About the Editors

Professor Anthony C Moffat
BPharm, PhD, DSc, CChem, FRSC, FRPharmS, FFIP, FFSSoc

Professor Anthony C Moffat is Emeritus Professor of Pharmaceutical Analysis at The School of Pharmacy, University of London, where he was previously Head of the Centre for Pharmaceutical Analysis. He was also Chief Scientist at the Royal Pharmaceutical Society. He has over 350 publications as well as the co-authorship of eight books.

Previously he worked for the Forensic Science Service for 23 years as Research Co-ordinator (Birmingham Laboratory), Resources Manager (Huntingdon Laboratory), Head of Quality Management (HQ, London), Assistant Director (Huntingdon Laboratory), and Head of the Drugs and Toxicology Division at the Home Office Central Research Establishment, Aldermaston. He has also been a Superintendent Pharmacist in a community pharmacy, Assistant Professor of Biochemistry, Baylor College of Medicine, Houston, Texas, and Chief Pharmacist, St Leonard's Hospital, London.

An active member of many professional and learned societies, his fellowships include the Royal Pharmaceutical Society, Royal Society of Chemistry, Forensic Science Society, International Pharmaceutical Federation and the American Association of Pharmaceutical Scientists as well as the membership of the International Association of Forensic Toxicologists.

Professor M David Osselton
BSc, PhD, CSci, CChem, FRSC, MEWI

Professor M David Osselton started his forensic toxicology career in 1974 when he went to work with Dr Alan Curry at the Home Office Central Research Establishment, Aldermaston. He gained casework experience as Senior Toxicologist working at the Home Office Forensic Science laboratories in Nottingham and Huntingdon before returning to Aldermaston in 1984 to succeed Dr Anthony Moffat as Head of Research in Alcohol, Drugs and Toxicology. In 1991, he was appointed Head of Toxicology for the Forensic Science Service. In 2007, Professor Osselton went to Bournemouth University as Head of the Centre for Forensic Sciences. He has wide experience in toxicology casework and has been involved in numerous high profile cases working for the defence and prosecution both in the UK and overseas. He is internationally known for his research interests in toxicology and lectures widely at conferences as a plenary and keynote speaker. Between 2003 and 2009 he was Lead Assessor (Toxicology) for the UK Council for the Registration of Forensic Practitioners (CRFP) and was Visiting Professor to the Department of Forensic Science and Drug Monitoring at Kings College, University of London (2004–2007). He is a Fellow/Member of a number of professional and learned bodies including the Royal Society of Chemistry, Royal Society of Medicine, Expert Witness Institute, International Association of Forensic Toxicologists (TIAFT), Society of Forensic Toxicologists (SOFT), LTG (formally the London Toxicology Group), UK Workplace Drug Testing Forum and is chair of the United Kingdom and Ireland Association of Forensic Toxicologists.

Dr Brian Widdop
BSc, PhD, SRCS, CChem, FRCS, FRCPath

Dr Brian Widdop was Director of the Medical Toxicology Unit Laboratory at Guy's Hospital, London, from 1970 until 2002. Dr Widdop has been a Speciality Assessor for the Council for the Registration of Forensic Practitioners, a member of the WHO IPCS Working Group on Analytical Toxicology, Chief Advisor to the South East Asia Regional Office of the WHO on analytical toxicology and was a Director of the Board of the UK Horse-racing Forensic Laboratory from 1991 to 2002. From 1997 to 2001, he was joint co-ordinator of the European proficiency Testing Scheme for Drugs of Abuse. Dr Widdop has published over 80 papers on various aspects of clinical and analytical toxicology and has spoken at many international meetings. He is also a member of the editorial board of the Journal of Analytical Toxicology.

Dr Widdop belongs to several international scientific societies and was a founder member of the London Toxicology Group. He has been a member of The International Association of Forensic Toxicologists for 42 years and was the recipient of the Alan Curry Award in 2002.

Dr Jo Watts
BSc, PhD

Dr Jo Watts attained her degree in pharmacology and toxicology followed by a PhD in neuropharmacology, both at The School of Pharmacy, University of London. She is a member of TIAFT and the LTG.

Foreword

As one of the past presidents of the International Association of Forensic Toxicologists (TIAFT) it is an honour as well as a pleasure for me to write a foreword for the fourth edition of this prestigious publication. Indeed, when a publication is prepared by an impressive number of leading toxicologists working in world-famous institutions, as editors or as former or new authors – all outstanding specialists in their respective fields of activity – we as toxicologists can only expect to have another great database in our hands with which to do research or our daily work.

In addition to the monographs revised from the previous editions, dealing with physicochemical and pharmacotoxicological properties of drugs and poisons, and the indexes of analytical data, review chapters have been included on various basic subjects of toxicology, such as hospital and forensic toxicology; immunoassays; analysis of alternative matrices; doping; driving under the influence of drugs and alcohol; therapeutic drug monitoring; workplace testing; quality assurance; pharmacokinetics; pesticides; volatile organic substances; natural toxins; different separation technologies; and spectrometric methods. New chapters by renowned experts have been added that deal with method development and validation; sampling, storage and stability; extraction; more recently developed analytical technologies such as liquid chromatography coupled to mass spectrometry; atomic absorption spectrometry, or inductively coupled mass spectrometry for the determination of inorganic poisons; pharmacogenomics; measuring and reporting uncertainty; drug facilitated sexual assaults; and paediatric forensic toxicology. These topics enable our younger and less young colleagues alike to familiarise themselves with these developments or to improve their knowledge.

Especially at a time when shortcuts are made for budgetary reasons in healthcare and forensic systems, we need to document our performances of reliable analytical results followed by correct interpretations of these results to proof our usefulness to decision makers. Therefore, this fourth edition is published at the perfect moment.

I remember very well at the beginning of my career in Luxembourg the moment I held the first edition from 1969, which was recommended to me by a French colleague. It was always a bible for me and is still an important part of my personal library. Several similar publications have been produced in the past, but they have never had the same impact on toxicology as *Clarke*. My professional work was also influenced by the renowned British scientists who I met during a TIAFT conference in Ghent back in the early '70s. What a lot has changed since those days!

It is an important advance that a chapter on interpretation has been added, as this is the major difference between analytical toxicology and analytical chemistry. Toxicological analysis is not analytical toxicology. From my work in forensic toxicology, I know that in court we are questioned more about interpretation of our results than about the performance of the analytical methods. Our customers should be aware that we are not 'only making measurements'.

Since toxicology is a multidisciplinary science, toxicologists need not only to have comprehensive knowledge of analytical methodology, but also to be proficient in the basics of medicine, physiology, clinical chemistry, biochemistry, pharmacodynamics and pharmacokinetics in order to provide the best possible contributions to clinicians and to forensic authorities. Toxicology is a difficult and a complex issue requiring collective information exchange among toxicology specialists from all related fields. Even the publishing of routine cases that may not be routine for other colleagues should be encouraged. In spite of the fantastic efforts in recent years to establish correlations between toxicant concentrations in body tissues and pharmacodynamic action, behaviour impairment, interindividual variability, pharmacogenetics, postmortem changes or concurrent existing pathologies, there is still a lot of research required to improve our knowledge. So, I can only recommend to my colleagues: let us do it!

Even now that a staggering amount of information is available via the internet, *Clarke* remains a reference for old and young toxicologists. It is an easily accessible tool which can be consulted either by reading the book or by browsing and searching the online version, to give us useful structured, and peer-reviewed information written by well-known experts.

I wish *Clarke* the best success that it deserves, to equal that of the previous three editions of this publication.

Robert Wennig, PhD
Past President of TIAFT

Preface

Clarke's Analysis of Drugs and Poisons aims to be the world's leading text on the analysis of drugs and poisons. Not only does it contain chapters on the methodology and techniques of modern analytical toxicology, but the monographs include analytical data on therapeutic drugs, drugs of abuse, drugs misused in sport as well as pesticides, metals and other poisons. This fourth edition builds on the previous editions with significant updating and improvements in scope and electronic form.

Clarke, as it is affectionately known, has gained a world-wide reputation as a reliable source of toxicological information. Its presence on the benches of many different types of pharmaceutical and toxicological laboratories is a testament to its usefulness.

Since the third edition was published in 2004, there have been about 120 new chemical entities brought onto the market. Some of these come from completely new chemical or pharmacological groups, but most are 'me too' drugs. In addition, there has been a growth of drugs misused in sport and those subject to abuse; eg legal cannabinoids and Mephedrone, and their derivatives. Nearly 400 monographs have been added to the fourth edition, with priority based on the importance of the substances covered in one of the following areas: drugs of abuse, forensic toxicology, hospital emergency toxicology, doping in sport, drugs subject to therapeutic drug monitoring and environmental toxicology. It has been impossible to include all the new drugs and poisons available, but work is continuing to add further data in the future.

The information in *Clarke* has been designed to provide methods and data to enable analysts to detect, identify, quantify and profile drugs and poisons in a wide variety of situations. In addition, information on how to interpret the analytical data is included, since this is often the most difficult part.

The book has been designed for use not only in hospital and toxicology laboratories, but also in numerous other analytical establishments. This includes quality control laboratories, and clinical laboratories engaged in drug investigations for purposes such as therapeutic drug monitoring or research into pharmacokinetics and patterns of drug metabolism. In addition, there is much information that will be of use in environmental toxicology, particularly the analysis of toxic metals and pesticides.

The needs of students studying analytical and forensic toxicology have not been forgotten and the chapters form an excellent basis for study. The spin-off book *Clarke's Analytical Forensic Toxicology* from the third edition of *Clarke* is a testament to meeting the requirements of the university teaching sector.

The book is in two volumes to make it easier to use. Volume 1 contains chapters comprising methodology and analytical techniques, and the subject index to both volumes; Volume 2 contains the analytical and toxicological data, indexes to the analytical data, a list of reagents and a repeat of the subject index to both volumes. Those who regularly use *Clarke* will be pleased to see that the original style and form of presentation of the information has been retained from the previous edition. This tried and tested format is clear, making it easy to find relevant information.

Clarke is now an established publication on MedicinesComplete, which provides online access to some of the world's leading drug and healthcare references. This includes such reference sources as *Martindale: The Complete Drug Reference*, *British National Formulary*, *The Merck Index* and *Stockley's Drug Interactions*. The online version of *Clarke* has the advantage that text searches can be performed thus aiding the reader to access relevant information more rapidly, either in *Clarke* alone or across multiple reference sources. Another advantage of the online version is that it can be updated online far more frequently and easily than the conventional book form.

Volume 1

Part 1: methodology and analytical chapters

This part now contains 44 chapters describing methodology and analytical techniques, which is an increase of 13 chapters from the previous edition. Three of the previous chapters have each been split into two because of the increased complexity of the topics covered. Thus there are now chapters on Driving Under the Influence of Alcohol as well as Driving Under the Influence of Drugs; Drugs in Human Sport as well as Drugs in Animal Sport; and Quality Control and Assessment in the Pharmaceutical Industry as well as Quality Control and Assessment in the Toxicology Laboratory. This latter chapter recognises the increase role of accreditation in the forensic toxicology laboratory and gives guidance on how to achieve this.

A new chapter on methodology in Drug-facilitated Sexual Assault has been included to recognise the rise in this type of crime and the need for good forensic toxicological analyses.

In terms of the use of particular analytical techniques, Method Development and Validation is a new chapter to assist those who need to develop their own methods and demonstrate that they are fit for purpose. Also included in this area are two new chapters on Sampling, Storage and Stability, as well as Extraction, since many toxicologists have asked for information on these topics. The increased use of liquid chromatography–mass spectrometry to replace gas chromatography–mass spectrometry in the analysis of organic compounds has been covered by a new chapter on this topic. Similarly, a new chapter on Atomic Absorption Spectroscopy, Inductively Coupled Plasma–Mass Spectrometry has been added to recognise the increased use of this combination of techniques in inorganic analysis.

Four new chapters have been included to assist the toxicologist to interpret analytical data and report the results in a meaningful and clear manner. The chapter on Measuring and Reporting Uncertainty is a clear exposition that all measurements are subject to error and gives guidance on how to measure and report the uncertainty. A chapter on Paediatric Forensic Toxicology recognises that children are not just small adults and need to be treated as a separate population. Similarly, the chapter on Pharmacogenomics clearly shows how we as individuals differ in our genetic makeup and how that might affect our response to drugs. Often one of the most difficult tasks a toxicologist has is to do is to interpret the results of the analyses; a new chapter on Interpretation of Results, together with the updated chapter on Pharmacokinetics, aims to assist toxicologists in this area. This backs up the information on interpretation given in each of the methodology chapters.

All the other chapters have been revised to bring them fully up to date.

The structure of the spectroscopic and chromatographic chapters has been retained from the previous edition to ensure that all the relevant information is given in an easy-to-read form. The chapter on emerging techniques has been completely rewritten to acknowledge the regulatory aspects of introducing new techniques and what new instrumentation might be available in the future.

The chromatographic and capillary electrophoresis systems have been extensively expanded and revised to include general screening systems as well as specialised systems for particular classes of drugs and poisons. The general systems for use have all been proven as robust

and reproducible over the years, and give excellent results for use in systematic toxicological analysis.

Subject index

The subject index covering both volumes can be found at the end of Volume 1.

Volume 2

Part 2: analytical and toxicological data

This part contains monographs for 2111 drugs and poisons, which is an increase of around 370 from the last edition. Not only have totally new monographs been introduced, but monographs from previous editions that were excluded from the third edition have been reinstated because the drugs concerned are still used in some parts of the world. The new additions have been chosen for drugs and poisons that are new and widely used prescription drugs, novel drugs of abuse or common poisons not previously included. For example, there are now 15 new monographs on metal salts. All the other monographs have been updated from the third edition. The use of the Recommended International Non-proprietary Name (rINN) for the drug name has been continued as this is now the international standard method of nomenclature.

The orientation of the chemical structures has been normalised so that the structures of similar compounds may be compared more easily. In addition, new chemical and analytical data have been added to aid the toxicologist and pharmaceutical analyst. This includes information on stability of drugs in solution and biological fluids at different temperatures, 1-chlorobutane extraction data, and infrared spectra of drug salts.

Analytical data for compounds on colour tests, thin-layer chromatography, gas chromatography and high performance liquid chromatography are given from which to choose systems that will separate and identify drugs, poisons and their metabolites. This is followed by full ultraviolet, infrared and mass spectral data together with listings of the major peaks to assist further in identifying compounds.

A major change has been made to the Quantification section of each monograph: it has been rearranged to give details of the analysis of each biological fluid or tissue separately instead of being ordered by technique. This makes finding an analytical method to use for a particular tissue very much easier. Additional data such as a method's limit of detection and limit of quantification have been added when available. This has meant a considerable increase in the size of each monograph and the list of the references at the end of the monograph, but it has improved the usability of the information. All the monographs have been brought up to date by the inclusion of new references and the deletion of old ones whenever possible. The references cited give further information on published methods for separating, identifying and quantifying drugs, poisons and their metabolites. Review articles are given whenever relevant to act as a further source of concise information.

The section entitled Disposition in the Body gives data on therapeutic concentration, toxicity, bioavailability, half-life, volume of distribution, clearance, distribution in blood, plasma : saliva ratio, protein binding and dose to enable analytical data to be interpreted in the context of a given case. In addition, abstracts from published clinical studies and case histories are included.

Part three: indexes to analytical data

This part contains indexes of analytical, chemical and therapeutic data, arranged in a similar order to how they appear in the monographs: CAS numbers, molecular formulae, therapeutic classes, molecular weights, melting points, colour tests, thin-layer chromatographic data, gas chromatographic data, high performance liquid chromatographic data, ultraviolet absorption maxima, infrared peaks, mass spectral data of drugs, and mass spectral data of pesticides. A list of reagents and proprietary test materials mentioned in the analytical procedures in Parts One and Two is also provided, as is a list of pharmacological terms.

Subject index

The subject index covering both volumes is repeated at the end of Volume 2.

Preparation of this edition

We are grateful to the editorial and production staff at Pharmaceutical Press who have helped in this project: Emma Burrows, Helen Carter, Tamsin Cousins, Amy Cruse, Simon Dunton, Marian Fenton, Rebecca Garner, Austin Gibbons, David Granger, Jo Humm, Jean Macpherson, Julie McGlashan, Louise McIndoe, Ithar Malik, Jason Norman, Karl Parsons, The Prescribers at The School of Pharmacy (London), Lucy White and John Wilson.

There were also the freelance staff who wrote and updated the monographs, to whom we owe thanks: Irene Chiwele, Mildred Davies, Laurent Y Galichet, Poppy McLaughlin, and Eva Reichardt. A team of copy-editors, proofreaders and indexers also contributed to the production of this publication.

Without the enthusiasm and dedication of these people this work would not have been published.

The Editorial Board members have also assisted in many ways: they authored, refereed manuscripts and monographs, and provided analytical data from their own laboratories. They and the authors have done a great job in providing up-to-date information in an easily accessible and readable manner.

General Notices

Health and Safety

This work is intended to be used by appropriately qualified and experienced scientists. Processes and tests described should be performed in suitable premises by personnel with adequate training and equipment. Care should be taken to ensure the safe handling of all chemical or biological materials, and particular attention should be given to the possible occurrence of allergy, infection, fire, explosion or poisoning (including inhalation of toxic vapours). Cautionary notes have been included in a number of monograph entries, but the possibility of danger should always be kept in mind when handling biological samples, and medicinal or other chemical substances.

Classification

At the head of each monograph, an indication is given of the classification of the compound according to its therapeutic or commercial use, its pharmacological action and/or its chemical group. The substance may, of course, have other uses or actions in addition to that stated.

Nomenclature

Monograph Titles

The main titles of the monographs are the Recommended International Non-Proprietary Names (rINNs), this includes both drugs and pesticides. For drugs of abuse, the most common chemical names or abbreviations have been used. It is worth noting that for rINNs and chemical nomenclature, it is now general policy to use 'f' for 'ph' (e.g. in sulpha), 't' for 'th' and 'i' for 'y'. For this reason, entries in alphabetical lists and indexes should be sought in alternative spellings if the expected spellings are not found.

The main title of a monograph is generally that of the free acid or base as this is the form in which the compound will usually be isolated in an analysis; details of the commonly available salts are included in subsidiary paragraphs within the monograph.

The following abbreviated names for radicals and groups are used in the titles.

Recommended name	*Chemical name*
acetonide	(isopropylidenedioxy)
aceturate	*N*-acetylglycinate
amsonate	4,4′-diaminostilbene-2,2′-disulfonate
besilate	benzenesulfonate
camsilate	camphorsulfonate
caproate	hexanoate
cipionate	cyclopentanepropionate
closilate	*p*-chlorbenzenesulfonate
edetate	ethylenediaminetetraacetate
edisilate	1,2-ethanedisulfonate
eglumine	*N*-ethylglucamine
embonate	4,4′-methylenebis (3-hydroxy-2-naphthoate) (=pamoate)
enantate	heptanoate
erbumine	*tert*-butylamine
esilate	ethane sulfonate
gluceptate	glucoheptonate
hibenzate	*o*-(4-hydroxybenzoyl)benzoate
isetionate	2-hydroxyethanesulfonate
lauril	*n*-dodecyl
laurilsulfate	*n*-dodecylsulfate
meglumine	*N*-methylglucamine
mesilate	methanesulfonate
metilsulfate	methylsulfate
mofetil	2-morpholinoethyl
napadisilate	1,5-naphthalenedisulfonate
napsilate	2-naphthalenesulfonate
octil	octyl
pivalate	trimethylacetate
steaglate	steroyl-glycolate
tebutate	*tert*-butylacetate
teoclate	8-chlorotheophyllinate
tosilate	*p*-toluenesulfonate
xinafoate	1-hydroxy-2-naphthoate

IUPAC Names

The nomenclature generally follows the definitive rules issued by IUPAC, 1993.

Proprietary Names and Synonyms

A selection of proprietary names have been included in the monographs. These can generally be applied to the UK, USA, Japan and a selection of African, Asian and European countries. Comprehensive lists of proprietary names worldwide, can be found in *Martindale: The Complete Drug Reference*, 37th edn, London, Pharmaceutical Press, 2011. Only single-substance preparations have been included except in the case of certain major classes of drugs for which the names of some compound preparations have been added. Some proprietary names that are not in current use have been retained. Names under the heading 'Synonyms' include alternative names, common titles, abbreviations and drug trial numbers.

CAS Registry Numbers

Chemical Abstract Service (CAS) registry numbers are provided, where available, in the monographs to assist readers to refer to other information databases.

Molecular Weights

Molecular weights have been calculated using the table of Atomic Weights as revised in 2001 by the Commission on Atomic Weights, IUPAC General Assembly, and based on the ^{12}C scale. Molecular weights have been corrected to one decimal place and are listed in ascending order in the index of Molecular Weights.

Physical Characteristics

Dissociation Constants

Numerous methods can be used for the determination of dissociation constants, and there are often differences in the various values reported in the scientific literature. The pK_a values given in the monographs have been taken from published data and should be regarded only as approximate. The temperature at which the determination was made is given where known.

Information on the theory, measurement and evaluation of dissociation constants is given in *The Pharmaceutical Codex*, 12th edn, London, Pharmaceutical Press, 1994.

Melting Points

The melting points recorded in the individual monographs are listed in ascending order in the index of Melting Points.

Partition Coefficients

Values for log *P* are given in a number of monographs. Where the pH of the aqueous phase is stated, the values given are apparent coefficients at that pH (not ion-corrected). Where no pH is stated for the aqueous phase, it can be assumed that log *P* is for the neutral form of the substance even though it is potentially ionisable.

The values given are approximates only but they serve to indicate the characteristics of the substance when it is submitted to an extraction process.

For a comprehensive collection of partition coefficients for drugs see C. Hansch *et al.*, *Exploring QSAR: Hydrophobic, Electronic and Steric Constants,* Washington, American Chemical Society, 1995. Information on the theory of partition coefficients can also be found in J. Sangster, *Octanol-Water Partition Coefficients: Fundamentals and Physical Chemistry*, New York, John Wiley, 1997.

Solubility

The solubilities given in the monographs, unless otherwise stated, apply at ordinary room temperature. They have been obtained from various sources and should not be regarded as precise because of variations depending on the method and condition of determination. In general, approximate values are given when a substance is soluble in less than1000 parts of solvent. Where no figure is given, the usual solubility terms have been adopted:

Very soluble	1 part in less than 1
Freely soluble	1 part in 1–10
Soluble	1 part in 10–30
Sparingly soluble	1 part in 30–100
Slightly soluble	1 part in 100–1000
Very slightly soluble	1 part in 1000–10000
Practically insoluble or insoluble	1 part in more than 10000

In the solubility statements, the word 'water' refers to purified water, the word 'ether' refers to diethyl ether and the word 'ethanol', without qualification, refers to ethanol (95%).

Temperature

Temperatures are expressed throughout the text in degrees Celsius (centigrade).

Analytical Data

All analytical data in the monographs apply to the form of the substance described in the main title of the monograph, unless otherwise specified.

In all lists or indexes of chromatographic data, a dash indicates that the value is not known, not that the substance does not elute.

Extraction

It has not been possible to give direct information on the best method for extracting individual substances from various biological samples. However, useful information can be gained from the data on solubility, dissociation constant and partition coefficient. The best solvent can be chosen by reference to solubility, the pH for extraction is indicated by the pK_a value, and the partition coefficient gives a quantitative measure of the phase volume ratios needed for a successful extraction from 1-chlorobutane.

Colour Tests

Where colour tests are given in the monographs, these names refer to the tests described in the Colour Tests chapter, where complete tables of colours are provided. Reference should be made to this chapter for an explanation of the system used for describing the colours. The reagents used for the colour tests are also listed within the list of reagents and additional colour reaction data for approximately 250 compounds is also presented. Colour tests applicable to biological fluids are described under the Hospital Toxicology chapter.

Thin-layer Chromatography

The thin-layer chromatographic systems referred to in the monographs are described in the TLC chapter on together with lists of data for drugs in important chemical and pharmacological classifications. General screening systems (systems TA to TF and systems TL, TAD, TAE, TAF, TAJ, TAK and TAL), which include over 1500 drugs and metabolites, are provided (see Chapter 39 for system details and references). In order to clarify the presentation of values, the data are expressed in terms of $R_f \times 100$ (hR_f). Complete lists of data, in ascending order, are given in the index of Thin-layer Chromatographic Data.

Gas Chromatography

The gas chromatographic systems referred to in the monographs are described in the GC chapter, together with lists of retention data for drugs in important chemical and pharmacological classifications. A general screening system (system GA), which includes over 1500 drugs and metabolites, is provided. An alternative screening system (system GB) is also included (see Chapter 40 for system details and references).

For most of the systems, the data are given in terms of Retention Index. Retention times or relative retention times are used in a few systems. Complete lists of retention data, in ascending order, are given in the indexes of Gas Chromatographic Data.

High Performance Liquid Chromatography

The HPLC systems referred to in the monographs are described in the HPLC chapter, together with lists of retention data for drugs in important chemical and pharmacological classifications. Six general screening systems (systems HA, HX, HY, HZ, HAA and HBK) covering between400 and 1600 drugs are provided (please note that values for system HBK have not been included within monographs and can only be found in the index) (see Chapter 41 for system details and references). The data are given in terms of Retention Index, retention time, relative retention time and column capacity ratio *k* (see Chapter 41). Complete lists of retention data, in ascending order, are given in the indexes of High Performance Liquid Chromatographic Data.

Ultraviolet Absorption

The wavelengths of principal and subsidiary peaks are recorded in each monograph for acid, alkaline and neutral solution, where available. These are generally listed from 230 nm.

Values in neutral solution are given for compounds for which values in acid or alkaline solution are not available or when the values in neutral solution differ significantly from those in acid or alkaline solution.

In many monographs, the ultraviolet spectrum is reproduced. In these spectra, the following notation is used:

———————	acid solution
.....	alkaline solution
- - - - - - - - - - - - - - -	neutral solution

Where more than one curve is shown, they do not necessarily relate to the same concentration and, consequently, points where the curves cross cannot be taken as true isosbestic points. The wavelengths of peaks in a few of the spectra may differ very slightly from those stated in the text. Where there is doubt, the values given in the text should be used. In monographs where the spectrum is reproduced, the A_1^1 value for each peak is stated, if available. The A values apply to the form of the substance described in the main title of the monograph, unless otherwise stated.

The A_1^1 values are divided into 3 categories in order to provide an indication of reliability:

- The letter 'a' after a figure indicates that the value is a mean value based on several reported figures, all of which lie within a range of ±10% of the mean.
- The letter 'b' after a figure indicates that the value is a single reported value of unknown reliability.
- The letter 'c' after a figure indicates that the value is a mean value based on several reported figures, some of which lie outside ±10% of the mean.

The phrase 'no significant absorption' indicates that no peaks are found at the concentrations normally used.

The A_1^1 values quoted in the monographs may be useful in identification, and may help in determining the strength of a solution which is required to obtain a curve within the instrumental range of absorption. They may also be useful to give an approximate indication of the amount of drug in a solution. However, because of instrumental differences and the possible effect of solvent and pH, A_1^1 values are subject to considerable variation and the values quoted should not be used when an accurate assay is required. In this case, a reference specimen should be examined at the same time as the sample.

The wavelengths of main peaks are listed for acid, alkaline and neutral solution from 230 nm in the index of Ultraviolet Absorption Data.

Infrared Absorption

The wavenumbers of the 6 major peaks in the range 2000–650 cm^{-1} (5–15 μm), in descending order or amplitude, are recorded in the monographs. In many cases, the infrared spectrum is also reproduced. When selecting the 6 principal peaks, those which are in the region where Nujol absorbs (1490–1320 cm^{-1}, 6.7–7.6 μm) have been omitted. Corrections for calibration errors have been applied where these are known.

The 6 principal peaks, in ascending order of the main peak, are listed in the index of Infrared Peaks.

Mass Spectrum

The *m/z* values of the 8 most abundant ions, in descending order of intensity, are included in many monographs. Where dashes occur in the listing, this indicates that less than eight ions have been observed.

The 8 principal ions, in ascending order of the main peak, are listed in the index of Mass Spectral Data of Drugs. A separate index for pesticides can also be found. The full mass spectra for the majority of the listed compounds are displayed within the monographs.

Quantification

The methods referred to in the references quoted under the heading 'Quantification' in the monographs are not intended to be recommended methods. These references are intended to be used as a guide to the literature on the particular subject.

Reagents

Reagents required for specific tests or methods are generally described fully in the appropriate place in the text. However, certain common reagents that are used throughout the book are described in the list of Reagents and Proprietary Test Materials. Reagent solutions are made in purified water unless otherwise specified. When ethanol, without qualification, is stated to be used, this refers to ethanol (95%).

Unless otherwise stated, solutions of solids in liquids are expressed as percentage w/v, and solutions of liquids in liquids as percentage v/v. When acids of various strengths are specified, e.g. 50% sulfuric acid, this implies the appropriate dilution by volume of the strong acid in water.

Disposition in the Body

Many of the monographs contain a section with the heading 'Disposition in the Body'. The information in these statements has been obtained from a detailed survey of published papers and other reference sources. Certain monographs have a single reference at the end of the statement, and this indicates that all the disposition information has been obtained from that source. Wherever possible, information is included on absorption, distribution, metabolism, excretion, therapeutic concentration, toxicity and pharmacokinetic parameters.

Entry to the literature is provided by the inclusion of abstracts of published papers on clinical studies or case histories. These abstracts include details of drug concentrations in plasma or other body fluids or tissues; in these data a dash means that the particular value was not determined, and ND or 0 means that the substance was not detected. Concentrations in body fluids or tissues are expressed in mg/L or μg/g.

In some monographs, the information is incomplete, the amount of detail being dependent upon that available in the literature searched. It should not be assumed that the statements presented reflect the only significant factors in the disposition of the drug concerned.

Therapeutic Concentration

This is the concentration range usually observed after therapeutic doses, as reported in clinical studies and other research projects. It should not be interpreted as the concentration range required for optimum therapeutic effects.

Toxicity

This statement may include drug concentrations in blood or other body fluids or tissues, which have been reported to be associated with toxic or lethal effects. Because of inter-subject variations or other variable factors, the reported toxic or lethal concentrations may occasionally lie close to or within the therapeutic range.

In some monographs, the toxic or lethal blood concentrations are stated in the form 60–89–150 mg/L. These figures have been obtained from a survey of a number of reported cases and represent the maximum concentrations found in 10, 50 and 90% of the subjects, respectively.

Maximum permitted concentrations in air (8–h exposure limit) are those recommended by the Health and Safety Executive in *Occupational Exposure Limits 2002*, Guidance Note EH40/2002 Supplement, London, HMSO, 2003.

Volume of Distribution

This relates to plasma concentrations after IV administration, unless otherwise stated. Values are based in a body-weight of 70 kg.

Clearance

This usually refers to the total plasma clearance (or total whole blood clearance) after IV administration. In some instances, the total clearance after an oral dose has been included if the drug is known to be well absorbed and is not subject to significant first-pass metabolism.

Numerous factors and inter-subject variations may affect the absorption, distribution, metabolism and excretion of drugs. These include age, sex and disease states such as renal impairment. In addition, results of analyses may be subject to unavoidable analytical inaccuracies. Consequently, there may be considerable variations in the observed drug concentrations and in values for pharmacokinetic parameters in individual cases. Hence, the values given in the monographs should be used only as a guide and should not be taken as absolute values.

Dose

The dose recorded under this heading in the monographs indicates the usual daily dose (oral unless otherwise stated) that may be administered for therapeutic purposes. It is intended solely as a guide in deciding whether the amount taken by an individual falls within the normal dosage range and should not be taken as a recommendation for treatment.

More detailed information on doses in different conditions and age groups may be found in *Martindale: The Complete Drug Reference*, 37th edn, London, Pharmaceutical Press, 2011; the *British National Formulary*, latest edition; or in the manufacturers' data sheets for the products.

Comments

This edition of *Clarke* could not have been completed without the comments on the second and the first editions, and the contribution of analytical data from many scientists involved in the analysis of drugs. In order to assist in the preparation of the next edition, the reader is invited to send any constructive comments and relevant new data concerning the analysis of drugs in biological materials to the Editor, Clarke's Analysis of Drugs and Poisons, Royal Pharmaceutical Society of Great Britain, 1 Lambeth High Street, London SE1 7JN, UK. In this way, future editions will be improved to the benefit of all of those who use it.

Deletions

The following substances which were included in Volumes 1 and 2* of the 1st and 2nd editions are now included in this edition:

Acetyldihydrocodeine
Adrenalone
Allantoin
Allylprodine
Alphameprodine
Alphamethadol
Aminometradine
Aminopentamide
Amisometradine
Amolanone
Amopyroquine
*Amotriphene
Amprotropine
Amydricaine
Amylocaine
Apoatropine
Azacosterol
Azamethonium Bromide
Benzalkonium Bromide
Benzamine
Benzathine Penicillin
Benzethidine
Betameprodine
Betaprodine
*Brocresine
Butallylonal
Butethamine
Butoxamine
Cetoxime
Chlorisondamine Chloride
Citronella Oil
Clamoxyquin
Clonitazene
*Cloponone
Codeine *N*-Oxide
Cyclamic Acid
Cyprenorphine
Demecolcine
Demeton-O
Desomorphine
Diampromide
Dibutoline Sulphate
*Diethylaminoethyl Diphenylpropionate
Dimenoxadole
*Dimethocaine
Dimethylthiambutene
*Dimophebumine
Dioxaphetyl Butyrate
Dioxathion
*Dioxyamidopyrine
*Diphenazoline
Dithiazanine Iodide
Embramine
Erythrityl Tetranitrate
*Ethylisobutrazine
Ethylmethylthiambutene
*Ethylpiperidyl Benzilate
Etonitazene
Etoxeridine
Etymide
Fenimide
*Fenmetramide
Furethidine
Hydromorphinol
Hydroxypethidine
*Imidocarb
*Iminodimethylphenylthiazolidine
*Iopydol
*Iopydone
Isobutyl Aminobenzoate
*Isometamidium
Isomethadone
Laudexium Methylsulphate
Leucinocaine
Levomethorphan
Levomoramide
Levophenacylmorphan
Lucanthone
Metabutethamine
Metabutoxycaine
Metazocine
*Methadone Intermediate
Methaphenilene
Methoxypromazine
Methylaminoheptane
Methyldesorphine
Methyldihydromorphine
Methylhexaneamine
Methyridine
Metofoline
Metopon
*Moramide Intermediate
Morpheridine
Morphine *N*-Oxide
Mustine
Myrophine
Naepaine
*Naftazone
Narcobarbital
Nicocodine
Nicomorphine
*Nifuroxime
Noracymethadol
Norbutrine
*Nordefrin
*Norgestrel
Norlevorphanol
*Octacaine
Octaverine
Orthocaine
Pamaquin
*Panidazole
*Paromomycin
Pentaquin
*Pethidine Intermediate A
Phenadoxone
Phenamidine
Phenampromide
*Phenatine
Phenisonone
Phenomorphan
Phenoxypropazine
Phenylpropylmethylamine
*Phthivazid
*Picloxydine
Pipamazine
Piperoxan
Pipethanate
Plasmocide
*Proadifen
Probarbital
Proheptazine
Properidine
Pulegium Oil
*Pyrrocaine
Quinapyramine Chloride
Racemethorphan
Racemoramide
*Resorantel
*Rifamide
*Rolicypram
Stilbamidine
Sulphasomizole
Sulphonal
*Taurolin
Teclothiazide
*Terodiline
*Tetracosactrin
*Tetraethylammonium Bromide
*Thozalinone
Thurfyl Nicotinate
*Tiletamine
Tolonium Chloride
Tolycaine
Triclobisonium Chloridc
Tropacocaine
Tropine
Tymazoline
Viomycin
Xenysalate

Abbreviations

A_1^1	Specific absorbance (abbreviation of $A_{1cm}^{1\%}$)
AAFS	American Academy of Forensic Sciences
AAS	Anabolic/androgenic steroids; atomic absorption spectrometry
4-ABA	4-Aminobenzoyl-β-alanine
ABFT	American Board of Forensic Toxicology
ABP	2-(2-Amino-5-bromobenzoyl)pyridine
ABV	Alcohol percentage by volume
AC	Acetylated
2-ACB	2-Amino-5-nitrobenzophenone
2-ACDP	2-Amino-5-chlorodiphenylamine
ACDP	2-Amino-2′-chloro-5-nitrobenzophenone; 2-Amino-5,2′-dichlorobenzophenone
ACE	Angiotensin-converting enzyme
ACFP	2-Amino-5-chloro-2′-fluorobenzophenone
ACh	Acetylcholine
AChE	Acetylcholinesterase
ACNB	2-Amino-2′-chloro-5-nitrobenzophenone
ACPO	Association of Chief Police Officers
AD	Alzheimer's disease
ADC	Analogue-to-digital converter
ADCB	2-Amino-5,2′-dichlorobenzophenone
ADH	Alcohol dehydrogenase
ADHD	Attention deficit hyperactivity disorder
ADI	Acceptable daily intake
AED	Atomic emission detector
AEME	Anhydroecgonine methylester
AES	Atomic emission spectrometry
AFID	Alkali flame ionisation detection
AFM	Atomic force microscopy/microscope
AFMAB	5-Amino-2′-fluoro-2-methylaminobenzophenone
AFNB	2-Amino-2′-fluoro-5-nitrobenzophenone
AFS	Atomic fluorescence spectrometry
agg.	aggregate (in botanical names), including two or more species which resemble each other closely
AGP	α_1-Acid glycoprotein
AIDS	acquired immunodeficiency syndrome
ALDH	Aldehyde dehydrogenase
ALL	Acute lymphoblastic leukemia
ALS	Amyloid lateral sclerosis
ALT	Alanine transaminase (alanine aminotransferase)
6-AM	6-Acetylmorphine
AMPA	α-Amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid
AMPK	AMP-activated protein kinase
AMT	α-Methyltryptamine
amu	Atomic mass units
ANB	2-Amino-5-nitrobenzophenone
AO	Aldehyde oxidase
AOAC	Association of Analytical Chemists
AORC	Association of Official Racing Chemists
APB	3-Amino-1-phenylbutane
APC	7-Ethyl-10-[4[*N*-(5aminopentanoic acid)-1-piperidino]-carbonyloxycamphothecin
APCI	Atmospheric Pressure Chemical Ionisation
APDC	Ammonium pyrrolidine dithiocarbamate
APEI	Atmospheric pressure electrospray ionisation
API	Atmospheric pressure ionisation; active pharmaceutical ingredients
APL	Acute promyelocytic leukaemia
APT	Attached proton test
AR	Analytical reagent
Art	artefact
5-ASA	5-Aminosalicyclic acid
ASL	Average signal level
ASP	Amnestic Shellfish Poisoning
AsPEX	Allele-specific primer extension
AST	Aspartate transminase (aspartate aminotransferase)
ASTM	American Society for Testing and Materials
ASV	Anodic stripping voltametry
ATD	Automated thermal desorption
ATR	Attenuated total reflectance
AUC	Area under the curve
AUFS	Absorbance units full scale
AV	Atrioventricular
BAC	Blood alcohol concentration
BBA	Butyl boronic acid
BBR	Blood-to-breath ratio
BC	Background correction
BCRP	Breast cancer resistance protein
1,4-BD	1,4-Butanediol
BDB	3,4-Benzodioxazol butanamine
BDMPEA	4-Bromo-2,5-dimethoxyphenethylamine
BE	Benzoylecgonine
BEN	Balkan endemic neuropathy
BGE	Background electrolyte
bid	Twice daily
BMAA	β-*N*-Methylamino-L-alanine
BMC	4-Bromomethyl-7-methoxycoumarin
BMI	Body mass index
BNCT	Boron neutron capture therapy
BOAA	β-I-Oxalylamino-L-alanine
BP	Blood pressure; Bristish Pharmacopoeia; butyrylated; benzophenone
Bp	Boiling point
B.P.	British Pharmacopoeia
BPH	Benign prostatic hyperplasia
BrAC	Breath alcohol concentration
BRP	Biological reference preparation
BSA	Bovine serum albumin; body surface area
BSH	Mercaptoundecahydrododecaborate
BSTFA	Bis(trimethylsilyl)trifluoroacetamide
BuChE	Butyrylcholinesterase
BUN	Blood urea nitrogen
BZP	*N*-Benzylpiperazine
CA	Carbonic anyhdrase
CAM	Base-modified PEG
CAP	College of American Pathologists
CAS	Chemical Abstracts Service
2-CB	4-Bromo-2,5-dimethoxyphenethylamine
CBD	Cannabidiol
CBN	Cannabinol
CBQCA	3-(4-Carboxy-benzoyl)-2-quinoline carboxaldehyde

CCD	Charge-coupled device
CD	Circular dichroism
2C-D	2,5-Dimethoxy-4-methyl-β-phenethylamine
CDT	Carbohydrate-deficient transferrin
CE	Capilary electrophoresis
CEC	Capillary electrophoresis; collision energy
2C-E	2,5-Dimethoxy-4-ethyl-β-phenethylamine
CEDIA	Cloned enzyme donor immunoassay
CFP	Ciguatera fish poisoning
CFTB	5-Chloro-2′-fluoro-2-(2,2,2-trifluroethylamino)-benzophenone
CG	Chorionic gonadotrophin
CGE	Capillary gel electrophoresis
cGMP	Cyclic GMP; current good (pharmaceutical) manufacturing practice
CHE	Cholinesterase
ChE	Cholinesterase
CHF	Congestive heart failure
-CHNO	Descarbamoyl artefact
CI	Chemical ionisation
2C-I	2,5-Dimethoxy-4-iodo-β-phenethylamine
CIA	Chemiluminescent immunoassay, capillary ion analysis
CID	Collision induced dissociation
CIEF	Capillary isoelectric focusing
CIn	Colour index
CIRMS	Combustion isotope ratio MS
CITP	Capillary isotachophoresis
CL	Clearance
Cl	Clearance
CL_{CR}	Creatinine clearance
C_{max}	Mean maximum plasma concentration
CMC	Critical micelle concentration
CNS	Central nervous system
$-CO_2$	Artefact formed by decarboxylation
COHb	Carboxyhaemoglobin
COMT	Catechol-*O*-methyltransferase
COPD	Chronic obstructive pulmonary disease
COSY	Correlation spectroscopy
COX	Cyclooxygenase
CPMACB	2-Cyclopropylmethylamino-5-chlorobenzophenone
CRA	Controlled Substances Act
CRS	Chemical reference substance
CSEI	Cation selective exhaustive injection
CSF	Cerebrospinal fluid
CSP	Chiral stationary phase
CT	Computed tomography
2C-T-2	2,5-Dimethoxy-4-ethylthio-β-phenethylamine
2C-T-7	2,5-Dimethoxy-4-propylthio β-phenethylamine
CTAB	Cetyl trimethyl ammonium bromide
CTFEAB	5-Chloro-2-(2,2,2-trifluoro)-ethylaminobenzophenone
CTX	Ciguatoxin
CV	Coefficient of variation
CVAA	2-Chlorovinylarsenous acid
CVAO	2-Chlorovinyl arsenous oxide
CVVHDF	Continuous veno-venous haemodiafiltration
CYP	Cytochrome P450
CZE	Capillary zone electrophoresis
2,4-D	2,4-Dichlorophenoxyacetic acid
DA	Dialkylated
DAB	2,5-Diaminobenzophenone
DACB	2,5-Diamino-2′-chlorobenzophenone
DAD	Diode array detection/detector
DAFB	2,5-Diamino-2′-fluorobenzophenone
DART	Direct analysis in real time
DBD	3,4-Benzodioxazol butanamine
DBQ	2,6-Dibromoquinone-4-chlorimide
DBZ	Dibenzosuberamine
DC	Direct current
DCCA	(3(2,2-Dichlorovinyl)-2,2-dimethylcyclopropane-carboxylic acid
DCMAB	2′,5-Dichloro-2-(methylamino) benzophenone
DDD	Dichlorodiphenyldichloroethane
DDE	Dichlorodiphenyldichloroethylene
DDS	Drug detection system
DEA	Drug Enforcement Agency
DEACFB	2-Diethylaminoethylamino-5-chloro-2′-fluorobenzophenone
DECP	Drug Evaluation and Classification Program
DEG	Diethylene glycol
dEPO	Darbepoietin
DEPT	Distortionless enhancement by polarisation transfer
DESI	Desorption electrospray ionisation
DFA	Drug-facilitated assault
DFSA	Drug-facilitated sexual assault
DHEA	Dehydroepiandrosterone
DHHS	Department of Health and Human Services
dH_2O	Distilled water
DHPLC	Denaturing HPLC
DIPT	Diisopropyltryptamine
DLLME	Dispersive liquid–liquid microextraction
DLS	Dynamic light scattering
DMA	2,5-Dimethoxyamfetamine
p-DMAB	*p*-Dimethylaminobenzaldehyde
DME	Dimethyl ether
DMES	Dimethylethylsilyl
DMF	Dimethylformamide
DMS	Differential mobility spectrometry
DMSA	Dimercaptosuccinic acid
DMSO	Dimethylsulfoxide
DNOC	Dinitro-*o*-cresol
DNS-Cl	Dansyl chloride
DOB	4-Bromo-2,5-dimethoxyamfetamine
DOD	(US) Department of Defense
DOM	2,5-Dimethoxy-4-methylamfetamine
DON	Deoxynivalenol
DOT	(US) Department of Transport
DPA	Diphenylamine
DPASV	Differential pulse anodic stripping voltametry
DPI	Dry powder inhalation/inhaler
DPV	Differential pulse voltametry
DQ	Design qualification
DRESS	Drug rash with eosinophilia and systemic symptoms
DRIFT	Diffuse reflectance IR Fourier transform spectroscopy
DSHEA	Dietary Supplement and Health Education Act
DSP	Diarrhetic shellfish poisoning
DTAB	Dodecyl trimethyl ammonium bromide
DUI	Driving under the influence
DUIA	Driving under the influence of alcohol
DUID	Driving under the influence of drugs
DVT	Deep vein thrombosis
DWI	Driving while intoxicated/impaired
EA	Enzyme acceptor
EAAS	Electrothermal AAS
EC	Electrochemical
ECD	Electron capture detection
ECG	Electrocardiogram
ECM	Enteric coated microcapsules
ECT	Electrical capacitance tomography
ED	Erectile dysfunction; enzyme donor
EDDP	2-Ethylidene-1,5-dimethyl-3,3-diphenylpyrrolidine
EDT	1,2-Ethanedithiol

EDTA	Ethylene diamine tetra-acetate
EDXRF	Energy-dispersive XRF
EEG	Electroencephalogram
EI	Electron Impact
EIA	Enzyme immunoassay
ELCD	Electrolytic conductivity detection
ELF	Epithelial lining fluid
ELISA	Enzyme-linked immunosorbent assay
ELS	Evaporative light-scattering
EMC	Erythromycylamine
EMCDDA	European Monitoring Centre for Drugs and Drug Addiction
EME	Ecgonine methyl ester
EMEA	European Agency for the Evaluation of Medicinal Products
EMIT	Enzyme-multiplied immunoassay technique
EMPA	Ethyl methylphosphonic acid
ENFSI	European Network of Forensic Science Institutes
EOF	Electroosmotic flow
EPBRP	European Pharmacopoeia biological reference preparations
EPI	Enhanced product ion
EPO	Erythropoietin
ESA	Electrostatic analyser
EQA	External quality assurance/assessment
ESI	Electrospray ionisation
ET	Ethylated
ETAAS	Electrothermal atomic absorption spectrometry
EtG	Ethyl glucuronide
EtS	Ethyl sulfate
ETV	Electrothermal vaporisation
EU	European Union
eV	Electron volts
EWDTS	European Workplace Drug Testing Society
FAAS	Flame atomic absorption spectrometry
FAB	Fast atom bombardment
FAEE	Fatty acid ethyl esters
FAIMS	Field asymmetric waveform ion mobility spectrometry
FAME	Fatty acid methyl ester
FASS	Field-amplification sample stacking
FDA	Food and Drug Administration
FEI	Federation Equestre Internationale
FFAP	Acid-modified PEG
FFT	Fast Fourier transform
fg	Femtograms
FIA	Flow injection analysis; fluorescent immunoassay
FID	Flame ionisation detection; free-induction decay (NMR)
FISH	Fluorescence in-situ hybridisation
Fp	Freezing point
FPBA	4-Fluoro-3-phenoxybenzoic acid
FPD	Flame photometric detector
FPIA	Fluorescence polarisation immunoassay
FPLC	Fast protein liquid chromatography
FPN	Ferric(III) chloride-perchloric acid-nitric acid
ft	Foot (feet)
FSH	Follicle stimulating hormone
FT	Fourier transform
FTD	Flame thermionic detection
FTIR	Fourier transform infrared
FTIRD	Fourier transform infrared detector
GABA	γ-Aminobutyric acid
GBL	γ-Butyrolactone
GC	Gas chromatography
GC-HRMS	High resolution mass spectrometry
GC-MS(-MS)	Tandem GC-MS
GCS	Glasgow Coma Scale
G-CSF	Granulocyte colony-stimulating factor
GFAAS	Graphite furnace atomic absorption spectrometry; electrothermal atomic absorption spectrometry
GFR	Glomerular filtration rate
GH	Growth hormone
GHB	γ-Hydroxybutyric acid
GI	Gastrointestinal
GLC	Gas-liquid chromatography
GLP	Good laboratory practice
GMND	Guamanian motor neuron disease
GMP	Good manufacturing practice
G6PDH	Glucose-6-phosphate dehydrogenase
GPS	Genomic prescribing system
GRM	Gastric release microcapsules
GSR	Gunshot residue
GTX	Gonyautoxins
h	Hour(s)
HBV	Hepatitis B virus
HCC	Hepatocellular carcinoma
hCG	Human chorionic gonadotrophin
HCL	Hollow cathode lamp
-HCl	Artefact formed by the elimination of hydrochloric acid
-HCN	Artefact formed by the elimination of hydrogen cyanide
HCV	Hepatitis C virus
HD	3β-Hydrosteroid dehydrogenase
HDO	Mustard sulfoxide
HDO_2	Mustard sulfone
HEACFB	2-Hydroxyethylamino-5-chloro-2′-fluorobenzophenone
HEPES	*N*-(2-Hydroxyethyl)-piperazine-*N*′-2-ethanesulfonic acid
HERG	Human ether-a-go-go-related gene
HFB	Heptaflurobutyrate
HFBA	Heptaflurobutyric anhydride
HGN	Horizontal gaze nystagmus
HHD	2-Chloro-2-hydroxyethyl sulfoxide
HIV	Human immunodeficiency virus
HLA	Human leukocyte antigen
HMBC	Heteronuclear multiple bond correlation
HMMC	4-Hydroxy-3-methoxymethcathinone
HMQC	Heteronuclear multiple quantum coherence
HMT	Hexamethylenetetramine
$-H_2O$	Artefact formed by dehydration of an alcohol or by rearrangement of an amino oxo compound
HOM	Humic organic matter
HPLC	High performance liquid chromatography
HR	Heart rate
HR-MS	High resolution mass spectrometry
HS	Headspace
HS-GC	Headspace gas chromatography
HSQC	Heteronuclear single quantum coherence
-HY	Acid-hydrolysed/acid hydrolysis
I	Spin quantum number
IA	Immunoassay
IBS	Irritable bowel syndrome
ICADTS	International Council on Alcohol, Drugs and Traffic Safety
ICH	International Conference on Harmonisation
ICP	Inductively coupled plasma
ICR	Ion cyclotron resonance
ICRAV	International Conference of Racing Analysts and Veterinarians
ID	Isotope dilution
i.d.	Internal diameter
IDA	Information dependent acquisition
IDLH	Immediately dangerous to life
IEC	Ion exchange chromatography

IFHA	International Federation of Horseracing Authorities
Ig	Immunoglobulin
IGF-1	Insulin-like growth factor-1
ILAC	International Laboratory Accreditation Co-operation
IM	Intramuscular
IMPA	Isopropylmethylphosphonic acid
IMS	Ion mobility spectrometry
INAA	Instrumental neutron activation analysis
INR	International normalised ratio
IOC	International Olympic Committee
IP	Identification points/intraperitoneal
IQC	Internal quality control
IR	Infrared
IRMA	Immunoradiometric assay
IRMS	Isotope ratio mass spectrometry
IS	Internal standard
ISE	Ion selective electrode
IT	Ion trap
IU	International unit
IUPAC	International Union of Pure and Applied Chemistry
IV	Intravenous
J	Indirect spin coupling
JRES	*J* resolved experiment
k	Column capacity ratio
K-EDTA	Potassium ethylenediamine tetraacetic acid
KIMS	Kinetic interaction of microparticles in solution
LA	Laser ablation
LAAM	Levomethadyl acetate
LAL	Limulus amoebocyte lysate test
λ	Wavelength
LAMPA	Lysergic acid *N*-(methylpropyl) amide
LC	Liquid chromatography
LC-MS(-MS)	Tandem LC-MS
LCTF	Liquid crystal tuneable filter
LD_{50}	Lethal dose to 50% of a population
LFA	Lateral flow assay
LH	Luteinising hormone
LIF	Laser or light induced fluorescence
LLE	Liquid–liquid extraction
LLOQ	Lower limit of quantification
ln	Logarithm to the base e (natural logarithm)
LOCI	Luminescent oxygen channeling immunoassay
LOD	Limit of detection
log	Logarithm to the base 10
LOQ	Limit of quantification
LPG	Liquified petroleum gas
LSD	Lysergic acid diethylamide; lysergide
LTFS	Low temperature fluorescence spectroscopy
M	Molar (moles per L)
M (COOH-)	Carboxy metabolite
M (nor-)	*N*-Desmethyl metabolite
M (OH-)	Hydroxy metabolite
M (ring)	Ring compound as metabolite
MACB	2-Methylamino-5-chlorobenzophenone
MACDP	2-Methylamino-5-chlorodiphenylamine
MALDI	Matrix assisted laser desorption and ionisation
6-MAM	6-Monoacetyl morphine
MANFB	2-Methylamino-5-nitro-2′-fluorobenzophenone
MAO	Monoamine oxidase
MAOI	Monoamine oxidase inhibitor
MAS	Magic-angle-spinning
mAU	Milli-absorbance units
MBA	Methyl boronic acid
MBDB	*N*-Methyl-1-(1,3-benzodioxol-5-yl)-2-butanamine
2,3-MBDB	Methyl-2,3-benzodioxazol butanamine
MBTFA	*N*-Methylbis(trifluoroacetamide)
MCF	(1*R*,2*S*,5*R*)-(–)-Menthylchloroformate
MCPA	Methylchlorophenoxy acetic acid
MCPA-CoA	Methylenecyclopropylacetyl-coenzyme-A
MCPP	2-(2-Methyl-4-chlorophenoxy)propionic acid
*m*CPP	1-(-3-Chlorophenyl)piperazine
MDA	Methylenedioxyamfetamine
MDE	Methylenedioxyethamfetamine
MDEA	Methylenedioxyethylamfetamine
MDI	Metered-dose inhalers
MDMA	3,4-Methylenedioxymetamfetamine
MDP2P	1-(3,4-Methylenedioxyphenyl)-2-propanone
MDPPP	3,4-Methylenedioxy-α-pyrrolidinopropiophenone
Me	Methyl
MECC (or MEKC)	Micellar electrokinetic capillary chromatography
MECK	Micellar electrokinetic chromatography
MEKC (or MECC)	Micellar electrokinetic capillary chromatography
MEL	Maximum exposure limit
mEq	Milliequivalent(s)
µg	Microgram(s)
µm	Micrometer(s)
MFD	Mass fragmentographic detection
MGF	Mechano growth factor
µM	Micrometre(s)
MHRA	Medicines and Healthcare Products Regulatory Agency
MIBK	Methyl isobutyl ketone
MID	Multiple ion detector
Min	Minute
MLR	Multiwavelength linear regression
MLS	Multi-angle light scattering
MMA	Multi-angle light scattering; 2-methoxy-metamfetamine
MMDA	3,4-Methylenedioxy-5-methoxyamfetamine
MMDBB	2,3-Dimethylbenzodioxazolbutanamine
6-MNA	6-Methoxy-2-naphthyl acetic acid
MND	Motor neurone disease, mono-*N*-dealkyldisopyramide
mol	Mole
8-MOP	8-Methoxypsoralen
MOPPP	4-Methoxy-α-pyrrolidinopropiophenone
MO/TMS	Methoxime/trimethylsilyl
Mp	Melting point
MPA	Methylphosphonic acid; *N*,*N*-dimethyl-*p*-phenylenediamine hydrochloride
MPHP	4′ Methyl-α-pyrrolidinohexanophenone
MPPP	4-Methyl-α-pyrrolidinopropiophenone
MQL	Minimal quantifiable limit
M_r	Relative molecular mass
MR	Metabolic ratio
MRI	Magnetic resonance imaging
MRL	Maximum residue limits
MRM	Multiple reaction monitoring
MRO	Medical Review Officer
MRPL	Minimum required performance level
MRS	Magnetic resonance spectroscopy
MS	Mass spectrometry
MSC	Multiplicative scatter correction
MSTFA	*N*-Methyltrimethylsilyltrifluoroacetamide
MTA	4-Methylthioamfetamine
MTSS	Merck tox screening system
m/z	Mass to charge ratio
NA	Numerical aperture
NAA	Neutron activation analysis
NACE	Non-aqueous capillary electrophoresis
NAD	Nicotinamide–adenine dinucleotide
NAPA	Acecainide; *N*-acetylprocainamide
NAPQI	*N*-Acetyl-*p*-benzoquinoneimine

NAT2	*N*-Acetyltransferase 2
NBD-F	4-Fluoro-7-nitro-2,1,3-benzoxadiazole
NBP	4-(4-Nitrobenzyl)pyridine
NCE	New chemical entity
NCI	Negative chemical ionisation
NC-SPE	Non-conditioned SPE
ND	Nordiazepam
NDPX	Norpropoxyphene
ng	Nanogram(s)
$-NH_3$	Artefact formed by elimination of ammonia
NHTSA	(US) National Highway Traffic Safety Administration
NIAPCI	Negative ion atmospheric pressure chemical ionisation
NICI	Negative ion chemical ionisation
NIDA	National Institute for Drug Abuse
NIR	Near-infrared imaging
NIST	National Institute of Standards and Technology
NLCP	National Laboratory Certification Program
nm	Nanometer(s)
NMDA	*N*-Methyl-D-aspartate
NMR	Nuclear magnetic resonance
NNRTI	Non-nucleoside reverse transcriptase inhibitor
NOE	Nuclear Overhauser enhancement
NOESY	Nuclear Overhauser enhancement spectroscopy
NPC	Normal phase chromatography
NPD	Nitrogen phosphorus detection
NRC	Nuclear Regulatory Commission
NRG-1	Naphthylpyrovalerone (naphyrone)
NSAI	Non-steroidal anti-inflammatory
NSAID	Nonsteroidal antiinflammatory drug
NSD	Nitrogen specific detector
NSP	Neurotoxic shellfish poisoning
OAB	Overactive bladder
$OATPT_2$	Organic anion transporting polypeptide 2
OC	Oesophageal cancer
ODS	Octadecylsilane
OECD	Organization for Economic Development and Cooperation
OES	Occupational exposure standard
OF	Oral fluid
OOS	Out-of-specification
OTA	Ochratoxin-A
P	Apparent partition coefficient
PAD	Peripheral arterial disease
PAGE	Polyacrylamide gel electrophoresis
PBMS	Particle beam MS
PC	Precipitation chromatography; principle component
PCA	Principal component analysis
PCB	Polychlorinated biphenyl
PCC	Pyridinium chlorochromate
PCEEA	*N*-(1-Phenylcyclohexyl)-2-ethoxyethenamine
PCEPA	*N*-(1-Phenylcyclohexyl)-3-ethoxypropanamine
PCMEA	N-(1-Phenylcyclohexyl)-2-methoxyethenamine
PCP	Phencyclidine
PCPR	*N*-(1-Phenylcyclohexyl)-propanamine
PCR	Polymerase chain reaction; principal component regression
PD	Pulsed discharge
PDA	Photodiode array
PDHID	Pulsed discharge helium ionisation detector
PDT	1,3-Propanedithiol
PEEK	Polyether etherketone
PEG	Polyethylene glycol
PEL	Permissible exposure limit
PFB	Pentafluorobenzoyl
PFK	Perfluorokerosene
PFP	Pentafluoropropionate; puffer fish poisoning
-PFP	pentafluoropropionylated
PFPA	Pentafluropropionic anhydride
PFTBA	Perfluorotributylamine
pg	Picogram(s)
pGp	*p*-Glycoprotein
PGRN	Pharmacogenetics Research Network
PGx	Pharmacogenomics
PH	Permethylated hydroxypropyl
PHA	4-Hydroxyamfetamine
PhAsO	Phenylarsine oxide
Ph. Eur.	European Pharmacopoeia
Ph. Int	International Pharmacopoeia
P*I*	PH of the isoelectric point of a protein
PIAPCI	Positive ion atmospheric pressure chemical ionisation
PICI	Positive ion chemical ionisation
PID	Photoionisation detection
PIFAB	Positive ion fast atom bombardment
PIS	Product ion spectrum
PJ	Personalised justice
pK_a	Negative logarithm of the dissociation constant
PLA	Phospholipase A
PLOT	Porous layer open tubular
PLS	Partial least-squares
PLSR	Partial least-squares regression
PM	Permethylated; personalised medicine
PMA	4-Methoxyamfetamine
PMEA	4-Methoxyethylamfetamine
PMMA	4-Methoxy-methamfetamine
PMN	Polymorphonuclear leukocytes
PMPA	Pinacoylmethylphosphonic acid
PN	Propionylated
PO	*per os* (oral)
p.o.	Per oral
P-III-P	Procollagen type III
PPARδ	Peroxisome proliferator activated receptor δ
ppb	Part(s) per billion
PPC	4-Phenyl-4 piperidinocyclohexanol
PPD	*p*-Phenylenediamine
ppm	Part(s) per million
PPP	α-Pyrrolidinopropiophenone
PQ	Performance qualification
PRP	Polyribosylribitol phosphate
PSI	Pre-column separating inlet
PSP	Paralytic shellfish poisoning
PSX	Polysiloxane
PtE	Phosphatidylethanol
PTFE	Polytetrafluoroethylene
PTV	Temperature-programmed sample inlet, programmable temperature vaporising
PVP	Poly(vinylpyrrolidone)
QA	Quality assurance
QC	Quality control
qPCR	Quantitative PCR
QQQ	Triple quadrupoles
QTOF	Quadrupole TOF
RCI	Racing Commissioners International
r.d.	Relative density
rDNA	Recombinant DNA
rf	Radio frequency
RFLP	Restriction fragment length polymorphism
rhEPO	Recombinant human erythropoietin
rhGH	Recombinant human growth hormone
RI	Retention index
RIA	Radioimmunoassay
RMTC	Racing Medication and Testing Consortium
RNA	Ribonucleic acid
RPC	Reversed-phase chromatography
RRT	Relative retention time

RSD	Relative standard deviation
RSS	Root sum square
RT	Retention time
s	second(s)
SAMHSA	Substance Abuse and Mental Health Services Administration
SARM	Selective androgen receptor modulator
SBW	Spectral band width
SC	Subcutaneous
SCF	Supercritical fluid
SCFC	Supercritical fluid chromatography
SCOT	Support-coated open tubular
SDS	Sodium dodecyl sulfate; standard deviation
SDS-PAGE	Sodium dodecyl sulfate polyacrylamide gel electrophoresis
SEC	Standard error of calibration; size exclusion chromatography
SEP	Standard error of prediction
SERM	Selective estrogen receptor modulator
SFE	Supercritical fluid extraction
SFST	Standardised field sobriety test
SHGB	Sex hormone binding globulin
SI	Système international d'unités
SID	Surface ionisation detection
SIM	Selected ion monitoring
SIMCA	Soft independent modelling of class analogies
SIR	Selected ion recording
SMAP	2-Sulfamoylacetylphenol
SNAP-25	Synaptosome-associated protein of 25,000 daltons
SNARE	Acronym derived from "soluble NSF attachment receptor"
SNP	Single nucleotide polymorphism
SNPA	*N*-Succinimidyl-*p*-nitrophenylacetate
SNR	Signal-to-noise ratio
SNV	Standard normal variate
SOFT	Society of Forensic Toxicologists
$-SO_2NH$	Artefact formed by elimination of the sulfonamide group
SOP	Standard operating procedure
SORS	Spatially offset Raman spectroscopy
sp.	Species (plural spp.)
sp.gr.	Specific gravity
SPE	Solid-phase extraction
SPME	Solid phase microextraction
SPR	Surface plasmon resonance
SRM	Selected reaction monitoring; standard reference materials
SSI	Sonic spray ionisation
SSNMR	Solid-state NMR
SSRI	Selective serotonin reuptake inhibitor
STA	Systematic toxicological analysis
STIP	Systematic toxicological identification procedure
STOCSY	Statistical TOCSY
STP	2,5-Dimethoxy-4-methylamfetamine; short tandem repeat
STR	Short tandem repeat
STX	Saxitoxin
SVT	Supraventricular tachycardia
2,4,5-T	2,4,5-Trichlorophenoxyacetic acid
$t_{1/2}$	Half-life
T_1	Spin-lattice or longitudinal relaxation time
T_2	Spin–spin or transverse relaxation time
TBA	Tetrabutyl ammonium hydrogen sulfate
TBAF	Tetrabutyl ammonium fluoride
TBAH	Tetrabutylammonium hydroxide
TBDM	Tert-butyldimethylsilyl
TBPE	Tetrabromophenolphthalein ethyl ester
TBSA	Total body surface area
TBW	Total body water
TCA	Tricyclic antidepressant
TCD	Thermal conductivity detector
TCM	Traditional Chinese medicine
TCP	3,5,6-Trichloro-2-pyridinol
TCRC	Time-coupled time-resolved chromatography
TDGO	Thiodiglycol sulfoxide
$TDGO_2$	Thiodyglycol sulfone
TDI	Tolerable daily intake
TDM	Therapeutic drug monitoring
TdP	torsades des pointes
TEA	Triethylamine
Tf	Transferrin
-TFA	Trifluoroacetylated
TFAA	Trifluroacetic anhydride
TFMPP	1-(3-Trifluoromethylphenyl)piperazine
TFPI	Tissue factor pathway inhibitor
TGS	Triglycine sulfate
THA	Tetrahexylammonium hydrogensulfate
THC	Tetrahydrocannabinol
THCA	11-Carboxytetrahydrocannabinol
THC-COOH	Tetrahydrocannabinol-11-oic-acid
THEED	Tetrahydroxyethylene diamine
THF	Tetrahydrofuran
TIAFT	The International Association of Forensic Toxicologists
TIC	Total ion current
TID	Thermionic detection
TIS	Turbo ion spray
TLC	Thin-layer chromatography
2,3,5-TMA	2,3,5-Trimethoxyamfetamine
3,4,5-TMA	3,4,5-Trimethoxyamfetamine
TMAH	Tetramethylammonium hydroxide
t_{max}	Time to maximum plasma concentration
TMCS	Trimethylchlorosilane
TMMA	2,3,5-Trimethoxymethamfetamine
TMS	Trimethylsilyl
TMSI	Iodotrimethylsilane
TMSTFA	Trimethylsilyltrifluoroacetyl
TNF	Tumour necrosis factor
TOC	Total organic carbon
TOCSY	Total correlation spectroscopy
TOF	Time of flight
TPAH	Tetrapentylammonium hydroxide
TPI	Terahertz pulsed imaging
TPMT	Thiopurine methyltransferase
TRXRF	Total reflection XRF
TSD	Thermionic specific detection
TSP	Trimethylsilyl [2,2,3,3-$^2H_4$]-proprionic acid sodium salt
TTX	Tetrodotoxin
TVAC	Total viable aerobic count
UAC	Urine alcohol concentration
UDP	Uridine diphosphate
UGT	UDP-glucuronosyltransferase
UHPLC	Ultra-high pressure LC
UK	United Kingdom
ULOQ	Upper limit of quantification
UN	United Nations
UPLC	Ultra performance liquid chromatography
USA	United States of America
USP	United States Pharmacopeia
UV	Ultraviolet
V	Volt(s)
VAMP	Vesicle associated membrane protein
var.	Variety
V_D	Volume of distribution
Vet.	Veterinary
VGDS	Voluntary genomics data submission

Vol	Volume(s)	Wt	Weight
VSA	Volatile substance abuse	w/v	Weight in volume
v/v	Volume in volume	w/w	Weight in weight
WADA	World Anti-Doping Agency	XRD	X-ray diffraction
WCOT	Wall-coated open tubular	XRF	X-ray fluorescence
WDXRF	Wavelength dispersive XRF	XRPD	X-ray powder diffraction
WHO	World Health Organization		

PART ONE

Chapters

Methodology and analytical techniques

CHAPTER

1 Hospital Toxicology

DRA Uges

Hospital toxicology is concerned with individuals admitted to the hospital with suspected poisoning and its prime aim is to assist in the treatment of the patient. The range of substances that may be encountered is huge and ideally the hospital laboratory will have the capability to identify and, if required, quantify pharmaceutical agents, illicit drugs, gases, solvents, pesticides, toxic metals and a host of other industrial and environmental poisons in biological fluids. In practice, few laboratories can offer such a comprehensive menu and resources are concentrated on those compounds most often involved in poisoning and for which toxicological investigations are particularly useful to the clinical services. In developed countries, hospital clinical chemistry laboratories are geared to provide these basic services and rely on support from central specialised toxicology laboratories for the rarer cases. Fortunately, in the vast majority of cases the diagnosis can be made on circumstantial and clinical evidence; there is no need for urgent analyses and these can be carried out as a routine exercise. However, when the patient's condition is severe and the diagnosis is not clear, toxicological tests may be crucial and the analytical results must be furnished quickly (usually within 1–2 h of the patient's arrival) if they are to have any bearing on diagnosis and treatment. Ideally, the toxic substance can be both identified and quantified within this time frame. When this is not possible, a qualitative result still has considerable value if the symptoms are consistent with the identified toxin and should be communicated to the clinician without delay.

These time constraints entail an inevitable compromise between speed and analytical accuracy and precision. Consequently, the quantitative methods used may fall short of the standards required, for example, for pharmacokinetic investigations. However, they must be of sufficient quality to allow an appropriate clinical decision to be made (Peters, Maurer 2002). In this area, close liaison between the laboratory personnel and the clinician who manages the patient is essential and can save hours of fruitless effort. An attempt must be made to obtain as much information about the patient as possible. This should include not only the clinical picture, but also any previous medical history of poisoning, details of drugs or other substances to which the patient may have had access and, in cases of accidental poisoning, substances to which the patient may have been exposed. This sort of dialogue between the clinician and an experienced analytical toxicologist can often yield clues as to what the cause of toxicity might be and therefore suggest which tests should be performed as a priority. Close communication must continue if the initial tests prove negative, so that the search can be widened, or if the clinician requires advice on the interpretation of positive results.

Laboratories that provide analytical toxicology analyses to assist with cases of acute and chronic poisoning often offer additional services in the area of drug abuse. An increasing number of central laboratories started with providing blood spot services. Dried whole spots on printed paper are sent to these laboratories for analysis, e.g. tacrolimus, anticonvulsants, antibiotics (tuberculosis, cystic fibrosis). This can range from diagnostic tests to uncover the covert misuse of laxatives and diuretics through to routine screening of urine samples from patients assigned to treatment and rehabilitation programmes. For the latter, the requirement is to establish the drug-taking patterns of new patients and to monitor their subsequent compliance with the prescribed treatment regime. Details of techniques suitable for these services are given in separate sections.

