

DPST solution

Sulfuric acid–ethanol reagent Spray the plate and then heat at 105°C for 10 min.

p-Toluenesulfonic acid solution Heat the plate at 120°C for 15 min, cool, spray with the reagent, heat again at 120°C for 10 min, and re-spray. Refer also to the Index of Colour Tests in the Indexes of Analytical Data.

CHAPTER

40 Gas Chromatography

S Dawling

The application of the principles of adsorption and partition to the technique of gas chromatography (GC) is attributed to the German scientist Fritz Prior in the late 1940s, and to Martin and Synge in the early 1950s, respectively. These discoveries undoubtedly paved the way for the adoption of GC as one of the most broadly used analytical techniques, and also earned the latter two UK scientists the Nobel Prize for chemistry in 1952. GC is applicable to a wide range of compounds of interest to toxicologists, pharmaceutical and industrial chemists, environmentalists and clinicians. If a compound has sufficient volatility for its molecules to be in the gas or vapour phase at or below 400°C, and does not decompose at these temperatures, then the compound can probably be analysed by GC.

The separation is performed in a column (containing either a solid or liquid stationary phase) that has a continuous flow of mobile phase passing through it (usually an inert carrier gas, but more recently supercritical fluids (SCFs) have been used for some applications), maintained in a temperature-regulated oven. When a mixture of substances is injected at the inlet, each component is adsorbed to some extent by the stationary phase, and also partitions between the stationary phase and the gas phase as it is swept towards the detector. Molecules that have greater affinity for the stationary phase spend more time in that phase and consequently take longer to reach the detector. The detector produces a signal proportional to the amount of substance that passes through it, and this signal is processed and fed into a recording device. Each substance that elutes from the column has a characteristic retention time, defined as the time interval from injection to peak detector response. Figure 40.1 shows a schematic of a GC system.

Identification of components was traditionally based primarily on peak retention time, but it is becoming increasingly more reliant on the nature of the response obtained from the detector. The analyst has two main goals: first, to make each different compound appear in a discrete band or peak with no overlap (or co-elution) with other components in the mixture, and, second, to make these bands uniform in shape and as narrow as possible. This is achieved partly by judicious choice of the column stationary phase and its loading, and partly by optimising the operating conditions of the column and detector. In addition, the method of introducing the sample into the chromatograph, the detector choice and chemical modification to improve the volatility of the compounds also contribute to converting a mediocre analysis into a first-class one.

There has been a continuous synergism between enhanced detector performance and column performance; each advance being mutually dependent on the other. Initially, high-sensitivity detectors permitted the development of a precise column theory that, in turn, enabled the design of columns that had much higher efficiencies. This improved efficiency, however, produced peaks of small volume compared with the sensing volume and dispersion that occurred in the collecting tubes of the contemporary detectors. Consequently, efficiency became limited by the geometry of the detector, and not by its intrinsic sensitivity. Detector design was modified to incorporate smaller tube dimensions, and the volume of the sensing cell was thus reduced greatly. The introduction of capillary columns suitable for routine use in GC in the mid-1980s provided much higher resolution efficiencies and smaller peak volumes, which provoked further modifications in detector design. The latest column developments mean that peaks of only a few milliseconds are a real possibility in both GC and liquid chromatography (LC). Since this matches the response time of the current sensor electronics, the ingenuity of the detector design engineers is again being tested. Today's biggest challenges are in the area of data manipulation as increased sensitivity and column resolution produce an enormous amount of data.

Gas chromatography columns

Packed columns made of glass or steel contain a stationary phase (see below), either loaded directly into the column if it is a solid at its operating temperature, or coated onto the surface of a solid support if it is liquid at its operating temperature. Thus, the operating principle of GC can be distinguished as either gas–solid chromatography (mainly an absorptive process by the stationary phase) or gas–liquid chromatography (mainly partition of the analytes between the mobile and stationary phases), based on the physical characteristics of the stationary phase. Capillary columns, introduced in the early 1980s, have now replaced packed columns for most applications. The original glass columns were fragile and have been superseded by fused-silica capillary columns. Fused silica is high-purity synthetic quartz, with a protective coating of polyimide applied to the outer surface. Since these columns retain their flexibility only as long as the coating remains undamaged, their operating temperature must be maintained below 360°C for standard columns (400°C for high-temperature polyimide coatings). The first capillary columns were 0.2, 0.25 or 0.32 mm in internal diameter (i.d.) and between 10 and 50 m long. Subsequently 'megabore' (0.53 mm i.d.), 'minibore' (0.18 mm i.d.) and 'microbore' (0.1 or 0.05 mm i.d.) columns have evolved. When coated with a heat-resistant polymer, these have the advantages of flexibility and strength, and can be threaded with ease through intricate pipe work. A single column can be fitted into almost any manufacturer's GC. Capillary columns provide improved resolution, sensitivity and durability, less bleed with increasing temperatures and ease of maintenance and repair, and they yield reliable and highly reproducible separations, typically over many hundreds or thousands of injections. This has reduced the number of columns required to achieve a satisfactory separation of quite complex mixtures.

The internal surface of the silica is deactivated by a variety of processes that can react silanol groups (Si–OH) on the silica surface with a silane reagent (usually a methyl or phenylmethyl surface is created). For gas–solid capillary chromatography, a fine layer (usually less than 10 μm) of stationary phase particles is adhered to the tubing (porous layer open tubular, or PLOT, columns). For gas–liquid capillary chromatography, the stationary phase may be coated or bonded directly onto the walls of the column (wall-coated open tubular, or WCOT), or onto a support (e.g. microcrystals of sodium or barium chloride) bonded to the column wall (support-coated open tubular, or SCOT). Cross-linked stationary phases have the individual polymer chains linked via covalent bonds. Both bonding and cross-linking impart enhanced thermal and solvent stability to the stationary phases (often designated 'DB'), and these should be used if they are available. Stainless-steel capillaries are usually reserved for applications that require extremes of temperature, or where the possibility of column breakage cannot be tolerated. Nowadays, the internal surface is specially deactivated chemically or by lining with fused silica, which allows for more flexibility and greater durability, and also reduces the possibility of degradation of analytes, which can be catalysed by the exposed metal surfaces.

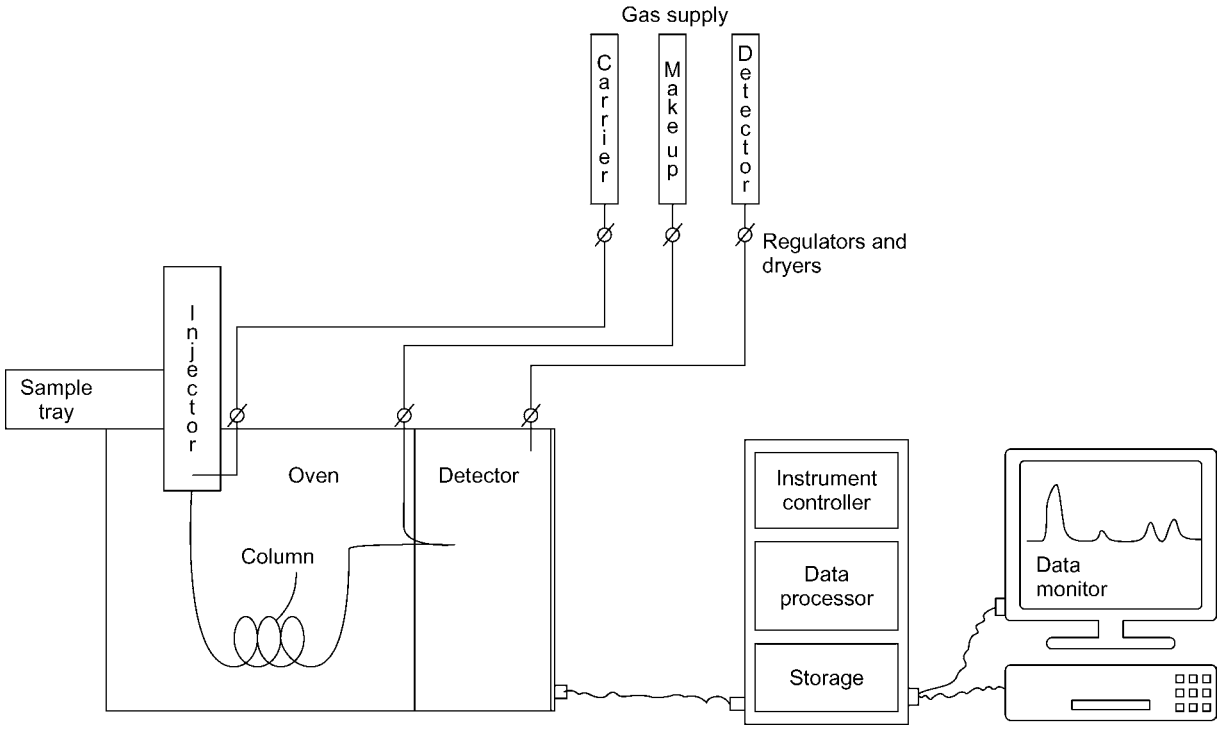

Figure 40.1 A modern GC system.

Stationary phases and support materials

Solid stationary phases

In gas–solid chromatography, the stationary phase is an active solid at its operating temperature. A conventional packed column is filled completely by stationary phase particles, but in a capillary column a fine layer (usually less than 10 μm) of particles is adhered by proprietary processes to the inner surface of the tubing, to create a PLOT column. These solid phases may be inorganic materials (e.g. aluminium oxides, molecular sieves, silica gel or graphitised carbon), or they may be organic polymers such as styrene. Both packed and capillary columns use similar solid-phase materials. Sample compounds undergo a dynamic gas–solid adsorption–desorption process with the stationary phase and, since the particles are porous, size exclusion and shape selectivity processes also occur. The carrier gas (mobile phase) merely serves to sweep towards the detector those solute molecules that are not currently adsorbed. The resultant columns are highly retentive, and separations impossible with liquid phases can be accomplished easily on PLOT columns above ambient temperature. These columns are generally reserved for the separation of low-molecular-weight materials, such as hydrocarbon and sulfur gases, noble and permanent gases, and low-boiling solvents. Since PLOT columns occasionally shed particles, their use is not advised with detectors that are affected adversely by the intrusion of particulate matter (the mass spectrometer is particularly vulnerable, as the column interface operates under vacuum).

Graphitised carbon black Carbopaks are graphitised carbon black, having adsorptive surfaces of up to 100 m^2/g. They are usually modified with a light coating of a polar stationary phase. Difficult separations of the C_1 to C_{10} hydrocarbons can be achieved rapidly. Carbopak C with 0.2% Carbowax 20 M has been used to resolve substances abused by 'glue-sniffers'. Carbopak C modified with 0.2% Carbowax 1500 and Carbopak C with 0.8% tetrahydroxyethylenediamine (THEED) are useful for the analysis of ethanol and ethylene glycol, respectively, in blood. Resolution is superior to that obtained with the Porapak and Chromosorb polymers, although the elution order is similar.

Molecular sieves Activated alumina is unique for its extremely wide pore-diameter range, and is very useful for separating most C_1 to C_4 molecules, separating light hydrocarbon saturates from unsaturates in the C_1 to C_5 range, and separating benzene, toluene and xylenes. Deactivation of alumina with potassium hydroxide reverses the elution of some molecules (acetylene and *n*-butane). Carbosieves are granular carbon molecular sieves that give good separation of C_1 to C_3 hydrocarbons. Carboxen 1006 is useful in resolving formaldehyde, water and methanol, and impurities in ethylene. Zeolites (5A, 13X) give a good general separation of inorganic gases. Carbon dioxide is irreversibly adsorbed below 160°C. Oxygen, nitrogen, carbon monoxide and methane are well separated. These columns have a tendency to adsorb water and carbon dioxide, which results in changes in retention over time.

Polymers Chromosorb 101–108 and Porapak are divinylbenzene cross-linked polystyrene copolymers. Incorporation of other functional groups, such as acrylonitrile and acrylic esters, into the polymer matrix provides moderately polar-to-polar surfaces with different pore sizes and surface areas (polarity increases with ascending number or letter). HayeSep phases are polymers of divinylbenzene and ethylene glycol dimethylacrylate. Separations range from free fatty acids to free amines, and small alcohols from methanol to pentanol. Tenax-TA is a porous polymer of 2,6-diphenyl-*p*-phenylene oxide, used both as a chromatographic phase and as a trap for volatile substances prior to analysis. It is also used for high-boiling alcohols, poly(ethylene glycol)s (PEGs), phenols, aldehydes, ketones, ethanolamines and chlorinated aromatics.

Liquid stationary phases

In gas–liquid chromatography (GLC), the stationary phase is a liquid or gum at the normal operating temperature. Components injected into the column are partitioned between the moving (mobile) gas phase and a stationary phase. Molecules that have greater affinity for the stationary phase spend more time immobilised in the column and consequently take longer to reach the detector. The process of immobilisation and subsequent release back into the mobile phase occurs thousands of times during the course of the analysis. The separation of components is dependent, to a large extent, on the chemical nature of the stationary phase. Stationary phases are essentially two types of high-boiling polymers – siloxanes (often incorrectly called silicones) and PEGs. Chiral stationary phases based on cyclodextrins (cyclic glucose chains) have

specific applications in the separation of enantiomers and are discussed separately.

Polysiloxanes Standard polysiloxanes (PSXs) are characterised by their repeating siloxane backbone in which each silicon atom has the potential to attach two functional groups, the type and amount of which distinguish the stationary phase and its properties (Fig. 40.2). The basic PSX is 100% methyl substituted so, when other groups are present, the amount is indicated as a percentage of the total substituent groups. For example, if 5% of Si atoms contain two phenyl groups and the remaining 95% of Si atoms are methyl substituted, this may be written as (5% diphenyl/95% dimethyl)-PSX, (5% phenyl/95% methyl)-PSX or simply as (5% phenyl)-PSX. In some instances, two different groups are present on the same Si atom, so a (10% cyanopropylphenyl/dimethyl)-PSX contains a total of 5% cyanopropyl, 5% phenyl and 90% methyl residues (see Fig. 40.2).

While PSXs are generally less polar in nature than PEGs, the substitution of polar residues for a proportion of the methyl groups confers added polarity to the column. Polar phases retain polar compounds more effectively than do non-polar compounds, and vice versa. The 100% methyl-substituted PSX is often considered the 'standard' non-polar phase, and has been used extensively in compilations of retention indices. This column is an ideal choice for starting a new application. However, substitution by *n*-octyl groups (up to 50%) renders the column extremely non-polar, and similar to squalene. Substitution with up to 5% phenyl groups still furnishes an essentially non-polar column with improved thermal stability. This phase has also been used for retention index (RI) work and is another good column with which to start a new application. Increasing the phenyl substitution to 20%, 35% or 50% yields columns classed as intermediate in polarity, which predictably retain aromatic compounds relative to aliphatic solutes. All these are available as bonded phases that can be solvent rinsed, are not damaged by organic acids or bases, and can tolerate small injections of water if sufficiently highly loaded, but are sensitive to strong inorganic acids and bases.

Substitution of cyanopropylphenyl groups (typically 6% or 14%) creates an intermediate-polarity mixed phase with unique elution relative to simple phenyl substitution but renders the column more susceptible to damage from oxygen, moisture and mineral acids. Fifty percent substitution is specifically designed to separate *cis*- and *trans*-fatty acid methyl esters (FAMEs). However, even low-level bleeding of the stationary phase produces a high background signal with certain types of detector (nitrogen–phosphorus detector). More polar columns are

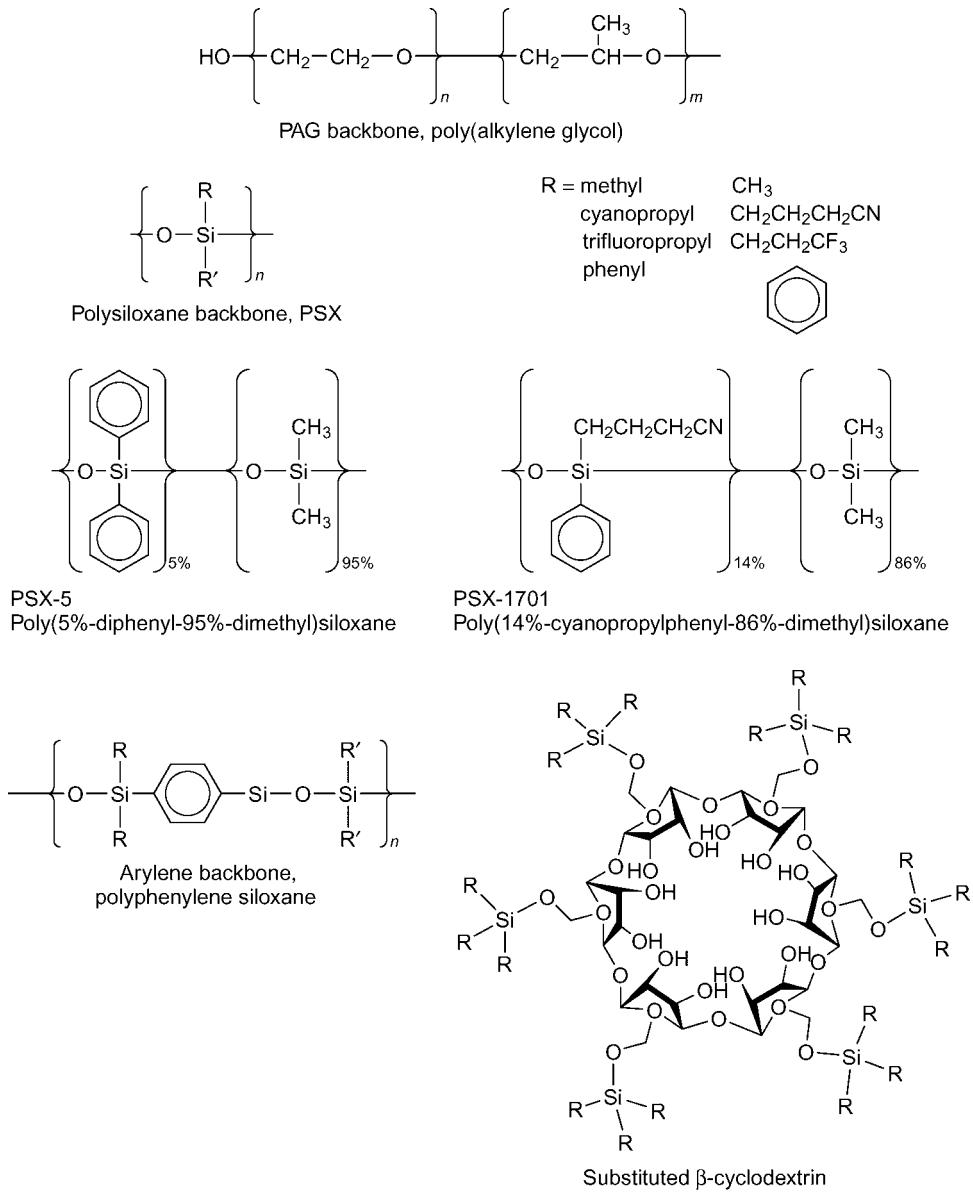

Figure 40.2 Structures of some common capillary GC stationary phases.

produced by substitution of biscyanopropyl and cyanopropylphenyl groups (80 : 20 or 90 : 10). Substitution with 100% biscyanopropyl gives the highest polarity of the PSXs. This phase can be operated at both high and low temperatures. To date, these are non-bonded columns, and therefore should not be rinsed with solvent. Trifluoropropyl-methyl-PSX is a mid-to-high polarity phase especially suited for otherwise difficult-to-separate positional isomers. Its unique interactions with nitro, halogen, carbonyl and other electronegative groups give it application in the analysis of herbicides and pesticides.

Increasing polarity in general is associated with some negative effects. Polar phases tend to have a narrower operating temperature range (higher minimum, lower maximum), are more prone to bleed at higher temperatures, are more sensitive to moisture and oxygen, and consequently have a shorter life expectancy than non-polar phases. More recently, low-bleed arylene stationary phases (sometimes designated 'mass spectrometry' or 'ms') have been introduced that have phenyl groups incorporated into the siloxane backbone (see Fig. 40.2). The incorporated phenyl groups confer additional strength to the backbone, which prevents the formation of cyclic fragments and associated 'bleed' at higher temperatures.

Poly(ethylene glycol)s PEGs are widely used polar stationary phases and their general structure (PAGs) is shown in Fig. 40.2. They are less stable, less robust (they are especially prone to oxidative damage), have lower temperature limits and a shorter life expectancy than polar PSX phases, but they have unique resolving qualities. Acid-modified PEG (FFAP) substituted with terephthalic acid is especially useful for separating acidic polar compounds, such as acids, alcohols, acrylates, ketones and nitriles. Nitroterephthalic acid-substituted PEG (e.g. Nukol) is designed for volatile fatty acids and phenols. Both are highly resistant to damage from water-based samples. Base-modified PEG (CAM) is suited to analysis of strongly basic compounds, such as primary amines, that do not chromatograph well on polar PSXs. Since this phase is usually cross-linked, it cannot be used with water or alcohol, but it can be solvent rinsed. New bonded and cross-linked PEG phases are now available to separate free fatty acids and other organic acids. These show superior inertness and can tolerate repeated injections of water, alcohols, aldehydes and acids without the need for acidification.

Chiral phases Second-generation chiral phases are based on cyclodextrins (toroidal shaped structures formed by α_{1-4} linkages of multiple glucose units). The enzyme cyclodextrin glucosyltransferase is used to cleave partially digested starch, and link the glucose units into three forms, referred to as α, β and γ, that have six, seven and eight glucose units, respectively. The mouth of the cyclodextrin molecule has a larger circumference than the base and is linked through secondary hydroxyl groups of the C2 and C3 atoms of each glucose unit. The primary hydroxyl groups are located at the base of the torus, on the C6 atoms. The number of glucose units thus determines the cavity size and electrophilic orientation (see Fig. 40.2), and affects the elution order of the enantiomeric forms. The hydroxyl groups can be functionalised selectively to provide various physical properties and inclusion selectivities. Six different cyclodextrin derivatives are manufactured: permethylated hydroxypropyl (PH), dialkylated (DA), trifluoroacetylated (TFA), propionylated (PN), butyrylated (BP) and permethylated (PM). Changes in elution order can be seen between the different derivatives, and also between cyclodextrin cavity sizes. Unlike the cyclodextrins used in high performance liquid chromatography (HPLC), these phases separate both aromatic and non-aromatic enantiomers of a wide range of chemicals, including saturated alcohols, amines, carboxylic acids, epoxides, diols, lactones, amino alcohols, amino acids, esters, pyrans and furans. Each phase has an area of specificity, as summarised in Table 40.1. Derivatised cyclodextrins are thermally stable, highly crystalline and virtually insoluble in most organic solvents. Chiral phases are fragile, however, and unless chemically bonded or cross-linked, they cannot be washed with solvent or taken to temperatures outside the 0–225°C range.

A subsequent development has been the embedding of PM cyclodextrins (usually 10% or 20% by volume) into columns that contain standard liquid stationary phases of intermediate polarity, such as 35% phenyl-PSX. Silyl-substituted cyclodextrins, such as 2,3-di-*O*-methyl-6-*O*-*t*-butyldimethylsilyl are also available embedded (usually 25–35% by weight) in 20% phenyl-PSX, another intermediate polarity stationary phase. These columns are useful for separating positional isomers (phenols, xylenes, etc.), as well as enantiomers.

Table 40.1 Chiral stationary phases and their analytical applications

Phase	*Application*
α-PH	Small linear and saturated amines, alcohols, carboxylic acids and epoxides
β-PH	Linear and cyclic amines and alcohols, carboxylic acids, amino alcohols, sugars, epoxides and haloalkanes
γ-PH	Cyclic and bicyclic diols, steroids and carbohydrates
α-DA	Small cyclic amines, alcohols and epoxides
β-DA	Nitrogen heterocyclics, lactones, aromatic amines, sugars, amino acid derivatives, bicyclics and epoxides
γ-DA	Large cyclic diols, aromatic amines with more than one ring, and multi-ring or compounds with bulky substituents
α-TA	Small alcohols, amino alcohols, amino alkanes and diols
β-TA	Alkyl alcohols, halocarboxylic acid esters, amino alkanes, halocycloalkanes, lactones, diols, alkyl halides, furans and pyrans
γ-TA	Large range of alcohols, diols, polyols, halocarbons, lactones, amine alcohols, halocarboxylic acid esters, furans, pyrans, epoxides, glycidyl analogues and haloepihydrins
γ-PN	Epoxides, alcohols $>C_4$ and lactones
γ-BP	Amino acids, some primary amines and furans
β-PM	Largest range of acids, alcohols, barbiturates, diols, epoxides, esters, halocarbons, ketones, lactones, terpenes; first choice for chiral method development

Solute–stationary phase interactions

For liquid stationary phases, three major types of interaction determine chromatographic elution: dispersion, dipole–dipole interaction and hydrogen bonding.

Table 40.2 shows the contribution of each of these interactions for the common types of liquid stationary phases. It should be remembered that hydrogen bonding interactions are considerably stronger than dipole–dipole interactions, which are themselves stronger than dispersion interactions. Thus, although the dispersion interaction between the various stationary phases is listed as strong or very strong, and the hydrogen bonding interactions as weak or moderate, if the analyte has functional groups that can undergo hydrogen bonding with the particular stationary phase employed, the hydrogen bonding interaction is likely to be stronger than interaction by dispersion. However, the reverse is true if the analyte also has a high proportion of groups in its molecular structure that can participate in dispersion interactions, as would be the case, for example, for long-chain fatty acids.

Dispersion is the dominant interaction for all PSX and PEG stationary phases; it can be simplified into the concept that the more volatile the compound (the lower its boiling point), the more likely it is to be in the mobile phase and so the faster it elutes from the column. Although this holds true for groups of compounds with similar functional groups or

Table 40.2 Contribution of different types of interactions to solute separation on GC stationary phases

Functional group	*Type of interaction*		
	Dispersion	*Dipole–dipole*	*Hydrogen bonding*
Methyl-PSX	Strong	None	None
Phenyl-PSX	Very strong	None	Weak
Cyanopropyl-PSX	Strong	Very strong	Moderate
Trifluoropropyl-PSX	Strong	Moderate	Weak
PEG	Strong	Strong	Moderate

within homologous series, it cannot be applied universally. In general, a difference of 30°C in boiling point is sufficient to predict and maintain elution order, but differences of less than 10°C can be overturned by the influence of other interactions.

Dipole–dipole interactions of PEG phases and the cyanopropyl- and trifluoropropyl-substituted PSXs enable these phases to separate solute molecules that have different dipole moments. Such solutes are those with positional isomers of electronegative groups, such as pesticides, halocarbons and many pharmaceuticals.

Moderate *hydrogen bonding* is exhibited by PEGs and cyanopropyl-substituted PSXs, with less marked effects shown by phenyl- and trifluoropropyl-substituted PSXs. Functional groups that exhibit strong hydrogen bonding include alcohols, carboxylic acids and amines; aldehydes, esters and ketones generally have less effect; hydrocarbons, halocarbons and ethers produce negligible hydrogen bonding. Although the amount of separation obtained through dipole–dipole interactions or through hydrogen bonding can be difficult to predict, resolution of compounds with smaller differences in dipole moments or in hydrogen bonding strengths requires larger percentages of siloxane substitution.

McReynolds constants

The retention behaviour of five carefully selected probe compounds (benzene, butanol, pentan-2-one, nitropropane and pyridine) has traditionally been used to classify stationary phases in terms of their polarity (McReynolds 1970; Rorschneider 1966). The retention indices of each of these five reference compounds are measured on the stationary phase being tested, and then compared with those obtained under the same conditions on squalene (a standard non-polar phase). The differences in the retention indices between the two phases (ΔI) for the five probe compounds are added together to give a constant, known as the *McReynolds constant*, which is used to compare the ability of stationary phases to separate different classes of compounds. Phases that provide McReynolds values of ± 4 can be substituted freely for each other; those differing by ± 10 units generally yield similar separations. Phases with McReynolds values below 100 are considered non-polar, those above 400 indicate a highly polar phase and values between 100 and 400 an intermediate polarity. Table 40.3 shows the McReynolds constants, operating temperature range and example applications for the most popular stationary phases. ΔI values for individual probes indicate the deviation from boiling point order and consequently represent the contribution of forces other than dispersion to elution for that probe. The probes are chosen to represent different functional groups as follows:

- Benzene for aromatics and olefins (π-type interactions)
- Butan-1-ol for alcohols, nitriles, carboxylic acids and diols (electron-attracting effect)
- Pentan-2-one for ketones, ethers, aldehydes, esters, epoxides and dimethylamino derivatives (dipole–dipole effect)
- Nitropropane for nitro and nitrile derivatives (electron-donating effect)
- Pyridine for bases (non-bonding electron attraction and hydrogen-bonding effects).

Moffat *et al.* (1974a) devised a system to assess the effectiveness of liquid stationary phases in packed columns by calculating the discriminating power, and examined a number of phases commonly used in toxicology

Table 40.3 Polarity (McReynolds values) of some common stationary phases, and example applications

Capillary phase[a]	*Temperature range (min./max.)*	*McReynolds values*[b]					$\sum\Delta I$	*Applications*
		x′	*y′*	*z′*	*u′*	*s′*		
SPB-octyl	−60/300	3	14	11	12	11	51	Separates by boiling point, polychlorinated biphenyls (PCBs)

[a]* is the proprietary prefix for the phase, for example: * = HP supplied by Hewlett Packard/Agilent; * = DB supplied by J&W; * = CPSil supplied by Chrompack; * = RT supplied by Resteck; * = SP supplied by Supelco; * = OV supplied by Ohio Valley. This list is not intended to be exhaustive.
[b]x′ = benzene; y′ = butan-1-ol; z′ = pentan-2-one; u′ = 1-nitropropane; s′ = pyridine.

(Moffat *et al.* 1974b). Contrary to popular belief, it was shown that one column could be used to elute all the drugs studied, and that for screening purposes a single column, either SE-30 or OV-17 (100% dimethyl-PSX or 5% phenyl-PSX capillary equivalents), was sufficient for the reliable identification of drugs.