Causes of hospital admissions for poisoning

Social and economic stresses or mental disorders often result in suicide attempts, particularly through drug overdose, one of the most common causes of emergency hospital admissions. Homicidal poisoning is relatively rare, but surviving victims of this practice are often investigated initially in the hospital environment. Individuals who have been administered substances without their knowledge to facilitate robbery or sexual abuse may also be admitted to hospital. Although in the latter scenario the victims tend to contact the medical services several days after the incident, if teenagers or young adults arrive in hospital semiconscious or disorientated, the administration of so-called date-rape drugs such as alcohol, gamma-hydroxybutyric acid (GHB), flunitrazepam or ketamine must always be considered. Poisoning in children is mainly accidental, but deliberate poisoning by parents, guardians or siblings does occur. Accidental poisoning usually takes place in the domestic environment, with young children and the elderly particularly at risk. Children may gain access to pharmaceutical products, cleaning agents (bleach, disinfectants), pesticides, alcoholic drinks and cosmetics. The confused elderly may misjudge their intake of medications or be poisoned by inappropriate handling of toxic household products. Both are susceptible to acute or chronic poisoning with carbon monoxide emitted by faulty domestic heating appliances. The workplace is another environment in which accidental poisoning occurs and the analytical results from the hospital laboratory can be important not only in medical diagnosis but also in any subsequent legal investigations that involve insurance claims.

Iatrogenic intoxications occur through inappropriate medical or paramedical treatment. Neonates require intravenous dosing and the need to work out doses per kilogram of body mass or per square metre (m^2) of body area introduces the risk that the total amount and volume of medicine to be administered may be miscalculated. Other causes of iatrogenic poisoning include drug interactions, use of the wrong route of administration and failure to take note of impaired liver or renal function, which reduces the patient's ability to eliminate the drug. A common example is the accumulation of digoxin in elderly patients with reduced renal function.

Qualitative screening or quantitative analysis?

Laboratories adopt different approaches to hospital toxicology. To a large extent, the range of equipment available and the skills and knowledge of the staff govern the policy adopted. Where resources are scarce, only a limited screen for common drugs and poisons may be carried out, with the main effort directed towards quantitative analyses for toxins indicated by circumstantial evidence and the patient's clinical signs. Specialised toxicology laboratories may pursue a systematic and comprehensive toxicological screen in every case, on the grounds that the clinical and circumstantial indicators are seldom reliable, and then proceed to quantify any substances detected. While the latter approach is more likely to yield useful information, it is expensive and time-consuming. As stated above, close liaison with the clinicians to obtain a comprehensive case history and a full clinical picture can often help to focus the resources on the qualitative and quantitative tests that are most relevant. The guidelines given in Table 1.1 are useful in this context.

Table 1.1 Guidelines to help focus resources on the most relevant qualitative and quantitative tests

Indications for qualitative screening	*Indications for quantitative analyses*
To distinguish between apparent intoxication and poisoning	When the type and duration of treatment depends on the concentration (e.g. antidotes for paracetamol and thallium)
When information about the patient is lacking (no medical history)	When the prognosis is gauged by the plasma concentration (e.g. paraquat)
When the clinical picture is ambiguous (e.g. seizures)	To distinguish between therapeutic and toxic ingestion of drugs
Where the clinical picture may be caused by a pharmacological group of drugs rather than one particular substance (e.g. laxatives, diuretics)	Mixed intoxications (e.g. methanol and ethanol)
Cases of mixed intoxication (drugs of abuse, alcohol)	Toxicological monitoring (e.g. aluminium, Munchausen's syndrome)
Poisoning with no immediately evident clinical picture (e.g. paracetamol)	Toxicokinetic calculations
Where no reliable or selective quantitative method is available (e.g. herbal preparations)	Research (e.g. efficacy of treatment), education, prevention, etc.
For forensic reasons	
At the special request of the clinician	
For purposes of statistics, research, education, prevention, etc.	

In larger clinical laboratories, the use of various liquid chromatography–mass spectrometry (LC-MS) techniques for therapeutic drug monitoring and toxicological assays has increased considerably and the introduction of liquid chromatography linked to triple quadrupole mass spectrometry (LC-MS(-MS)) has brought about an enormous increase in reliability and sensitivity both in this application (Boermans *et al.* 2006) and in forensic toxicology (Roman *et al.* 2008). Although LC-MS(-MS) is not a comprehensive screening method, if sufficient information on the likely cause of poisoning in a drugs overdose case is available, it is possible to obtain both qualitative and quantitative data for a selection of up to 15 drugs and their metabolites within 40 minutes.

Applications

Confirmation of diagnosis

Most patients who reach hospital in time respond well to measures designed to support the vital processes of respiratory and cardiovascular function and, as mentioned above, toxicological investigations are of only historical value. However, it is still useful to have objective evidence of self-poisoning as this usually instigates psychiatric treatment and follow-up.

Differential diagnosis of coma

When circumstantial evidence is lacking, a diagnosis of poisoning may be difficult to sustain simply on the basis of clinical examination, since coma induced by drugs is not readily differentiated from that caused by disease processes. Apparent poisonings can be caused by hypoglycaemic coma, a cerebrovascular accident, exhaustion (after seizures), brain damage, meningitis, withdrawal symptoms, idiosyncratic reactions (e.g. to theophylline and caffeine), allergic reactions (shock), viral infections or unexpected symptoms of a disease (e.g. Lyme disease). In these situations, toxicological analyses serve either to confirm poisoning as the cause of coma or to rule it out in favour of an organic disorder that requires alternative medical and pathological investigations.

Diagnosis of brain death

A patient with brain death may be a potential donor of organs. In such cases, the patient should have a deep coma of known origin with no indication of a central infection and normal metabolic parameters. When the primary cause of coma is drug overdose, it is important to ensure that the drug has been eliminated prior to confirming the diagnosis of brain death. This also applies to drugs that may have been given in therapy. For example, thiopental is often given in the treatment of brain oedema and during neurosurgery. The half-lives of thiopental and its metabolite, pentobarbital, increase if cardiac function is diminished or the patient is hypothermic, and therefore plasma concentrations of both compounds must always be measured. Midazolam and diazepam are also administered frequently in treating cases of brain damage, and the continued presence of active concentrations of these drugs and their metabolites should also be excluded using specific and sensitive procedures, such as high performance liquid chromatography (HPLC) and LC-MS. Even if benzodiazepines or their metabolites cannot be detected, there remains the possibility that some may still be present; for instance, active concentrations of hydroxymidazolam glucuronide may be present, since the half-life may be increased considerably with end-stage organ failure. This may suggest a provocation test with the specific benzodiazepine antagonist flumazenil. Similarly, the presence of active levels of anticonvulsants (phenobarbital, carbamazepine, phenytoin and valproate), which are also given in the treatment of brain damage, must be excluded. Again, the use of sensitive and specific chromatographic methods is essential.

Influence on active therapy

Although supportive therapy remains the cornerstone of the management of acute poisoning, specific antidotes are available for metals (chelation agents), anticholinesterase inhibitors (atropine), methanol and ethylene glycol (ethyl alcohol, formepizole, 4-methylpyrazole), paracetamol/acetaminophen (*N*-acetylcysteine), digoxin (antibody fragments), calcium blockers (calcium salt), cumarines (phytonadione) and opioids (naloxone). Given a clear diagnosis, a clinician usually administers the antidote without waiting for laboratory confirmation, but subsequent analyses may help to decide whether to continue with the therapy. For example, both parenteral and oral therapy with desferrioxamine in cases of iron poisoning is indicated if patients deteriorate and the serum iron concentration is extremely high. Measurements of cholinesterase activity in serum or red cells are useful in a situation of high-dose infusions of atropine into patients exposed to organophosphate insecticides or thiocarbamates. Measures designed to reduce the absorption of poisons from the gut, such as the use of emetics, purgatives, gastric lavage and irrigation, are now considered to be of limited value and unwarranted in most cases of poisoning. The efficacy of whole-bowel irrigation is also questionable, although some advocate its use to remove sustained-release or enteric-coated preparations of, for example, iron salts and other potentially lethal poisons that have passed into the small bowel, and in the decontamination of body packers. A single oral dose of activated charcoal has largely replaced other means of reducing absorption, although it is generally useful only when given within 1 h of ingestion and fails to absorb inorganic ions, alcohols, strong acids or alkalis, or organic solvents.

Techniques to increase the rate of elimination of poisons, such as diuresis, adjusting the urinary pH, haemodialysis and peritoneal dialysis, venous–venous haemofiltration and charcoal haemoperfusion, are now rarely used. Forced diuresis is now frowned upon; it is probably beneficial only in cases of poisoning with thallium and, when coupled with alkalisation of urine, chlorophenoxy herbicides. Alkalisation of urine effectively increases the elimination of salicylates, phenobarbital and chlorophenoxy herbicides. Acidification of the urine has little merit in increasing the elimination of weakly basic substances, such as amfetamines and phencyclidine. New insights provide the indication of high-dose Intralipid after a severe overdose of a wide variety of drugs, e.g. lidocaine, antidepressants (see www.lipidrescue.org). Haemofiltration also has a role in this context. 'Gut dialysis', or the use of multiple oral doses of activated charcoal, is thought to operate by creating a drug

concentration gradient across the gut wall that leads to movement of the drug from the blood in the superficial vessels of the gut mucosa into the lumen. So far, its efficacy has been demonstrated for carbamazepine, dapsone, phenobarbital, quinine and theophylline, and there is evidence for its application in poisoning with calcium antagonists. Most of these procedures carry inherent risks to the patient and, as pointed out already, their applications are limited to only a handful of poisons. Toxicological analyses to identify and quantify the poison should be used to ensure that they are used appropriately and at the same time to prevent overtreatment of patients who would recover without such interventions.

Medicolegal aspects of hospital toxicology

The primary role of the hospital toxicologist is to assist clinicians in the treatment of poisoned patients, irrespective of any other aspects that surround the case. However, some cases may have a criminal element. These can range from iatrogenic poisoning, in which a patient or relative sues a health authority and its staff for neglect, through to the malicious administration of drugs or poisons by a third party. The latter category includes victims of drug-facilitated sexual assault who have been administered drugs such as flunitrazepam or GHB to induce confusion and amnesia, and non-accidental poisoning in children. Mothers are the most frequent perpetrators of child poisoning and do so to attract sympathy and attention as a consequence of the child's illness (Munchausen's syndrome by proxy). When these situations arise, the hospital toxicologist is obliged to take special precautions to conserve all residual samples (human matrices as well as medicines) and documentation that may feature subsequently as part of a forensic investigation (see Chapter 9).

Clinical manifestations and biomedical tests

Specific acute clinical manifestations and vital signs of the patient that can be important in suggesting the cause of poisoning are set out in Table 1.2.

Biochemical tests that gauge the physiological status of the patient are more important in terms of the immediate management of the condition and some of the abnormalities found can also be diagnostic of the type of agent involved (see Table 1.6). These, together with the clinical manifestations and history, provide the basis for the order in which the toxicological tests are carried out.

Other indicative features

Some poisons have characteristic odours that may be discerned on the patient's body or on clothes, or in breath and samples of vomit, as listed in Table 1.3. Colours of the skin and of urine samples can also be useful indicators (Tables 1.4 and 1.5). However, these clues should be interpreted with caution and are not a substitute for proper clinical and toxicological evaluation.

The results of biomedical tests are usually available before any toxicological tests have been completed; Table 1.6 highlights their potential diagnostic value.

Assays required on an emergency basis

Table 1.7 lists the toxicological assays (mainly in serum, plasma or blood) that should be performed as soon as possible after admission and highlights those that should preferably be provided by all acute hospital laboratories. Emergency requests for the analysis of rarer poisons may be referred to a specialised centre. Such lists vary according to the pattern of poisoning prevalent in different countries or regions, and Table 1.7 is therefore presented only as a guideline. Notes that indicate the relevance of the assays are also included.

Table 1.2 Disturbance of clinical features and indications of possible causes

Clinical feature	*Disturbances and poisons indicated*
General appearance	Restlessness or agitation (amfetamines, cocaine, lysergide (LSD), opiate withdrawal), apathy, drowsiness, coma (hypnotics, organic solvents, lithium)
Neurological disturbances	Electroencephalogram (EEG) (central depressants), motor functions (alcohol, benzodiazepines, GHB), speech (alcohol, drugs of abuse), movement disorders (hallucinogens, amfetamines, butyrophenones, carbamazepine, lithium, cocaine, ethylene glycol), reflexes, seizures (most centrally active substances in overdose or withdrawal), ataxia
Vital signs	
Mental status	Psychosis (illicit drugs), disorientation, stupor
Blood pressure	Hypotension (phenothiazines, beta-blockers, nifedipine, nitroprusside and other vasodilators)
	Hypertension (corticosteroids, cocaine, phenylpropanolamines, anticholinergics)
Heart	Pulse, electrocardiogram (ECG) elevation of QT-time (tricyclic antidepressants, orphenadrine, calcium blockers, class III antiarrhythmics, fluoroquinolones, macrolide antibiotics, antipsychotics, antimycotics, lithium and many drug–drug interactions)
	Irregularities, torsades de pointes (phenothiazines, procainamide, amiodarone, lidocaine), heart block (calcium blockers, beta-blockers, digoxin, cocaine, tricyclic antidepressants)
Temperature	Hyperthermia (LSD, cocaine, methylenedioxymetamfetamine (MDMA), selective serotonin reuptake inhibitors (SSRIs), dinitro-*o*-cresol (DNOC))
	Hypothermia (alcohol, benzodiazepines)
Respiration	Depressed (opiates, barbiturates, benzodiazepines)
	Hypoventilation (salicylates)
Muscles	Spasm and cramp (strychnine, crimidine, botulism)
Skin	Dry (parasympatholytics, tricyclic antidepressants)
	Perspiration (parasympathomimetics, cocaine)
	Gooseflesh (strychnine, LSD, opiate withdrawal)
	Needle marks (parenteral injections: drugs of abuse, insulin),
	Colour (red, carboxyhaemoglobin; blue, cyanosis, e.g. with ergotamine; yellow, DNOC)
	Blisters (paraquat, barbiturates)
Eyes	Pinpoint (opiates, cholinesterase inhibitors, quetiapine)
	Dilated pupils (atropine, amfetamines, cocaine)
	Reddish (cannabis)
	Reflex, movements, lacrimation, nystagmus (phenytoin, alcohol)
Nose	Nasal septum complications (cocaine)
Chest	Radiography (bronchoconstriction, metals, aspiration)
Abdomen	Diarrhoea (laxatives, organophosphates)
	Obstruction (opiates, sympatholytics such as atropine)
	Radiography (lead, thallium, condoms packed with illicit drugs)
Smell	Sweat, mouth, clothes, vomit (see Table 1.3)

Quality management

It is essential that the whole laboratory process be controlled strictly and subjected to regular internal and external assessments. All administrative and analytical activities should be described in detailed standard operating procedures (SOPs), which should be reviewed and, if necessary, updated at regular intervals. The laboratory should have in place a system of internal quality controls and also participate in external proficiency-testing schemes. Particular attention should be given to the storage of raw analytical data, results and residual samples, and no unauthorised person should have access to patient information.

Table 1.3 Odours associated with poisoned patients

Odour	*Potential agents or situation*
Acetone/nail polish remover	Acetone, propan-2-ol, metabolic acidosis
(Aeroplane) Glue	Toluene, aromatic hydrocarbon sniffing
Alcohol	Ethanol (not with vodka), cleaners
Ammonia	Ammonia, uraemia
Bitter almonds, silver polish	Cyanide
Bleach, chlorine	Hypochlorite, chlorine
Disinfectant	Creosote, phenol, tar
Formaldehyde	Formaldehyde, methanol
Foul	Bromides, lithium
Hemp, burnt rope	Cannabis
Garlic	Arsenic, dimethyl sulfoxide (DMSO), malathion, parathion, yellow phosphorus, selenium, zinc phosphide
Mothballs	Camphor, naphthalene, *p*-dichlorobenzene
Smoke	Nicotine, carbon monoxide
Organic solvents	Diethyl ether, chloroform, dichloromethane
Peanuts	Rodenticide
Pears	Chloral hydrate, paraldehyde
Plants with special odours	For example *Taxus*, *Convallaria*
Rotten eggs	Disulfiram, hydrogen sulfide, hepatic failure, mercaptans (additive to natural gas), acetylcysteine
Shoe polish	Nitrobenzene
Turpentine	Turpentine, wax, solvent of parathion, polish

Table 1.4 Typical colours of the skin with poisoning

Colour of skin	*Poison or situation*
Blue, cyanosis	Hypoxia, methaemoglobinaemia, sulfhaemoglobin
Blue, pigment	Dye (amitriptyline or chloral hydrate tablets), paint
Yellow (jaundice)	Liver damage (alcohol, borate, nitrites, scombroid fish, rifampicin, mushrooms, metals, paracetamol, phosphorus, solvents)
Yellow	DNOC
Reddish	Carbon monoxide
Black, necrosis	Sodium or potassium hydroxide, sulfuric acid, burning, intra-arterial injection

Table 1.5 Urine colours associated with various poisons

Colour of urine	*Poison or drug*
Red/pink	Ampicillin, aniline, blackberries, desferrioxamine, ibuprofen, lead, mercury, phenytoin, quinine, rifampicin
Orange	Warfarin, rifampicin, paprika
Brown/rust	Chloroquine, nitrofurantoin

Table 1.6 Biochemical and haematological abnormalities in poisoning

Abnormality	*Indication*
Acid–base disturbances	
Metabolic acidosis	Ethylene glycol, salicylate, methanol, cyanide, iron, amfetamines, MDMA
Metabolic alkalosis	Chronic use of diuretics or laxatives
Respiratory acidosis	Opiates
Respiratory alkalosis	Salicylates, amfetamines, theophylline
Increased anion gap	Ethylene glycol
Increased osmolar gap	Alcohols, glycols, valproate
Electrolyte disturbances	
Hypocalcaemia	Ethylene glycol, oxalates, phosphates, diuretics, laxatives
Hyperkalaemia	Digoxin, potassium salts
Hypokalaemia	Theophyllline, insulin, oral antidiabetic drugs, diuretics, chloroquine
Hypernatraemia	Sodium chloride, sodium bicarbonate
Hyponatraemia	MDMA, diuretics
Glucose	
Hypoglycaemia	Insulin, oral antidiabetic drugs, ethanol (children), paracetamol (with liver failure)
Liver enzymes	
Raised transaminases	Paracetamol, amfetamines, MDMA, iron, *Amanita phalloides*, strychnine
Haematological	
Anaemia, raised zinc protoporphyrin, basophilic stippling	Lead
Carboxyhaemoglobin	Carbon monoxide
Methaemoglobinaemia	Chlorates, nitrites
Raised prothrombin time	Paracetamol, coumarin anticoagulants

Where possible, the laboratory should seek accreditation by an external authority (see Chapter 22).

Request forms

A specially designed request form for toxicological analyses is a useful way not only to obtain essential demographic information on the patients and the analyses required but also to gather details of symptoms, drugs prescribed, biochemical abnormalities and previous medical history. This supplements the oral information provided by the clinician. On completion of the analyses, a copy of the form with the results and interpretation entered can be returned to the clinician. An example of a request form is shown in Fig. 1.1.

Collection and choice of samples

Blood, serum or plasma

Blood is usually easy to obtain and the analytical results can be related to the patient's condition and also be used in pharmacokinetic or toxicokinetic calculations. A 10 mL sample of anticoagulated blood (sodium edetate) and 10 mL of clotted blood should be collected from adults on admission (proportionately smaller volumes from young children). Most quantitative assays are carried out on the plasma, but anticoagulated whole blood is essential if the poison is associated mainly with the red cells (e.g. carbon monoxide, cyanide, lead, mercury). Serum from coagulated blood can also be used, although the levels are almost always the same as those in plasma. Serum has the advantage that there is no potential interference from any additive. The disadvantage is that clotting takes time and occurs only at room temperature, which creates problems with the analysis of unstable analytes that require samples to be cooled immediately by immersion in ice. It is advisable in addition to collect a 2 mL blood sample into a fluoride/oxalate tube if ethanol ingestion is suspected. However, since most of the fluoride tubes used in hospitals do not contain enough sodium fluoride to completely inhibit microbial production of alcohol (the minimum fluoride concentration required in blood is 1.5% w/v), these samples are not acceptable for forensic purposes. There are conflicting reports of the dangers of contamination of samples collected after the use of disinfectant swabs containing ethanol or 2-propanol and then analysed for ethanol content. Volunteer studies (Malingre *et al.* 2005) have suggested that this is not a

Table 1.7 Emergency toxicological assays

Assay(s)	*Intervention*	*Comments*
Anticholinesterase inhibitors[a]	Atropine (since 2008 the use of pralidoxime or obidoxime is contraindicated)	Measure serum (or preferably red cell) cholinesterase activity
Antiepileptics (carbamazepine, phenytoin)	Multiple-dose activated charcoal	—
Benzodiazepines	Flumazenil antidote only in severe cases	Consider presence of active metabolites; withdrawal seizures
Beta-blockers	Glucagon, isoprenaline	—
Calcium antagonists	Calcium salt infusions, Intralipid	Verapamil: severe prognosis
		Nifedipine: acidosis
Carboxyhaemoglobin[a]	Hyperbaric oxygen	No value after administration of oxygen
Chloroquine	High doses of diazepam	Monitor serum K^+
Cocaine	Diazepam, haloperidol	—
Digoxin[a]	Potassium salts, Fab antidote	Monitor serum K^+, measure serum digoxin prior to giving Fab fragments
Ecstasy group (methylenedioxyamfetamine (MDA), MDMA)	Single-dose activated charcoal, diazepam, dantrolene	Check for metabolic acidosis and hyponatraemia, hyperthermia
Ethanol[a]	Haemodialysis, vitamin B	Monitor blood glucose in children
Iron[a]	Desferrioxamine, IV + PO	Measure unbound iron; colorimetric assays for serum iron unreliable in presence of desferrioxamine
Isoniazid	Pyridoxine	—
Lithium[a]	Haemodialysis, vitamin B	Measure serum level 6 h after ingestion
Methaemoglobin[a]	Methylene blue	Methaemoglobinaemia caused by nitrites, chlorates, dapsone, aniline
Methanol, ethylene glycol plus other alcohols	Methylpyrazole or ethanol and haemodialysis	Monitor serum ethanol levels to ensure optimum antidote administration
Methotrexate	Folinate, venous–venous haemofiltration	Measure plasma methotrexate level 4–6 h after ingestion
Opiates	Naloxone	—
Osmolality	—	Increased by alcohol, glycols, severe valproate overdose
Paracetamol[a]	*N*-Acetylcysteine, methionine	Measure serum level at least 4 h after ingestion; prothrombin time and international normalised ratio (INR) are useful prognostic indicators
Paraquat (qualitative urine test)[a]	Activated charcoal	Urine test diagnostic; plasma levels useful in predicting outcome
Salicylate[a]	HCO_3^- infusion, haemodialysis	Repeat serum salicylate assays may be needed because of continued absorption of the drug
Strychnine	Diazepam	—
Thallium	Prussian (Berlin) blue orally	Treatment continued until urine thallium levels <0.5 mg/24 h
Theophylline[a]	Multiple-dose activated charcoal	Measure serum theophylline in asymptomatic patients 4 h after ingestion
Tricyclic antidepressants	Multiple-dose activated charcoal, Intralipid, HCO_3^-	QT time

[a]To be provided by all acute hospital laboratories.

significant problem, whereas Higuchi *et al.* (2005) reported a definite risk during collection from hospital patients, particularly when the swab was used to wipe the syringe needle after sampling. On balance it is advisable to avoid the use of these swabs in the hospital setting where careless sampling techniques are most likely to occur. The vigorous discharge of blood through a syringe needle can cause haemolysis and invalidate a serum iron or potassium assay.

Urine

Urine usually contains higher concentrations of drugs, poisons and their metabolites than blood and is therefore ideal for qualitative screening. Most drugs remain detectable for much longer periods in urine than in blood. For example, GHB will have almost entirely disappeared from blood by the time a patient reaches hospital but can often still be found in a urine sample. Some substances are detectable only as a metabolite in urine (e.g. oxaxepam as oxazepam glucuronide; nicotine as cotinine). However, the detection of a substance in urine does not necessarily mean that this is the cause of the poisoning since it may have been taken days before the event and may not be related to the acute situation. In emergency cases, particularly when the patient is unconscious, the delay in obtaining a urine sample may be unacceptable and many clinicians are now reluctant to use catheterisation routinely on unconscious patients. Where a sample can be obtained, a volume of <25 mL is sufficient for most purposes.

Stomach contents

This sample includes vomit, gastric aspirate or stomach washout. Stomach washout is no longer a routine treatment procedure, but when it is carried out it is important to obtain the first sample of washout rather than a later sample, which will be diluted considerably. If the sample is obtained soon after the overdose, it may be possible to recognise the presence of undegraded tablets and capsules, or the characteristic odour of certain compounds. Stomach contents can be substituted for urine in toxicological screening, and are useful for identifying poisons derived from plants and fungi, and for other poisons that are difficult to detect in blood or urine. However, as with urine, quantitative

Figure 1.1 Request form for toxicological analysis.

analyses serve no purpose, for example, in reflecting the amount of poison absorbed.

Saliva, sweat and/or oral fluids

There is growing interest in the use of saliva (see Chapter 18) or sweat (Barnes *et al.* 2008) as an alternative non-invasive test sample (see Chapter 18) and in its potential uses in hospital toxicology. Other human matrices (e.g. oral fluid, sweat) as well as other matrices including dried whole blood spot (for transportation), hair (patient non-compliance), plasters (drugs of abuse), liquor (antibiotics, MTX), pus (antibiotics) and tissue are sent to TDM and toxicology laboratories.

Toxicological screening

Toxicological screening schemes can be divided into limited, specific or extensive ('general unknown') screening. The choice of scheme is clearly strongly dependent on the range of technical equipment available, the expertise of the laboratory staff and the information provided about the patient. All analytical techniques have their own advantages and disadvantages and in this chapter several different methods and approaches are described.

Fast limited screening

Immunoassays

Commercially available immunoassays (IAs), such as fluorescence polarisation immunoassay (FPIA), enzyme multiplied immunoassay technique (EMIT), radioimmunoassay (RIA) and enzyme-linked immunosorbent assay (ELISA; see Chapter 31), give quick qualitative results and, in some cases, a semi-quantitative result in plasma for a variety of substances or groups of compounds. Their limitations in terms of specificity and sensitivity must always be considered when interpreting results. Hospital laboratories that provide therapeutic drug monitoring (see Chapter 2) and screening services for drugs of abuse are ideally placed to invoke these assays as part of a toxicological investigation. However, in recent years, larger hospital laboratories have tended to move to LC-MS(-MS) for therapeutic drug monitoring, especially for immunosuppressant drugs (e.g. ciclosporin, everolimus, sirolimus, mycophenolate) on the grounds of better specificity, more flexibility and lower costs.

Alcohol dehydrogenase test for ethanol

This quantitative test is based on the oxidation of ethanol to acetaldehyde by alcohol dehydrogenase (ADH) in the presence of nicotinamide adenine dinucleotide (NAD) and is applicable to serum and plasma. Several commercial ADH kits are available and the test can be performed on routine clinical chemistry analysers. Propan-2-ol and other higher alcohols can also reduce NAD to give positive readings. Methanol and acetone do not react and therefore a gas chromatographic method for alcohols is much preferred. Ethylglucuronide, as a marker for strong or recent ethanol use, is easily measured by LC-MS(-MS) in urine or plasma.

Direct (colour tests) in serum or urine samples

Blood glucose Hypoglycaemia is a feature of overdose with insulin, hypoglycaemic agents and ethanol. It can also occur in the early stages of liver damage after severe poisoning with paracetamol.

Ketones in urine Dip a 'Labstix' strip briefly into the urine and read after 10–15 s. A positive result for ketones may indicate intoxication by acetone or isopropyl alcohol. This test may also be positive in starvation or in diabetic ketosis.

Carbon monoxide in whole blood Dilute a sample of the blood 1 in 20 with 0.01 mol/L ammonia and compare the colour with a sample of normal blood treated similarly. A pinkish tint suggests the presence of carboxyhaemoglobin (COHb). Modern clinical gas analysers automatically measure the COHb and therefore this colour test is rarely required.

Salicylates Trinder's reagent is used (40 mg of mercuric chloride in 850 mL of water; add 120 mL of 1 mol/L hydrochloric acid and 40 g of hydrated ferric nitrate and dilute to 1000 mL with water).

Trinder's test in serum Add 4.5 mL of Trinder's reagent to 0.5 mL of serum, shake well and centrifuge. A violet colour in the supernatant liquid indicates the presence of salicylate or salicylamide.

Trinder's test in urine Add 5 drops of Trinder's reagent to 1 mL of urine (pH 5–6). A violet colour indicates the presence of salicylate or salicylamide. A positive result is obtained after therapeutic doses of acetylsalicylic acid (aspirin) or aminosalicylic acid. The red colour is formed with a phenolic OH group.

Volatile reducing substances (including alcohols and aldehydes): dichromate test in serum or urine

- Add 1 mL of urine or serum to a test-tube.
- Apply one drop of 2.5% (w/v) potassium dichromate in 50% (v/v) sulfuric acid to a strip of glass-fibre filter paper.
- Insert this paper in the neck of the test-tube.
- Lightly cork the tube, and place it in a boiling water-bath for 2 min.

A colour change to green indicates a positive result. Ethanol gives a positive reaction if present above 400 mg/L, in which case the blood-ethanol concentration should be measured.

Confirmation of methanol

- Add one drop of 2.5% (w/v) potassium dichromate in 50% (v/v) sulfuric acid to 1 mL of urine and allow to stand at room temperature for 5 min.
- Add one drop of ethanol and a few milligrams of chromotropic acid.
- Gently add about 0.5 mL of concentrated sulfuric acid down the side of the tube so that it forms a layer in the bottom.

A violet colour at the interface indicates methanol. Note that the metabolite formaldehyde also gives a positive reaction in this test.

Organophosphorus compounds: cholinesterase inhibitors in serum

- To each of three tubes add 2 mL of 0.02% (w/v) dithiobisnitrobenzoic acid in 0.1 mol/L sodium dihydrogenphosphate buffer, pH 7.4 solution and 1.0 mL of 0.5% (w/v) aqueous acetylthiocholine iodide solution.
- To the first tube add 20 µL of control plasma and stand next to the second 20 µL of sample plasma.
- To the third tube add 20 µL of 20% (w/v) aqueous pralidoxime or obidoxime chloride solution (which reverses the inhibitor activity) and 20 µL of test plasma.
- Vortex the contents of all three tubes and allow them to stand at room temperature for 2 min.

If a cholinesterase inhibitor is present, the yellow colour in the control tube will be deeper than that in the sample tube. Further confirmation is provided if the depth of colour in the pralidoxime tube is similar to that in the control tube.

Trichloro-compounds: Fujiwara test in serum or urine

- To 1 mL of urine add 1 mL of 20% (w/v) sodium hydroxide solution and 1 mL of pyridine.
- Heat in a boiling water-bath for 2 min.
- A blank urine sample and an authentic solution of trichloroacetic acid should be tested at the same time, both blank and control solutions being treated in a similar fashion to the sample.

The development of a red colour in the pyridine layer indicates ingestion of a trichloro-compound.

Metabolites of carbon tetrachloride may also give a positive result with this test, but carbon tetrachloride is metabolised only partially to trichloromethyl compounds and the test may fail to detect this agent. If carbon tetrachloride poisoning is suspected, evidence of hepatotoxicity should be sought by carrying out the appropriate serum-enzyme assays.

Paraquat and diquat – dithionite test in urine

- To 1 mL of urine add 1 mL of a freshly prepared 0.1% (w/v) solution of sodium dithionite in 1 mol/L sodium hydroxide.

A blue colour indicates the presence of paraquat.

A green colour is given by diquat, but paraquat may also be present.

A strong blue colour obtained with a urine sample taken more than 4 h after ingestion suggests a poor prognosis.

Confirmation of the severity of the poisoning is obtained by measuring the paraquat concentration in plasma.

Paracetamol: cresol–ammonia test in urine

- To 0.5 mL of urine add 0.5 mL of 36% (v/v) hydrochloric acid.
- Heat the mixture for 10 min at 100°C.
- Mix two drops of the mixture with 10 mL of water and add 1 mL of 1% (w/v) *o*-cresol in water, and 4 mL of 2 mol/L ammonium hydroxide.

A blue colour appears if paracetamol is present. The test is very sensitive and can detect therapeutic concentrations. The presence of the parent drug and its conjugated metabolites can be detected for several days after

overdose. If a positive result is obtained, a plasma-paracetamol determination should be carried out immediately.

Cyanide in blood

Dräger test-tube method

- Dispense 5 mL of heparinised blood into a special 25 mL test-tube (about 10 cm long) fitted with a rubber stopper with two holes.
- Insert into one hole a newly opened Dräger test-tube for cyanide.
- Add 5 mL of 10% (v/v) sulfuric acid and close the tube immediately.
- Close the open hole with a finger while sucking the cyanide air from the mixture through the Dräger test-tube with a Dräger pump for 3 min.

An orange–red colour indicates a positive reaction. This can be made semi-quantitative by treating a standard solution of potassium cyanide (0.625 mg/L is equivalent to 0.5 mg/L CN) in the same way (toxic concentrations >0.5 mg/L).

Use of the Cyantesmo kit for rapid detection of cyanide in blood has been described by Rella *et al.* (2005).

Thallium in urine

- Dissolve 1.6 g of sodium hydroxide, 1.2 g of potassium sodium tartrate and 1.36 g of potassium cyanide in 10 mL of water.
- Freshly prepare a 250 mg/L solution of dithizone in chloroform (reagent should be green).
- Add 1 mL of the cyanide reagent to 5 mL of urine in a glass-stoppered test-tube and vortex for 10 s.
- Add 2 mL of the dithizone solution, vortex for 1 min and centrifuge (5 min).

Thallium produces a pink–red layer in the chloroform. A blank urine sample and a standard solution of thallium (1 mg/L) should be treated in the same way for comparison.

Toxicological screening by thin-layer chromatography

Thin-layer chromatography (TLC) is still sometimes applied to urine samples. Unfortunately, TLC methods for newer drugs are rarely developed anymore.

Many TLC systems have been developed for use in hospital toxicology. These include the commercial Toxilab system, which provides standards for the substances and metabolites most commonly encountered in intoxicated patients. The most generally used mobile phase is chloroform–methanol (9 : 1 v/v), although some countries now require the less toxic dichloromethane instead of chloroform. In hospital toxicology it is advisable to use at least two separate mobile phase systems to obtain a more definitive result. Silica-gel plates of 20 × 20 cm with or without fluorescent indicator are the most popular, although smaller sizes can also be used.

Solvent extraction procedure for acidic, neutral and basic drugs

- Pipette 10 mL of the sample (urine or stomach contents) in each of two 20 mL screw-capped glass bottles or stoppered test-tubes.
- To one bottle (A) add 1 to 2 mL of 1 mol/L sulfuric acid.
- To the other bottle (B) add of 1 to 2 mL of 1 mol/L sodium hydroxide solution (check the pH with an indicator paper).
- Add 10 mL of dichloromethane to each bottle or tube. Shake gently for about 5 min, and centrifuge for 5–10 min.
- Remove the top aqueous layer using a Pasteur pipette connected to a water-operated vacuum pump.

Back-extraction procedure for stomach contents extracts

- Add 3 mL of 0.5 mol/L sodium hydroxide solution to the acid dichloromethane extract (A), and 3 mL of 0.25 mol/L sulfuric acid to the alkaline dichloromethane extract (B).
- Shake the bottles again, centrifuge and discard the organic solvent layers.
- Make bottle A acidic by the addition of 0.5 mL of 3 mol/L sulfuric acid, and make bottle B alkaline by the addition of 0.5 mL of 6 mol/L sodium hydroxide solution.
- Add 10 mL of dichloromethane to each bottle, shake, centrifuge and remove the aqueous layers as above.

Drying and concentration

- Remove residual moisture from the two extracts (from either urine or stomach contents) by filtering through phase-separating paper, and collect the filtrates in 10 mL conical test-tubes.
- Add a little tartaric acid to the basic extract to prevent the loss of volatile bases, and evaporate to dryness under a stream of air or nitrogen.
- Dissolve each residue in 0.1 mL of methanol.

Chromatography of acidic and neutral drugs

Location reagents

- Mercuric chloride–diphenylcarbazone: (a) dissolve 0.1 g of diphenylcarbazone in 50 mL of ethanol; (b) dissolve 1 g of mercuric chloride in 50 mL of ethanol; prepare both solutions daily. Mix solutions (a) and (b) just before spraying.
- Mercurous nitrate: a saturated aqueous solution of mercurous nitrate.
- Dragendorff: (a) mix 2 g of bismuth subnitrate, 25 mL of acetic acid and 100 mL of water; (b) dissolve 40 g of potassium iodide in 100 mL of water. Mix together 10 mL of (a), 10 mL of (b), 20 mL of acetic acid and 100 mL of water. Prepare the mixture every 2 days.
- Furfuraldehyde: (a) dilute 2 mL of redistilled furfuraldehyde to 100 mL with acetone; (b) dilute 4 mL of sulfuric acid to 100 mL with acetone; prepare immediately before use. Spray with (a) first, followed by (b).

Reference solutions Prepare solutions (1 mg/mL) in methanol of authentic samples of drugs, as indicated in Table 1.8.

Method

- Divide a TLC plate (silica-gel G, 250 μm) into eight equal columns by scoring lines with a spatula.
- Apply 10 μL aliquots of the reference solutions and 25 μL aliquots of the sample extract to the columns on the plate in the sequence shown in Table 1.8.
- Evaporation of the spots can be hastened by the use of a cold-air blower.
- Develop the plate for a distance of about 10 cm from the origin in a tank that contains 100 mL of a 4 : 1 mixture of chloroform–acetone (system TD). Alternatively, system TE or system TF may be used (Table 1.9).
- After development, remove the plate from the tank and dry under a stream of cold air.

Visualisation

- Examine the plate under ultraviolet (UV) light.
- Cover columns 3 to 8 (Table 1.8) with a glass plate and spray columns 1 and 2 with mercuric chloride–diphenylcarbazone reagent. White spots on a violet background indicate the presence of barbiturates and related compounds.
- Cover columns 1 and 2 and 5 to 8 with glass plates, and spray columns 3 and 4 with mercurous nitrate spray. Black spots are given by barbiturates and related compounds.
- Cover columns 1 to 4 and 7 and 8 with glass plates, and spray columns 5 and 6 with Dragendorff spray. An orange spot is given by methaqualone.

Phenylbutazone	78	66	68	Positive	—

[a]Violet with furfuraldehyde reagent.
[b]Weak reaction with Dragendorff spray.
[c]Positive reaction with Dragendorff spray.

- Cover columns 1 to 6, and spray columns 7 and 8 with furfuraldehyde reagent. A violet spot is given by meprobamate.
- The chromatographic system distinguishes between certain types of barbiturates (Table 1.9), which is sufficient for most clinical situations. If doubt exists, or if it is crucial to know which barbiturate is present, the sample should be examined by HPLC or GC. Certain antibiotics give white spots with mercurous nitrate spray, but do not react with mercuric chloride–diphenylcarbazone reagent (Table 1.9).

Chromatography of basic drugs

Solvent extraction from urine

- Mix together 5 mL of urine, 0.5 mL of 4 mol/L sodium hydroxide solution and 2.5 mL of dichloromethane.
- Centrifuge and remove the aqueous phase.
- Pass through a filter paper containing 1 g of anhydrous sodium sulfate and evaporate the filtrate to dryness.
- Dissolve the residue in 50 µL of dichloromethane or methanol.

Location reagents/spray reagents

- Acidified iodoplatinate: dissolve 0.25 g of platinic chloride and 5 g of potassium iodide in sufficient water to produce 100 mL and add 5 mL of concentrated hydrochloric acid.
- Mandelin's reagent: dissolve 0.5 g of ammonium vanadate in 1.5 mL of water and dilute to 100 mL with concentrated sulfuric acid. Filter the solution through glass wool.
- Sulfuric acid (9 mol/L).

Reference solutions Prepare solutions in methanol (1 mg/mL) of authentic samples of drugs as listed in Table 1.10.

Method

- Divide a TLC plate (silica-gel G, 250 µm) into eight equal columns by scoring lines with a spatula.
- Apply 10 µL aliquots of the authentic solutions and 25 µL aliquots of the sample extract to the columns on the plate in the sequence shown in Table 1.10.
- Evaporation of the spots can be hastened by the use of a cold-air blower.
- Develop the plate for a distance of about 10 cm from the origin in a tank that contains a 100 : 1.5 mixture of methanol–strong acetic acid (system TA). After development, remove the plate from the tank and dry under a stream of cold air until the plate no longer smells of ammonia. (Avoid using hot air to dry the plate, as this may volatilise certain drugs.)
- Alternatively, system TB or system TC may be used.

Visualisation

- Examine the plate under UV light ($\lambda = 254$ and 350 nm).
- Cover columns 3 to 8 with a glass plate and spray columns 1 and 2 with acidified iodoplatinate solution. Most basic drugs give violet or blue colours.
- Cover columns 1 and 2 and 5 to 8 with glass plates, and spray columns 3 and 4 lightly with Mandelin's reagent. Various colours are given by many basic drugs (see Chapter 30).
- Cover columns 1 to 4 and 7 and 8, and spray columns 5 and 6 lightly with 9 mol/L sulfuric acid. Most phenothiazines are extensively metabolised, and urine extracts yield a number of spots on the chromatogram with colours ranging from pink to blue.
- If a pure solution of a suspected drug has been applied to column 7, spray this and column 8 with a reagent with which it is known to react. Alternatively, if the R_f values and spray reagent reactions derived from columns 1 to 6 suggest the presence of a drug for which a further detection reagent exists, use this reagent on column 8 to obtain additional evidence.

Details of R_f values and spot colours are given in Table 1.11. Acidified iodoplatinate solution reacts with many basic drugs to give violet or blue

Dihydrocodeine	26	08	13	Blue	White	—	One at R_f 16; drug and metabolite have elongated spots
Codeine	33	06	18	Blue	—	—	
Nortriptyline	34	27	16	Violet	Violet	Yellow (violet centre)	
Morphine	37	00	09	Blue	—	—	
Promazine	44	41	30	Green	—	—	Many, which give pink or blue spots with 9 mol/L sulfuric acid
Chlorphenamine	45	33	18	Violet	—	—	One, below the parent drug
Imipramine	48	49	23	Violet	Blue	Quenches	Desipramine; a second metabolite sometimes occurs between imipramine and desipramine
Methadone	48	61	20	Pink (grey rim)	—	—	Methadone degradation product at R_f 15
Procyclidine	48	63	31	Violet	—	—	
Thioridazine	48	43	30	Brown (blue rim)	Blue (violet rim)	Quenches	Pair of blue spots, with pink spots above and below with Mandelin's reagent
Chlorpromazine	49	49	35	Violet (blue rim)	Pink	Yellow (weak)	Many, which give pink or blue spots with 9 mol/L sulfuric acid
Promethazine	50	37	35	Violet (blue rim)	Pink	—	One, below the parent drug
Quinine	50	02	11	Violet	—	Blue (strong)	One immediately below and one immediately above the parent drug; both strongly fluoresce
Amitriptyline	51	55	32	Violet	Violet	Yellow (violet centre)	Nortriptyline; a second metabolite sometimes occurs between amitriptyline and nortriptyline
Clomipramine	51	54	34	Violet	Blue	Quenches	One or two, both below the parent drug
Dosulepin	51	50	42	Red (blue rim)	White	Blue (weak)	One or two, both below the parent drug
Doxepin	51	52	37	Violet	Grey	Blue (orange rim)	One or two, both below the parent drug
Pethidine	52	37	34	Violet	—	—	One, below the parent drug
Dibenzepin	54	20	35	Violet	Blue	Quenches	Two, both just below the parent drug
Nicotine	54	39	35	Brown	—	—	Metabolites coalesce to give spot at R_f 60
Opipramol	54	06	22	Blue	Yellow	Green	
Diphenhydramine	55	45	33	Violet	—	—	One or two, both just below the parent drug
Orphenadrine	55	48	33	Violet	Yellow	Blue	One, below the parent drug and with the same reactions to Mandelin's reagent
Chlorprothixene	56	51	51	Violet	Pink	Orange	
Cyclizine	57	49	41	Violet (blue rim)	—	—	One, below the parent drug
Mianserin	58	39	58	Blue	Violet	Quenches	Two, below the parent drug
Butriptyline	59	61	48	Pink	Grey	Green	One or two, both below the parent drug
Trimipramine	59	62	54	Violet	Blue	Quenches	One or two, both below the parent drug
Carbamazepine	60	04	56	—	Yellow (blue rim)	Green (strong)	
Pentazocine	61	15	12	Violet	Grey	White	
Dextropropoxyphene	68	59	55	Violet	Grey	—	Several; one at R_f 40 which gives a blue streak with acidified iodoplatinate solution; the parent drug is rarely seen in urine extracts
Lidocaine	70	35	73	Blue	—	—	Metabolites of lidocaine are not extractable from urine
Buclizine	75	61	83	Red	—	—	

colours. False-positive reactions can occur with endogenous urine components; urine extracts from heavy smokers contain nicotine, the metabolites of which coalesce to give a brown spot. Mandelin's reagent reacts with fewer compounds, but gives more distinct colours and some spots exhibit characteristic fluorescence under UV light. The presence of drug metabolites in urine extracts can result in a characteristic pattern of spots on the chromatogram.

Mobile phase A mixture of ethyl acetate–cyclohexane–methanol–25% (v/v) aqueous ammonia (70 : 15 : 10 : 5) (for basic neuroleptic drugs).

Chromatography

- Apply two 5 µL portions of the extract to a plastic silica-gel plate F 254 nm (10 cm × 20 cm) and the same amount of a standard mixture of drugs.
- Allow the solvent front to travel 8 cm, remove from the tank and dry with a hot-air blower.
- Remove any residual traces of ammonia by heating the plate at 100°C for 2–5 min.

Visualisation procedure

- Examine the plate under UV light (254 nm; see Table 1.12).
- Cut the plate into two sections and spray one half with acidified iodoplatinate reagent and the other with Mandelin's reagent and examine the plates in daylight (Table 1.12).
- Heat the Mandelin-sprayed section at 100°C for 5 min and re-examine (Table 1.12).

If after TLC, the same extract is used for GC analysis, an acid hydrolysis step (10 mL urine refluxed with 3 mL 36% hydrochloric acid for 15 min; neutralised) has to be carried out before extraction.

Gas–liquid chromatography screening for alcohols and other volatile substances

In normal practice it is advisable to measure the more volatile alcohols (methanol, ethanol, acetone and isopropyl alcohol) separately from the higher alcohols, trichloroethanol and the metabolites of GHB, but for screening it is possible to detect all at two different temperature steps.

Standard solutions in water

- Ethanol: 0.5, 1.0, 2.0, 3.0 and 5.0 g/L.
- Acetaldehyde, acetone, methanol and isopropyl alcohol: 0.1, 0.3, 0.5, 1.0 and 2.0 g/L.
- Ethylene glycol, propylene glycol and trichloroethanol: 0.05, 0.1, 0.2, 0.5 and 1.0 g/L.

Internal standard solution in water

- 0.3 g/L propan-1-ol or 0.1 g/L propylene glycol.

Apparatus

- Gas chromatograph with flame ionisation detector (FID) on 275°C.
- Column DBWAX (60 m × 0.53 mm i.d., 1.0 µm; Megabore J&W Scientific, 125-7062; Fisons).
- Injector temperature 250°C, split mode; He, 4.3 mL/min. He 3.0 mL/min; headspace injector at 60°C.
- Temperature programme: 100°C for 5 min to 175°C for 15 min.

Table 1.12 Thin-layer chromatography of some neuroleptic drugs

Drug	*hR_f*		*Acidified iodoplatinate*		*Mandelin's spray*	
	8 min	*254 nm*	*Daylight*	*Daylight*	*5 min, 100°C, daylight*	*5 min, 100°C, 350 nm*
Alimemazine	79	Positive	Positive	Red	Red	Red–purple
Amitriptyline	69	Purple	Brown	Grey	Blue–grey	Yellow–red
Chlorprothixene	73	Purple	Brown	—	—	—
Citalopram	55	Deep blue	Brown	—	White	Pink fluorescence
Clomipramine	70	Deep blue	Brown	Blue	Blue	Green
Clozapine	55	Deep blue	Brown	Red–brown	Grey	Rose
Desipramine	37	Purple	Brown	Blue	Brown–blue	Yellow
Nordoxepin	39	Purple	Brown	—	—	—
Doxepin	64	Purple	Brown	Yellow–grey	Brown	Brown–red
Fluphenazine	50	Purple	Brown	Orange	Red	Red–purple
Fluoxetine	42	Deep blue	Yellow–brown	White	White	Yellow
Fluvoxamine	44	Deep blue	Yellow–brown	—	White	Purple
Imipramine	65	Purple	Brown	Blue	Brown–blue	Yellow
Levomepromazine	73	Purple	Brown	Purple–brown	Blue	Red–purple
Maprotiline	35	Positive	Brown	Not visible (grey)	Beige–brown	Red–brown
Nefazadon	63	Deep blue	Yellow	Pink–red	Grey–pink	Pink
Norfluoxetine	40	Deep blue	Red–brown	White	White	Yellow
Nortriptyline	42	Purple	Brown	Grey	Brown–blue	Yellow fluorescence
Olanzapine	53	Deep blue	Brown	Grey	Grey	Blue
Paroxetine	35	Deep blue	Brown	Blue	Green	Blue
Perazine	46	Purple	Blue	Orange–grey	Red	Red–purple
Pericyazine	45	Blue	Brown	Brown	Brown	Positive
Perphenazine	36	Purple	Blue	Pink	Red	Red–purple
Promazine	60	Purple	Blue	Orange	Red	Red–purple
Protriptyline	35	Blue	Brown	Positive	Positive	Blue
Thioridazine	65	Purple	Brown	Blue	Blue	Positive
Trifluoperazine	52	Purple	Brown	Brown	Brown	Positive
Trimipramine	78	Purple	Brown	Blue	Blue	Yellow fluorescence
Venlafaxine	69	Deep blue	Yellow	Grey–pink	Grey–pink	Pink

Assay
- Pipette 0.1 mL of whole blood (serum or urine), or aqueous standard into a tube of about 1.5 mL with a stopper.
- Add 0.5 mL of internal standard solution.
- Close the tube and vortex.
- Inject 0.2 μL onto the gas chromatograph.
- Calculate the retention times and prepare a calibration curve of concentration versus peak height ratios of the standards and the internal standard.

The elution order of the compounds is: acetaldehyde (about 3.3 min), acetone, methanol, propan-2-ol, ethanol (about 4.1 min), propan-1-ol (internal standard, about 5.0 min), trichloroethanol, propylene glycol and ethylene glycol. Acetonitrile may have the same retention time as ethanol.

Gas chromatographic screening for drugs

Gas–liquid chromatography (GLC) with capillary columns and a nitrogen–phosphorus detector (NPD), or with an electron capture detector (ECD) in series, is a powerful screening system that is sensitive enough to detect many of the compounds of interest in small samples of serum, plasma or whole blood, as well as in urine specimens.

Much greater selectivity and specificity are obtained by coupling the gas chromatograph to a mass spectrometer (see Chapter 37).

Solvent extraction of serum, plasma or whole blood for basic drugs
- To 1 mL of plasma add 0.1 mL of the internal standard (3.0 mg promazine hydrochloride per litre of water), 0.2 mL of 1 mol/L sodium hydroxide and 10 mL of a mixture of hexane–isoamyl alcohol (99 : 1 v/v).
- Vortex or shake mechanically for 5 min.
- Centrifuge at 2000*g* for 10 min.
- Place the tubes into a freezing bath at −40°C until the water phase is frozen, or remove the intermediate and water phases by suction.
- Transfer the organic layer into a clear test-tube and evaporate to dryness under a stream of nitrogen in a water-bath at about 60°C.
- Redissolve the extract in 100 μL of methanol.
- Inject 3 μL onto the GC column (splitless with a delay of 30 s at 250°C).

Chromatography
- Column: Cp-SiL 5 CB (10 m × 0.32 mm i.d., 0.12 μm) or Cp-SiL 19 CB (10 m × 0.32 mm i.d., 0.19 μm).
- Temperature programme: 130°C to 230°C at 100°/min for 30 s.
- Gas flow rates: bypass He 30 mL/min, septum purge He 5 mL/min, overall He 150 mL/min and column flow He 1 mL/min.
- Detector: NPD (300°C).

HPLC screening using the systematic toxicological identification procedure

The systematic toxicological identification procedure (STIP) system (system HZ) is based on a rapid and simple extraction method followed by isocratic reversed-phase HPLC with diode-array detection (DAD). A library of retention times and UV spectra is available for about 400 common drugs. A disadvantage of the system is that a large number of drugs elute between 1 and 3 min and this problem is exacerbated with substances devoid of a characteristic UV spectrum (e.g. maximum <210 nm). In such cases a second chromatographic analysis may be required. The technique is also less sensitive than GC screening methods.

Extraction procedure This is applied to serum or plasma to prepare extracts of both acidic and basic drugs:
- Add 1 mL acetonitrile to 1.0 mL of sample (serum or plasma) and vortex for 2 s.
- Add 6 mL of dichloromethane and vortex for a further 2 s.
- Add 100 μL of 2 mol/L hydrochloric acid or 2 mol/L of sodium hydroxide.
- Mix gently for 2 min and centrifuge.
- Remove the water and protein layer and transfer the organic layer into a new tube.
- Evaporate the organic layer to dryness at 40°C under a steam of nitrogen.
- Dissolve the residue in 100 μL of the mobile phase.
- Inject an exact volume of 40 μL onto the HPLC column (the acidic extract and the basic extract are analysed consecutively).

STIP column Lichrospher RP–18e; (125 mm × 4.0 mm i.d., 5 μm; Merck, Darmstadt, no. 21568).

Mobile phase
- Mix 530 mL of ultrapure water, 146 μL of triethylamine and about 750 μL of phosphoric acid (85%). (Note that the number of free silol groups differs with each column batch. The column supplier should therefore provide the exact volume of phosphoric acid per column for neutralising the free silol groups.)
- Add 10% (w/v) potassium hydroxide to pH 3.3.
- Add 470 mL acetonitrile (pH ± 4.0), de-gas (e.g. by sonication); flow rate 0.6 mL/min.

The retention times in the library and on the chromatogram have to be the same (window <10%), otherwise the retention times have to be corrected by changing the phosphate concentration or the flow rate of the mobile phase.

Detection The diode array spectra are matched with the reference spectra present in the database. The retention times and UV maxima of drugs eluted with the STIP mobile phase are given in the Index of High Performance Liquid Chromatographic Data in volume 2.

Screening and quantification using LC-MS(-MS)

The following LC-MS(-MS) method can qualitatively and quantitatively determine over 100 drugs and metabolites in serum or plasma with the use of one precipitation/dilution step. In comparison with the STIP procedure it provides faster analyses with lower limits of quantification, less analytical interference and more selectivity, and is sensitive enough to detect and quantify drugs with low molecular weights (100–500). Moreover, assays are generally linear over larger ranges than with HPLC-DAD methods. The method described uses the mass of the mother ion and just one transition (daughter) ion and is suitable for both clinical toxicology and therapeutic drug monitoring applications. In laboratories with a high throughput, the reduction in reagent usage, simplified and more rapid sample preparation, and shorter analysis times and subsequent lower operational costs compensate for the initial high outlay on the equipment.

As LC-MS has fewer disadvantages than HPLC-DAD and as LC-MS (-MS) is superior to all other chromatographic systems, we describe just LC-MS(-MS).

Apparatus Fisher Scientific LC Triple Quad Mass detector system consisting of a Surveyor MS pump, a Surveyor plus Autosampler and a TSQ Quantum Mass Selective Detector with instrument control and data analysis for the mass spectrometer and related instruments provided by Xcalibur software, all obtained from Thermo Fisher Scientific (Waltham, MA, USA).

Other LC-MS(-MS) systems can be used with approximately the same degree of sensitivity.

Mass detector settings
- ESI, positive ion mode
- Spray voltage 3500 V
- Sheath gas (high-purity N_2) pressure 35 arbitrary units (AU)
- Auxiliary gas (high-purity N_2) pressure 5 AU
- Collision gas (Ar) pressure 1.5 mtorr
- Capillary temperature 350°C.

Sample analyses are performed in the selected-reaction monitoring mode (SRM) with a dwell time of 0.1 s per mass unit and the scan width set at *m/z* 0.5.

Column Silica-based polar end-capped C_{18}; (50 mm × 2.1 mm i.d., 5 μm; HyPurity Aquastar, Interscience, Breda, The Netherlands).

Mobile phase Acetonitrile–water–buffer (5 g ammonium acetate, 35 mL 100% acetic acid, 2 mL trifluoroacetic acid made up to 1000 mL with water (pH 3.4–3.60)).

Table 1.13 Chromatographic gradient

Time (min)	*TFA buffer (%)*	*Water (%)*	*ACN (%)*
0.00	5.0	95	0.0
2.00	5.0	0.0	95
3.00	5.0	0.0	95
3.10	5.0	95	0.0
3.60	5.0	95	0.0

Chromatographic separation is performed by means of a gradient with a flow rate of 0.3 mL/min and an analysis time of 3.6 min (Table 1.13).

Assay

- To 100 µL of serum or edetate plasma in an HPLC vial, add 750 µL of protein precipitation reagent (acetonitrile–methanol (840 : 160)) containing a suitable internal control substance (e.g. 0.04 mg/L cyanoimipramine or a deuterated substance).
- Vortex for 1 min and store at −20°C for at least 10 min to stimulate protein precipitation.
- Vortex for a further 1 min; centrifuge at 11 000*g* for 5 min
- Using the auto-injector, inject 5 µL of the clear supernatant onto the HPLC column every 3.6 min.

Notes: (1) A mixture of methanol and water (50 : 50) is used as the wash solvent for the injector. (2) Owing to the high sensitivity of the LC-MS(-MS) system it may be necessary to reduce the volume of sample extracted to 10 µL for some substances.

Calibrators and quality control samples Stock solutions of drugs or metabolites are prepared and spiked into blank serum or edetate plasma samples to yield calibration and quality control standards at appropriate concentrations which are carried through the analytical procedure.

Ionisation suppression TFA is known to cause signal suppression during ionisation (Annesley 2003), but it provides superior peak shapes in comparison to other volatile acids. When TFA is used at low concentrations, the positive effect on the peak shape overrules the negative effect of the signal suppression. Another source of ion suppression is the matrix effect and any method developed must always be tested for this eventuality. Possible ways to resolve ion suppression are: switching to atmospheric pressure chemical ionisation (APCI), changing ionisation polarity, improving the sample preparation procedure and/or changing the chromatographic conditions (Jessome, Volmer 2006; Leverence et al. 2007).

Interpretation of chromatograms It is strongly advised that the retention times and peak shapes of the chromatograms are always visually checked by an experienced analyst. The peak height of the internal control should be approximately the same (within ±10%) during the whole analytical run to assure that no preparation errors have occurred and the LC-MS(-MS) system is working correctly.

As stated previously, the method is designed to be operated throughout the day in high-volume laboratories dealing primarily with therapeutic drug monitoring assays. Urgent clinical toxicology assays can be given priority at any time by preparing the patient sample, a calibration standard and a control standard, and the results are available to the clinician within 45 minutes.

Drugs and active metabolites analysed by the described LC-MS(-MS) method are indicated in Table 1.14.

Tests for specific compounds and groups of compounds

Alcohols, acetone, acetaldehyde and glycols

Ethanol is frequently taken at the same time as other drugs and can intensify the action of depressant drugs. A blood-ethanol determination helps to distinguish this from normal alcoholic intoxication; it is also useful in the clinical assessment of unconscious patients admitted with head injuries and smelling of drink, especially since younger and younger children are binge drinking. Children are particularly at risk from hypoglycaemia following the ingestion of alcohol. Methanol is available in a variety of commercial products (antifreeze preparations, windscreen washer additives, duplicating fluids). Acetone is sometimes consumed by alcoholics as a substitute for ethanol; children may take nail cleaner fluid; diabetics may be comatose from high endogenous acetone levels. Acetone is also a metabolite of isopropyl alcohol. It can be useful to measure acetaldehyde as a toxic metabolite of ethanol, since some patients are unable to metabolise this compound for genetic reasons or because of an interaction with disulfiram, metronidazole, tolbutamide, watercress and other substances. Acetaldehyde is also a major metabolite of paraldehyde. Ethylene glycol is a principal component of automotive antifreeze products. Poisoning by either methanol or ethylene glycol is often associated with severe metabolic acidosis and electrolyte imbalance; therapy with ethanol infusions or other antidotes must be instituted without delay.

Enzymatic assays based on ADH and breath analysers are applicable only to ethanol; a qualitative and quantitative GLC method is required for the other alcohols.

Gas chromatography of alcohols

- Column: 0.3% Carbowax 20M on 80–100 mesh Carbopak C (2 m × 2 mm i.d.) glass
- Column temperature: 120°C
- Carrier gas flow rate (N_2): 30 mL/min
- Detection: FID.

Reference solutions Prepare an aqueous solution containing 0.2 mg/mL each of ethanol, methanol, propan-2-ol and propan-1-ol and inject 1 μL onto the column. The retention times for these compounds are listed in Table 1.15.

Identification assay

- Add 50 μL of whole blood or urine to 0.5 mL of distilled water in a stoppered test-tube.
- Vortex for 10 s.
- Inject 1 μL onto the column.
- Identify any peaks that appear by reference to the standard chromatogram.

Quantification

Ethanol standard solutions Dilute 8 g of ethanol in 100 mL of distilled water to give a stock solution of 80 g/L. Dispense 100, 250, 500, 750 and 1000 μL volumes into 20 mL graduated flasks using an accurate microsyringe and fill to the mark with distilled water. This gives standard ethanol solutions containing 0.4, 1, 2, 3 and 4 g/L.

Methanol standard solutions Dilute 8 g of methanol in 100 mL of distilled water to give a stock solution of 80 g/L. Dispense 50, 150, 250, 500 and 1000 μL volumes into 20 mL graduated flasks using an accurate microsyringe and fill to the mark with distilled water. This gives standard methanol solutions of 0.2, 0.6, 1, 2 and 4 g/L.

Table 1.15 Retention times of alcohols relative to propan-1-ol

Alcohol	*Relative retention time*
Water	0.30
Methanol	0.36
Ethanol	0.50
Propan-2-ol	0.79
Propan-1-ol	1.00

Store the standards at 4°C and prepare fresh from the stock solutions at least once a week.

Internal standard Add 100 µL of propan-1-ol to 500 mL of distilled water to give a solution containing 0.16 g/L.

Assay

- Add 50 µL of sample and 50 µL aliquots of standards to 0.5 mL of internal standard solution.
- Mix for a few seconds.
- Inject 1 µL onto the column.
- Construct a calibration graph of concentration versus the peak-height ratios of the ethanol or methanol standards to the internal standard and read off the ethanol or methanol concentration in the sample.

Accuracy is improved by injecting duplicates and calculating mean peak-height ratios.

Ethylene glycol and diethylene glycol in serum by HPLC

- Apparatus: HPLC with UV detection ($\lambda = 238$ nm)
- Column: RP 8 select B column (4 mm × 150 mm i.d.)
- Mobile phase: methanol–water (72 : 28 v/v); flow rate 1.5 mL/min.

Assay

- Add 0.1 mL internal standard solution (1 mg/mL propane-1-3-diol in water) to 0.1 mL of sample and mix.
- Add 0.2 mL of 5 mol/L sodium hydroxide and 5 µL benzoyl chloride.
- Close the test-tube and mix for exactly 10 min.
- Wait for exactly 10 min.
- Add 0.4 mL pentane; vortex for 5 min and centrifuge for 3 min at 3000*g*.
- Inject 20 µL of the pentane layer onto the HPLC.

The retention time of the diethylene glycol derivative is about 3 min, and of the ethylene glycol derivative about 4 min.

Alcohols in serum by osmolality If no specific assay for alcohols is available, the osmolal gap should be measured:

$$(\text{measured mOsmol/kg in patient's serum}) - (\text{calculated osmolality}/0.93) = \text{osmol gap}$$

- In practice, osmol gap = measured mOsmol/kg − 290.
- Milligrams of alcohol per litre of serum = osmol gap × relative molecular mass.
- Each measured osmol gap unit = F g/L alcohol in serum; $F = 0.026$ for methanol; 0.043 for ethanol; 0.05 for ethylene glycol; 0.055 for acetone; and 0.059 for propan-2-ol.

Screening for abuse of solvents

The term 'glue-sniffing' comes from the abuse of adhesives, which often contain solvents such as toluene, ethyl acetate, acetone or ethyl methyl ketone. These, and similar compounds, also occur in a diverse range of other commercial products that may be abused, such as shoe-cleaners, nail varnish, dry-cleaning fluids, bottled fuel gases (butane and propane), aerosol propellants and fire extinguishers (bromochlorodifluoromethane). The identification, quantification and interpretation of solvents abused are described in detail in Chapter 11.

Antidepressants and antipsychotics

Antidepressants and antipsychotics comprise a diverse group of compounds that includes the tricyclic antidepressants, antipsychotic agents and lithium. Other substances, mainly the newer drugs, include the selective serotonin reuptake inhibitors (SSRIs), monoamine oxide inhibitors (MAOIs) and atypical antipsychotics such as clozapine and olanzapine. Tricyclic antidepressants remain an important cause of suicide, and serious poisoning can lead to cardiac disturbances (increasing QRS-complex), respiratory depression, metabolic acidosis, convulsions and coma. These drugs are gradually being replaced by the less toxic SSRIs such as citalopram, fluoxetine, fluvoxamine, paroxetine and sertraline. However, these drugs can induce aggressive and suicidal behaviour. These drugs are also used as drugs of abuse.

Analysis of antidepressants and antipsychotics by GLC To detect the misuse of these drugs, especially the more recent ones and depot preparations, GLC methods have the advantage of producing a lower limit of quantification. Alternative systems are described in Chapter 40.

Extraction procedure

- To 1.0 mL of blood, plasma or urine in a 15 mL Pyrex centrifuge tube, add 1.5 mL of ammonium chloride buffer (pH 9.5) and 5 mL of the extraction solvent (chloroform–propan-2-ol–*n*-heptane (10 : 14 : 26 v/v/v)).
- Vortex for 1 min; centrifuge at 2000*g* for 5 min.
- Remove the aqueous layer (by suction or freezing).
- Transfer the organic layer to a clean brown glass test-tube and evaporate to dryness under a stream of nitrogen in a water-bath at about 60°C.
- Redissolve the extract in 100 µL of methanol.
- Inject 3 µL onto the GC column.

Chromatography

- Column: Cp-SiL 5 CB (10 m × 0.32 mm i.d, 0.12 µm) or Cp-SiL 19 CB (10 m × 0.32 mm i.d, 0.19 µm).
- Temperature programme: 130°C to 230°C at 100°/min for 30 s.
- Gas flow rates: bypass He 30 mL/min, septum purge He 5 mL/min, overall He 150 mL/min, and column flow He 1 mL/min.
- Detector: NPD (300°C).

The retention indices for various substances are given in Table 1.16.

Analysis of antidepressants by HPLC

Extraction procedure

- To 1.0 mL of blood, plasma or urine in a 15 mL centrifuge tube, add 1.5 mL of ammonium chloride buffer (pH 9.5) and 5 mL of the extraction solvent (chloroform–propan-2-ol–*n*-heptane (10 : 14 : 26 v/v/v)).
- Vortex for 1 min; centrifuge at 2000*g* for 5 min.
- Remove the aqueous layer (by suction or freezing).
- Transfer the organic layer into a clean brown glass test-tube and evaporate under vacuum or stream of nitrogen to dryness.
- Redissolve the residue in 0.1 mL of the mobile phase.
- Inject 60 µL of the serum extract.

Chromatography

- HPLC apparatus with an isocratic pump.
- Detector: UV (0.01 absorption units full scale, AUFS) and for some drugs a fluorescence detector in series. UV maxima mostly at 254 nm, except those shown in Table 1.17. Optionally, a fluorescence detector in series with UV detector can be used (Table 1.18).
- Column: Microspher Si (100 mm × 4.6 mm, i.d.) (Chrompack, Middelburg, The Netherlands, no. 28400) or Lichrosorb 60 Si5 m (150 mm × 3 mm i.d.) (Merck, Darmstadt, Germany).
- Mobile phase: methanol–dichloromethane–buffer (30% acetic acid–diethylamide (20 : 1 v/v) pH 3.2; 10 : 90 : 1.5); flow rate 1.0 mL/min.
- The flow rate of the mobile phase is 1.0 mL/min, except for hydroxyzine and mianserin when it is 0.8 mL/min, and for chlorphenamine, fluoxetine, fluvoxamine, maprotiline, oxomemazine, pipamperone, protriptyline, tiapride and their main metabolites when it is 1.3 mL/min.
- The limit of quantification (LOQ) for most drugs is 5–10 µg/L of serum or less and 25 µg/L or less for the metabolites. Haloperidol's LOQ is 3 µg/L. The coefficient of variation (CV) in the therapeutic range is mostly 1–5%. The newer SSRIs (fluoxetine, fluvoxamine, paroxetine and sertraline) can also be determined easily and reliably by this method. Antipsychotics not measurable by this method are trazodone, droperidol, penfluridol, fluspirilene and biperiden.

Benzodiazepines, zolpidem and zopiclone

Benzodiazepine tranquillisers are prescribed widely and therefore occur more frequently than any other type of drug in overdose cases. The effects of these drugs in overdose are usually mild, although they may have a synergistic effect when taken with alcohol or other drugs. The anticonvulsive benzodiazepine clonazepam (Rivotril) is also used to detoxify patients with very severe (other) benzodiazepine dependence. Although these drugs do not seem to cause lethal intoxications, reports of deaths from benzodiazepines have been published, most of which refer to elderly people or cases of combined overdose of flunitrazepam and opiates. Over 30 benzodiazepines are available; some of these are both the parent compound and a metabolite of other benzodiazepines. The intrinsic activity varies enormously from one to the other. For example, alprazolam has a therapeutic effect at a serum concentration of 1 µg/L, whereas oxazepam becomes effective only at 1000 µg/L. This phenomenon makes comprehensive screening for the group very difficult. Several of the metabolites (including some glucuronides) are also active. In patients with renal failure the metabolite midazolam glucuronide can still be active even if the parent compound and its hydroxy-metabolite are no longer measurable (see Diagnosis of brain death). Several immunoassays are available to screen for the benzodiazepines in urine. However, in most of these the antibodies do not react with the glucuronides and prior enzyme hydrolysis of the urine is therefore required. The hypnotics zolpidem and zopiclone have similar dynamic and toxic activity to the benzodiazepines. Although these are not benzodiazepines, they exhibit cross-reactivity with some benzodiazepine immunoassays.

Analysis All benzodiazepines and their unconjugated metabolites (except the parent drug potassium clorazepate) are extractable from body fluids into an organic solvent and can be quantified in serum or plasma by normal-phase HPLC with UV detection. GC with ECD can also be used (see Chapter 40). All analytes of benzodiazepines, whatever the matrix (blood, urine) or analytical method (immunoassay or chromatography), require a hydrolysis step (see also Analytical methods below). Smith *et al.* (2006) described as LC-MS(-MS) system for the screening of 30 benzodiazepines.

Benzodiazepines by reversed-phase HPLC

Reagents

- Borax buffer (pH 9.0): 43 mmol/L, 1.621 g disodium tetraborate plus 15 mL of 0.1 mol/L HCl and sufficient water to make 100 mL.
- Buffer (pH 5.9): 1.19 g disodium hydrogenphosphate·$2H_2O$ plus 8.17 g potassium dihydrogenphosphate plus sufficient water to make 1 L. Add 1 mol/L sodium hydroxide or 1 mol/L phosphoric acid to pH 5.9.
- Aqueous methanol: 150 mL of methanol plus 350 mL of water.

Extraction procedure

- Pipette 0.5 mL serum plus 0.2 mL pH 9 buffer into a centrifuge tube.
- Add 0.1 mL internal standard A or 0.2 mL of B and 5.0 mL dichloromethane.
- Vortex for 1 min; centrifuge at 2000*g* for 5 min.
- Remove the aqueous and interface layers.
- Transfer the organic layer to a clean test-tube and evaporate under vacuum or a stream of nitrogen to dryness.
- Redissolve the residue in 0.1 mL mobile phase.
- Inject 50 µL onto the HPLC column.

Table 1.19 gives the retention times.

Internal standard Two internal standards can be used: A, 2.0 mg nitrazepam/L in aqueous methanol; or B, 4.0 mg nordazepam/L in aqueous methanol.

Mobile phase Tetrahydrofuran (THF)–methanol (40 : 60), buffer pH 5.9; flow rate 1.0 mL/min.

Table 1.19 Retention times and LOQ data for benzodiazepines

Benzodiazepine	*Retention time (min)*	*LOQ (µg/L)*	
		254 nm (A)	*310 nm (B)*

Apparatus HPLC with UV detection ($\lambda = 254$ nm (0.02 AUFS) and 310 nm (0.005 AUFS) for clonazepam, nitrazepam and flunitrazepam and their metabolites).

Column Nucleosil $5C_{18}$ (250 × 4.6 mm i.d., 5 µm).

Cholinesterase inhibitors (organophosphate and carbamate pesticides)

There are no simple direct chemical tests for these compounds. The toxic effects are usually associated with depression of the cholinesterase activity of the body, and measurement of the plasma or serum cholinesterase can be used as an indication of organophosphorus or carbamate poisoning. Plasma or serum cholinesterase (pseudocholinesterase) is inhibited by a number of compounds and can also be decreased in the presence of liver impairment. Erythrocyte cholinesterase (true cholinesterase) reflects more accurately the cholinesterase status of the central nervous system. However, pseudocholinesterase activity responds more quickly to an inhibitor and returns to normal more rapidly than erythrocyte cholinesterase activity. Thus, measurement of pseudocholinesterase activity is quite adequate for diagnosing acute exposure to organophosphorus or thiocarbamate compounds, but cases of illness that may be caused by chronic exposure to these compounds should also be investigated by determining the erythrocyte cholinesterase activity. A colorimetric method for this purpose is described in Chapter 16.

Paraquat and diquat

Paraquat (1,1-dimethyl-4,4-bipyridylium chloride) is the most important bipyridyl herbicide. Although deaths are reported from accidental paraquat exposure by inhalation and transdermal absorption, accidental or deliberate intake is nearly always oral ingestion. Diquat is less toxic than paraquat. Granular preparations usually contain 2.5% w/w of paraquat and 2.5% w/w of diquat; liquid preparations may contain 20% w/v of paraquat alone. A qualitative test for paraquat in urine is described earlier in the section 'Paraquat and diquat – dithionite test in urine'. Measurement of the plasma paraquat concentration is a useful prognostic test and Scherrmann *et al.* (1987) published a nomogram of the interrelationship of time after ingestion, plasma concentration and probable outcome. The main use of an assay is to prevent overtreatment of patients who either are not at risk or have no chance of survival. Paraquat can be measured in plasma by immunoassay, although the methods are not widely available. HPLC methods have also been described (see Chapter 16). An alternative colorimetric method is described below.

Quantification of paraquat in plasma by colorimetry This method is based on that of Jarvie and Stewart (1979).

Standard solutions Prepare standard solutions of paraquat in plasma containing 0, 0.1, 0.2, 0.5, 1.0 and 2.0 mg of paraquat per litre; store frozen until required.

Extraction solvent Mix 50 mL of water-saturated isobutyl methyl ketone and 50 mL of water-saturated isobutyl alcohol and then add 0.5 g of sodium dodecylsulfate.

Method

- Add 2 mL of water and 10 mL of the extraction solvent to 2 mL of plasma (or standard solution) in a 15 mL glass-stoppered centrifuge tube.
- Mix gently for 5 min on a roller mixer.
- Centrifuge for 5 min at 1500*g*.
- Carefully transfer 8 mL of the solvent phase into a second tube that contains 0.8 mL of 2.5 mol/L sodium chloride and stopper the tube.
- Vortex for 5 min and centrifuge for 2 min at 1500*g*.
- Carefully remove the solvent phase.
- Transfer 0.7 mL of the aqueous phase into a 4 mL glass tube.
- Add 100 µL of a freshly prepared 3% (w/v) solution of sodium dithionite in 0.3 mol/L sodium hydroxide.
- Shake the mixture briefly and transfer to a semi-micro-quartz cuvette.
- Scan the solution immediately between 384 and 460 nm against a blank that contains 0.7 mL of 2.5 mol/L sodium chloride and 100 µL of the sodium dithionite solution. The absorbance caused by paraquat is obtained by subtracting the reading at 460 nm from that at

397 nm. A more specific assay can be obtained by using the second derivation of the UV maximum.
- The LOQ in serum is 50 μg/L.
- If diquat is also present, it will be extracted and gives rise to additional small peaks between 430 and 460 nm. Corrections can be made for this, but the increase in paraquat concentration is small (10–15%) and is usually insignificant in clinical situations.

Chlorophenoxyacetic acid herbicides

Poisoning with chlorophenoxyacetic acids, such as 2,4-dichlorophenoxyacetic acid (2,4-D), 2,4,5-trichlorophenoxyacetic acid (2,4,5-T) and methylchlorophenoxyacetic acid (MCPA), causes metabolic acidosis, myoglobinuria, rhabdomyolysis, elevated liver function tests, hypophosphataemia, miosis and tachycardia (Roberts *et al.* 2005). Plasma levels above 100 mg/L are associated with toxic symptoms.

These compounds can be measured spectrophotometrically at a maximum of about 284 nm, or after acid extraction and methylation by gas chromatography with FID or MS detection (see Chapter 16).

Chlorophenoxyacid herbicides in serum or urine by GLC

- To 1 mL of serum or urine add 0.1 mL of internal standard (2 mg/mL of MCPA or 2,4-D in methanol), 1 mL of 2 mol/L hydrochloric acid, and 5 mL of diethyl ether.
- Vortex for 1 min, centrifuge for 5 min at about 2000*g*.
- Transfer the ether layer to a conical test-tube.
- Add 0.1 mL of methylation reagent (0.2 mol/L trimethyl anilinium hydroxide in a 1 : 1 (v/v) mixture of methanol (freshly prepared)).
- Vortex for 30 s and centrifuge for 5 min at 1500*g*.
- Inject 1 μL of the lower layer onto the GC column.

Chromatography

- Column: 2% OV17 or Gaschrom Q.
- Oven temperature: 205°C.
- Injector temperature: 310°C.
- Detector (FID) temperature, 300°C.

The retention indices are 1605 (2,4-D), 1740 (2,4,5-T) and 1580 (MCPA).

Analgesics: paracetamol, salicylates and other non-steroidal anti-inflammatory drugs

Acute overdose with most of the analgesics rarely causes severe toxicity with the exceptions of paracetamol (acetaminophen) and salicylates.

Paracetamol Paracetamol (acetaminophen) is widely available as an over-the-counter medicine and is frequently taken in overdose. Paracetamol is metabolised by the liver to *N*-acetyl-*p*-benzoquinoneimine (NAPQI), which is normally inactivated by liver glutathione. After paracetamol overdose, the glutathione stores become depleted to leave toxic amounts of NAPQI to bind to proteins and cause centilobular necrosis. Drugs that induce hepatic CYP450 enzymes (e.g. phenobarbital) and chronic high ethanol abuse may enhance paracetamol toxicity. Intravenous infusion of *N*-acetylcysteine to replenish the glutathione stores is an effective treatment, especially when given during the early stages of poisoning. During the first 12 h after ingestion of a severe overdose, no clinical features other than vomiting may occur. After 12 h, hepatic necrosis causes continued vomiting, which may also induce abdominal pain after 24 h. Signs of jaundice become apparent after 36–72 h and the patient may develop hepatic encephalopathy and hepatic failure. Serum or plasma paracetamol measurements play a crucial role in the early diagnosis; management protocols and nomograms that relate these to time after ingestion and the likelihood of developing liver damage have been published (Smilkstein *et al.* 1991). The sample analysed should ideally not be taken until 4 h after ingestion, as prior to this the processes of absorption and distribution are incomplete. However, in practice this is not always feasible since the exact time of ingestion may not be known. Measuring a second paracetamol level about 4 h after the first can be useful, especially in cases of staggered overdose, and can give a better indication of prognosis. A half-life of about 4 h indicates a healthy liver and one of about 12 h predicts a severe necrosis.

Reliable commercial kits are available for paracetamol measurements in serum or plasma, designed for use on routine clinical analysers and based on either immunoassays (Edinboro *et al.* 1991) or enzymatic reactions (Morris *et al.* 1990). Numerous GC and HPLC methods have also been published.

Salicylates Salicylic acid is most often derived from acetylsalicylic acid (aspirin) and severe overdose results in respiratory alkalosis and metabolic acidosis. Children below the age of 4 years are particularly susceptible to salicylate poisoning. Continued absorption of aspirin is common after the initial admission to hospital. Sustained-release salicylate preparations may form concretions in the stomach that result in prolonged absorption as they gradually disintegrate. Application of salicylate-containing ointments to abnormal skin can also lead to significant toxicity, as can the use of teething gels in infants. Chronic salicylate poisoning can occur in rheumatic patients who take large doses of aspirin, and salicylism should be considered in any elderly patient with unexpected delirium or dementia. Ingestion of methyl-salicylate is rare, but it is potentially more dangerous because of rapid absorption. Treatment of severe salicylate poisoning involves sodium bicarbonate infusions, multiple doses of oral-activated charcoal and, in severe cases, haemodialysis. Toxicity is associated with plasma salicylate concentrations of 300 mg/L or greater. Adults with plasma salicylate concentrations less than 450 mg/L and children with plasma salicylate concentrations less than 350 mg/L do not require specific treatment. The slow and continuous absorption of the drug may necessitate repeat plasma salicylate determinations.

Colorimetric assay for salicylates

Standard solutions Prepare aqueous solutions that contain 0, 200, 500 and 800 mg/L of salicylic acid. These should be stored frozen when not in use.

Assay

- Add 5 mL of Trinder's reagent to 1 mL of the serum sample in a 15 mL centrifuge tube.
- Vortex for 30 s and centrifuge for 5 min at 1500*g*.
- Measure the colour intensity of the supernatant liquid at 540 nm.
- Determine the concentration in the sample by comparison with the standard solutions.

Other NSAIDs Other NSAIDs include the arylacetic acids (e.g. diclofenac), arylpropionic acids (e.g. ibuprofen, ketoprofen, naproxen), heterocyclic acetic acids (e.g. indometacin, ketorolac, sulindac), pyrazolones (phenylbutazone), oxicams (e.g. piroxicam) and mefenamic acid. Most patients who take an overdose of these drugs are asymptomatic, but the chronic use of mixtures of analgesic drugs has been linked to renal damage, including papillary necrosis and chronic interstitial nephritis. These compounds are extractable at acidic pHs and most can be determined by the STIP method or other suitable HPLC methods.

Antiepileptics (carbamazepine, oxcarbazepine, phenytoin, phenobarbital, primidone, valproate, ethosuximide, clonazepam, clobazam)

Antiepileptic drugs are commonly prescribed in combination in epilepsy treatment. Symptoms of acute overdose simulate those of barbiturate poisoning. Laboratories that offer a routine therapeutic drug monitoring service for these drugs have little difficulty in adapting their normal procedures to the occasional overdose case (see Chapter 2). Immunoassays for some of the antiepileptic drugs lack linearity and exhibit different cross-reactivities in the toxic range, and HPLC or GC (see Chapter 40) assays are preferred alternatives in toxicological investigations. 10-Hydroxycarbazepine, the active metabolite of oxcarbazepine, can be determined in plasma by the Pinkerton method (detection at 240 nm), as described under caffeine.

Normal-phase HPLC determination of phenobarbital, phenytoin, primidone, carbamazepine, clobazam, diazepam, ethosuximide, clonazepam and nitrazepam

This method uses the same column, reagents and apparatus as the normal-phase HPLC method described for antidepressants above.

Valproic acid determination by GC

Apparatus Gas chromatograph provided with a capillary column, but also an all-glass column (1.8 m × 3 mm i.d., with 5% (w/w) FFAP on Gas-Chrom Q 60/80 mesh). Temperature 170°C. Carrier gas N_2, 30 mL/min.

Internal standard 150 mg cyclohexane carboxylic acid per litre of dichloromethane.

Standards 0, 25, 50, 100 and 200 μg valproic acid per mL of human or calf serum.

Assay
- Pipette 0.2 mL of serum into a nipple tube.
- Add 20 μL 6 mol/L sulfuric acid and 200 μL internal standard solution.
- Vortex for 30 s and centrifuge for 10 min at 1500*g*.
- Inject 2 μL into the gas chromatograph.
- LOQ is 2 mg/L.

This method is also suitable for measuring gamma-hydroxybutyric acid in serum. An alternative method for GHB and its metabolites using micellar kinetic chromatography has been reported by Dahlen and Vriesman (2002).

Reagents
- Buffer: 93.6 g sodium dihydrogenphosphate per L of water (pH 3.3).
- Dichloromethane 50% water saturated: dichloromethane washed with ultrapure water, dried over a molecular sieve (0.4-nm Perl form plus 2 mm; Merck) and mixed with equal parts of water-saturated dichloromethane.
- THF (HPLC grade).

Mobile phase THF–methanol–dichloromethane (50% saturated; 6 : 0.2 : 93.8 v/v/v); degassed; flow rate 1.0 mL/min.

Apparatus HPLC with UV detection ($\lambda = 254$ nm).

Column 150 mm × 3 mm i.d., with regular 5 μm silica gel.

Standards
- In dichloromethane make a stock solution with 2.5 mg diazepam, 2.5 mg desmethyldiazepam, 50 mg carbamazepine, 100 mg phenytoin (as acid), 200 mg phenobarbital (as acid), 400 mg ethosuximide, 0.5 mg nitrazepam and 0.5 mg clonazepam per litre.
- Store in ampoules at −20°C.
- Pipette 0, 50, 100, 200 and 400 μL into separate tubes and add 1.0 mL of human or calf serum; mix.
- Prepare a calibration curve.

Internal standard Use 2 mg hexobarbital/L of dichloromethane.

Assay
- Into a small test-tube or injection vial, pipette 0.25 mL of serum, 0.25 mL of buffer and 2.5 mL of internal standard.
- Vortex for 1 min and centrifuge at 2000*g* for 5 min.
- Inject approximately 50 μL of the lower layer (dichloromethane) into the HPLC column (the needle of the automatic injector is arranged to pass through the serum–water layer into the dichloromethane layer or the water layer can be removed by a vacuum pump).
- If clonazepam or nitrazepam has to be measured, evaporate the dichloromethane layer to dryness under vacuum or a stream of nitrogen at 40°C.
- Redissolve the residue in 50 μL of mobile phase and inject 30 μL into the HPLC column.

Retention times for antiepileptic drugs are given in Table 1.20.

Valproic acid is normally measured by immunoassay (see Chapter 31) or by GC.

Table 1.20 Retention times for antiepileptic drugs

Anticonvulsant	*Retention time (min); strongly dependent on pH of mobile phase*
Trimethadione	1.0
Methylphenobarbital	1.1
Hexobarbital	1.2
Phenobarbital	1.25
Barbital	1.3
Ethosuximide	1.35
Diazepam	1.4
Methylphenytoin	1.4
Heptobarbital	1.4
Phenytoin	1.6
Sulthiame	1.8
Clonazepam	2.0
Nitrazepam	2.15
Nordiazepam	2.6
Carbamazepine	3.0
Carbamazepine-epoxide	(5.6, often undetectable)
7-Aminoclonazepam	8.8
Primidone	No detection

Carbon monoxide

Carbon monoxide is one of the most frequent causes of fatal poisoning. Common sources of carbon monoxide are vehicle exhaust fumes, smoke from fires, and improperly maintained and ventilated heating systems. More rarely, exposure to dichloromethane vapours from paint strippers, degreasing agents and aerosol propellants can lead to carbon monoxide poisoning because the solvent can be metabolised by mixed-function oxidases to carbon dioxide and carbon monoxide. The affinity of carbon monoxide for haemoglobin is 200–300 times that of oxygen and therefore most of the toxic effects result from diminished oxygen delivery to the tissues. Symptoms progress from headache, nausea, gastrointestinal upset, hyperventilation, hypertension and drowsiness to coma. Chronic poisoning as a result of continuous exposure to small amounts of carbon monoxide leads to non-specific symptoms such as headaches, dizziness, fatigue and general malaise, and is often undiagnosed. Elevated carboxyhaemoglobin (COHb) concentrations confirm a diagnosis of carbon monoxide poisoning. When a patient is removed from the contaminated atmosphere, the COHb disappears rapidly, particularly if oxygen is administered. A qualitative test for COHb is described under 'Carbon monoxide in whole blood' in the section 'Direct (colour tests) in serum or urine samples'.

Hospital clinical chemistry laboratories are usually equipped with automated differential spectrophotometers (CO-oximeters) that simultaneously measure the absorption of a blood haemolysate at four or more wavelengths to determine total haemoglobin, the percentage saturation of oxyhaemoglobin and COHb, as well as methaemoglobin and sulfhaemoglobin (Widdop 2002).

If such an apparatus is not available, the spectrophotometric method of Rodkey *et al.* (1979) can be used.

Quantification of carboxyhaemoglobin in blood by spectrophotometry

Principle When a reducing agent (sodium dithionite) is added to the blood, both the oxygenated form and the methaemoglobin are converted quantitatively to the reduced form, which has the visible spectrum B shown in Fig. 1.2. Carbon monoxide has a much greater affinity for haemoglobin than oxygen, and the COHb is not reduced by sodium dithionite. Thus, even when treated with sodium dithionite, COHb retains its normal twin-peaked spectrum, marked A in Fig. 1.2. The maximal difference between the spectra of A and B is at 540 nm, while at 579 nm the spectra have the same absorbance (isosbestic point). The percentage saturation of carbon monoxide in a blood sample (A) can be calculated from measurements of the absorbance of the carbon monoxide-free sample (B) and the untreated sample (C), after reduction of each with sodium dithionite.

Standards Gas bottles of pure carbon monoxide can be obtained. Alternatively, commercial reference standards of haemolysed blood in sealed glass ampoules are available (IL, Warrington, UK).

Assay
- Dilute 0.2 mL of the heparinised whole-blood sample with 25 mL of a 1 mL/L solution of aqueous ammonium hydroxide.
- Mix well.

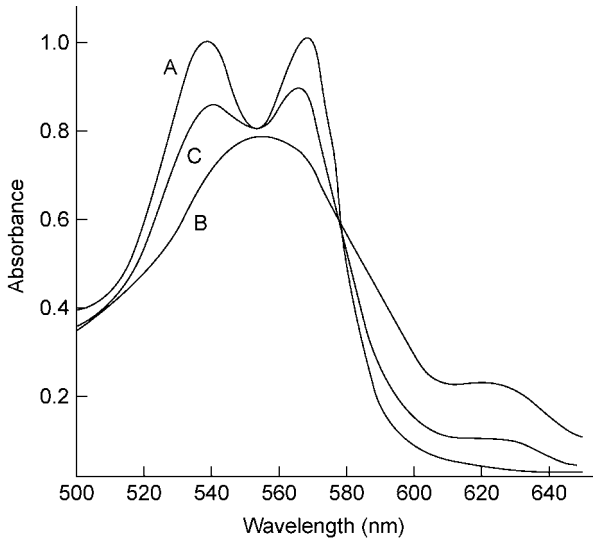

Figure 1.2 Ultraviolet spectra of (A) carboxyhaemoglobin, (B) reduced haemoglobin and (C) a blood sample from a patient poisoned with carbon monoxide.

- Transfer 5-mL aliquots of this mixture into three tubes, labelled A, B and C.
- Saturate A with carbon monoxide by bubbling the gas very slowly through the mixture for 5–10 min (take care to avoid frothing) to give a 100% COHb standard.
- Saturate solution B with pure oxygen by bubbling the gas slowly through the mixture for at least 10 min to displace all the bound CO (again take care to avoid frothing) to give a 0% COHb standard.
- Add to all three tubes a small amount of sodium dithionite (approximately 150 mg) and 10 mL of ammonium hydroxide solution (the sodium dithionite must be freshly obtained or have been stored in a sealed container in a dessicator to prevent inactivation by contact with moist air).
- Vortex for a few seconds.
- Record the absorbances of A, B and C against the ammonium hydroxide solution between 500 and 650 nm and measure the absorbances at 540 nm and at 579 nm. (Wash out the sample cell thoroughly between the recordings and wash the cell with a little of the solution, the absorbance of which is about to be recorded.)
- Calculate the ratios of the absorbances at 540 and 579 nm for each of the solutions A, B and C.
- Calculate the percentage COHb saturation as follows:

$$\%\text{Saturation} = \frac{\text{ratio for C} - \text{ratio for B}}{\text{ratio for A} - \text{ratio for B}} \times 100$$

- Interpretation: normal, <5%; smokers, <10%; headaches, 10–20%; toxic, 20–30%; potentially fatal, >45%.

Metals

The detection of poisoning with toxic metals is an important feature of hospital toxicology; in modern laboratories the favoured techniques are atomic absorption spectrophotometry (AAS) and inductively coupled plasma-MS (ICP-MS). These techniques and their applications are described in Chapters 17 and 43.

Theophylline and caffeine

Theophylline is prescribed to asthmatic children and adults, but serious toxicity can be caused by both therapeutic excess and overdose. Clinical features include severe hypotension, cardiac arrhythmias and convulsions. Biochemical disturbances include hyperinsulinaemia, hyperkalaemia, glycosuria and metabolic acidosis. Many theophylline preparations are of the slow-release type, so that the onset of toxic symptoms may be delayed for up to 12 h following overdose. Treatment consists of gastric lavage for patients who reach hospital within 1 h of the overdose and multiple oral doses of activated charcoal, which is thought to be as efficient as charcoal haemoperfusion as an elimination procedure. The plasma theophylline concentration is an important diagnostic test and should be measured urgently. In asymptotic patients levels should be measured 4 h or more after ingestion.

Caffeine is prescribed for neonatal apnoea. It is also an ingredient of many proprietary stimulant preparations and an important adulterant in drugs of abuse, such as the so-called 'smart drugs'. Some patients have an idiosyncrasy for theophylline or caffeine, developing tachycardia at low serum concentrations. Although the lethal dose is large (about 10 g), severe caffeine intoxication with tachyarrhythmias followed by cardiovascular collapse has caused deaths in children. Caffeine also potentiates the effects of sympathomimetic drugs, which contribute to adverse cardiac disorders.

Commercial immunoassay kits are available to determine theophylline and caffeine in serum or plasma. These drugs can be determined by the STIP chromatography system.

Measurement of xanthines in serum by normal-phase HPLC

Apparatus HPLC with UV detection ($\lambda = 273$ nm).

Column Normal-phase ODS-silica (5 μm).

Mobile phase Methanol–THF–water–acetic acid (100 : 30 : 900 : 1); add sufficient sodium hydroxide solution to give pH 5.6 (pH is critical).

Assay

- To 50 μL of serum (plasma) add 100 μL of internal standard solution (5 mg 8-chlorotheophylline per L of 1 mol/L sodium acetate) and 2 mL of a mixture of chloroform (or dichloromethane) and isopropyl alcohol (1 : 9 v/v).
- Vortex, centrifuge at 1500*g* for 5 min.
- Cool the tube to −40°C to freeze the water layer.
- Transfer the organic layer into a second test-tube.
- Evaporate to dryness under a stream of nitrogen at 50°C or under vacuum.
- Re-dissolve the residue in 20 μL of mobile phase solution.
- Inject 10 μL into the HPLC.

Other xanthines and their metabolites also elute. Retention times relative to theophylline are 0.49 for 3-methylxanthine, 0.63 for theobromine, 0.88 for paraxanthine, 1.36 for caffeine and 1.46 for the internal standard 8-chlorotheophylline.

Measurement of caffeine in serum by reversed-phase HPLC with direct injection

Apparatus HPLC with a 10 μL loop injector and DAD ($\lambda = 273$ nm; 0.1 AUFS).

Column

- Pinkerton ISRP GFF II (250 × 4.6 mm i.d., code 731472 W; LC Service, Emmen, The Netherlands).
- Guard column: ISRP GFF II (10 × 4.6 mm i.d., code 731474; LC Service, Emmen, The Netherlands). (Flush the guard column backwards once a week with pure acetonitrile.)

Mobile phase 0.1 mol/L potassium dihydrogenphosphate–acetonitrile (80 : 20); add sufficient 4 mg/L potassium hydroxide to pH 6.8; flow rate 1.0 mL/min (for 10-hydroxycarbazepine use 1.2 mL/min).

Assay

- Centrifuge 0.5 mL of serum in a microcentrifuge at maximal speed or filter through a 0.45 μm filter.
- Inject enough serum (approximately 30 μL) to flush and fill the 10 μL loop.
- Rinse the injector with water prior to each injection.
- Calculate the concentration from the peak height ratios.
- If the concentration is too high, dilute the sample with blank serum.

The analytical range of the method is 1–40 mg/L for caffeine in serum.

Cardioactive drugs

There are several classes of cardiac drugs. The cardiac glycoside digoxin is the oldest still in use and therapeutic overdose is far more common

than deliberate overdose. Serious digoxin overdose has a mortality rate of up to 20% and may be combated by the administration of oral activated charcoal, magnesium sulfate and ovine fragment antidigoxin antibodies. Digoxin is usually measured in serum by immunoassay (see Chapter 31), but the presence of Fab fragments interferes with the assay, as does that of other cardiac glycosides such as digitoxin. When considering the use of Fab-fragment therapy, a serum digoxin immunoassay carried out prior to administration can be used to calculate the total body burden and the amount of antidote required. Other cardioactive drugs can be measured in serum or plasma by HPLC (Chapter 41), by GC (Chapter 40) or by the LC-MS(-MS) method described above.

Measurement of common antiarrhythmic drugs in serum or plasma by HPLC

Apparatus HPLC column with UV detection ($\lambda = 205$ nm). For flecainide, fluorescence detection can be used ($\lambda_{ex} = 205$ nm, $\lambda_{em} = 365$ nm).

Column Nucleosil $5C_{18}$ (150 × 4.6 mm i.d., 5 μm).

Mobile phase Acetonitrile–buffer (4 g/L KH_2PO_4 adjusted to pH 4.45 with phosphoric acid, 72 : 28), flow rate 1.5 mL/min. For flecainide assay use 68 : 32.

Assay

- To 0.5 mL serum add 0.2 mL borax buffer (pH 9.0), 0.1 mL internal standard solution (e.g. 5 mg/L of chlorodiisopyramide) and 5 mL dichloromethane.
- Vortex for 2 min and centrifuge for 5 min at 1500*g*.
- Place the tube in a freezing bath at −40°C for sufficient time to freeze the water layer.
- Transfer the organic layer into a clean test-tube.
- Evaporate to dryness under a stream of nitrogen, or under vacuum.
- Add 0.2 mL of mobile phase and re-dissolve.
- Inject 50 μL onto the HPLC column.

Retention times for antiarrhythmic drugs are given in Table 1.21.

Measurement of the calcium antagonists verapamil and diltiazem in serum or plasma by HPLC

Apparatus HPLC column with UV detection ($\lambda = 206$ nm, 0.02 AUFS).

Column Nucleosil $5C_{18}$ (150 × 4.6 mm i.d., 5 μm).

Mobile phase Acetonitrile–buffer (13.6 g/L KH_2PO_4 adjusted to pH 2.5 with phosphoric acid, 70 : 30), flow rate 1.5 mL/min.

Assay

- To 1 mL serum add 0.1 mL internal standard (1 mg/L of the other drug) and 0.3 mL buffer pH 2.5 and mix.
- Add 5 mL diethyl ether; vortex for 1 min.
- Centrifuge for 5 min at 2000*g*.
- Place the test-tube in a freezing bath at −40°C until the water layer is frozen.

Table 1.21 Retention time and LOQ data for antiarrhythmic drugs

Antiarrhythmic	*Retention time (min)*	*LOQ (mg/L serum)*
Tocainide	3.0	0.1
Nordisopyramide	4.0	0.1
Lidocaine	4.5	0.1
Mexiletine	4.8	0.1
Disopyramide	7.5	0.25
Quinidine	9.0	0.25
Bupivacaine	12	0.1
Internal standard	13.5	
Flecainide	20 [(a)]	0.05
Dipyridamole	23 [(a)]	0.1

[(a)]For these drugs a higher concentration of acetonitrile in the mobile phase is recommended.

- Transfer the organic layer to a conical test-tube.
- Add 0.1 mL 0.5 mol/L sulfuric acid.
- Vortex for 1 min; centrifuge for 5 min at 1500*g*.
- Inject 50 μL of the water layer onto the HPLC column.

Retention times are verapamil 2.7 min, norverapamil 3.8 min and diltiazem 5.8 min.

Quantitative fluorescence method for quinine and quinidine in serum Quinine and quinidine are stereoisomers. Quinine is still widely used as an antimalarial as well as in elderly patients to treat night cramps. Quinidine is used as an antiarrhythmic agent. The isomers have similar toxic properties and severe overdose causes cardiac arrhythmias and visual disturbances that may result in permanent blindness. Multiple-dose oral activated charcoal is thought to increase the elimination of these drugs. Chloroquine is often used for self-euthanasia and, in contrast with quinine, it is mainly present in the erythrocytes. Therefore, whole blood analysis by LC-STIP or LC-MS (-MS) is required.

Standard Prepare solutions in human or calf serum that contain 5, 10, 20 and 40 mg/L.

Assay

- To 0.2 mL of serum (plasma) add 40 μL of 2 mol/L tris(hydroxymethyl)methylamine and 4 mL of dichloromethane–isopropyl alcohol (3 : 1).
- Vortex for 30 s and centrifuge at 2000*g* for 5 min.
- Carefully transfer the solvent layer to a second test-tube.
- Add 4 mL of 0.05 mol/L sulfuric acid.
- Vortex for a few seconds and centrifuge at 2000*g* for 5 min.
- Transfer the aqueous layer to a fluorimeter cell and measure the fluorescence ($\lambda_{ex} = 350$ nm, $\lambda_{em} = 450$ nm).

Drugs of abuse

Drugs of abuse may be taken deliberately or accidentally in overdose, or administered to others by a third party. Laboratory personnel should be aware of potential legal implications that might arise subsequently from any cases that involve drug abuse, and make sure that full documentation is collected and retained. Hospital toxicologists include drugs of abuse screening as part of their portfolio of tests provided to aid diagnosis and treatment, and for this purpose urine is the sample of choice. Quantitative assays in serum or plasma are rarely needed urgently and are usually reserved for cases with medicolegal implications. Routine analysis of drugs of abuse in urine also forms part of drug-dependence treatment programmes in which laboratory tests are used to assess the drug-taking pattern of new patients and subsequently to monitor their compliance with treatment. Apart from classic drugs of abuse such as heroin, cocaine and amfetamines, misuse of common medicines (codeine, oxycodone, benzodiazepines, etc.) is also widespread. In addition, the Internet is an increasing source of information on the purported recreational pleasures induced by a variety of substances, many of which provide little more than a placebo effect. Other forms of drug misuse include the covert use of laxative or diuretic drugs; early detection of this practice can avoid a futile search for a medical cause of the symptoms (see Detection of diuretics and laxatives). Tests for the abuse of volatile substances are described in Chapter 14.

Analytical methods

Fast immunoassay screening tests are described above and more information can be found in Chapters 3, 18 and 31. For routine drug-dependence screening programmes, in which large batches of urine samples are analysed daily, the analytical protocol usually comprises rapid automated immunoassay screening using a clinical chemistry analyser followed by the re-examination of positive samples using a more selective chromatographic technique.

Chromatographic analysis of drugs of abuse

Deglucuronidation Several of these drugs are excreted extensively as glucuronides in the urine. It is therefore recommended that acid or

enzymatic hydrolysis of the urine is carried out prior to extraction. Enzymatic hydrolysis is a gentler procedure that avoids the destruction of drugs that are acid labile.

Acid hydrolysis

- To 10 mL of urine in a screw-capped bottle add 2 mL of 36% (v/v) hydrochloric acid.
- Screw the cap on to the bottle and allow it to stand in a boiling water-bath for 15 min.
- Cool the bottle, and transfer the contents to a clean beaker.
- Add solid sodium bicarbonate to adjust the pH to 8.5.
- When frothing has subsided, transfer the solution back into the screw-capped bottle.

Enzyme hydrolysis

- Dissolve 5000 Fishman units of mixed glucuronidase–sulfatase (from *Helix pomatia)* in 1 mL of acetate buffer (pH 5).
- Adjust 10 mL of the urine to pH 5.0 (4.9–5.1) with 0.1 mol/L hydrochloric acid.
- Add 1 mL of the enzyme solution and incubate at 37°C overnight.

Thin-layer chromatography procedure for drugs of abuse in urine
Table 1.22 gives R_f values and colour reactions for drugs of abuse.

Standard solutions Dissolve 100 mg of each drug in 10 mL of methanol containing 1 drop of acetic acid:

- Standard I: methadone, heroin, codeine and morphine.
- Standard II: methaqualone, pethidine and ephedrine.
- Standard III: dextropropoxyphene, cocaine, benzoylecgonine and amfetamine.
- Standard IV: dextromoramide, pentazocine and methylamfetamine.
- Standard V: the urine extract of a drug-free heavy smoker.
- Standard VI: MDMA and methylenedioxyethylamfetamine (MDEA).

TLC plates Plastic or glass plates coated with silica gel (10 × 20 cm 60 GF 254, 250 μm), with fluorescence indicator.

Assay

- Hydrolyse 20 mL of the urine (see above).
- Add 50 mg of ammonium chloride and adjust the pH to 9.2–9.4 with 25% (v/v) aqueous ammonia (use a pH-meter).
- Transfer this mixture on to an Extralute column (Merck); wait for 5 min.
- Add two consecutive 20 mL volumes of the extraction solvent (dichloromethane–propan-2-ol (1 : 1 v/v)). (For safety reasons, dichloromethane can be substituted for chloroform.)
- Collect both extracts into a conical test-tube.
- Add 1 drop of acetic acid (to avoid volatilising amfetamines) and dry under air or nitrogen in a water-bath at 50°C or under vacuum.
- Re-dissolve the residue in 50 μL of methanol.
- Apply, on a line marked 1.5 cm from the bottom of the plate, 5 μL of the standard solutions and the urine extracts, about 15 mm from each other in the following order: standard I, II, patient extracts, III, IV, V.

Plate A, general drugs (mobile phase: ECMA)

- The mobile phase is ethyl acetate–cyclohexane–methanol–25% (v/v) aqueous ammonium hydroxide (70 : 15 : 10 : 5; mix shortly before use). Use 100 mL for one or two plates.
- Development time exactly 8.0 min (about 8 cm).
- Dry the plate in air, or use a handheld hot-air blower.
- The plate has to be free of ammonia; place it at 100°C for 2–5 min before spraying. Examine the plate at 254 and 366 nm.
- Place above hydrochloric acid vapour for 3 min.
- Spray with acidified iodoplatinate solution.
- Spray again with sodium nitrite solution (approximately 5 g of sodium nitrite in 20 mL of water; freshly prepared).

Plate B, opiates (mobile phase: EMA)

- The mobile phase is ethyl acetate–methanol–25% (v/v) aqueous ammonium hydroxide (85 : 10 : 5).
- Develop the plate for 30 min.
- Air-dry for 15–20 min or use an air blower.
- Elute the plate again for 15 cm in ethyl acetate.
- Air dry and then heat for 2 min at 100°C.
- Apply the detection sequence described for plate A.

Plate C, amfetamines, ephedrine (mobile phase: BMA)

- The mobile phase is *n*-butyl alcohol–methanol–acetic acid (70 : 20 : 10).
- Develop the plate over a distance of 10 cm.
- Air-dry briefly and then use a hot-air blower until visually dry.
- Heat for 15 min at 100°C.
- Cool to ambient temperature.
- Observe under UV light at 254 nm and then spray with 1% (w/v) ninhydrin in ethanol.

Table 1.22 R_f values and colour reactions for drugs of abuse

	R_f *in mobile phases*			*Acidic iodoplatinate*	*Ninhydrin*		*Copper spray*
	CMA	*EMA*	*BMA*		*366 nm*	*100°C; 366 nm*	
Standard I							
Methadone	81	67	—	Orange-brown	—	—	—
Heroin (powder only)	50	44	7	Violet-brown	—	Blue	Orange
Codeine	30	27	20	Violet-grey	—	—	—
Morphine	17	15	7	Blue	—	Blue	Orange
Standard II							
Methaqualone	87	78	77	Brown	—	—	—
Pethidine	60	52	28	Brown	(Pink)	Pink-red	Orange
Ephedrine	22	22	10	(Grey)	(Violet)	Red-violet	Brown-red
Standard III							
Dextropropoxyphene	91	75	15	Brown	—	—	—
Cocaine	84	70	38	Red-brown	—	—	—
Amfetamine	39	36	34	Blue-violet	Violet	Red-brown	Orange-violet
Standard IV							
Dextromoramide	89	74	30	Brown	—	—	—
Pentazocine	75	62	58	Red-brown	—	Red	Orange-red
Metamfetamine	36	33	20	Violet	—	Violet	Red
Nicotine	60	50	1	Blue-violet	—	(Blue-violet)	(Orange-violet)

- Expose the plate to UV light at 366 nm for 5 min (amfetamine violet).
- Spray again with 1% (w/v) ninhydrin reagent and leave the plate in an oven at 80–100°C for about 20 min.
- Expose to UV light again at 366 nm for 5 min.
- Spray with copper nitrate reagent (1 mL of saturated aqueous solution of copper nitrate, 0.1 mL of 4 mol/L nitric acid and 100 mL of methanol) to improve the differentiation between amfetamine and ephedrine.

Notes on specific compounds and groups

- Many amfetamine derivatives are in use and it is preferable to detect these by HPLC or GLC. In the mobile phase BMA, spraying with ninhydrin after development at 366 nm and 20 min at 80°C to 100°C causes the following amfetamine derivatives to turn violet:
  - MDMA, $R_f = 0.19$
  - MDA, $R_f = 0.32$
  - 4-Methoxyamfetamine (4-MA), $R_f = 0.31$.
- After spraying with methanolic copper nitrate spray, amfetamine, metamfetamine and most amfetamine derivatives turn red. Only MDEA, $R_f = 0.27$, remains colourless with ninhydrin as well as with the copper nitrate spray.
- Cocaine gives a bright blue colour with acidified iodoplatinate solution. In practice, cocaine is rarely detected in urine samples by this technique because the drug is rapidly metabolised to benzoylecgonine, a polar substance that extracts poorly into organic solvents.
- It is essential to distinguish between codeine (a common constituent of cough medicines) and morphine. A small amount of codeine is thought to be *O*-demethylated to morphine in humans. A high intake of codeine can give rise to the detection of the *N*-demethylated metabolite, norcodeine.
- Dextropropoxyphene is metabolised extensively in the liver, but the parent drug is not detected in urine samples. The appearance of the metabolites is quite characteristic.
- Heroin (diacetylmorphine) is rapidly deacetylated to morphine in the body and is not excreted in urine. The detection of heroin is based, therefore, on the identification of morphine in urine (see below). Heroin detected in an extract may indicate an attempt by the patient to deceive the analyst by the direct addition of the drug to the urine sample.
- Methadone is *N*-demethylated in the body to give a product that undergoes spontaneous cyclisation to yield two metabolites in the urine. Methadone and the metabolites are usually found together, but occasionally only the metabolites are detected. Detection of a large amount of methadone in a urine sample in the absence of metabolites suggests direct addition by the patient to deceive the analyst.
- Morphine and codeine appear as blue spots. The TLC system described above is useful after an immunoassay for opiates as it can differentiate between morphine (as a metabolite of heroin) and codeine. Less than 10% of morphine is excreted as unchanged morphine and therefore the sensitivity of the test is increased by hydrolysing the conjugated metabolites prior to extraction.

Screening for drugs of abuse by chromatography with mass selective detection (GC-MS)

GC-MS is the method of choice for confirming the results of immunoassay tests, and the procedure described by Maurer (2011a, 2011b) is ideal for this purpose (see also Chapters 26 and 40). GC-MS analysis of drugs is also applied to hair testing (Paterson *et al.* 2001).

Liquid chromatography with MS is used increasingly in clinical and forensic toxicology. An important advantage of LC-MS over GC-MS is that no derivatisation is needed (Marquet 2002). With the introduction of LC-MS(-MS) into clinical laboratories, this technique may eventually supersede GC-MS in this area.

Screening for drugs of abuse by gradient-elution HPLC with diode array, fluorescence or electrochemical detection

Apparatus Gradient HPLC set-up, DAD ($\lambda = 215$ nm; 0.100 AUFS) and optionally an electrochemical detector (0.85 V/Ox; ATT = 128) and a fluorescence detector ($\lambda_{ex} = 290$ nm, $\lambda_{em} = 340$ nm).

Table 1.23 HPLC gradient mobile phase at 1 mL/min

Time (min)	*% A*	*% B*
0	100	0
30	30	70
35	30	70
40	20	80
45	100	0
60	100	0

Column Lichrospher RP-18e (125 × 4.0 mm, 5 µm).

Mobile phases

- Mobile phase A is 0.025 mol/L triethylammonium phosphate buffer in water (pH 3.0).
- Mobile phase B is acetonitrile (HPLC grade).

Activation and cleaning of the column with 50% A plus 50% B Use HPLC gradient mobile phase at 1 mL/min, as in Table 1.23.

Solid-phase extraction column A 10 mL Certify solid-phase extraction (SPE) column (Varian), conditioned with 2 mL of methanol and 2 mL of buffer pH 6.0.

Assay

- To 1.0 mL serum or urine add 3.0 mL of 0.1 mol/L phosphate buffer pH 6 and 50 µL of the internal standard (25 µg/L of nalorphine in water).
- Vortex for a few seconds and centrifuge if not clear.
- Transfer the diluted mixture to the SPE column without vacuum.
- Wash the column without vacuum with 1.0 mL buffer pH 6.0.
- Wash with 1 mL of phosphate buffer pH 6–methanol (80 : 20), then with 1.0 mL of 1 mol/L acetic acid.
- Dry the SPE column for 2 min under maximal vacuum.
- Dry the wall of the SPE column.
- Wash the column under light vacuum with 1.0 mL hexane.
- Dry under maximal vacuum for 5 min.
- Centrifuge at 1500*g* for 5 min.
- Elute the column without vacuum with 1.2 mL of a mixture of hexane–ethyl acetate (80 : 20 v/v). This is fraction 1 (acid components).
- Elute the SPE column without vacuum with 2.4 mL (dichloromethane–propan-2-ol–25% ammonium hydroxide (80 : 20 : 2)) into a second test-tube. This is fraction 2 (basic extract).
- Dry both extracts under a stream of nitrogen.
- To fraction 1 add 100 µL of 33% (v/v) acetonitrile in water and vortex for 30 s.
- To fraction 2 add 100 µL of 0.025 mol/L of triethylammonium phosphate buffer pH 3; vortex for 30 s.
- Inject 60 µL of both extracts on to the HPLC column and start the gradient elution.

The LOQ of each substance is about 50 µg/L in urine with UV detection (Table 1.24), and much lower with fluorescence or electrochemical detection.

Detection of diuretics in urine by thin-layer chromatography

Reagents

- Ammonium amidosulfonate (5% w/v in water).
- Mandelin's reagent (50 mg ammonium monovanadate in 10 mL of 96% sulfuric acid; warm until a clear solution is obtained and use as spray reagent while still warm).
- Naphthylethylenediamine dihydrochloride (5% (w/v) in 100 mL of acetone–water, 3 : 1 (v/v)).
- Sodium 1,2-naphthaquinone-4-sulfonate solution (200 mg sodium 1,2-naphthaquinone-4-sulfonate in 15 mL water–ethanol, 1 : 1 (v/v)).
- Sodium hydroxide (0.1 mol/L and 6 mol/L).
- Sodium nitrite (1% w/v in water).
- Van Urk's reagent (100 mg 4-dimethylaminobenzaldehyde in 10 mL ethanol; add 1 mL 36% HCl; use freshly prepared).
- Sulfuric acid 9 mol/L (96% sulfuric acid–water, 1 : 1 (v/v)).

Table 1.24 HPLC retention time and detection data for drugs of abuse

Illicit substance or metabolite	*Retention time (min)*	*UV maximum (nm)*	*Electrochemical detection (0.85 V)*	*Fluorescence (λ_{ex} = 290 nm; λ_{em} = 340 nm)*
Morphine-3-glucuronide	1.81	212, 240, 283	−	−

Cannabinol	35.63	222, 285	+	−

[a]2-Ethylidene-1,5-dimethyl-3,3-diphenylpyrrolidine.
[b]11-Carboxytetrahydrocannabinol.

Reference mixture Use mixtures of 0.2% (w/v) in methanol of hydrochlorothiazide, sulfafurazole, phenacetin and prazepam.

Standards Prepare 0.1% (w/v) in methanol of the following standard solutions:

- I: amiloride, clopamide, quinethazone, and triamterene.
- II: chlorothiazide, etacrynic acid, indapamide and spironolactone.
- III: acetazolamide, chlorotalidone, furosemide and polythiazide.
- IV: bumetanide, cyclopenthiazide, hydrochlorothiazide, mefruside and canrenoate.

Reference mixture (R_f values) Hydrochlorothiazide $R_f = 0.11$, sulfafurazole $R_f = 0.33$, phenacetin $R_f = 0.52$ and prazepam $R_f = 0.72$ on TLC glass plates with silica-gel F254 indicator.

Method

- Consider first a deglucuronidation step (see Deglucuronidation).
- Solution A: mix 25 mL of urine with 1 mL of 36% (v/v) hydrochloric acid.
- Solution B: mix 25 mL of urine with 1 mL 6 mol/L sodium hydroxide.
- Transfer solutions A and B on to separate Extrelut-20 SPE columns.

- Wait for 5–10 min.
- Elute both columns twice with 20 mL of ethyl acetate.
- Transfer both extracts into a conical tube.
- Dry under vacuum.
- Re-dissolve the residue in 0.1 mL of methanol.

Chromatography Add standards, extracts and reference solution to a silica-gel F254 indicator on four TLC plates (20 × 20 cm) in the sequence:

- I, 5 µL
- II, 5 µL
- Urine, 2 µL
- Urine, 5 µL
- Urine, 10 µL
- III, 5 µL
- IV, 5 µL
- Reference, 2 µL.

Elution (for all four TLC plates)

- 20 min in chloroform–methanol (9 : 1 v/v).
- Dry with hot-air blower.

Detection A

- Observe under a UV-lamp at 254 and 366 nm; calculate the R_F values.

Detection B

- Plate I: spray with warm Mandelin's reagent.
- Plate II: spray with naphthylethylenediamine solution, then spray with 36% (v/v) hydrochloric acid.
- Heat at 100°C for 10 min.
- Spray with 9 mol/L sulfuric acid, and dry with hot-air blower.
- Spray with 1% sodium nitrite solution, and dry with a hot-air blower.
- Spray with 5% ammonium aminosulfonate, and dry a with hot-air blower.
- Spray with 0.5% naphthylethylenediamine, and dry with a hot-air blower.
- Plate III: spray with naphthoquinone sulfonate solution.
- Spray lightly with 0.1 mol/L sodium hydroxide, and dry with hot-air blower.
- Spray with sodium 1,2-naphthaquinone-4-sulfonate solution.
- Dry with a hot-air blower for 10 min until the standards become a clear orange.
- Plate IV: spray with Van Urk's reagent, and dry for 5 min at 100°C.

Observe each plate after each spraying procedure (Table 1.25 gives the data for diuretic drugs). Interference may arise from the presence of benzodiazepines, which are hydrolysed to aminobenzophenones that also undergo diazotisation. Sulfonamides are also detected by this procedure and give yellow colours with the Van Urk's reagent after heating.

Detection of laxatives in urine by thin-layer chromatography

Reference solutions

1. Dissolve 2 mg of phenolphthalein in 1 mL of ethanol and dilute to 10 mL with dichloromethane.
2. Dissolve 2 mg of danthron in 10 mL of dichloromethane.
3. Dissolve 2 mg of rhein in 10 mL of dichloromethane. (A method for preparing rhein from sennoside A or B has been described by Lemli (1965).)
4. Bisacodyl and oxyphenisatin metabolites:
   - — Dissolve 2 mg of each substance in 2 mL of ethanol.
   - — Add 20 µL of 6 mol/L sodium hydroxide, heat for 30 min at 70°C.
   - — Cool, neutralise with 20 µL of 6 mol/L hydrochloric acid.
   - — Add 8 mL of dichloromethane and 2 mg of the parent substance to each corresponding solution.

The precipitate of sodium chloride that forms on neutralisation does not interfere with the chromatography.

Method Enzymatic hydrolysis of the glucuronide metabolites is essential before extraction.

Assay

- Adjust 20 mL of urine to pH 5 with 0.1 mol/L hydrochloric acid.
- Add 2 mL of acetate buffer (pH 5), and 10 000 units of mixed glucuronidase/sulfatase (from *Helix pomatia*).
- Heat in a water-bath at 60°C for 2 h.
- Pour the urine on to an unbuffered Extrelut column (see TLC diuretics above) and leave for 2–3 min to allow the sample to soak into the column.
- Place a 50 mL test-tube under the column outlet and pour 20 mL of a mixture of dichloromethane–isopropyl alcohol (9 : 1 v/v) on to the column.
- When the elution is complete, insert into the top of the column a hollow rubber stopper connected by a rubber tube to a pressure bulb.
- Apply gentle pressure to discharge residual solvent.
- Place the tube that contains the eluate in a beaker of hot water.
- Evaporate the extract to dryness under a stream of nitrogen.
- Dissolve the residue in 100 µL of dichloromethane just prior to examination by the following TLC systems.

System A

- High-performance silica gel (10 × 20 cm) with fluorescent indicator and concentration zone.
- Mobile phase: *m*-xylene–isobutyl methyl ketone–methanol (10 : 10 : 1).

System B

- As used for system A.
- Mobile phase: hexane–toluene–acetic acid (3 : 1 : 1).

Table 1.25 Thin-layer chromatographic data for diuretic drugs

[a] T = tailing.
[b] + = fluorescence.
[c] At 366 nm strong fluorescence (yellow–green).

Assay

- Score two plates vertically to divide them into two (10 × 10 cm) zones.
- Score a horizontal line parallel to the concentration zone at a distance of 5 cm.
- To one plate apply 5 µL aliquots of the reference solutions of bisacodyl, danthron, oxyphenisatin and phenolphthalein to each zone, together with a 3 µL and a 10 µL aliquot of the urine extract, also to each zone.
- Develop the plate using system A.
- To the second plate apply 5 µL aliquots of the reference solutions of danthron, phenolphthalein and rhein to each zone, together with a 3 µL and a 10 µL aliquot of the urine extract. Develop this plate using system B.
- Remove the plates and dry under a hot-air blower.

Detection

- Danthron is visible as a yellow spot on the system A plate, or as an orange spot on the system B plate. Examine the plates under UV light at 254 and 366 nm. All the substances absorb at 254 nm; danthron and rhein give an orange fluorescence at 366 nm.
- Spray the left-hand side of each plate with 6 mol/L sodium hydroxide. Bisacodyl and its hydrolysis products give violet spots; oxyphenisatin appears as three faint pink spots; phenolphthalein and rhein give a violet and a red spot, respectively.
- Spray the left-hand side of the system A plate with a freshly prepared 1% (w/v) solution of potassium ferricyanide.
- Heat both plates to 100°C and spray the right-hand side immediately with Mandelin's reagent (see TLC of diuretics above).

The R_f values and colour reactions of these compounds and their hydrolysis products are given in Table 1.26.

Detection of diuretics and laxatives in urine by HPLC

Apparatus

- Gradient HPLC with DAD ($\lambda = 250$ nm; 0.08 AUFS; ABS mode: 2) and optionally an electrochemical detector; 0.85 V/Ox, ATT = 128 and a fluorescence detector, sensitivity low; $\lambda_{ex} = 290$ nm and $\lambda_{em} = 340$ nm; range −25 to + 250 mV.
- Pre-column: Lichrospher 60, RP-select B, 5 µm (Merck no. 1.50963).
- Column: Lichrospher 60, RP-select B (125 × 4.0 mm, 5 µm, Merck no. 1.50981).
- Mobile phase A: 0.025 mol/L triethylammonium phosphate buffer (pH 3.0).
- Mobile phase B: acetonitrile; flow rate 1.0 mL/min.

The HPLC gradient programme is given in Table 1.23.

Reagents

- Acetonitrile
- Dichloromethane
- Disodium hydrogenphosphate
- Ethyl acetate
- Potassium hydrogenphosphate
- Sodium hydroxide
- 1 mol/L triethylammonium phosphate
- 37% hydrochloric acid
- 0.1 mol/L phosphate buffer pH 6.0 (13.6 g potassium dihydrogenphosphate in water to 1 L, add sufficient 1 mol/L potassium hydroxide to pH 6.0)
- 2 mol/L sodium hydroxide solution (80 g sodium hydroxide per litre of water)
- Phosphate-buffered saline (PBS) pH 7.2 (1.41 g disodium hydrogenphosphate dihydrate and 0.27 g potassium dihydrogenphosphate plus 8.75 g sodium chloride in sufficient water to 1 L, pH 7.2)
- 0.025 mol/L triethylammonium phosphate buffer pH 3.0
- 2 mol/L hydrochloric acid
- Beta-glucuronidase/arylsulfatase.

Method

- Pipette into each of two test-tubes 1.0 mL standard solution I and into two other test-tubes 1.0 mL of standard solution II (see Detection of diuretics in urine by thin-layer chromatography for preparation of standard solutions).
- Add to each tube 1.0 mL of phosphate buffer pH 6.0.
- Pipette into each of two other test-tubes 1.0 mL of the patient's urine.
- Add 1.0 mL phosphate buffer pH 6.0 and beta-glucuronidase–arylsulfatase (75 : 1).
- Incubate at 37°C for 14 h.
- Add to one series of test-tubes (with standard solutions I and II and patient's urine) 100 µL of 2 mol/L hydrochloric acid.
- Add to the other series 100 µL of 2 mol/L sodium hydroxide.
- Check the pH of both with pH test-paper; one tube has to be acidic and one basic. (Note: chrysophanic acid and phenolphthalein colour the solution reddish.)
- Add to both tubes 5 mL ethyl acetate.
- Shake for 20 min in a rotary mixer and allow to stand for 5 min; centrifuge for 5 min at 1500*g*.
- Transfer both organic layers into two clean tubes (this is easier if the tubes are first put into a freezing bath at −40°C for a short time).
- Add to both tubes 5 mL of PBS buffer pH 7.2.
- Mix for 5 min in a rotary mixer, stand for 5 min; centrifuge for 5 min at 1500*g*.
- Transfer both organic phases into two clean test-tubes.
- Dry under stream of nitrogen at 40°C; add to the extract 150 µL 20% (v/v) acetonitrile in triethylammonium phosphate buffer (pH 3).
- Vortex for 1 min and centrifuge for 5 min at 1500*g*.
- Inject 20 µL onto the HPLC column.

Always run a blank gradient with 65 µL triethylammonium phosphate buffer before the patient's serum or urine extracts. Table 1.27 gives HPLC retention time and detection data for diuretics and laxatives.

GC systems for the detection of diuretics and laxatives are described in Chapter 40.

Interpretation and advice

An experienced hospital toxicologist is expected not only to provide valid analytical data but also to assist the clinician in relating the findings to a particular case of poisoning. This may be quite straightforward

Table 1.26 Thin-layer chromatographic data for laxatives and their hydrolysis products

Substance	*System A R_f relative to phenolphthalein*	*System B R_f relative to rhein*	*Visible*	*Colour after spray with Mandelin's*	*Colour with NaOH*

[a]Standard mix (5 mg of each substance in water–methanol = 1 : 1 (keep at −80°C).
[b]Chrysophanic acid is the major metabolite in urine of several anthraquinone stimulant laxatives, such as senna, aloes, danthron, rhubarb (*Rhei radix*) and buckthorn (*Rhamnus*).

when the presence of a high concentration of a drug or poison is consistent with the patient's symptoms and the circumstantial evidence. In other cases, factors such as the patient's age, sex, health and previous exposure must be taken into account. For example, addicted patients may have developed a tolerance to extremely high concentrations of opiates, benzodiazepines and ethanol, and exhibit relatively mild toxicity. An elderly invalid with respiratory problems is far more susceptible to an overdose of a central depressant drug than a healthy young adult, and so may have life-threatening symptoms with only moderate plasma concentrations. The route of administration (inhalation, oral ingestion, intravenous injection, etc.) can have a very significant effect on the subsequent toxicity, which must also be taken into account when interpreting plasma concentrations (see Chapter 24). Mixed overdoses of drugs and alcohol are common, and synergistic reactions can confuse the clinical picture. The hospital toxicologist must therefore develop a good background knowledge of drug interactions. However, there are situations in which the analytical results fail to offer an adequate explanation. This can result from mistakes in sample collection; for example, blood samples taken from an arm being used to infuse a therapeutic agent may have very high concentrations of that agent because of contamination. The ingestion of large amounts of sustained-release preparations can result in disproportionately low blood concentrations. Systems for collecting and referring samples to the laboratory can occasionally break down and the samples received and analysed (with negative results) may be from the wrong patient. Negative results on the correct samples must also be interpreted with caution. The patient may not be poisoned after all and the clinical effects may be caused by an organic disorder. Alternatively, the toxic agent responsible is not detected, which may instigate a wider analytical search or application of a more sensitive assay. A list of therapeutic and toxic concentration ranges for drugs is given in Table 1.28. The hospital toxicologist may also be asked to apply toxicokinetic principles (see Chapter 24) to the quantitative data to answer questions raised by the clinician; examples in which this is relevant are described below.

How much (A) of the poison is still in the body at a serum concentration C?

$$A = C \times V_d(\text{L/kg body mass}) \times \text{body mass(kg)}$$

where V_d is the volume of distribution.

How long will it take for a measured serum concentration (C_o) to decrease to below the toxic concentration (C_{tox})?

- $C_{tox} = C_o \times e^{-k_{el}t}$
- k_{el} is the elimination constant, $0.693/t_{1/2}$.
- If the elimination is not saturated, the kinetic parameter k_{el} of the patient can be calculated as follows, using two serum concentrations measured during the elimination phase:
  - Elimination constant $k = (\ln C_1 - \ln C_2)/(t_2 - t_1)$
  - $t_{1/2} = (\ln 2)/k = 0.69/k$
  - Clearance $Cl = kV_d$, where V_d is volume of distribution.

What is the efficiency of an extracorporeal elimination treatment?
Severe cases of intoxication sometimes require extracorporeal elimination treatments, such as haemodialysis or haemoperfusion. For the clinician it is important to have an estimate of how many hours the dialysis or haemoperfusion has to be continued and when the next blood

[d]Case report.

sample should be withdrawn. The efficiency of haemodialysis (or haemoperfusion) can be determined as follows:

- Measure the blood flow rate (mL/min) through the artificial kidney.
- As the drug levels are measured in plasma and the drug is cleared from the plasma, the blood flow rate has to be converted into the plasma flow rate [blood flow rate × (1 − haematocrit)].
- Measure the drug plasma levels in samples taken before (C_{bef}) and after (C_{aft}) the artificial kidney.
- $[(C_{bef} - C_{aft})/C_{bef}] \times$ blood flow $\times (1 -$ haematocrit$) =$ clearance (mL/min).
- This extracorporeal clearance has to be added to the physiological clearance of the poisoned patient: $(Cl_{own} + Cl_{extra} = Cl_{total})$.
- The half-life time during extracorporal clearance is $(\ln 2)/k = 0.69V_d/Cl_{total}$.

As an alternative to these formulae, the toxicologist can use a commercially available toxicokinetic or pharmacokinetic software program. The pharmacokinetics software package MW/Pharm (Mediware, University Groningen, The Netherlands) is very suitable and flexible for both therapeutic drug monitoring (TDM) and toxicological calculations. AutoKinetic by SW Tönnes, Frankfurt, Germany, is a less comprehensive program that uses Excel. A method for calculating the dialysis time needed to alleviate cases of alcohol poisoning has been described by Hirsch *et al.* (2001)

Reporting results

Reports (verbal or written) should be submitted to the clinician by an authorised toxicologist who is fully responsible for the results and the advice provided. If the methods used were not validated, this should be indicated to the clinician so that he or she can judge the possible margin of error.

Sources of information

The practice of hospital toxicology requires knowledge and experience of pharmacotherapy, bioanalyses, good laboratory practice, pharmacokinetics, toxicokinetics, pharmacodynamics, basic toxicology,

clinical toxicology, forensic toxicology, chemistry, and indications and contraindications of the different treatments. Numerous sources of information are available and those listed in Further reading are among the most useful. It is advisable to consult several sources before giving advice.

Books that deal specifically with poisoning by industrial chemicals, household products and natural toxins are also useful sources of reference.

Therapeutic and toxic concentrations

Table 1.28 lists the therapeutic and toxic serum concentration ranges for a large number of drugs. Therapeutic serum levels are the steady-state concentrations that need to be reached for the drug to exert a significant clinical benefit without unacceptable side-effects. Where concentrations are shown in brackets this refers to extreme, but still acceptable, values. Toxic serum levels are concentrations above which unacceptable, concentration-dependent, toxic effects may appear. The toxic levels are expressed as a range, which means that the toxic effects may start somewhere in this range, depending on the patient and his or her clinical history. It should be taken into account that these values are never static and may change with advancing knowledge or with other (therapeutic) uses of the drug. Toxic and, where applicable, normal ranges are also given for substances that have no therapeutic use. It is emphasised that these data are intended merely as guidelines and that there is wide individual susceptibility towards the effects of drugs and poisons. In other words, the physician should treat the patient according to his or her clinical signs and not the analytical results. The University Medical Center of Groningen (The Netherlands) provides a list with all their determinations in human matrices, including clinical chemistry, TDM and kinetic parameters. See http://www.bioanalysis.umcg.nl/.

CHAPTER

2 Therapeutic Drug Monitoring

M Hallworth

Introduction

Therapeutic drug monitoring (TDM) may be defined as the use of drug or metabolite monitoring in body fluids as an aid to the management of therapy (the term therapeutic drug *management* is now also employed as an alternative description). Since antiquity, physicians have adjusted the dose of drugs according to the characteristics of the individual being treated and the response obtained, and this practice is easiest when the response is readily measurable, either clinically (e.g. in the case of antihypertensive drugs, analgesics or hypnotics) or with an appropriate laboratory marker (e.g. in the case of anticoagulants, hypoglycaemic agents or lipid-lowering drugs). Dose adjustment is much more difficult (but no less necessary) when drug response cannot be rapidly assessed clinically (e.g. in the prophylaxis of seizures or mania), or when toxic effects cannot be detected until severe or irreversible (e.g. nephrotoxicity or ototoxicity). Provided that certain basic conditions are satisfied and appropriate analytical methods are available, the plasma concentration of a drug or metabolite may serve as an effective and clinically useful surrogate marker of response in these cases. However, it must be stressed that TDM is not simply the provision of an analytical result but a process that begins with a clinical question and continues by devising a sampling strategy to answer that question, determining one or more drug concentrations using a suitable method and interpreting the results appropriately.

TDM has been practised routinely in clinical laboratories since the mid-1970s, but the scientific foundations of the subject date back to the 1940s, when Marshall first tested the concept that the activity of a drug is dependent on its plasma concentration. In 1960, Buchthal showed a relationship between seizure control and plasma phenytoin concentration in patients being treated for epilepsy, and Baastrup and Schou described the plasma concentration–pharmacological effect relationship for lithium in 1967. This work coincided with the rise of clinical pharmacology during the 1960s and the demonstration of the fundamental concepts of pharmacokinetics and pharmacodynamics, which underpin the interpretation of drug concentration measurements.

Fundamental concepts

Different patients need different doses of drug to produce optimum pharmacological effect because individuals vary widely in the way that they absorb and dispose of drugs, and in the way that they respond to drugs. The steps between prescribing a drug to a patient and obtaining the desired response are summarised in Fig. 2.1, which also indicates the distinction between pharmacokinetics and pharmacodynamics. *Pharmacokinetics* describes the way in which a patient's system handles drugs, and encompasses uptake of drugs into the body, distribution throughout body compartments, and the metabolism and elimination of drugs (and their metabolites) from the body. These processes are described in more detail in Chapter 24.

Pharmacodynamics is concerned with the interaction of pharmacologically active substances with target sites (receptors), and the biochemical and physiological consequences of these actions. For example, the effects of a given tissue concentration of digoxin on cardiac muscle are modified by the local potassium concentration, which affects the concentration–response relationship and means that plasma drug concentrations are not the sole determinant of response. In simple terms, pharmacokinetics may be said to be the study of what patients do to drugs, and pharmacodynamics of what drugs do to patients.

If plasma drug concentrations are to be a useful surrogate marker of response, two premises must be satisfied. The first is that the drug concentration in plasma accurately reflects the concentration at the site of action (the receptor), which may be located in the plasma compartment itself or may be deep in target tissue. This assumption is true for many drugs, but is far from universal – for example, the blood–brain barrier may mean that plasma concentrations of drugs that act on the brain are unrepresentative of concentrations at the site of action, and adequate concentrations of an antibiotic in the blood may not guarantee effective concentrations at the centre of a poorly perfused abscess. There may also be significant time differences between peak concentrations of a drug in plasma and maximum penetration to the receptor, which complicates the interpretation of plasma concentration measurements. Further, the total (free plus protein-bound) concentration of drug in plasma may not reflect the pharmacologically active free-drug concentration, especially for those drugs that are strongly bound by plasma proteins (see below).

The second premise is that drug concentration at the receptor should provide an accurate indication of pharmacological response. This may not be true if other drugs interact with the receptor, if receptor numbers are reduced (e.g. in the phenomenon of tolerance when patients have been on a drug for some time), or if the coupling of receptors to signal transduction pathways is modified.

Criteria for assessing the clinical value of drug monitoring

The essential criteria for TDM to be clinically useful for a particular drug may therefore be developed and summarised as:

- Poor correlation between the dose given and the plasma concentration obtained in different patients (wide inter-individual pharmacokinetic variability). Clearly, if the dose given is an effective predictor of plasma concentration in all patients, then measuring an individual's plasma concentration is superfluous. Adherence testing (determining whether patients actually take their drugs) may be a useful adjunct to TDM programmes (see below), but is unlikely to justify such a programme in the absence of other indications for monitoring.
- Good correlation between plasma concentration and pharmacological effect in different patients (low inter-individual pharmacodynamic variability). If plasma concentration measurements do not give accurate information about response, they are at best useless and at worst misleading. So both the premises stated above must be satisfied (plasma drug concentration predicts receptor concentration and receptor drug concentration predicts response). Active metabolites are generally undesirable as they contribute to the effect but make a variable (or zero) contribution to the measured concentration, depending on the assay system; for example, a metabolite may have 10% of the biological activity of the parent drug but show 100% cross-reactivity in an immunoassay. This criterion also normally requires that the action of the drug at the receptor site be essentially reversible. If this is not the case, and the drug binds irreversibly to the receptor, the pharmacodynamic half-life (or duration of effect) may be markedly longer than the pharmacokinetic half-life (or length of time that the drug can be detected in the circulation). For example, the anticonvulsant vigabatrin acts as a suicide inhibitor for the enzyme γ-aminobutyric acid transaminase and irreversibly inactivates the enzyme. In this situation, the drug may not develop its

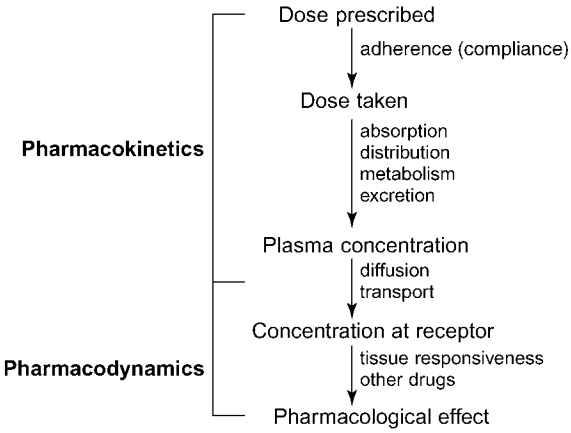

Figure 2.1 Processes involved in drug action.

maximal clinical effect until days or weeks after dosing has been started, and it may still be exerting an effect when no drug can be detected in the plasma. It is difficult to argue that TDM has a useful contribution to make in these circumstances. Exceptions to this general rule are certain anticancer agents where, even though the action of the drug is irreversible, an index of the body's total exposure to the drug can be used to predict subsequent response.

- TDM is clinically relevant only for drugs that show significant toxic or undesirable effects at plasma concentrations only slightly above those required for useful effects. These drugs are described as having a low therapeutic index, defined as the mean toxic dose divided by the mean effective dose. If there is a wide margin between effective concentrations and undesirable effects, as is the case for penicillin, effective therapy may be achieved by giving the drug to all patients in large excess, with no need for individualisation of therapy. In contrast, the aminoglycoside antibiotics have relatively narrow margins between effective concentrations and those that produce unacceptable toxicity, and concentration monitoring has an essential role in ensuring maximal effect with minimal toxicity.
- Similarly, TDM is redundant for drugs where there is a better clinical marker of both the desired effect and any associated adverse effects, for example blood pressure, plasma glucose concentration, prothrombin time or plasma creatinine concentration. Plasma drug concentrations have little to offer in this situation, except in the elucidation of rare cases where a high dose of drug fails to produce the desired effect, when TDM may help differentiation between poor adherence (non-compliance), poor drug absorption, receptor dysfunction or the use of the wrong drug for the situation.

Application of these criteria results in a relatively short list of drugs for which concentration monitoring has a proved clinical role (those marked with +++ in Table 2.1). Measurement of other drugs may contribute in certain cases or in particular clinical circumstances, but cannot be said to be generally useful in dosage optimisation (marked as ++ in Table 2.1). Concentration monitoring has not been shown to be applicable to the drugs marked as ± in Table 2.1.