Installing, conditioning and maintaining columns

Column installation

A GC column is attached at one end to the injector and at the other end to the detector. Attachment is typically via a nut and ferrule, the nut attaching to a screwthread on the injector and detector. As the nut is tightened, the ferrule is compressed and helps produce a gastight fitting. Fused-silica capillaries should have their ends freshly cut after insertion through ferrules, to eliminate blockages. The injector end of the column should be fitted first, adjusting the height of the protrusion above the ferrule according to the type of inlet being used, then tightening the fittings just enough to prevent leakage when tested with a proprietary leak-testing fluid (not soap solution, which leaves a residue). The detector end of the capillary column may be immersed into a small tube of methanol to ensure adequate flow, and the capillary end re-cut and then attached to the detector and checked for leaks. The detector is activated and the column tested at room temperature with an injection of 1 or 2 μL of methane, when a needle-sharp peak should be obtained. When the carrier gas pressure has been adjusted to give a flow of approximately 1–2 mL/min of carrier gas, the column may be heated and a test mixture injected. Commercial columns are invariably supplied with a chromatogram obtained from a test mixture, and it should be possible to obtain a performance at least equal to that supplied. Various test mixtures are used, including a mixture of dimethylphenol and dimethylaniline with straight-chain paraffins. Any acidity or alkalinity of the column is apparent in loss of the peak shape of the amine or phenol. The efficiency obtained is a function of the entire chromatographic system. Poor efficiency or peak shape often results from a non-swept volume somewhere in the system.

It may be necessary to add an additional gas supply to the column outlet to ensure that the detector is purged effectively, because most detectors are designed to operate with packed columns and a flow rate of about 30 mL/min, as opposed to the 1 or 2 mL/min delivered by a capillary column (see Detector systems below).

Column conditioning

Modern capillary columns require only minimal conditioning before use to remove volatile impurities that remain from the manufacturing process. For thorough conditioning, the column should be installed in the injector port only, with the detector end disconnected. With the column at room temperature, a low carrier gas pressure (14–35 kPa) should be maintained for half an hour to purge oxygen from the system. The temperature may then be raised by about 1°/min until a temperature about 10°C above the desired maximum operating temperature has been reached, and the column is maintained at this for 2 h. Care must be taken not to exceed the maximum operating temperature. After conditioning, the column is connected to the detector, and a period of further conditioning undertaken only if the background signal is excessive. Some phases are particularly oxygen sensitive and can be ruined by careless conditioning. A constrictor fitted to the detector helps prevent back diffusion of oxygen if air or oxygen is supplied to the detector.

Guard columns and retention gaps

A guard column and a retention gap are essentially the same thing, but they are installed to serve different purposes. These 1–10 m lengths of fused-silica tubing are attached to the front of the chromatography column via a press-snap connector or zero dead-volume union, and then installed into the injector port. The surface of the silica is deactivated to minimise solute interactions, but no stationary phase is added. The tubing diameter should be the same as that of the column, but if different it should ideally be of a wider bore. The function of a guard column is to trap deposits of non-volatile residues, preventing them from contaminating the analytical column. Solutes are not retained by the guard column (since there is no stationary phase) and pass directly onto the column. Portions can be cut periodically from the top of the guard column as deterioration in chromatography requires, without any appreciable loss of resolution from the analytical column. A retention gap is used to improve peak shape when poor chromatography is the result either of a large injection volume (>2 μL) or of solvent–stationary phase polarity mismatches. Greatest improvement is seen in early eluting peaks, or for solutes with similar polarity to that of the solvent.

Maximum operating temperatures

Maximum operating temperatures for stationary phases are usually quoted assuming isothermal operation with a flame ionisation detector (see Table 40.3). Other detectors may impose different limits, the mass spectrometer being much more susceptible to bleeding of the stationary phase than the thermal conductivity detector. All phases bleed at high temperatures through loss of smaller-sized (and hence lower-boiling) polymer chains, although normally this is not noticeable. Operating temperature has a profound effect on column life, particularly for capillary columns. Loss of stationary phase or breakdown of the thin film into pools exposes part of the tubing surface and results in serious loss of performance. Additionally, in columns that contain PSX phases with two different functional groups, one group (usually that which confers additional polarity) is preferentially lost. This results in a change of relative separation (or in RI – see discussion below) as well as a loss of resolution. The temperature limit of a column may be influenced by the deactivation procedure used in production, rather than by the stationary phase itself. Newer silica columns have a very low metal oxide content, thought to act as a catalyst for the degradation of both sample and stationary phase, and thus enable phases to be run at higher temperatures. Fused-silica capillary columns have a protective external coating of polyimide that is slowly degraded at elevated temperatures (maximum temperature originally 360°C, now up to 400°C), which can also limit column life. However, separations are usually achieved at much lower temperatures.

Temperature programming

For complex mixtures with components of widely varying retention characteristics, it is often impractical to choose a column temperature that allows all the components to be resolved. Increasing the column temperature throughout the analysis dramatically reduces the time taken for higher-boiling compounds to elute, and simultaneously improves the sensitivity of the assay, as the peaks are remarkably sharper. If the early eluting compounds are resolved inadequately, a lower starting temperature or slower initial ramp should be used, taking care to observe the temperature requirements of the type of injector used. All instruments currently manufactured are available with a temperature program option, and a multi-ramp programmer is particularly useful for capillary chromatography. The first ramp can be used during splitless injection (see later) to bring the column rapidly up to the initial chromatography temperature, followed by a slower analytical ramp to perform the separation. One problem with temperature programming is that the backpressure increases with temperature and reduces the carrier gas flow if a mass-flow controller is not used. For polar stationary phases, the polarity increases with temperature, which causes distortion of RI data (see discussion on the use of RIs below). Column bleed also increases, which results in a rising baseline that can be mitigated somewhat by adequately conditioning the column before use.

Evaluating column performance

A column's performance is assessed on the basis of its efficiency (the narrowness of a peak), the peak shape (whether it tails or fronts) and its ability to resolve compound mixtures. This section deals with separation theory, and the reader may find it useful to refer at intervals to Fig. 40.3.

Retention time

Retention time (t_R) is the time taken for a given solute to travel through the column, and is the time assigned to the corresponding peak on the chromatograph. It is a measure of the amount of time that the solute spends in the column, and is therefore the sum of time spent in both the stationary and the mobile phases.

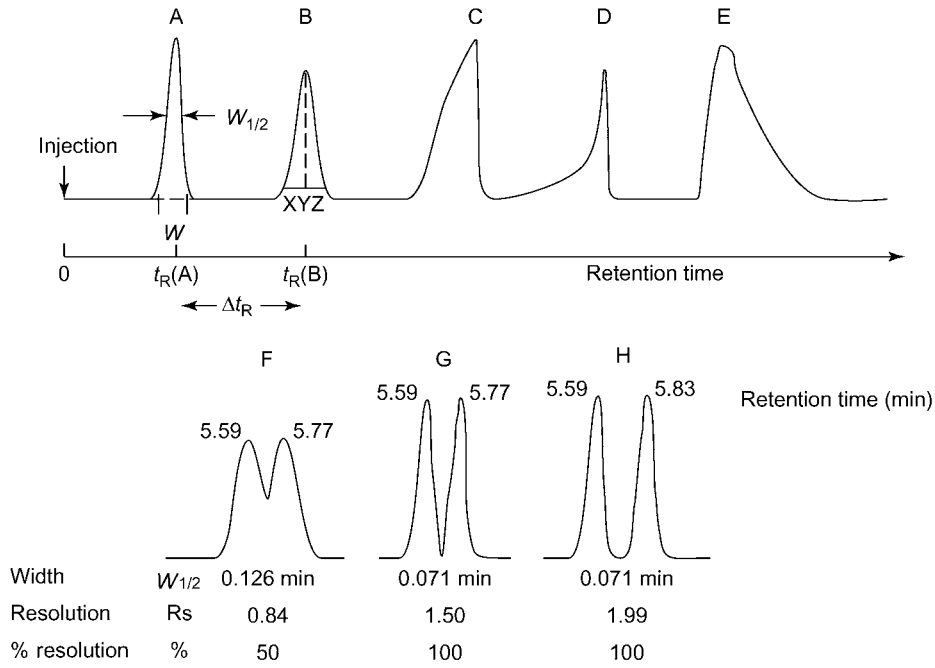

Figure 40.3 A and B are symmetrical peaks that show the measurement of significant parameters: W, width at the base of the peak; $W_{1/2}$, width at half peak height; t_R(A) and t_R(B), retention times of peaks A and B, respectively; Δt_R, the difference in retention time between A and B; XYZ, a line drawn at 10% of peak height.
Peak C is symptomatic of column overload with solute.
Peak D is symptomatic of degradation of a thermally unstable solute.
Peak E is symptomatic of adherence to active sites in the injection port or on the column.
Resolution of two compounds A and B.
F and G: peaks A and B have identical retention times (5.59 and 5.77 min, respectively), but in G the peaks are narrower ($W_{1/2}$ = 0.071 versus 0.126 min, respectively), and are fully resolved (Rs = 1.50 versus 0.84, respectively).
H: the peak widths of A and B are the same as in G, but the retention time of peak B is later (5.83 versus 5.77 min, respectively). Again, the peaks are fully resolved and Rs is larger than in G (Rs = 1.99 versus 1.50).

Retention time of a non-retained compound or hold-up time (t_M or t_0) The retention time, t_M, is the time taken for a non-retained solute to travel along the column; it represents the transit time for the mobile phase (carrier gas) in the column and is a column-specific parameter, applicable only under the prevailing conditions of gas flow and oven temperature. It is the same for all solutes on the column, and no other peak can be expected to elute earlier than this time. t_M is obtained by injecting a non-retained compound suitable for the detector system being used (butane or methane for flame ionisation detection (FID) or thermal conductivity detection (TCD); acetonitrile for nitrogen–phosphorus detection (NPD); methylene chloride for electron-capture detection (ECD); vinyl chloride for photoionisation detection (PID) or electrolytic conductivity detection (ELCD)).

Average linear velocity

The average linear velocity ($\bar{\mu}$) represents the average speed of carrier gas through the column, usually expressed in cm/s, and is considered more meaningful than measuring the flow (usually expressed in mL/min) at the column effluent, since flow is dependent on column diameter. This term directly influences solute retention times and column efficiency. Velocity is controlled by altering the column head pressure, and is calculated from equation (40.1):

$$\bar{\mu}(\text{cm/s}) = \frac{L}{t_M} \tag{40.1}$$

where L is the column length (cm), and t_M is the retention time (in seconds) of a non-retained solute.

Retention factor

The retention factor (k) is the ratio of the amount of time a solute spends in the stationary and mobile phases and is calculated from t_R and t_M using equation (40.2):

$$k = \frac{t_R - t_M}{t_M} = \frac{t'_R}{t_M} \tag{40.2}$$

where t_M is the retention time of a non-retained solute, t_R is the retention time of the solute and t'_R is the adjusted retention time of the solute.

Since all compounds spend an identical time in the mobile phase, k is a measure of retention by the stationary phase. A compound with a retention factor of 4 spends twice as much time in the stationary phase (but not twice as much time on the column) as a compound with a retention factor of 2. Thus, k provides relative rather than absolute information, and is to a large degree independent of the operating conditions.

Separation factor

The separation factor (α) is a measure of the time interval between two peaks. If α equals 1, then the peaks have the same retention time and co-elute. Separation factor is calculated using the equation:

$$\alpha = \frac{k_2}{k_1} \tag{40.3}$$

where k_1 is the retention factor of the first peak, and k_2 the retention factor for the second peak.

The value of α does not indicate whether the peaks are resolved completely from one another, however. Two peaks may have only 0.01 min between them on one column but still be resolved completely, while on another column they may have 0.1 min between them but not be resolved adequately (refer to Fig. 40.3).

Number of theoretical plates or column efficiency

The theoretical plate is an indirect measure of peak width at a specific retention time. Higher plate numbers indicate greater column efficiency and narrower peaks. The number of plates per metre of column (N) is calculated from either form of equation (40.4):

$$N = 16(t_R/w_b)^2 \tag{40.4a}$$

$$N = 5.54(t_R/w_h)^2 \tag{40.4b}$$

where t_R is the time from injection to peak maximum for the solute, w_b is the peak width at base in units of time, and w_h is the peak width at half height in units of time.

Efficiency is thus a function of the column dimensions (diameter, length, film thickness or loading), the type of carrier gas and its flow, and the chemical nature of the solute and the stationary phase. For most applications in drug analysis, the chromatogram contains only two or three compounds, but an efficient column maximises the probability that a peak consists of only one compound and that it is the compound of interest. Other more complex separations (e.g. of flavours or trace residues in foods) may require two-dimensional chromatography or heartcutting (see later) to obtain sufficient separation.

Resolution

Resolution (R) takes into account both retention time and the peak width. For any pair of compounds, resolution can be calculated using either form of equation (40.5):

$$R = 1.18\left(\frac{t_{R2} - t_{R1}}{w_{h1} - w_{h2}}\right) \tag{40.5a}$$

$$R = 2\left(\frac{t_{R2} - t_{R1}}{w_{b1} - w_{b2}}\right) \tag{40.5b}$$

where suffixes 1 and 2 refer to the two peaks being evaluated; t_R = retention time; w_h = peak width at half height in units of time; w_b = peak width at base in units of time

An R value of 1.5 indicates baseline resolution, with numbers above 1.5 indicating the presence of baseline between the peaks (higher values indicate less overlap between peaks). In practice a value of about 1.2 is needed to be able to distinguish between two peaks occurring independently and a value of >1.0 to be able to quantify either peak reliably in the presence of the other. Sometimes the parameter percentage resolution is used, as this concept is easier to visualise (calculated by dividing the height of the valley between the peaks by the total peak height). equations (40.5a) and (40.5b) allow the operator to calculate resolution directly from the chromatogram, but they give little indication of the factors that contribute to it, or the parameters that can be modified by the analyst. A preferred relation is equation (40.7c), which shows that resolution is a product of three parameters, selectivity, capacity and the square root of the efficiency.

$$R = \frac{\alpha - 1}{\alpha}\left(\frac{k}{k+1}\right)\frac{\sqrt{N}}{4} \tag{40.5c}$$

where α = separation factor, k = retention factor, N = theoretical number of plates.

Phase ratio (β) The phase ratio of a column is a calculated term relating the column radius (r) in millimeters and the film thickness (d_f) in micrometres:

$$\beta = \frac{r}{2d_f} \tag{40.6a}$$

If all other conditions are held constant, then changes in phase ratio can be used to predict expected shifts in retention of solutes using equation (40.6b):

$$k\beta = \frac{kr}{2d_f} \tag{40.6b}$$

where k = retention factor.

Thus, to increase solute retention the phase ratio must be decreased, which can be brought about either by decreasing column diameter or by increasing film thickness. Sometimes it will be necessary to alter either the column diameter (e.g. to reduce flow though a detector) or to alter film thickness (e.g. to increase efficiency), but as long as the phase ratio remains constant then these changes can be accomplished without compromising separation. Table 40.8 shows calculated phase ratios for the most common sizes of capillary columns and loadings.

Peak shape or asymmetry

A well-designed GC system should give symmetrical peaks, as tailing or fronting adversely affects resolution. Tailing may result from non-swept volume in the system or from component–stationary phase or component–support interactions. Tailing of polar compounds can often be remedied by the use of a more polar stationary phase. Fronting (shark's fin peaks) is usually caused by overloading, particularly with capillary columns, and can be resolved either by making a smaller injection or by using a column with a higher stationary phase ratio. Column capacity is the maximum amount of a solute that can be chromatographed successfully without loss of peak shape. Table 40.4 shows the relationship between column capacity, film thickness and column diameter. Peak fronting caused by thermal decomposition can be reduced by either lowering the injection temperature or using a cold on-column injector system.