Indications for drug monitoring

The main reasons for measuring drugs in plasma may be summarised as:

- To ensure that sufficient drug is reaching the drug receptor to produce the desired response (which may be delayed in onset, e.g. for antidepressant drugs)
- To ensure that drug (or metabolite) concentrations are not so high as to produce signs or symptoms of toxicity
- To guide dosage adjustment in clinical situations where pharmacokinetic parameters are changing rapidly (e.g. in neonates or in patients with changing hepatic or renal function)
- As an aid to defining the pharmacokinetic and pharmacodynamic parameters of new drugs.

A fifth indication, the assessment of adherence (compliance), remains a matter of some controversy. Clearly, if the assessment of adherence is accepted as a valid indication for concentration monitoring, it could be necessary to provide an analytical service for virtually every drug in the pharmacopoeia, at enormous cost. Furthermore, although gross non-adherence to a regime is associated with very low or undetectable concentrations of drug in blood, variable adherence can be difficult or impossible to detect, and the variability between patients that makes dosage individualisation necessary also implies that surprisingly low plasma concentrations for a given dose of drug are not necessarily due to poor adherence. Adherence can be assessed in other ways, for example by tablet counting, by supervision of medication or by the use of carefully designed questions that are non-judgmental ('How often do you forget to take your tablets?'). Assessment of adherence is thus not a primary indication for measuring plasma drug concentrations, although, if an analytical service is provided for other reasons, concentration monitoring may have a role for patients with poor symptom control who deny poor adherence despite careful questioning and reinforcement.

Even if concentration measurements of a drug have been shown to be of value, this does not mean that they are required in all situations in all patients who receive the drug. Indeed, indiscriminate use of TDM services has done much to erode the cost-effectiveness of the process and has frequently harmed rather than helped patient care. As with any laboratory test, a clear clinical question should be formulated before recourse is made to concentration measurements. The question helps to decide what measurements should be made and how the results can be interpreted. Examples of suitable questions might be 'My patient is not responding to therapy – could this be because of inadequate plasma concentration or is a different drug required?' or 'Could this patient's symptoms be explained by drug toxicity?'. When requesting physicians lose sight of this fundamental principle, and do tests as 'routine', answers without questions are obtained. The dangers of this are well illustrated by the all too frequent example of a patient on anticonvulsant therapy for epilepsy who has a 'routine' blood test done in primary care, with the result found to be significantly above the target or 'therapeutic' range for the drug. The laboratory may then telephone the result as a matter of urgency and cause an inexperienced physician to react with an inappropriate dose reduction, which precipitates seizures in a patient who was perfectly well controlled on the original dose.

Analytical requirements

Sample

Blood, urine, saliva and hair may be considered as possible samples for TDM analyses. By its very nature, hair is a retrospective medium which can give an indication of drug concentrations in the weeks or months preceding sampling. This is a valuable property in the field of detection of drugs of abuse (see Chapter 19), but it has little relevance to individualisation of therapy. Applications of hair analysis to TDM are therefore limited at present, although there have been studies on long-term monitoring of antipsychotic drugs, such as haloperidol, in psychiatric in-patients. Similarly, the variation of drug concentrations in urine brought about by factors such as the state of hydration and urinary pH means that there are no applications in TDM in which urine is preferred to plasma as a sample matrix.

Plasma (or serum) is normally the preferred sample for TDM analyses, but has the disadvantage that it requires an invasive procedure for collection (venepuncture). Some drugs (e.g. many immunosuppressants) are concentrated in the red cells and so whole blood (with an appropriate anticoagulant – e.g. ethylenediamine tetraacetic acid (EDTA)) is more suitable than plasma. When plasma samples are used, care must be taken with anticoagulants and the use of gel separation barriers, both of which can cause interference with some drugs or assay systems. However, in the absence of such effects there are no clinically significant differences between serum and plasma and either may be used.

Table 2.1 Main drugs subject to therapeutic monitoring

Drug	*Notes*	*Suggested assay method (* = commercial kits available)*	*Plasma concentrations associated with optimum response*	*Clinical value of TDM*
Amikacin	Monitoring essential in ensuring efficacy with minimum toxicity.	1. Immunoassay* 2. GLC (Isoherranen, Soback 1999; Mayhew, Gorbach 1978) 3. HPLC (Isoherranen, Soback 1999; Soltes 1999)	Vary with dose schedule.	+++
Amiodarone	Effects may last months after drug stopped (elimination half-life 50 days). Active metabolite (desethylamiodarone, DEA).	1. HPLC (Lesne, Pellegrin 1987) 2. LC-MS (Kollroser, Schober 2002) 3. Capillary electrophoresis (CE) (Zhang *et al.* 1996)	0.5–2.5 mg/L (0.7–3.7 μmol/L) (amiodarone + DEA)	++
Amitriptyline	Large genetic differences in rate of metabolism. Some evidence for concentration–effect relationship. Metabolised to nortriptyline.	1. GLC (Ulrich *et al.* 1996) 2. HPLC (el Yazigi, Raines 1993; Kabra *et al.* 1981) 3. LC-MS (Kirchherr, Kühn-Velten 2006; Sauvage *et al.* 2006)	100–250 μg/L (amitriptyline + nortriptyline)	++
Antiretroviral drugs (protease inhibitors [-avir suffix]) and non-nucleoside reverse transcriptase inhibitors (NNRTIs) – efavirenz, nevirapine	Large inter-individual variability in drug concentrations. Appropriate TDM may have a role in maximising efficacy and reducing toxicity.	1. HPLC (Titier *et al.* 2002) 2. LC-MS (D'Avolio *et al.* 2007; Ghoshal, Soldin 2003)	Suggested minimum target trough concentrations: amprenavir 400 μg/L, indinavir 100 μg/L, lopinavir 1000 μg/L, nelfinavir 800 μg/L, ritonavir 2100 μg/L, saquinavir 100 μg/L, efavirenz 1000 μg/L, nevirapine 3400 μg/L	++
Amprenavir	See Antiretroviral drugs			
Caffeine	More predictable concentration–effect relationship than for theophylline. Low toxicity.	1. Immunoassay* 2. HPLC (Dobrocky *et al.* 1994; Meatherall, Ford 1988; Schreiber-Deturmeny, Bruguerolle 1996) 3. LC-MS (Zhang *et al.* 2008)	5–20 mg/L (25–100 μmol/L) (in neonatal apnoea)	++
Carbamazepine	Active metabolite present (carbamazepine 10,11-epoxide). The drug induces its own metabolism, so levels fall after a few weeks on the same dose.	1. Immunoassay* 2. HPLC (Kouno *et al.* 1993; Matar *et al.* 1999; Meatherall, Ford 1988; Pienimaki *et al.* 1995; Romanyshyn *et al.* 1994) 3. GLC (Burke, Thenot 1985; Chen, Khayam-Bashi 1991; Kumps 1982) 4. GC-MS (Speed *et al.* 2000) 5. LC-MS (Subramanian *et al.* 2008) 6. Electrokinetic chromatography (Pucci, Raggi 2005)	4–12 mg/L (17–51 μmol/L)	+++
Chloramphenicol	Clearance reduced by hepatic or renal dysfunction. Potentially fatal concentration-dependent toxic reaction in neonates with immature hepatic metabolism.	1. HPLC (Davidson, Fitzpatrick 1986; Meatherall, Ford 1988)	10–25 mg/L (31–77 μmol/L)	++
Chlorpromazine	Extensively metabolised, some metabolites have pharmacological activity. TDM rarely used.	1. HPLC (Mercolini *et al.* 2007) 2. LC-MS(-MS) (Kirchherr, Kühn-Velten 2006)	30–500 μg/L (94–1600 nmol/L)	±
Ciclosporin	Complex pharmacokinetics and distribution. Monitoring useful in differentiating underdosage and toxicity	1. Immunoassay* (Schutz *et al.* 1998) 2. HPLC (Holt, Johnston 1995) 3. LC-MS (Keevil *et al.* 2002; Poquette *et al.* 2005)	Vary with type of transplant and time post-transplantation. Whole-blood concentrations (EDTA anticoagulant) are determined.	+++
Clobazam	Value of monitoring limited by development of tolerance to drug. Active metabolite (*N*-desmethylclobazam) present in higher concentrations than parent drug.	1. HPLC (Kunicki 2001) 2. GLC (LeGatt, McIntosh 1993)	—	±
Clonazepam	Value of monitoring limited by development of tolerance to drug.	1. HPLC (de Carvalho, Lanchote 1991; Le Guellec *et al.* 1998) 2. GLC (de Carvalho, Lanchote 1991) 3. GC-MS (Song *et al.* 1996) 4. LC-MS (Marin *et al.* 2008)	15–60 μg/L (50–190 nmol/L)	±

table continued

Table 2.1 continued

Drug	*Notes*	*Suggested assay method (* = commercial kits available)*	*Plasma concentrations associated with optimum response*	*Clinical value of TDM*
Clozapine	Wide inter-patient pharmacokinetic variability; problems with toxicity. Dose–concentration relationship for therapeutic effect and some side-effects. Full effect may take weeks to develop.	1. HPLC (Weigmann *et al.* 1997; Wilhelm, Kemper 1990) 2. LC-MS (Kirchherr, Kühn-Velten 2006; Niederlander *et al.* 2006)	Target clozapine concentration: 350 µg/L (1100 µmol/L) Clozapine : norclozapine ratio at steady state is approximately 1.32	++
Darunavir	See Antiretroviral drugs			
Desipramine	Curvilinear concentration–response relationship. Concentrations above and below range are associated with lower efficacy.	1. HPLC (Chen *et al.* 1997; el Yazigi, Raines 1993; Kabra *et al.* 1981; Yoo *et al.* 1995) 2. GC-MS (Pommier *et al.* 1997) 3. LC-MS (Kirchherr, Kühn-Velten 2006)	100–160 µg/L (380–600 nmol/L)	++
Diazepam	No defined therapeutic range – tolerance develops rapidly.	1. GLC (Karnes *et al.* 1988) 2. GC-MS (Kudo *et al.* 1988) 3. HPLC (Azzam *et al.* 1998) 4. LC-MS (Marin *et al.* 2008)	-	±
Digitoxin	See Digoxin	1. Immunoassay* 2. LC-MS (Tracqui *et al.* 1997)	12–25 µg/L (15–33 nmol/L)	++
Digoxin	Elimination prolonged in renal failure. Significant pharmacodynamic variability.	1. Immunoassay* (Wahyono *et al.* 1991) 2. HPLC (Tzou *et al.* 1995) 3. LC-MS (Tracqui *et al.* 1997)	0.8–2.0 µg/L (1.0–2.6 nmol/L) In heart failure: 0.5–1.0 µg/L (0.6–1.3 nmol/L)	++
Disopyramide	Concentration-dependent protein binding complicates concentration–effect relationship.	1. Immunoassay* 2. GLC (Kapil *et al.* 1984; Vasiliades *et al.* 1979a) 3. HPLC (Mayer *et al.* 1991; Vasiliades *et al.* 1979a)	2.0–5.0 mg/L (5.9–14.7 µmol/L)	++
Doxepin	Large genetic differences in rate of metabolism. Some evidence for concentration–effect relationship. Metabolised to desmethyldoxepin (active).	1. GLC (Vasiliades *et al.* 1979b) 2. HPLC (Kabra *et al.* 1981) 3. LC-MS (Badenhorst *et al.* 2000; Kirchherr, Kühn-Velten 2006; Sauvage *et al.* 2006)	50–250 µg/L (as doxepin + metabolite) (180–900 nmol/L)	++
Efavirenz	See Antiretroviral drugs			
Ethosuximide	Poor relationship between dose and plasma concentration, but effect usually quantifiable by EEG monitoring.	1. HPLC (Matar *et al.* 1999; Meatherall, Ford 1988) 2. GLC (Grgurinovich, Miners 1980; Kumps 1982; Riva *et al.* 1982) 3. GC-MS (Speed *et al.* 2000)	40–100 mg/L (280–710 µmol/L)	++
Everolimus	Analogue of sirolimus.	1. Immunoassay* 2. LC-MS (Korecka *et al.* 2006)	3–8 µg/L (3.1–8.3 nmol/L)	++
Felbamate	Risk of aplastic anaemia and hepatic failure. Interactions with other anticonvulsants.	1. HPLC (Tang 2008) 2. Electrokinetic chromatography (Pucci, Raggi 2005) 3. LC-MS (Thompson *et al.* 1999)	20–60 mg/L (85–250 µmol/L)	±
Flecainide	Elimination prolonged in renal failure. Significant pharmacokinetic variability (CYP2D6 polymorphism).	1. Immunoassay* 2. HPLC (Wilson *et al.* 1998) 3. LC-MS (Breindahl 2000) 4. GLC (Stas *et al.* 1989)	0.2–1.0 mg/L (0.4–2.1 µmol/L)	++
Flucytosine	Wide pharmacokinetic variability. Serum concentrations relate well to efficacy and toxicity. Monitoring may reduce risk of toxicity.	1. HPLC (Bury *et al.* 1979)	2 h (peak) concentration >25 and <100 mg/L	++
Fluoxetine	Long half-life. Active metabolite norfluoxetine.	1. LC-MS (Kirchherr, Kühn-Velten 2006; Sauvage *et al.* 2006)	150–800 µg/L (fluoxetine + norfluoxetine)	±
Gabapentin	Good relationship between plasma concentration and dose, but no relationship between plasma and CSF concentrations. Simple pharmacokinetics, short half-life.	1. HPLC (Ratnaraj, Patsalos 1998) 2. LC-MS (Ifa *et al.* 2001) 3. GC-MS (Borrey *et al.* 2005)	2–20 mg/L (12–120 µmol.L) suggested	±

Table 2.1 continued

Drug	*Notes*	*Suggested assay method (* = commercial kits available)*	*Plasma concentrations associated with optimum response*	*Clinical value of TDM*
Gentamicin	Monitoring essential in ensuring maximum effect with minimum toxicity. Once-daily dosing requires different target ranges.	1. Immunoassay* 2. HPLC (Adams *et al.* 1998; Delaney *et al.* 1982; Isoherranen, Soback 1999; Soltes 1999; Yusuf *et al.* 1999) 3. GLC (Isoherranen, Soback 1999; Mayhew, Gorbach 1978) 4. GC-MS (Preu *et al.* 1998)	Vary with dose schedule.	+++
Haloperidol	Large genetic differences in rate of metabolism (CYP2D6 substrate). Monitoring is useful in assessing phenotype and adjusting therapy.	1. HPLC (Angelo, Petersen 2001; Wilhelm, Kemper 1990) 2. LC-MS (Hoja *et al.* 1997) 3. GLC (Tyndale, Inaba 1990)	5–15 μg/L (13–40 nmol/L)	++
Imipramine	Large genetic differences in rate of metabolism. Plasma concentrations correlate with clinical improvement.	1. GC-MS (Pommier *et al.* 1997) 2. HPLC (Chen *et al.* 1997; el Yazigi, Raines 1993; Kabra *et al.* 1981; Yoo *et al.* 1995) 3. LC-MS (Kirchherr, Kühn-Velten 2006; Sauvage *et al.* 2006)	150–300 μg/L (imipramine + desipramine)	++
Itraconazole	Variable absorption. Monitoring is advisable when the drug is used for prolonged periods.	1. HPLC (Uno *et al.* 2006) 2. LC-MS (Vogeser *et al.* 2003)	Trough concentration >0.5–1.0 mg/L	++
Indinavir	See Antiretroviral drugs			
Kanamycin	See Amikacin	1. Immunoassay* 2. GLC (Isoherranen, Soback 1999) 3. HPLC (Adams *et al.* 1997; Isoherranen, Soback 1999; Kubo *et al.* 1985; Soltes 1999) 4. GC-MS (Preu *et al.* 1998)	Vary with dose schedule	+++
Lamotrigine	Wide range of concentrations associated with seizure control. Complex interactions with other anticonvulsants.	1. HPLC (Croci *et al.* 2001; Greiner-Sosanko *et al.* 2007; Matar *et al.* 1999) 2. LC-MS (Subramanian *et al.* 2008) 3. Electrokinetic chromatography (Pucci, Raggi 2005)	1–15 mg/L (?) (4–60 μmol/L)	++
Levetiracetam	Good safety profile, no evidence to justify monitoring.	1. HPLC (Contin *et al.* 2008) 2. GC (Greiner-Sosanko *et al.* 2007) 3. LC-MS (Guo *et al.* 2007) 4. Electrokinetic chromatography (Pucci, Raggi 2005)	6–20 mg/L (35–118 μmol/L) suggested	±
Lidocaine	Good concentration–effect relationship. Active metabolite complicates interpretation.	1. GLC (Willis *et al.* 1984) 2. HPLC (Barat *et al.* 1996; Halbert, Baldwin 1984) 3. LC-MS (Abdel-Rehim *et al.* 2000)	2–6 mg/L (9–26 μmol/L)	++
Lithium	Variable absorption characteristics. Sodium balance affects excretion.	1. Flame emission spectroscopy/AAS (Popov *et al.* 1986) 2. Ion-selective electrodes (Bertholf *et al.* 1988; Christian 1996) 3. Colorimetry (Christian 1996; Gorham *et al.* 1994)	0.5–0.8 mmol/L (prophylaxis); up to 1.2 mmol/L in acute mania	+++
Lopinavir	See Antiretroviral drugs			
Methadone	Monitoring may be valuable for drug addicts on methadone substitution. Administered as racemate.	1. Immunoassay* 2. HPLC (Pham-Huy *et al.* 1997) 3. LC-MS (Moody *et al.* 2008) 4. GC-MS (Bermejo *et al.* 2000) 5. CE (Kelly *et al.* 2007)	150–50 μg/L (430–720 nmol/L) (total plasma methadone – *R*+*S* isomers)	++
Methotrexate	Concentration monitoring necessary to assess need for 'rescue' therapy (folinic acid) on high-dose regimes.	1. Immunoassay* (Aherne *et al.* 1978) 2. HPLC (Emara *et al.* 1998)	<5–10 μmol/L at 24 h post-dose; <0.5–1.0 μmol/L at 48 h; <0.1 μmol/L at 72 h	+++
Mycophenolate mofetil	Pre-dose concentrations vary widely and are poor reflections of total exposure to the drug. Measures of area under the curve preferred.	1. Immunoassay* 2. HPLC (Hosotsubo *et al.* 2001; Shipkova *et al.* 1998; Svensson *et al.* 1999) 3. LC-MS (Brandhorst *et al.* 2006; Premaud *et al.* 2006)	3.0–9.0 μmol/L (1.0–3.0 mg/L) (as mycophenolic acid; depends on transplanted organ) AUC in range 30–60 μg h/L recommended	++
Nelfinavir	See Antiretroviral drugs			

table continued

Table 2.1 continued

Drug	*Notes*	*Suggested assay method (* = commercial kits available)*	*Plasma concentrations associated with optimum response*	*Clinical value of TDM*
Netilimicin	See Gentamicin	1. Immunoassay* 2. HPLC (Isoherranen, Soback 1999; Soltes 1999) 3. GLC (Isoherranen, Soback 1999; Mayhew, Gorbach 1978) 4. GC-MS (Preu *et al.* 1998) 5. CE (Calcara *et al.* 2005)	Vary with dose schedule.	+++
Nevirapine	See Antiretroviral drugs			
Nortriptyline	Large genetic differences in rate of metabolism. There is an optimum therapeutic window; plasma concentrations above or below this are associated with worsening mood.	1. GLC (Ulrich *et al.* 1996) 2. HPLC (el Yazigi, Raines 1993; Kabra *et al.* 1981) 3. LC-MS (Kirchherr, Kühn-Velten 2006; Sauvage *et al.* 2006)	50–150 µg/L (190–570 nmol/L)	++
Oxcarbazepine	Prodrug for 10-hydroxycarbamazepine. No evidence to justify routine monitoring.	1. HPLC (Greiner-Sosanko *et al.* 2007; Levert *et al.* 2002; Matar *et al.* 1999; Pienimaki *et al.* 1995) 2. GLC (von Unruh, Parr 1985) 3. GC-MS (von Unruh, Paar 1986) 4. LC-MS (Paglia *et al.* 2007; Subramanian *et al.* 2008)	13–28 µg/L (50–110 nmol/L) suggested	±
Phenobarbital	Now rarely used. The value of monitoring is limited by development of tolerance to the drug.	1. Immunoassay* 2. HPLC (Kouno *et al.* 1993; Matar *et al.* 1999; Meatherall, Ford 1988; Romanyshyn *et al.* 1994) 3. LC-MS (Subramanian *et al.* 2008) 4. GLC (Burke, Thenot 1985; Kumps 1982) 5. GC-MS (Speed *et al.* 2000)	10–40 mg/L (40–170 µmol/L) (tolerance means these ranges need to be interpreted flexibly) 15–20 mg/L (65–85 µmol/L) in prophylaxis of febrile convulsions in children	++
Phenytoin	Saturable metabolism means that the concentration–dose relationship is unpredictable. Monitoring vital for safe use of drug.	1. Immunoassay* 2. HPLC (Kouno *et al.* 1993; Matar *et al.* 1999; Meatherall, Ford 1988; Romanyshyn *et al.* 1994) 3. LC-MS (Subramanian *et al.* 2008; Zhang *et al.* 2008) 4. GLC (Burke, Thenot 1985; Kumps 1982) 5. GC-MS (Speed *et al.* 2000) 6. Electrokinetic chromatography (Pucci, Raggi 2005)	5–20 mg/L (20–80 µmol/L)	+++
Primidone	Metabolised to phenobarbital. No evidence that monitoring primidone concentration improves management.	1. HPLC (Matar *et al.* 1999; Meatherall, Ford 1988; Romanyshyn *et al.* 1994) 2. GLC (Burke, Thenot 1985; Kumps 1982) 3. GC-MS (Speed *et al.* 2000)	See Phenobarbital	±
Procainamide/*N*-Acetylprocainamide	Active metabolite (*N*-acetyl-procainamide, NAPA) complicates the concentration–effect relationship.	1. Immunoassay* 2. HPLC (Lessard *et al.* 1998) 3. GLC (Kessler *et al.* 1982)	4–10 mg/L (17–42 µmol/L) Procainamide + NAPA should not exceed 30 mg/L	++
Propranolol	No evidence that monitoring improves management.	1. HPLC (Braza *et al.* 2000; Sood *et al.* 1988) 2. LC-MS (Umezawa *et al.* 2008) 3. GC-MS (Quaglio *et al.* 1993)	—	±
Quinidine	Active metabolite (3-hydroxyquinidine) complicates interpretation.	1. Immunoassay* 2. HPLC (Carignan *et al.* 1995; Meineke *et al.* 1995) 3. GLC (Kessler *et al.* 1982) 4. GC-MS (Quaglio *et al.* 1990)	2–6 mg/L (6.2–18.5 µmol/L)	++
Risperidone	Active metabolite 9-hydroxyrisperidone. No clear role for monitoring.	1. HPLC (Balant-Gorgia *et al.* 1999) 2. LC-MS (Flarakos *et al.* 2004; Kirchherr, Kühn-Velten 2006)	20–60 µg/L (including metabolite)	±
Ritonavir	See Antiretroviral drugs			
Salicylate	Role for monitoring in avoiding toxicity on chronic anti-inflammatory therapy	1. Colorimetry (Stewart, Watson 1987; Trinder 1954) 2. HPLC (Dawson *et al.* 1988; Stewart, Watson 1987) 3. LC-MS (Bae *et al.* 2008)	150–300 mg/L (110–220 µmol/L)	±

Table 2.1 continued

Drug	*Notes*	*Suggested assay method (* = commercial kits available)*	*Plasma concentrations associated with optimum response*	*Clinical value of TDM*
Saquinovir	See Antiretroviral drugs			
Sirolimus	Monitoring is a regulatory requirement. Pre-dose concentrations are a good index of exposure	1. Immunoassay* 2. HPLC (Shaw *et al.* 2000) 3. LC-MS (Poquette *et al.* 2005)	4–12 µg/L (chromatographic assay) when given with ciclosporin, increasing to 12–20 µg/L when ciclosporin discontinued. Whole blood samples determined.	+++
Tacrolimus	Monitoring of value in ensuring maximum effect with minimal toxicity. Pre-dose concentrations reflect total exposure.	1. Immunoassay* 2. LC-MS (Poquette *et al.* 2005; Taylor *et al.* 1997)	Typically 15 µg/L following kidney transplantation, reducing to 5–10 µg/L in stable patients. Whole blood samples used.	++
Teicoplanin	See Vancomycin	1. Immunoassay* 2. HPLC (Mochizuki *et al.* 2007)	20–60 mg/L (trough) for *Staphylococcus aureus*, 10–60 mg/L for other infections.	++
Theophylline	Highly variable hepatic metabolism. Monitoring helps with dosage individualisation.	1. Immunoassay* 2. HPLC (Kizu *et al.* 1999; Meatherall, Ford 1988; Schreiber-Deturmeny, Bruguerolle 1996) 3. LC-MS (Zhang *et al.* 2008)	10–20 mg/L (55–110 µmol/L)	+++
Tiagabine	No evidence to justify routine monitoring at present.	1. GC-MS (Chollet *et al.* 1999) 2. HPLC (Gustavson, Chu 1992)	20–40 µg/L (50–97 µmol/L) suggested	±
Tipranavir	See Antiretroviral drugs			
Tobramycin	See Gentamicin	1. Immunoassay* 2. GLC (Isoherranen, Soback 1999; Mayhew, Gorbach 1978) 3. HPLC (Isoherranen, Soback 1999; Soltes 1999)	Vary with dose schedule.	+++
Topiramate	No evidence to justify routine monitoring at present.	1. Immunoassay* 2. GLC (Holland *et al.* 1988; Wolf *et al.* 2000) 3. LC-MS (Christensen *et al.* 2002; Subramanian *et al.* 2008)	5–25 mg/L (15–60 µmol/L) suggested	±
Valproic acid	Complex pharmacokinetic profile. Poor relationship between plasma concentration and effect (in epilepsy). The role of monitoring in bipolar affective disorder is unproven.	1. Immunoassay* 2. GLC (Grgurinovich, Miners 1980; Kumps *et al.* 1981; Kumps 1982; Riva *et al.* 1982) 3. GC-MS (Speed *et al.* 2000) 4. LC-MS (Cheng *et al.* 2007) 5. Electrokinetic chromatography (Pucci, Raggi 2005)	Concentrations above 50 mg/L (350 µmol/L) are more likely to be associated with efficacy.	±
Vancomycin	Monitoring is useful in ensuring maximum effect with minimum toxicity	1. Immunoassay* 2. HPLC (Favetta *et al.* 2001; Li *et al.* 1995; Pfaller *et al.* 1984)	Peak (1 h) 20–40 mg/L (14–28 µmol/L) Trough 5–10 mg/L (3–7 µmol/L)	++
Vigabatrin	Plasma concentrations show linear relationship to dose. Irreversible mode of action.	1. HPLC (Franco *et al.* 2007; Ratnaraj, Patsalos 1998; Tsanaclis *et al.* 1991) 2. GC-MS (Borrey *et al.* 2005)	Not relevant.	±
Voriconazole	High pharmacokinetic variability. Relationship between concentration and efficacy is unclear.	1. HPLC (Pennick *et al.* 2003) 2. LC-MS (Egle *et al.* 2005)	2–6 mg/L (?)	±
Zonisamide	Little evidence to justify routine monitoring at present.	1. HPLC (Furuno *et al.* 1994; Greiner-Sosanko *et al.* 2007; Shimoyama *et al.* 1999) 2. LC-MS (Subramanian *et al.* 2008) 3. CE (Makino *et al.* 1997)	10–20 mg/L (47–94 µmol/L)	±

+++ Monitoring has proven clinical value.
++ Monitoring may have value in isolated cases or specific circumstances.
± Monitoring has not been shown to be applicable.

Plasma also contains a considerable amount of protein and many drugs of interest in the TDM field (e.g. phenytoin) show significant protein binding. This means that the total (free plus protein-bound) concentration of the drug in plasma varies with protein concentration, even though the free (pharmacologically active) concentration remains constant. This variation of measured drug concentration with plasma protein concentration complicates the interpretation of plasma drug levels, and has led to strategies to measure only the circulating free (unbound) drug. This can be achieved either *in vitro* by determining the concentration of drug in a plasma ultrafiltrate (obtained by centrifugation of plasma through an appropriate filter or by equilibrium dialysis across a semipermeable membrane) or by sampling an *in vivo* ultrafiltrate. Saliva is sometimes used as the latter, although care must be taken to ensure that the saliva : plasma concentration ratio is constant and unaffected by salivary pH or salivary flow rate. This is not always the case, but where these conditions are satisfied (for drugs that are not ionisable or are un-ionised within the salivary pH range, e.g. theophylline, carbamazepine and phenytoin), saliva can provide an effective, non-invasive sample matrix for determination of the pharmacologically active component of drug in plasma. Saliva sampling can be particularly useful in children or in adults with needle phobia, although there are still problems with collection and potential contamination. Drug concentrations in saliva are normally lower than in plasma or serum and the matrix itself provides some analytical challenges, as mucoproteins present in saliva make samples difficult to handle or pipette accurately, and centrifugation is time-consuming and not completely effective in removing debris. For these reasons, salivary monitoring still has not found wide application, though it undoubtedly has a role in some circumstances (see Baumann (2007) and Chapter 18).

Timing of measurements

The primary requirement for an appropriate specimen if TDM is to be used to assess the adequacy of response is that the specimen be taken when the drug concentration in the body is at steady state, that is when the effects of any recent dose changes have been allowed to stabilise. The time to reach steady state is determined by the elimination half-life of the drug and there is a fixed relationship between the number of half-lives that have elapsed since the drug was commenced and the progress towards steady-state concentration (see Chapter 24). The plasma concentration after 3.3 half-lives have elapsed is 90% of the predicted steady-state concentration and 94% of steady-state concentration is reached after four half-lives. For drugs with a long plasma half-life (e.g. digoxin, 20 to 50 h; phenytoin, 22 h) a week or two (or even longer) may be required before steady state is reached, especially if renal function is poor as in the case of digoxin. It is usual to allow at least four half-lives to elapse before monitoring the effect of any dose change. Obviously, if toxicity is suspected after a dose change it would be unwise to wait for steady state before checking the plasma concentration. Computer programs with the ability to predict steady-state concentrations from measurements made before steady state is attained may also be helpful.

The other issue relating to appropriate sample timing is the question of when the sample should be taken in relation to the last dose of the drug. As drugs are normally administered at fixed time intervals, there is inevitably variation of plasma concentration between one dose and the next. For most purposes, the most reproducible parameter for long-term monitoring is the steady-state trough concentration – a measurement immediately prior to the next oral dose. The importance of precise sample timing depends somewhat on the half-life of the drug: drugs with long half-lives (e.g. phenytoin) show little variation in concentration across the dosage interval and accurate specimen timing is less important than for drugs with short half-lives such as theophylline (half-life 7 h). For these drugs, toxic symptoms may correlate better with peak plasma concentrations than with trough concentrations and, if toxicity is suspected, a sample timed at 1–6 h post-dose (depending on the release characteristics of the preparation and the speed of absorption) may be more appropriate. Some antibiotics require high peak concentrations and low trough concentrations for optimal effects (e.g. aminoglycosides, for which this is now achieved by once-daily dosing regimes). In the case of lithium, a strong case has been made for standardising the sampling time at exactly 12 h post-dose. The area under the concentration–time curve (AUC) may also be a better predictor of response than either the peak or the trough concentration (e.g. in the case of ciclosporin), but the determination of AUC requires more complex sampling regimes. Sampling at exactly 2 h post-dose has been shown to predict AUC for ciclosporin more closely than trough sampling but it presents practical difficulties for routine monitoring.

Some drugs exhibit a distribution phase immediately after the dose has been given and for the duration of this phase the plasma concentration will be unrepresentative of the pharmacologically relevant receptor concentration. This is particularly the case for digoxin, where clinically misleading concentrations may be obtained in the first 4 or 5 h following a dose (whether oral or intravenous) while the drug equilibrates between plasma and tissue compartments.

Case example

A 70-year-old woman was seen by her general practitioner at a 09:30 appointment. She described a one-week history of feeling tired and nauseated, and was on long-term digoxin therapy. A blood sample taken for various biochemical tests including digoxin was received in the laboratory at 11:30. The digoxin concentration was 3.1 μg/L (3.9 nmol/L) (target range 0.8–2.0 μg/L; 1.0–2.6 nmol/L). A telephone call to the surgery established that the patient had taken her digoxin tablets that morning and thus the 09:30 sample was approximately 2 h post-dose. A repeat sample taken the following day, 8 h after the morning dose, showed a digoxin concentration of 2.0 μg/L (2.6 nmol/L). A modest reduction in digoxin dose was advised, but the specimen at 09:30 gave a misleading view of the severity of the situation.

Measurement techniques

A suitable analytical technique is obviously the bedrock of drug analysis, and studies to establish a correlation between plasma drug concentration and response cannot begin until a measurement technique has been developed and validated. The final stage of establishing the clinical value of an assay is prospective randomised controlled trials comparing patients who have been monitored with a control group who have been managed without the aid of concentration monitoring. Unfortunately, there are virtually no drugs for which unequivocal evidence of the clinical benefit of monitoring has been obtained by large-scale trials. Lithium and phenytoin provide the best examples.

Much early pharmacokinetic knowledge was obtained from studies using colorimetry, spectrophotometry and spectrofluorimetry, but these methods have now been virtually abandoned for quantitative clinical work because of their lack of specificity. The exception is for lithium, which is still frequently measured by colorimetric methods or flame atomic emission spectroscopy, although ion-selective electrodes are slowly displacing spectrometric techniques. Many antibiotics were once measured by bioassay, but this has poor specificity for combinations of drugs and is too slow, imprecise and labour intensive for present-day applications. Thin-layer chromatography (Chapter 39) is also now rarely used for quantitative measurement of therapeutic concentrations.

The techniques that are most widely used for routine clinical measurement of drug concentrations are immunoassays (Chapter 31), gas chromatography (GC) (Chapter 40) and high performance liquid chromatography (HPLC) (Chapter 41), either alone or, increasingly, coupled with mass spectrometry (Chapter 37) as the hyphenated methods GC-MS or LC-MS (Chapter 38). Selection of the most appropriate method for a given drug or clinical situation is not easy, and the choice depends on the availability of staff, expertise and equipment, the nature of the service to be provided, and the range of drugs to be assayed. The widely varying chemical nature of the substances to be assayed for TDM purposes means that it will rarely be possible to offer a comprehensive service based on a single analytical principle. Compromises will usually have to be made between using the best method for each individual analyte and using techniques that allow quantification of a wide range of substances.

Table 2.2 Comparison between chromatography and immunoassay for therapeutic monitoring

	Chromatography	*Immunoassay*
Applicability	Wide	Limited
Specificity (metabolites, etc.)	Yes	Sometimes
Speed of analysis	Slow–medium	Slow–fast
Capital cost (equipment0	High	High–low
Reagent costs (consumables)	Low	Medium–high
Skill required	Medium–high	Low-medium
Suitability for urgent/ point-of-care testing	Poor	Good

The basic requirements of any method are that it should be specific for the substance being assayed (without interference from structurally related compounds or endogenous plasma components), capable of precise quantification, and sufficiently sensitive to detect concentrations normally found in therapy in a sample small enough for clinical work (certainly less than 1 mL plasma and ideally 10–100 μL). Immunoassays and chromatographic techniques each have their own strengths and weaknesses, which are summarised in Table 2.2.

Chromatographic methods

Chromatographic methods are flexible and adaptable to a wide range of compounds. In most cases methods for new compounds can be devised relatively quickly compared with immunoassays, for which development times can be significant, particularly if a new antiserum must be raised. Chromatographic techniques frequently allow quantification of a range of related compounds in a single run, which has advantages when a number of drugs are prescribed together (e.g. anticonvulsants) or when separate quantification of a drug and its active metabolites is required. The combination of flexibility, specificity and sensitivity makes chromatographic techniques the method of choice for many toxicological applications. However, for TDM purposes they have a number of disadvantages. In comparison with immunoassays they are slower and more labour-intensive, frequently demanding a significant level of technical expertise. Sample throughput is usually lower than for automated immunoassays, although partially or fully automated chromatographic systems can improve this. Sample volume is often higher for chromatographic procedures, which is a particular disadvantage for paediatric applications. Sample preparation is also more laborious, since extraction or formation of a chemical derivative may be required before the chromatographic step. Total analytical time from a 'cold' start is also significantly longer, which makes chromatographic techniques less applicable for urgent measurements outside normal laboratory hours, or for point-of-care applications.

Both GC and HPLC still have a role, but the previously dominant position of GC in clinical work has steadily been eroded and HPLC or LC-MS are now the chromatographic methods of choice for most TDM applications (see Table 2.1). LC-MS and LC tandem-mass spectrometry (LC-MS[-MS]) provide highly specific and accurate methods and are rapidly becoming routine procedures (Chapter 1). The cost of instruments has fallen dramatically in recent years, but remains considerable and the skilled labour required to develop and operate these systems has important revenue consequences. LC-MS and LC-MS(-MS) offer great advantages in terms of speed, flexibility, sensitivity, reproducibility, reliability and low sample volume requirements. Moreover, they are invaluable in measuring difficult compounds such as immunosuppressants and for establishing reference procedures. A more comprehensive treatment of chromatographic and MS techniques is given in Chapters 37, 38, 40 and 41.

Immunoassays

Immunoassays, as conventional separation radioimmunoassays, have been applied to the determination of therapeutic drugs since the late 1960s, and these techniques still have a role when very high sensitivity is required, though safety and ease of use are significant disadvantages. However, the advent of homogeneous (i.e. not requiring a phase separation step) non-isotopic immunoassays in the mid-1970s proved to be the foundation for widespread adoption of commercial immunoassay kits into clinical laboratories. A bewildering variety of techniques is now available and more details will be found in Chapter 31. These kits have obvious advantages. They are generally technically simple, requiring little operator skill, and are amenable to automation on equipment commonly found in routine clinical laboratories. Sample throughputs can thus be very high and analysis times very short. Their main disadvantage is lack of specificity, either because of interference from endogenous plasma components (haemoglobin, bilirubin, etc.) that can affect the efficiency of the detection system, or because of cross-reactivity of the primary antibody with metabolites or structurally related compounds. Drugs with a large number of metabolites with similar structures (e.g. benzodiazepines, ciclosporin) pose particular problems in this respect. The development of sophisticated homogeneous non-isotopic systems is now virtually exclusive to large diagnostic companies, which limits the practical applicability of immunoassays to compounds for which there is a commercial market for an assay system. Cross-reactivity, specificity and sensitivity of available immunoassays may vary, even with the same technique on different platforms.

Free-drug concentrations

Free-drug concentrations, as indicated above, may be determined by measuring drug concentrations in a plasma ultrafiltrate obtained by centrifugation of plasma through an ultrafiltration membrane with a molecular weight cut-off of approximately 30 000 daltons, by equilibrium dialysis or by ultracentrifugation. The three separation methods usually give similar results, although systematic differences have been reported and it is advisable to compare the results of two or more techniques when validating a new method. Ultrafiltration and centrifugation are non-equilibrium techniques and are often preferred in the clinical setting as they can be completed more rapidly than the other methods. Where drug binding to protein is temperature dependent, careful control of temperature during the separation step is essential. Monitoring of free-drug concentration undoubtedly provides better clinical information than total concentration monitoring, but the increased methodological complexity and time required have limited its widespread application.

Chirality

The question of stereoselective analyses for therapeutic drugs has attracted increasing attention in recent years, Many pharmacologically active compounds contain a carbon atom linked to four different substituents and thus have the potential to exist in two different stereoisomeric forms. This property is called *chirality,* and the pairs of mirror-image isomers are called *enantiomers*. Frequently, only one enantiomer possesses a particular pharmacological action and the other may be inactive, or active in a different way. For example, the *d*-isomer of propoxyphene is a narcotic analgesic, while the *l*-isomer has no narcotic properties and is used as a cough suppressant. Enantiomers may also show marked differences in pharmacokinetic properties, such as clearance and volume of distribution (Chapter 24), and stereoselective analytical methods capable of resolving individual isomers are required if meaningful TDM information is to be obtained. These methods rely on HPLC. Immunoassays are of little use in this situation because it is difficult or impossible to produce antibodies that have enough specificity towards different enantiomers to enable them to be measured separately.

No chiral drugs are currently monitored routinely for TDM purposes, although the separate determination of the *d*- and *l*- isomers of amfetamine in urine samples from drug users prescribed dexamfetamine has been used to distinguish those compliant with the therapy from those also using 'street' amfetamine, which is a racemate.

Quality assurance

Rigorous quality assurance is essential in TDM analyses, as clinical decisions depend on the analytical results. Both internal quality control

procedures and external quality assessment schemes are necessary, and further details are given in Chapters 21 and 22. External assessment schemes are available for the majority of drugs routinely monitored and often have an important role in highlighting inappropriate methods or those that perform poorly. The potential for interference by other drugs or metabolites in TDM assays means that particular care needs to be taken in preparing specimens for external quality assurance schemes to ensure that they are as clinically realistic as possible. 'Spiking' parent drug into a plasma base material is unlikely to produce an effective material for method comparison.

Interpretation of results

In the 40 years or so that TDM has been practised in routine clinical laboratories, it has been demonstrated repeatedly that making drug concentration measurements available to clinicians does not in itself result in improved clinical care. Improved outcome depends on the application of the result to a specific clinical situation with appropriate expertise. This is facilitated by a multidisciplinary approach in which pharmacists, laboratory staff and clinicians work together to share expertise and promote best use of the service. If the laboratory is to provide an effective service, clinicians must be prepared to provide basic information, such as the reason for a particular request, the dose regime, the time of the last dose and the presence of any drugs that might cause pharmacological or analytical interference.

In particular, it is important to understand that the widely quoted (and just as often misused) 'therapeutic ranges' for drugs represent a guide to the approximate concentrations that produce a therapeutic response in the majority of patients rather than a set of inflexible limits between which patients must be forced. 'Target ranges' has been suggested as a better term, which at least carries the connotation that the ranges are something to aim at rather than implying that all concentrations within the range are therapeutic (and all outside are not). Many patients need plasma drug concentrations above (sometimes substantially above) the upper limit of the therapeutic range for effective therapy, and such concentrations must not provoke a knee-jerk dosage reduction. Specialist clinicians usually appreciate this fact, but non-specialists frequently do not and the laboratory or pharmacist has an important educational role here. Conversely, plasma drug concentrations below the lower limit of the therapeutic range may produce perfectly satisfactory responses in some patients, and arbitrary dose increases to get concentrations into the 'therapeutic range' will merely increase the likelihood of toxicity without added benefit. 'Interpretation' of plasma drug concentrations by comparing them with an arbitrary range and commenting 'sub-therapeutic' or 'toxic' does far more harm than good.

Optimum drug concentrations for a particular patient are highly individual and depend on many pharmacodynamic factors as well as the severity of the underlying disease process. This does not undermine the relevance of TDM, but it does require a degree of interpretative expertise and an understanding of the reason behind a particular request and how the result obtained relates to the clinical question. Whether this expertise resides with the clinician, the pharmacist or the laboratory scientist is less important than the fact that it exists somewhere and can be accessed when needed, although, in the nature of the service, laboratory staff are likely to be best placed to monitor interpretation across a range of clinical situations. The cardinal principle, oft repeated but still forgotten, is to treat the patient, not the drug level.

Case example

A 52-year-old woman with complex partial epilepsy treated with phenytoin 200 mg/day was still experiencing frequent seizures (1–2 per week). Her plasma phenytoin concentration over this period was in the range 8.8 to 10.1 mg/L (35–40 μmol/L) (target range 10–20 mg/L; 40–80 μmol/L). The dose was (rather rashly) increased to 300 mg/day, which saturated the patient's capacity to metabolise phenytoin and provoked a marked rise in plasma concentration to 30.3 mg/L (120 μmol/L). The patient was fit-free but severely ataxic, and the dose was reduced to 250 mg/L. On this dose, plasma concentrations were within the target range at approximately 14 mg/L (55 μmol/L), but fits recurred, albeit at decreased frequency, indicating that the broad population target range of 10–20 mg/L (40–80 μmol/L) was not optimal for this particular individual. A dose increase to 275 mg/day produced plasma concentrations a month apart of 19.7 and 17.7 mg/L (76 and 70 μmol/L), and the patient was untroubled by toxicity and remained fit-free for the next 2 years. Clearly, optimum phenytoin concentrations in this patient are confined to the upper reaches of the population 'target range'.

Factors affecting interpretation

As implied above, many factors may affect interpretation of plasma drug concentrations and it is impossible to go into specific detail in the confines of this chapter. Each of the following may have a bearing on the significance of a particular drug concentration at a particular time:

- Pharmacokinetic factors such as the age of the patient, the time since the last dose, administration of a loading dose and whether steady state has been achieved.
- Pharmacodynamic factors such as receptor density, presence of interfering drugs or drug metabolites, and concentration of endogenous substances such as potassium.
- Clinical factors such as the severity of the primary condition and the presence of other diseases.

Pharmacodynamic monitoring, biomarkers and pharmacogenetics

This chapter began by defining TDM as the use of drug or metabolite measurements in body fluids as an aid to monitoring therapy. In recent years, other methods of controlling drug therapy have been introduced and, though they do not fit the strict definition of TDM, they merit discussion as they are becoming increasingly important. Pharmacodynamic monitoring is the study of the biological effect of a drug at its target site, and has been applied in the areas of immunosuppressive therapy and cancer chemotherapy. For example, the biological effect of the immunosuppressant ciclosporin (see above) can be assessed by measuring the extent of inhibition of calcineurin phosphatase, or the interleukin-2 concentration of peripheral blood lymphocytes. The main disadvantage of pharmacodynamic monitoring is the fact that the assays involved are often significantly more complex and time-consuming than the measurement of a single molecular species by chromatography and immunoassay.

Any biochemical measurement that can be used to determine efficacy, extent of toxicity or individual pharmacodynamics for a therapeutic agent is termed a therapeutic *biomarker*. Biomarker monitoring can provide an integrated measure of all biologically active species (parent drug and metabolites) so that therapeutic ranges can be defined more closely. In addition, biomarkers are often free from the matrix and drug disposition problems that bedevil TDM in some areas, notably immunosuppressants.

Pharmacogenetic studies (studies of hereditary influences, including ethnicity, on pharmacological responses) have clear and wide-ranging clinical relevance. The enzymes that are responsible for the metabolism of drugs and other compounds exhibit wide inter-individual variation in their protein expression or catalytic activity, resulting in different drug metabolism phenotypes between individuals. This variation may arise from transient effects on the enzyme, such as inhibition or induction by other drugs, or may be at the gene level and result from specific mutations or deletions. *Pharmacogenetic polymorphism* is defined as the existence in a population of two or more alleles (at the same locus) that result in more than one phenotype with respect to the effect of a drug. The term 'pharmacogenomics' was coined to describe the range of genetic influences on drug metabolism, and its application to the practice of tailoring drugs and dosages to individual genotypes to enhance safety and/or efficacy ('personalised medicine') undoubtedly represents a massive growth area for 21st-century medicine (Chapter 25).

Determination of an individual's ability to metabolise a specific drug, by administering either a test dose of the drug or a compound

metabolised by the same enzyme system (phenotyping) or by specific genetic analysis (genotyping) can inform and improve the clinician's ability to adjust drug dosing according to the specific requirements of the individual patient. For example, a number of enzymes of the cytochrome P450 superfamily show genetic polymorphisms that account for differences in clinical response. The CYP2D6 isoform has more than 75 allelic variants, and metabolises a range of drugs widely used in medicine, including many antiarrhythmics and antidepressants. Debrisoquine is also a substrate for this isoform, and debrisoquine hydroxylase activity determined by the rate of metabolism of a test dose of debrisoquine has been widely used for the determination of CYP2D6 phenotype and the differentiation of poor metaboliser (PM), extensive metaboliser (EM) and ultra-extensive metaboliser (UEM) phenotypes. Debrisoquine is no longer available and dextromethorphan has replaced it as a probe drug for clinical use. Alternatively, genetic analysis can be used to define the CYP2D6 phenotype and identify the alleles associated with the PM phenotype (of which the most common are CYP2D6*3, *4, *5, *6 and *7). Once determined, the phenotype or genotype can be used to guide dosing for any of the drugs metabolised by the CYP2D6 isoform. CYP2D6 is absent in 15–30% of Asian people.

The clinical applications of pharmacogenomics are extensive. Examples might include anticoagulation (polymorphism of the CYP2C9 isoform), oncology (thiopurine methyltransferase isoforms and the serum Her2/neu receptor), psychiatry (CYP2D6 isoforms), epilepsy and pain control.

The combination of classic TDM, pharmacodynamic biomarkers and pharmacogenetics will undoubtedly accelerate the development of new drugs and facilitate their clinical use. It will also have a major role in delivering therapeutic efficiency and improved patient outcome with less need for plasma concentration monitoring. However, integrating the information available from all three strands is a complex challenge that will require sophisticated decision support software and effective strategies for presenting the information in an accessible format to those responsible for patient care. Pre-treatment pharmacogenetic profiling will allow identification of individuals who are likely to be particularly susceptible to or resistant to a proposed treatment strategy, allowing better choice of starting dose or the use of a different drug. Pharmacodynamic factors such as age, disease and other drugs mean that pharmacogenetics can never tell the whole story, and biomarkers of effect and drug or metabolite concentration measurements will be needed to complete the picture and deliver truly personalised therapeutics.

CHAPTER

3 Workplace Drug Testing

A Verstraete and M Peat

Introduction

Workplace drug testing began in the USA during the 1980s as a result of accidents in the railroad industry, and the political environment of the 'war on drugs' and the 'crack' epidemic. It is now an accepted practice, with between 30 and 40 million such tests being carried out in the USA annually. In Europe, Australia and other industrialised countries, workplace drug testing has gained increasing acceptance over the past decade. For example, in the UK, workplace testing was established about 15 years ago and in 2004 it had an estimated annual turnover of £12 million. European laboratories have followed the American lead in setting up careful protocols for sample collection, analysis and medical review of results. However, there are differences both in criteria for the minimum concentration of a drug or metabolite in a urine specimen that constitutes a positive result, and in the selection of target drugs. Moreover, in the UK in particular, the ethos is that testing should be part of a package of measures that includes formulation of company policy, education of the workforce as regards the dangers of drug misuse, and treatment and/or rehabilitation programmes. Specific legislation has been enacted in Finland, Norway and Ireland to govern the principles and practices of workplace testing. The European Guidelines drawn up by representatives of the leading European laboratories are designed to establish best practice and at the same time take account of the individual requirements of national custom and legislation. The Guidelines relate to collection of samples, laboratory analyses and interpretation of the results.

Evolution of workplace testing in the USA

The major milestones in the evolution of workplace testing in the USA were:

- A major railroad accident in which there were several fatalities. The National Transportation Safety Board determined that use of cannabis (marijuana) by one of the engineers was a causal factor in the accident.
- The introduction of 'crack' cocaine and the deaths of high-profile sports and entertainment figures from cocaine use.
- The declaration of a 'war on drugs' and a change of the US Government's policy to focus on reducing the supply of drugs.

In 1986 President Reagan issued an Executive Order (Federal Register 1986) that required those federal employees in safety- and security-conscious positions to be drug tested. This Order also led to the publication by the Department of Health and Human Services (DHHS) of the *Mandatory Guidelines for Drug Testing of Federal Employees* (Federal Register 1988a), which became known as the National Institute for Drug Abuse (NIDA) Guidelines (or today as the Substance Abuse and Mental Health Services Administration (SAMHSA) Guidelines). These were modified in 1994 (Federal Register 1994) to change the cut-offs for cannabis detection and in 1998 (Federal Register 1998) to change the cut-offs for opiate detection. SAMHSA currently has responsibility for the *Guidelines*.

This confluence of events set the stage for the introduction of drug-testing programmes to the non-federal workplace. Their introduction focused on the expected improvement in safety and public health, and on the economic savings to be expected from decreased absenteeism, staff turnover rate and reduced health care costs. A limited number of major corporations were already performing pre-employment testing and claimed improvements in these, although they generally had not published their data. As the decade progressed, a number of studies (see Peat (1995) for earlier references and American Management Association (2001) for a more recent study) were published, the majority of which showed that some benefits were to be expected.

A major impetus to more widespread workplace drug testing was the publication by the Department of Transport (DOT; Federal Register 1988b) in 1988 of rules for drug testing of workers in the airline, pipeline, railroad and trucking industries. Those involved in mass transit were included originally, but were removed from the rules after a court challenge. Eventually, they were included under the 1991 Omnibus Transportation Employee Testing Act (US US Senate Public Law 1991). The DOT rules, known as *CFR Part 40* (Federal Register 1988b), originally covered between two and three million workers. After the rules were amended to cover alcohol testing in 1994 and to include mass transit workers, the number increased to approximately eight million. *CFR Part 40* was revised in 2000 (Federal Register 2000); the revision did not extend the scope of drug testing, but has had a significant impact on how it is practised.

In the USA, the DHHS *Guidelines* and *CFR Part 40* are the two major sets of rules that govern the practice of drug testing in the Federal workplace and in that regulated by the DOT. Similar rules for testing are performed under the auspices of the Nuclear Regulatory Commission (NRC) and the Department of Defense (DOD).

As stated previously, although there is far less regulation of workplace drug testing in other countries, the standards for acceptable practice are similar to those of the USA and cover specimen collection, laboratory analysis and medical review of results.

The question that underlies these drug-testing programmes is 'Have they been effective in reducing drug use in the workplace and/or in the general population?' For the USA, there are certainly data (Quest Diagnostics 2008) that suggest a reduction in the number of positives throughout the 1990s and that this reduction correlates with a reduction in the admitted use of illicit drugs (SAMHSA 2000). In all probability, numerous factors are responsible for the reduction in drug use, including targeted education programmes and supply reduction programmes, in addition to workplace drug testing.

Prevalence of drug use in the workforce and in the workplace

In the USA, of the 16.4 million illicit drug users aged 18 years or older in 2004, 12.3 million (75.2%) were employed either full or part time (SAMHSA 2005). In a survey in 1991–1993 the highest rates of current and past-year illicit drug use were reported by construction workers, food preparation workers, waiters and waitresses. The lowest rates of current illicit drug use were found among police officers and detectives, administrative support workers, teachers and childcare workers (SAMHSA 1996). A recent survey in the USA showed (Frone 2006) that illicit drug use in the workforce involved an estimated 14.1% of employed adults (17.7 million workers): 11.3% used cannabis, 1.0% used cocaine and 4.9% used psychotherapeutic drugs (sedatives, tranquillisers, stimulants and analgesics) for non-medical purposes. Illicit drug use in the workplace involved an estimated 3.1% of employed adults (3.9 million workers): 1.6% used cannabis, 0.1% used cocaine and 1.8% used psychotherapeutic drugs. In terms of being at work under

the influence of an illicit drug, 1.7% were impaired from cannabis, 0.2% from cocaine and 1.4% from psychotherapeutic drugs.

Illicit drug use in the workforce and in the workplace is not distributed uniformly in the employed population. At-risk, though circumscribed, segments of the US workforce (men aged 18–30 years in building and grounds maintenance occupations) were identified with prevalence rates up to 55.8% for any use of illicit drugs and up to 28.0% for illicit drug use in the workplace (Frone 2006). The highest risk was seen in men aged between 18 and 30 years, working in occupations where illicit drug use is particularly prevalent (legal, food preparation and serving, building and grounds maintenance occupations).

A survey carried out in Europe, in 2007, showed that 23 million people had used cannabis in the previous year, 4.5 million had used cocaine, 3 million had used drugs of the ecstasy group, 2 million had used amfetamines and 1–2 million had used heroin (EMCDDA 2007). A UK study (Smith *et al.* 2004) reported that 13% of employed people admitted to using drugs over the previous year and 7% in the previous month. Another European survey showed that among 15 to 24 year olds using cannabis, 54% were students, 30% were employed and 12% were unemployed (Taylor 2004).

The incidence of drug-positive samples found in workplace drug testing samples ranges from 1% to 20%. In pre-employment testing about 5% of samples are positive. In the UK, some surveys of drug use have reported a particularly high incidence (25%) in junior medical doctors and dentists (Newbury-Birch *et al.* 2002).

Regulatory process in the USA

The DHHS *Guidelines* (Federal Register 1988a) were mandatory rules that governed the laboratory procedures for testing urine specimens from federal employees. They did not govern directly the testing of employees in the transportation sector, although they were incorporated into the DOT rules for such testing in 1988.

A number of professional organisations responded to the publication of the *Guidelines*. As they were somewhat restrictive in scope (e.g. covered only five drugs or drug classes), the College of American Pathologists (CAP) introduced a similar but voluntary programme in the early 1990s. This included other drugs and allowed laboratories to use procedures other than immunoassay and gas chromatography–mass spectrometry (GC-MS). Today there are approximately 40 laboratories certified by DHHS and 45 accredited by the CAP. In a number of US states, laboratories must be accredited by either programme before being allowed to carry out workplace drug testing. However, only those laboratories certified by DHHS are allowed to perform workplace testing on federal employees and on those covered by the DOT Regulations.

The DHHS *Guidelines* (Federal Register 1988a) consist of a number of subparts, two of which relate directly to laboratory testing; these are subpart B (Scientific and Technical Requirements) and subpart C (Certification of Laboratories Engaged in Urine Drug Testing for Federal Agencies). Within subpart B are included sections on drugs to be tested, specimen collection procedures, laboratory personnel, testing procedures, quality assurance and quality control, and the reporting and review of results. Subpart C includes sections on performance testing, the certification process and inspections. These sections of the *Guidelines* have become models for other accreditation programmes, particularly those of the CAP and the American Board of Forensic Toxicology (ABFT; American Academy of Forensic Sciences and the Society of Forensic Toxicologists 1991). Each of the important sections is discussed in more detail below and, where applicable, discussed in the light of today's practices in the USA and Europe.

Legislation in Europe

A survey of the legislation on workplace drug testing in Europe was published by the European Monitoring Centre for Drugs and Drug Addiction (EMCDDA 2006). Three countries have specific legislation: Finland (2003), Norway (2005) and Ireland (2005). Much of the legal framework, where it exists at all, comes from interpretations of a combination of various national laws, including those on Labour Codes, privacy, data protection, and health and safety at work. A multinational company, therefore, may not be able to implement the same procedure in all its offices. Some common patterns can be discerned.

There is an *agreement on some basic principles*, e.g. the European Convention on Human Rights and the EU directives on data protection and health and safety at work. National data protection authorities have made clear statements on workplace drug testing in some countries

Many countries state that testing can take place when there is a health, safety or security risk, or when it is 'necessary', 'proportionate', 'justified' or 'reasonable', or when there is a suspicion of drug taking.

The *emphasis is on the health aspects*, rather than on the possible illegality of drug taking: in many countries the occupational doctor can inform the employer only whether an employee is 'fit for work', rather than revealing the full results of the test. There are statements that testing should form part of an overall health policy and that one should test whether the person is fit for duty (as opposed to detecting any traces of drugs). The employer has a legal duty to provide a safe place of work.

Regarding the *employment aspects*, countries vary considerably in their emphasis on testing before or during employment. Testing is permitted for job applicants in some countries in certain situations; changes in contracts including a clause agreeing to testing must be negotiated with unions or workers' associations; employees must give prior informed consent. In some countries even a contractual agreement clause is not considered to be voluntary consent.

Sanctions: some countries specifically penalise unjustified testing with criminal fines, either as a breach of workers' privacy or as a breach of privacy generally. However, the EU directive on data protection leaves it to the Member States to define any sanctions for breach of data protection.

In Finland, the Act on Workplace Drug Testing (759/2004) permits workplace drug testing, paid for by the employer, for successful job applicants or current employees. This occurs in certain defined circumstances, where intoxication or addiction may endanger life, health, national or traffic safety, security of information in the public interest, or business or professional confidentiality. The State Council Decree on Good Practice in Workplace Drug Testing (218/2005) outlines the details of the testing procedures. The Occupational Health Care Act (1383/2001) requires that the need for a test to be assessed by a health care professional, not by the employer. Only a general conclusion on the health of an employee (fit, fit with restrictions or not fit) can be given to the employer. The employer is also obliged to prepare a written comprehensive prevention programme on alcohol and drugs policy in the enterprise in cooperation with the workers. Tests must follow the Act on Patients' Rights (785/1992): this requires the 'informed consent' of the patient. Thus, an employee has the right to refuse testing.

In Ireland, the Safety, Health and Welfare at Work Act 2005 requires employees not to be under the influence of drugs at work, and to submit to drug tests if reasonable; it is an offence, punishable by a fine or imprisonment, to fail to do this. The employer can ask a doctor to check an employee's medical fitness to work. The doctor must tell the employer of the decision, and the employee the reason for the decision. The employer is obliged to provide a safe place of work.

In Norway, Act No. 62 of 17 June 2005 relating to Working Environment, Working Hours and Employment Protection states that the employer can demand medical examinations (e.g. drug testing) only when pursuant to law or regulation:

- for positions which are associated with special risk
- when the employer finds it necessary in order to protect the life or health of employees or a third party.

These provisions apply both in relation to employees and to job applicants. Section 9-4 is exhaustive in the sense that the consent of the employee or job applicant does not provide a sufficient legal basis for drug testing. The testing must also comply with the general provisions in section 9-1, which state that all controlling measures must be objectively justified and not place a disproportionate burden on the employee. The employer must discuss controlling measures with the elected representatives of the employees as early as possible and provide information to the employees themselves about certain aspects of the controlling measures.

Workplace policies on drugs and alcohol

In many European countries, testing is only possible in the framework of a comprehensive alcohol and drugs policy. Such a policy is an important instrument in preventing and dealing with alcohol- and drugs-related job performance problems.

A comprehensive alcohol and drugs policy should include several elements:

- Prevention of alcohol and drugs problems through information, education and training.
- Education to explain the need for the policy, and to help the supervisors and managers who will have to deal with issues arising from the policy.
- The policy statement which explains the rules, and the consequences if the rules are broken.
- Procedures for intervention in cases of acute or chronic use of alcohol or other drugs.
- Measures to prohibit or restrict the availability of alcohol in the workplace.
- Assistance for employees, available both before and after drug/alcohol problems develop.
- Ways of monitoring and measuring the success of the policy, which is where testing fits in.

Successful drug and alcohol policies must reflect the interests and concerns of the entire organisation. A workplace policy has to provide for responses both to immediate impairment and to anyone developing dependency problems. The workplace is an excellent environment for promoting the sensible use of alcohol, awareness of the side-effects of medicines, and an understanding of the harmful effects of illegal drugs. Having an Employee Assistance Programme in place can reduce many of the home and work stress factors that could contribute to excessive drug and alcohol use.

If testing is included in the policy, the prospect brings the objectives of the company's drug and alcohol policy sharply into focus. Employees will know the policy is there, and that they are expected to comply with it. Testing provides a deterrent to irresponsible use, and helps people with problems to face up to them.

Drugs to be tested

The DHHS *Guidelines* clearly define the drugs that can be tested under the regulatory programmes and the cut-offs (or thresholds) to be used for both the initial testing by immunoassay and confirmation testing by GC-MS. These two procedures are the only ones allowed for under the *Guidelines*.

Table 3.1 includes details of the drugs tested and the cut-offs used in the USA, and those adopted for testing in the European Union (EU; European Workplace Drug Testing Society (EWDTS 2002)), the UK (London Toxicology Group 2001) and Australia/New Zealand (Standards Australia 2001). The EWDTS guidelines have been accepted by the European Accreditation (EA) body as a benchmark for workplace drug testing.

There are two points to make regarding Table 3.1:

- When the DHHS and European programmes are compared, significant differences are found between the cut-offs used for the opiates and amfetamines. Initially, the DHHS included a cut-off of 300 ng/mL for opiates, but this was raised to 2000 ng/mL in 1998 to resolve some of the issues associated with the medical review of opiate positives following poppy seed ingestion and prescription codeine use. On the other hand, the cut-off for amfetamines has remained at 1000 ng/mL since 1989. That proposed by the European programmes is more realistic, considering the increasing use of the so-called 'designer amfetamines' throughout the 1990s.
- Phencyclidine (PCP) has always been included in the DHHS *Guidelines*, even though it is not widely used in the USA. It is even less widely used in Europe and therefore its exclusion from the EU proposal is not surprising.

The majority of testing in the USA is performed in the non-regulated workplace and, although a large number of these programmes follow the federal guidelines, a number include drugs or drug classes other than the five listed in Table 3.1 or test these five drugs or drug classes at different cut-offs. Table 3.2 lists the other drugs or drug classes that are tested and the differing cut-offs used. It can be seen that laboratories that perform workplace drug testing in the USA need to be prepared to offer a variety of tests and cut-offs if they are to satisfy fully the demands of the marketplace.

The current DHHS *Guidelines* require that all confirmations be performed by GC-MS using the cut-offs listed in Table 3.3. There are a number of points to be made regarding Table 3.3:

- Currently, the DHHS *Guidelines* do not require certified laboratories to confirm the presence of methylenedioxymethamfetamine (MDMA), methyldioxyamfetamine (MDA) and methylenedioxyethamfetamine (MDE), whereas the European guidelines do. In addition, the UK and Australia/New Zealand guidelines use cut-offs for the confirmation of ephedrine and pseudoephedrine. Draft proposals (Federal Register 2004b) to amend the DHHS *Guidelines* require the inclusion of MDMA, MDA and MDE.
- The DHHS *Guidelines* require a laboratory report of metamfetamine as positive only if its concentration is 500 ng/mL or greater, and if that of amfetamine is 200 ng/mL or greater. This reporting criterion was introduced in 1991 after several specimens were reported as positive for metamfetamine when the specimen contained large amounts of pseudoephedrine or ephedrine. It was discovered subsequently (Hornbeck *et al.* 1993) that these hydroxylated sympathomimetics could convert to metamfetamine in either the extraction or chromatographic stages of the analysis. None of these specimens contained amfetamine when tested, and therefore the introduction of the reporting rule prevented the reporting of 'false-positive' metamfetamine results. Today, the vast majority of laboratories use a pre-oxidation step with periodate (Klette *et al.* 2000; Paul *et al.* 1994) to prevent the possibility of this happening.
- As with the initial testing cut-offs, there is a difference in the thresholds used for opiate confirmations. The DHHS cut-off is 2000 ng/mL for morphine and codeine, whereas the European ones are 300 ng/mL (the UK and EU). There is also a difference across the three regions in the opiates to be tested. All require morphine

Table 3.1 Initial testing cut-offs (μg/L) for those drugs and/or drug classes included in regulatory programmes in urine

Drug or drug class	*USA DHHS*	*EU*	*UK*	*Australia/NZ*
Amfetamines	1000	300	300	300
Cannabis	50	50	50	50
Cocaine	300	300	300	300
Opiates	2000	300	300	300
Phencyclidine	25	Not tested	25	Not tested

Table 3.2 Initial testing cut-offs (μg/L) for those drugs and/or drug classes included in non-regulatory programmes in urine

Drug or drug class	*Cut-off in the USA (μg/L)*
Amfetamines	300 or 500
Barbiturates	100 or 200
Benzodiazepines	100, 200 or 300
Cannabis	20, 25 or 100
Cocaine	150
Methadone	100 or 300
Methaqualone	100 or 300
Opiates	300
Propoxyphene	100 or 300

Table 3.3 Confirmation cut-offs (μg/L) for those drugs and/or drug classes included in regulatory programmes in urine

Drug or drug class	*Drugs tested*	*US DHHS*	*EU*	*UK*	*Australia/NZ*
Amfetamines	Amfetamine	500	200	200	300
	Metamfetamine	500	200	200	300
	MDMA, MDE		200	200	300
	Pseudoephedrine			200	500
	Ephedrine			200	500
Cocaine	Benzoylecgonine	150	150	150	150
Cannabis	THCA	15	15	15	15
Opiates	Morphine	2000	200	300	300
	Codeine	2000	200	300	300
	6-AM	10	10	10	10
	Dihydrocodeine			300	
Phencyclidine	PCP	25	Not tested	25	Not tested

and 6-acetylmorphine (6-AM) under certain circumstances in some cases; the DHHS, Australia/New Zealand and UK guidelines also require codeine, and the UK one requires dihydrocodeine. The DHHS *Guidelines* require that certified laboratories analyse the specimen for 6-AM (with a cut-off of 10 ng/mL) if the morphine concentration exceeds 2000 ng/mL.

- Cannabis (marijuana) use is confirmed by quantifying one of the major urinary metabolites of tetrahydrocannabinol (THC), 11-carboxytetrahydrocannabinol (THCA) and the cut-off value of 15 ng/mL has been also adopted by the European programmes.

Table 3.4 details the other drugs that may have to be confirmed in non-regulated programmes and the different cut-offs that may be used for the five drug classes tested for in the regulated programme. Although several compounds are listed under some of the drug classes, this does not imply that all these tests are performed on every non-regulated specimen with a positive initial testing result.

Lysergide testing

Over the years there has been discussion regarding the usefulness of incorporating lysergide (LSD) into workplace drug testing programmes. There are many reasons for its exclusion, one of the major ones being that demographically those included in workplace drug-testing programmes are not in the age group expected to be users. Nevertheless, certain populations, such as inductees into the US military, are being tested using cut-offs for screening and confirmation of less than 1 ng/mL for LSD. A second major reason is the analytical challenge presented. Today, both enzyme and microparticle immunoassays are available for screening urine specimens, and LSD can be confirmed using tandem mass spectrometry. However, there has been concern regarding testing

Table 3.4 Confirmation cut-offs (μg/L) for those drugs and/or drug classes included in non-regulatory programmes in urine

Drug or drug class	*Drugs tested*	*USA*	*EU*	*UK*	*Australia/NZ*
Amfetamines	Amfetamine	300 or 500	200	200	300
	Metamfetamine	300 or 500	200	200	300
	MDMA, MDA	300 or 500	200	200	300

Propoxyphene	Propoxyphene	100 or 300	300	300	

for unchanged LSD, and work published by Klette *et al.* (2000) and Poch *et al.* (2000) shows clearly that the 2-oxo-3-hydroxy LSD metabolite is the preferred target analyte.

Testing procedures

As already indicated, the DHHS *Guidelines* mandate the use of immunoassay as the initial test and GC-MS as the confirmatory procedure. These are also the testing procedures generally used for non-regulated testing, although some laboratories may be using MS-MS technology or liquid chromatography–mass spectrometry (LC-MS, or LC-MS-MS) for the confirmation of the non-regulated analytes.

The immunoassay methods have to have been approved by the Food and Drug Administration (FDA), which in the USA has regulatory authority for approval of diagnostic reagents. Although workplace drug testing is not being performed for diagnostic purposes, it was believed that requiring FDA approval would bring at least some standardisation to the reagents used. However, no regulations were introduced that required the immunoassay kits to use antibodies directed towards certain members of a drug class, and if the kits used for regulated and non-regulated testing are compared there is some variation in the target antigen (Liu 1995).

Nearly all drug-testing laboratories use either reagents based on enzymes (e.g. EMIT or CEDIA), microparticles (KIMS) or fluorescence polarisation (TDx). Table 3.5 shows the calibrators used in each of the immunoassays for the drugs tested today.