Table 40.4 Relationship of capacity (ng solute)[a] of GC columns with diameter and film thickness

Film thickness d_f (μm)	*Column internal diameter (mm)*			
	0.18–0.20	*0.25*	*0.32*	*0.53*
0.10	20–35	25–50	35–75	50–100
0.25	35–75	50–100	75–125	100–250
0.50	75–150	100–200	125–250	250–500
1.00	150–250	200–300	250–500	500–1000
3.00	—	400–600	500–800	1000–2000
5.00	—	1000–1500	1200–2000	2000–3000

[a]Capacity is defined as the maximum amount of solute that can be injected without peak broadening by >10% at half-height. Approximate values are given for capacity (ng) per component. Actual sample capacity depends on the operating conditions, and the polarity of the stationary phase and the solute (polar phases and solutes give lower values).

Peak shape is usually expressed by the peak asymmetry (A_s). In Fig. 40.3, the peak asymmetry factor for substance B is given by equation (40.7):

$$A_s = \frac{YZ}{XY} \tag{40.7}$$

where a vertical line is drawn through the peak maximum and XYZ is drawn at 10% of the peak height. A symmetrical peak has $A_s = 1$.

Use of retention indices

If gas chromatographic retention data are to be exchanged between laboratories, they must be independent of the instrument used. The concept of retention index (RI) has been shown to be more reliable than that of relative retention time (i.e. the retention time of the solute relative to that of a reference compound). The RI system uses a homologous series of compounds (i.e. a series of compounds that increase in size by an additional methylene unit) to provide the reference points on the scale. The most commonly used is the system described by Kovats (1961) using straight-chain saturated hydrocarbons (*n*-paraffins or *n*-alkanes). For any column temperature and stationary phase, the elution times of members of a series of *n*-alkane homologues are assumed to increase by an index of 100 for each additional methylene unit. On this scale, H_2 has an index of zero, methane has an index of 100, ethane 200, and so on up the scale of alkanes. The RIs of unknown substances are measured against this scale, obviating the need to correct data between laboratories because of variations in retention time. The method is illustrated in Fig. 40.4, in which phenobarbital has a retention time of 4.5 min and an RI of 1957.

$$\mathrm{RI} = 100(P_{z+n} - P_z) \times \frac{\log t_R(x) - \log t_R(P_z)}{\log t_R(P_{z+n}) - \log t_R(P_z)} \tag{40.9a}$$

where t_R is the retention time, P_z is the carbon number of the smaller *n*-alkane, P_{z+n} is the carbon number of the larger *n*-alkane and x is the unknown solute.

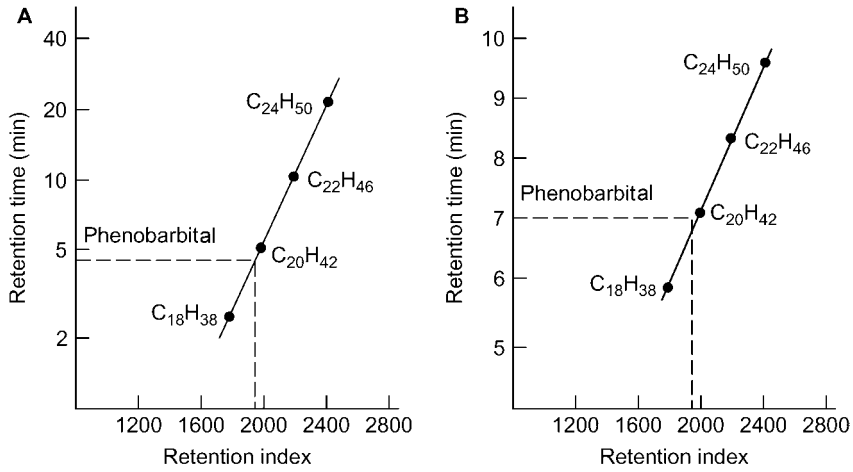

Figure 40.4 Calculation of the RI of phenobarbital from a plot of a series of homologous *n*-alkanes. (A) Packed column, isothermal conditions, retention time for phenobarbital is 4.5 min, RI = 1953; (B) capillary column, temperature programmed to run at 10°/min, retention time for phenobarbital is 7.01 min, RI = 1960.

Retention indices collected from many sources show remarkable agreement, even when measurements were made on different (though equivalent) phases and at different temperatures (Ardrey, Moffat 1981).

Most capillary GC is performed in temperature-programmed mode and the relationship between the retention time and chain length is almost linear, provided that the ramp rate is constant throughout the run and $n > 7$. The simplified equation (40.8b) is used to calculate RI (see Fig. 40.4 for an illustration).

$$\mathrm{RI} = 100(P_{z+n} - P_z) + \frac{t_R(x) - t_R(P_z)}{t_R(P_{z+n}) - t_R(P_z)} \qquad (40.8b)$$

Other homologous series have been proposed and good results were found with the alkan-2-ones and *n*-aldehydes. Use of other series (*n*-alkyl esters, *n*-alkylbenzenes, *n*-alkyl iodides) has been less successful. When using a specific detector to identify compounds, the accuracy is increased by splitting a small percentage of the column effluent to a flame ionisation detector to give a 'real-time' calculation of RI, rather than relying on either historical retention times for *n*-alkanes or using an alternative homologous series. Alternatively, Franke *et al.* (1993) have proposed the use of an RI reference mix (a selected group of compounds that structurally resemble those under investigation) rather than a homologous series. Retention indices for unknown compounds can then be normalised relative to the known RI values of the reference compounds. The main advantage of this approach is that both temperature-dependent and column-ageing effects on RI, which arise from polarity mismatch between the homologous series and the investigated solutes, are somewhat reduced and the data are therefore more reproducible over time.

As would be expected, there is better agreement for non-polar (most hydrocarbon-like) compounds than for polar compounds, and also for non-polar versus polar stationary phases where there is less difference in retention time between the *n*-alkane index markers. Using capillary columns, reproducibility can be as good as to within one RI unit for a non-polar phase, and to within a few units for a more polar one.

Good temperature, pressure and flow control, and precise measurement of the injection time and peak elution, are essential for accurate measurement of RIs. The carrier gas flow rate and the polarity of the stationary phase are temperature dependent. Thus, the partitioning of polar compounds into the stationary phase is affected by temperature to a greater extent than that for the *n*-alkanes. Differences between constant-flow and constant-pressure modes of operation are exaggerated when the column is ramped in several stages. It is common practice to have an initial fast rate of increase in temperature followed by one or more slower ramp rates, since the number of low-boiling compounds of interest is usually lower than the number of higher boiling compounds. Inaccuracies in RI calculation can also arise with high solute concentrations because of problems identifying the crest of the peak. This can also result in a trace component that elutes on the back of the concentrated one, as the major component begins to take part in the separation process by acting as a 'dynamic stationary phase'. This delays the elution of the trace component.

Column deterioration with use can lead to a preferential destruction or loss of the more labile component of a mixed phase. For example, in columns that contain mixed cyanopropyl- and methyl-PSX phases, the cyanopropyl group is preferentially lost, so that the column polarity is reduced. The elution of the index markers (*n*-alkanes) remains unchanged, but the progressive loss of cyanopropyl substituents results in a poorer interaction with polar compounds and an apparent *decrease* in their RI. With single-component stationary phases, the effect is still present, though less noticeable, as there is loss of retention of both RI markers and polar compounds.

Inlet systems

The inlet system provides the means of introducing the specimen into the GC. Obtaining a narrow sample band at the start of the chromatographic process is critical to achieve good resolution, since broad sample bands usually produce broad peaks, especially for analytes that elute early. The choice of injector depends on the characteristics of the specimen or residue, the quantity and characteristics of the analytes to be separated, and the temperature and nature of the stationary phase and the column. Solids may be dissolved in a suitable solvent and injected with a micro-syringe. It is best to keep the solution as concentrated as possible to reduce the size of the solvent peak. Liquids can be injected using a micro-syringe, but with sensitive detection systems the sample should be dissolved in a suitable solvent to reduce the sample size and avoid overloading the detector. Gases and vapours may be introduced by injection through the inlet port septum using a gas-tight syringe.

The three common types of GC injectors are split, splitless and cold on column. In reality, splitless injection is an extreme example of split injection and both are carried out using the same hardware. Conventional glass syringes of 1–10 µL volume with stainless-steel needles can be used on all but cold-on-column injectors, and the injection is made by piercing a silicone rubber septum. Care must be taken to select septa that have low bleed characteristics at the operating temperature, and those with Teflon backs are most reliable in this respect. Unstable materials can be decomposed by the high temperature of the injection system, particularly if the system is constructed of metal. For labile substances, cold-on-column injection is preferred, but clean extracts must be used to minimise column contamination.

Split and splitless injectors

Split injectors are used for more concentrated samples, since only a fraction of the sample actually enters the column. An inlet splitter allows a high flow of carrier gas through the injector while maintaining a low flow (1–4 mL/min) through the column: the excess gas and associated sample components are vented to the atmosphere through the split line. The ratio of these two flows (the split ratio) controls the proportion of the injected sample that reaches the column. The total flow through the injector may be from 10 mL/min to 100 mL/min, which gives split ratios of 10 : 1 to 100 : 1. A good splitter should be linear, i.e. it should split high- and low-boiling point compounds equally. The function of the splitter is not primarily to reduce sample volume, but rather to ensure that the sample enters the column as a compact plug. Split injections, therefore, produce some of the most efficient chromatographic separations, and allow the use of very narrow capillary columns. A lower split ratio channels a larger fraction of the injected sample down the column and may result in column overload. High split ratios waste large amounts of carrier gas and insufficient analyte may reach the column.

In splitless injection, all the carrier gas passes to the column. This is useful for very volatile compounds, for low sample concentrations or for trace analysis. The flow rate in the injector is the same as that in the column (1–4 mL/min), and the only path for the injection to take is into the column, since the split vent is closed. At a fixed time after injection (usually 15–60 s), the injector is purged by opening the split vent to introduce a much larger flow of carrier gas through the injector (typically 20–60 mL/min) and any remaining sample in the injector is discarded through the split vent. Since the rate of sample transfer onto the column is so slow (because of the low gas flow), peaks are usually somewhat broader than for split injections. Care should also be taken to ensure that the volume of the injector liner is not exceeded by the expanding solvent injected (Table 40.5), otherwise splitting of early peaks will be observed. Temperature conditions can be adjusted to narrow or focus the sample band at the top of the column. Splitless injections should therefore be made with the initial column temperature at least 10°C below the boiling point of the solvent (Table 40.5), and the initial temperature should be held at least until after the purge activation time. Solvent condenses on the front of the column and traps the solute molecules, which focuses the sample into a narrow band (known as the solvent effect). Individual solutes with a boiling point 150°C above the initial column temperature condense and focus at the top of the column in a process known as cold trapping. Either the solvent effect or cold trapping must occur before efficient chromatography can be obtained. Some newer chromatographs have the option of a pulsed splitless injection. In this mode, the column head pressure is increased immediately upon injection (typically to 174 kPa) and held there for 30–60 s, before returning to the normal operating pressure. This facilitates band sharpening and, while the process is not guaranteed to increase the fraction of the injection delivered onto the column, sensitivity is often improved because of improved chromatography.

Glass liners for split and splitless injectors come in a variety of shapes and volumes and it is prudent to start with a straight liner and to investigate some of those that cause turbulence (e.g. the inverted cup style) later if this is unsatisfactory. A plug of deactivated glass wool in the liner helps prevent the deposition of non-volatile or particulate material on the column, but may cause some peak deterioration, and for the best results needs to be placed at a consistent position in the liner. Packing of splitless injection liners with deactivated glass wool may decrease the chromatographic performance, but this must be weighed against the potential for damage to the stationary phase from the repeated injection of non-volatile or particulate material.

Table 40.5 Boiling points and expansion volumes for commonly used injection solvents

Solvent	*Boiling point (°C)*	*Expansion volume (μL) per L of solvent*[a]	*Suggested GC oven starting temperature (°C)*
Methylene chloride	40	330	15–30
Carbon disulfide	46	355	15–30
Acetone	56	290	30–45
Methanol	65	525	40–55
n-Hexane	69	165	40–60
Ethyl acetate	77	215	45–65
Acetonitrile	85	405	55–75
iso-Octane	99	130	70–90
Water	100	1180	70–90
Toluene	111	200	80–100

[a]Values are given at 250°C and 105 kPa head pressure.

Large-volume injectors

The analysis of trace amounts of components or contaminants in complex matrices such as foods, beverages and environmental samples is difficult. Adequate sensitivity to detect trace components is provided by specific detectors such as the NPD or ECD, but regulatory standards require positive identification of these compounds by mass spectroscopy (MS). To overcome the inferior sensitivity of MS, large-volume injectors have been developed. Examples include the Apex pre-column separating inlet (PSI), the temperature-programmed sample inlet (PTV) from Gerstel and time-coupled time-resolved chromatography (TCRC). The inlet typically consists of a length (10–50 cm) of standard (2 mm i.d.) glass chromatography column that can be deactivated or packed with traditional materials. The first two injectors are mounted directly in the GC injector port; the latter is a free-standing column coupled by a four-way valve into the GC inlet. Injection volumes range from 125 μL for the PSI, 1 mL for the PTV and up to 20 mL for the TCRC. Injection of larger volumes (up to 60 mL) is possible for some applications, but result in discrimination in favour of high-boiling components and loss of volatiles.

Large-volume injectors remove the solvent from the sample prior to its introduction onto the capillary column, typically by low-temperature evaporation through the split vent. As the sample is concentrated towards the bottom of the injector, the injector is heated, the split vent is closed and the analytes are introduced onto the GC column in splitless mode. Those injectors that can be heated selectively and cooled allow the precise introduction of selected components only from the sample, and thus reduce the quantity of non-volatile components (e.g. sugars) that might overload or destroy the analytical column. The TCRC has a small mobile oven (2–8 mm width) that can be scanned along the length of the column to produce band compression. Prior to the next injection, the injector columns are usually baked to vent high-boiling compounds to waste. Sensitivity can often be improved 50- to 100-fold and time is saved in sample preparation, since extensive clean-up or extraction procedures are no longer required.

Cold-on-column injection

Cold-on-column injection is most suited to compounds that are thermally labile. The injection needle must be fine enough to enter the column bore, usually fused-silica or stainless steel with a fused-silica insert. The top of the column is held at a temperature low enough for the solvent that contains the sample to condense, usually by an air- or carrier gas-cooled sleeve. The solvent temporarily swamps the stationary phase and ensures that the sample components concentrate in a narrow band. Any solvent or sample that remains in the injector is backflushed with carrier gas, often by automatic valves. The proximal end of the column is then brought rapidly to the operating temperature, when the solvent vaporises and chromatography begins. The potential for rapid column contamination or deterioration means that cold-on-column injection is usually restricted to those applications where its use is essential.

Volatiles interface

The volatiles interface allows automated analysis of gaseous samples. The interface is a low-volume highly inert switching block, and is ideally suited to trace-level detection. A portion of the carrier gas supply is diverted through the specimen sampler and released under controlled conditions onto the column. The remainder of the carrier gas goes to a flow sensor, which prevents fluctuations in column gas flow that would otherwise occur when the switching valves are opened and closed. The interface can be run in split, splitless or cold-on-column modes as described in the sections above. Samples may be introduced from external devices, such as air samplers or purge-and-trap devices (see section below), or from headspace analysis, which permits analysis of volatile substances in a liquid sample while minimising contamination of the column. This technique is used in the assay of ethanol and other solvents in blood and for complex household preparations, such as polishes, which contain volatile substances (see Chapter 14).

Thermal desorption and purge-and-trap injection

The analysis of samples that have been pre-concentrated onto solid adsorbents is common in the fields of industrial air monitoring, analysis of residues in food, soil and water, petrochemical analysis and environmental monitoring. The methods of preparing samples for analysis are described in the section on specimen preparation. These samples require special interfaces with GCs to ensure good chromatography. In some instances the sample preparation device and injector are manufactured as stand-alone pieces of equipment that require very little modification of conventional injectors, while others must be dedicated pieces of equipment. Once collected, the concentrated sample must be desorbed into the chromatograph using the heated injector port. The major problem here is the possible introduction of water into the chromatograph from moisture adsorbed during collection from high-humidity samples. Release of solutes from the adsorbent should be as rapid and complete as possible to allow for rapid and sensitive analysis and for a narrow sample band to be introduced into the chromatograph. This is achieved either by cooling the column oven cryogenically to refocus the sample in the injector prior to injection or by using a dry purge system coupled to the gas chromatograph via a volatile interface (see above) designed to operate above ambient temperature. Here, the specimen is thermally desorbed from the collection tube onto a narrower (1 mm i.d.) tube of the same adsorbent material. The concentrated solute is then released into the chromatograph, ensuring rapid and complete sample introduction. Adsorbents must be thermally stable to reduce interference from background contaminants.

With solid phase microextraction (SPME) the adsorbed sample is introduced into the heated injector port via a special sleeved needle (see under Specimen preparation). This technique requires the injector liner to be narrow (usually 0.75 mm as opposed to 2 or 4 mm) to increase the linear velocity of carrier gas through the liner and ensure that a narrow band of sample is introduced onto the column.

Solid injection

When solvent interference is serious the sample may be injected as a solid. The 'moving needle' injector has found application in steroid analysis and for the determination of anticonvulsant drugs. A solution of the material to be injected is placed on the tip of the glass needle with a syringe. A small flow of carrier gas sweeps the solvent out of the top of the device to waste. The dry residue is then introduced by moving the needle into the heated injection zone of the chromatograph with a magnet. This form of injection can be used only with compounds that do not volatilise with the solvent.

Backflush

Upon vaporisation, the injected sample undergoes considerable expansion, sometimes up to 100 to 1000 times its original volume, which creates a pulse of pressure that often exceeds the column carrier gas pressure. If the volume of the liner is smaller than the expanded solvent volume (see Table 40.5), some of the sample is propelled out of the injector in a process known as backflush. This can appear as a broad tailing solvent front, since it now takes longer to flush the expanded solvent out of the injector and carrier gas line. Backflush can also cause injector contamination, since the analytes condense in the cooler carrier gas line, from where they may bleed continuously into the injector and cause high background or spurious peaks. Carryover or peak ghosting can occur when the next injection backflushes and carries previously condensed compounds back into the vapour phase and onto the column. Backflush can usually be solved by using a smaller injection volume, a less expansive solvent, a lower injector temperature, a liner with an upper restrictor, or a faster carrier gas flow. The use of an adjustable septum purge gas (usually 0.5–1 mL/min) also decreases the potential for backflush, as components that would normally condense on the cooler septum and travel into the carrier gas lines are swept away by the septum purge. Too high a purge flow results in loss of highly volatile components.

Injector discrimination

Injector discrimination occurs because not all the compounds in the sample vaporise at the same rate. Since the sample remains in the liner for a limited time, this usually results in some loss of higher-boiling solutes. This can be alleviated by increasing the residence time of the sample within the injector, or by using a higher injector temperature or smaller injection volume. However, there is usually a compensatory loss in lower-boiling compounds. Discriminating behaviour can usually be managed by making reproducible injections.

Gas pressure and flow control

For accurate and reproducible GC, either a constant carrier gas flow or a constant carrier gas pressure must be maintained. Under isothermal conditions, simple pressure control is adequate for packed or capillary columns and back pressure can be monitored by a pressure gauge between the flow controller and the injector. A decrease indicates a leaking septum and an increase suggests contamination of the injector liner or the top of the column. This also ensures that the flow controller is performing correctly. Since the back pressure rises to equal the supply pressure, flow becomes pressure controlled. Flow control is highly desirable, if not essential, during temperature programming with packed columns and can be used to advantage with capillary columns. The added convenience of a digital (electronic) flow controller may be worthwhile.

Since the carrier gas becomes less viscous as the column oven temperature rises, the gas pressure must be increased as the run progresses to maintain constant velocity (or constant flow) throughout the analysis. Fig. 40.5 shows the effects of increasing the column temperature on the carrier gas flow and velocity if the head pressure is held constant during the run. As flow and velocity do not respond identically to increasing temperature (see Fig. 40.5D), late-eluting analytes are recovered more quickly using constant flow than under constant-pressure conditions. Furthermore, since column efficiency is a function of the carrier gas velocity (Fig. 40.6), resolution at the end of the chromatogram is improved under constant flow conditions. Switching between conditions of either constant flow or constant pressure can sometimes resolve otherwise co-eluting compounds. Table 40.6 shows the relationship between flow and pressure for various lengths and diameters of capillary columns. It shows the calculated head pressure (kPa) required to achieve the stated gas velocity or flow through a 25 m column operating at 150°C. Note that head pressure values above 280 kPa are not usually practicable using standard pressure regulators. Increasing the column length has a direct and proportional increase on head pressure for both velocity and flow calculations.

The way in which carrier gas velocity affects column efficiency is best demonstrated by reference to the van Deemter curves in Fig. 40.6. These demonstrate that the optimum column efficiency (minimum height equivalent of a theoretical plate, HETP) occurs at intermediate

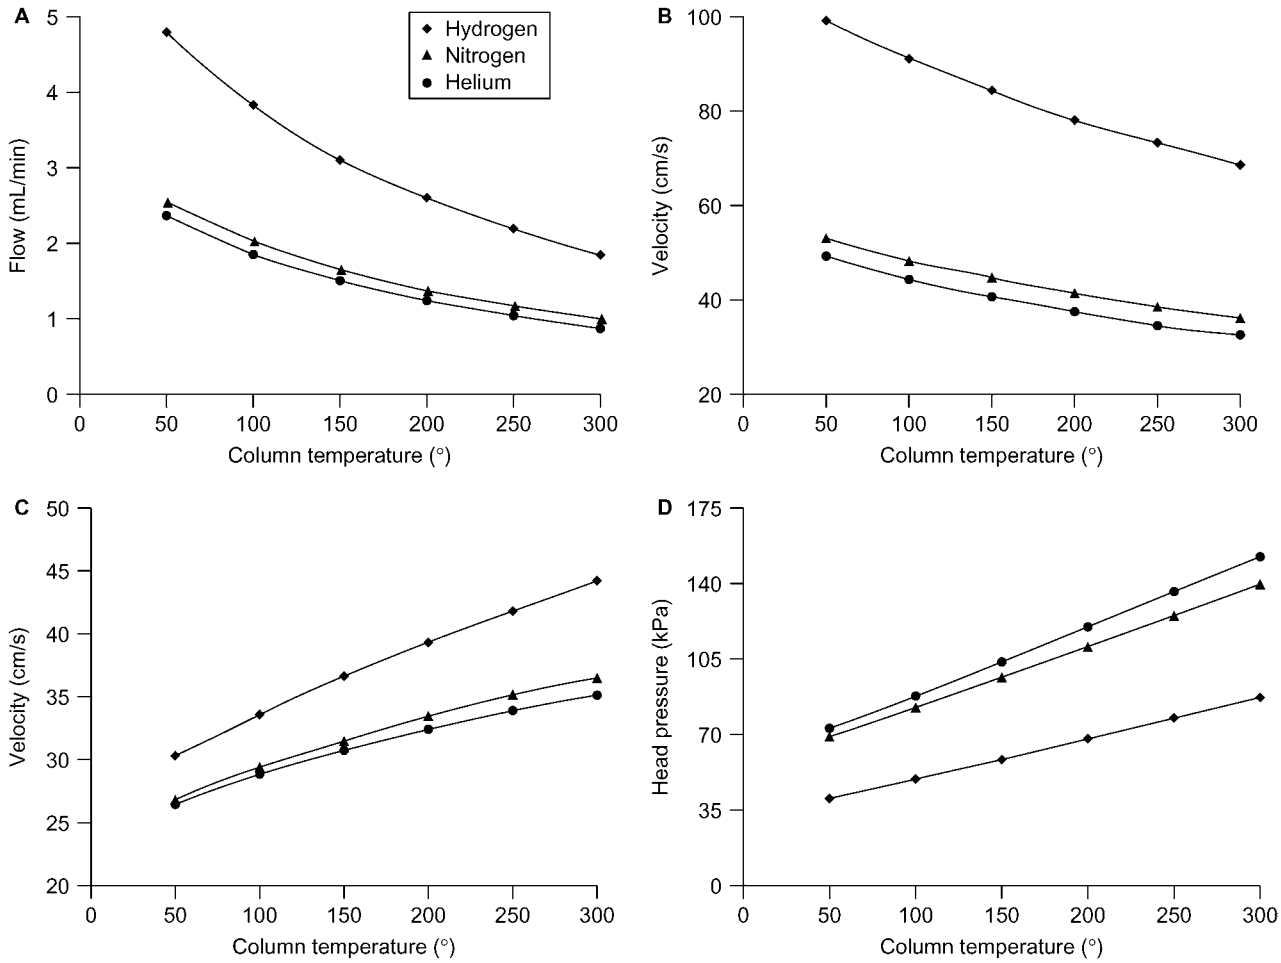

Figure 40.5 Effect of temperature on carrier gas flow and velocity. (A) and (B) are under conditions of constant carrier gas head pressure (140 kPa). (A) shows the change in column flow (mL/min) with change in temperature from 50°C to 300°C. (B) shows the change in velocity (cm/s) with change in temperature from 50°C to 300°C. (C) and (D) are under conditions of constant carrier gas flow (1 mL/min). (C) shows the change in carrier gas velocity (cm/s) with change in temperature from 50°C to 300°C. (D) shows the change in column head pressure (kPa) with change in temperature from 50°C to 300°C. All calculations are for a 25 m column of 0.25 mm i.d. operating at atmospheric pressure and 150°C.

velocity, and that column efficiency is compromised at both low and very high velocities. A small loss in efficiency for a shorter analysis time is usually tolerated. Curves are shown for the three most common carrier gases (helium, nitrogen and hydrogen), and it can be seen that the chromatography is much less tolerant to changes in nitrogen velocity than to helium. Helium is favoured by most users, as analysis times are half that with nitrogen, with only a slight loss in efficiency. While hydrogen gives the best dynamic range and shortest analysis times, there are safety issues relating to its use. While the gas used for the carrier gas should always be of the highest purity available, a lower-quality gas can sometimes be used for the makeup or detector, since these do not contribute to column deterioration by oxidation. Regardless of quality, it is advisable always to use a scrubber (to remove oxygen and hydrocarbons) followed by a dryer (to remove water vapour) between the supply and the instrument. Metal trap bodies are recommended, as plastics are permeable to impurities in laboratory air, especially when large amounts of organic solvents are used. Most traps have an indicator to show when they are saturated, and they can be changed without interruption to the gas flow. Stainless steel or copper tubing is recommended for plumbing of all gases, as plastics are permeable to moisture and oxygen, and Teflon, nylon, polyethylene, polypropylene and PVC contain contaminants that degrade gas purity.

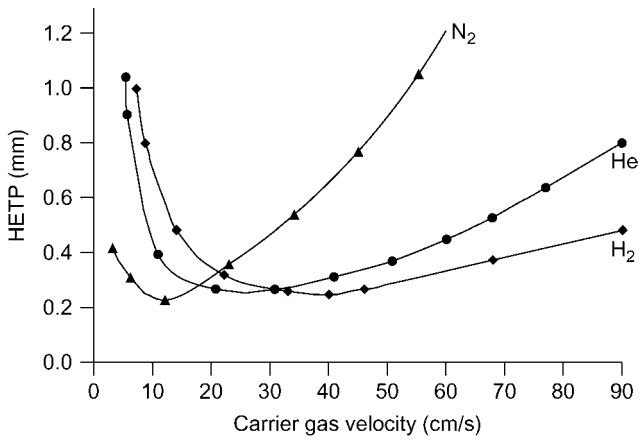

Figure 40.6 Van Deemter plots for a 25 m × 0.25 mm i.d. WCOT OV-101 column. HETP = height equivalent of a theoretical plate.

Detector systems

The choice of chromatography detector for an application depends on factors such as cost, ease of operation, consumables supply, sensitivity, selectivity and the linear working range.

Some detectors respond to almost all solutes, while others (selective detectors) respond only to solutes with specific functional groups,

Table 40.6 Relationship of gas chromatography column diameter to column flow, velocity and head pressure (kPa)

	Column internal diameter (mm)					
	0.10	***0.18***	***0.20***	***0.25***	***0.32***	***0.53***
Velocity 30 cm/s						
Hydrogen	329.1	93.2	10.8	74.5	28.7	10.4
Nitrogen	654.1	181.5	144.9	90.4	54.2	19.5
Helium	724.5	201.5	160.0	100.1	60.0	215.3
Flow 1 mL/min						
Hydrogen	675.5	157.3	115.9	58.2	24.8	3.66
Nitrogen	959.1	240.8	181.5	95.9	43.2	6.76
Helium	1007.4	254.6	193.2	102.8	46.9	7.38

Data for a 25 m column operating at 150°C.

atoms or structural configurations. Additional functional groups can often be added to solutes, generally after extraction (see below under Derivatisation), to achieve a response from a selective detector and gain additional sensitivity and selectivity. The use of detectors such as the ECD to identify amenable compounds, and the NPD to detect compounds that contain phosphorus and nitrogen, removes many of the extraneous peaks frequently observed when using non-selective detectors, such as the FID. However, these selective detectors have also led to the detection of substances such as plasticisers from blood-collection tubes or transfusion lines, which interfere in many toxicological analyses. Detectors that detect the presence of a solute and also give information about its structure are increasingly popular and MS, Fourier transform infrared spectroscopy and atomic emission spectrometry have been invoked to achieve this goal. Detector sensitivity is measured as signal-to-noise ratio, in which the signal corresponds to the height of the peak, and the noise to the height of the baseline variability. A signal-to-noise ratio of 8 to 10 is considered sufficient to confirm the presence of a peak. Each type of detector has a linear operating range in which the response obtained is directly proportional to the amount of solute that passes through, although this can be modified slightly by the nature of the solute and the chromatographic conditions (mobile phase type and flow, detector temperature). The linear operating range is considered to be exceeded when the incremental response obtained from the detector varies by more than 5% from that expected.

Most detectors (except MS) rely on gas other than the mobile phase (combustion, reagent or purge gas) for their operation. Usually, a total flow of at least 30 mL/min is necessary to sweep the solute molecules physically through the body of the detector at sufficient speed to prevent refluxing and produce narrow peaks. Thus, the addition of a 'makeup' gas is invariably required with capillary columns. Recommended gases and their flows for each detector are included in the manufacturer's instruction manuals, and it is important to follow these guidelines (and those on maintenance) to achieve the stated performance.

Here, only the most widely used detectors are considered in detail. Several other types of detectors are available; for a more detailed discussion, the reader is referred to the text by Scott (1996).