Given the difference in target antigens and calibrators, different detection rates on specimens that contain the same drug(s) and/or metabolites might be expected. For example, the CEDIA and EMIT assays for amfetamine have almost 100% cross-reactivity to *d*-amfetamine, whereas the KIMS assay has little cross-reactivity to *d*-metamfetamine. In fact, the latter was designed to comply with the Reporting Rule issued by DHHS for metamfetamine positives, and therefore is effective in detecting 'real-life' specimens that contain metamfetamine and its metabolite, amfetamine. Conversely, if a proficiency-testing specimen contained only metamfetamine it would give a negative result. Similar dichotomies exist in examining the benzodiazepines, for which the detection of the more traditional members of the group is not a problem, but the assays vary widely in their ability to detect some of the later members, such as lorazepam and flunitrazepam metabolites (Drummer 1998). Even when the procedures are targeted towards the same antigen and use the same calibrators, there can be variation in their ability to detect positive specimens. For example, immunoassays that have greater specificity towards the target urinary metabolite of THC (THCA), may not be as efficient as those that cross-react more widely to the THC metabolites in detecting urine specimens from cannabis users, particularly when cut-offs are used.

One of the major concerns in the past few years has been the ability of the amfetamine assays to detect MDMA, MDA and MDE. Some of the manufacturers have introduced special kits, whereas others have relied on the inherent cross-reactivity of their existing amfetamine assay. From existing data (Zhao *et al.* 2001), it appears that either approach is satisfactory, with the most variation being seen in specimens with concentrations close to the cut-off. In an attempt to resolve this problem, the draft proposals (Federal Register 2004b) from the DHHS on the new guidelines require that '*d*-metamfetamine be the target analyte and the test kit must cross-react with MDMA, MDA and MDE (approximately 50–150% cross-reactivity)'. Whether this requirement can be satisfied, given the vagaries of immunoassays, remains to be seen.

Some of the issues that surround initial testing by immunoassay have been discussed already. Far fewer issues relate to confirmation testing by GC-MS. Numerous GC-MS procedures have been published for the identification and quantification of the drugs and their metabolites in urine specimens, and increasingly so for their detection in hair, oral fluid and other specimens. Confirmation analyses of drugs and metabolites in hair, oral fluid and sweat will require procedures with more sensitivity than those currently used for urine specimens, and the draft proposals (Federal Register 2004b) from the DHHS recognise this in that they permit the use of MS(-MS) technology with GC and LC interfaces. The use of these technologies is likely to raise issues similar to those that were debated two decades or so ago, when GC-MS was mandated for confirmation of drugs and metabolites in urine. Some of these issues are set out and discussed below:

- How reliable is the use of ion ratios and how many ions should be monitored? Experience has certainly shown that the monitoring of three ions for the analyte and two for the deuterated internal standard, and the use of a 20% range for ion ratios, result in satisfactory positive identification of the analyte.
- How diagnostic are the ions? Most toxicologists believe that using ions of higher mass is more appropriate than using ones of lower mass. For example, using *m/z* 91 for amfetamine is not recommended. On the other hand, there are a number of assays in use today that routinely use isotopes for identification and ratio purposes. Perhaps the best example is the confirmation of PCP, for which large numbers of laboratories use *m/z* 242 and its carbon isotope, *m/z* 243. This has become an accepted practice for this drug because, apart from *m/z* 205, there are no other diagnostic ions. Another example of a drug class for which isotopes may be used, with less justification, is the benzodiazepines (halogen isotope ratios are used).
- What is an acceptable chromatographic peak shape? Two integral parts of the DHHS *Guidelines* are the need for proficiency testing (the *Guidelines* use the term performance testing) and regular inspections of the certified laboratories. The latter has become known as the National Laboratory Certification Program (NLCP) and requires that each laboratory be inspected at 6-monthly intervals. There are allowances within the *Guidelines* for other inspections, specifically special inspections that can be performed at the direction of DHHS and outside the normal cycle. A number of accepted practices have evolved as a result of the inspections. Two examples are the detailed quality-control requirements and the definition of acceptable peak shape. The acceptance criteria for these practices, and others, are not included in the DHHS *Guidelines* themselves, but are included in the Resource Manual for the NLCP. Within this

Table 3.5 Calibrators used in commercial immunoassays

Drug or drug class	*CEDIA*	*EMIT*	*OnLine (KIMS)*	*TDx/ADx*
Amfetamines	*d*-Metamfetamine	*d*-Metamfetamine	*d*-Amfetamine	*d*-Amfetamine
Barbiturates	Secobarbital	Secobarbital	Secobarbital	Secobarbital
Benzodiazepines	Nitrazepam	Lormetazepam	Nordiazepam	Nordiazepam
Cannabis	THCA	THCA	THCA	THCA
Cocaine	Benzoylecgonine	Benzoylecgonine	Benzoylecgonine	Benzoylecgonine
Methadone	Methadone	Methadone	Methadone	Methadone
Methaqualone	Methaqualone	Methaqualone	Methaqualone	Methaqualone
Opiates	Morphine	Morphine	Morphine	Morphine
Phencyclidine	PCP	PCP	PCP	PCP
Propoxyphene	Propoxyphene	Propoxyphene	Propoxyphene	Propoxyphene

manual, an acceptable chromatographic peak shape has been defined as having greater than 90% resolution and symmetry.
- What are the limits of detection and quantification and how are they determined? The definition of these criteria has also evolved since 1988. Initially, the majority of certified laboratories used the traditional definitions based on the analysis of drug-free specimens and, although this is still acceptable, the favoured definitions are now ones based on serial dilutions and satisfying quantitative and ion-ratio criteria.

Although it is straightforward to define these criteria for GC-MS analysis of urine specimens, it is difficult to imagine the same criteria being applied to MS(-MS) technology, particularly if chemical ionisation or electrospray are used.

Quality control

The DHHS *Guidelines* stress the importance of appropriate quality control and quality assurance programmes, but do not define specific requirements. Within the DOT Regulations (Federal Register 2000) is the requirement that 1% of samples referred to testing laboratories by employers and other bodies that manage drug-testing programmes should be blind quality-control specimens. These must be double-blind to the laboratory and must include negatives, positives and specimens that may be adulterated or substituted.

In addition to these double-blind specimens, the laboratory itself is required to analyse a further 1% as blind specimens through the initial immunoassay testing. These specimens are best described as 'single blinds' in that their identity is known before the specimens are released for reporting. The DHHS *Guidelines* indicate the following requirements for open quality control (when the identity is known to the analyst):

- Initial testing: each analytical run of specimens to be screened shall include:
  - sample(s) certified to contain no drugs;
  - positive controls fortified with drug or metabolite;
  - at least one positive control with the drug or metabolite at or near the cut-off;
  - a minimum of 10% of the total specimens in each analytical run shall be controls.
- Confirmation testing (in which each analytical run of specimens to be confirmed) shall include:
  - sample(s) certified to contain no drug;
  - positive controls fortified with drug or metabolite;
  - at least one positive control with the drug or metabolite at or near the cut-off.

Currently, there are no requirements to include 'single blinds' in confirmation batches or to confirm those 'single-blind' controls that have tested positive by immunoassay, although a number of certified laboratories do so.

More detailed guidelines were developed over time, as a result of the inspection process, and the NLCP now considers the following to be appropriate quality control for initial testing batches:

- A minimum of 10% of the total specimens and controls in each analytical run shall be controls, for example if the batch size is 50 (including controls) then at least 5 need to be open controls.
- The controls shall include:
  - sample(s) certified to contain no drug or metabolite;
  - positive controls targeted to contain drug or metabolite at no greater than 125% of the cut-off;
  - 'negative' controls targeted to contain drug or metabolite at no less than 75% of the cut-off.
- Positive controls have to test positive and negative controls negative before a batch can be released for reporting.
- Specimens have to be bracketed by acceptable controls before they can be released for reporting.

Although there are no specific requirements for the trend analysis of control values, there are expectations that a certified laboratory should monitor these to determine assay drift. In addition, when validating an immunoassay the laboratory is expected to ensure that there is adequate separation between the values of the 'negative' control and the cut-off and those of the cut-off and positive control.

The DHHS *Guidelines* for quality control of confirmation assays were also vague and required further clarification through the NLCP. The situation here was further complicated by the requirements to re-test specimens. Both the DHHS *Guidelines* and DOT Regulations recognised the possibility that drug concentrations may decrease over time in positive specimens, even when they were frozen. This was viewed as a particular problem for THCA and benzoylecgonine. To prevent a specimen that initially tested as positive from reporting as 'negative' on a re-test, it was decided that the reconfirmation test should determine only the presence or absence of the drug or metabolite, that is no cut-offs were to be used for GC-MS analyses of re-test specimens. The laboratories were therefore asked to test these specimens to their 'limits of detection' for the specific drug. The issue quickly arose that each laboratory essentially used a different limit of detection for these re-tests and there was no standardisation. In the early 1990s, guidance issued by the NLCP required certified laboratories to have 'limits of detection' of at least 40% of the confirmation cut-off for these re-tests. For THCA and benzoylecgonine this meant that they had to confirm at 6 and 60 ng/mL, respectively, using the standard acceptance criteria for ion ratios and chromatographic peak shape. To ensure that they can do so, the NLCP challenges laboratories with re-test specimens as part of the performance testing programme and requires that a 40% of cut-off control be included in all re-test batches.

The NLCP considers the following to be an acceptable quality control programme for confirmation analyses:

- Each batch contains a certified negative sample.
- Each batch contains one cut-off control, targeted to be 125% of the cut-off.
- Each re-test batch contains a control targeted to be 40% of the cut-off.
- The acceptable range for the control is plus or minus 20% of a validated mean concentration for that control pool.
- If the laboratory prepares its calibrators and controls in-house, these need to be prepared from at least two different lot numbers of drug or metabolite.

Certification of data is an integral part of the operation of a drug-testing laboratory and is covered by the DHHS *Guidelines*. All results, including negatives, have to be reviewed by a certifying scientist before they can be reported. The larger laboratories have two different categories of certifying scientist, those trained to review negative results and those trained to review positives. The major difference between the two is in the level of expertise and experience; those who can report positives must have knowledge of GC-MS and of the quality control of GC-MS procedures. Both groups need to have knowledge of accessioning (the receipt of specimens), chain-of-custody protocols, immunoassays and quality control of these assays. The certification process includes a review of testing data, quality-control results, chain-of-custody documentation (external and internal) and any other documentation associated with the specimen being reported. A certifying scientist with the experience and training to release positives is also required to compare the initial immunoassay and GC-MS results for consistency (when this can be done) and may be asked to provide technical assistance to medical review officers (MROs) and others who receive drug testing results.

Testing procedures, quality control and quality assurance have been discussed in some detail, with the emphasis being placed on the protocols expected of DHHS-certified laboratories. Laboratories are expected to follow similar protocols for CAP accreditation, and these have been used as a framework for accreditation in other programmes. This is not necessarily because they are ideal, but because they have become the standard of care for accepted laboratory practice in drug testing and increasingly so in forensic toxicology. It is worthy of comment that the majority of laboratories that perform comprehensive forensic toxicology now have a quality-control programme, not necessarily for all analytes but certainly for those that they test routinely. This was not the case in the early 1990s.

Table 3.6 Proposed initial testing cut-offs for alternative specimens

Drug or drug class	*Hair (pg/mg)*	*Oral fluid (μg/L)*	*Sweat (ng/patch)*
Amfetamines	500	50	25
Cocaine	500	20	25
Cannabis	1	4	4
Opiates	200	40	25
Phencyclidine	300	10	20
MDMA	500	50	25

Proposed changes to the DHHS *Guidelines*

The DHHS is considering expanding the *Guidelines* to include specimens other than urine and to lower the cut-offs in urine. Although these proposals (Federal Register 2004b) have not been adopted, it is probably worthwhile to summarise the proposed cut-offs for these alternative specimens. The three new specimens being considered are hair, oral fluid and sweat (Tables 3.6 and 3.7). Today, each of these specimens is being used outside the federally regulated workplaces for workplace and/or criminal justice testing.

Within the proposal there are a number of footnotes to Tables 3.6 and 3.7.

Hair

- It will be permissible to test initially all specimens for 6-AM using a 200 pg/mg cut-off.
- For a specimen to be positive for cocaine, both cocaine and benzoylecgonine must confirm positive and the ratio of metabolite to parent cocaine must be equal to or greater than 0.05.
- If the specimen confirms positive for 6-AM, it must also contain morphine at a concentration equal to or greater than 200 pg/mg.
- For a specimen to be positive for metamfetamine it must contain amfetamine at a concentration equal to or greater than 50 pg/mg.

Oral fluid

- It will be permissible to test initially all specimens for 6-AM using a 4 ng/mL cut-off.
- For a specimen to be positive for metamfetamine it must contain amfetamine at a concentration equal to or greater than the limit of detection.

Standards Australia has now published guidelines for specimen collection and the detection and quantification of drugs in oral fluids (Standards Australia 2006). The guidelines were developed by a committee made up of practising toxicologists, pathologists, industry representatives, unions, and government officials with input from the accreditation authority. They cover the collection, on-site testing, transport and laboratory testing, and confirmation for drugs in the fluid.

The standard focuses on testing for amfetamine-related stimulants, cocaine, cannabis and opiates. It describes the training of persons collecting oral fluids and performing on-site drug screens, the conduct of quality control testing and proficiency testing on-site as well as the ISO/IEC 17025 or 15189 requirements for laboratory-based testing. A referee specimen should be available if a result is disputed. The standard uses the concept of 'target concentration' rather than 'cut-off' to indicate a concentration sufficient for detection of drug use, since international agreement for cut-offs has not yet been reached for any application. These concentrations are those that should be detectable in order to identify relatively recent drug use. The standard recommends the use of quality controls not only in a laboratory setting but also on site. For on-site tests one negative and one positive control should be run each day and one quality control sample should be analysed for every 25 specimens. Quality control samples are prepared in oral fluid at or within 50% of the concentration nominated by the manufacturer to detect the drug reliably and for which performance data are available.

Sweat

- For a specimen to be positive for metamfetamine it must contain amfetamine at a concentration equal to or greater than the limit of detection.

Clearly, there will be a dramatic increase in the complexity of the analyses needed to test these alternative specimens for workplace drug testing, and in the proficiency testing and inspection programmes involved in certifying laboratories to do such testing.

Although no mention has yet been made regarding the specimen volume to be collected, it is important to realise that the current urine testing programme requires the collection of at least 45 mL, of which 30 mL is placed in bottle A and 15 mL in bottle B. Bottle B is considered to be the donor's and can be opened only at the request of the donor. This request is generated by the MRO and the bottle is normally opened for re-test purposes by a second certified laboratory. Given the sensitivity of current technology available for testing urine specimens, there are no concerns regarding specimen availability during this process. However, that may not be the case for the alternative specimens, for

Table 3.7 Confirmation cut-offs for alternative specimens

Drug or drug class	*Drugs tested*	*Hair (pg/mg)*	*Oral fluid (μg/L)*	*Sweat (ng/patch)*
Amfetamines	Amfetamine	300	50	25
	Metamfetamine	300	50	25
	MDMA	300	50	25
	MDA	300	50	25
	MDE	300	50	25
Cocaine	Benzoylecgonine	50		
	Cocaine	500		
	Cocaine or benzoylecgonine		8	25
Cannabis	THCA	0.05		
	THC		4	1
Opiates	Morphine	200	40	
	Codeine	200	40	
	Morphine, codeine or 6-AM			25
	6-AM	200	4	
Phencyclidine	PCP	300	10	20

which the minimum specimen sizes are recommended to be hair 100 mg (2×50 mg), oral fluid 2 mL (1.5 mL for the primary specimen and 0.5 mL for the split specimen) and sweat (two FDA-approved patches worn for 7–14 days).

More than 2000 comments were received from 285 responders representing drug-testing laboratories, manufacturers of testing kits, federal employees who will be drug tested, agencies that may choose to use new drug testing methods, private sector employers and members of the public at large. The proposed changes have not been adopted yet. Their implementation will require laboratories to be proficient in the use of more sensitive immunoassays (particularly enzyme-linked immunosorbent assay (ELISA)) and tandem mass spectrometry (probably with an liquid chromatography interface).

Table 3.8 provides a comparison of hair, oral fluid and sweat as specimens for drug detection.

Point-of-collection tests

The proposed changes to HSS *Guidelines* also included a section on point-of-collection tests (POCTs). This establishes the criteria for POCT devices that may be used as part of the Federal Workplace Drug Testing Program, i.e. when federal agencies may use a POCT, what the responsibilities are of a federal agency that chooses to use a POCT, and the procedures that must be followed in using a POCT.

A POCT device that may be used in a Federal Workplace Drug Testing Program is one that:

- is FDA-cleared; and
- effectively determines the presence or absence of drugs and determines the validity of a specimen, either as an integral feature of the POCT device or as a set of compatible devices or procedures.

POCT devices may be:

- *non-instrumented*, for which the endpoint result is obtained by visual evaluation (i.e. read by human eye); or
- *instrumented*, for which the result is obtained by instrumental evaluation (e.g. a densitometer, a spectrophotometer, a fluorometer).

Oral fluid (saliva) and urine specimens may be tested using a POCT.

For drug POCTs the quality control requirements are as follows:

- Each day testing is performed using devices with visually read endpoints, each individual performing drug tests using these devices must test at least one negative control and one positive control (with the concentration of the drugs or metabolites in the range of 25% above the cut-off concentration) before donor specimens are tested.
- Each day testing is performed using devices with semi-automated or automated testing devices with machine-read endpoints (i.e. spectrophotometer); at least one negative control and one positive control must be tested on each device used.

For validity POCTs, for each day that testing is performed, at least one control that is normal for the specific validity test and one control that is abnormal must be tested. The results must be correct before donor specimens are tested.

At least one specimen out of every 10 specimens that test negative must be submitted to an DHHS-certified laboratory as part of a quality assurance programme. None of these proposed changes has been adopted.

Adulterated and substituted specimens

Over the past decade, increasing attention has been paid to attempts to 'beat the drug test'. There have always been donors who have attempted this through diuresis, through substitution of the specimen (with clean urine or another fluid) or through deliberate adulteration of the collected specimen. The DOT first issued guidance on this in 1992 and recommended that laboratories identify adulterants in a 'forensically acceptable manner'. A 'dilute urine specimen' was defined as one that contained less than 20 mg/dL creatinine and had a relative density (specific gravity) of less than 1.003. At that time regulations allowed an observed urine collection on a donor producing dilute urine at their next scheduled collection, and at the request of the employer. In practice this was hardly ever done. Collection guidelines also required the collector to perform an observed collection if there were suspicious circumstances during collection or if the urine temperature was out of range (the acceptable range being 32–38°C).

In recent years use has been made of the Internet to sell products that are supposedly designed to beat drug tests. While a number of these include the instructions to drink copious amounts of water before taking the test (i.e. diuresis), others are designed specifically to oxidise the THCA metabolite of cannabis and thereby reduce the ability of the laboratory to confirm cannabis use. Some examples include nitrite, chromate (chromium(VI)), halogens and peroxide. Although

Table 3.8 Comparison of hair, oral fluid and sweat as specimens for drug detection

Specimen	*Detection window*	*Advantages*	*Disadvantages*
Hair	Months – dependent to some extent upon the drug	Can be used as a long-term measure of drug use	Not a suitable specimen for detecting recent drug use
		Relatively non-invasive collection	May be an invasive collection if head hair is unavailable
		Can obtain a second specimen for re-testing (if necessary)	Requires sensitive immunoassays and MS-MS technology
		Relatively resistant to adulteration	Deposition of drug and/or metabolite in hair is reported to be dependent upon hair colour
			Potential environmental contamination
Oral fluid	Hours or days – dependent to some extent upon the drug	Relatively non-invasive collection	Short detection window for some drugs
		An 'observed' collection and therefore resistant to adulteration and substitution	Requires sensitive immunoassays and MS-MS technology
		For some drugs correlates to free drug concentration in plasma	Collection methods can dilute the specimen, which makes drug detection more difficult
			After cannabis use, THC in the buccal cavity is the detected material, THCA is not detected
Sweat	Up to weeks – dependent to some extent upon the drug	Cumulative measure of drug use Can monitor drug use for a period of weeks with a sweat patch	Requires sensitive immunoassays and MS-MS technology High inter-subject variability For workplace drug testing, application of sweat patch for several days is impractical

accurate data are difficult to obtain, recent data from Quest Diagnostics show that the rate of substituted specimens in 2007 was 0.05% for workers covered by federal regulations and 0.01% for those in the general workplace. The comparable rates for adulterated specimens were 0.01% and 0.0%, respectively.

The *CFR Part 40* (Federal Register 2000) requires certified laboratories to detect adulterated and substituted specimens. The DHHS has issued detailed proposed rules (Federal Register 2004b) for such testing, which include definitions and the testing and quality control procedures to be used. Steps that the MRO can use for review of these non-negative specimens are also included. These rules are for federal employees only. The DOT issued a Notice of Proposed Rule Making in November 2005 which differed from the rules covering federal employees in the handling of substituted specimens. Under the DHHS rules the definitions for a dilute, substituted and adulterated specimen are as follows:

- Dilute: creatinine greater than or equal to 2 mg/dL, but less than 20 mg/dL and relative density is greater than 1.0010 but less than 1.0030, except when the definition of a substituted specimen is met.
- Substituted: creatinine less than 2 mg/dL and relative density less than 1.0010 or equal to or greater than 1.0200.
- Adulterated:
  - Nitrite is greater than or equal to 500 µg/mL.
  - pH is less than 3 or greater than or equal to 11.
  - The presence of chromium(VI) is verified.
  - The presence of a halogen is verified.
  - The presence of glutaraldehyde is verified.
  - The presence of pyridine is verified.
  - The presence of a surfactant is verified.
  - The presence of any other adulterant is verified.

With these Rules, DHHS required the laboratories to verify the presence of an adulterant using a test different from the one used to detect it. For example, the laboratories could use a general oxidant screening test, but if this was positive it would have to verify the presence of chromium(VI) by a specific analytical procedure. If they did not do this then the specimen would be reported as invalid and the MRO would then have to interview the donor and, if there was no medical explanation, require a recollection under direct observation. This has led to an increase in the number of invalids reported by the laboratories (Quest Diagnostics 2008). In the federal workplace the rate has risen from 0.08% in 2004 to 0.11% in 2007, and in the non-federal workplace from 0.10% to 0.13%.

The following definitions are now used for invalid specimens:

- Inconsistent creatinine concentration and relative density (i.e. creatinine concentration is less than 2 mg/dl and relative density is greater than 1.0010 but less than 1.0020, or relative density is less than or equal to 1.0010 and creatinine concentration is greater than or equal to 2 mg/dL).
- The pH is greater than or equal to 3 and less than 4.5 or greater than or equal to 9 and less than 11.
- The nitrite (or nitrite equivalent) concentration is greater than or equal to 200 µg/mL but less than 500 µg/mL.
- The possible presence of chromium(VI) is determined
- The possible presence of a halogen is determined.
- The possible presence of glutaraldehyde is determined.
- The possible presence of an oxidising agent is determined.
- The possible presence of a surfactant is determined.
- Interference occurs with the immunoassay drug results.
- Interference occurs with the GC-MS confirmation tests.
- The physical appearance of the specimen is such that it may damage the laboratory's instruments.

Under the proposed rules for DOT, the definition of a substituted specimen remains the same but includes a requirement that the MRO order an immediate re-collection under direct observation for a negative dilute with a creatinine concentration greater than or equal to 2 mg/dL but equal to or less than 5 mg/dL. This requirement obviously means that the laboratory reports both the creatinine concentration and the relative density to the MRO.

These rules are interesting for a number of reasons. First, a workplace drug-testing laboratory now has to perform tests that, historically, have not been performed in toxicology laboratories. Second, the toxicologist and/or MRO may be called upon to defend these specimen validity testing procedures and their results when legally challenged, for example in an arbitration hearing. Defending a non-negative result may present new challenges in terms of the interpretation of the data. Third, they expand the duties of the laboratory to include the identification of new and existing adulterants, which is a major analytical challenge. Finally, they are the first such rules to prescribe quality-control protocols for diluted, adulterated or substituted specimens.

This brief overview of some of the newer requirements and of the expansion of the programmes to include alternative specimens demonstrates that the range and complexity of workplace drug testing has increased dramatically and will continue to do so.

Collection of specimens

The proper collection, packaging and transporting of urine specimens is a crucial part of a drug-testing programme. Although this is the most frequently challenged aspect of the process in any legal proceeding, it is also the least regulated one. Until the introduction of the updated *CFR Part 40* (Federal Register 2000), there were no requirements for training or certification of collectors, and there are still no requirements for certification. The training programme is one that depends upon the 'train the trainer' concept and requires an evaluation of the individual's ability to collect specimens and complete the appropriate chain-of-custody documentation in certain situations. A collector who makes errors is required to undergo error-correction training. These errors are documented either by the laboratory when receiving specimens or by the MRO when reviewing the chain-of-custody documentation.

It has been accepted practice, and is now a requirement, in the industries regulated by the DOT that a urine specimen be collected and split into two portions (sometimes referred to as bottles A and B) and that the minimum volume should be 45 mL. As described above, at least 30 mL is placed in bottle A and 15 mL in bottle B. During the collection process the collector is required to monitor the temperature of the urine (within 4 min of the collection), ensure that the donor does not substitute or adulterate the specimen and complete the necessary chain-of-custody documents. This process is itemised into the following major steps:

- Preparation of the collection area, for example adding a blue dye to the toilet water and taping of the taps.
- Confirmation of the donor's identity using photographic evidence and requesting him or her to remove outer clothing and to empty pockets.
- Having the donor randomly select a collection container and two bottles, which should be wrapped separately (only the collection container should be taken into the toilet enclosure).
- Checking the temperature of the sample within 4 min of voiding and noting the result on the chain-of-custody form. The collector then has to ensure that there is at least 45 mL of urine in the container and that the specimen has no unusual odour, colour or physical properties (e.g. excessive frothing) that may indicate attempted adulteration.
- Pouring at least 30 mL into bottle A and 15 mL into bottle B in the presence of the donor, and immediately closing the bottles and applying tamper-evident seals across the lids or caps of the bottles.
- Ensuring that the donor initials the seals and completes his or her section of the chain-of-custody form. The collector then completes the remaining sections of the form.
- Preparing the specimen bottles for shipment to the laboratory.

Although these are the recommended steps for the completion of a regulated chain of custody, it is also the general procedure used to collect all urine specimens. The steps most often challenged are that the

collector did not complete the process in the presence of the donor and that more than one specimen was being collected at the same time (i.e. there were multiple specimens and chains of custody in various stages of collection).

Completion of the chain-of-custody form is an important part of this process, and in the regulated arena a five-part document is used (see Fig. 3.1 for Copy 1 of this document). There are several sections to the form:

STEP 1: COMPLETED BY COLLECTOR OR EMPLOYER REPRESENTATIVE

A. Employer Name, Address, I.D. No.

B. MRO Name, Address, Phone and Fax No.

C. Donor SSN or Employee I.D. No. _____

D. Reason for Test: ☐ Pre-employment ☐ Random ☐ Reasonable Suspicion/Cause ☐ Post Accident ☐ Return to Duty ☐ Follow-up ☐ Other (specify) _____

E. Drug Tests to be Performed: ☐ THC, COC, PCP, OPI,AMP ☐ THC & COC Only ☐ Other (specify) _____

F. Collection Site Address:

Collector Phone No. _____

Collector Fax No. _____

OMB No. 0930-0158

STEP 2: COMPLETED BY COLLECTOR

Read specimen temperature within 4 minutes. Is temperature between 90° and 100° F? ☐ Yes ☐ No, Enter Remark	Specimen Collection: ☐ Split ☐ Single ☐ None Provided (Enter Remark)	☐ Observed (Enter Remark)

REMARKS

STEP 3: Collector affixes bottle seal(s) to bottle(s). Collector dates seal(s). Donor initials seals(s). Donor completes STEP 5 on Copy 2 (MRO Copy)

STEP 4: CHAIN OF CUSTODY - INITIATED BY COLLECTOR AND COMPLETED BY LABORATORY

I certify that the specimen given to me by the donor identified in the certification section on Copy 2 of this form was collected, labeled, sealed and released to the Delivery Service noted in accordance with applicable Federal requirements.

X _____ Signature of Collector

_____ (PRINT) Collector's Name (First, MI, Last)

AM PM Time of Collection

/ / Date (Mo./Day/Yr.)

SPECIMEN BOTTLE(S) RELEASED TO:

_____ Name of Delivery Service Transferring Specimen to Lab

RECEIVED AT LAB:

X _____ Signature of Accessioner

_____ (PRINT) Accessioner's Name (First, MI, Last)

/ / Date (Mo./Day/Yr.)

Primary Specimen Bottle Seal Intact

☐ Yes

☐ No, Enter Remark Below

SPECIMEN BOTTLE(S) RELEASED TO:

STEP 5a: PRIMARY SPECIMEN TEST RESULTS - COMPLETED BY PRIMARY LABORATORY

☐ NEGATIVE ☐ POSITIVE for: ☐ MARIJUANA METABOLITE ☐ CODEINE ☐ AMPHETAMINE ☐ ADULTERATED ☐ DILUTE ☐ COCAINE METABOLITE ☐ MORPHINE ☐ METHAMPHETAMINE ☐ SUBSTITUTED ☐ REJECTED FOR TESTING ☐ PCP ☐ 6-ACETYLMORPHINE ☐ INVALID RESULT

REMARKS _____

TEST LAB (if different from above) _____

I certify that the specimen identified on this form was examined upon receipt, handled using chain of custody procedures, analyzed, and reported in accordance with applicable Federal requirements.

X _____ Signature of Certifying Scientist

_____ (PRINT) Certifying Scientist's Name (First, MI, Last)

/ / Date (Mo./Day/Yr.)

STEP 5b: SPLIT SPECIMEN TEST RESULTS - (IF TESTED) COMPLETED BY SECONDARY LABORATORY

_____ Laboratory Name

_____ Laboratory Address

☐ RECONFIRMED ☐ FAILED TO RECONFIRM - REASON _____

I certify that the split specimen identified on this form was examined upon receipt, handled using chain of custody procedures, analyzed, and reported in accordance with applicable Federal requirements.

X _____ Signature of Certifying Scientist

_____ (PRINT) Certifying Scientist's Name (First, MI, Last)

/ / Date (Mo./Day/Yr.)

Drug Form Part 1
Face Inks: 000 BLK/000 RED
Date: 05/09/00
Not To Use For Colormatch
Follow PMS Guide For Colors

Figure 3.1 Federal drug testing custody and control form.

- Copy 1 includes five sections:
  - Information on the company requesting the test, the name, etc., of the MRO, the donor's social security or identification number (in the regulated programmes the donor's name cannot be used to identify the donor on Copy 1), the reason for testing and the drugs to be tested
  - Information on the collector and the collection (noting the temperature and any remarks concerning the collection itself)
  - Chain-of-custody information to be completed by the collector
  - Documentation of receipt at the laboratory
  - Certification of laboratory test results and analysis of split samples (if performed).
- Copies 2–4 carry essentially the same information, except that Copy 2 includes a section for the MRO to complete after receiving results from the laboratory and additional information on the donor (name and contact information).

Most laboratories have incorporated barcode bottle seals attached to the bottom of Copy 1. These are the seals used in the collection process and the barcode number on these matches that on the chain-of-custody form.

Within this process there are obvious opportunities for inadvertent errors (e.g. failure of the collector to complete all the necessary parts of Steps 2–4). Over time, the DOT has defined a number of so-called fatal errors (which if present require the testing of the specimen to be cancelled) and a number of correctable errors, which require the laboratory or the MRO to obtain a statement of correction from the collector. The 'fatal errors' are as follows:

- The barcode numbers on the bottle seals and the chain-of-custody form do not match.
- The collector's printed name and signature are both missing from Step 4.
- Bottle A's seal is broken, absent or shows obvious signs of tampering.
- Bottle A contains less than 30 mL of urine.

The correctable flaws are:

- The collector's signature is omitted.
- There is no donor's signature and there is no remark explaining why the donor failed to sign.
- The Certifying Scientist's signature is missing from a non-negative specimen.
- A non-DOT chain-of-custody form has been used for a DOT-mandated test.

The MRO is required to cancel the test when a statement of correction cannot be obtained. Although the steps outlined above are those required for a regulated specimen collection, similar procedures are used outside the regulated industries. A number of laboratories have simpler chain-of-custody procedures, which resemble requisitions used in medical testing, but the confirmation of identity, preparation of the collection area, completion of the chain-of-custody form and sealing of the specimen bottles in the presence of the donor, and, increasingly, the collection of split specimens are normal practices today.

Almost all drug testing programmes in the USA have provisions for 'shy bladder syndrome'. In this situation the donor fails to provide an adequate urine volume after remaining at the collection site for up to 3 h and being provided with 1.25 L of liquid. The donor is deemed to have a 'shy bladder' and is required to undergo a medical examination. If there is a reasonable medical explanation, the test is cancelled. If the donor requires a negative test for employment, specimens other than urine may be used, for example hair or oral fluid.

In the regulated industries, observed collections have to be performed by same-gender collectors and can currently be performed only in five special cases:

1. When the specimen temperature is out of range at the collection site. In this case there has to be an immediate observed collection.
2. Where the collector has identified an apparent tampering with the specimen at the collection site, for example the addition of bleach to the urine. Again, there has to be an immediate observed collection.
3. If the previous specimen has been declared invalid by the laboratory and when there is no obvious medical explanation for this. The most obvious example of this is where the laboratory has proof of adulteration, but cannot specifically identify the adulterant.
4. When the MRO has cancelled the test because the bottle B specimen was unavailable or had been adulterated and was so identified by the laboratory performing the re-confirmation.
5. In return-to-work and follow-up tests, for which the employer can, in certain circumstances, decide to conduct observed collections.

These general guidelines are also followed outside the regulated industries, although some employers and some sectors may have more rigorous ones. For example, the US military requires observed collections for all specimens.

Despite these safeguards, donors are still able to adulterate urine specimens by adding oxidising agents after voiding. The amount of such material added is extremely small (a vial of it can be hidden easily in a shoe or sock) and, if it is liquid, the volume is insufficient to alter the temperature of the specimen. Alternative specimens to urine have advantages in that their collection can be considered non-invasive and can be observed. For example, collection of oral fluid is usually performed using a pad or swab and the donor can do this themselves in the presence of the collector. Collection of hair is also 'observed', although some questions remain as to the invasive nature of this process, particularly when non-head hair has to be collected.

Role of the medical review officer

The concept of the MRO was introduced in the DHHS *Guidelines* (Federal Register 1988a). The MRO's initial role was to receive the testing results from the laboratory, contact the donor to determine whether a positive drug result could have arisen from the legal use of a drug and, if not, to verify the result as positive and contact the employer. Where the legal use of a medication explained the result, the MRO would report the result as negative and communicate this to the employer.

Increasingly, MROs serve as gatekeepers for drug-testing results and as administrators of functions ancillary to the process, such as the collection and storage of all documentation. Given the breadth of these tasks and the extent of drug testing in the USA, some physicians practise as MROs full time. Many others act as MROs in the course of their duties as occupational health physicians and corporate medical directors.

Before the introduction of the federal programmes, the laboratory toxicologists had filled the interpretative role, and few issues had arisen. However, within the federal programmes, which introduced random and post-accident testing to a large percentage of the workforce, there was a need for additional safeguards. It was anticipated that MROs would serve as the final quality-assurance check on the laboratory result and, indeed, they have done so. For example, some vigilant MROs who could not rationalise the laboratory result with the donor's demographics and medical history first raised the phenomenon of the conversion of ephedrine and pseudoephedrine to metamfetamine. They questioned the findings and requested the re-tests in which the second laboratory could not confirm the findings. Another reason for their introduction was a purely legal one; in the USA only licensed physicians can access prescription records, and it was obvious that this could be essential to determine the legitimacy of a donor's claim.

When the MRO receives a positive result, he or she has to contact and interview the donor, obtain prescription records (if necessary) and then verify the laboratory result as positive or negative before reporting the result to the employer. These reviews are generally straightforward; for example, there is no legal reason for a donor to test positive for PCP, whereas a large majority of specimens that test positive for codeine do so because of prescription use or, in countries such as the UK, because of the extensive use of codeine in over-the-counter medicines. Questions arise in other areas, particularly in the interpretation of metamfetamine and morphine positives; these are discussed in more detail later in the chapter.

The MRO is also responsible for reviewing non-negative results from donors. These include adulterated, substituted and invalid specimens.

Before the new *CFR Part 40* (Federal Register 2000) was issued, MROs had very little role in the review of substituted and adulterated specimens; they simply received the results from the laboratory, reviewed the paperwork and reported them to the employer. There was no requirement to contact the donor and no ability for the donor to request a re-test. The new *CFR Part 40* changed that and incorporated a requirement for the MRO to contact the donor to determine whether there was a medical reason for the laboratory findings, although this would be extremely unlikely, and allowed the donor to request a re-test. These particular re-tests were to be performed using the same criteria for defining a specimen as substituted or adulterated as used in the initial set of tests. For example, if a specimen was determined to be substituted with creatinine readings of 1.8 and 1.7 mg/dL, with relative density readings of 1.0008 on bottle A, but bottle B had a creatinine reading of 2.1 mg/mL and a relative density of 1.0008, the re-test specimen would be reported as 'Failed to Confirm: Substituted Specimen'. Some of the interpretative issues relevant to adulterated and substituted specimens are discussed later in the chapter.

Interpretation of amfetamine-positive results

This particular drug-testing result has caused confusion among the MRO community and continues to do so. Some of this stems from the reporting rule for metamfetamine. This rule requires that for metamfetamine to be reported as positive there must be at least 200 ng/mL of amfetamine present, in addition to at least 500 ng/mL of metamfetamine. If both amines are present in concentrations greater than 500 ng/mL by GC-MS, both are reported as positive and there is no confusion. Difficulty arises when the amfetamine concentration determined by the laboratory is between 200 and 500 ng/mL (i.e. less than the amfetamine confirmation cut-off) but the metamfetamine concentration is above 500 ng/mL. In this situation, the MRO receives only a metamfetamine-positive result, rather than one that indicates that both metamfetamine and amfetamine are positive. Once the MRO understands that the laboratory must comply with this reporting rule, the confusion disappears.

The second area of confusion is in the differentiation of *d*- and *l*-metamfetamine. *l*-Metamfetamine is found in the USA in Vicks Inhaler (an over-the-counter decongestant product) and, although its use can result in the detection of metamfetamine and amfetamine in urine, the concentrations are generally low (Fitzgerald *et al.* 1988). Moreover, given the low cross-reactivities of immunoassays to the *l*-isomers of metamfetamine and amfetamine, a positive result is unlikely following normal use. However, a metamfetamine user may still claim that the positive is because of his or her use of Vicks Inhaler and, in such cases, the MRO can request a GC-MS separation of the isomers. These are usually qualitative analyses and reported as *x*% of the *d*-isomer and *y*% of the *l*-isomer. Where the *l*-isomer is greater than 80%, the MRO reports the result as negative.

Although some drugs can metabolise to metamfetamine and amfetamine (e.g. benzphetamine and selegiline), these are available only on prescription in the USA and the interpretation of positive amfetamine results is relatively straightforward. In other countries, this may not be the case. Cody (2002) has reviewed the issue of precursor medications.

Interpretation of opiate-positive results

This is another area that has caused confusion in the MRO community. From 1989 to 1998 the cut-off used for the opiates was 300 ng/mL, both in the initial testing and in the confirmation of codeine and morphine by GC-MS. During this period there was no requirement that a certified laboratory should be able to confirm the presence of the characteristic metabolite of heroin, 6-AM, although several did so routinely. In 1998 the cut-offs were raised to 2000 ng/mL and the laboratories were required to confirm the presence of 6-AM if the morphine concentration exceeded 2000 ng/mL. The GC-MS cut-off for 6-AM was set at 10 ng/mL. The major reason for raising the opiate cut-offs was associated with MRO reviews of opiate-positive samples. Use of the 300 ng/mL cut-off criterion resulted in a large number of positive results that derived from either poppy-seed ingestion or therapeutic doses of codeine, and which were subsequently verified as negative by the MROs.

Where there was a prescription for codeine, the MRO's review presented no problems. However, in the absence of a prescription for codeine (or morphine) the MRO was required to observe 'clinical signs of opiate use' before reporting a verified opiate-positive result back to the employer. This requirement remains for some results, even within the new *CFR Part 40*, unless the specimen has tested positive for 6-AM, which is conclusive evidence of heroin use.

Under the new *CFR Part 40*, if the morphine concentration is greater than 15 000 ng/mL the donor has the responsibility for providing evidence that the presence of morphine was the result of a legitimate use of a drug, and not the illicit use of heroin or morphine. There are certainly no reports that indicate such urinary morphine concentrations from poppy-seed ingestion, even under extreme conditions (Selavka 1991), so if the donor cannot provide this evidence the MRO verifies the result as a positive.

Passive exposure

Passive exposure is an issue that still causes confusion to some MROs; it essentially deals with the passive inhalation of cannabis smoke and the unwitting ingestion of cocaine or cannabis. Although passive exposure to crack (free-base cocaine) smoke has been claimed as an excuse for a positive urine benzoylecgonine, there is no evidence that this is valid. In two studies that investigated this (Baselt *et al.* 1991; Cone *et al.* 1995), no urine specimens gave immunoassay readings above 300 ng/mL.

However, unwitting ingestion of cocaine may result in positive urine specimens with the cut-offs currently used. There is no doubt that an individual who ingests a drink fortified with cocaine can test positive. In one study in which a volunteer consumed 25 mg cocaine hydrochloride (Baselt, Chang 1987), urine benzoylecgonine concentrations were greater than 300 ng/mL for 48 h. The question most often raised is the use of decocainised coca teas. As with decaffeinated coffee, these teas contain small amounts of cocaine; one study found an average of 4.8 mg per tea bag (Jackson *et al.* 1991). After the ingestion of one cup of this tea, immunoassay results were positive for 21–26 h. Obviously, the more regular the use, the more likely these specimens are to be positive and to be so for longer periods. From the MRO's viewpoint, these are not legitimate uses of cocaine and in the regulated industries would be validated as positives. Outside these industries, MROs may be more flexible in their interpretation after consulting with the donor.

Passive inhalation of cannabis smoke continues to be an excuse offered by donors for their positive results. There is no doubt that environmental exposure to cannabis smoke can occur through passive inhalation, but the question is whether it produces measurable concentrations in urine and if so for what time. In a number of early studies (Law *et al.* 1984; Mørland *et al.* 1985; Perez-Reyes *et al.* 1982) there was evidence for the presence of THCA in urine after passive exposure, but the concentrations measured were orders of magnitude lower than the cut-offs in use in workplace drug testing. In a more extreme study by Cone *et al.* (1987), volunteers were exposed to 4 and 16 cannabis cigarettes for 1 h for 6 consecutive days. After exposure to 4 cigarettes few urine specimens were positive, while after 16 cigarettes many more specimens were positive with a maximum THCA concentration of 87 ng/mL reported by GC-MS. The authors stressed, however, that these were extreme conditions, in that exposure was in a non-ventilated, tightly sealed small room and that it occurred for multiple days. In fact, the smoke was of such intensity that goggles were required by a number of the volunteers. It is generally accepted that social exposure to cannabis smoke (at parties, in outdoor arenas) will not result in a positive urine specimen.

Interpretation of adulterated and substituted specimens

Nearly all the adulterants that are commonly used today to oxidise THCA are listed in the Federal Register (2004a) and the provision

for new adulterants. Nitrite can be detected in urine as a result of bacterial infection, the ingestion of certain foodstuffs and the use of some medications. In one study that considered these sources and the presence of nitrite in normal urine (Urry *et al.* 1998), the highest urinary concentration was approximately 130 μg/mL; the cut-off used today is 500 μg/mL, almost four times this concentration. Some of the other adulterants include chromium(VI), peroxide, iodine and bleach; none of these should be detected as a result of normal physiology and metabolism. However, a donor may claim that their presence is the result of workplace exposure or the ingestion of vitamins or herbal material, and the MRO needs to be prepared to refute these claims.

The interpretation of substituted results has generated considerable discussion, with some individuals arguing that urine specimens with creatinine concentrations less than 5 mg/dL can be provided under rare conditions. Barbanel *et al.* (2002) reviewed over 800 000 urine specimens. In this population both creatinine and relative density measurements were taken from over 13 000 specimens, and none of these satisfied the criteria for a substituted specimen. These authors also examined the medical records of patients who satisfied one of the criteria and reported that these were neonatal, moribund or so severely ill that essentially none could have been in the working population.

The DOT has also provided further information (Edgell *et al.* 2002). In a study in which 12 volunteers (5 men and 7 women) consumed 2.5 L of water over a 6-h period and urine specimens were collected for the measurement of creatinine and specific gravity, none of the 500 specimens collected was identified as substituted using the criteria.

In 2003 at a conference organised by the Federal Aviation Authority, information was presented that indicated that a small number of female flight attendants produce urine with creatinine readings between 4 and 5 mg/dL and this led to the introduction of the updated DHHS and DOT rules.

Conclusion

This chapter focuses on the DHHS *Guidelines* and the DOT *Regulations*, as these are used to test almost 25% of specimens and have become the standard of care for the industry in the USA. Without question they are detailed, and some toxicologists may argue that, in certain aspects, they are unreasonable. However, their introduction and evolution through the NLCP have resulted in a dramatic improvement in the quality of drug testing carried out, including the quality of the laboratory testing. The future challenge for all involved is to balance the desire to proscribe procedures against the need to allow laboratories to select their own technology, procedures and quality-control programmes. The expansion of the programme into the testing of alternative specimens and into specimen validity analyses will be a test of this challenge.

CHAPTER

4 Driving Under the Influence of Alcohol

AW Jones

Introduction

Historical background

An editorial published in the July 1904 issue of the *Quarterly Journal of Inebriety* drew attention to the potential danger of driving an 'automobile wagon' after consumption of alcohol (Editorial 1904). Although nothing was mentioned about the amounts of alcohol consumed before driving, this editorial gave an early warning signal that driving after drinking was a hazardous business. Scores of experimental and epidemiological studies have subsequently appeared providing unequivocal evidence of the role played by alcohol abuse and alcohol-related impairment in road traffic crashes. Statistics from many nations confirm that 20–50% of all fatal crashes involve an alcohol-impaired driver (Evans 1990; Kennedy *et al.* 1996; Logan, Schwilke 1996; Zador *et al.* 2000). Indeed, alcohol consumption represents a well-known risk factor in all kinds of transportation accidents, including boating (Smith *et al.* 2001), bicycling (Li *et al.* 2001), pedestrians (Margolis *et al.* 2000) and use of snowmobiles (Ostrom, Eriksson 2002).

Drinking driving legislation

The UK Licensing Act of 1872 made it an offence to be 'drunk in charge on any highway or other public place of any carriage, horse, cattle or steam engine'. It took until 1925 before the offence was extended to cover 'any mechanically propelled vehicle'. The evidence needed to charge a person with driving under the influence of alcohol (DUIA) depended to a large extent on the testimony of an eye-witness, the arresting police officer and in particular the results of a clinical examination of the suspect (Wayne 1965).

Alcohol and impaired driving laws were initially not very effective because they contained wording such as 'drunk and incapable', which was not easy to prove in a court of law. This was later changed to 'being under the influence of drink or a drug to such an extent as to be incapable of having proper control of a vehicle'. Successful prosecution for DUIA was not always easy to obtain and much depended on the conclusions of the clinical test made by a physician or police surgeon. During this examination, questions were asked about recent use of alcohol and/or medication and orientation in time and place, and simple cognitive and psychomotor tests were made to assess performance.

Proof beyond a reasonable doubt that a person was unfit to drive through drink or drugs was not always readily available, which meant that many suspects were acquitted if the case went to trial. The concentration of alcohol in a specimen of blood or urine from the accused was not given sufficient weight by the courts. The blood alcohol concentration (BAC) served only as supporting evidence of alcohol influence. All this changed after the British Road Traffic Act of 1967, which stipulated a punishable limit of alcohol concentration in blood (80 mg/100 mL) and urine (107 mg/100 mL), above which it was an offence to drive or to be in charge of a motor vehicle on the public roads.

When prohibition was abolished in the USA in 1933, attention was drawn to the problem of alcohol consumption and transportation safety. Driving while intoxicated (DWI) was thought to pose a serious public health problem because the ownership and use of motor vehicles had increased appreciably during a decade of prohibition. Representatives of the US federal government (Department of Justice, Bureau of Prohibition) wrote to the leading researcher in medical–legal aspects of alcohol, Professor Erik MP Widmark at the University of Lund in Sweden, for advice (Andreasson, Jones 1996a). The US Department of Justice was anxious to find a more objective and scientific way to test for drunkenness. They described the situation as follows:

> Such tests in our various states vary from smelling the offender's breath to making him walk a chalk line, but no scientific test apparently is applied. We are particularly anxious to know what the alcoholic content of the blood must be before a person can be described as being under the influence of alcohol. Some median line must have been established on one side of which an offender is not under the influence of liquor and on the other side of which he may be said to be intoxicated. Just what that line is, we would like to know.

The concentration of alcohol determined in a specimen of blood was considered a more objective way to establish whether a person was under the influence of alcohol. Widmark (1889–1945) had already developed a method to measure the concentration of alcohol in a small volume (0.1 mL) of fingertip blood (Widmark 1922). He also showed that a person's BAC could be translated into the amount of alcohol consumed, which often made more sense to a judge and jury than the BAC itself (Widmark 1941).

Finding a high concentration of alcohol in blood or urine meant that the person's unusual behaviour could be attributed to heavy drinking rather than a medical condition or injury that might mimic the signs and symptoms of drunkenness (Smith 1960). Injuries sustained in a car crash, such as skull trauma, might account for the person's unusual or irrational behaviour and be mistakenly confused with overconsumption of alcohol. Low blood sugar (hypoglycaemia) causes cognitive and behavioural impairment resembling that seen after acute alcohol intoxication (Saunders 1992; Service 1995). Knowledge of whether an apprehended driver suffered from type 1 or type 2 diabetes and might recently have taken too much insulin is obviously important (Daneman 2006). People with neurological disorders, such as epilepsy or Parkinson's disease, show hand tremor and ataxia, which might be confused with the influence of alcohol. A person's strange or erratic behaviour might be attributed to a psychiatric problem, such as mania or schizophrenia, and have nothing to do with drink or drugs.

Alcohol and traffic safety literature

Much has been written on the subject of traffic safety and the role played by overconsumption of alcohol as well as other psychoactive substances. Major developments in the field of alcohol and traffic including legislation, enforcement strategies, epidemiology, crash statistics, countermeasures, police procedures, as well analysis of alcohol in body fluids can be gleaned from the proceedings of 18 international conferences devoted to the subject. The first meeting was held in Stockholm in 1950 and the nineteenth was in Oslo in 2010. The proceedings from the most recent meetings (since 2000) are available on CDs and many of the articles can be downloaded as pdf documents from the International Council on Alcohol, Drugs and Traffic Safety (ICADTS) website, which can be located

at the address www.icadts.com. Another useful website for information and publications about alcohol and traffic safety is that of the US National Highway Traffic Safety Administration (NHTSA), which contains a treasure trove of information on the subject of alcohol, drugs and driving. Scores of reports, monographs and brochures dealing with all aspects of traffic safety can be downloaded gratis as pdf documents from NHTSA's website www.nhtsa.dot.gov.

Articles and reports on the subject of alcohol and alcohol-related impairment appear in a wide variety of scientific journals devoted to legal medicine and toxicology as well as those specialising in biomedical alcohol research and substance abuse. Some scientific journals that focus specifically on aspects of transportation safety including human factors are listed under Further reading at the end of the chapter.

Statutory alcohol limits for driving

Different countries have their own structure and traditions when it comes to dealing with the problem of alcohol and road traffic safety. This is reflected in, among other things, the setting of statutory alcohol limits for driving, the methods used to enforce the law and the sanctions imposed for people convicted of this crime. Statistics about road traffic fatalities, the attitude of the media and the public towards drinking and driving, the activity of temperance movements and various political influences, as well as the way the courts interpret the law, are also important considerations. Other factors that deserve attention in connection with DUIA are the relative cost and availability of alcoholic beverages, opening hours of bars and restaurants, and the resources available to the police for apprehending and prosecuting offenders. The punishable alcohol limits for driving seem to depend as much on politics as on traffic safety research. The BAC limit chosen needs to balance the traffic safety hazard posed by alcohol-impaired drivers, the methods available for enforcement and public acceptability.

Blood alcohol concentration limits

In 1936 Norway introduced a statutory BAC limit for driving of 0.50 mg/g blood (~50 mg/100 mL), which is now set at 0.20 mg/g (~20 mg/100 mL). This was followed by Sweden, where in 1941 a BAC limit of 0.80 mg/g (~80 mg/100 mL) was introduced as well as a more serious offence, which carried enhanced penalties above a BAC of 1.50 mg/g (~150 mg/100 mL). These alcohol limits were subsequently lowered to 0.50 mg/g (~50 mg/100 mL) in 1956 and 0.20 mg/g (~20 mg/100 mL) in 1990. The upper limit representing aggravated drunken driving is now 1.0 mg/g (since 1994) and more severe sanctions are imposed for those convicted. Most EU nations, apart from the UK and the Republic of Ireland, enforce a punishable BAC limit of 50 mg/100 mL and operationally also define higher limits above which there are enhanced penalties.

Lowering the statutory alcohol limit for driving does not solve the problem of DUIA although this might help to draw attention to the problem and hopefully have a pedagogic influence on young people learning to drive. Besides lowering BAC limits, a more effective law enforcement will require that the police be allowed to conduct random alcohol testing of drivers, otherwise limits of 20 or 50 mg/100 mL will be difficult to enforce.

After the British Road Safety Act of 1967, a police officer in uniform was able to stop a driver and request a roadside breath alcohol test if (a) there was a reasonable cause to believe the driver had been drinking alcohol, (b) the driver had committed a moving traffic offence or (c) the vehicle concerned was involved in a collision. Obtaining a positive roadside breath alcohol test meant that the suspect was arrested and obliged to provide a specimen of blood or urine for determination of the ethanol content. The concentration of alcohol in the blood or urine became the sole deciding factor for a successful prosecution after the 1967 Act of Parliament.

In the early 1970s, a committee within the UK Department of the Environment was commissioned to review the situation after the passing of the 1967 Road Traffic Act and also to recommend improvements (Blennerhassett 1976). Among other things, this committee felt that the science and technology of breath alcohol analysis had advanced to such an extent that this test could be made at a police station and the results subsequently used as evidence for prosecution. Sidestepping the need to obtain specimens of blood or urine would therefore simplify and speed up police procedures. Obtaining immediate results to confront the suspect that he or she was in breach of the law was another advantage of evidential breath alcohol testing. Hitherto, breath alcohol tests had only been used for orientation purposes, as a preliminary screening test, and positive results always had to be followed up by blood or urine samples analysed at a forensic laboratory, which took more time.

Breath alcohol concentration (BrAC) limits

Because statutory limits of BAC existed in most countries before instruments suitable for breath alcohol analysis were developed, it became the standard practice to convert the suspect's BrAC into the coexisting BAC by means of a calibration factor (Jones 1996). This factor was known as the blood-to-breath ratio of alcohol (BBR) and had been derived empirically from experiments in which volunteers had consumed known amounts of alcohol. The results of many such blood–breath correlation studies pointed to a mean BBR of 2100 : 1 and this factor was used for law enforcement purposes in the USA and Canada (Jones 2000b).

The Breathalyzer instrument was developed in the mid-1950s and was widely used for testing drunken drivers throughout the USA and Canada (Borkenstein, Smith 1961). Although the Breathalyzer instrument was calibrated on the assumption of a 2100 : 1 BBR, evidence was mounting to show that this factor varied both between and within individuals and was closer to 2300 : 1 than to 2100 : 1(Begg *et al.* 1964; Wright *et al.* 1975; Emerson *et al.* 1980). Nevertheless, use of a BBR of 2100 rather than 2300 : 1 meant that the results of a breath alcohol test were to the benefit of the suspect because the venous BAC was underestimated by about 10%. This was deemed acceptable for law enforcement purposes because it gave a suspect the benefit of the doubt.

The need to convert BrAC into BAC was, however, becoming increasingly troublesome as more and more studies showed that the BBR varied as a function of time after the end of drinking (Jones 1978). This problem was solved by introducing a statutory definition of the concentration of alcohol in a specimen of breath as evidence of DUIA. In the USA this threshold was set at 0.08 g/210 L breath, which was equivalent to 0.08 g/100 mL blood (Mason, Dubowski 1976). When European countries began using evidential breath alcohol instruments in the 1980s, there was a lack of consensus about the BBR and values ranging from 2000 : 1 to 2400 : 1 were adopted when the threshold BrAC were set according to

$$\text{Statutory BrAC} = (\text{existing BAC})/\text{BBR}$$

The British Road Transport Act of 1981 stipulated alcohol concentrations of 35 µg/100 mL breath, 80 mg/100 mL blood or 107 mg/100 mL urine (Cobb, Dabbs 1985). This implies a BBR of about 2300 : 1 ([80/35] × 1000 = 2286 : 1, which rounds to 2300 : 1). The Republic of Ireland, the Netherlands and Belgium adopted the same 2300 : 1 ratio when their threshold BrAC limits were introduced.

Other European nations, such as France and Spain, assumed a BBR of 2000 : 1, which gives an advantage to the suspect if the mean BBR in reality is closer to 2300 : 1. In Germany and the Nordic countries, the BAC for legal purposes is reported as mass/mass units (e.g. 0.50 mg/g), which is the same as 0.527 mg/mL (density of blood = 1.055 g/mL). Dividing 0.527 mg/mL by 2100 (BAC/BrAC ratio) gives a threshold BrAC of 0.25 mg/L ([0.50/2100] × 1000 = 0.25 mg/L). A wide variety of concentration units are used to report BAC and BrAC for legal purposes as well as BBR ratios, which is the cause of confusion when alcohol and traffic safety statistics are compared between countries (Jones 1992a).

Table 4.1 lists the statutory limits of alcohol concentration in blood and breath for driving in various countries, the operational BBR, the name of the breath analyser used for evidential purposes and the analytical principle on which the instrument operates (Harding, Zettl 2008; Jones 2010a).

Table 4.1 Statutory BAC and BrAC limits in various countries, the blood/breath ratio (BBR) that operates, the evidential breath alcohol instrument approved and the principle for analysis of ethanol

Country	*Statutory BAC*[a]	*Statutory BrAC*[a]	*BBR*	*Evidential breath alcohol analyser*[b]	*Operating principle*[c]
Australia	0.05 g/100 mL	0.05 g/100 mL[d]	2100	Alcotest 7110	Infrared (9.5 μm) and EC

[a]Most countries also enforce a higher limit defining a more serious offence carrying enhanced penalties.
[b]Instruments carry a country code, such as Intoxilyzer 6000 Ire for Ireland or N for Norway.
[c]Those infrared instruments operating at 3.4 μm are equipped with several wavelength filters to give enhanced selectivity.
[d]In these countries, ethanol analysed in the breath is reported as BAC by pre-calibration with an assumed BBR.
[e]Also known as BAC DataMaster.
BAC, blood alcohol concentration; BrAC, breath alcohol concentration; EC, electrochemical.

Apprehending offenders

The first suspicion of driving under the influence of alcohol or drugs usually arises from observations made about the suspect's driving by the police authorities. The vehicle is then stopped and contact is made with the driver. The smell of alcohol on the breath and the person's general appearance and behaviour are among the first things that arouse suspicion that the driver might be under the influence of alcohol (Moskowitz *et al.* 1999). Next a roadside breath alcohol test is conducted and, if the result is above the legal limit for driving, the suspect is arrested and transported to a police station or other location where an evidential breath alcohol instrument is available.

Under some circumstances, a physician is called to examine the driver and to determine the degree of alcohol influence or whether other drugs might have been involved (Penttila, Tenhu 1976). This is followed by sampling blood for analysis of alcohol and even other drugs that might be present. The results from the clinical examination formed the main thrust of the prosecution case before the introduction of laws on alcohol concentration itself (Jones 1988). The clinical examination is still important in some countries to furnish evidence of impairment caused by drugs other than alcohol (Bramness *et al.* 2003).

Figure 4.1 presents a flow diagram showing the events and tests made during a traffic stop and suspected DUIA. A negative roadside breath alcohol test might mean that the driver is allowed to continue to drive or instead questioned further if evidence exists that drugs other than alcohol were present. Many countries now enforce zero-tolerance laws for driving after use of illicit drugs and toxicological analysis of the concentration in a blood sample is the key piece of evidence in such cases (Jones 2005).

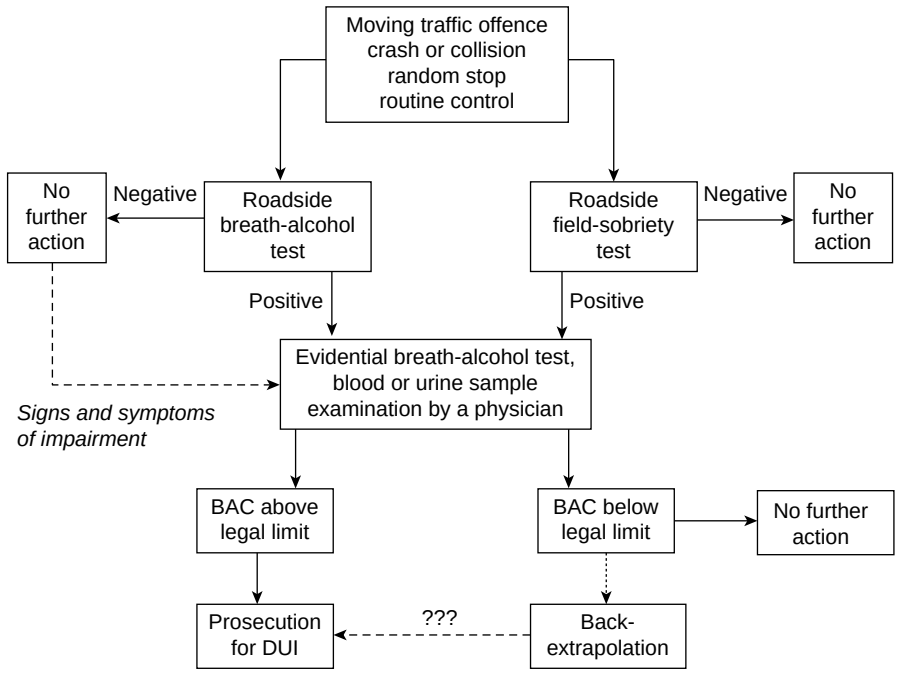

Figure 4.1 Flow chart of the events leading to the apprehension, testing and arrest of alcohol- and drug-impaired drivers.

Depending on how the law is written, the prosecution might want to know the BAC or BrAC that existed at the time of driving and not at the time of sampling, which is usually 30–120 min later (Montgomery, Reasor 1992; Anderson 2005). This requires back-calculating the BAC to compensate for metabolism occurring between time of driving and time of sampling. Such an exercise is controversial, especially if the BAC was below the legal limit at the time the blood was sampled (Ferner 1996). Expert evidence is necessary whenever a back-extrapolation is made and the court needs to be informed about the many variable factors and assumptions made (Lewis 1987; Gullberg 1994).

Effects of alcohol on performance and behaviour

Ethanol-induced impairment

The signs and symptoms of drunkenness are common knowledge, although the mechanisms by which ethanol exerts its effect on the brain are less well known. Ethanol acts as a depressant of the central nervous system and its effects are felt almost immediately after drinking begins, which testifies to rapid uptake from the gut, transport to the brain and passage through the blood–brain barrier. Different areas of the brain react differently to alcohol depending on the amounts ingested, the speed of absorption and the concentration gradient in the various brain regions.

The cerebral cortex is influenced at relatively low concentrations of alcohol in the blood, as seen by altered thought processes and the loss of inhibitions and self-control. The limbic system (hippocampus) is the area of the brain that controls memory and emotions, which succumb as the BAC increases further. The cerebellum is the brain region important for muscular coordination and fine manual skills and excess alcohol alters a person's posture, perception and articulation. The hypothalamus controls, among other things, the hormones of the pituitary gland, including vasopressin (antidiuretic hormone), the release of which is inhibited by alcohol, as seen by an increase in the production of urine after drinking. On reaching a very high BAC, the medulla (brainstem) suffers from alcohol narcosis, which impacts on heart rate and body temperature drops and breathing becomes more difficult. The impairment of such vital body functions often results in unconsciousness or alcoholic coma with circulatory collapse and a grave risk of death from asphyxia.

Molecules of ethanol interact with various brain receptors and neurotransmitter systems in a similar way to the general anaesthetic gases (Eckardt *et al.* 1998). Examples of drugs that share some of the same receptor sites as ethanol are sedative hypnotics, such as benzodiazepines or barbiturates. These depressant drugs act as agonists for the major inhibitory neurotransmitter γ-aminobutyric acid type A ($GABA_A$, De Vries *et al.* 1987). $GABA_A$ is a so-called ligand-gated ion-channel and its configuration in the cell membrane is altered when an agonist binds (Ulrichsen *et al.* 1988). Binding to the receptor opens an ion channel, facilitating the flow of chloride ions into the cell, which damps or stops the firing of adjacent neurons (Wallner *et al.* 2006). This suggests that impairment of body functioning is worsened if a person combines alcohol with a sedative drug, such as diazepam or some other depressant; such drug–alcohol interactions are sometimes life threatening. Even therapeutic doses of diazepam impair a person's ability to perform skilled tasks such as driving, the effect being exaggerated after consumption of small amounts of ethanol (Kerr *et al.* 1991).

On reaching a BAC of 20–30 mg/100 mL, the individual usually becomes less inhibited and more talkative and relaxed, and experiences a mild euphoria. As more alcohol is consumed, and higher BACs are reached (50–80 mg/100 mL), the ethanol-induced effects on performance and behaviour become more obvious. A person's self-control and judgement are impaired, which means that people are more likely to take risks. As the BAC reaches and exceeds 100 mg/100 mL, the classic signs of drunkenness are seen, including slurred speech, unsteady gait and slower reaction times.

The speed of onset and intensity of the effects of ethanol depend to a large extent on the quantities consumed, whether it is in the form of beer or spirits, the speed of drinking, and also the rate of gastric emptying. The individual's previous experience with alcohol and the development of tolerance and degree of habituation are also important points to consider when the effects of a given BAC are interpreted (Kalant 1998). After a single acute dose of ethanol, the behavioural impairment is greater at a given BAC on the ascending limb of the BAC curve compared with the same BAC on the descending limb several hours later (Martin, Earleywine 1990; Earleywine, Martin 1993; Martin, Moss 1993). The brain can seemingly adapt to the impairment effects of alcohol during a single exposure; this phenomenon is known as acute tolerance or the Mellanby effect, named after a British pharmacologist, Sir Edward Mellanby (1884–1955), who first made the observation, mainly through experiments in dogs (Mellanby 1920).

Table 4.2 Clinical signs and symptoms of alcohol influence shown as a function of increasing BAC

BAC (mg/100 mL)[a]	*Signs and symptoms of alcohol influence*[b]
<20	Sobriety, lack of outward signs, possible smell of alcohol on breath
20–50	Loss of inhibitions, more talkative, impairment of certain cognitive skills, especially those requiring divided attention
50–100	Lack of judgement and control, more rowdy and daring, slowed reaction time, especially in choice situations
100–150	Lack of coordination, unsteady gait, slurred speech, prolonged reaction to sights and sounds
150–200	Obvious drunkenness, aggression, ataxia, slowed reaction time even when relatively simple tasks are performed, nausea and vomiting especially after rapid absorption
200–300	Confusion, inability to stand upright or walk without help, slurred speech, motor areas of the brain are now markedly impaired, distorted perception of time and judgement risk lapsing into a comatose state
300–400	Stupor or comatose state with shallow breathing, risk of respiratory arrest, loss of gag reflex and danger of inhalation of vomit leading to asphyxia and death
400–500	Profound risk of death from respiratory paralysis and cardiopulmonary arrest

[a]The subjective and objective effects of alcohol are more pronounced on the rising part of the BAC (blood alcohol concentration) curve close to the C_{max} compared with several hours after passing C_{max}; this phenomenon is known as the development of acute tolerance.
[b]Large inter-subject variations exist within a given BAC interval depending on age, previous experience with alcohol speed of drinking, and central nervous system tolerance.

Table 4.2 lists typical signs and symptoms of alcohol influence as a function of the person's BAC at or near the peak concentration (Jones 2009a). Note that these observations do not apply to a specific individual, but are intended to present a general picture of the effects of alcohol on vital body functions and performance and behaviour. Both acute (Mellanby effect) and chronic tolerance to alcohol depend on the age and sex of the individual as well as on the pattern of drinking and the amounts consumed daily (Kalant 1998). This tends to skew the relationship between BAC and the signs and symptoms of alcohol influence shown in Table 4.2 and accordingly great care is need when this information is interpreted in any individual case.

A typical example of central nervous tolerance and outward signs of alcohol influence is provided by the driver (Mr Henri Paul) of the car in which Diana Princess of Wales was killed in a single-vehicle crash in Paris in 1997. According to postmortem reports, the driver had a BAC of 170 mg/100 mL (0.17 g%). This high BAC stood in sharp contrast to CCTV footage from the Ritz Hotel shortly before the crash showing Mr Paul walking around the hotel. He showed no obvious indications of alcohol influence, such as an unsteady gait or unusual movement or behaviour and even had occasion to bend down and tie his shoelace. The disparity between the postmortem BAC and the CCTV footage is easily explained by the relative insensitivity of such tests to disclose the influence of alcohol or drugs. The long investigation of the case produced evidence to suggest that Mr Paul had begun drinking alcohol earlier the same day (his day off) and it is also well documented that he took two further drinks after returning to the Ritz Hotel before the fatal drive.

If the vehicle had been fitted with an ignition interlock device, this might have prevented the crash or, at the very least, Mr Paul would not have been able to start the engine. Consumption of alcohol over a lengthy period of time allows the brain to adapt to the effects of this drug so that an individual might seem perfectly normal on CCTV. However, when performance of skilled tasks and divided attention are required, such as driving at high speed and trying to avoid the paparazzi, reaction time and performance are seriously affected. Accordingly, tolerance to the effects of alcohol can account for the discrepancy between the postmortem report and CCTV footage prior to the crash.

Clinical tests of drunkenness

A critique of the traditional clinical tests of alcohol influence is the subjective nature of such tests. Much depends on the enthusiasm and experience of the examining physician, including his or her skill and training for this purpose. Up until 1982, every driver apprehended in Sweden underwent a clinical examination in conjunction with sampling of blood for determination of alcohol. This provided a mass of information about the relationship between a driver's BAC and the conclusions from clinical tests of alcohol influence (Bonnichsen *et al.* 1967). A physician examines the driver about one hour after arrest and administers a standardised questionnaire and simple cognitive and psychomotor tests are made on the suspect. The physician then has to conclude whether the individual is under the influence of alcohol or whether some medical condition or use of other drugs might be involved.