Flame ionisation detector

This is the most widely used of all detectors, since it responds to nearly all classes of compounds. The effluent from the column is mixed with hydrogen and the mixture is burnt at a small jet in a flow of air. A polarising current is applied between the jet and an electrode situated above it. When a component elutes from the column it burns in the flame to create ions that carry a current between the electrodes and provide the signal. The background current and noise are both low. Any of the usual carrier gases can be used and minor changes in gas flow are without effect. Sensitivity is moderate (0.1–10 ng), with linearity extending sometimes as high as six orders of magnitude. The response of the FID is dependent on the number of carbon atoms in the molecule, but the response is lowered if oxygen or nitrogen is also present in the molecule. It responds to all organic compounds that contain carbon–hydrogen bonds with the exception of formic acid. Both the sensor design and electronics are simple, and manufacturing cost is therefore low. The FID is easy to clean, and when operating with capillary columns it is virtually maintenance free. With packed columns, however, there is a tendency for a build-up of stationary phase bleeding from the column, which must be removed periodically. The insensitivity of the detector to water is a useful feature that allows aqueous solutions to be used.

Nitrogen–phosphorus detector or alkali flame ionisation detector

The introduction of alkali metal vapours (usually supplied by an electrically heated bead of rubidium chloride or caesium chloride) into the flame or 'plasma' of an FID confers an enhanced response to compounds containing phosphorus and nitrogen. By adjustment of the plasma gases the detector can be made virtually specific for phosphorus compounds (e.g. a phosphorus : carbon response ratio of 50 000 : 1 and a phosphorus : nitrogen response ratio of 100 : 1). Even when optimised for nitrogen compounds, it retains its response to phosphorus (e.g. a nitrogen : carbon response ratio of 5000 : 1 and a nitrogen : phosphorus response ratio of 10 : 1). This detector is particularly useful for drug analysis, since most drugs contain nitrogen, while the solvent and the bulk of the co-extracted material from a biological sample do not. The NPD is ideal for detecting pesticides that contain phosphorus, and therefore has wide application in environmental and regulatory analysis (air, soil, water and residues in food). The extreme sensitivity to compounds that contain phosphorus can be further exploited by the preparation of derivatives that contain this element. Sensitivity is excellent (1–10 pg), with a good linear range of up to four or six orders of magnitude. A disadvantage is the need for the supply of three gases and, unlike with the FID, their control is absolutely critical to selectivity. The detecting element (bead) lasts between 1 and 3 months depending on usage. Stationary-phase bleeding from packed columns coats the bead and collector assembly but can be rinsed off using methanol or dilute (0.1 mol/L) sulfuric acid. Most of the early problems that arose from poor reproducibility in bead coating have now been resolved, and the most stable detectors nowadays have a geometry that enables the bead to be located and fixed in its optimal position with relative ease.

Electron-capture detector

The early form of this detector consists of a small chamber with a pair of electrodes and a radioactive source, usually ^{63}Ni, placed close to the cathode to ionise the carrier gas. Potential applied to the electrodes produces a steady background current. Electron-capturing solutes arriving in the chamber remove some of the electrons and reduce the detector current. The response of the detector is therefore a loss of signal rather than an increase, as is given by most other detectors. Although the ECD can be polarised from a suitable low-voltage direct-current supply, it is more sensitive when a pulsed power supply is used, and in modern detectors the polarising pulses are modulated to maintain a constant current. A voltage that depends on the modulation frequency is generated as the output signal. Additional carrier gas is necessary, even with packed columns, to obtain a flow of at least 60 mL/min to purge the detector adequately and avoid peak broadening and distortion. Sensitivity can also be improved dramatically by raising the operating temperature of the detector, and decreasing the makeup gas flow.

The ECD is a selective detector with a very high sensitivity to compounds that have a high affinity for electrons; for many compounds, the sensitivity of the ECD often exceeds that of MS, and sometimes even that of the NPD. Compounds that contain a halogen, nitro group or carbonyl group are detected at 0.1–10 pg, 1–100 pg and 0.1–1 ng, respectively. This makes it very useful for compounds such as the benzodiazepines or halogenated pesticides and herbicides. Alternatively, the great sensitivity of the detector may be utilised by preparing derivatives with halogenated reagents, such as trifluoroacetic, heptafluorobutyric or pentafluoropropionic (PFP) anhydrides. Linearity (at best only two or three orders of magnitude) is a limiting factor for quantitative analysis.

In older models, the addition of a small amount of quench gas, such as methane, improves stability and linearity, and is essential if argon or helium carrier gas is used. Newer models can be operated successfully with helium as both carrier and detector gas. The ECD, because of its high sensitivity, can be contaminated easily: an impure cylinder of gas can damage a detector beyond repair in a matter of only a few hours. Cleaning is difficult, although some material can be removed by heating the detector to its maximum operating temperature overnight, and the injection of water in 100 µL aliquots through an empty glass column can also help. However, if contamination is avoided, it is virtually maintenance free. The radioactive source requires special handling procedures that may be subject to federal legislative regulations. More recently, it has been shown that this detector can work with greater sensitivity and operate over an increased linear range using a helium plasma in place of the radioactive source.

Fourier-transform infrared detector

In the Fourier-transform infrared detector (FTIRD), the column effluent is conducted through a light pipe and swept by a scavenging gas into the path of an infrared light beam that has been processed by an interferometer. The interferometer directs the entire source light to a beam splitter, which sends the light in two directions at right angles. One beam takes a fixed path length to a stationary mirror, while the other takes a variable path length to a computerised moving mirror. The two beams are recombined, and the difference in path lengths creates constructive and deconstructive interference, or an interferogram. The recombined beam is then passed through the sample. Analyte molecules absorb light energy of specific wavelengths from the interferogram, and the sensor reports variation in energy versus time for all wavelengths simultaneously. For molecules to be infrared active they must be able to undergo a change in dipole moment with the transition to their excited state. As a result, many compounds that are symmetrical do not respond.

Fourier transformation refers to the mathematical computation that converts the data from an intensity versus time plot into an intensity (percentage transmission) versus frequency spectrum. Each dip in the spectrum corresponds to light absorbed, and can be interpreted as characteristic of specific functional groups in the molecule. Computer libraries allow for easy and rigorous comparison of spectra. FTIR can be fully quantitative, but it is relatively insensitive (10 ng range). Its advantages are that it is non-destructive, and it can distinguish between isomers (MS cannot). Because of the logistical difficulties of combining FTIR with GC, this combination of techniques has started to emerge only recently.

Atomic emission detector

With the atomic emission detector (AED), carrier gas that elutes from the column delivers solutes into a high-temperature helium plasma, where heat energy is absorbed by the constituent elements. In returning to their ground state, they emit energy as light, the wavelength of which is characteristic for each element. Emitted light is focused by a quartz lens and spherical mirror onto a diffraction grating, and the dispersed light is focused onto a diode array that is continuously scanned (wavelength usually 170–800 nm). Typically, some 15 elements can be monitored simultaneously, and each is plotted against time. The composite chromatogram allows the percentage elemental composition of each peak to be determined. Sensitivity is very good, but the detector is complex and expensive to operate and is not widely used.

Mass spectrometer

A gas chromatograph is an almost ideal inlet device for quadruple MS. The detector is maintained under vacuum, and in the most common technique of electron impact (EI) the column effluent is bombarded with electrons. Compounds absorb energy, which causes them to ionise and fragment in a characteristic and reproducible fashion. The resultant ions are focused and accelerated into a mass filter that allows fragments of sequentially increasing mass to enter the detector stepwise. The mass filter scans through the designated range of masses (usually up to about 700 amu) several times per second. The abundance of each mass at a given scan time produces the mass spectrum, which can be summed and plotted versus time to obtain a total ion chromatogram. The MS detector can be operated either in full scan mode (collecting all the ions within a given mass range) or selected-ion monitoring (SIM) mode, which collects only pre-selected masses characteristic for the compound under study. Sensitivities for the two modes of operation are quite different: 1–10 ng for full scan, increasing to 1–10 pg in SIM because of the dramatic decrease in background noise. The linear range is excellent and often spans five or six orders of magnitude. Recent advances in computer technology, coupled with improved detector design, have revolutionised the use of the MS detector from a research tool to one of routine application. This technique is described in more detail in Chapter 37.

Ion-trap mass spectrometer

As with other forms of mass spectrometers, EI or chemical ionisation (CI) is used to produce an ion source, but this is focused into the ion-trap mass spectrometer in pulses rather than continuously. The fundamental difference is that all the solute ions generated over the entire pulse period are trapped in the detector and are then sequentially ejected in increasing mass number from the trap into the electron multiplier. The addition of helium into the trap (133 mPa) contracts the ion trajectory to the centre of the trap, where it is further focused by the ring electrode, to form dense ion packets that are expelled more efficiently than diffuse clouds, and thus greatly improve resolution. The spectral patterns can be quite different from those produced by mass filter spectrometers, and are often characteristic of the conditions under which the instrument is run, which makes comparison difficult between instruments. However, because the ion collection period is longer, the sensitivity of the ion trap in full scan mode is similar to that obtained in SIM on the average MS. Furthermore, an improved mass range (sometimes up to several thousand atomic mass units) gives this type of detector many applications, particularly for quantitative trace analysis, and for higher mass components. This technique is described in more detail in Chapter 37.

Dual detector systems

The simultaneous use of a combination of a universal detector (FID) with a specific detector to monitor the effluent of a column can provide useful information about the properties of functional groups and substituents in a molecule. The FID response is roughly dependent on the number of carbon atoms in a molecule and is quite predictable. However, the ECD response varies widely for different compounds is dependent on the electron-deficient part of the compound and is difficult to predict. The NPD response of a compound depends to some extent on the number of phosphorus or nitrogen atoms in a molecule, but it also depends on their environment. Thus, by using the FID as a reference, and measuring the ECD or NPD response relative to it, another characteristic for identification is obtained in addition to retention behaviour.

Dual detector systems can be used in several ways. The column can be split at the detector end and the effluent passed into two different detectors that operate in parallel. This approach allows the most flexibility, since the choice of detectors is wide, and the effluent can be split in proportion to the sensitivity required from each detector. For capillary columns this is accomplished easily with zero-dead-volume press-fit tee connectors, but it is a more complicated operation for packed columns. Additional makeup gas may be required to ensure a good flow through the detectors, and care should be taken to use tubing of a total area smaller than or equal to the analytical column to avoid loss of peak shape through refluxing at the detector. Alternatively, the GC oven houses two completely separate but identically matched columns, each connected to a single detector. This is not an ideal approach, as matching columns is difficult and has to be checked at frequent intervals. Another approach is to stack the detectors in series, and some manufacturers deliberately provide detectors in identical modules for this purpose. There are limitations to the choice of possible detector combinations, as the first

detector must always be a non-destructive detector, such as the ECD, AED or FTIRD.

Specimen preparation

Prior to chromatography, it is usually necessary to isolate the compound(s) of interest from either a biological matrix (plasma, urine, stomach contents, hair or tissue) or some other matrix, such as soil, air or water. Removal of extraneous material and concentration of the compounds of interest usually take place simultaneously. The high water solubility of some drug metabolites (e.g. glucuronide conjugates) requires chemical conversion to a less polar entity to permit isolation from water-based samples, and a hydrolysis procedure is often used for this purpose.

Isolation and concentration

Protein precipitation

If the analyte is present in blood in high concentration, a simple protein precipitation step often provides a suitable extract, although the possibility of losing significant amounts of analyte with the precipitate must be considered. Mixing with a solution of mercuric chloride or barium sulfate readily precipitates plasma proteins, and centrifugation provides a supernatant for direct injection onto the chromatography column. Use of perchloric or trichloroacetic acids (10%) is not advised, unless the resultant solution is neutralised prior to injection. Dimethylformamide is a good organic precipitation reagent that is well tolerated by most GC stationary phases. Other organic precipitating agents are methanol, acetone and acetonitrile, all of which should be added in the proportion of two volumes to each volume of blood. While the extract is still water based, most columns with a high stationary-phase loading (5 μm film thickness) can tolerate the injection of 1 μL of water. If the column is not water tolerant, it is possible to evaporate small volumes of the supernatant to dryness for reconstitution in a more suitable solvent.

Liquid–liquid extraction

Liquid–liquid extraction is the most frequently used method to isolate and concentrate solutes for GC. The pH of the specimen is adjusted to ensure that the compounds to be extracted are not ionised (basic for bases, acid for acidic compounds). Bearing in mind that some portion of the aqueous acid or base will dissolve in the solvent, the use of strong mineral acids or alkalis is not advised as this adversely affects column performance. Best results are obtained with acidic buffers (phosphate or acetate) and with ammonium hydroxide or basic buffers (borate), using a 5 : 1 ratio of solvent to specimen. The solvent chosen should be sufficiently polar to partition the compound of interest without co-extracting excessive amounts of polar contaminants. For more water-soluble drugs, such as beta-blockers, the addition of 2–10% of a polar solvent (e.g. isopropanol or butanol) is helpful, or solid sodium chloride can be added to 'salt out' the analyte. If a derivatisation step is to be carried out subsequently, the use of a solvent compatible with the derivatisation eliminates the need for an evaporation step. Use of solvents with a higher density than the sample (e.g. dichloromethane) can lead to difficulty in isolation of the organic phase. Purification of extracts by back extraction (re-extraction of the analytes from the organic solvent at the opposite pH followed by re-extraction into solvent at the original pH) may be helpful for trace analysis. The use of a small volume of solvent for the final extraction serves as a concentration step without the need for separation and evaporation of the organic phase.

Solid–liquid or solid-phase extraction

Solid–liquid extraction uses a polypropylene cartridge with a small amount (200 mg to 3 g) of high-capacity (1–20 mL) silica-based packing at the base of the reservoir. On introduction of the sample matrix, the compounds of interest are withheld by the packing. Impurities are then rinsed selectively from the column, and the final elution releases the compound of interest. Evaporation followed by reconstitution in a suitable solvent provides a clean, concentrated sample ready for analysis by GC. Bonded-phase packings that have been modified by the addition of various functional groups are available. The mechanisms of interaction for the matrix, analytes and packings are similar to those in LC (see Chapter 38). Polar stationary phases retain polar analytes (normal phase) and are eluted with organic solvents, while non-polar stationary phases retain non-polar analytes (reversed-phase) and are eluted with aqueous solvents. Ion-pair extraction uses a non-polar stationary phase and polar analyte, with a counter-ion added to the sample solution, and allows retention of the (now neutral) analyte by a reversed-phase mechanism. In ion-exchange extraction, the adsorbent surface is modified with ionisable functionalities. Analytes with ionic charges opposite to those on the packing are retained. Solvents that contain counter-ions of greater strength are used to elute the analytes of interest from the tube.

Solid-phase microextraction

Solid-phase microextraction (SPME) requires no solvents or complicated apparatus and can concentrate volatile and non-volatile compounds in both liquid and gas samples. The unit consists of a fused-silica fibre attached to a stainless-steel plunger coated with a stationary phase (mixed with solid adsorbents as required). The plunger is inserted through a septum into a vial that contains the sample, and the fibre is exposed by depressing the plunger either into the liquid or into the headspace for 20–30 min. The retracted fibre is inserted into the injection port of the GC, and is desorbed when the plunger is depressed. The unit may be reconditioned and used 50 to 100 times. For field analysis, adsorbed samples can be stored and transported in the needle sealed in a special container for subsequent analysis by GC (or LC). Pesticides recovered from water samples have been shown to be more stable when stored in this way than in water. The special small-volume injection liner fits any model of chromatograph, and produces sharper peaks because of the higher linear gas velocity, with little or no backflush. Suitable stationary phases are:

- 100 μm dimethyl-PSX film for low-molecular-weight compounds or volatiles, or a thinner film (7 μm) for higher-molecular-weight semi-volatile compounds
- 85 μm polyacrylate film for polar compounds
- 65 μm film of dimethyl-PSX-divinyl benzene for volatile alcohols and amines
- For surfactants, 50 μm Carbowax-templated resin
- For trace-level volatiles, a 75 μm Carbowax-carboxen phase is suitable.