Figure 4.2 presents the results of a clinical examination of apprehended drivers by physicians or police surgeons (Bonnichsen *et al.* 1967). The results from examination of more than 7000 apprehended drivers is shown as a function of their BACs. The examining physician did not know the driver's BAC, although some bias might have existed through knowledge that the person examined was suspected of DUIA and had failed a roadside breath alcohol test (BAC > 50 mg/100 mL). The conclusion of the examination – whether the driver was not under the influence of alcohol, or slightly, moderately or heavily impaired – was arranged according to the BACs. Although the degree of alcohol influence was more evident at higher BACs, there were large discrepancies, with many people being judged as not under the influence of alcohol despite a high BAC (upper left plot in Figure 4.2). Studies of this nature underscore the problem of relying on subjective criteria as evidence to assess whether a person was under the influence of alcohol or drugs for legal purposes.

One obvious explanation for discrepancies between results of the clinical examination and the actual BAC is the degree of skill and training on the part of the physicians or police surgeons who perform the tests. But even when the same physician performs the clinical examination, the results leave much to be desired, as evidenced by Table 4.3. Here a study was made of 244 alcohol-impaired drivers subsequently examined by the same physician and in this way eliminating variability between observers (Bonnichsen *et al.* 1967). Nevertheless, even with this study design, there was still considerable overlap between the results of the examination in terms of degree of alcohol impairment at the same BAC interval. This dichotomy can be accounted for, at least in part, by individual differences in tolerance to alcohol and the ability of some people to pull themselves together in a critical situation. Furthermore, the relative simplicity of the tests conducted, plus the driver's demeanour, educational standard and ability to converse politely, verbal skills and ability to perform simple mental tasks can account for the differences within similar BAC ranges shown in Figure 4.2.

In many European nations, the police are allowed to perform random breath testing of motorists without having any prior suspicion of DUIA. By contrast, such testing is not permitted under the fourth amendment of the constitution of the USA, which protects people from unreasonable search and seizure. However, the US Supreme Court has ruled that sobriety checkpoints entail such a minimal intrusion that they should be permitted and are thus used in many states under certain circumstances (Voas 1991). However, in most US states the arresting police officer still needs probable cause that a driver was under the influence of alcohol before a blood or breath alcohol test can be made. Hence the development of so-called standardised field sobriety tests (Burns 2003), which involve three behavioural tests at the roadside.

Standardised field sobriety tests

Much has been written about the pros and cons of standardised field sobriety tests (SFSTs) (Hlastala *et al.* 2005; Stuster 2006). Such tests were developed and evaluated to assist police officers in making a decision whether to arrest a person for driving under the influence of alcohol or

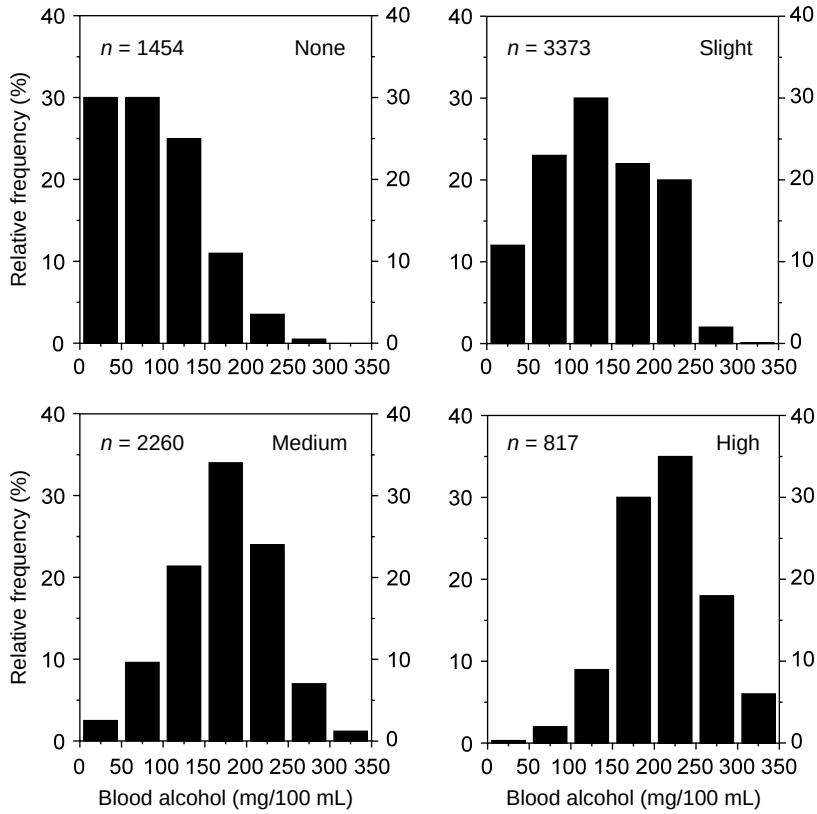

Figure 4.2 Relative frequency distributions comparing the results of clinical tests of drunkenness made by physicians with the suspect's blood alcohol concentration (BAC). The results were sorted according to whether the suspects were judged not under the influence or slightly, moderately or highly influenced as a function of the BAC.

Table 4.3 Numbers of apprehended drivers judged as not under the influence of alcohol or slightly, moderately or severely influenced after clinical examination and questionnaire in relation to blood alcohol concentration (BAC; all 244 individuals were examined by the same physician)

BAC (mg/100 mL)	*Degree of alcohol influence*				*Total (%)*
	None	*Slight*	*Moderate*	*Severe*	
0–49	3	26	0	0	29 (12)
50–99	2	37	0	0	39 (16)

drugs (Brick, Carpenter 2001). SFSTs are usually carried out at the roadside in close proximity to the traffic stop. Failing in these tests will usually lead to arrest and further testing with a more objective blood or breath alcohol analysis (Rubenzer 2008). The SFSTs were developed by psychologists to be administered by highway patrol or other police officers who undergo training in the theory and practice of behavioural and impairment effects of alcohol (Burns 2003). The battery of SFSTs comprises three types of test of the driver: horizontal gaze nystagmus (HGN), disturbances in balance and coordination, and ability to divide attention among several tasks at once.

The first test, and the one considered to be the most sensitive of the three, is HGN, which is an involuntary jerking or bouncing of the eyeball in the lateral direction when the eyes gaze to the side (McKnight *et al.* 2002). When under the influence of ethanol and some other drugs, the brain's ability to properly control eye muscles is impaired, which makes the eyeball jerk or bounce back and forth. An alcohol-impaired person will have difficulty in tracking a moving object placed before the eyes and the degree of jerking increases as a function of the BAC (Chiang, Young 2007).

The second SFST is the walk-and-turn test, which is a kind of divided-attention task. The suspect has to listen to instructions given by the police officer and then take nine steps forward walking heel-to-toe along a straight line, before turning on one foot and then walking back in the same direction. Stepping off the line or losing balance is counted as evidence that the person is under the influence of alcohol or some other impairing drug.

The third SFST is called the one-leg stand test, which requires the motorist to stand with one foot held approximately 15 cm (6 inches) above the ground while counting in thousands (1001, etc.) for approximately 30 s. The police officer has to score the number of mistakes made, such as swaying and using the arms to maintain balance or putting the foot down during the 30 s duration of the test. The results from the three tests are then averaged into a combined error score.

It must be fairly obvious that many sober people will have difficulties in passing the above-described tests, whether because of old age and infirmity, problems with blood pressure, other medical conditions, failure to understand instructions or the fact that they might be using certain prescription drugs. The environmental conditions, such as weather, the road surface, the traffic intensity and the type of shoes worn can all play a role in the outcome of SFSTs. Of the three SFSTs, HGN is considered to be most sensitive and objective and positive results have been reported at BACs as low as 40 mg/100 mL (McKnight *et al.* 2002). Others have strongly criticised the HGN test on physiological grounds and the fact that ophthalmic problems or use of drugs other than alcohol can skew the results (Booker 2001, 2004). Furthermore, the police officer who

administers SFSTs is often expected to testify in court as to how the tests were conducted and the way the suspect responded to questions, which opens the officer to cross-examination by the lawyers hired by the defence.

Controlled laboratory experiments

Much more is known about the dose–concentration relationships for the effects of ethanol on sensory, cognitive and psychomotor functioning than for other licit or illicit drugs. Goldberg (1943) made the first quantitative studies of the effects of alcohol on performance and behaviour and also interpreted the results in relation to BAC and the drinking habits of volunteer subjects. He established BAC thresholds for onset of and recovery from impairment using a battery of sensory, cognitive and psychomotor tests in non-drinkers, moderate drinkers and alcoholics. This work laid the foundation for many later studies aimed at establishing the time-course of alcohol-induced effects on performance and behaviour (Drew *et al.* 1958; Evans *et al.* 1974; Franks *et al.* 1976).

A host of other types of experimental approaches have been developed to measure the effects of alcohol on skills resembling driving (Moskowitz *et al.* 1985). The effects of alcohol on visual functions, cognitive tasks, sedation, drowsiness, vigilance and psychomotor performance, such as standing steadiness, reaction time (simple and choice) and hand steadiness, have been well studied (Fillmore, Vogel-Sprott 1995, 1998; Farquhar *et al.* 2002). The results show that divided attention tasks are more sensitive to the effects of alcohol (Ferrara *et al.* 1994). Examples of the types of experimental approach to document the effects of alcohol on human performance and behaviour and risk of a crash are given in Table 4.4.

The international scientific literature dealing with the effects of alcohol on driving-related skills was the subject of an in-depth review by Moskowitz and Fiorentino (2000). These investigators made a detailed evaluation of 112 articles published between 1981 and 1997 on the subject of alcohol-related impairment. Results were evaluated according to the BAC of the person tested and the type of cognitive, psychomotor or behavioural test used. One major aim of the review was to establish the lowest BAC at which impairment could reliably be detected for each particular driving-related task. Furthermore, an attempt was made to determine the thresholds of impairment in terms of BAC for each of 12 separate tasks performed. The authors reached the following conclusions (BAC units of g/dL given in the original report are also shown as mg/100 mL):

- Alcohol impairs some driving skills beginning with any significant departure from zero BAC. By BACs of 0.05 g/dL (50 mg/100 mL) the majority of the experimental studies examined reported significant impairment. By 0.08 g/dL (80 mg/100 mL), more than 94% of the reviewed studies showed impairment in the skills that they measured.
- Specific performance skills are differentially affected by alcohol. Some skills are significantly impaired by BACs of 0.01 g/dL (10 mg/100 mL), while others do not show impairment until BACs of 0.06 g/dL (60 mg/100 mL).
- Discrepancies among the reported BAC thresholds of impairment within a behavioural area reflected a lack of standardisation of testing methods, instruments and measures in the studies reviewed.
- All drivers can be expected to experience impairment in some driving-related skills by 0.08 g/dL (80 mg/100 mL) or less.

Table 4.4 Methods used to establish the relationship between blood alcohol concentration (BAC) and alcohol-related impairment

Type of testing	*Examples of the type of measurements made*
Physiological measures	Pulse rate, respiratory rate, blood pressure, nerve conduction velocity, body temperature, etc. before and after intake of a known amount of alcohol
Subjective feelings and objective measures of alcohol influence	Administration of a questionnaire about mood changes and subjective feelings of intoxication after consumption of alcohol and comparison with objective assessment by trained observers or a physician
Controlled laboratory studies of performance decrement after subjects drink known amounts of alcohol	Use of a battery of tests of cognitive and psychomotor functioning including mental arithmetic, accuracy in number recall, etc.
	Eye movements (horizontal gaze nystagmus)
	Standing steadiness (body sway)
	Hand steadiness (tremor)
	Tracking
	Divided attention tasks
	Tests of simple and choice reaction time
Driving simulators	Video-controlled driving tasks both interactive and non-interactive or use of highly sophisticated driving simulators including a dummy car and other equipment
On-the-road driving tests	Assessment of mistakes made during actual driving performance using specially constructed vehicle, e.g. monitoring of steering, speed, braking and response to critical situations
Roadside surveys and case–control studies	Epidemiological studies of crash-risk assessment as function of BAC; so-called case–control studies of drivers involved in a crash compared with carefully matched non-accident control drivers

Blood alcohol and crash risk

Statistics derived from postmortem reports from road traffic fatalities in various countries show that 20–50% of drivers had been drinking alcohol before the crash and their BAC was above the legal limit for driving (Brewer *et al.* 1994; Margolis *et al.* 2000; Baker *et al.* 2002). The most compelling evidence of the effects of alcohol on driving performance comes from so-called on-the-road driving tests. These types of studies involve the use of specially adapted vehicles and take advantage of closed-off roads or tracks to evaluate steering, emergency braking and evasive manoeuvres around fixed objects, and also the response of the driver to critical situations (Laurell 1977). Along the same lines, various computer-controlled driving simulators have been developed with steering wheel and dummy car to test the effect of alcohol and drugs on driving performance. Some such driving simulators are highly sophisticated and can be programmed to generate a wide range of hazardous conditions likely to be encountered in the real world, such as variations in speed, light–dark environment, different road conditions, weather (rain, snow, ice) and traffic intensity in various combinations.

Perhaps the most convincing evidence of the role of alcohol consumption and elevated BAC for the probability of causing a crash comes from the so-called roadside surveys and case–control studies. Several controlled epidemiological studies have documented that the risk of a crash increases as the BAC increases. The most widely cited study of this nature was conducted in the city of Grand Rapids (Michigan, USA) in the early 1960s and the results were published in 1965 (Borkenstein *et al.* 1974; Hurst *et al.* 1994). Roughly 6000 drivers involved in collisions had their BACs determined indirectly by analysis of breath and this was compared with about 7500 control drivers. The crash and control groups were regrettably not matched for crash location, time of day, day of week and direction of travel, although other variables were considered, such as age of the driver, experience at the wheel, sex, race,

education, marital status, drinking frequency, occupation of the driver, etc. This enormous undertaking was possible thanks to full cooperation from the police authorities and use of trained interviewers who designed and administered a detailed questionnaire to crash and control groups.

In the Grand Rapids study, the breath samples were stored in specially constructed plastic bags and transported for later analysis with a Breathalyzer instrument. The stability of alcohol in breath on storage is sometimes suspect and tends to give lower concentrations than expected if breath had been analysed directly. Losses of ethanol from the breath would tend to underestimate the true blood alcohol level in the accident and control drivers. Nevertheless, a relative risk curve of the probability of a crash showed a slight dip at BAC between 20 and 40 mg/100 mL, but a sharp increase in risk as BAC passed 80 mg/100 mL. The results of the Grand Rapids study were a strong motivating factor when countries such as the UK introduced statutory alcohol limits for driving in the 1960s.

Because of certain methodological problems with the data collected in the Grand Rapids study, including the method of breath alcohol analysis, two further case–control studies have been undertaken, one in Florida and the other in California (Compton *et al.* 2002; Moskowitz *et al.* 2002). Advantage was taken of modern hand-held instruments for breath alcohol analysis using electrochemical detection. The results provided immediate information on whether the people tested had consumed alcohol and also gave an estimate of their BAC. Attempts were also made to correct problems from the earlier studies such as 'missing cases', that is people leaving the crash scene before they could be tested. These so-called hit-and-run drivers had a major impact on the relative risk scores for the crash group because it is very likely that these drivers in many cases had been drinking alcohol (Moskowitz *et al.* 2002).

In the latest roadside surveys, hit-and-run drivers were actively pursued by the police and, whenever possible, breath alcohol tests were performed. Even some of the control group refused to provide a breath alcohol test and the study investigators attempted to obtain a sample without consent by using a passive alcohol sensor. This device, which is shaped like a flashlight, was kept close to the driver's face when he or she was engaged in conversation (Voas *et al.* 2006; Fell, Compton 2007). Activating the device draws a sample of the breath into the instrument for determination of alcohol. Although the readings are expected to be lower than if a proper deep lung end exhalation had been made, the presence or absence of alcohol can be established (Lestina, Lund 1992).

These and other methodological improvements give much credence to the relative risk curve shown in Figure 4.3 (Compton *et al.* 2002). The material comprised 5000 crash-involved drivers and 10 000 control non-accident-involved drivers sampled at the same site, time, day of the week and duration of travel as the crash driver. Of the crash drivers, 12% drove away from the crash site, but were pursued by police; of these 20% had consumed alcohol and could be included in the statistical analysis.

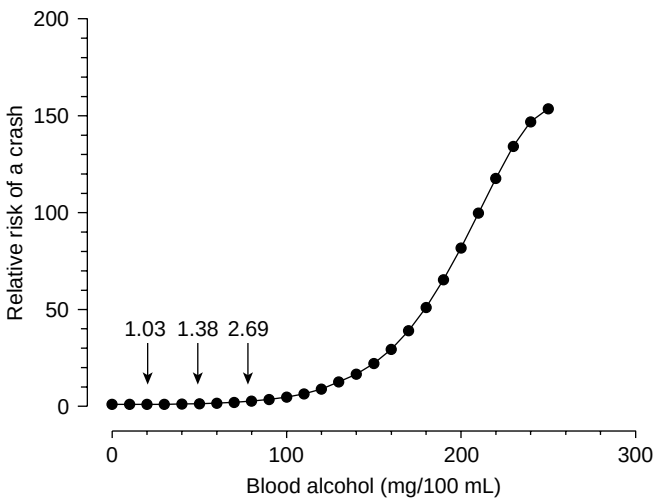

Figure 4.3 Relative crash risk as a function of the driver's blood alcohol concentration (BAC), estimated indirectly by analysis of breath (zero BAC = risk 1.0).

The numbers above the arrows shown on this plot indicate the relative risk of a crash at BACs of 20 mg/100 mL, 50 mg/100 mL and 80 mg/100 mL. Although there is an increase in risk as the BAC increases, the major effect of alcohol occurs when the BAC passes 80 mg/100 mL, in confirmation of the Grand Rapids study. The confidence intervals for the relative risk scores at various BAC levels have not yet been reported. It also needs to be made clear in a multiple-vehicle crash in which one of the drivers had been drinking whether it was this person who was responsible for the crash. Culpability assessment is an important feature of this kind of controlled epidemiological study of the role played by alcohol and drugs in traffic crashes (Robertson, Drummer 1994; Stewart 2005).

Analysis of alcohol in body fluids

Concentration units

No standardisation exists of the way in which blood and breath alcohol concentrations are reported for legal or scientific purposes as is obvious from information presented in Table 4.1. This sometimes leads to confusion when scientific articles and reports are compared and contrasted and results are reviewed in legal proceedings. The word 'concentration' has little meaning when used alone because it can be expressed in different ways depending on the choice of units. In the UK, BAC for legal purposes is reported as mg/100 mL, which often appears as the ambiguous mg% (Emerson 2004). In the USA, the concentration unit for blood ethanol in law enforcement is g/100 mL (% w/v), whereas most European countries present results as mg/mL or g/L.

For historical reasons, Germany and Scandinavian countries report BAC as mass/mass units, either mg/g or g/kg, because the blood aliquots analysed were originally measured by weight rather than by volume (Widmark 1922). The density of whole blood averages 1.055 g/mL, which means that a BAC expressed as mass/mass is not exactly the same as mass/volume, the difference being 5.5% (Lentner 1981). Accordingly, a person with a BAC of 100 mg/100 mL (mass/volume) has a mass/mass concentration of 95 mg/100 g and this difference should be considered when international comparisons are made. For example, a difference of 5.5% can determine whether a person is classified as being above or below the legal limit for driving and is a confounding factor when alcohol crash statistics are compared between nations.

Other ways of reporting BAC often appearing in scientific journals include mg/dL, g/L or μg/L. By the time most EU countries enacted statutory blood alcohol limits for driving, the aliquots of blood were measured by volume and the concentrations of alcohol were therefore reported as mass per unit volume; whether grams, milligrams or micrograms of ethanol in a volume of millilitres, decilitres or litres seemed arbitrary.

In hospital clinical chemistry laboratories the use of SI units has gained wide acceptance (Powsner 1984). On this scale the amount of substance is 'mole' rather than mass, and litre is the preferred unit of volume. The molecular weight of ethanol is 46.06, which means that a concentration of 1 mol/L corresponds to 46.06 g/L and 1.0 mmol/L is 46.06 mg/L, and so on (Stewart, Watson 1983). Many publications in the field of clinical and biomedical alcohol research report concentrations of ethanol and other drugs in terms of mmol/L. A simple calculation shows that a blood ethanol concentration of 100 mg/100 mL is the same as 21.7 mmol/L.

Many clinical chemistry laboratories at general hospitals need to measure concentrations of ethanol in blood and other body fluids because casualty patients often arrive for treatment after heavy drinking. Their BAC needs to be known before surgical treatment is given (Watt *et al.* 2005; Cherpitel 2007). The specimen used for analysis in hospital laboratories is usually plasma or serum and not whole blood, which is the body fluid used in forensic science and toxicology (Winek, Carfagna 1987). Ethanol is not evenly distributed between plasma and erythrocyte fractions of whole blood and this fact needs to be considered if and when

hospital laboratory results find their way into courts of law (Wright 1968; Charlebois *et al.* 1996). Careful measurement of the water content of body fluids by dessication showed that plasma was ~92% w/w water compared with ~80% w/w for whole blood and ~70% w/w for red cells (Jones 1992b).

A multicenter study from Germany reported 1.16 : 1 as the mean distribution ratio of water between serum and whole blood with a standard deviation (SD) of 0.0163 (Iffland *et al.* 1999). This implies that 95% of people will have a distribution ratio of water (and therefore of ethanol) within 1.16 ± 2 SD or from 1.12 to 1.19. For forensic purposes, if the concentration of ethanol had been determined in plasma or serum by mistake, the concentration in whole blood needed for use in a criminal trial on impaired driving is obtained by dividing serum alcohol by 1.2 (mean ± 2 SD). This calculation would provide a conservative estimate of the concentration of ethanol that would be expected in whole blood had that been the specimen analysed.

Determination of alcohol in blood and urine

Few, if any, substances can be determined in body fluids with such a high degree of accuracy, precision and specificity as ethanol (Moriya 2005). The older analytical methods required that ethanol be removed or separated from the biological matrix prior to analysis by taking advantage of its volatility. This required a pre-analytical stage involving distillation, diffusion or aeration; alternatively proteins in the blood were removed by precipitation (e.g. with perchloric acids) and the aqueous supernatant was then used for analysis of ethanol. One of the first analytical methods reliable enough to be used for legal purposes and for prosecution of drunken drivers was the microdiffusion method developed by Widmark (Widmark 1922). This involved microdiffusion in special flasks and chemical oxidation of ethanol with a mixture of potassium dichromate and sulfuric acid in excess. The amount of oxidising agent used up in the oxidation reaction was determined by iodometric titration with sodium thiosulfate and a starch indicator. Wet chemistry methods of analysis lacked selectivity, which meant that if other volatile materials were present in the blood specimen (e.g. methanol, acetone or ether) these would be oxidised and resulted in falsely high ethanol concentrations.

The selectivity for identification of ethanol was improved in the early 1950s when methods utilising milder oxidation conditions with enzymes (alcohol dehydrogenase) were developed. (Bonnichsen, Theorell 1951; Bücher, Redetzki 1951). At alkaline pH (~8.8) in a phosphate buffer, the coenzyme nicotinamide adenine dinucleotide (NAD^+) is reduced to NADH as ethanol is oxidised to acetaldehyde, which is trapped with semicarbazide to drive the reaction to completion. The quantitative analysis of ethanol was achieved by measuring the formation of the reduced coenzyme (NADH) by ultraviolet (UV) photometry at a wavelength of 340 nm.

The gold standard method in use today for the qualitative and quantitative analysis of blood ethanol concentrations in blood and urine for legal purposes is headspace gas chromatography (HS-GC) with automated sampling with a flame ionisation detector (FID) as outlined below (Jones, Schuberth 1989). The principles of GC applied to quantitative and qualitative analysis of drugs and poisons is dealt with elsewhere in this book and will not be repeated here. The advantage of GC over other analytical methods is that the target analyte (ethanol) is separated from non-volatile components of blood at the injection port and potential interfering compounds (e.g. acetone, methanol) are separated on the column prior to quantitative analysis. Accordingly, GC provides both a qualitative and a quantitative analysis in a single analytical run (Tagliaro *et al.* 1992).

All determinations for legal purposes should be done in duplicate by two technicians working independently with different sets of equipment. Aliquots of blood (100 µL) are removed from evacuated tubes by means of diluter-dispenser equipment and immediately diluted 11 times (1 + 10) with *n*-propanol (0.08 g/L) as the internal standard. If the difference between the two independent determinations exceeds some preestablished threshold value, the blood samples should be re-analysed. If the average BAC is less than 10 mg/100 mL, the result is reported back to the police as negative, so a concentration of 10 mg/100 mL serves as the limit of quantitation. The FID response shows good linearity for ethanol and other alcohols over a wide range of concentration from 10 mg/100 mL to 500 mg/100 mL that might be encountered in forensic blood samples. An analytical procedure for blood ethanol analysis that has proved robust and reliable over many years is described in brief below:

1. The tubes of blood are placed in racks and mechanically inverted for about 5–10 min to ensure homogeneity of the specimen. This step is important because sedimentation of red cells occurs on standing and without proper mixing there is a risk that a plasma-rich aliquot of blood is removed from the tube and analysed.
2. The stoppers are removed from a batch of evacuated tubes and aliquots of blood (100 µL) are diluted 1 + 10 with an aqueous solution of the internal standard (*n*-propanol), the concentration of which is usually about 8–10 mg/100 mL. This dilution step requires a high degree of precision and accuracy and automated diluter-dispenser equipment is available for this purpose. The blood specimen and internal standard are immediately ejected into a glass vial, which is then fitted with a Teflon-lined stopper and made airtight by crimped-on aluminium caps in readiness for HS analysis.
3. Equipment for HS-GC analysis is available from several manufacturers, although the first instruments (since the early 1970s) were produced by the Perkin-Elmer company. The quantitative analysis of ethanol is accomplished by measuring the peak area ratios of the response on the gas chromatogram for ethanol and the internal standard after electronic integration. When this EtOH : PrOH ratio is plotted as a function of the concentration of ethanol in the known standards, a linear calibration plot is obtained. The concentrations of ethanol in the unknown blood samples are found by interpolation using computer software and linear regression analysis for the relationship between peak area ratio (ethanol to internal standard) and known concentration of ethanol in the standards.
4. The calibration standards are made from 99.5% v/v ethanol by weighing to give a 10% w/v stock solution and volumetric dilution from this to give working standards spanning the concentration range of interest (e.g. 10–500 mg/100 mL). Within each analytical run it is useful to include ethanol standards prepared from another source or purchased from an independent manufacturer. The ethanol standards of known strength are dispersed among the blood samples within each analytical run.
5. It is also advisable to include a blank (ethanol-free) specimen of blood diluted with internal standard in the same way as the unknowns. Each analytical run might also include an aqueous mixture of potential interfering substances (e.g. acetaldehyde, methanol, acetone, isopropanol) to check adequate resolution from the ethanol and internal standard peaks.

The standard deviation of alcohol analysis by HS-GC tends to increase as the concentration of ethanol in the blood samples increases. In a recent study, the critical differences between duplicate determinations for acceptable agreement were 1.6 mg/100 mL (BAC 20 mg/100 mL), 3.6 mg/100 mL (BAC 50 mg/100 mL) and 6.9 mg/100 mL (BAC 100 mg/100 mL) (Jones 2007c). For blood specimens that show acceptable agreement, a deduction is usually made from the mean ethanol concentration and the reduced value is used for prosecution. The amount deducted needs to be higher at higher concentrations of ethanol to ensure the same legal security for all suspects regardless of their BAC. After making the appropriate deduction, the prosecution BAC is not less than the true concentration with 99% or 99.9% certainty.

The identity of an unknown volatile in blood can be established by comparing the retention time (RT) with that of known reference substances (Jones, Pounder 2007; Emerson 2004). Use of different chromatographic conditions for analysis makes it extremely unlikely that two compounds will have the same RT on both stationary phases, especially if these are chosen to have differing polarity. Alternatively, enhanced selectivity can be achieved by analysis using different methods, such as GC and enzymatic oxidation, as is customary in Germany and Austria. Urine samples can be treated and analysed in exactly the same way as blood specimens.

Table 4.5 Retention times of ethanol and other low-molecular-weight volatile substances analysed by headspace gas chromatography on four different stationary phases used in forensic science and toxicology laboratories (retention times relative to *n*-propanol as internal standard are shown in parentheses)

Volatile substance	*Retention time (min) Carbopak C*[a]	*Retention time (min) Carbopak B*[b]	*Retention time (min) Rtx-BAC1*[c]	*Retention time (min) Rtx-BAC2*[d]
Acetaldehyde	0.56 (0.38)	0.53 (0.29)	1.19 (0.53)	0.82 (0.34)
Acetone	1.00 (0.68)	0.86 (0.46)	2.05 (0.91)	1.36 (0.57)
n-Butanol	4.68 (3.16)	4.11 (2.22)	4.63 (2.06)	5.28 (2.20)
Ethanol	0.72 (0.49)	0.98 (0.53)	1.32 (0.59)	1.27 (0.53)
Methanol	0.49 (0.33)	0.67 (0.36)	1.06 (0.47)	0.96 (0.40)
Methyl ethyl ketone	2.45 (1.66)	1.49 (0.81)	3.08 (1.37)	2.49 (1.04)
Isopropanol	1.16 (0.78)	1.31 (0.71)	1.66 (0.74)	1.48 (0.62)
n-Propanol	1.05 (1.00)	1.85 (1.00)	2.25 (1.00)	2.40 (1.00)
t-Butanol	1.90 (1.28)	1.68 (0.91)	1.98 (0.88)	1.65 (0.69)

[a]Column: glass with 0.2% Carbowax (polyethylene glycol) 1500 (2 m × 0.5 mm i.d.).
[b]Column: glass with 5% Carbowax (polyetheylene glycol) 20M (2 m × 0.5 mm i.d.).
[c]Column: capillary (30 m × 0.53 mm i.d.).
[d]Column: capillary (30 m × 0.53 mm i.d.).

Table 4.5 presents the absolute retention times (min) as well as retention times relative to the internal standard (*n*-propanol) seen during a typical HS analysis of volatiles in blood (Jones 2009b). The results are shown for two types of glass-packed columns with stationary phases – Carbopak C and Carbopak B – as well as more modern capillary columns (Rtx-BAC1 and Rtx-BAC2).

Urine–blood alcohol relationship

The functioning of the kidney and the physiology of ethanol excretion including analysis and interpretation of urine alcohol concentration have been reviewed (Jones 2006). Ethanol passes by diffusion from the renal artery blood with the glomerular filtrate into the urine, which is stored in the bladder until voided. Controlled drinking experiments have shown that the concentration–time profile of ethanol in urine differs from that of blood alcohol (Jones 1992b). The urine alcohol concentration (UAC) curve is displaced in time and runs on a higher level compared with that for the corresponding BAC. Furthermore, if a pool of residual alcohol-free urine were present in the bladder before drinking, this would dilute the alcohol concentration in freshly produced urine (Biasotti, Valentine 1985). Urine is almost 100% w/w water compared with 80% w/w water in blood, so the UAC : BAC ratio after equilibration is expected to be greater than unity or approximately 1.25 : 1 (100/80).

Urine is produced at a rate of approximately 1 mL per minute or 60 mL per hour, resulting in a total volume of 1–2 litres per 24 h. Much depends on total intake of fluids and the intensity of diuresis, which is higher after drinking alcohol, sometimes by 10-fold for short periods (Bendtsen, Jones 1999). However, alcohol-induced diuresis is only evident during the absorption stage of the blood alcohol curve and close to the C_{max} value (Jones 1990a). During the post-absorptive period, the UAC always runs above the BAC, mainly because of the difference in water content of the two fluids.

Figure 4.4b shows typical UAC and BAC profiles after subjects drank a bolus dose of alcohol (0.85 g/kg) as neat whisky in 25 min (Jones 2009a). The subjects emptied their bladders before drinking and urine was collected thereafter at hourly intervals and blood samples were taken at 30 to 60-min intervals. In Figure 4.4a, the median volumes of urine collected are shown as a function of sampling time for up to 8 h post drinking. Medians are plotted because of large inter-subject variation in urinary volumes, which are not normally distributed. The shift or displacement in UAC and BAC profiles is evident from Figure 4.4b. The UAC is less than BAC for the first 60 min after drinking (absorption phase) and always higher than BAC for the rest of the time alcohol is in the body (post-absorptive phase).

The shapes of UAC and BAC profiles during repetitive drinking over several hours, as might be expected in a typical drink–driving scenario, have not yet been published.

The threshold concentration limit of alcohol in urine in the UK and Republic of Ireland is 107 mg/100 mL urine, which was arrived at from the statutory BAC of 80 mg/100 mL on the assumption of a UAC : BAC

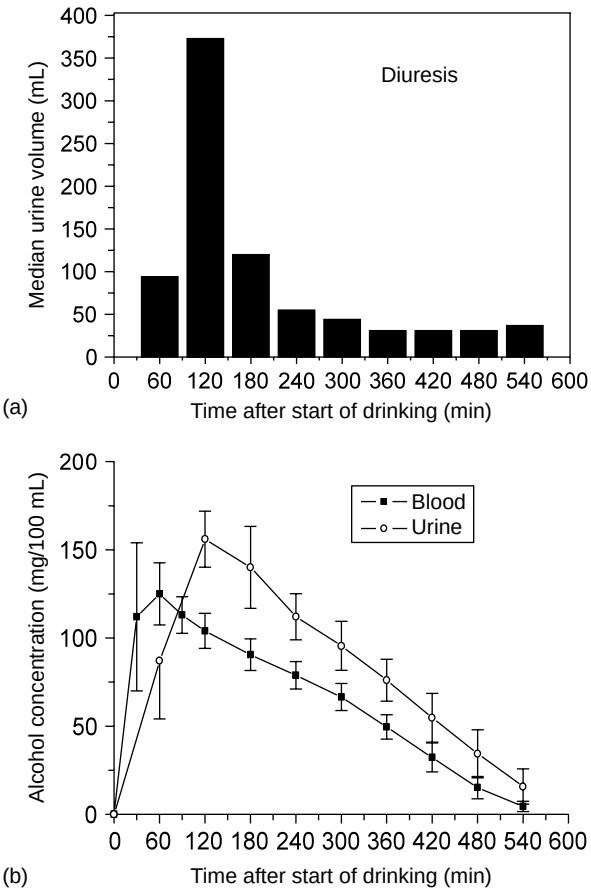

Figure 4.4 Concentration–time profiles of alcohol (mean curves, $n = 16$) in venous blood and urine after a bolus dose (0.85 g/kg ethanol) as neat whisky taken on an empty stomach (b). Plot (a) shows the volumes of urine collected at hourly intervals after drinking alcohol over a period of 25 min.

ratio of 1.33 : 1(Payne *et al.* 1967). When drink–driving law is interpreted by the courts, there is no need to consider the UAC : BAC ratio or make any inter-conversion between the two because both are defined by statute (Curry 1972).

Urine is produced in batches so that the UAC reflects the average concentration of alcohol in the blood passing through the kidney during the period that urine is formed and stored in the bladder. The storage time of urine in the bladder is not known in cases of DUIA and the UAC might therefore reflect the BAC prevailing several hours earlier, even before the time of driving. During the storage time of urine in the bladder, the concentration of ethanol in the blood decreases appreciably through metabolism in the liver. Ethanol-metabolising enzymes do not exist in the bladder. Under these circumstances, the UAC : BAC ratio of alcohol is expected to be abnormally high.

This pooling effect of ethanol in the bladder is avoided by having the suspect first empty the bladder of any 'old urine' and then provide a fresh specimen about 30–60 min later. It is the concentration of alcohol in this second of two voids that determines whether the person exceeds the statutory UAC limit of 107 mg/100 mL. Another important requirement is to include a chemical preservative, sodium fluoride (1% w/v), in the specimen container used to store and transport the urine specimen for analysis (Jones *et al.* 1999). The fluoride ions act as an enzyme inhibitor to prevent the production of ethanol, which might otherwise occur if there was sugar in the urine and the person suffered from a urinary tract or yeast infection. The inclusion of urine as an alternative body fluid to blood in the prosecution of impaired drivers was intended for people who might refuse to provide blood for religious reasons or claim that they suffer from blood injury phobia.

Both inter- and intra-individual variations in the urine-to-blood relationship exist as demonstrated by the scatter plot in Figure 4.5 (Jones 2002). The venous BAC was plotted against the UAC for the second of two urine voids collected from several hundred drunken drivers. The Pearson correlation coefficient ($r = 0.978$) indicates a strong positive association between the two variables. However, the scatter of the individual data points around the regression line (residual standard deviation) is 21 mg/100 mL, which suggests that there is considerable uncertainty in using the regression equation to predict BAC from UAC or vice versa.

The relative frequency distribution of UAC : BAC ratios is seen in Figure 4.6 and resembles a normal distribution of values with mean of 1.23 : 1 and median 1.22 : 1 (Jones 2002). Both ratios are slightly lower than 1.33 : 1, which is the ratio used to set the statutory UAC limit in the UK. Accordingly, a ratio of 1.33 : 1 instead of 1.23 or 1.22 for setting the UAC limit gives a slight benefit to the person who opts to give a urine specimen compared with blood. The mean UAC : BAC ratio of 1.23 : 1 would lead to a threshold UAC of 80 × 1.23 or 98 mg/100 mL instead of 107 mg/100 mL.

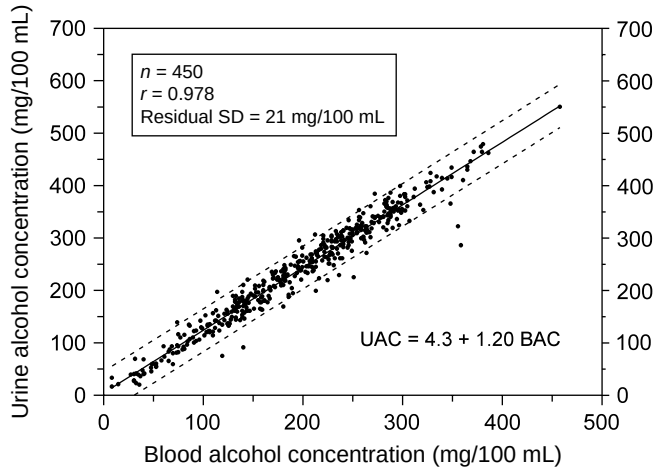

Figure 4.5 Scatter plot and correlation–regression analysis of the relationship between venous blood alcohol concentration (BAC) and urine alcohol concentration (UAC) for the second of two consecutive voids of the bladder ~60 min apart.

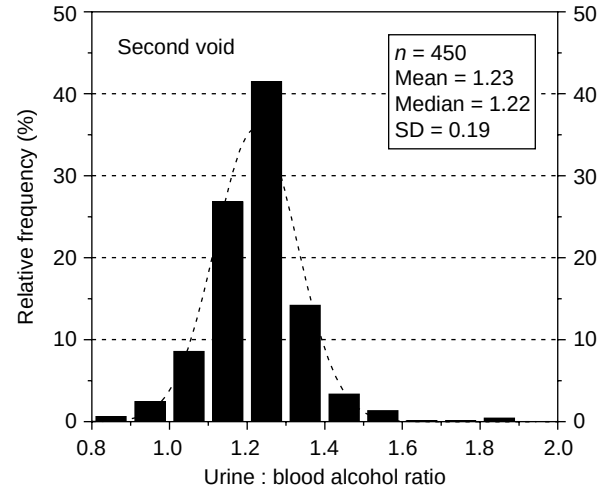

Figure 4.6 Relative frequency distribution of UAC : BAC ratios of alcohol in apprehended drivers for analysis of the second of two voids ~60 min apart.

Determination of alcohol in breath

The smell of alcohol on the breath probably represents the oldest, albeit primitive biomarker for overindulgence in alcoholic beverages. The first scientific investigations measuring exhaled alcohol date back to the 1870s when it was shown that only a very small fraction of the total amount of ethanol consumed was recoverable in the breath collected for several hours after the end of drinking (Jones 1996). In an important paper from the 1930s, the distribution ratio of ethanol between blood and air was investigated under *in vitro* and *in vivo* conditions (Liljestrand, Linde 1930). This work showed that the concentration of alcohol in alveolar air was about 2000 times less than that in an equal volume of blood, which indicates a blood : breath alcohol ratio of approximately 2000 : 1.

Methods of breath alcohol analysis can be classified and discussed according to whether the results are intended as a qualitative screening test or will be used as evidence for prosecution (Harding, Zettl 2008). The first practical breath alcohol screening test used by police for testing drivers was the chemical tube and bag device. The task of the police officer was to judge whether a change in colour (yellow to green) of crystals (potassium dichromate on silica) had occurred. The chemical reagent was packed into a narrow tube; one end of this was attached to a plastic bag (~1 L) and the suspect exhaled through the other end of the tube to inflate the bag in about 15 s. The production of a green stain up to a red graduation mark on the middle of the tube indicated that the suspect's BAC was above the legal limit for driving. Later, much-improved devices for breath alcohol testing became available and these are used worldwide for testing motorists at the roadside or even as they sit behind the wheel of their car. Current generation hand-held devices for breath alcohol screening are based on the electrochemical oxidation of alcohol, and widely known instruments for this purpose are Alcolmeter, Alcotest and AlcoSensor. These instruments have been manufactured in a wide range of models with manual or automated sampling, and with analogue or digital display or simply showing pass or fail results of the test.

Evidential breath alcohol testing is performed under more controlled environmental conditions and a special room is sometimes made available at the police station. The procedure follows strict rules and regulations that differ slightly between different jurisdictions or countries. Information about the suspect is recorded and the test procedure must start with an instrument calibration, which involves analysis of a known strength air–alcohol vapour standard from a wet bath simulator or a compressed dry gas standard (Dubowski, Essary 1992, 1996).

Another requirement is that the air from the room is analysed as a blank test and this is done before and after the subject provides breath samples. In most instances, two consecutive samples of breath are analysed 2–6 min apart. The results of all tests, including date and time, are printed out in real time and also stored in computer memory for verification later if necessary. With the latest generation of evidential instruments, such as those based on infrared technology (see Table 4.1), the entire breath ethanol exhalation profile is recorded and stored for later inspection and further analysis if necessary (Jones 2009b). Quality assurance aspects of evidential breath alcohol testing have been reviewed elsewhere (Dubowski 1994; Gullberg 2000).

Key developments in methods for the determination of alcohol in breath are summarised in Table 4.6 (Jones 1996, 2000a). The first device (the Breathalyzer) sufficiently practical to be used by police officers appeared in the mid-1950s and gained wide acceptance throughout North America (Borkenstein, Smith 1961). Instruments employing physiochemical methods of analysis, such as GC, infrared spectrometry and electrochemical oxidation appeared in the 1970s (Jones 1996). Today's instruments for breath alcohol testing are considerably automated and the police operator has only to observe and encourage the suspect to provide end-expired breath samples at the appropriate time in the test programme.

Infrared (IR) and electrochemical (EC) methods of analysis differ in several ways, including selectivity for different volatile materials and long-term stability of calibration. The IR method is non-destructive analysis, which means that the breath specimen can be stored for a later verification analysis if necessary. However, neither IR nor EC is completely specific for measuring ethanol in breath. The EC detectors respond to other alcohols (e.g. methanol, *n*-propanol and isopropanol), and also to acetone, which is an endogenous volatile exhaled in breath. Indeed, the concentrations of acetone can increase considerably under some conditions, such as in untreated diabetes or after prolonged fasting (Flores, Franks 1987). The hand-held instruments fitted with EC detectors are mainly used for roadside screening of motorists (Zuba 2008).

Table 4.6 Chronological developments in methods used for the analysis of ethanol in breath that have been used for legal purposes

Period	*Method for analysis of ethanol in breath*
1930–1950	Chemical oxidation with potassium permanganate (Drunkometer and Intoximeter), iodine pentoxide (Alcometer), trapping a portion of the breath on an absorbent (e.g. silica gel) allowing later confirmatory analysis at a laboratory (Intoximeter)
1954	Chemical oxidation of ethanol with a mixture of potassium dichromate and sulfuric acid contained in specially designed glass ampoules and with the quantitative analysis done by photometry (Borkenstein Breathalyzer)
1969	Use of compact and portable instruments for gas chromatography (GC) with thermal conductivity detector (AlcoAnalyzer) or flame ionisation detector (GC Intoximeter)
1970	Single-wavelength infrared analyser operating at 3.39 μm (Intoxilyzer 4011) measuring C–H stretching in ethanol molecules
1975–1980	Hand-held electrochemical (fuel cell) instruments, such as Alcolmeter, AlcoSensor and Alcotest mainly intended for roadside screening analysis as replacement for the chemical tube and bag device from the mid-1950s
1990–present	Multiple -wavelength infrared spectrometry at wavelengths of 3.39–3.42 μm for (C–H) bond stretching (Intoxilyzer 5000 and DataMaster) or at 9.5 μm for (C–O) bond stretching (Alcotest 7110 and Ethylometer)
	Dual-sensor technology combining electrochemical oxidation (fuel cell) and infrared t 9.5 μm (Alcotest 7110). Intoxilyzer 8000 measures the absorption of infrared energy at both 3.4 and 9.5 μm wavelengths
2000–present	Small compact mass spectrometers for determination of ethanol and other volatiles.[a] Fourier transform infrared spectroscopy (FTIR) analysers.[a]

[a]Not yet used for legal purposes.

Breath analysers fitted with multiple IR detectors have emerged as the instruments of choice for evidential testing, mainly because this technique is more robust and the calibration remains stable over longer periods (Harding, Zettl 2008). The first IR breath analysers measured the C–H stretching frequencies in ethanol molecules that occur in the wavelength range 3.3–3.4 μm (Harte 1971). Most of the instruments listed in Table 4.1 are equipped with several IR wavelength filters to ensure a higher selectivity for identifying ethanol if there happened to be interfering substances present that contain C–H bonds in the molecule, such as acetone. Instruments are equipped with between three and five narrow-band filters covering the wavelengths 3.3–3.5 μm. Some IR breath analysers are equipped with IR technology designed to measure the C–O bond stretching frequency, which is prominent at a wavelength of ~9.5 μm. Other analysers are equipped with both 3.4 and 9.5 μm wavelength detectors (Intoxilyzer 8000) and even dual technology such as ~3.4 μm IR detector and an EC detector to offer enhanced selectivity of analysis (Alcotest 4011).

The physiological principles of gas exchange in the lungs have been reviewed elsewhere (Jones 1990b; Hlastala 1998). Ethanol rapidly equilibrates between the pulmonary blood and the alveolar air by diffusion across the alveolar capillary membrane in a fraction of a second. However, during a prolonged exhalation alcohol and other volatiles undergo re-equilibration with the watery mucous surfaces covering the upper airways that receive ethanol from the bloodstream. Moreover, during exhalation the alveolar air cools from about 37°C at the interface to 34°C when the breath leaves the mouth (Jones 1982c). Because the solubility coefficient of ethanol in plasma and water is about 6.5% per degree Celsius, the exhaled concentration of ethanol is lower than the alveolar concentration (Jones 1983a). How much lower depends on factors such as body temperature, breathing pattern, and the temperature and humidity of the ambient air breathed, as well as the completeness of ethanol equilibration between the mucous surfaces of the upper airway, nose and mouth, and the expired air (Hlastala 2002, 2003).

Unlike respiratory gases (N_2, O_2 and CO_2), ethanol is highly soluble in water and it seems likely that early proponents of breath alcohol testing for legal purposes failed to appreciate the importance of re-equilibration of ethanol between the exhaled air and the airway surfaces (Wright *et al.* 1975; Hlastala 2002). Such interactions probably account for much of the variability in BBRs of ethanol observed in practice. The final end-expired BrAC also depends on pre-exhalation manoeuvre, body temperature, lung size as well as the temperature and humidity of ambient air breathed (Jones 1982a; Jones 1982b; Hlastala, Anderson 2007). Studies have shown that hyperventilation lowers and hypoventilation raises the expired BrAC compared with a normal inhalation and exhalation (Jones 1982b; Mulder, Neuteboom 1987). Abnormalities in breathing pattern influence equilibration of ethanol between airway mucus and respired air. People with lung dysfunction, such as thickening of the mucus as seen in asthma or chronic obstructive pulmonary disease, were shown to have higher BBRs than an age-matched control group of men with healthy lungs (Hahn *et al.* 1991).

The concentrations of ethanol in exhaled breath increase after re-breathing the initial exhalation a number of times (Jones 1983b). During the process of re-breathing, more time is available to achieve equilibration of ethanol between the air phase and the watery surfaces covering the upper airway. Furthermore, the temperature of the breath increases after re-breathing and ethanol concentration increases by ~6.5%/°C (Jones 1983a).

Blood–breath alcohol relationship

The concentrations of ethanol in near-simultaneous samples of blood and breath are highly correlated according to controlled drinking experiments and in tests made with apprehended drivers (Jones, Andersson 1996b; Jones, Andersson 2003). A physiological relationship

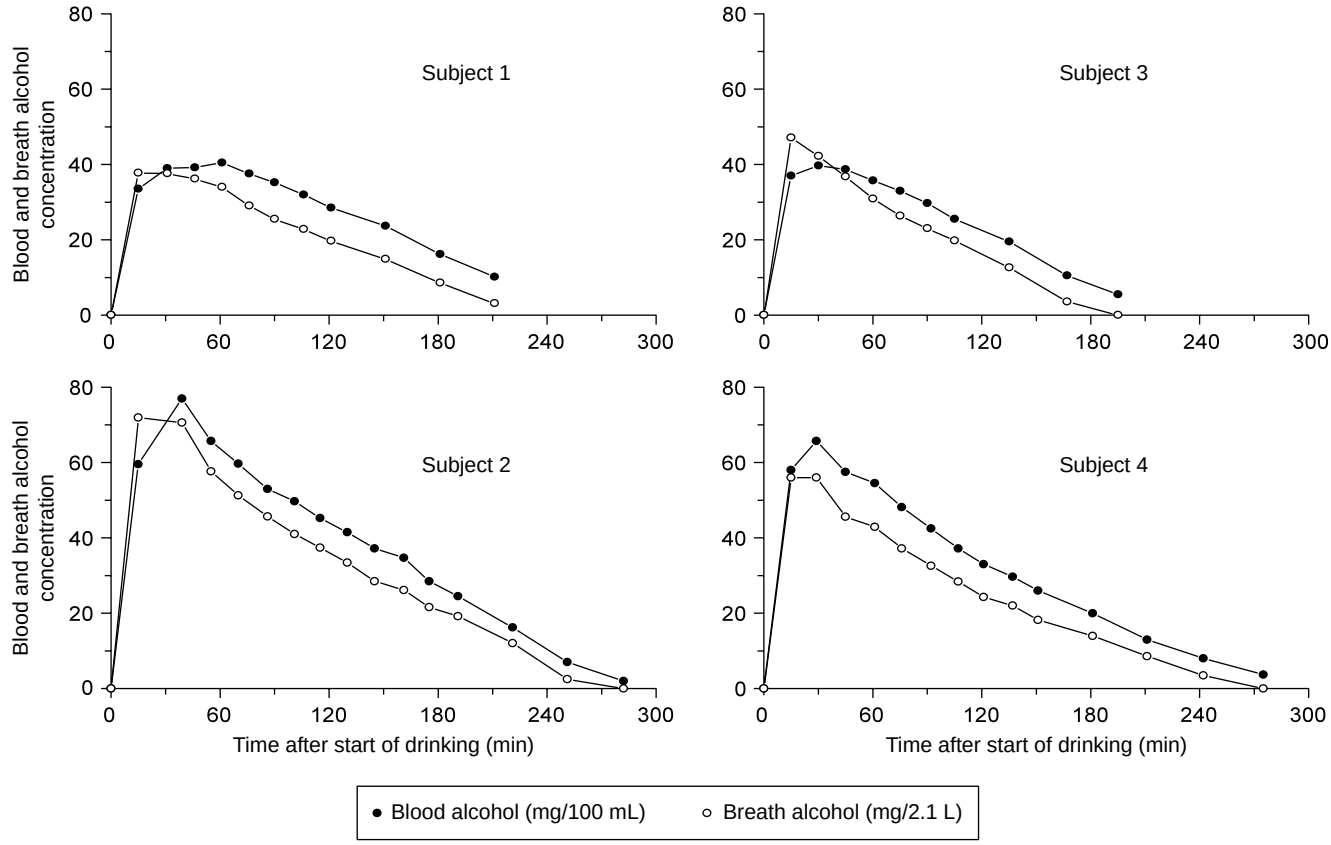

Figure 4.7 Comparison of the concentration–time profiles of ethanol in venous blood and end-expired breath derived from controlled drinking studies involving four volunteers who drank a moderate dose of ethanol starting 2 h after lunch.

between BAC and BrAC means that resulting concentrations are highly correlated, although breath contains about 2000 times less ethanol than an equal volume of blood (Harding, Field 1987; Harding *et al.* 1990). This difference in concentration should be considered when blood and breath alcohol concentration curves are plotted on the same coordinates, such as by appropriate choice of units for BAC (mg/100 mL or g/100 mL) and BrAC (mg/2.0 L or g/210 L).

Figure 4.7 compares BAC and BrAC profiles from an experiment in which four healthy men consumed a moderate dose of alcohol in the morning after an overnight fast (Jones 2010a). The alcohol (96% v/v) was diluted with orange juice and alcohol consumption was finished in 15 min. Thereafter, near simultaneous specimens of venous blood and end-expired breath were taken for analysis repeatedly for up to 6 h.

These plots demonstrate that the relationship between alcohol concentration in blood and breath varies as a function of time after the end of drinking. During the first 60 min, the breath level (mg/2 L) might be slightly higher than the concentration in blood (mg/100 mL) but at all later times the breath instrument readings are lower than the coexisting BAC. The closeness of agreement between BAC and BrAC also depends on whether BrAC was reported as mg/2 L or mg/2.3 L, and therefore the assumed BBR. Studies originating from several countries have shown that a BBR of 2300 : 1 gives closer agreement when sampling is done in the post-absorptive phase (>60 min post drinking). Most alcohol-impaired drivers are tested 1–2 h after their last drink, making it a reasonable assumption that they have reached the descending limb of the blood alcohol curve.

One reason for the discrepancy between BAC and BrAC time profiles is the use of venous blood for the determination of alcohol concentration. The time course of alcohol in breath runs much closer to the arterial blood concentration rather than that of venous blood, which is the blood sample analysed for legal purposes in DUIA investigations (Jones *et al.* 2004). However, because of medical risks with sampling arterial blood, this specimen is not so practical for use in drink–driving offences. According to a recent study the mean BBR for blood from the radial artery and exhaled air was 2280 : 1 (Lindberg *et al.* 2007).

Despite many physiological sources of variation inherent in the sampling and analysis of ethanol in breath, there is a significant correlation between BAC and BrAC as shown in Figure 4.8 derived from tests with apprehended drivers (Jones 2010a). Venous BAC was determined by automated HS-GC and BrAC was analysed with an IR analyser Intoxilyzer 5000.

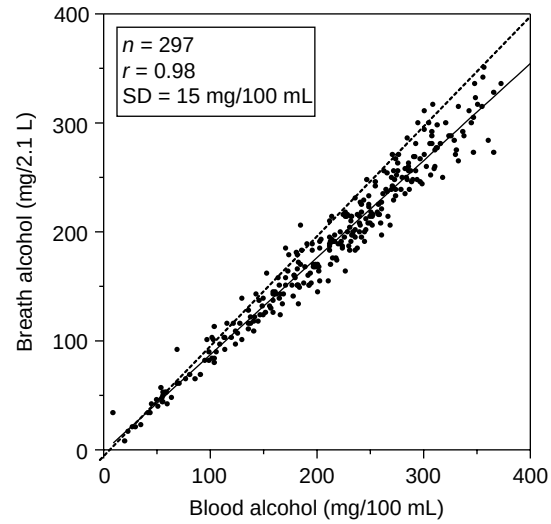

Figure 4.8 Scatter plot and correlation-regression analysis of venous BACs and end-expired BrACs in tests made with apprehended drivers.

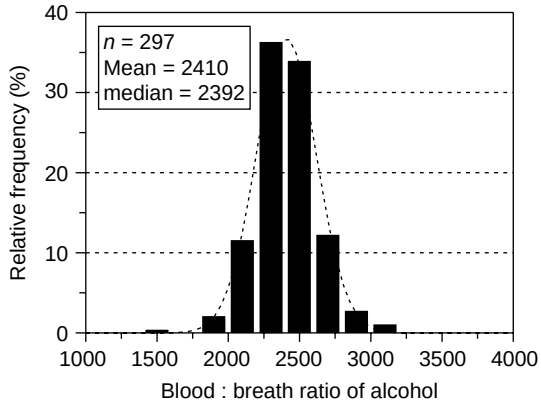

Figure 4.9 Relative frequency distribution of BAC : BrAC ratios of alcohol in apprehended drivers tested with the Intoxilyzer 5000 infrared analyser.

The magnitude of biological and analytical variation in BAC/BrAC ratio can be gleaned from the relative frequency distribution shown in Figure 4.9 (Jones 2010a). The mean and median BAC : BrAC ratios are close to 2400 : 1 in these apprehended drivers, which is considerably higher than the BBR assumed for legal purposes (2000 : 1–2300 : 1). This means that a person who submits to a breath alcohol test gains a certain advantage compared with the person who provides a blood sample. One exception to this occurs if the breath test is done shortly after the end of drinking (absorption phase) when arterial–venous differences in ethanol concentration are at their greatest. Under these circumstances, BrAC expressed as mg/2 L might be higher than BAC in units of mg/100 mL.

Allowing for uncertainty

An important consideration when physical or chemical methods are used to establish whether an analytical result complies with some legal specification, e.g. the legal BAC for driving, is the inherent uncertainty (Hibbert 2001; Andersson 2002). All measurements are subject to error and the final results, if used for criminal prosecution, need to be accompanied by an explicit quantitative statement of the amount of error or uncertainty (Brach, Dunn 2004). Uncertainty is formally defined as *a parameter associated with the result of measurement, which characterises the dispersion of the values that could reasonably be attributed to the measurand* (Hund *et al.* 2001).

The magnitudes of random errors are best determined by statistical methods to assess variations between duplicate determinations and the systematic error or bias is established by analysing known-strength standard solutions of alcohol (Gullberg 1993). By combining random and systematic errors, a statement can be made about the overall uncertainty in the analytical method, which can then be used to determine an allowance (deduction factor). In this way the final prosecution BAC can be presented with a high degree of statistical certainty as being not less than the true value, usually 99% or 99.9% (King 1999; Hibbert 2001).

The analytical precision of GC methods for determining blood ethanol depends strongly on the ethanol content in the samples analysed; the standard deviation of the measurements increases almost linearly with increasing BAC (Jones 1989). This means that the amounts deducted from the mean to allow for uncertainty also increase with the ethanol concentration in the blood specimen (Jones, Schuberth 1989). The usual practice in the UK is to deduct 6 mg/100 mL from the mean result if this less than 100 mg/100 mL or deduct 6% if the mean concentration exceeds 100 mg/100 mL (Walls, Brownlie 1985; Emerson 2004). Other countries have developed their own statistical methods to compensate for uncertainty in BAC results when these are reported to the courts for prosecution of impaired drivers (Fung *et al.* 2000).

When evidential breath alcohol instruments started in the UK, other safeguards were considered necessary (Cobb, Dabbs 1985). First, it was the lower of two breath test results that was used for prosecution. Second, although the statutory breath alcohol limit was 35 µg/100 mL, a prosecution would be brought only if the BrAC was 40 µg/100 mL or more. This safeguard was felt necessary to compensate for biological variations in the BBR. The operational BBR is therefore 2000 : 1 (80/40) instead of the BBR used to set the statutory BrAC of 2300 : 1 (80/35). Third, if the breath test result was between 40 and 50 µg/100 mL, the suspect was given the opportunity to provide a blood specimen instead and this was sent for the determination of alcohol concentration. If the blood option was taken, the result of the breath test became null and void and was not used for prosecution.

This option (which is no longer in force) to allow a suspect to provide a blood sample seems questionable without any consideration being given to the metabolism of alcohol during the time it takes for a physician or nurse to arrive and draw the specimen. An unusually long time delay could mean that the person was over the critical 40 µg/100 mL breath (guilty) at time of testing, but below the punishable BAC limit of 80 mg/100 mL (not guilty) when blood was eventually taken.

Quality assurance of analytical results of alcohol testing is imperative to ensure the legal security of the individual under a 'concentration *per se*' statute. This legal framework creates a razor-sharp difference in penalty for those who find themselves just below or just above the critical threshold, e.g. 79 mg/100 mL instead of 81 mg/100 mL. This gives strong support for making an allowance for uncertainty considering the consequences for the individual accused of driving with excess alcohol.

Alcohol in the body

Besides a thorough knowledge and expertise in analytical chemistry and statistical quality assurance, forensic scientists and others who intend to testify in court as expert witnesses in impaired driving cases also need to understand the basic principles of absorption, distribution, metabolism and excretion of ethanol in the body, as reviewed elsewhere (Jones 2008).

Alcoholic beverages are primarily composed of ethanol (CH_3CH_2OH) and water in proportions varying from 2% v/v up to 55% v/v ethanol. Also present are tiny amounts of other low-molecular-weight substances, such as other alcohols, aldehydes, lactones, etc. (<1% v/v). These other substances are known collectively as congeners and are derived as by-products from the fermentation process or might be incorporated during the manufacturing process, such as during ageing and storage in wooden casks (McAnalley 2008). The cleanest alcoholic beverage is vodka and those richest in congeners are fruit brandies, whiskies and cognacs, which usually have a characteristic colour, taste and smell (Bonte 2000).

The concentrations of congener alcohols are too low to exert their own pharmacological effect on the individual, although they are often incriminated in the unpleasant after-effects of an evening's heavy drinking, known as the alcohol-induced hangover (Greizerstein 1981; Wiese *et al.* 2000). Qualitative and quantitative analysis of congeners can help to identify the origin of a particular drink and this approach has gained forensic applications in relation to clandestine production of distilled spirits. Some scientists advocate that the profile of congeners and their metabolites in body fluids can be used as a way to identify the particular alcoholic beverage consumed (Krause, Wehner 2004). Another forensic application of congener analysis is in connection with alleged consumption of alcohol after driving, the so-called hip-flask defence, described in more detail by Iffland and Jones (2003). This defence tactic has become increasingly common in some countries (e.g. Finland, Germany and Sweden) and is often difficult for the prosecution to disprove. Identification and quantification of the major congener alcohols along with the blood ethanol concentration can help to establish whether a certain drink (usually spirits) was recently ingested and sometimes confirm or challenge alleged post-offence drinking (Bonte 2000).

Amount of alcohol consumed

The strength of alcoholic beverages is usually printed on the bottles or containers as alcohol percentage by volume (ABV, % v/v). Beers usually range in strength from 2% to 10% v/v, table wines from 6% to 14% v/v,

Table 4.7 Concentrations of ethanol in beer, wine or spirits and the amounts of ethanol contained in one standard drink. In the UK a unit of alcohol corresponds to 8 g ethanol; a standard drink in the USA is almost double, 14 g ethanol

Alcoholic beverage (volume of one drink)	*Alcohol (% v/v)*	*Alcohol (% w/v)[a]*	*Ethanol (g) in one standard drink[b]*
Beer (12 ounces or ~360 mL)	2	1.6	5.8
	3	2.4	8.6
	4	3.2	11.5
	5	4.0	14.4
Table wine (5 ounces or ~150 mL)	8	6.3	9.5
	10	7.9	11.8
	12	9.5	14.2
Fortified wine (3 ounces or ~90 mL)	16	12.6	11.3
	18	14.2	12.7
	20	15.8	14.2
Distilled liquor (1.5 ounces or ~45 mL)	35	27.6	12.4
	40	31.6	14.2
	50	39.5	17.8

[a]Volume per cent (% v/v) multiplied by 0.79 g/L to give weight per cent (% w/v).
[b]Weight per cent (% w/v) multiplied by volume of drink consumed in decilitres (100 mL) gives grams of ethanol consumed.

fortified wines (sherry and port) from 15% to 20% v/v and distilled liquors from 40% to 50% v/v. The density of ethanol at room temperature is close to 0.79 g/mL and this can be used to convert ABV (mL/100 mL) into percentage weight/volume (g/100 mL), e.g. % v/v × 0.79 g/mL = %w/v. The amount of alcohol in a drink is the volume in decilitres multiplied by percentage alcohol by weight (Brick 2006). Knowledge of the amount of ethanol consumed in grams is needed in many types of forensic blood alcohol calculation (Ferner, Chambers 2001). Examples of the amounts of pure ethanol in various alcoholic beverages in relation to ABV are given in Table 4.7.

According to the American Medical Association, moderate drinking corresponds to an intake of 1–2 standard drinks per day for men and 1 drink for women and elderly people (>65 years). The age and sex differential stems from the fact that, on average, women weigh less than men and also have less body water (Seidl *et al.* 2000). Body weight, body water and lean body mass also decrease in elderly people. For the same dose of alcohol (grams per kg body weight) a woman achieves a higher BAC than a man and the female body is therefore more exposed to the toxic effects of ethanol after excessive drinking.

The drinking pattern harmful to health varies widely between different individuals owing to factors such as age, sex, genetics, state of health and nutrition, as well as amounts of ethanol consumed and the frequency of intake (Zakhari, Li 2007). Clinicians and specialists in alcohol diseases consider that amounts exceeding 60–80 g per day (about 1 bottle of wine) for men and somewhat less for women will eventually lead to alcohol-related health problems, such as liver dysfunction and cirrhosis (Dufour 1999; Zakhari, Li 2007).

In the USA, 'one standard drink' corresponds to a 12-ounce (~360 mL) bottle of beer (5% v/v), 5 ounces (~150 mL) of wine (12% v/v) or 1.5 ounces (~45 mL) of distilled spirits (Dufour 1999). One standard drink therefore contains approximately 14 g of pure ethanol (about 0.6 fluid ounces), but the exact amount varies depending on the ethanol content of the beverage consumed (Miller *et al.* 1991). Care is needed when reading the medical literature to appreciate the difference between the US standard drink (14 g) and the British unit of alcohol.

In the UK, alcoholic consumption and patterns of drinking are often discussed in terms of 'units of alcohol' and the number of units per day has become widely used as a yardstick to document overconsumption (Wansink, Van Ittersum 2005). One unit of alcohol corresponds to a single bar measure of distilled spirits (40% v/v) or 25 mL, which contains exactly 8 g of ethanol. One unit of alcohol is consumed in half a pint (275 mL) of medium-strength beer (3–4% v/v) or 100 mL of wine (10% v/v), but glass size and alcohol content vary. One imperial pint of beer (568 mL) at 4.2% v/v contains 2.4 units and 175 mL table wine (13% v/v) contains 2.1 units of alcohol (Seabrook 2007). Keeping tabs on the quantities of alcohol consumed during social occasions is not easy and much depends on the generosity of one's host. A 125-mL glass of wine contains 1 unit (8 g) if the ABV is 8%, but many table wines are closer to 10–12% v/v. Care and consistency are needed when calculating the units of alcohol that a person has consumed or the weight of ethanol used in any blood alcohol calculation.

Absorption

After the consumption of beer, wine or spirits, the alcohol (ethanol) contained in these beverages reaches the stomach where the absorption process begins. The rate of absorption occurs much faster from the upper part of the small intestine (duodenum and jejunum), owing to the infinitely larger absorption surface area provided by the microvilli covering the surface of epithelial cells. The effects of alcohol are felt very soon after drinking begins, which is proof of rapid absorption into the bloodstream and transport to the brain. The larger the amount consumed, and the faster drinking occurs, the higher the BAC and, accordingly, the more pronounced the effects on the individual (Zakhari 2006).

The absorption rate of ethanol is highly variable and depends on many factors (Friel *et al.* 1995). Alcohol taken in the form of beer or wine is generally absorbed more slowly than alcohol ingested as whisky or vodka, not only because of the lower concentration of ethanol but also because malt and fermented beverages contain sugars and other constituents that retard stomach emptying (Jones 2008). Eating a meal before or during drinking is effective in slowing the rate of absorption by delaying gastric emptying (Jones, Jonsson 1994b). Under these conditions, peak BAC is appreciably lower and the effects on the individual are less pronounced when the same dose of ethanol is taken after a meal compared with after an overnight fast (Millar *et al.* 1992).

The nature of the food in terms of its fat, protein or carbohydrate content seems less important than the amounts or bulk eaten (Jones *et al.* 1997). Thus a large portion of mashed potatoes proves just as effective as eating a beef steak in delaying the rate of ethanol absorption. Medication with drugs that alter gastric motility can either slow or accelerate gastric emptying and alter the speed of uptake of alcohol accordingly. Smoking cigarettes seems to delay the opening of the pyloric sphincter, thereby slowing the rate of ethanol absorption into the blood as reflected in a lower C_{max} and delayed t_{max} in smokers (Johnson *et al.* 1991).

The bioavailability of ethanol after oral administration is usually never 100%, especially if drinking occurs together with or after a meal. Some of the ethanol seemingly undergoes oxidative metabolism during contact with the gastric mucosa or during the first passage of blood through the liver. The existence of this first-pass metabolism needs to be considered when blood alcohol calculations are made, but unfortunately this is not always the case and misleading information is sometimes presented to the courts. To ensure 100% bioavailability, the ethanol dose must be administered intravenously, which is not the case in a typical drink–driving situation. Drinking on an empty stomach ensures that absorption is close to 100% if a moderate dose is taken (>0.5 g/kg) because ethanol dilution experiments have been used to estimate total body water (Jones 1984). The results of ethanol dilution experiments agree well with isotope dilution techniques (Endres, Gruner 1994).

Distribution

After absorption from the gut, the molecules of ethanol enter the portal venous blood and are transported by the bloodstream throughout the body to all organs and tissues. Ethanol distributes into the total body water space; unlike many other drugs, it does not bind to plasma proteins, and solubility in fat and bone is negligible (Wilkinson 1980;

Zakhari 2006). Concentrations of ethanol are initially highest in the portal venous blood. The hepatic portal vein carries alcohol to the liver and then the hepatic vein carries it to the heart; after the blood picks up oxygen in the lungs, ethanol is distributed into all the body fluids and tissues.

The speed of distribution and equilibration in the various organs and tissues depends on the heart minute volume and on the ratio of blood flow to tissue mass. The concentration of ethanol in blood and tissues at equilibrium depends not only on the dose ingested but also on the water content of the fluid analysed and the age, body weight and sex of the individual. The proportion of fat to lean muscle tissue in the body is an important determinant of the BAC reached at equilibrium. Women have a higher proportion of adipose tissue per kilogram of body weight than men, which makes females more vulnerable to the toxic effects of ethanol; they also achieve a higher BAC for the same ingested dose (Kwo *et al.* 1998; Li *et al.* 2000; Dettling *et al.* 2007).

Because ethanol distributes into the total body water without binding to plasma proteins, it is an easy task to convert a measured BAC into the quantity of alcohol absorbed and distributed into all body fluids at the time the blood was drawn. This calculation is accomplished using the Widmark equation (see below) or some modification (Watson *et al.* 1981). If the time of starting to drink is known, then the total amount of alcohol consumed can be calculated by adding the amount destroyed by metabolism (Gullberg, Jones 1994):

$$\text{Ethanol in body (g)} = \text{BAC (g/L)} \times \text{Body weight (kg)} \times \text{Distribution factor } (\rho)$$

The distribution factor (ρ, 'rho') is an important concept to understand in all types of blood alcohol calculations (Forrest 1986). The value of ρ depends on the person's age, sex and body composition, particularly the amount of fat to lean body mass (Yelland *et al.* 2008). Because alcohol distributes solely into water and not the fat, average ρ factors for women ($\sim$0.60 L/kg) are less than for men ($\sim$0.70 L/kg). These factors represent ratios between the water content of the entire body and water content of the blood, which is the fluid analysed in forensic work relating to enforcement of alcohol-impaired driving laws (Widmark 1981; Andreasson, Jones 1996b).

Total body water in men ($\sim$60% of weight) and women ($\sim$50% of weight) in health and disease have been determined by isotope dilution experiments (Schoeller *et al.* 1980). The water content of whole blood is close to 80% w/w as determined by desiccation or freeze drying (Iffland *et al.* 1999; Seidl *et al.* 2000). Blood water is actually slightly less in women because of their lower haematocrit (35–45%, mean 41%) compared with that of men (43–49%, mean 46%). Using broadly average values for blood and body water leads to the following distribution factors for ethanol: $60/80 = 0.75$ for men and $50/80 = 0.63$ for women. Experimentally determined values in non-obese healthy individuals agree well with average values of 0.7 for men and 0.6 for women (Martin *et al.* 1991; Norberg *et al.* 2001).

The ρ factor can vary widely between different individuals and much depends on the degree of obesity (Barbour 2001). A good starting point when considering an appropriate ρ factor is to calculate the person's body mass index (BMI), which is the ratio of body weight in kilograms to the square of height in metres (kg/m^2; Jones 2007a). A BMI over 30, which is considered as being clinically obese, should raise a warning flag to consider carefully the distribution factor ρ used in blood alcohol calculations. Unfortunately, only limited research has been done on the relationship between BMI and inter- and intra-individual variations in the distribution factors, although values as low as 0.40 L/kg are not unlikely in morbidly obese individuals (Jones 2007a).

Attempts have been made to update the basic Widmark equation as defined above to take into consideration variable body composition (more obesity) of people since the time of Widmark in the 1930s (Widmark 1932). Obesity is highly prevalent in today's society and needs to be considered in blood alcohol calculations, such as when calculating the person's BMI or estimating total body water (Watson *et al.* 1981; Seidl *et al.* 2000; Barbour 2001). Several computer programs can be purchased or are available gratis over the internet to perform blood alcohol calculations. Although some of these programs plot graphs showing the hypothetical blood alcohol concentration–time plots, the final results are seldom much of an improvement over use of a handheld calculator. The most important point to remember is uncertainty in the ρ factor, such as $0.7 \pm 20\%$ for men and $0.6 \pm 20\%$ for women. There might be a definitive advantage in computing a ρ factor by taking into consideration total body water (TBW) or BMI based on anthropometric information (age, height and weight), which has the advantage that the values obtained are tailored to the specific individual concerned.

Metabolism and excretion

The bulk of the dose of alcohol ingested undergoes oxidative metabolism by enzymes mainly located in the liver (Zakhari 2006). The proximate metabolite of ethanol is acetaldehyde, which is a highly toxic substance that is fortunately rapidly oxidised further to acetate (Meier-Tackmann *et al.* 1990). Most of the acetate leaves the liver with the hepatic venous blood and enters into intermediary metabolism, being converted into acetyl-coenzyme A, which then participates in the citrate cycle. Acetate is metabolised mainly in peripheral tissues to give the end-products carbon dioxide and water. After administration of ethanol labelled with ^{14}C, the end-product $^{14}CO_2$ is almost immediately detectable in the exhaled breath.

A small fraction of ethanol (<0.1%) is removed from the body by non-oxidative metabolism involving hepatic conjugation reactions to produce ethyl glucuronide and ethyl sulfate. These water-soluble metabolites are transported to the kidney where they are excreted into the urine. Compared with ethanol itself, ethyl glucuronide and ethyl sulfate are excreted in urine for a considerably longer time, thus making analysis of these metabolites a useful biomarker to disclose recent drinking. Other examples of non-oxidative metabolites include fatty acid ethyl esters, which are formed by the reaction of ethanol with short-chain fatty acids, and an enzyme-catalysed reaction with certain phospholipids to produce phosphatidylethanol. Although these non-oxidative metabolites account for only a small fraction (<0.1%) of the dose of ethanol administered, their analysis in blood, other body fluids and hair has attracted considerable research interest, both clinical and forensic. They are increasingly being used as biomarkers of acute and chronic alcohol ingestion.

Between 2% and 6% of the dose of alcohol ingested is excreted unchanged together with urine, expired air and in perspiration. Ethanol is easy to measure in urine, breath and sweat, and these alternative specimens are widely used in clinical and forensic work to test whether a person has recently consumed alcohol. The fate of ethanol in the body, including the excretion in breath, urine and sweat (2–6% of dose), oxidative metabolism into acetaldehyde and acetate (95%) and the formation of non-oxidative metabolites ($\sim$0.1%), is illustrated in Figure 4.10.

The liver is well equipped with enzymes (biological catalysts) specialising in detoxification of drugs, poisons and environmental chemicals that might enter the body with the food eaten or the air breathed. The oxidative enzyme mainly responsible for metabolism of ethanol is known as alcohol dehydrogenase (ADH) class I, which is located in the cytosol or soluble fraction of the hepatocytes (Ashmarin *et al.* 2000; Jornvall *et al.* 2000). ADH converts ethanol into acetaldehyde and this proximate metabolite is rapidly converted into acetate by low-K_m aldehyde dehydrogenase (ALDH), found in the mitochondria (Goedde, Agarwal 1987; Vasiliou, Pappa 2000).

Both ADH and ALDH display racial and ethnic differences in their catalytic activity including polymorphisms that have clinical consequences and determine a person's sensitivity to alcohol (Yamamoto *et al.* 1993). Many people of East Asian descent (e.g. Japanese and Chinese) inherit an inactive form of the enzyme that metabolises acetaldehyde, the low-K_m mitochondrial enzyme (Mizoi *et al.* 1983). These individuals are rendered highly sensitive to drinking small amounts of

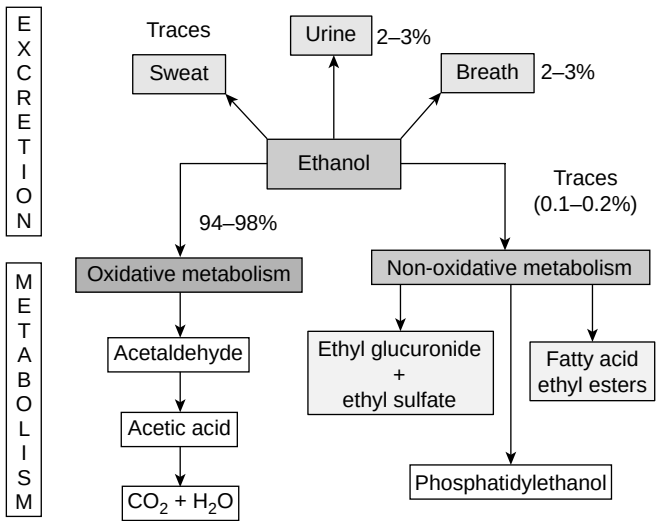

Figure 4.10 Fate of alcohol in the body, illustrating the amounts disposed of by excretion unchanged in urine, breath and sweat, and through metabolism in the liver by oxidative and non-oxidative mechanisms.

alcohol because the concentration of acetaldehyde in blood is higher, which triggers a range of unpleasant effects, including nausea, facial flushing, hypotension and tachycardia (Agarwal, Goedde 1987; Thomasson *et al.* 1993). This defect in the ALDH enzyme in East Asians creates a genetic aversion to drinking alcohol and protects them from becoming alcoholic or for that matter from DUIA. The prescription drug Antabuse is used clinically for the treatment of alcoholism and this aversion therapy works by blocking the metabolism of acetaldehyde, resulting in adverse effects due to the build-up of acetaldehyde after drinking alcohol (Karamanakos *et al.* 2007).

Besides involvement of the ADH pathway in the metabolism of ethanol, another important enzyme is located in the microsomal fraction of the hepatocytes, belonging to the cytochrome P450 (CYP) family, namely CYP2E1 (Lieber 1997, 2004). The cytochrome enzyme has a higher K_m for oxidation of ethanol (60–80 mg/100 mL) compared with ADH (5–10 mg/100 mL). This makes CYP2E1 more important for clearing ethanol from the bloodstream after a period of heavy drinking, as might occur in impaired drivers, who reach high BACs, e.g. 170 mg/100 mL on average. Another important feature of CYP2E1 is the phenomenon of enzyme induction, which is the property of metabolising substrate more effectively after continuous exposure, as occurs in binge drinkers (Teschke, Gellert 1986; Oneta *et al.* 2002). The rate of elimination of alcohol from the bloodstream might be as high as 36 mg/100 mL per hour in alcoholics when they enter detoxification (Pach *et al.* 1977; Jones, Sternebring 1992). However, after a few days of abstinence, this enhanced capacity to metabolise ethanol is seemingly lost as enzyme protein is newly synthesised (Keiding *et al.* 1983).

The disappearance rate of ethanol from blood has been investigated in hundreds of controlled dosing studies and 15 mg/100 mL per hour still remains a good average value for moderate drinkers (Widmark 1981; Jones 1984; Jones 1993). In alcohol-impaired drivers the average rate of ethanol elimination from blood is slightly higher, being closer to 19 mg/100 mL per hour because in this population of drinkers there is an overrepresentation of binge drinkers and alcoholics (Jones, Andersson 1996a). Another useful rule of thumb is that rate of elimination of ethanol from the whole body is close to 0.1 g/kg body weight per hour, which means that a person weighing 80 kg eliminates 8 g ethanol (100%) per hour or one unit of alcohol. Accordingly, in an elapsed time of 6 h after the start of drinking before sampling blood in a drink–driving case, ~48 g of pure ethanol is destroyed by metabolism (6×0.1 g/kg per h $\times 80 = 48$). Over the same period of time, the BAC decreases by 6×15 mg/100 mL per hour or 90 mg/100 mL.

Blood alcohol curves

The BAC reached after drinking alcohol depends on the quantity consumed, the speed of drinking, the efficacy of absorption into the blood, the distribution into body water and the removal of ethanol through metabolism and excretion. The fate of ethanol in the body is usually displayed in the form of a blood concentration–time (C–t) profile that depicts absorption, distribution and elimination processes. The shapes of BAC curves are likely to show considerable inter-individual variations, especially the parameters C_{max} and t_{max}, which denote the maximum concentration in blood and the time of its occurrence. Typical examples of such curves are shown in Figure 4.11 for nine healthy men who drank a bolus dose of ethanol (0.68 g/kg) as neat whisky on an empty stomach (Jones 1984).The C_{max} and t_{max} read from the curves are representative pharmacokinetic parameters and the ratio C_{max}/t_{max} is sometimes used to indicate the rate of absorption of ethanol into the bloodstream.

The magnitude of inter-individual variations in BAC curves is well illustrated by Figure 4.12, which shows the concentration–time data plotted on the same x–y coordinates. These curves were generated from drinking experiments with 12 healthy men who consumed 0.80 g ethanol per kg body weight in the morning after an overnight fast (Jones, Jonsson 1994a). The alcohol that they consumed was made from pure ethanol (95% v/v) after dilution to 20% v/v with sugar-free orange juice and the drink was finished in 30 min.

The experiment outlined above was expanded to include 53 male volunteers and mean and range of C_{max} and t_{max} as well as the rise in BAC after end of drinking before reaching C_{max} are shown in Table 4.8. The C_{max} ranged from 76 mg/100 mL to 145 mg/100 mL (two-fold difference) even for standardised drinking conditions, namely same beverage and drinking time and with the dose adjusted for differences in body weight. The time necessary to reach C_{max} was also highly variable and ranged from 0 min to 120 min, although most volunteers had peaked by 60 min post drinking. The mean rise in BAC measured from end of drinking to C_{max} was 33 mg/100 mL (range 0–77 mg/100 mL). This large inter- and intra-individual variation seen in controlled drinking experiments underscores the need for caution when expert witnesses and others testify in court about BACs expected based on various drinking scenarios.

Forensic pharmacokinetics of ethanol

Knowledge about the pharmacokinetics of ethanol is important in forensic science and toxicology because a person's BAC can be interpreted in terms of the amount of alcohol in the body or the total quantity consumed (Wagner *et al.* 1990; Brick 2006). Another common request in forensic casework is the estimation of the BAC at some time other than when blood was taken, such as the time of driving. This requires making a back-extrapolation or back-tracking of BAC, which is often a controversial practice owing to the many uncertainties involved, although certain guidelines can be given when this information is needed by the courts (Lewis 1987; Stowell, Stowell 1998).

As mentioned previously, Widmark administered known amounts of alcohol to volunteers and determined the concentrations (C) in capillary blood at various times (t) post drinking to establish the shapes of the resulting C–t plots (Widmark 1932). These experiments showed that the BAC first rose fairly rapidly as alcohol was being absorbed from the gut and a peak or C_{max} was reached after about 30–60 min post drinking. Thereafter, on reaching the post-absorptive phase, the BAC decreased at a more or less constant rate per unit time, which suggests that the elimination followed zero-order kinetics.

Figure 4.13 shows a typical blood alcohol curve for one male subject who drank 0.68 g ethanol per kg body weight as neat whisky in 30 min on an empty stomach (Jones 2010b). Pharmacokinetic parameters of ethanol are derived and shown on this plot using the method first proposed by Widmark (Andreasson, Jones 1996b; Widmark 1981). It is important to establish the linear segment in the post-absorptive declining phase so that this line is extrapolated back to the time of starting to drink, which gives the y-intercept (C_0). The intercept is interpreted as the BAC if

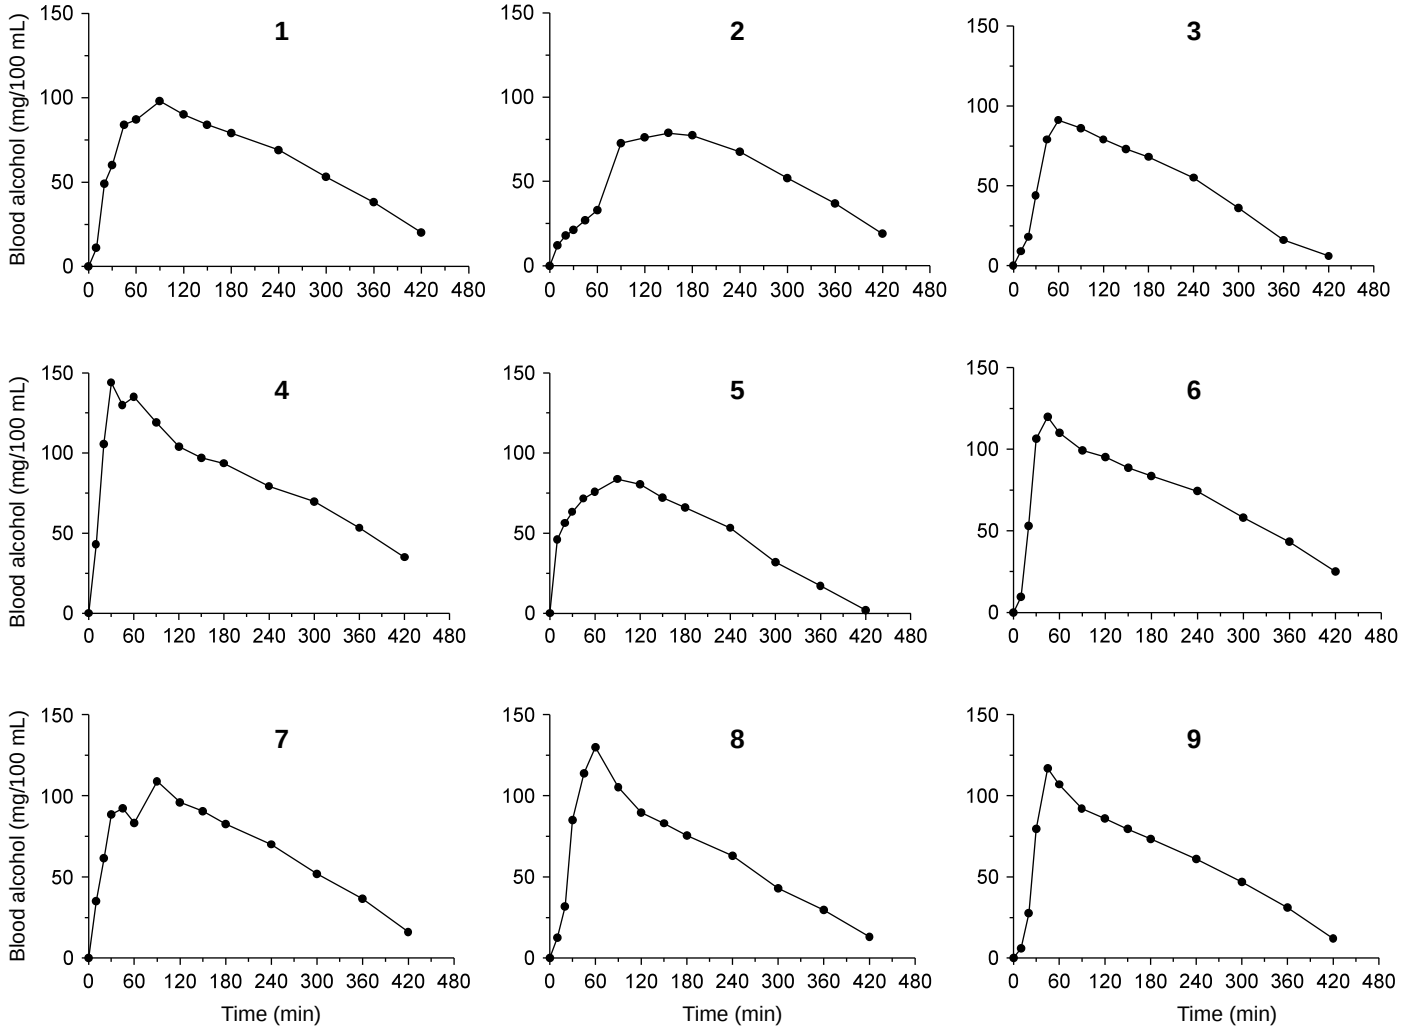

Figure 4.11 Individual concentration–time profiles of ethanol in nine healthy volunteers who drank a bolus dose of ethanol (0.68 g/kg) as neat whisky in 20 min on an empty stomach.

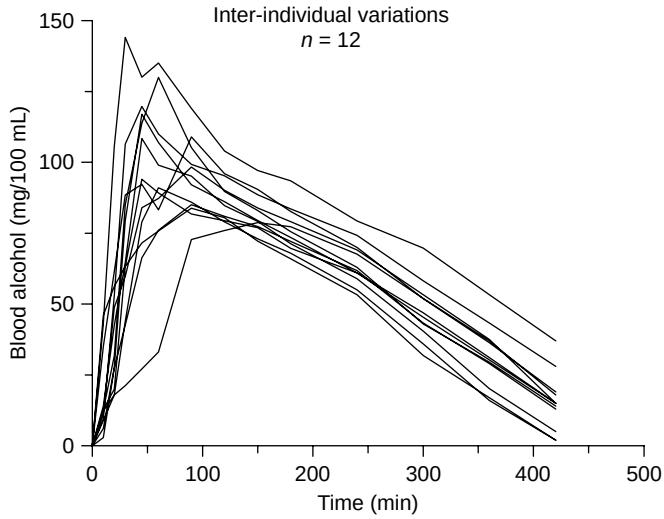

Figure 4.12 Inter-individual variations in blood alcohol curves in 12 healthy volunteers who drank a bolus dose (0.80 g/kg) as pure ethanol diluted with orange juice to 20% v/v and consumed in 30 min after an overnight fast.

absorption and distribution of the entire dose occurred instantaneously without any metabolism. The value of C_0 is used in the calculation of the slope of the elimination phase and other pharmacokinetic parameters, such as the volume of distribution (ρ factor). Widmark denoted the linear post-peak elimination phase by the Greek letter β and it is the best-fitting straight line to *C–t* data. This slope is sometimes reported as k_0 to denote a zero-order reaction. The value of β or k_0 is best derived by linear regression analysis of *C–t* data points and the method of least squares. The regression coefficient, which is the negative slope in the regression equation, $C_t = C_0 - \beta t$, is the elimination rate of alcohol from the bloodstream in concentration per unit time, such as mg/100 mL per hour.

Two different models are generally used to describe the pharmacokinetics of ethanol. The simplest and most practical for forensic purposes is that described above, namely zero-order kinetics. This method is appropriate provided that the BAC is above 20 mg/100 mL so that the hepatic metabolising enzymes are saturated with substrate. In almost all alcohol-related case work, whether impaired driving, sexual assault or alcohol-related deaths, forensic scientists are dealing with people having much higher BACs, as evidenced by an average BAC of 170 mg/100 mL in impaired drivers.

At blood ethanol concentrations below 20 mg/100 mL, the elimination rate of ethanol decreases and the *C–t* curve levels off, becoming

Table 4.8 Peak blood alcohol concentration (BACs; C_{max}), times needed to reach the peak and rate of increase in BAC to peak level after 53 subjects drank 0.80 g ethanol per kg body weight in 30 min after an overnight fast. The drink was made of ethanol solvent (95% v/v) and diluted with a sugar-free orange drink to a concentration of 20% v/v

[a]Increment in the BAC after end of drinking and before peak (C_{max}) was reached.

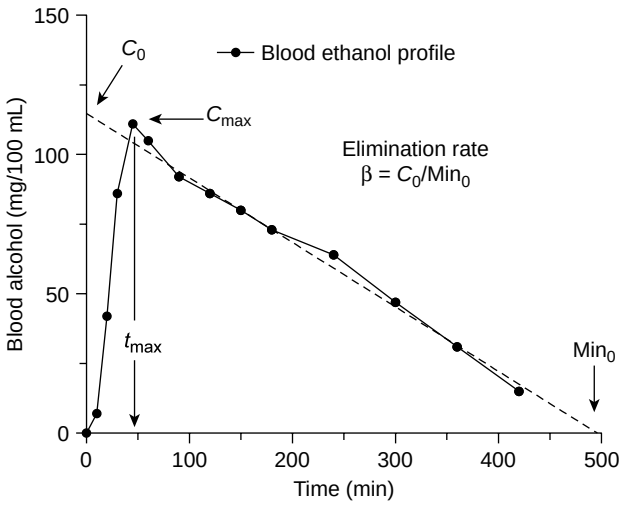

Figure 4.13 Representative blood alcohol curve for a male subject who drank a bolus dose of ethanol (0.80 g/kg) on an empty stomach with pharmacokinetic parameters derived according to Widmark's method.

curvilinear. The entire post-absorptive phase looks more like a hockey stick than a straight line (Figure 4.14). Pharmacologists generally consider that ethanol is metabolised by capacity-limited or saturation kinetics and not zero-order kinetics. Accordingly, the entire post-absorptive portion of the *C*–*t* curve is best described by the Michaelis–Menten equation, which also applies to other drugs such as γ-hydroxybutyrate, phenytoin and salicylic acid (Wagner *et al*. 1985; Wagner 1989; Rowland, Tozer 1995).

In the case of ethanol, the linear part changes into a curvilinear part as BAC drops below 20 mg/100 mL ($\sim 2 \times K_m$ of ADH). However, a pseudo-linear segment exists for about two-thirds of the post-absorptive elimination phase and below 20 mg/100 mL first-order kinetics operates, with an elimination half-life of about 15–20 min. The well-known rate equation for drugs with saturation kinetics is that developed by Michaelis and Menten:

$$-\frac{dC}{dt} = \frac{V_{max} \times C}{K_m + C}$$

where V_{max} is the maximum velocity of the enzymatic reaction, C is the substrate concentration and K_m is called the Michaelis–Menten constant and is a measure of the affinity of the enzyme for its substrate. The lower the K_m, the higher the affinity. The above equation collapses into two limiting forms depending on the concentration of substrate. When C is much greater than K_m, the Michaelis constant in the denominator can be eliminated from the equation and C cancels, so the elimination rate ($-dC/dt$) approaches its maximum velocity, $-dC/dt = V_{max}$ as expected for zero-order kinetics. When C is much less than K_m (at low BAC) the elimination rate ($-dC/dt$) becomes proportional to the substrate concentration; $-dC/dt = (V_{max}/K_m) \times C$, where V_{max}/K_m represents the reaction rate constant for first-order kinetics (k_1). This breakdown of the Michaelis–Menten equation is a consequence of capacity-limited kinetics and does not reflect any sudden change in the order of the biochemical reaction.

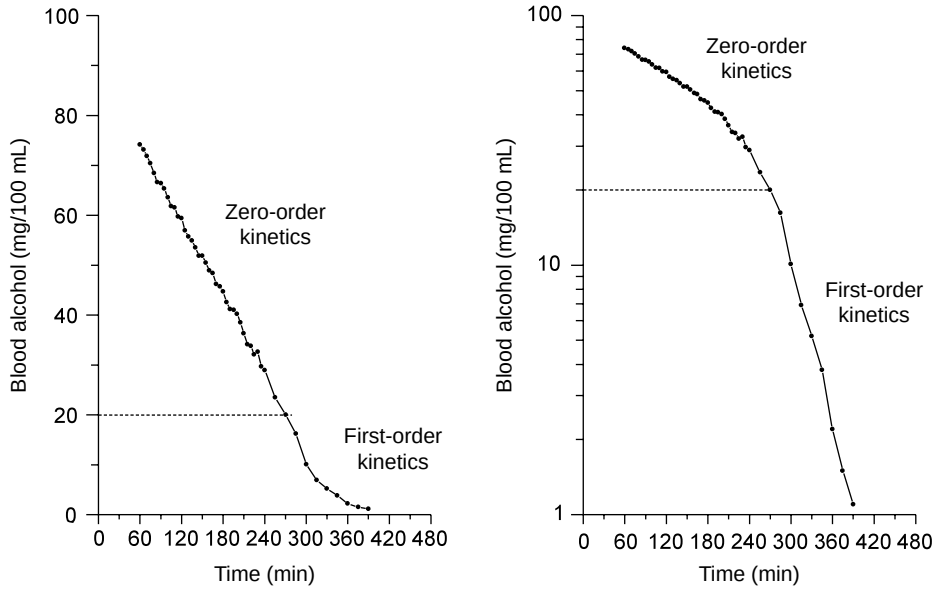

Figure 4.14 Blood alcohol concentration (BAC) curves demonstrating saturation kinetics of ethanol involving a zero-order model (BAC >20 mg/100 mL) and a first-order kinetic model at lower concentrations. Graph (a) is plotted on Cartesian coordinates and illustrates the hockey-stick shape of the curve; graph (b) shows the corresponding semi-logarithmic plot.

Absorption and elimination kinetics

Much less is known about the absorption kinetics of ethanol than about the elimination kinetics. The mathematical modelling of the absorption phase is complicated because uptake from the gut is sometimes so fast that insufficient *C–t* data points are available for curve fitting. Furthermore, ethanol is a drug absorbed from both the stomach and the upper part of the small intestines. Indeed, the rate of uptake of alcohol after passing through the pyloric sphincter is much faster than from the stomach. The speed of absorption and time of occurrence of C_{max} therefore depend to a large extent on factors that influence gastric emptying, such as fed or fasting state before drinking.

Unlike many prescription drugs, the dose of ethanol is not swallowed immediately, but is instead ingested in portions often over several hours. In most experiments dealing with the pharmacokinetics of ethanol, a single moderate dose is consumed in 5–15 min as a bolus. In the real world, people more often consume spirits, beer and/or wine repetitively in divided doses, which makes it much more difficult to model the shape of the BAC curve. Unlike most drugs, ethanol is absorbed to some extent through the gastric mucosa and ~20% of the dose enters the bloodstream in this way, although empirical support for this is not easy to find in the literature.

A mathematical model of the entire BAC curve is possible if it is assumed that absorption occurs according to first-order kinetics and that elimination, which occurs simultaneously, is a zero-order process. Under these assumptions, the entire concentration–time profile of ethanol can be fitted to the equation:

$$C_t = C_o(1 - e^{-kt}) - k_o t$$

where C_t = BAC at some time t after administration; C_0 = initial back-extrapolated BAC at the time of starting to drink; k = first-order absorption rate constant; k_0 = zero-order elimination rate constant; and t = time after drinking.

Factors that influence gastric emptying, such as food in the stomach, will delay the rate of absorption resulting in a lower C_{max} and delayed t_{max}. With a rapid absorption, the C_{max} might coincide with time of last drink or occur before the first blood sample is taken. With delayed absorption, as might occur under some circumstances, a plateau in the *C–t* profile is likely, which implies that the rates of absorption and elimination are the same. Other evidence exists that, even with delayed absorption, the BAC reaches about 80% of the final C_{max} within 15–30 min of the end of drinking (Jones, Neri 1991).

Because ethanol exhibits saturation-type kinetics, the peak BAC and the area under the curve (AUC) increase more than proportionally with increase in the dose administered, which is particularly evident after very small doses (Wagner *et al.* 1985). When the rate of delivery of ethanol to the liver is slow, the AUC is smaller for a given dose and vice versa (Levitt, Levitt 1994). The systemic availability (bioavailability) of ethanol must be considered when blood alcohol calculations are made for legal purposes. If some part of the dose of ethanol fails to reach the systemic circulation, owing to first-pass metabolism or other reason, then the results of calculations of BAC are obviously incorrect.

If only the post-absorptive phase of the *C–t* profile is considered, then the equation widely used in forensic science practice is:

$$C_t = C_o - \beta t$$

where C_t is the blood alcohol concentration, C_0 is the extrapolated concentration of alcohol in blood at the time of starting to drink (*y*-intercept) and β is the zero-order slope of the declining phase, sometimes denoted as k_0.

Disappearance rate of alcohol from blood

The slope of the pseudo-linear declining phase of the blood alcohol curve represents the rate at which ethanol is eliminated from the bloodstream. People who drink excessively over long periods of time develop a higher capacity to metabolise ethanol compared with moderate or occasional drinkers. This phenomenon, known as metabolic tolerance, is reflected in a steeper slope in the *C–t* plot during the post-absorptive phase and is often seen in alcoholics during detoxification after a period of binge drinking. Elimination rates of alcohol up to 35 mg/100 mL per h have been reported in these individuals. However, after a few days of abstinence, the rate returns to the expected 15 mg/100 mL per h (range 10–20 mg/100 mL per h) seen in moderate drinkers. The faster rate of metabolism is considered to reflect induction of the microsomal enzyme CYP2E1 as discussed earlier, and this occurs after heavy drinking lasting several days or weeks without an alcohol-free period. The quantities of alcohol necessary and the duration of drinking required to cause induction of the microsomal enzymes have not been determined in humans.

The information in Table 4.9 gives a likely physiological range of elimination rates of ethanol from blood in humans and the circumstances under which such rates might be encountered (Jones 2010b). Accordingly, for the vast majority of people, the rate of ethanol elimination is likely to vary three-to-four fold or from 10 per 35 mg/100 mL per h. In blood alcohol calculations for research and legal purposes, back-extrapolation with an alcohol burn-off rate of 10–25 mg/100 mL per h is appropriate (mean 15 mg/100 mL per h). In apprehended drunken drivers, because of the many alcoholics in this population, the average elimination rate of alcohol from blood is 19 mg/100 mL per h, being slightly faster in women than in men (Jones, Andersson 1996a).

The information about elimination rate of ethanol in impaired drivers has been determined by taking two blood samples about 1 h apart in over 1000 offenders. Under the assumptions of zero-order

Table 4.9 Rates of ethanol elimination from blood that might physiologically be observed under various conditions or circumstances

Elimination rate	*Expected values (mg/100 mL per h)*[a]	*Conditions or circumstances in which such rates might be expected*
Very slow	8–10	Malnourished individuals or people eating low-protein diets. Medical conditions such as advanced liver cirrhosis or portal hypertension and reduced hepatic blood flow. Administration of a drug (e.g. 4-methylpyrazole or fomepizole) that blocks the action of alcohol dehydrogenase
Slow	10–13	Healthy individuals after overnight (10 h) fast and a single bolus dose of ethanol (<1 g/kg)
Moderate	13–17	Regular drinkers after consumption of alcohol in the fed state and consumption of a moderate dose to reach BAC of 1.0 g/L
Rapid	17–25	Typical values seen in many apprehended drivers according to evaluation of double blood samples
Ultra-rapid	25–35	Heavy binge drinkers or alcoholics during detoxification with high starting BAC of 200–300 mg/100 mL. Caused by induction of microsomal enzyme (CYP2E1) through chronic exposure to ethanol or other drugs. People with a genetic predisposition for rapid metabolism of ethanol. Medical condition leading to a hypermetabolic state (e.g. burn trauma)

Modified from Jones (2010b, 2008).
[a]Values below 8 mg/100 mL and above 35 mg/100 mL per hour should be considered suspect and details of the study carefully examined, including dose of alcohol administered and the shape of the resulting BAC curve.

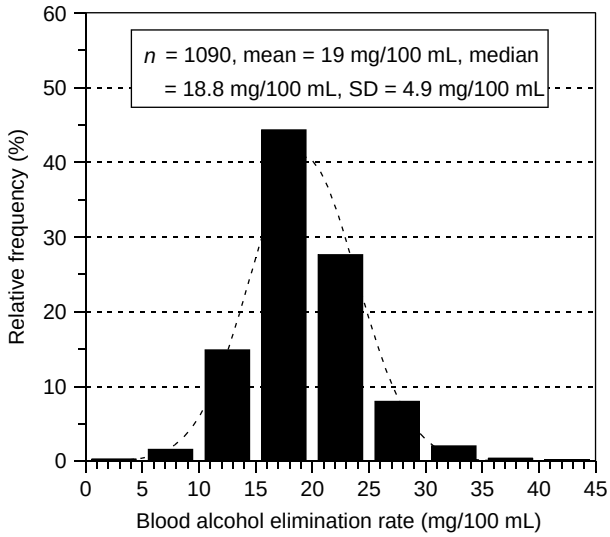

Figure 4.15 Relative frequency distribution of the elimination rates of ethanol from blood determined by taking two blood samples about 1 h apart from apprehended drunken drivers.

kinetics and the existence of the post-absorptive limb of the BAC curve when the first blood sample was taken, the elimination rate (β) of ethanol is given by:

$$\beta(\text{mg/100 mL per hour}) = (\text{BAC}_1 - \text{BAC}_2)/t_{\text{diff}}$$

In the above equation, BAC_1 is the concentration of ethanol in the first blood sample, BAC_2 is the concentration in the second sample and t_{diff} is the time difference between sampling in hours. Support for this method was also obtained when three consecutive blood samples were available from suspected drunken drivers.

A relative frequency distribution of the elimination rates of ethanol from blood in apprehended drivers derived from double blood samples is shown in Figure 4.15 (Jones, Andersson 1996a). This bell-shaped curve seems a good approximation to a normal distribution, which permits calculation of the proportion of individuals having defined elimination rates of alcohol in the entire population of offenders. These rates are given by multiples of the SD (9 mg/100 mL per h) such that 95% of people are expected to be between 9 and 29 mg/100 mL per h. Extreme values, such as less than 9 mg/100 mL per h, probably reflect individuals with unusually slow rates of absorption of ethanol and as such might not have reached their peak BAC when the first blood sample was taken. Extremely rapid rates of elimination are more difficult to explain. Some very high values might be artefacts caused by problems in sampling blood or incorrect recording of the blood-sampling times on the tubes. Enhanced metabolic activity in some individuals gives them an ultra-rapid rate of ethanol elimination and values as high as 35 mg/100 mL per h have been documented.

Back-extrapolation

The process of back-extrapolation (back-tracking) the blood or breath alcohol concentration from the time of sampling to the time of driving has many proponents and many critics (Lewis 1987; Al-Lanqawi *et al.* 1992; Ferner 1996). With only a single blood or breath sample available, nothing is known about the pharmacokinetic profile of ethanol, such as the stage of ethanol metabolism or whether the BAC was rising, declining or on a plateau at the time of the traffic offence (Jackson *et al.* 1991). Neither is the disappearance rate of ethanol from blood known in any individual cases, although two blood samples taken 60 min apart can give useful information on this point (Jones, Andersson 1996a). Much work has been published on the rate of metabolism of ethanol in controlled drinking studies and in alcoholics during detoxification. The results demonstrate that the slope of the descending limb of the BAC curve varies as much between different subjects as it does within the same subject on different occasions (Jones, Jonsson 1994a; Yelland *et al.* 2008). This makes it rather pointless to perform alcohol drinking studies to determine that person's capacity to eliminate alcohol from the bloodstream. A more pragmatic approach is to work with a range of values such as 10–25 mg/100 mL per h if and when back-extrapolation is required by the courts. If evidence of the offence of drink driving involved breath alcohol tests, then the elimination rates of alcohol from breath should be utilised in the back-tracking calculations, such as 4.4–10.9 μg/100 mL per h for low and rapid elimination, respectively. These breath alcohol elimination rates were derived from BACs of 10 and 25 mg/100 mL per h and assuming a 2300 : 1 BAC : BrAC ratio as practised in the UK.

Examples of back-calculating a measured blood or breath alcohol concentration from the time of sampling to the time of driving are given in Table 4.10. Slow, medium and rapid rates of alcohol elimination are assumed and used in the calculation along with elapsed times of 1–5 h between driving and blood sampling or analysis of breath. One necessary assumption for back-calculating is that the person had reached the post-peak part of the concentration–time profile at the time of the offence and at the time of sampling of blood or breath. Support for this assumption requires careful questioning and consideration of the prior drinking pattern, such as the type and time of last drink and the amount of alcohol it contained in relation to the time of driving or an accident. If 60 min or more had elapsed after the end of drinking to the time of the offence, this makes it highly unlikely that the person was still absorbing alcohol. Studies have shown that, after drinking alcohol over several hours, the small amounts contained in the last drink before driving have no marked influence on C_{max} or time to reach peak BAC (Jones *et al.* 2006).

Drunk-driving defence challenges

The enforcement and prosecution of alcohol–driving laws in most nations is nowadays based almost entirely on the concentration of

Table 4.10 Examples of back-calculation of BAC and BrAC from time of sampling to time of driving. The calculation assumes a measured BAC of 60 mg/100 mL or a BrAC of 26 μg/100 mL and low, median and high rates of alcohol elimination for times (*t*) of 1–5 h

alcohol determined in a specimen of blood or breath from the suspects. Such laws are known as 'alcohol concentration *per se*' laws and represent a considerable simplification over the older 'under the influence' or impairment-based DUIA laws. Under a *per se* statute, the prosecution are not required to prove that a driver was unfit to drive as a result of excess alcohol and instead needs to show that only the concentration of ethanol was at, or above, a certain statutory concentration (Voas 1991). The *per se* law is therefore a much more pragmatic way to prosecute offenders, but at the same time draws considerable attention to the reliability of the sampling and the analysis of specimens to arrive at the concentration of ethanol (Jones, Logan 2007).

The use of evidential breath alcohol testing commenced in European countries in the early 1980s when more automated and reliable technology had become available. Breath alcohol testing cannot totally replace the need for blood sampling because some people are genuinely unable to provide a proper sample for various health or medical reasons. Lung dysfunction in some people of short stature or in smokers may result in them being incapable of providing a continuous forced exhalation for a sufficiently long time, such as 6 seconds, at a fixed pressure and flow rate. However, in this connection, a breath sample captured after an exhaled volume of only 500 mL gives a good indication of the concentration of alcohol in end-exhaled breath. Some people refuse to cooperate with the police in providing a proper breath sample, whereas a blood sample can be taken by force if necessary. Furthermore, a person injured in a traffic crash might need emergency hospital treatment, so that obtaining blood is more practical than breath sampling at a police station. The advantages and limitations of blood versus breath alcohol testing are summarised in Table 4.11.

Punishments and sanctions for driving under the influence of alcohol are becoming increasingly burdensome and include immediate revocation of the driving licence for 1–2 years, monetary fines, house arrest and community sentences. A person with a BAC or BrAC considerably over the legal limit is liable to receive enhanced penalties for a DUIA conviction. A person with a BAC over 100 mg/100 mL in Sweden risks losing the driving permit for 2 years and is also expected to re-take the driving test. Before re-taking the test, the authorities require proof that the drinking habits of the individual concerned are moderate. This is achieved by medical examination, questionnaire and psychological assessment including use of biomarkers for overconsumption of alcohol.

The widespread use of alcohol concentration *per se* laws means that analysis of alcohol in body fluids provides the gold standard evidence for prosecution and other information about the person's behaviour and driving ability is not needed to win the case. A *per se* law is easier to enforce because of the clear-cut definition of when an individual is breaking the law. Such a law makes challenging the correctness of the results of the chemical analysis of alcohol in blood, breath or urine the major factor in a defence and a host of imaginative ideas have been tested and documented in drink–driving case law.

The legal framework behind a concentration *per se* law places special demands on the reliability of the methods used to determine alcohol in blood and breath and quality assurance of the entire process. The accuracy, precision and specificity of the methods of analysis must conform to high standards and the elements of analytical quality control must be rigorously enforced. This should include regular external proficiency tests of laboratory performance or reliability of the evidential breath analyser by testing needs to be verified by analysis of known-strength simulator solutions of ethanol. Other necessary scientific safeguards to boost the quality of the results are well-constructed rules and regulations governing sampling, labelling, transport, preservation and storage of body fluids. Finally an allowance should be made to compensate for uncertainty in the analysis and to ensure that a suspect is not over the legal limit because of inherent analytical errors.

In the USA many lawyers and law firms specialise in defending alcohol-impaired drivers and have developed a high level of expertise in the science and pitfalls of alcohol testing in biofluids.

Blood and urine samples

Examples of the top 10 challenges directed against the results of blood alcohol analysis when used as evidence for the prosecution of DUIA offenders are given in Table 4.12 and their strengths and weaknesses have been reviewed elsewhere (Jones, Logan 2007). Experience has shown

Table 4.11 The advantages and disadvantages of blood (BAC) and breath (BrAC) alcohol analysis for prosecuting alcohol-impaired drivers

BAC	*BrAC*
Less influenced by sampling and physiological variations – higher overall precision	More prone to breath sampling and physiological variations
Blood specimens can be taken from living, dead and uncooperative persons	Only feasible with people willing to cooperate with the sampling procedure
Blood sampling is possible regardless of state of health, e.g. hospitalised victims of traffic crashes	Some individuals, owing to respiratory dysfunction (asthma or chronic obstructive pulmonary disease), genuinely fail to meet sampling requirements of some instruments
Blood ethanol concentration is relatively stable during storage decreases by 3 mg/100 mL per month	Storage of breath samples is more problematic and long-term stability of ethanol is questionable
Confirmatory analysis of blood sample is easily done because specimens are usually stored for up to 12 months at 4°C	It is possible to store breath for later analysis but this procedure is more troublesome
Drugs other than alcohol can be determined in the same blood sample	Not possible with breath samples
Blood samples can be used to analyse for biomarkers of heavy drinking and damage to the liver	Not possible with breath samples
Longer time to obtain results of blood alcohol analysis as samples must be shipped to a laboratory	Use of breath alcohol analysis gives on-the-spot results of alcohol influence
Sampling of blood is an intrusive procedure	Breath sampling is non-intrusive
A physician, nurse or phlebotomist, for a fee, takes the blood specimens	Trained police officers operate the instruments used for breath alcohol analysis
Time delay of about 30–120 min after the time of driving until sampling blood	Breath analysis can in principle be made at the roadside much closer to the time of the driving offence
Less subject to pre-analytical variations, such as the method or equipment used to take blood	Results of breath alcohol analysis are influenced by the subject's breathing pattern just before or during delivery of a sample
Blood samples can be taken any time after drinking and still give valid results	Breath analysis is suspect if done within the first 15 min after end of drinking
The concentration of ethanol in blood depends to some extent on sampling site, whether from an artery, vein or capillary	The time course of breath alcohol runs much closer to the arterial blood rather than the venous blood alcohol concentration

Table 4.12 Examples of the types of challenges aimed at discrediting the admissibility or validity of blood alcohol test results when alcohol-impaired drivers are prosecuted

Rank	*Challenges to blood test results*	*Brief description and references*
1	Hip-flask defence[a]	The suspect maintains that alcohol was consumed after driving or involvement in a crash but before the blood or breath sample was obtained (Iffland and Jones 2002; Simic *et al.*, 2004)
2	Laced drinks	Above the legal alcohol limit for driving but without intent; someone had spiked beer with additional alcohol (spirits) without the drinker's knowledge (Langford *et al.* 1999)
3	Rising blood alcohol defence	Driving shortly after the last drink, possibility of being below the legal limit at the time of driving but above the limit 1–2 h later when the blood sample was taken (Jones *et al.* 1991)
4	Unintentional intake of alcohol	Driving after being engaged in wine tasting or after use of medication containing alcohol, such as cough syrups or vitamin preparations or possibly a drug–alcohol interaction (Franklin and Stephens 2000)
5	Contamination of blood with alcohol during collection	Swab used to clean the skin before sampling blood contained alcohol (Peek *et al.* 1990)
6	Blood specimen was coagulated or diluted or wrong tubes were used	Evacuated tubes contained incorrect chemical preservative or the volume of blood specimen was deficient, or might be diluted with intravenous fluids during sampling (Riley *et al.* 1996; Jones and Fransson 2003)
7	Discrepancy in analytical results reported by an independent laboratory	Large discrepancy between analytical result from the government laboratory and that from a private laboratory (Oliver *et al.* 1975)
8	Mix-up of specimens[b]	Alleged mix-up of the blood specimen either at the police station or the forensic laboratory
9	Endogenous production of alcohol	Alcohol produced naturally in the body by the action of yeasts or bacteria on dietary sugars (Logan and Jones, 2000; Al-Awadhi *et al.* 2004)
10	Phobia of blood sampling	Alleged phobia of the sight of blood and needles, genuine failure to provide a specimen (Gudjonsson and Sartory 1983)

[a]Also a common argument against results of breath alcohol testing.
[b]Resolved by re-analysis of ethanol content or by DNA testing.

that most challenges are bogus and are simply intended to confuse the non-scientist and hopefully raise a reasonable doubt in the eyes of the judge or jury. Issues related to blood sampling procedure (pre-analytical), the chain of custody, the way the laboratory analysis was performed or whether the suspect suffered from some medical condition that meant that BAC was higher than expected for the amount consumed are often raised (Jones, Logan 2007).

When a venous blood sample is taken for the determination of ethanol, obviously the skin should not be swabbed with an alcohol-containing liquid. Studies have shown, however, that when evacuated tubes are used to draw blood the risk of carry-over and contamination of the blood specimen with alcohol from the swab is negligible (Goldfinger, Schaber 1982). If an alcohol swab had inadvertently been used to disinfect the skin, this raises a suspicion in the mind of a jury that the blood might have been contaminated (Peek *et al.* 1990).

The convictions of a large number of DUIA offenders were quashed after they had pleaded guilty to the charge (*Regina v Bolton Magistrates Court Ex parte Scally*). Evidence surfaced after the trials that the swabs used to sterilise the skin before sampling blood were impregnated with alcohol. According to the analytical reports, all suspects were above the legal limit for driving (80 mg/100 mL) and as such they pleaded guilty to the charge of driving with excess alcohol in blood. Interestingly, the convictions were quashed not because of scientific evidence showing that blood *de facto* might have been contaminated with alcohol, but because the suspects were not informed by the prosecution that alcohol swabs had been used when they were asked to enter a plea of guilty or not guilty. In another UK case, a deficient volume of blood in the tubes sent for analysis was alleged to give a higher than expected concentration of alcohol when analysed by HS-GC because of salting out. This notion was tested experimentally and no such increase was observed; rather, there was a small decrease in BAC when the volume of blood in the tube was deficient (Jones, Fransson 2003; Miller *et al.* 2004). However, at trial the prosecution did not call expert evidence to rebut the defence argument about salting out and the suspect was duly acquitted.

As mentioned previously, an important safeguard when urine is the specimen used for determination of alcohol is to ensure that the tube contained sodium fluoride (1% w/v) as a preservative (Jones *et al.* 1999). In the UK it is recommended that the fluoride concentration should be in excess of 1.5%. Secretion of glucose in the urine is likely in diabetics or in those with other disturbance in carbohydrate metabolism. If these individuals also have a urinary tract or yeast (*Candida albicans*) infection, without fluoride alcohol might be produced post-sampling by fermentation of glucose (Alexander *et al.* 1988; Saady *et al.* 1993). The question of residual urine having a higher concentration of alcohol than was present in the blood at the time of sampling is avoided by collecting two voids 60 min apart. The well-known physiological variation in urine : blood ratios of alcohol is a non-issue because of a statutory definition of 107 mg/100 mL urine as being the same as 80 mg/100 mL blood (Curry 1972).

Breath samples

In terms of analytical precision, accuracy and specificity, blood alcohol determinations by GC are far superior to the results of breath alcohol analysis using the latest generation of instruments. A major reason for this is the dominance of physiological variation inherent in sampling and analysis of ethanol in the end-exhaled air, whereas a blood alcohol analysis is essentially devoid of physiological sources of variation (Gullberg 2003).

Among many quality assurance and procedural aspects of evidential breath alcohol testing, none is more important than the 15-min observation and deprivation period (Gullberg 1992; Wigmore, Leslie 2001). The result of a breath alcohol test is not considered valid if this is made within 15 min (20 min in some countries) after a person last consumed alcohol or had some alcohol-containing liquid in the mouth, such as cough medicine or an oral hygiene product (Fessler *et al.* 2008). Some of the latest breath alcohol instruments are capable of monitoring the authenticity of the exhalation profile of ethanol from its slope and waviness. The existence of an abnormal curve is one indication of contamination with 'mouth alcohol'. However, the slope detector is not foolproof, especially when the oral mucosa is contaminated with relatively low concentrations of alcohol (Buczek, Wigmore 2002).

Table 4.13 Examples of the types of challenges directed against the admissibility or validity of breath alcohol test results when alcohol-impaired drivers are prosecuted

Rank	*Challenges to breath test results*	*Brief description and references*
1	Erroneous or impossible result	Denial of drinking and claiming that a medical condition or a legally prescribed drug was responsible for the excess alcohol. Alternatively, a medication being used led to abnormally slow metabolism of alcohol (Gomm *et al.* 1990; Logan *et al.* 1998)
2	Alcohol in the mouth (mouth alcohol effect)	False high result caused by 'mouth alcohol' from recent drinking or regurgitation of stomach contents containing alcohol (Kechagias *et al.* 1999; Wigmore and Leslie 2001)
3	Interfering volatile substances present in the breath sample	Inhalation of organic solvent vapours by exposure in the workplace, uptake into the body via the lungs and lack of selectivity of the breath analyser (Denney 1990; Gill *et al.* 1991a, 1991b, 1991c)
4	Faulty instrument	Large difference between duplicate determinations of breath alcohol, error in calibration or failure to obtain zero results from room air
5	Inability to provide a proper breath sample	Lung dysfunction, (e.g. asthma or chronic obstructive pulmonary disease) prevented the person from providing a sufficient volume of breath to satisfy the requirements of the instrument or use of inhalers containing alcohol (Gomm *et al.* 1991; Ignacio-Garcia *et al.* 2005)
6	False high reading	Alcohol trapped under dentures or denture adhesives or production in the oral cavity by yeast infection (*Candida)* in mouth or upper airway. Blood (and alcohol) in the mouth during breath testing from injuries sustained in a crash (Harding *et al.* 1992; Trafford and Makin 1994; Chu *et al.* 1998)
7	Medical condition	Subject suffers from a medical condition or metabolic disturbance that allegedly produces volatiles in the breath indistinguishable from ethanol, e.g. acetone, methane, hydrogen (Marks 1984; Logan *et al.* 1994)
8	Elevated body and breath temperature	Suffering from a fever at the time of the breath alcohol test; alcohol concentration increases by 6.5% per 1°C rise in body temperature (Fox, Hayward 1989)
9	Blood : breath ratio	Tests were made during the absorption phase when the blood : breath ratio of alcohol was abnormally low owing to arterial–venous differences (Jones 1978; Jones *et al.* 2004)
10	Instrument malfunction	Printout from the instrument corrupted in some way, showing wrong date or time of the test (Denney 1998)

This might occur if a person suffers from gastric reflux and regurgitates stomach contents just before providing the breath sample (Jones 2007b). Stomach contents contain appreciable amounts of alcohol if the absorption rate is unusually slow and prolonged.

Table 4.13 gives examples and supporting literature citations to many well-documented challenges to the validity of results of breath alcohol analysis for legal purposes. As already mentioned, some people, especially those suffering from lung dysfunction, might be incapable of providing a proper sample owing to low forced expiratory volumes (Honeybourne *et al.* 2000; Stephens and Franklin 2001). This makes it advisable to allow a blood or urine option in these special cases, which is a better approach than allowing a police officer or instrument operator to decide whether the suspect was purposely failing to provide a specimen.

Concluding remarks

Road traffic crashes caused by drunken drivers will always plague society for the simple reason that alcohol is a legal drug and social drinking is an accepted part of normal life. Alcohol is readily available for purchase almost without restriction and is enjoyed by the vast majority of people in public places, such as restaurants and bars, making it necessary to obtain transport home afterwards. Many factors contribute to the cause of traffic crashes, not least of which is the human element and impairment of the driver caused by irresponsible use of alcohol or other psychoactive drugs.

This overview of DUIA has focused on many aspects of the problem including different types of legislation, alcohol-related impairment, methods used for analysis of alcohol in blood, breath and urine, the disposition and fate of alcohol in the body, and a plethora of defence arguments challenging the use of BAC or BrAC as evidence for prosecution of offenders. Alcohol-impaired drivers in most countries are typically men (85–90%) aged 35–45 years, which suggests that campaigns to improve road traffic safety and deterring DUIA should be directed specifically at this risk group of individuals. Teaching about the health hazards of excessive drinking and ethanol-induced impairment of skilled tasks, such as driving, should start during adolescence, such as in high schools, before young people reach the age to take a driving test.

The high average BAC values found in apprehended drivers in most countries (160–170 mg/100 mL) make it abundantly clear that these individuals are not moderate drinkers. Many apprehended drivers, especially repeat offenders, suffer from a substance abuse problem and they might be diagnosed as being clinically alcohol-dependent. This suggests that more attention should be given to the underlying alcohol-use disorder when offenders are sentenced. Instead of the more conventional penalties for this traffic offence (fines or imprisonment), it might prove more beneficial to focus on psychological counselling and rehabilitation for alcohol abuse.

CHAPTER

5 Driving Under the Influence of Drugs

BK Logan and MD Osselton

Introduction

Forensic aspects of alcohol, drugs and driving

The impact of the toll caused by driving under the influence of drugs (DUID) became more and more apparent over the decade ending in 2010. Numerous initiatives in Europe and the USA have led to drug testing of drivers stopped at survey or enforcement checkpoints (Beirness, Beasley 2010), arrested during random or for-cause traffic stops (Senna *et al.* 2010), and killed in motor vehicle crashes (Schwilke *et al.* 2006); this has demonstrated an incidence of drug use in the driving population that mirrors or in some cases exceeds the rates of alcohol use. With this increased recognition of its prevalence, additional efforts have been directed into drug-impaired driving enforcement (Boorman, Owens 2009) and comprehensive testing, and a variety of legislative approaches have been adopted to enable prosecution of drug-impaired drivers (Walsh *et al.* 2002). Also of concern is the issue of combined drug and alcohol use, as studies including those cited above suggest that as many as 50% of impaired driving deaths involving alcohol may also be positive for drugs. Drugs and alcohol together can act in either an additive or a synergistic manner, causing greater impairment than would be expected when either substance is taken on its own.

Recognition of the role played by alcohol in impairment and crash causation has led to the development of effective processes to legislate against it, strategies to detect and document alcohol impairment, and provisions to sanction, treat and rehabilitate offenders. The resources for addressing the drug-impaired driving problem have been slower to develop but are gaining more attention as the scale of the problem becomes more widely known. Forensic toxicologists play an important role in many phases of this problem. In the area of research, they assist with study design, contributing insight into the drugs most frequently encountered in the driving population, and implementing novel analytical techniques such as oral fluid (OF) testing, as a convenient means of obtaining a timely, less-invasive sample. Toxicologists also participate in the training of law-enforcement personnel to ensure that they appropriately apply the use of clues or indicators of drug use in assessment tools, and understand the dangers and adverse effects of those drugs on driving. Increasingly this training is also being provided to the lawyers who try the cases, and to the judges who have to decide these complex scientific issues, and toxicologists play a key role in such educational programmes. In the laboratory, the toxicologist will design and validate methods for the detection and quantification of drugs in biological specimens and also ensure that analytical procedures meet national or international standards of good practice and that test results are appropriately reported and legally defensible. The toxicologist typically consults with the lawyers in the trial preparation phase, providing education and perspective on the strengths and weaknesses of the test results and any limits to their interpretation. At trial, the toxicologist provides unbiased and objective evidence about the chain of custody and the analytical results. The toxicologist also has a role in educating the jury as to the likely effects. The consequences to the offender (arrest, detention, trial, legal expenses, fines, loss of licence, imprisonment) are serious, and defendants deserve assurances that the laboratory employs appropriate analytical safeguards and standards, and that the individual who interprets the results has the appropriate education and qualifications.

This chapter will consider the roles of the toxicologist in all these aspects of DUID and some of the considerations that help to ensure that valid and meaningful results and testimony can be provided to the court.

Enforcement and prosecution

There are two main approaches to legislating against drivers who drive while under the influence of drugs. The first is an impairment standard, under which a driver is guilty of the crime of driving under the influence (DUI) or driving while intoxicated/impaired (DWI) if it can be shown that their driving ability is affected by drug or alcohol use. The statutory language used varies widely. This important variable is often overlooked in the quest to derive thresholds for impairment associated with blood drug concentrations. As discussed later, there are several barriers to establishing these thresholds, not the least of which is that legislative standards vary by state and country. For example, in the USA individual jurisdictions use language such as 'impaired to the slightest degree', 'such that the person cannot exercise the same standard of care as a sober person', 'so that the person is less able than the person ordinarily would have been' and so on, which seem to require different standards of evidence. This 'affected by' approach is the most straightforward, and relates the person's behaviour to the crime of impaired driving. Evidence to support these charges may include:

- Appearance (flushed face, bloodshot eyes, pinpoint or dilated pupils)
- Speech (slow, slurred, mumbling, erratic, confused, etc.)
- Response to questions
- Ability of the suspect to produce a driver's licence from their purse or wallet
- Coordination on exiting the vehicle
- Ability to stand without swaying or using a support for balance
- Performance of simple tests of coordination
- The presence of gaze nystagmus (an involuntary jerking of the eye)
- Divided attention and balance.

All of the above provide cumulative evidence that a subject may be in a state in which the cognitive and psychomotor skills needed for safe driving are to some degree and for some reason deficient. Having established the presence of impairment, the investigation then proceeds to confirming by chemical tests that the reason for the deficit is use of alcohol and/or drugs.

Alcohol is generally the first substance to be tested for, as reliable portable breath tests allow testing for alcohol use in the field at the point of contact or arrest (Dubowski, 1994). If elevated, the breath alcohol concentration may help to explain the person's behaviour, and if low or negative it may provide reasonable suspicion that the person is under the influence of a drug, leading to collection of a blood or oral fluid sample. In the USA these indicators of intoxication may be needed legally to provide 'probable cause' (a higher standard than reasonable suspicion) to place a subject under arrest in order to allow the collection of a biological sample for testing. In the UK a blood specimen can be collected only if a medical practitioner (the forensic medical examiner or FME) is prepared to state that he or she believes that the driver is impaired through the use of drugs. In some European countries and Australian states, biological samples can be collected simply by demand of the law-enforcement officer on the basis of suspicion of driving or a random traffic stop.

The second approach to prosecuting impaired driving behaviour is the so-called 'per se approach'. Under this construction, the government,

based on its obligation to preserve public health and welfare and in consideration of the risks to its citizens of sharing the roadways with impaired drivers, has moved to outlaw driving after having consumed a drug with potentially intoxicating properties. This approach is called 'per se' if a quantitative standard in blood, oral fluid or urine is set above which driving is prohibited, or as 'zero tolerance' if the law defines the offence as having any detectable amount of a proscribed substance present in the body. Generally these laws apply only to scheduled substances, but would include prescription medications in situations where the subject does not have a legitimate prescription. Having a valid prescription is generally an absolute defence to a 'per se' charge, but the individual in most jurisdictions could still be charged under the 'affected by' standard, even if they have a prescription, if they show evidence of impairment. Examples of the diversity of statutory language are shown in Table 5.1.

At trial, the prosecution must generally show either that the subject had a proscribed drug present in their body or that they were impaired by their drug use, depending on the violation that is charged. In the first instance, the toxicologist's testimony can be quite straightforward, and relates to their qualifications, the chain of custody, the proper handling and analysis of the specimen, and the analytical results.

In cases where there is an element of impairment in the charge, the toxicologist's testimony becomes more complex, and must relate the individual's drug consumption to observed patterns of driving or other behavioural or physiological indicators. With appropriate education, qualifications and training, the toxicologist can consider the observations of the arresting officer or other witnesses concerning behavioural effects, such as balance, speech, motor sway, pupil size, wakefulness, performance in field sobriety tests, and other factors to arrive at opinions about whether the observed effects could be accounted for by the class or classes of drugs present. Blood drug concentrations can also be helpful in assessing whether drug consumption reflects therapeutic, recreational or overdose use and the likelihood of drug–drug or drug–alcohol interactions, and may sometimes be helpful in indicating recent drug use. It is generally agreed, however, that for most drugs there is no good quantitative correlation between blood drug concentrations and specific degree of impairment or signs and symptoms exhibited by the driver. Nor can blood drug concentrations be reliably expressed in terms of an equivalent blood alcohol concentration (BAC). Oral fluid and urine are currently considered to be good indicators of drug exposure or consumption, but are even more difficult to relate to a degree of impairment. The toxicologist must recognise the limitations of their expertise and should not be tempted to step outside their area of expertise by providing opinions about medical diagnosis, appropriateness of prescribing practices, law-enforcement procedure or other peripheral issues.

Assessing the effect of a drug on driving performance

It is important to understand the means by which drugs affect individual components of the driving task and how they can affect their overall performance. This may be achieved in a number of ways, and three are considered here.

Behavioural domain analysis and assessment

Before a new drug is approved for use, it should be evaluated for its cognitive and psychomotor effects. This allows the prescribing physician not only to reach informed patient care decisions based on the patient's medical condition, and the efficacy of the drug to treat it, but also to balance those needs with the patient's need to drive or engage in other physically or cognitively challenging tasks.

For purposes of this assessment, driving can be analysed on a functional level. Five functional domains can be described, and may be tested in a study or research environment at no risk to the driver, while providing information about the potential of a drug to cause impairment. Various analyses are possible, but Table 5.2 describes an approach using five domains:

1. Alertness/arousal
2. Attention and processing speed
3. Reaction time/psychomotor functions

Table 5.1 UK and selected US statutory language for DUI involving drugs

United Kingdom

Road Traffic Act 1988 (c. 52) Part I (4)

1. A person who, when driving or attempting to drive a motor vehicle on a road or other public place, is unfit to drive through drink or drugs is guilty of an offence.
2. Without prejudice to subsection (1) above, a person who, when in charge of a motor vehicle which is on a road or other public place, is unfit to drive through drink or drugs is guilty of an offence
3. For the purposes of subsection (2) above, a person shall be deemed not to have been in charge of a motor vehicle if he proves that at the material time the circumstances were such that there was no likelihood of his driving it so long as he remained unfit to drive through drink or drugs.

United States

Colorado Revised Statutes Section 43-4-1301(1)

(f) 'Driving under the influence' means driving a vehicle when a person has consumed . . . one or more drugs . . . which . . . one or more drugs alone . . . affects the person to a degree that the person is substantially incapable, either mentally or physically, or both mentally and physically, to exercise clear judgment, sufficient physical control, or due care in the safe operation of a vehicle.

(g) 'Driving while ability impaired' means driving a vehicle when a person has consumed . . . one or more drugs . . . which . . . one or more drugs alone . . . affects the person to the slightest degree so that the person is less able than the person ordinarily would have been, either mentally or physically, or both mentally and physically, to exercise clear judgment, sufficient physical control, or due care in the safe operation of a vehicle.

Florida Statutes Annotated Section 326.193

1. A person is guilty of the offense of driving under the influence and is subject to punishment as provided in subsection (2) if the person is driving or in actual physical control of a vehicle within this state and
   (a) The person is under the influence of . . . any chemical substance . . . or any controlled substance . . . when affected to the extent that the person's normal faculties are impaired.

Indiana Code Annotated Section 9-13-2-86

'Intoxicated' means under the influence of . . .

2. a controlled substance
3. a drug other than alcohol or a controlled substance so that there is an impaired condition of thought and action and the loss of mental control of a person's faculties to an extent that endangers a person.

Table 5.2 Classification of psychological/behavioural domains related to skills needed for safe driving

Domain	*Description*	*Assessment tools*	*Examples of effects on driving*
Alertness/arousal	Level of consciousness, ranging from full alertness, to drowsiness, somnolence, stupor and coma	Self-report (e.g. visual analogue scales and sleepiness scales); laboratory performance measures (e.g. psychomotor vigilance testing); and sleep laboratory measures of daytime wakefulness	Drifting out of lane, driving off the road, rear-end collisions, failure to obey traffic signals
Attention and processing speed	Capacities or processes involved in being receptive to internal or external stimuli	Tests of focused or selective attention (i.e. concentration); sustained attention or vigilance; divided attention; shifting or alternating attention; and working memory	Rear-end collisions, driving unsafely for conditions, weaving, poor emergency response
Reaction time/psychomotor functions	Speed of response and coordination of skilled movement	Choice reaction time; driving simulator or over-the-road driving tasks; psychomotor tasks (e.g. upper motor speed and coordination	Rear-end collisions, dangerous merging, unsafe lane changes
Sensory–perceptual functioning	Visual, auditory, proprioceptive and sensorimotor abilities that enable the critical driving tasks	Ability to perceive vehicle movement and roadway conditions, and to provide appropriate feedback to the operator on the consequences of motor movement	Collisions, dangerous manoeuvres, risky driving
Executive functions	Planning, approaching, organising, monitoring, prioritising and carrying out various cognitive activities	Mental flexibility; adaptive problem solving; abstract reasoning; impulse control; risk taking, organisational ability and planning	Risky, aggressive driving, last-minute lane changes, poor performance in high-demand situations

4. Sensory–perceptual functions
5. Executive functions.

A behavioural assessment protocol can be designed to evaluate all five of these domains, and a drug that impairs performance in one or more domain at a magnitude known to be associated with increased crash risk can be presumed to have a negative impact on driving safety. This approach allows the assessment of the impact of drug or combined alcohol and drug use on skills essential to safe driving, in a laboratory environment.

Empirical toxicological assessment

When considering a newly developed drug, or one about which relatively little has been published behaviourally, the compound's known pharmacology should be considered. Sedative hypnotic drugs, narcotic analgesics, central nervous system (CNS) depressants, anaesthetics, dissociative drugs and hallucinogens all have clear detrimental effects on the above domains. Stimulants increase wakefulness and attentiveness and improve reaction time; however, overstimulation leads to sleep disturbance and fatigue, anxiety, irritability, impulsiveness and increased risk taking. Under conditions of abuse, stimulants might be expected to have a different effect from that when used under a doctor's supervision. Nevertheless, comparing a new drug with other drugs with known effect profiles can inform opinions about the relative risk of a drug for causing impairment.

Epidemiological monitoring

Once a drug is available on the market, epidemiological data can be reviewed to identify over-representation of certain drugs in crash-risk statistics and relative risk of impairment for drugs or drug classes based either on comparison with control populations or through culpability assessment (Longo *et al.* 2000).

Based on all of the above considerations, several European nations (France, Belgium, Spain and Germany) have developed graduated warning systems regarding the potential of a drug to cause impairment (ICADTS Working Group 2007; ICADTS Drugs List 2007). Under these schemes, panels of psychologists, safety experts, pharmacologists and toxicologists have evaluated drugs for their potential effects under different dosing intervals and amounts, and rated the drugs for their relative risk for impairment. These systems provide prescribing physicians with drug alternatives based on the likelihood of impairing effects or side-effects, and help the patient make good decisions about timing of dose and when and whether to drive.

Identifying the drug- or alcohol-impaired driver

Operating a motor vehicle is a complex task that requires integration of many psychomotor and cognitive tasks. If the processes involved in driving are analysed, it becomes clear that the operator is called upon to steer the vehicle, maintain speed consistent with signage and road conditions, maintain headway between vehicles, maintain lane position, monitor the activity of other drivers, pedestrians and animals, monitor rear view and side mirrors, operate other controls in the vehicle and execute goal-directed driving. At the same time, the operator may also deal with other potential distractions such as passenger activity, operating the radio or CD player, eating, smoking, talking on a mobile phone, engaging in conversation, and so on. The demands of these tasks can vary, requiring adaptation, and can be further influenced by the driver's familiarity with the vehicle and locality, the vehicle's condition, road conditions and/or construction, and lighting or weather, among other things. As demanding as any of these single tasks might be, their coordination represents an additional demand, namely the ability to prioritise, shift and divide attention appropriately between these tasks while performing each competently.

The integration of all the tasks can be compromised easily by the presence of drugs or chemicals that impact cognition, information processing or psychomotor control. Particularly sensitive are divided-attention tasks, of which driving is clearly a good example. Drugs that fall into this category are any that act on the CNS, and those with CNS depressant, sedative or hallucinogenic effects. An additional complication is seen with stimulants and opioids, which not only have important effects acutely but have potential late-phase or withdrawal effects that can also impair performance. Table 5.2 lists some of the general driving behaviours and how they can be related to the driving domains discussed previously. There is no basis for assigning specific types of impairment to specific classes of drugs, however, as each domain may be affected in different ways by a given class of drugs but with the same net deterioration in performance.

Once a driver has been stopped by the police for demonstrating suspicious driving behaviour, the officer then looks for indicators of possible intoxication that would lead to an arrest or to a request for blood, breath or urine samples for chemical testing. On this first contact through the car window, clues that might indicate drug use include:

- Smell (principally the smell of burning marijuana; cannabis)
- Confusion, disorientation or lack of engagement

- Unusual behaviour, statements or responses by the driver to an officer's questions (including slow or slurred speech and physical responses), inappropriate answers to simple questions, unusual nervousness
- Hyperreflexive head body or hand movements, and general motor restlessness
- Flat, dull or overexcited demeanour
- Unusually large or small pupils, unusual eye movements
- Impairment of fine motor skills and balance
- The presence of tablet containers, drug wraps or drug paraphernalia, while not evidence of drug use as such, should not be overlooked.

Generally, after noting the presence of some of these indicators or clues, the officer escalates the investigation to determine the cause of the suspected impairment. The subject is first asked to exit the vehicle. This provides the officer an opportunity to observe some gross motor skills and balance. The subject may be asked to perform some tasks designed to test his or her psychomotor and cognitive abilities, and divided-attention skills. If drug influence is suspected, documenting the physiological parameters influenced by the use of these drugs (pulse, blood pressure, muscle tone, eye movement, pupil size and reaction to light, etc.) can assist in identifying the class or classes of drugs that might account for the observed impairment.