An alternative approach uses a small magnetic stir bar encapsulated in glass and coated with a layer of dimethyl-PSX. The bar is left to stir in the sample for 30–120 minutes and then removed and placed in a thermal desorption tube. From there, it is introduced onto the GC as described in the section Thermal desorption. Both approaches give similar performance for higher-boiling compounds (>350°C), but SPME is inferior for lower-boiling compounds such as naphthalene and fluorene (b.p. 218°C and 298°C, respectively).

Supercritical fluid extraction

A supercritical fluid (SCF) is a substance that is maintained above its critical temperature and pressure, where it exhibits physicochemical properties intermediate between those of a liquid and those of a gas. Properties of gas-like diffusivity, gas-like viscosity and liquid-like density combined with a pressure-dependent solvating power provided the impetus to apply SCFs to analytical separation. The initial applications most often involved isolation of flavours and contaminant residues from food and soil. These have now been extended to the isolation of drugs from blood and other aqueous-based media by using adsorbents added in-line (such as molecular sieves, diatomaceous earth, silica gel, etc.) to filter proteinaceous material and adsorb water. It is possible, by adding small volumes of co-solvent to the SCF, to extract highly polar solutes with excellent efficiency. In contrast to the conventional extracting solvents, the fluid most often used in supercritical fluid extraction (SFE), supercritical CO_2, is non-polluting, non-toxic and relatively inexpensive. Additionally, extractions are carried out quickly at temperatures that avoid degradation of temperature-sensitive analytes and provide clean extracts with extremely high efficiency. Several dedicated SFE analysers are available; each consists of a gas supply, pump and controller used to pressurise the gas, temperature-controlled oven, extraction vessel, internal diameter regulator and collection device.

The CO_2 supply is compressed to a selected pressure (e.g. 28 000 kPa) and its is temperature adjusted (e.g. 50°C). As the supercritical CO_2 passes through the sample material, the solutes are extracted to an equilibrium solubility level, typically about 10% (w/w). The gaseous solution that leaves the extractor is passed through the pressure-reduction valve, where the pressure (and thus the dissolving power) of the CO_2 is reduced. The solutes precipitate in the separator, and the CO_2 is recycled through the system several times until the extraction is completed, when it is vented to waste.

Headspace analysis

This method of isolation is used for analytes with volatility higher than that of the common extraction solvents. A detailed description of the technique is given in Chapter 14.

Purge and trap

Purge and trap is a powerful procedure for extracting and concentrating volatile organic compounds from soil, sediment, water, food, beverages, etc. It is especially useful for poorly water-soluble compounds and those with boiling points above 200°C. The procedure involves bubbling an inert gas (nitrogen or helium) through an aqueous sample or suspension at ambient temperature, which causes volatile organic compounds to be transferred into the vapour phase. During the purge step, purge gas sweeps the vapour through a trap containing adsorbent materials that retain the volatilised compounds. Water vapour may be removed by dry purging. The trap is rapidly heated to 5–10°C below the desorption temperature. The valve is then switched to join the trap flow to the carrier gas flow, and the trap heated to its desorption temperature for a fixed time. Adsorbent tubes are usually packed with multiple beds of sorbent materials, each one more active than the preceding one, which allows compounds with a wide range of boiling points and polarities to be analysed simultaneously. During the purge, the smaller and more non-polar solutes are readily carried down the beds and, since the carrier gas passes in the opposite direction during the desorption phase, the larger and more polar compounds do not come into contact with the innermost active beds, from which their release may be difficult to effect.

Thermal desorption

This technique is used extensively for air monitoring in industrial hygiene, environmental air, indoor air or source-emission monitoring. The device may be portable or fixed and of varying size. Air is pumped continuously through the device at a fixed rate, during which time components are extracted gradually and concentrated onto the adsorbent beds; the arrangement of the beds is the same as described above for the purge and trap, and prevents potentially irreversible binding of large molecules. The direction of the flow is simply reversed during desorption. Analysis requires a special interface to the GC, which is described above in the section Thermal desorption and purge-and-trap injection. The adsorbents must have high capacity to remain active during the entire sampling period, and show an acceptable pressure drop during sampling. Ideally, a minimal amount of unwanted analytes should be absorbed, as these will contribute to the background noise.

Pyrolysis

Analytical pyrolysis can be a very useful tool for characterization of complex materials, including synthetic polymers (e.g. plastics) and natural organic polymers such as humic organic matter (HOM). Conventional pyrolysis with a unit connected to the exterior of the GC injection port is of only limited use for HOM, first because of the formation of much carbonaceous residue of virtually zero diagnostic value, and second because of loss of high-boiling pyrolysis products with great diagnostic value during the sample transfer from the pyrolysis unit to the GC column. Such products are long-chain alkanes, alkylbenzenes, fatty acids and dicarboxylic acids, as well as steranes and hopanes. These large compounds originate in the HOM as they are not formed during pyrolysis, and are diagnostically distinct from smaller products such as phenols that might originate either from the HOM itself or equally from the breakdown of lignin, carbohydrates and proteins, which are the starting material for HOM. To circumvent this deficiency, an in-column pyrolysis unit has been devised that sits in the GC oven (Gorecki, Poerschmann 2001). This is a silicosteel metal capillary (0.53 µm diameter) connected through butt connectors to a fused-silica restrictor inserted in the injection port which prevents backflush, and to the analytical column. The unit can be heated up to 750°C in 13 ms, and can be cooled again to ambient temperature in 4 s. The much reduced discrimination traditionally related to transfer of higher-boiling fractions is thus overcome, and this arrangement greatly extends the application of pyrolysis as a means of sample introduction into GC.

Tissues and hair

Tissues and hair require treatment prior to drug extraction to break down the biological matrix and enable a good recovery of the drug. For solid tissues, good results are obtained by incubation of a portion of the tissue with a mixture of a collagenase, a protease and a lipase in a buffer of suitable pH. For small amounts of tissues (100 mg), overnight treatment at room temperature suffices, although gentle agitation or occasional mixing speeds up the process. Larger amounts of tissue benefit from mechanical homogenisation prior to incubation. For the analysis of hair, an initial washing to remove residues from cosmetic products or environmental contaminants is recommended, followed by incubation with either caustic alkali (for basic drugs) or mineral acid (for acidic drugs). After adjustment of the pH, drug recovery can proceed by the usual procedures established for the specific compounds under investigation. For additional information see Chapter 10 and Chapter 19.

Hydrolysis

Recovery of conjugated drug metabolites from biological fluids can be increased by hydrolytic cleavage of the conjugate bond prior to extraction. This offers a vast improvement in sensitivity for qualitative analysis, particularly from urine, and is essential to identify drugs (e.g. laxatives) that are excreted almost exclusively as conjugated metabolites. However, reliable quantitative analysis of conjugated metabolites requires that the unconjugated metabolite must first be removed or quantified, and then the total (conjugated plus unconjugated) metabolite be measured after hydrolysis in a subsequent separate procedure. For quantitative work, appropriate standards that contain conjugated metabolites must be carried through the procedure to monitor the efficiency of the hydrolysis step.

Enzymatic hydrolysis

The use of a specific enzyme to cleave chemical bonds is the more specific of the two approaches but it incurs additional cost and time. It also provides cleaner extracts, and therefore prolongs the life of the chromatography column. There are a number of commercial preparations of purified glucurase and sulfatase harvested from different species. It is important to pay attention to the pH and temperature optima of the specific enzyme preparation. Temperature-tolerant preparations allow heating up to 60°C, which permits relatively short incubation times (2 h).

Chemical hydrolysis

This quicker and less expensive approach can provide suitable extracts for chromatography for some analytes, although they are generally more demanding in terms of clean-up procedures. Typically, strong mineral acids or alkalis are used, often with boiling or treatment in a microwave or pressure cooker. Extracts must be neutralised, otherwise the chromatography column deteriorates quickly. Care should be taken to ensure the stability of the analytes to the hydrolysis conditions. Vigorous hydrolysis conditions often yield undesirable by-products or, if several compounds can be hydrolysed to a single entity, preclude accurate identification of the original compound present. For example, both the acid and the enzymatic hydrolysis of benzodiazepines remove glucuronide conjugates, but acid hydrolysis also converts two or three drugs to the same benzophenone compound (diazepam, temazepam and ketazolam are all converted into 2-methylamino-5-chlorobenzophenone). While this compound has good chromatography characteristics, the approach is unsuitable for those applications (such as forensic analysis) that require absolute identification of the drug ingested.

Derivative formation

Derivatisation enables the analysis of compounds that otherwise could not be monitored readily by GC. To some extent the availability of stable polar stationary phases in capillary columns and the use of temperature programming has negated the requirement for derivatisation, although it is still widely used. Choice of reagent is based on the functional group that requires derivatisation, the presence of other functional groups in the molecule and the reason for performing the reaction. Although the retention characteristics are changed, the order of elution of a series of derivatives will be the same as that for the parent compounds. The preparation of derivatives modifies the functionality of the solute molecule to increase (or sometimes decrease) volatility, and thereby shortens or lengthens the retention time of a substance, or to speed up the analysis.

Another common reason for derivatisation is to improve resolution and reduce tailing of polar compounds (hydroxyl, carboxylic acids, hydrazines, primary amines and sulfhydryl groups). For instance, hydroxylated compounds often have long retention times and column adsorption causes tailing, which results in low sensitivity. However, they readily form silyl ethers and these derivatives show excellent chromatography, and sensitivity can often be improved by a factor of 10 or more. Derivatisation can also help to remove the substance peak away from interfering material. For example, the reaction of amfetamine with acetone enables successful differentiation from methyl ethyl ketone on most stationary phases. Derivatives may also be used to make the molecule amenable to detection by selective detectors, or can be used to improve the fragmentation pattern of the compound in the mass spectrometer.

The reaction may be carried out during extraction (e.g. extractive alkylation), on the dry residue after solvent extraction (e.g. silylation) or during injection (e.g. methylation). In choosing a suitable reagent, certain criteria must be used. A good reagent produces stable derivatives without harmful by-products that interact with the analytical column, in a reaction that is almost 100% complete. Poor reagents cause rearrangements or structural alterations during formation, and contribute to loss of sample during reaction. Most manufacturers of derivatising reagents provide information on the potential uses of each product, along with standard operating instructions. Entire texts, such as that by Blau and Halket (1993), are devoted to this topic.

Chiral separations

Chiral compounds can be derivatised to improve their chromatographic characteristics, and the enantiomers separated on a chiral stationary phase. Both enantiomers behave similarly, provided that steric hindrance does not preclude a reaction with one enantiomer. An alternative approach is to use a chiral derivatising reagent which, when reacted with enantiomers, produces diastereoisomers that can then be separated on a conventional stationary phase. As with enantiomers, diastereoisomers still produce similar mass spectra, but are resolved in time by the chromatography column. This approach is less expensive and also less restrictive, since a dedicated column is not required. Care should be taken to ensure the enantiomeric purity of the derivatising reagent, and to guard against racemisation during the reaction. *n*-Trifluoroacetyl-L-propyl chloride (TPC) in triethylamine and chloroform (or ethyl acetate) is a commonly used chiral reagent that couples with enantiomeric amines. Excess reagent is washed off with 6 mol/L HCl and the organic phase is dried over magnesium sulfate. For chiral alcohols, (1*R*,2*S*,5*R*)-(–)-menthylchloroformate (MCF) reacts well if pyridine is used as a catalyst.

Quantitative determinations

Quantitative work usually requires some form of sample preparation to isolate the drug from the bulk of the sample and some degree of concentration or, more rarely, dilution. These processes inevitably introduce a degree of analytical error. A further difficulty is caused by the non-reproducibility of injected volumes. To compensate for these errors, it is usual to compare the response of the unknown with the response of an added internal standard. The internal standard should be added as early as possible in the assay process and should have chromatographic properties matching the drug's as closely as possible, preferably with a longer retention time. It is often possible to obtain unmarketed analogues of drugs, or compounds specially synthesised for use as internal standards (e.g. a methyl addition or a halogen substitution). However, the internal standard usually does not behave exactly as the drug and careful control of variables, such as pH, is necessary. If a derivative is to be prepared, the internal standard should also be amenable to derivatisation. Use of an inappropriate internal standard can seriously affect precision (Dudley 1980). If a mass spectrometer is being used as the detector, then the ideal internal standard is a ^{3}H- or ^{13}C-substituted analogue of the drug, a number of which are readily available at reasonable cost. Calibration should include points of higher and lower concentrations than the sample, and quality assurance samples should be included at appropriate concentrations in frequently run assays. Peak measurement may be by peak height or by the peak area obtained by integration. If the peaks show even a modest degree of tailing, use of peak area usually provides a more accurate quantitative result. A plot of the ratio of peak height (or area) of the drug to internal standard versus concentration is a straight line with most detectors. Care should be taken in the preparation of standards to match the matrix to that of the specimens, and to allow for any associated salt or water of crystallisation in the calculation of the concentration. The best results are obtained when the amount of internal standard used produces a peak response ratio of 1 at the mid-point of the calibration range.

Optimising operation conditions to customise applications

Additional sensitivity can be achieved by increasing sample size, using a concentration step, derivatisation, injecting a larger sample volume, selecting a different stationary phase or using the detector at a higher sensitivity level.

When attempting a new analysis, it is advisable first to review published literature for a method that can be copied or for a method that involves a similar type of compound and can be adapted. Column manufacturers' catalogues are a useful source of information and invariably show examples of separations performed with their columns. Data on boiling points and RI (see monographs in Volume 2) are also useful indicators. If the review is not helpful, a start can be made with a standard column, such as a 100% methyl-PSX capillary column (25 m with a 0.5 µm film) and using standard flow conditions (1–2 mL/min helium). The oven temperature should be taken from 80°C to 300°C at 10°/min (or started at 200°C or 250°C if only an isothermal oven is available). A solution of the compounds of interest in ethanol or methanol should be injected with the injector temperature set at 250°C. If a peak tails, derivatisation or use of a more polar stationary phase should be considered. Fine-tuning is carried out once some peaks have been obtained. Having established the chromatography, the extraction and concentration steps can be determined. Manufacturers' catalogues are again a useful source for both derivatisation and solid-phase extraction procedures.

Good preventive maintenance is essential. The injector (or liner) should be cleaned periodically, and any glass wool changed regularly (approximately every 100 to 1000 injections, depending on the quality of the extracts). For capillary columns, the performance is improved by periodically removing the first 5–10 cm of capillary tubing, or a retention gap could be considered for dirty samples. It is advisable to monitor performance by selecting certain performance criteria (e.g. a certain response size or amount of acceptable separation between two closely eluting components) to indicate when maintenance is required. The manufacturers' instructions for cleaning detectors should be followed.

The presence of traces of contaminants in the carrier gas supply shortens the column life drastically, and also causes detector deterioration. In-line filters (to remove oxygen, hydrocarbons, etc.) and molecular sieves (to remove water vapour) are strongly recommended, and the use of stainless-steel gas tubing minimises further contamination.

Carrier gas flow should be optimised for a particular column and a particular carrier gas. This is most important for capillary columns. Fig. 40.6 shows the relationship between efficiency expressed as the HETP versus carrier gas velocity (van Deemter plot) for a 28 m × 0.25 mm i.d. WCOT OV-101 column. Modifying the mobile phase in GC has very little effect compared with that observed with HPLC or thin-layer chromatography (TLC) and, in general, affects efficiency rather than selectivity. Nitrogen gives higher efficiency but at the expense of longer analysis time, while the less dense, but more hazardous, hydrogen gives lower efficiency but faster analysis. In practice, nitrogen is usually used for packed columns and helium for capillary columns. Certain detectors impose restrictions on the choice of carrier gas, but an additional supply of gas can be added to the column effluent to purge the detector. Experimenting with higher flow and a lower operating temperature (or vice versa) can give rewarding results for the separation of compounds that elute closely. This effect is particularly noticeable for two compounds that have different polarities, as the retention of the more polar compound is influenced to a greater extent the longer it resides in the column (non-polar compounds elute in boiling point sequence). Conditions of constant flow improve the efficiency of late-eluting peaks and produce faster chromatography than do constant pressure conditions.

For a particular separation, the lowest temperature compatible with a reasonable analysis time should be used. In general, retention times double with each 20°C decrease in temperature. If the time is excessive, it is generally better to reduce the stationary phase loading or use a shorter column than to increase the column operating temperature. There is a maximum temperature at which a column can be operated and there is also a minimum temperature below which efficiency drops sharply. Manufacturers give the temperature operating ranges for each of their stationary phases (see Table 40.3). The stationary phase must be a liquid at the temperature of operation, and if a column is run at too low a temperature to obtain longer retention times the stationary phase may still be in the solid or semi-solid form. When using temperature programming, experimentation with a faster initial ramp followed by a slower subsequent ramp or an isothermal period can help resolve problematic separations.

Efficiency can also be improved by decreasing the column diameter or increasing the column length. The resultant increase in analysis time (particularly if the flow must be reduced to accommodate the increased pressure demand imposed by a narrower column) can usually be offset by using a slightly higher operating temperature (temperature increases affect retention time much more than do increases in gas flow). As shown in Table 40.7, reducing the diameter of a capillary column markedly increases efficiency, but the retention time remains constant only as long as the same phase ratio is maintained. Therefore, unless there is a simultaneous reduction in film thickness, retention increases in direct proportion to the phase ratio.

The solvent used for the sample can sometimes produce unexpected derivatives that give different retention times (traces of acetic anhydride that remain in butyl acetate avidly derivatise primary amines at room temperature). An inert non-polar solvent should be used if possible to minimise the co-extraction of unwanted contaminants. Acetone, other ketones, ethyl acetate and carbon disulfide readily form derivatives with primary amines and should be avoided.

The choice of injector type and injection solvent also play an important part in the chromatography. A solvent volume should be chosen that does not expand to exceed the capacity of the injector (see Table 40.5), otherwise backflush and irreproducible results are obtained. Split injection significantly reduces the amount of solvent and associated contaminants that enter the column and, although the analyte response is reduced, the improvement in the signal-to-noise ratio often results in enhanced sensitivity.

The use of a selective detector, such as an ECD (with the preparation of a strongly responsive derivative if appropriate), can improve sensitivity typically up to 100-fold. Similarly, switching from full scan to SIM in MS improves the sensitivity, usually by a factor of 10. However, selective detectors should not be used as a substitute for cleaning up of sample extracts, as loading contaminants onto the column affects the chromatography adversely, even if the selective detector does not respond to the compounds. Increasing the detector temperature may also improve sensitivity.

Fronting or splitting of peaks indicates column overload. If the detector sensitivity permits, the best option here is to inject a smaller sample volume (or a more dilute sample), rather than to increase the column loading or diameter, otherwise efficiency is also affected.

If trace impurities are sought in the presence of a preponderant component, a number of stationary phases of differing polarities should be tried. Trace impurities are seen easily if they emerge before the main component of a mixture, while they may be lost completely in the tail if they elute just after the large peak. Early peaks are also sharper and thus, for the same peak area, higher – an effect that can contribute enormously to the successful detection of trace substances.

Table 40.7 Relationship of film thickness, phase ratio (β)[(a)], efficiency (*N*)[(b)] and column diameter

Film thickness d (*μm*)	*Column internal diameter (mm)*

[(a)]Phase ratio β = *r*/2*d*, where r = column radius (mm), *d* = film thickness (μm).
[(b)]*N*, theoretical plates per metre; maximum efficiency calculated for a solute with *k* = 5.

Two-dimensional GC

For most quantitative applications in drug analysis the chromatogram contains only two or three compounds, while some qualitative applications may contain 20 or more peaks of interest. Using an efficient column maximises the probability that a peak in a given time window consists of only one compound and that it is indeed the compound of interest. Other separations are far more complex, and the compound of interest may be present at minute concentrations relative to the background (e.g. flavours in foods or trace residue analysis in foods or groundwater). While these analyses can be fine-tuned to a limited extent by the use of element-specific detectors, the problem of obtaining a clean peak for positive identification and quantitation often remains. Consideration of equation (40.5c) shows column resolution to be related to two terms that can be varied by the analyst. The first of these is N, the number of theoretical plates, which in a typical capillary column is a few more than 100 000 plates. However, since R increases with the square root of N, a substantial increase in resolution can be obtained only by a very large increase in column length, and with a correspondingly large increase in analysis time. Some 500 million theoretical plates would be needed to separate 99 compounds out of a 100 component mixture. The other term is α, which describes the selectivity of a stationary phase for a particular pair of analytes. A modest increase in α can have a significant impact on resolution. This same philosophy was applied by analysts in the 1970s and 1980s who used two or more complementary stationary phases in parallel housed in different packed columns to make positive peak identifications (Moffat *et al.* 1974b). These columns were selected to have chemical properties as different as possible, but were limited by temperature compatibility since they were often placed in the same GC oven, and sometimes were split off from the same injector to allow reproducible temperature programming. However, recent advances in electronic pressure control and electronic proportional back-pressure regulators with pressure sensing, the manufacture of inert connector fittings and improvements in cryogenic focusing devices are enabling analysts to contemplate using two different analytical columns in series to achieve a satisfactory result.

Two main multidimensional approaches are receiving attention for routine use: two-dimensional gas chromatography (GC × GC) and 2D-GC with heartcutting. Instruments are now commercially available with two independently operated and controlled column ovens in a variety of injector and detector configurations. 2D-GC techniques began with heartcutting, in which only a timed portion of the chromatographed effluent from the first column was diverted from the detector or waste line into a second column of different polarity. A connector (or modulator) was employed to trap and focus the first eluent into narrow bands and transfer it to the second column at a rate that preserved the separation already achieved. In GC × GC the entire chromatography effluent from the first column is introduced to the second one. Difficulties arise when the retention of a solute on the second column exceeds the modulation cycle and 'wraparound peaks' appear with the solutes in subsequent cycles. A more recent modification, aimed at preventing this phenomenon, is called stopped-flow GC × GC. Here, the flow through the first column is stopped for a brief period, typically a few seconds, during each modulation cycle. This allows not only for better preservation of the separation of the first column, but also for longer separation times on the second column because subsequent bands are held up. This renders the secondary separation time independent of the modulation cycle, and increases the options for varying the chromatography conditions. A disadvantage is the longer run time and associated larger data file. Time-of-flight (TOF)-MS is almost mandatory to de-convolute the rapid analysis in the second column. These techniques have been demonstrated across many areas of industry, for example for identification of flavours in liquors, pesticide residues in foods and essential oils, and oxygenates in gasoline. The topic was recently reviewed by Pierce *et al.* (2008), and detailed examples showing hardware configurations can be found at www.chem.agilent.com/cag/prod/GC/Simplified_2DGC.

Specific applications

The systems given below are applicable to the routine screening, separation and identification of groups of drugs and chemicals. They are not exhaustive lists and references to specific systems for individual drugs and chemicals are given in the relevant monographs. Some of these systems use columns that are identical or very similar in terms of discriminating power (see Table 40.3), but are operated with different temperature programmes for specific groups of compounds. Moreover, some groups of substances are chromatographed as derivatives rather than as the parent compounds.

The most commonly used general screening system is a 100% dimethyl-PSX (methyl-PSX or X-1) capillary column (for packed columns, SE-30, OV-1 or OV-101 is equivalent). This should always be used for screening purposes, since it has the best chance of eluting any compound of interest. Analysts have collaborated to compile comprehensive lists of retention indices using this system (De Zeeuw 2002), some of which are included in the Index of Gas Chromatographic Data.

Most of the data are for the drugs themselves, but thermal decomposition may occur and the peak observed may be for the decomposition product (referred to as 'artefact') rather than the original drug. Where the drug is known to chromatograph badly, or to decompose, data are given for suitable derivatives (e.g. methyl or ethyl esters for the sulfonamides, and TMS derivatives for hydroxides). Wherever possible, the RI of the drug is given, since this is a more reproducible parameter than retention time or relative retention (see discussion above). However, if a laboratory prefers routinely to use the latter parameters, the RI data can be converted easily after chromatography of a few representative drugs and using a regression analysis of RI against either retention time or relative retention. RIs for some additional non-drug substances that might interfere with toxicological analyses, but are not included in the monographs. A nitrogen–phosphorus (alkali flame ionisation) detector is the best detector for nitrogenous drugs and phosphorus-containing pesticides, but an FID should also be used, since some drugs do not contain nitrogen (e.g. some anti-inflammatory agents). ECDs are excellent for benzodiazepines and halogen-containing compounds, such as some phenothiazines and herbicides. Extra selectivity can always be obtained by using element-specific detectors (e.g. those for phosphorus and sulfur for compounds that contain these elements). Additional specificity or confirmation of identity can be obtained by using a mass-selective detector, such as MS or an ion-trap detector. Where improved fragmentation can result from the use of derivatisation, data for suitable derivatives have been included. As mass spectrometry has matured as a technique, significant improvements in detection of higher-mass fragments have enabled the use of larger derivatising reagents such as heptafluorobutyrate (HFB). In any analysis for an unknown compound, the data obtained from complementary techniques, such as TLC, HPLC or colour tests, should always be assessed for compatibility with the GC result. (In the tables of retention indices given here, a dash indicates that no value is available for the compound, not that it does not elute.)

General screen, systems GA and GB

Both systems use standard columns that are able to chromatograph a wide variety of drugs and chemicals. System GB uses a slightly more polar column, which gives better peak shapes for hydroxylated compounds (many drug metabolites are hydroxylated), better resolution between structural isomers and improved peak shape for primary amines over the less polar GA. However, the retention indices are very similar for GA and GB, and can be interconverted using the equations:

$$\text{GB RI} = 1.079 \times (\text{GA RI}) - 66$$

or

$$\text{GA RI} = (\text{GB RI}+66)/1.079$$

As the stated values for drugs are retention indices, the operating conditions for the columns may be varied to suit particular laboratory situations.

System GA

Details are taken from the TIAFT book (De Zeeuw 2002) and the PMW Spectral Library (Pfleger *et al.* 2004). Chromatography details are given for both systems below.

- *Column:* 3% SE-30 or OV-1 on 80 to 100 mesh Chromosorb G HP (acid washed and dimethyldichlorosilane treated) glass (2 m × 2 mm i.d.); it is essential that the support be fully deactivated.
- *Temperature:* Normally between 100°C and 300°C; for isothermal conditions, an approximate guide to temperature is to use the RI divided by 10.
- *Carrier gas:* N_2, 45 mL/min.
- *Capillary column:* 100%-dimethyl-PSX (X-1) (10–15 m × 0.32 or 0.53 mm i.d., 1.5–3 µm).
- *Carrier gas:* He.
- *Temperature programme:* 135°C for 4 min to 200°C at 13°/min to 312° at 6°/min for 6 min.
- *Column:* HP1 (100%-dimethyl-PSX) fused-silica capillary (12 m × 0.2 mm i.d., 0.33 µm).
- *Injector:* 280°C splitless mode.
- *Temperature programme:* 100°C for 2 min to 310°C at 30°/min for 8 min.
- *Carrier gas:* He, 1 mL/min.

System GB

Data generated by the author.

- *Column:* 5% phenyl–95% dimethyl-PSX (X-5) capillary (20–30 m × 0.2 or 0.25 mm i.d., 0.5–1 µm).
- *Carrier gas:* He, 1 mL/min.
- *Temperature programme:* 90°C for 0.7 min to 240°C at 35°/min to 290°C at 8°/min to 325°C at 25°/min for 6 min.
- *Reference compounds: n*-Alkanes with an even number of carbon atoms, or a reference drug mix that contains amfetamine (1125), ephedrine (1365), benzocaine (1545), methylphenidate (1725), diphenhydramine (1870), tripelennamine (1976), methaqualone (2135), trimipramine (2215), codeine (2375), nordazepam (2490), prazepam (2648), papaverine (2825), haloperidol (2930) and strychnine (3116). (RI values for system GA are given in parentheses for the drug mix.)
- *Retention indices:* Values for drugs in these systems are found in drug monographs and in the Indexes of Analytical Data; they are also included in the systems for specific groups of drugs that follow. The search window should be ±50 RI units if hydrocarbons are used to calculate RI, or ±30 RI units if a reference drug mixture is used for the RI calculation.

Amfetamines and other stimulants

Amfetamines are basic drugs that require strongly alkaline conditions to be extracted from aqueous solution. The conditions are too basic to extract the phenolic metabolites, but these can be recovered at pH 8 or 9 and the extracts combined prior to chromatography. For high sensitivity, back extraction into dilute sulfuric acid (0.05 mol/L) is a useful clean-up procedure. When using packed columns, derivatives are almost always required for the primary and secondary amines, since the peaks tail badly. Suitable derivatives are acetyl, trifluoroacetyl, pentafluoropropionate or TMS (see Derivative formation). With capillary columns, derivatives are used most often to improve mass spectral patterns or to modify the separation of compounds that elute closely. For hydroxylated metabolites, derivatisation is invariably required to achieve acceptable chromatography. Data for the most commonly used derivatives are given in Table 40.8. Care must be taken to avoid drug loss during solvent evaporation, which can be obviated by adding a small amount of concentrated aqueous acid (20 µL 6 mol/L HCl) to the organic solvent. Unless otherwise stated, GC retention data and mass spectral data are identical for both D- and L- (+ and –) enantiomers. To differentiate enantiomers (such as D- and L-metamfetamine or amfetamine), a chiral column or chiral derivatising reagent is required (Cody, Schwarzhoff 1993). At present, all amfetamine- or metamfetamine-producing drugs (aminorex, amfetaminil, clobenorex, ethylamfetamine, fencamine, fenethylline, fenproporex, mefenorex, prenylamine, benzfetamine, dimethylamfetamine, famprofazone, furfenorex) are racemates (with the exception of L-selegiline, L-metamfetamine and dexamfetamine). Stereo-inversion does not occur in humans (Nagai, Kamiyama 1991). Drugs that are metabolised to amfetamines, but are not themselves classified as such, are also listed. System GA or GB, previously described, may be used as well as system GC.

Table 40.8 GC retention data and mass spectral data for the amfetamines and derivatives (reference compounds are *n*-alkanes with an even number of carbon atoms; AC, acetyl; ET, ethyl; HFB, heptafluorobutyrate; PFP, pentafluoropropionate; TFA, trifluoroacetyl; TMS, trimethylsilyl)