Tests of impairment

Historically, a variety of roadside impairment tests has been used to assist with the assessment of whether a driver is impaired. Picking up coins, counting backwards, serial addition or subtraction, alphabet recitation, standing on one leg and so on have all had their proponents, but many are not suitable for use because of their dependence on the subject's fluency in a particular language, or baseline ability to count or perform simple arithmetic. Other tests require specialised equipment or the active participation of the officer, which can jeopardise the officer's safety and can bring unnecessary physical risk to an impaired subject. By far the most popular test battery now employed in North America and many other countries involves three tests: the walk-and-turn test, the one-leg-stand test and an assessment of horizontal gaze nystagmus (HGN). This battery of standardised field sobriety tests is derived from work funded by the National Highway Traffic Safety Administration (NHTSA) in the 1970s and 1980s (Burns, Moskowitz 1977). The first two tests are classic divided-attention tests that require the subject to listen to a set of straightforward directions (a cognitive task) while performing a separate balance (psychomotor) test. In the walk-and-turn test, the subject places his or her feet on a straight line and must maintain balance without use of the arms while receiving the test instructions. During the second phase of the test, the subject must walk the requisite number of steps, heel to toe, down the line, according to the initial instructions, turn in a prescribed manner and return the same number of steps down the line, while maintaining balance. The person assessing the test is watching for inability to remember or follow instructions, use of arms for balance, stepping off the line, not walking heel to toe or taking the wrong number of steps. In the one-leg-stand test, the subject must again maintain balance while receiving the instructions, then execute the test according to the instructions, which are to raise the foot 15–25 cm (6–10 inches) off the ground and maintain it there while counting out loud, by thousands, to 30 000. This again divides the subject's attention between a cognitive (counting) and a psychomotor (balancing) task. The officer is watching for ability to remember and follow instructions, use of arms for balance, putting the raised foot down or hopping to maintain balance. While neither of these tests is a test of driving itself, they are arguably more challenging and models driving better than a test of, say, simple reaction time. When used individually, these tests have been shown to have an overall efficiency (the percentage of time the test returned a correct answer to the question, and the subject's breath alcohol was >1.0 g/L) of 75.5% and 75.1% for the walk-and-turn and one-leg-stand, respectively (Burns, Moskowitz 1977).

HGN is not a divided-attention test but rather takes advantage of the CNS-depressant properties of alcohol and other drugs, which produce among other things an observable lateral jerking of the eye, or nystagmus, that can be observed by asking the subject to track a stimulus such as a fingertip or penlight across the field of vision while keeping the head still. While pronounced nystagmus can result from other causes (brain damage, inner-ear disturbances, thermal imbalance in the inner ear, rotation, etc.), it is produced reliably by alcohol at blood concentrations known to impair driving ability. Further, other CNS-depressant drugs can also elicit HGN (e.g. depressants, phencyclidine (PCP) and volatile solvents), which makes the test a useful indicator of use of some other classes of drugs in addition to alcohol.

Only limited evaluation of these field sobriety tests has been done for different categories of drug use. In investigations of suspected drug-impaired driving, the value of these and similar tests is to demonstrate an inability on the part of the subject to integrate simple psychomotor and cognitive skills, and as such to demonstrate evidence of impairment. The Drug Evaluation and Classification Program (DECP) that has been established in some jurisdictions in the USA, and modified for use in other countries such as Germany and Australia, seeks to classify subjects as under the influence of a specific class or classes of drugs based on certain psychomotor and physiological measurements. Table 5.3 shows a matrix that relates these effects to the classes of drugs recognised in the DECP. In some European countries, such as the UK and Norway, impairment assessment is done by a physician.

On-site chemical tests

Of increasing interest to the law-enforcement and traffic safety community is the use of 'point of contact' or 'on-site' drug testing. The use and acceptability of such tests vary in different countries. Urine was initially used for this purpose in some countries, and lateral-flow immunoassay-based dipstick devices or test cups were commercially produced and have since proliferated. The devices test for common drugs of abuse including cocaine, marijuana and opiates and are generally sensitive and specific enough for this purpose, although there are quality differences between manufactured devices. Four such devices showed sensitivity ranging from 82.9% to 100% for cannabinoids and from 82.5% to 100% for cocaine, and all showed 100% for opiates. Accuracy ranged from 94.0% to 98.3% for marijuana, from 97.4% to 98.0% for cocaine, and from 99.7% to 100% for opiates (Buchan *et al.* 1998). The benefit of the on-site urine test was the ability to confirm the officer's suspicions about drug use at the time of the arrest, and the devices had great potential for use in enforcement checkpoints or during random screening in jurisdictions where 'per se' laws were in effect. The limitations of the devices included the limited scope of drugs that could be detected (typically five to seven drug classes on any given device, with variable cross-reactivity to compounds within the class) and, on a practical level, the need to transport the subject to a private location to provide the urine sample. Often observed collection was not possible owing to the unavailability of a same-sex observer, creating the potential for substitution or adulteration. While urine is a good specimen for screening, it is essentially 'out of the body' and drugs may be detected in urine after the effects on driving ability have worn off; hence this is not a good specimen for interpretative purposes.

More recently, on-site oral fluid drug testing has gained in popularity. OF testing offers the same benefits of an immediate result to corroborate the officer's opinion regarding drug use, but has the advantages over urine of being capable of being conducted at the roadside, eliminating the cost and time of transporting the subject. It also offers the opportunity of obtaining a sample proximate to the time of driving, it provides a non-invasive, clean sample, and collection can be directly observed irrespective of the sex of the suspect or the arresting officer. OF also has an advantage over blood of not requiring a licensed collector or phlebotomist, and the associated cost of that procedure. Following the result of a field test, OF can also be collected and sent to a laboratory for the confirmatory test needed for forensic purposes. OF test devices currently have a limited scope compared with a laboratory test but they can cover the major drug

Table 5.3 Symptomatology chart for drug effects (IACP, DECP Program)

Categories	*Depressants*	*Stimulants*	*Hallucinogens*	*PCP*	*Narcotic analgesic*	*Inhalants*	*Cannabis*
HGN	Present	None	None	Present	None	Present	None

classes encountered in the driving population. OF on-site tests have been deployed in a large-scale roadside random testing programme in Australia, with some success (Boorman, Owens, 2009), and on-site OF testing has recently been trialled by police in the UK. Studies conducted as part of the Driving under the Influence of Drugs and Alcohol (DRUID) project in the European Union have evaluated available on-site devices and found them to be significantly improved over their earlier versions (DRUID 2009).

The merits of OF as a sample for confirmatory testing are discussed below. Any on-site drug test needs to take account of the fact that not all drugs that can cause impairment will be detected in an on-site test and that the primary consideration in whether to release a driver would be his or her appearance of sobriety and fitness to drive.

Choice of specimen for drug testing in impaired driving cases

The three options for sample collection for DUI enforcement purposes are blood, OF and urine. Each has its advantages and disadvantages.

Urine has the advantage of being easily collected (privacy issues around observed collection have been discussed above). The concentration of drugs in urine is dependent on the volume of liquid consumed, the degree of hydration of the subject and the time of ingestion, as it is on the amount of drug ingested. Urine drug concentrations are often several orders of magnitude higher than blood drug concentrations, making urine an ideal sample for preliminary screening. Depending on the drug, it or its metabolites may be detected for days or occasionally weeks after administration. Shorter-acting drugs may be detected in the urine even after the effect of the drug has disappeared. This is true, for example, of some of the short-acting benzodiazepines, γ-hydroxybutyric acid (GHB) and zaleplon.

Urine drug concentrations can be normalised for creatinine concentration, which corrects for dilution caused by the ingestion of large volumes of water, but such a correction is of limited value in a single urine specimen, and does not add to an interpretation of the degree of intoxication. Urine is, therefore, an excellent specimen for answering the question 'Did the donor at some time prior to providing the specimen use or ingest this drug?', but it is of little use in determining whether the subject was impaired or intoxicated at the time that the sample was collected. The investigator must consider the result of the urine drug test in the light of objective evidence of impairment (slurred speech, staggering gait, inappropriate conduct or response, poor coordination, glassy stare, agitation, restlessness, etc.) to reach any conclusion about the subject's fitness to drive. The toxicologist can then use his or her specialised knowledge to assess whether the observed effects are consistent with the known properties of the drugs present. Another limitation of urine is that, following drug use, it may take some time before a drug is metabolised and excreted. If ingestion had been very recent, the urine may test negative for the presence of the drug, even though the drug is present in the body and exerting an effect on the subject.

In spite of these limitations, urine has been a popular specimen for drug testing in impaired driving cases because of the ease with which it can be collected, the essentially unlimited volume for testing, and the ease with which urine can be screened in the laboratory by immunoassay on automated instruments.

Blood has emerged as the preferred specimen for collection and analysis in impaired-driving investigations. The presence of drugs in the circulating blood, in equilibrium with the brain, provides the most direct measure of a person's likelihood of intoxication. From an interpretive standpoint, blood drug concentrations can usually be related to some degree to published concentrations associated with known doses

or patterns of therapeutic or recreational use. Blood drug concentrations are a function of the dose, time since last use, and whether the use is acute or chronic. They can be useful in distinguishing drug use from abuse and assessing the likelihood of drug interactions, and can be related to behavioural studies of effects on critical abilities related to driving, although relationships between blood drug concentration and any specific degree of impairment or effect on driving have not been established for many drug substances. Apart from alcohol, the exception to this may be other members of the depressant drug class, which have been studied to a greater degree (Bramness *et al.* 2003, 2004). Hysteresis or varying early phase and late phase effects for a given concentration as a result of acute tolerance or withdrawal make this relationship more complex for stimulant drugs, and issues of chronic tolerance can impact on the interpretation of opiate concentrations. Consequently, the interpretation of blood drug concentrations still needs to be treated with care and the full range of possible ingestion patterns, and likely effects, must be considered.

Blood must be collected by a medical professional, which can add expense and time to the collection process. The time factor is a consideration for drugs such as zolpidem, tetrahydrocannabinol (THC) and some of the synthetic cannabinoids (JWH-018 and JWH-250), which are distributed and metabolised out of the blood rapidly. Consequently the concentrations in the blood at the time of collection may not reflect the concentrations present at the time impairment is first observed or during driving.

Typical volumes of blood available for testing are around 10 mL which is usually adequate for a sensitive broad-spectrum screen, confirmation and quantification. It can be difficult to collect an adequate volume from some individuals with collapsed veins. Drugs are typically quite stable in blood provided that it is collected over an enzyme inhibitor such as sodium fluoride. Collection with an anticoagulant such as heparin, citrate or oxalate is important in order to prevent clotting and inhomogeneity in sampling.

As noted above there is increased interest in OF testing for drugs in driving investigations. OF (a mixture of salivary, parotid and crevicular ultrafiltrates and mucus) has gained popularity as an alternative to blood because of the ease and low cost of collection proximate to the time of driving, and the increasing reliability of on-site test devices. In the USA, 16 states now allow OF collection in their DUI statutes, and others are following suit. In some European countries, OF is also accepted in court for traffic enforcement cases subject to appropriate laboratory confirmation. Several large-scale surveys of drivers have also recently assessed the utility of OF for traffic investigation, and have found generally good correlation between the presence of drugs in OF and the presence in a subsequently collected blood sample (Diplock, Plecas, 2009). This meets the requirement in 'per se' jurisdictions where the mere presence of a proscribed drug in a body fluid constitutes the offence. OF drug concentrations are, however, more difficult to interpret quantitatively than blood concentrations. Partition of drugs into OF is a function of many factors: salivary flow, oral pH, drug polarity and pK_a, contamination of the oral cavity with drug (especially an issue for smoked drugs such as cocaine or marijuana), and the degree of protein binding of the drug in blood (only non-bound drug partitions into the OF). Consequently, it is inadvisable to try to predict blood drug concentrations based on OF concentrations, and there are currently limited data available to determine whether impairment can be predicted based on quantitative OF test results (Wille *et al.* 2009). Analytically, the target compounds in OF can be different from whole blood, as the less polar parent drug is often the major analyte present in OF as is the case with THC and cocaine. More polar highly bound drugs, such as the benzodiazepines, can be present at much lower concentrations in OF.

In summary, blood remains the specimen of choice in DUID investigations, but OF is emerging as a valuable alternative within the correct statutory framework.

Laboratory approaches to drug testing in DUID cases

At the heart of every DUID investigation is a forensically defensible drug test. This generally means a test with appropriate scope to identify the range of drugs that are known to affect driving and are prevalent in the impaired driving population at large, supplemented with other drugs that may be an issue locally. Prescription drugs, over-the-counter drugs and drugs of abuse should all be included. Two sets of guidelines with largely overlapping recommendations for scope and limit of detection in blood and urine, for both screening and confirmation, are shown in Table 5.4 (Farrell *et al.* 2007; Walsh *et al.* 2008).

Most laboratories begin the analytical process with a test for volatiles to establish any role for alcohol in the subject's impairment. This can also disclose the presence of volatiles including anaesthetic gases, and solvents subject to abuse such as toluene, xylene or difluoroethane.

The volatiles screen is usually followed by an immunoassay screen. The immunoassay provides a valuable role in screening for the presence of certain drug classes, for example identifying the presence of amfetamines or benzodiazepines but not the identity of the specific amfetamine or benzodiazepine. The variable cross-reactivity of the assay to members within a class must be kept in mind. For example, many benzodiazepine immunoassay tests do not cross-react well with lorazepam (Ativan), so a chromatographic screen will be needed to exclude those drugs with poor cross-reactivity.

Appropriate cut-offs need to be established depending on the matrix being tested (see Table 5.4). It is not appropriate to apply most urine drug screening cut-offs to blood analysis, since urine drug concentrations may exceed those in the blood by several orders of magnitude, and the presence of some drugs might be subsequently missed.

Table 5.4 Recommended scope and analytical cut-offs of toxicological analysis in DUID investigations

[f]Free drug, not conjugated.

Preliminary drug screening

Many different types of immunoassay screening tests are available commercially. The techniques in most widespread use include enzyme multiplied immunoassay technique (EMIT), ELISA, kinetic interaction of microparticles in solution (KIMS) and fluorescence polarisation immunoassay (FPIA; see Chapters 3, 18 and 32). When applied appropriately, with the correct calibrators and controls, any of these techniques is suitable for drug screening in DUID cases. ELISA is in most widespread use, and has the advantage as a heterogeneous assay with a separation step of being readily applied to blood in addition to other matrices. Homogeneous systems such as EMIT typically require some pretreatment (protein precipitation or extraction) prior to analysis of samples other than urine or serum. An immunoassay panel for blood or urine typically includes cocaine metabolites, opiates, amfetamines, methylenedioxyamfetamines, cannabis metabolites, methadone, PCP, propoxyphene, barbiturates and benzodiazepines. For OF, the same general targets would be included, with the exception of using a THC-specific assay for cannabinoids, and a cocaine-specific assay rather than a metabolite assay. Immunoassay is only a presumptive technique, and should not be

considered proof of the identification of a compound without a complementary confirmatory analysis. Immunoassay screening covers only a partial range of drugs, and typically would not detect other potentially impairing compounds such as novel analgesics, tramadol and tapentadol, or anticonvulsant drugs such as gabapentin, topiramate or leveteracitam, or partial γ-aminobutyric acid (GABA) agonists such as zolpidem or zopiclone. All these drugs may play a role in driver impairment and underscore the need for a comprehensive chromatographic screen (GC-MS or LC-MS) in addition to the immunoassay.

Chromatographic screening

The 'gold standard' for confirmatory identification of drugs in biological samples is GC-MS or LC-MS. Typically, two fractions, one for basic drugs and the second for weakly acidic or neutral drugs, are obtained.

Basic drugs

Drug extraction

The procedure described below efficiently extracts basic drugs, including those commonly encountered in DUID cases such as those indicated in Table 5.4. The procedure described below includes a back -extraction into acid, which produces a very clean extract and reduces the amount of time required to analyse the GC-MS data, and the time spent on system maintenance. The back extraction, however, eliminates weak bases or amphoteric compounds, notably some benzodiazepines, which must be analysed for using a separate confirmatory procedure that does not include the back-extraction step.

1. Add 1 mL of the sample to a 20-mL disposable glass culture tube.
2. To each tube add 50 µL internal standard.
3. Add 1 mL pH 9.0 borate buffer to each tube and vortex mix for approximately 10 seconds.
4. Add 3 mL *n*-butyl chloride to each tube, cap, and rotate on a tube rotator for a minimum of 5 minutes.
5. Centrifuge until the organic and biological matrix layers are separated.
6. Transfer the *n*-butyl chloride organic layer to a clean, labelled, 10-mL, conical, disposable centrifuge tube.
7. Back extract by adding 200 µL 3 mol/L HCl to the *n*-butyl chloride.
8. Cap and rotate for at least 5 minutes.
9. Centrifuge until separated; aspirate and discard the (upper) *n*-butyl chloride layer.
10. Remove any remaining butyl chloride by blowing air over the lower layer.
11. Add 100 µL concentrated ammonium hydroxide and 100 µL saturated ammonium carbonate to each tube to make the extract alkaline.
12. Vortex mix for 15–30 seconds.
13. Add 150 µL of chloroform and vortex mix for 15 seconds.
14. Centrifuge until the organic and aqueous layers are separated.
15. Using a serological disposable pipette, transfer approximately 50–75 µL of the lower organic layer into two labelled autosampler vials for GC-MS analysis.

GC-MS analysis

Many different conditions of flow rate, columns and temperature programming can be used for the GC-MS analysis of basic drugs to emphasise or optimise certain separations for frequently encountered compounds that might co-elute or interfere. The conditions for optimum separation have to be balanced against the run time so as to effectively use the laboratory's resources and keep up with casework. The following method is an example of such a system that allows the chromatography of approximately 250 commonly encountered basic drugs and metabolites.

Simultaneous analysis is performed on a dual-column gas chromatograph with a nitrogen phosphorus detector (NPD) on column 1 and a mass-selective detector (MSD) on column 2. Use of identical columns and simultaneous injection permits the comparison of the mass- and nitrogen-specific chromatograms, which assists with data interpretation and peak identification. In this example, both columns are 5% phenylmethylsiloxane column (DB-5 or equivalent) 30 m × 0.25 mm i.d., 0.25 mm film thickness. The temperature programme starts at 90°C, rises by 15°C/min for 12 minutes (to 180°C), then rises by 8°C/min for 15 minutes (to 300°C) and holds for 4 minutes. The total run time is 31 minutes.

Weakly acidic and neutral drugs

Extraction

The procedure described here isolates drugs with acidic and neutral character, such as non-steroidal anti-inflammatory compounds and paracetamol, carbamates (such as carisoprodol and meprobamate), barbiturates and anticonvulsants (such as carbamazepine and phenytoin; Logan *et al.* 2000).

1. Add approximately 1 g XAD resin (washed in ethyl acetate) to disposable glass culture tubes (20 mL).
2. Add 5 mL deionised water and 50 µL internal standard to each tube.
3. Add 1 mL of sample to the appropriately labelled tubes.
4. Thoroughly vortex mix each tube for approximately 60 seconds and allow to stand for at least 60 seconds to allow settling.
5. Aspirate the blood–water layer from each tube, leaving the XAD in the tube.
6. Add 6 mL ethyl acetate to each tube and vortex thoroughly for 60 seconds.
7. Centrifuge until separated, and transfer the ethyl acetate to an appropriately labelled, clean, conical, disposable tube.
8. Evaporate to dryness at approximately 50°C under air until very dry (approximately 20 minutes).
9. Reconstitute using 75 µL acetonitrile and wash with 500 µL heptane.
10. Vortex mix for about 15 seconds and centrifuge until separated.
11. Aspirate the heptane layer (top), and transfer the acetonitrile layer to labelled autosampler vials for GC-MS analysis.

GC analysis

As with basic drugs, many GC protocols are suitable for this screen. Since the number of compounds being tested for is considerably smaller (~30), the run time is correspondingly shorter. GC is performed on a gas chromatograph equipped with a flame ionisation detector (FID, for screening) or a: MSD (for confirmation). Helium is used as the carrier gas. The column is a 5% phenylmethylsilicone column (DB-5 or equivalent), 30 m × 0.32 mm i.d., 0.25 mm film thickness. The temperature programme starts at 60°C, rises by 10°/min for 16 minutes, then rises by 20°C/min to 295°C and holds for 1 minute. The total run time is 21 minutes.

Determining an appropriate protocol for your laboratory

While attention should be paid to the opinion of the arresting officer about what drugs are suspected in any given case, the toxicologist should apply a good broad-spectrum drug screen to be able to exclude the possibility of other drugs with similar effects. For example, as discussed later, an individual withdrawing from intravenous amfetamine use may appear drowsy and have constricted pupils, poor psychomotor performance and injection marks. This constellation of symptoms is very similar to those caused by a narcotic analgesic, and consequently a test only for opiates would not disclose the actual drug responsible for the person's intoxication.

The class of CNS-depressant drugs is probably the most challenging analytically, since it includes some chemically very diverse drugs, from solvents and inhalants, to long- and short-acting benzodiazepines, antidepressants, antihistamines and novel recreational agents such as GHB and butane-1,4-diol. Practically speaking, an escalation approach is the most economical and effective, beginning with the commonly encountered drugs and expanding and adding assays for drugs that could account for the symptoms observed on the basis of review of the preliminary data.

It is critical that laboratories performing this work observe accepted standards for forensic analysis, including: maintaining security and chain of custody, maintaining written protocols for commonly performed

Table 5.5 CNS-depressant drugs associated with impaired driving

Antidepressants	*Anxiolytics*	*Sedative hypnotics*	*Analgesics*	*Antipsychotics*	*Anticonvulsants*	*Muscle relaxants*	*Antihistamines*

procedures, validating method accuracy through use of appropriate standards and controls, verifying the identity of any drugs reported (using MS wherever possible), implementing the scientific review of data, participating in proficiency testing programmes and ensuring that staff have appropriately documented qualifications and training.

Priority drugs associated with driving impairment

CNS depressants

Many drugs have CNS-depressant properties either as a targeted effect or as a side-effect of the drug. While not intended to be a comprehensive list, Table 5.5 presents some common drugs with CNS-depressant activity that have been implicated in impaired driving cases. Most of these drugs exert their effects through the GABA pathways, with the exception of the opiates which cause sedation through the opioid μ and κ receptors.

Alcohol is the best-known example of a CNS-depressant, and the general presentation of alcohol impairment is seen with these drugs, as discussed below. Performance in divided-attention tests, such as field impairment tests, is affected similarly by many CNS-acting drugs and observable nystagmus can be seen using the HGN test. Driving has been affected demonstrably in driving simulators, in on-road driving studies and from epidemiological and anecdotal reports for many drugs, and monographs concerning the benzodiazepines, GHB and carisoprodol are included in two special issues of *Forensic Science Reviews* (Vol. 14, 2002, and Vol. 15, 2003). By virtue of their common effect, combining alcohol with prescription or recreational drugs causes an additive or synergistic effect. Drugs with CNS-depressant properties are frequently prescribed in combination for the legitimate treatment of a constellation of effects associated with illness. One of the most commonly encountered examples in DUID casework is that of chronic pain patients. A patient who suffers from chronic debilitating back pain might be prescribed one or two centrally acting muscle relaxants such as carisoprodol or cyclobenzaprine, a barbiturate such as butalbital, an opioid analgesic such as propoxyphene, hydrocodone or oxycodone, a sleeping aid such as zolpidem, and often an antidepressant drug to treat the depression that typically accompanies chronic pain. The resultant combined effect makes some decrement in driving performance almost inevitable, and the patient, pharmacist and physician have an obligation to monitor the effectiveness of the treatment, select drugs with the least likelihood for impairment, use minimum effective doses, advise the patient of the risks to driving, and take care when adjusting the dose, changing the dosing schedule or adding new medications. The patient needs to be similarly advised that fatigue, alcohol and his or her illness itself can lead to unexpected changes in the risk of impairment. Whether the impairment is a result of legitimate, compliant, prescription use or not is immaterial from a public safety standpoint, and a driver impaired by use of prescription drugs must be subject to the same removal from the road as a recreational drug user.

As noted earlier, there is currently insufficient information to relate blood drug concentrations to a specific degree of impairment; however, CNS-depressant drugs do display a qualitative dose–response relationship between concentration and effect, with higher concentrations being associated with more obvious symptoms, progressing from mild impairment to unconsciousness, even in subjects with some tolerance. Effects on driving can occur with the therapeutic use of a single drug. Blood drug concentration data can help to establish whether a subject is following his or her prescribed course of medication.

A subject under the influence of a CNS-depressant will typically display signs that are familiar from impairment through alcohol. Consistently noted are problems with fine or coarse motor control, staggering gait (ataxia), loss of balance, impairment in divided-attention tests, poor concentration and slurred speech. Subjects often have a sleepy or dazed appearance, may have difficulty understanding questions or responding appropriately, and may be disoriented to time and place. Readily observable HGN is a consistent and common feature of CNS-depressant intoxication. Driving behaviours commonly noted include weaving within or between lanes, failure to notice and obey traffic signals, failure to obey posted speed limits, wide turns, rear-end collisions, no use of turn signals and driving at night without lights.

Marijuana

Marijuana (cannabis) is the most popular recreational drug after alcohol in most jurisdictions. Obtained from the plant *Cannabis sativa*, the leaves and buds contain a variety of cannabinoids that posses psychoactive effects, the predominant one being Δ^9-THC. Cannabinoids have significant behavioural and physiological effects that contribute to changes in a person's ability to drive safely. The drug is popular for its relaxation-promoting and euphoric properties, accompanied by sedation and changes in perception. Accompanying effects include altered time and distance perception, poor concentration, impaired learning and recall, increased appetite and mood changes. Associated physiological effects include increased pulse and blood pressure, and bloodshot conjunctivae. A loss of convergent vision is also reported.

Beginning in 2008, synthetic cannabinoid agonists developed as investigational drugs started to appear in the recreational drug market. Sold as 'Spice', 'Pep-spice', 'K2' and by many other names, they are marketed as incense products or 'legal highs', and often labelled not for human consumption. A very diverse range of structural families has been identified with significant binding and agonist effects at the cannabinoid CB1 receptor, responsible for the intoxicating effects of THC. Preliminary data suggest that these compounds have very similar effects to marijuana, and will probably become important to consider in DUID investigations. The compounds most frequently reported to date are JWH-018, JWH-019, JWH-073, JWH-250, CP47,497, HU-210, WIN55212, RCS-4 among many others. These drugs generally do not cross-react with cannabinoid immunoassays, and will probably require detection levels of less than 1 ng/mL in blood, necessitating LC-MS(-MS) or other high-sensitivity mass-spectrometric techniques.

The predominant effects of concern with respect to the effects of cannabinoids on driving are sedation, vigilance, and the effects on concentration, divided attention, perception, and temporal and spatial orientation. The sedative effects can be similar to those of CNS depressants, and the associated driving behaviours are similar also, resulting in weaving, slowed responses and inattentiveness, frequently resulting in collisions.

The epidemiological literature with respect to cannabis has been reviewed extensively by Huestis (2001). Many of the underlying studies, however, suffer from a lack of appropriate control groups, and confounding factors (time, dose, duration, last use, combined use of cannabis with alcohol or other drugs, laboratory test cut-offs, etc.) make comparisons between these studies difficult. The ability to compare and compile study data is another reason for the international efforts towards standardised methods for drug testing in DUID research (Walsh *et al.* 2008).

In concert, however, the behavioural, epidemiological and toxicological studies that have been undertaken to date point towards a general picture of an overrepresentation of cannabinoid-positive blood, OF or urine samples (indicating use) in drivers involved in accidents or arrested for impaired driving, when compared with the general population. This has been further demonstrated in the recent roadside surveys discussed earlier (Bierness *et al.* 2010).

The second source of evidence for a relationship between cannabis use and driving impairment comes from laboratory-based tests of psychomotor performance. These studies often suffer from limitations on what dose of drug can ethically be administered to subjects and which subjects can be included. Studies may also be subject to observation effects in which the participants can exert greater effort because of the motivating factor of being under observation in the study. The value of the studies is that they can isolate and demonstrate decrements in specific measures of psychomotor and cognitive performance (e.g. tracking, reaction time, error rate, vigilance, learning, recall, divided attention). By extension, the evidence for impairment in the driving task after cannabis use, which incorporates many of these components, is verified. Laboratory-based studies suffer from a practical limit to which subjects can be dosed with recreational drugs; consequently, they probably underestimate the potential effect in chronic or frequent recreational users.

Finally, and perhaps most convincingly, a limited number of studies have been performed in which subjects have been administered cannabis and then tasked with driving in electronic driving simulators, or actually operating vehicles on open or closed driving courses. These studies have also been reviewed by Huestis (2001), and reveal evidence of significant mild-to-moderate decrements in driving performance at the doses given. In an early study, Klonoff (1974) tested the effects of low doses of THC (5–8.5 mg) on subjects who were then asked to undertake closed-course and on-street driving in an urban setting in Vancouver, Canada. The authors reported impairment of attentiveness (increased distractibility), problems with braking, bad judgement and difficulty in concentrating. These effects were most pronounced on city streets when the demands of the driving were greatest. Illustrating some of the contradictions of these studies, however, some drivers actually improved in performance after the cannabis dose. This highlights one of the mitigating effects of cannabis intoxication, whereby some subjects have demonstrated an ability to focus concentration on tasks for short periods of time and perform quite well. This has led to the conclusion that sustained attention, or vigilance, rather than attention in general is most affected by cannabis. This finding can explain why it may be difficult to demonstrate impairment in field sobriety tests, which by their nature are of short duration. A research group in Australia has studied the effects of marijuana smoking on standardised field sobriety tests (Papafotiou *et al.* 2005a). They found that there was a dose-dependent increase in errors in the field sobriety tests, with between 30% and 40% of subjects showing clear indicators of impairment. The same doses of marijuana produced impairment in driving performance (Papafotiou *et al.* 2005b).

On-road driving studies performed in the Netherlands (Robbe, O'Hanlon 1993, 1999) have produced other evidence of impairment. Volunteers smoked cannabis in doses of 100, 200 and 300 μg/kg (the latter being consistent with a 'user-preferred dose') and were assessed in an on-road driving task 40 and 100 minutes later. Drivers showed evidence of decrements in maintaining lateral vehicle position (weaving) at all doses, equivalent to blood alcohol levels of between 0.3 and 0.7 g/L. Importantly, no correlation was found between the blood THC concentrations and the degree of effect. Using similar methodology, the authors showed that, when cannabis was combined with alcohol, the effects of both drugs on driving were increased.

In summary, cannabis is a psychoactive drug that can influence mood, concentration and judgement, in addition to its sedating properties, all of which contribute in a dose-related fashion to impairment of vehicle operation. Compared with many other drugs, the level of impairment after mild-to-moderate single-dose recreational use is low, equivalent to a BAC in the range 0.3–0.7 g/L. Combining alcohol and cannabis produces a greater impairment than either alone, and cannabis use should be considered in determining the likely impairment in subjects with low BACs. The blood THC and metabolite concentrations are not well correlated with effect, although some authors have explored the possibility of relating these concentrations to time since last use (Huestis *et al.* 2005).

CNS stimulants

In contrast to the sedative drugs discussed above, stimulants generally increase neural activity, which, in moderation, may not be entirely detrimental. Caffeine can revive the drowsy driver, and patients with attention deficit hyperactivity disorder (ADHD) or narcolepsy can benefit from appropriate doses of methylphenidate or amfetamine. Just as these drugs can act to restore some balance in these individuals, they can upset the delicate neural homeostasis in a healthy individual. Stimulants, principally cocaine and the amfetamines, are used recreationally for their excitatory, euphorigenic properties. In this context they produce intense, overwhelming and distracting effects. After acute administration, users report feeling elated or powerful, having superior intellect and insight, and sexual arousal and stimulation. Time may appear to pass more quickly, speech becomes faster and less coherent, and users can become impatient and agitated, sometimes to the point of violence. These perceptual changes are accompanied by increases in pulse and blood pressure, pupillary dilatation, sweating and psychomotor restlessness, manifested as pacing, fidgeting and scratching. Simple reaction time may be improved under the influence of stimulants, but this is only one component of driving; in fact, complex reaction time, which demands impulse control, intelligent decision-making and appropriate response, may be affected adversely. The intensity of these effects depends on the dose, on the route of administration, and to some extent on the user's experience with, and tolerance of, the effects of the drug. Inevitably, these effects, when combined, are detrimental to complex task performance and make drivers less attentive, while the psychomotor excitation demands greater focus on muscle control and vehicle operation. These opposing effects result in poorer driving. As with any other drugs, the effects are likely to become more apparent when demands are high, such as when driving in bad weather, in heavy traffic, in an unfamiliar environment or in a defective vehicle.

In addition to these acute effects, humans display both acute and chronic tolerance of the effects of stimulants. With cocaine and the amfetamines, the initial excitatory, euphoric phase can be followed by a withdrawal phase, the intensity of which depends on the duration and intensity of drug use. Binges of metamfetamine use are generally longer, of the order of days, than those for cocaine use, for which binges typically run only to hours, and amfetamine withdrawal is often more severe. This is in part a reflection of the different half-lives of the drugs, with cocaine having a 1–2 h half-life, while for amfetamines it is of the order of 7–15 h. During excitation, there is some downregulation of the dopamine receptors, reduction in dopamine transporter activity and reduction in concentrations of the enzyme tyrosine hydroxylase, responsible for dopamine synthesis. This decline in dopamine activity has the opposite effect to that experienced during excitation. Subjects are typically fatigued, lack energy, can be irritable and depressed, and are anhedonic and dysphoric. Sometimes delusions and pseudohallucinations can occur, and the subject can become psychotic. Often this is called the 'crash' phase, during which the subjects sleep a fitful, restless sleep, sometimes for days in the case of metamfetamine withdrawal. During this phase, subjects can appear as if under the influence of a CNS-depressant or opiate, and a poorer complex task performance is expected, such as in driving a vehicle. Drivers have been reported as being lethargic, sleepy, with very poor lane travel (weaving), and frequently drive at high speed, drive off the road or drive into oncoming traffic.

Isenschmid (2001) and Logan (2001) reviewed the available epidemiological, psychomotor performance and anecdotal evidence for impairment in driving after stimulant use, from the effects of both the acute excitation and later withdrawal phases, and concluded that these effects are real and significant. Blood cocaine and amfetamine drug concentrations must be interpreted with caution, since a single blood drug measurement does not predict what phase of intoxication the subjects may be experiencing, and consequently what pattern of effects are likely to predominate. Nevertheless, blood drug concentrations can show whether drug use is consistent with recreational doses in the case of cocaine, and may help distinguish between legitimate dosing of amfetamines in the treatment of narcolepsy, ADHD or eating disorders, and recreational use. The doses of stimulant drugs required to produce the sought-after euphoric effects are accompanied inevitably by deterioration in driving performance.

Hallucinogens

Drugs with hallucinogenic properties have an obvious deleterious effect on driving. Inability to distinguish illusion from reality results in poor decision-making and consequently poorer driving. Drugs such as psylocibe mushrooms, mescaline, lysergide (LSD), ketamine and PCP can produce fully formed hallucinations, seeing objects, shapes or individuals that are not present, and synaesthesia or blending of sensory information such as 'seeing' sounds, or 'hearing' colours. Ketamine and its psychomotor effects on driving have been evaluated (Mozayani 2001). Many other drugs can produce milder hallucinations, including, as noted earlier, cannabis and stimulants.

Methylenedioxy-substituted amfetamines, such as MDMA (ecstasy), methylenedioxyamfetamine (MDA) or methylenedioxyethamfetamine (MDEA; Eve) can also produce hallucinations, particularly tactile ones, that enhance sensitivity to touch. However, the predominant impairing effects of that class of compounds appear to be more related to their excitatory and stimulant properties (Logan, Couper 2001).

Interpretation of results

In many jurisdictions, the law requires that the presence of drugs in blood should be quantified and reported to the court. This then poses the question 'If you have a quantitative measurement, what does it mean?'. Unlike alcohol, where a large body of information is available that enables the toxicologist to offer a generalised statement about the effects that might be expected when an individual has a known BAC, it is not possible to relate blood drug concentrations to drug effects or degrees of intoxication. Drugs affect different people in different ways and it is unlikely that anybody who has used a particular psychoactive drug will exhibit all of the signs and symptoms listed in the sections above to a noticeable degree. One approach to using quantitative results is to employ population profiles or cumulative frequency plots (Figure 5.1) to allow the results of a particular analysis to be compared with those of a population of drivers who have previously been classified as unfit to drive by qualified medical personnel. Examination of data plotted in this way allows the toxicologist to compare an analytical result against the frequency with which it has been encountered in a casework population. Although impairment and symptoms cannot be correlated directly with blood drug concentrations, cumulative data plots enable the toxicologist to assist the court by comparing specific case results against a population of drivers who have previously been certified as unfit to drive. For example, Figure 5.1 shows population profiles for diazepam, nordiazepam and temazepam in 354 cases where all three drugs were detected. According to this figure, a subject with a blood diazepam concentration of 2 μg/mL would have a higher concentration than 75% of the 354 cases previously reviewed. This provides the court with some context for understanding the drug concentration reported in any individual case.

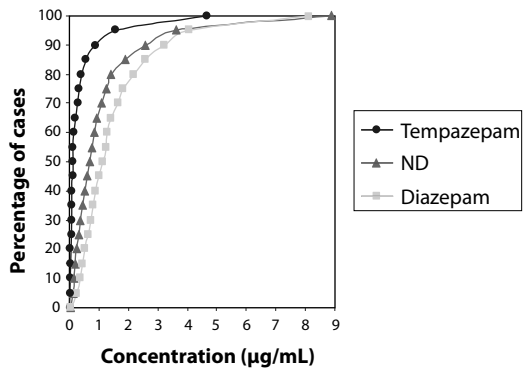

Figure 5.1 Cumulative frequency profiles for diazepam, nordiazepam (ND) and temazepam in 354 cases where all three drugs were detected.

CHAPTER

6 Drug Testing in Human Sport

DA Cowan

Introduction

Drug abuse in sport is often called doping, the international word 'dope' being used both as a noun and as a verb. This is thought to originate from the Dutch word 'doop' which means 'Christian baptism'. It seems likely that the religious fervour associated with this ceremony resulted in the use of the same word, in a somewhat cynical and contemptuous way, to describe the state of intoxication and euphoria induced by certain drugs. The word does not appear in this context before the twentieth century despite the practice of horse 'nobbling', which was known well before this time and is described separately in Chapter 7. The word appears to have come into use early in the twentieth century, and it is probably associated with the rise of the pharmaceutical industry.

The abuse of drugs in an attempt to enhance performance in human sporting competitions is not new. For example, the Greek authors Phylostratos and Galen commented on the ethics of competitors in the Olympics who would take any preparation to improve their performance. Roman gladiators were often drugged to make their fights more lusty and bloody as demanded by the spectators.

The effect of drugs on performance is often extremely difficult to determine, and there is little definitive published work for any species. The results that have been published are often conflicting; some workers suggest an increase in the competitor's performance and others suggest no improvement. The test system may not adequately relate to the appropriate sporting performance, such as increase in muscle strength and sprint running. Changes in speed of less than 1% cannot be demonstrated with statistical significance because of the many variable and uncontrollable factors, yet an improvement of only 1% represents a lead of 1 metre in a 100-metre sprint or 17.6 yards over 1 mile, which is an enormous lead in either race. Furthermore, athletes may take far larger amounts of drugs than would be ethically acceptable in most human experiments.

The toxic side-effects of drugs are less difficult to ascertain, but the conclusions drawn from the available data are often circumstantial (e.g. the possible links between taking anabolic steroids and liver cancer). Nevertheless, there is sufficient evidence of the harmful effects when certain drugs are misused to justify their prohibition from sports competitions.

Rules

In human sports, the main controlling body is the International Olympic Committee (IOC). However, since 2004 doping issues have been taken over by the World Anti-Doping Agency (WADA; originally called the International Anti-Doping Agency). The IOC and WADA jointly issued the Olympic Movement Anti-Doping Code, which defined doping as:

> The use of an expedient (substance or method) that is potentially harmful to athletes' health and/or capable of enhancing their performance, or
> The presence in the athlete's body of a prohibited substance or evidence of the use thereof or evidence of the use of a prohibited method.

The stated intention of the Medical Commission of the IOC was to ban those drugs that are likely to be harmful when misused, with the minimum of interference with the normal therapeutic use of drugs. Thus, a competitor who is undergoing a legitimate course of treatment is not disqualified.

However, this creates many problems in deciding which drugs should or should not be prohibited, and whether or not a competitor who requires a particular drug treatment should be allowed to compete.

WADA has recently published the new World Anti-Doping Code (WADA 2009h). In this document doping is defined as 'the occurrence of one or more of the anti-doping rule violations set forth in Article 2.1 through Article 2.8 of the Code'. WADA has published criteria that it uses when deciding what should be prohibited. Among these is Article 4.3.1.2 of the Code, which gives as one of the criteria for prohibiting a substance as 'Medical or other scientific evidence, pharmacological effect or experience that the *use* of the substance or method represents an actual or potential health risk to the *athlete*' (note that the italicised words are WADA-defined terms).

The IOC and now WADA list examples of prohibited drugs according to their pharmacological classification (Table 6.1), but the entries are often far from explicit, using the words 'and other substances with similar chemical structure or similar biological effect(s)'. For most substances, the mere presence of the substance or a diagnostic metabolite in the biological fluid sampled constitutes an offence, but for some substances (Table 6.2) there is a reporting threshold. Furthermore, certain methods are prohibited (Table 6.3); one category of which is to attempt to prevent detection of doping. WADA states that 'The use of any drug should be limited to medically justified indications'. It has a system in place (WADA 2009d) whereby athletes being treated with certain medications such as β_2-agonists may obtain a 'Therapeutic Use Exemption' certificate that will allow them to use that medication without contravening the WADA Code. WADA maintains a comprehensive set of guidance documents to help with the exemption process to permit needed medical treatment. Also WADA permits the use of certain substances (Table 6.4) other than during competitions. Finally, some sports prohibit additional substances (Table 6.5) and WADA publishes a comprehensive Prohibited List (WADA 2010b) each year.

Reported analytical findings

Data for human sports have been available since 1987 and are presented for the years 1987, 1990, 1995, 2000 and 2005 in Table 6.6. Figure 6.1 shows the proportion of samples analysed by WADA-accredited laboratories in the years 1988 to 2008 reported for the three most commonly found prohibited substances. Note the marked increase in the reporting of testosterone in recent years following the reduction of the reporting threshold by WADA. Note also the decrease in the reporting of salbutamol in the last 2 years following the increase in the reporting threshold by WADA.

Sampling

Sample collecting procedures must take into consideration both scientific and legal aspects:

- The health of the individual being sampled must be safeguarded.
- Incorrect labelling, contamination or sample switching must be avoided at the time of sample collection and subsequently.

Table 6.1 Substances prohibited by the World Anti-Doping Agency at all times

Category	Substance
Anabolic agents	1. Anabolic androgenic steroids (AAS)
	(a) Exogenous[(a)] *AAS, including:*
	1-androstendiol (5α-androst-1-ene-3β,17β-diol)**; 1-androstendione** (5α-androst-1-ene-3,17-dione)**; bolandiol** (19-norandrostenediol)**; bolasterone; boldenone; boldione** (androsta-1,4-diene-3,17-dione)**; calusterone; clostebol; danazol** (17α-ethynyl-17β-hydroxyandrost-4-eno[2,3-*d*]isoxazole)**; dehydrochlormethyltestosterone** (4-chloro-17β-hydroxy-17α-methylandrosta-1,4-dien-3-one)**; desoxymethyltestosterone** (17α-methyl-5α-androst-2-en-17β-ol)**; drostanolone; ethylestrenol** (19-nor-17α-pregn-4-en-17-ol)**; fluoxymesterone; formebolone; furazabol** (17β-hydroxy-17α-methyl-5α-androstano[2,3-*c*]-furazan)**; gestrinone; 4-hydroxytestosterone** (4,17β-dihydroxyandrost-4-en-3-one)**; mestanolone; mesterolone; metenolone; methandienone** (17β-hydroxy-17α-methylandrosta-1,4-dien-3-one)**; methandriol; methasterone** (2α, 17α-dimethyl-5α-androstane-3-one-17β-ol)**; methyldienolone** (17β-hydroxy-17α-methylestra-4,9-dien-3-one)**; methyl-1-testosterone** (17β-hydroxy-17α-methyl-5α-androst-1-en-3-one)**; methylnortestosterone** (17β-hydroxy-17α-methylestr-4-en-3-one)**; methyltrienolone** (17β-hydroxy-17α-methylestra-4,9,11-trien-3-one)**; methyltestosterone; mibolerone; nandrolone; 19-norandrostenedione** (estr-4-ene-3,17-dione)**; norboletone; norclostebol; norethandrolone; oxabolone; oxandrolone; oxymesterone; oxymetholone; prostanozol** (17β-hydroxy-5α-androstano[3,2-*c*] pyrazole)**; quinbolone; stanozolol; stenbolone; 1-testosterone** (17β-hydroxy-5α-androst-1-en-3-one)**; tetrahydrogestrinone** (18α-homo-pregna-4,9,11-trien-17β-ol-3-one)**; trenbolone** and other substances with a similar chemical structure or similar biological effect(s)
	(b) Endogenous[(b)] *AAS when administered exogenously:*
	androstenediol (androst-5-ene-3β,17β-diol)**; androstenedione** (androst-4-ene-3,17-dione)**; dihydrotestosterone** (17β-hydroxy-5α-androstan-3-one)**; prasterone** (dehydroepiandrosterone, DHEA)**; testosterone**
	and the following metabolites and isomers:
	5α-androstane-3α,17α-diol; 5α-androstane-3α,17β-diol; 5α-androstane-3β,17α-diol; 5α-androstane-3β,17β-diol; androst-4-ene-3α,17α-diol; androst-4-ene-3α,17β-diol; androst-4-ene-3β,17α-diol; androst-5-ene-3α,17α-diol; androst-5-ene-3α,17β-diol; androst-5-ene-3β,17α-diol; 4-androstenediol (androst-4-ene-3β,17β-diol); **5-androstenedione** (androst-5-ene-3,17-dione); **epi-dihydrotestosterone; epitestosterone; 3α-hydroxy-5α-androstan-17-one; 3β-hydroxy-5α-androstan-17-one; 19-norandrosterone; 19-noretiocholanolone**
	2. Other anabolic agents, including but not limited to:
	Clenbuterol, selective androgen receptor modulators (SARMs), tibolone, zeranol, zilpaterol
Hormones and related substances	The following substances and their releasing factors are prohibited: 1. **Erythropoiesis-stimulating agents (e.g. erythropoietin (EPO), darbepoietin (dEPO), haematide)** 2. **Growth hormone (GH), insulin-like growth factors (**e.g. **IGF-1), mechano growth factors (MGFs)** 3. **Chorionic gonadotrophin (CG) and luteinizing hormone (LH) in males** 4. **Insulins** 5. **Corticotrophins** and other substances with similar chemical structure or similar biological effect(s)
β_2-Agonists	**All β_2-agonists including their D- and L-isomers are prohibited.**
	Therefore, formoterol, salbutamol, salmeterol and terbutaline when administered by inhalation also require a Therapeutic Use Exemption in accordance with the relevant section of the International Standard for Therapeutic Use Exemptions
	Despite the granting of a Therapeutic Use Exemption, the presence of salbutamol in urine in excess of 1000 μg/L will be considered as an *Adverse Analytical Finding* unless the *Athlete* proves, through a controlled pharmacokinetic study, that the abnormal result was the consequence of the use of a therapeutic dose of inhaled salbutamol
Hormone antagonists and modulators	The following classes are prohibited: 1. **Aromatase inhibitors** including, but not limited to: **anastrozole, letrozole, aminoglutethimide, exemestane, formestane, testolactone** 2. **Selective oestrogen receptor modulators (SERMs)** including, but not limited to: **raloxifene, tamoxifen, toremifene** 3. **Other anti-oestrogenic substances** including, but not limited to: **clomiphene, cyclofenil, fulvestrant** 4. **Agents modifying myostatin function(s)** including but not limited to: **myostatin inhibitors**
Diuretics and other masking agents	**Masking agents are prohibited**. They include: **Diuretics, probenecid, plasma expanders** (e.g. IV administration of **albumin, dextran, hydroxyethyl starch** and **mannitol**) and other substances with similar biological effect(s) Diuretics include: **acetazolamide, amiloride, bumetanide, canrenone, chlorthalidone, etacrynic acid, furosemide, indapamide, metolazone, spironolactone, thiazides** (e.g. **bendroflumethiazide, chlorothiazide, hydrochlorothiazide**), **triamterene**, and other substances with a similar chemical structure or similar biological effect(s) (except drosperinone and topical dorzolamide and brinzolamide, which are not prohibited)

[(a)] 'Exogenous' refers to a substance that is not ordinarily capable of being produced by the body naturally.
[(b)] 'Endogenous' refers to a substance that is capable of being produced by the body naturally.

Table 6.2 WADA Code. Summary of urinary concentrations above which WADA-accredited laboratories must report findings for specific substances (WADA 2009f)

Substance	*Urinary concentration to be reported*
Carboxy-THC[a]	>15 µg/L
Cathine[b]	>5 mg/L
Ephedrine	>10 mg/L
Epitestosterone[c]	>200 µg/L
Methylephedrine	>10 mg/L
Morphine[d][e]	>1 mg/L
19-Norandrosterone[c]	>2 µg/L
Salbutamol[d][f]	>1 mg/L
testosterone/epitestosterone (T/E) ratio[g]	>4

[a] 11-Nor-delta 9-tetrahydrocannabinol-9-carboxylic acid.
[b] Unless it may be as a metabolite of a permitted substance such as pseudoephedrine.
[c] Threshold adjusted if specific gravity >1.020.
[d] Sum of glucuronide conjugate and free drug concentrations.
[e] Unless it may be as a metabolite of a permitted substance such as codeine.
[f] Concentrations greater than 500 µg/L and less than 1 mg/L should be reported as consistent with the use of a β_2-agonist.
[g] Testosterone/epitestosterone ratio. Although a report must be issued for samples with a T/E ratio greater than 4, samples with lower ratios must also be reported if there is evidence of an exogenous origin of testosterone.

Table 6.3 Methods prohibited by the World Anti-Doping Agency at all times

Enhancement of oxygen transfer

The following are prohibited:

1. Blood doping, including the use of autologous, homologous or heterologous blood or red blood cell products of any origin
2. Artificially enhancing the uptake, transport or delivery of oxygen, including but not limited to perfluorochemicals, efaproxiral (RSR13) and modified haemoglobin products (e.g. haemoglobin-based blood substitutes, microencapsulated haemoglobin products)

Chemical and physical manipulation

1. Tampering, or attempting to tamper, in order to alter the integrity and validity of Samples collected during Doping Controls is prohibited. These include but are not limited to catheterisation, urine substitution and/or alteration
2. Intravenous infusions are prohibited except in the management of surgical procedures, medical emergencies or clinical investigations

Gene doping

The transfer of cells or genetic elements or the use of cells, genetic elements or pharmacological agents to modulate expression of endogenous genes having the capacity to enhance athletic performance is prohibited **Peroxisome proliferator activated receptor** δ (PPARδ) **agonists** (e.g. GW 1516) and **PPARδ-AMP-activated protein kinase** (AMPK) **axis agonists** (e.g. AICAR) **are prohibited**

Table 6.4 Substances prohibited by the World Anti-Doping Agency only in-competition

Stimulants	All stimulants (including both their D- and L- optical isomers where relevant) are prohibited, except imidazole derivatives for topical use and those stimulants included in the 2009 Monitoring Program[a] Stimulants include: *(a) Non-specified stimulants:* Adrafinil; amfepramone; amiphenazole; amfetamine; amfetaminil; benzphetamine; benzylpiperazine; bromantan; clobenzorex; cocaine; cropropamide; crotetamide; dimethylamfetamine; etilamfetamine; famprofazone; fencamine; fenetylline; fenfluramine; fenproporex; furfenorex; mefenorex; mephentermine; mesocarb; methamfetamine (D-); methylenedioxyamfetamine; methylenedioxymethamfetamine; *p*-methylamfetamine; modafinil; norfenfluramine; phendimetrazine; phenmetrazine; phentermine; 4-phenylpiracetam (carphedon); prolintane A stimulant not expressly listed in this section is a Specified Substance *(b) Specified stimulants (examples):* Adrenaline[b]; cathine[c]; ephedrine[d]; etamivan; etilefrine; fenbutrazate; fencamfamin; heptaminol; isometheptene; levmetamfetamine; meclofenoxate; methylephedrine[d]; methylphenidate; nikethamide; norfenefrine; octopamine; oxilofrine; *p*-hydroxyamfetamine; pemoline; pentetrazol; phenpromethamine; propylhexedrine; selegiline; sibutramine; strychnine; tuaminoheptane and other substances with a similar chemical structure or similar biological effect(s)
Narcotics	The following narcotics are prohibited: **Buprenorphine, dextromoramide, diamorphine (heroin), fentanyl and its derivatives, hydromorphone, methadone, morphine, oxycodone, oxymorphone, pentazocine, pethidine**
Cannabinoids	Cannabinoids (e.g. hashish, marijuana) are prohibited
Glucocorticosteroids*	All glucocorticosteroids are prohibited when administered by oral, intravenous, intramuscular or rectal routes In accordance with the International Standard for Therapeutic Use Exemptions, a declaration of use must be completed by the Athlete for glucocorticosteroids administered by intra-articular, periarticular, peritendinous, epidural, intradermal and inhalation routes, except as noted below Topical preparations when used for auricular, buccal, dermatological (including iontophoresis/phonophoresis), gingival, nasal, ophthalmic and perianal disorders are not prohibited and require neither a Therapeutic Use Exemption nor a declaration of use

[a] The following substances included in the 2009 Monitoring Program (bupropion, caffeine, phenylephrine, phenylpropanolamine, pipradol, pseudoephedrine, synephrine) are not considered as Prohibited Substances.
[b] **Adrenaline** associated with local anaesthetic agents or by local administration (e.g. nasal, ophthalmological) is not prohibited.
[c] **Cathine** is prohibited when its concentration in urine is greater than 5 mg/L.
[d] Each of **ephedrine** and **methylephedrine** is prohibited when its concentration in urine is greater than 10 mg/L.
[e] WADA use the term 'glucocorticosteroid' for what is more conventionally known as a corticosteroid.

- The rights of the individual or team must be safeguarded against error by the analyst.

Samples in human sport are now usually collected by agencies certified in accordance with the ISO 9001 standard (www.iso.org/iso/iso_catalogue/management_standards/iso_9000_iso_14000.htm) and using doping control officers who have been appropriately trained to collect the samples. Apart from its Code (WADA 2009h), WADA publishes an International Standard for Testing (WADA 2009c), which incorporates elements from ISO/PAS 18873 (which was withdrawn in 2005) and the ISO 9000 series of quality management system standards. WADA and most international federations always provide a second portion of the sample for defence use. This is to be opened only after the first sample has been found to contain a banned drug, and after the competitor has been notified and invited to attend the second analysis, with his or her own expert if the competitor so wishes.

Table 6.5 Substances prohibited by particular sports and only in-competition	
Alcohol	Alcohol (ethanol) is prohibited in-competition only, in the following sports. Detection will be conducted by analysis of breath and/or blood. The doping violation threshold (haematological values) is 0.10 g/L. ■ Aeronautic (FAI) ■ Archery (FITA, IPC) ■ Automobile (FIA) ■ Boules (IPC bowls) ■ Karate (WKF) ■ Modern Pentathlon (UIPM) for disciplines involving shooting ■ Motorcycling (FIM) ■ Ninepin and Tenpin Bowling (FIQ) ■ Powerboating (UIM)
Beta-blockers	Unless otherwise specified, beta-blockers are prohibited in-competition only, in the following sports. ■ Aeronautic (FAI) ■ Archery (FITA, IPC) (also prohibited Out-of-Competition) ■ Automobile (FIA) ■ Billiards and Snooker (WCBS) ■ Bobsleigh (FIBT) ■ Boules (CMSB, IPC bowls) ■ Bridge (FMB) ■ Curling (WCF) ■ Golf (IGF) ■ Gymnastics (FIG) ■ Motorcycling (FIM) ■ Modern Pentathlon (UIPM) for disciplines involving shooting ■ Ninepin and Tenpin Bowling (FIQ) ■ Powerboating (UIM) ■ Sailing (ISAF) for match race helms only ■ Shooting (ISSF, IPC) (also prohibited Out-of-Competition) ■ Skiing/Snowboarding (FIS) in ski jumping, freestyle aerials/halfpipe and snowboard halfpipe/big air ■ Wrestling (FILA) Beta-blockers include, but are not limited to, the following: **acebutolol, alprenolol, atenolol, betaxolol, bisoprolol, bunolol, carteolol, carvedilol, celiprolol, esmolol, labetalol, levobunolol, metipranolol, metoprolol, nadolol, oxprenolol, pindolol, propranolol, sotalol, timolol**

Urine

Urine is the preferred body fluid. Its collection is non-invasive, it is generally available in sufficient quantity, and the drugs or their metabolites tend to be present in relatively high concentrations. The disadvantages are that a drug may be present as its metabolites or in a conjugated form, and the parent drug may be present only in a relatively low concentration. Furthermore, the relationship with the concentration in blood is very imprecise.

Substitution of samples is clearly a possibility that must be avoided and particular care is required during the period of waiting before a sample is obtained to balance this risk against the desire for privacy on the part of a person. It has been reported that racing cyclists have carried a rubber bladder of (negative) urine under their arm, connected by a rubber tube to the appropriate discharge point.

Blood

The principal advantage of a blood sample is that its integrity is easier to safeguard because it is usually collected by a doctor or phlebotomist experienced in the procedure. In addition, drug concentrations in blood are interpreted more easily than those in urine and certain drugs that are not excreted in urine in significant quantities (e.g. human growth hormone) can be detected in blood. Since the 2000 Olympic Games in Sydney, blood has been collected routinely by some federations (e.g. the International Cycling Union) as a 'health check'. Any competitor whose haematocrit is above 50% is not permitted to compete. This test is intended to limit the use of erythropoietin (EPO) to stimulate red cell production. However, this haematocrit test is readily circumvented and depends on too many factors; the use of haemoglobin concentration is preferred. Furthermore, blood samples may also be collected for more sophisticated tests to indicate the use of EPO. In addition, the administration of small doses (so-called micro-dosing) of EPO has been shown (Ashenden *et al.* 2006) to reduce the chance of detection of EPO use and yet still raise haemoglobin concentrations, hence the need to collect blood samples. Recently, tests for recombinant human growth hormone (rhGH) administration and for blood transfusion have been developed (see later) that rely on the use of blood samples.

Other matrices

At the present time, WADA does not permit the use of alternative biological matrices such as oral fluid or hair to counter an analytical finding obtained from either a urine or blood sample. Nevertheless, Kintz has reviewed hair testing and doping control in human sport (Kintz 1998) and an interesting case report of its use in detecting a variety of prohibited substances in body builders has been published (Dumestre-Toulet *et al.* 2002) (see Chapter 19).

Table 6.6 Prohibited substances most commonly reported by WADA-accredited laboratories, in order of frequency[(a)]

Number of reports									
Substance	***1987***	***Substance***	***1990***	***Substance***	***1995***	***Substance***	***2000***	***Substance***	***2005***
Nandrolone	262	Nandrolone	192	Testosterone	293	Salbutamol	367	Testosterone	1132
Pseudoephedrine	100	Testosterone	171	Cannabis	224	Nandrolone	325	Cannabis	503
Testosterone	83	Pseudoephedrine	123	Nandrolone	212	Testosterone	306	Salbutamol	357
Ephedrine	58	Stanozolol	79	Methandienone	132	Cannabis	295	Nandrolone	298
Phenylpropanolamine	57	Phenylpropanolamine	64	Salbutamol	132	Pseudoephedrine	136	Stanozolol	233

Amfetamine	24	Methandienone	23	Clenbuterol	31	Lidocaine	64	Ephedrine	93

[(a)] 1987 was first year of available data.

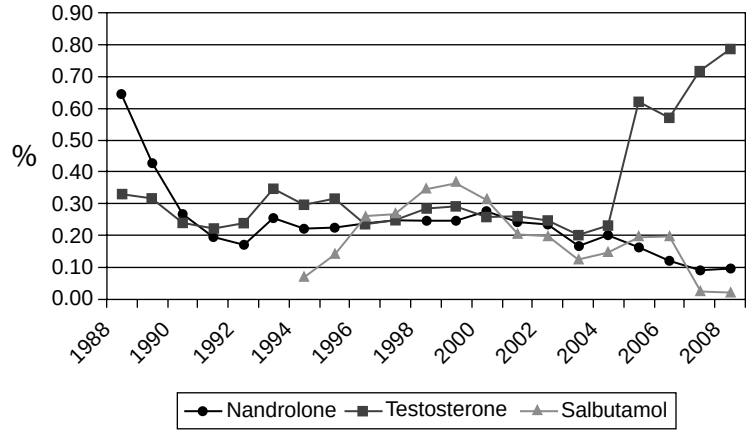

Figure 6.1 The proportion of human sports samples analysed by WADA-accredited laboratories in the years 1988 to 2008 reported for the three prohibited substances most commonly found.

Analytical approach

With the exception of anabolic steroids, prohibited substances are generally administered at or near the therapeutic dose, which results in relatively low concentrations in biological fluids. The laboratory is provided with a coded sample to preserve the anonymity of the athlete. They may also be given a declaration of any drug that has recently been taken by the athlete but, apart from that, there is usually no evidence whether or not a drug has been administered, or what sort of drug it might be. As with equine testing, any drug used in human treatment or in veterinary practice may be found. Thus, screening procedures are designed to be both sensitive and of wide coverage. The material analysed is usually in a fairly fresh condition. The analyst thus has a clearer picture of a normal sample than does the forensic or hospital chemist, who may be required to examine a wide variety of materials in various states of decomposition. Any sample that fails a screening test is invariably submitted to rigorous confirmatory testing (see below) before an adverse report is issued. The WADA-accredited laboratory must reliably be able to detect and confirm the presence of prohibited substances or their metabolites at least down to a minimum required performance level (MRPL; see Table 6.7) (WADA 2009f).

However, WADA states that 'for non-threshold substances prohibited in-competition only, it is not recommended that laboratories report below 10% of the MRPL'. This refers to stimulants, narcotics and beta-blockers only (the latter being prohibited only by particular sports) since, for glucocorticoids, WADA states that 'laboratories are not to report below the MRPL'.

Although, with some exceptions, the parent drug is the entity that appears in the Prohibited List, screening procedures rely upon the detection of either the unchanged drug or its metabolites. The identification of the corresponding metabolites is often useful supplementary evidence to support the identification of the parent drug, and indeed WADA expects the laboratory to identify as many of the presumptive analytical findings from the screening procedures as possible. In addition, the presence of metabolites in the appropriate concentrations relative to the parent drug helps to support the conclusion that a drug has been administered. Conversely, the absence of any expected metabolites is possible evidence that a sample has been contaminated; this should be refutable by a proper chain of custody. Occasionally, the parent drug is not excreted in urine at a detectable concentration and a knowledge of the metabolic pathways is thus essential. An example of this is the identification of 19-norandrosterone and 19-noretiocholanolone (Fig. 6.2) in the urine of humans as evidence of the administration of the anabolic steroid nandrolone or a 19-norsteroid precursor.

Drugs can be used either to improve or to impair athletic performance, though in human sport the latter category of drug is

Table 6.7 Minimum required performance levels

Prohibited class	*Specific examples/ exceptions*	*Concentration*
Stimulants		0.5 mg/L
	Strychnine	0.2 mg/L
Narcotics		0.2 mg/L
	Buprenorphine	10 µg/L
Anabolic agents		10 µg/L
	Clenbuterol	2 µg/L
	Methandienone	2 µg/L
	Methyltestosterone	2 µg/L
	Stanozolol	2 µg/L
	Epitestosterone	2 µg/L
Hormone antagonists and modulators	Aromatase inhibitors, SERMs and other anti-oestrogenic substances	50 µg/L
Beta$_2$-Agonists		100 µg/L
Beta-blockers		0.5 mg/L
Diuretics		0.25 mg/L
Glucocorticosteroids		30 µg/L
Peptide hormones	hCG	5 IU/L

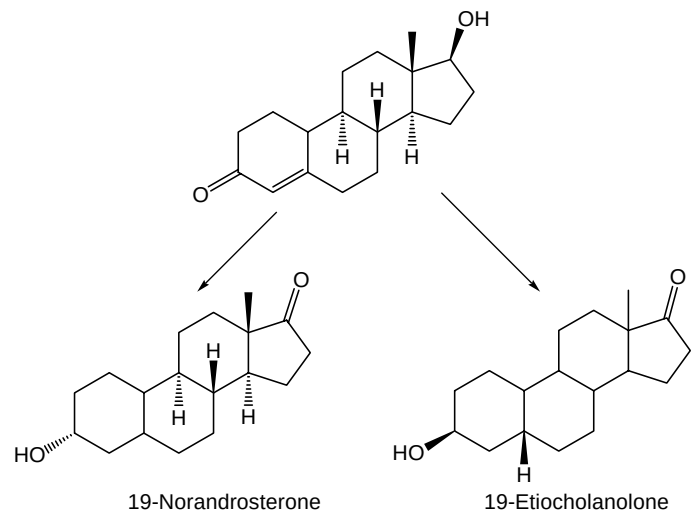

Figure 6.2 Main metabolites of nandrolone (19-norandrosterone).

unlikely to be used. No single analytical scheme will suffice to cover so many different types of compound; various approaches have evolved in sports drug testing laboratories to address this challenge.

Some drugs are notable for being excreted in urine almost entirely in conjugated form as, for instance, most anabolic steroids. When the presence of these drugs is suspected, hydrolysis before extraction is essential, although liquid chromatography–tandem mass spectrometry (LC-MS(-MS)) of intact conjugates is starting to be used.

Liquid–liquid extraction may be used, for example with alkalinisation of the urine, to prepare samples for the detection of basic drugs by gas chromatography (GC) with nitrogen-selective detection. Alternatively, drugs have been extracted on the styrene–divinylbenzene copolymer XAD-2 resin. The development of solid-phase extraction (SPE) in the cartridge format in the late 1970s (Shackleton, Whitney 1980) and the rapid advances made in the technology associated with the technique have provided an attractive alternative to liquid–liquid extraction in many drug-screening programmes. Immunochemical methods that covered anabolic steroids were first introduced into human drug screening programmes in the 1970s (Brooks *et al.* 1979). However, in the late 1980s, these were largely replaced by GC-MS methods. Unlike many horseracing drug testing laboratories, human sports drug testing laboratories have not employed thin-layer chromatography (TLC) and do not use enzyme-linked immunosorbent assay (ELISA) extensively, but have used XAD-2 resin in columns for sample extraction and now, more commonly C_8 and C_{18} SPE.

Instrumental methods based on GC-MS, GC–high resolution mass spectrometry (GC-HRMS), GC-MS(-MS) and LC-MS(-MS) are preferred by most laboratories.

Solvent extraction

In general, the choice of solvent is dictated by the wide range of drugs to be covered, or the need to extract a specific drug as in confirmatory analysis procedures.

In many sports drug testing laboratories throughout the world, SPE has replaced liquid–liquid extraction for the isolation of drugs from both urine and plasma. Based upon the studies of Shackleton and Whitney (1980), the use of C_{18} or C_8 bonded-phase cartridges for the isolation of anabolic steroids and their metabolites is the most common approach for sample extraction.

Sample preparation

Extraction method for drugs and metabolites

Note the initial pH and specific gravity of each sample.

Basic drugs

1. Take an aliquot (4.0 mL) of each urine sample in a 10 mL centrifuge tube.
2. Add 0.5 mL of 5 mol/L potassium hydroxide solution, approximately 3 g of sodium chloride, 100 µL of diphenylamine as a reference standard solution (80 mg/L, final concentration 2 mg/L) and 1.6 mL of *t*-butyl methyl ether.
3. Vortex thoroughly and then mix for at least 10 min on a rotary mixer.
4. Centrifuge to separate the phases at 800*g* for 5 min.
5. Remove about 1 mL of the ethereal layer and transfer to an autosampler vial containing approximately 20 mg of anhydrous sodium sulfate to dry the extract (take care that none of the lower aqueous layer is transferred).
6. Examine 2 µL of this extract by GC using a cross-linked 5% phenylmethylsilicone-fused silica column (12.5 m × 0.32 mm i.d., 0.52 µm) using nitrogen–phosphorus detection.

The use of sodium chloride to increase the ionic strength of the aqueous phase increases the extraction of many of the compounds into the ether, which obviates the need for solvent evaporation. Although some polar compounds, such as ephedrine, are readily extracted in this procedure, it is best suited to less polar compounds.

Anabolic steroids and corticosteroids

1. Condition C_{18} or C_8 SPE cartridges with methanol and then water. Add 4 mL of the urine sample.
2. Wash with an equal volume of water and then elute the adsorbed steroids with an equal volume of methanol.
3. Remove the methanol under nitrogen, dissolve the residue in 1 mL of 0.1 mol/L phosphate buffer (pH 6.2) containing β-glucuronidase from *Escherichia coli* (approximately 1.4 units using 4-nitrophenyl-β-D-glucuronide as the substrate at 37°C).
4. Incubate for either a minimum of 2 h at 50°C or overnight at 37°C.
5. Cool and add approximately 100 mg potassium carbonate and extract the steroids with 5 mL distilled diethyl ether.
6. Divide the ether into two portions.
7. Evaporate each portion under nitrogen, dry the residue in a vacuum desiccator over phosphorus pentoxide–potassium hydroxide.
8. To one portion, add 200 µL of LC mobile phase, transfer to an autosampler vial and immediately cap the vial.
9. Examine the solution by LC-MS(-MS) for corticosteroids (and anabolic steroids such as tetrahydrogestrinone that are not amenable to trimethylsilylation for GC-MS analysis).
10. Derivatise the other portion by the addition of 100 µL N-methyl-N-trimethylsilyl-trifluoroacetamide–ammonium iodide–ethanethiol (1000 : 2:6) and heating at 60°C for at least 15 min.
11. Examine the solution by capillary column GC-MS.

Mass spectral and chromatographic data for many anabolic steroids and their metabolites have been published by Ayotte *et al.* (1996) and are given as system GAI (see Chapter 40):

- Column: methylsilicone fused silica (25 m × 0.2 mm i.d., 0.11 µm), connected to a mass spectrometer.
- Temperature programme: 180°C for 1 min to 280°C at 8°/min.
- Carrier gas: He.

Diuretics

1. Take an aliquot (2.0 mL) of each urine sample in a 10 mL centrifuge tube.
2. Add 100 µL mefruside internal standard (10 µg/mL) and 2 mL 0.1 mol/L acetate buffer (pH 5.2).
3. Vortex thoroughly for 30 s.
4. Decant the urine onto a cross-linked polymeric sorbent cartridge with hydrophilic and lipophilic moieties (such as Abselut Nexus) and allow it to pass through the column. Do not let the bed dry out.
5. Add 1 mL of purified water onto each cartridge and allow it to pass through the column. Do not let the bed dry out.
6. Add 1 mL of methanol–water (20 : 80) onto each cartridge and allow it to pass through the column. Apply vacuum to the column to dry the bed.
7. Release the vacuum and place a labelled 10 mL glass centrifuge tube under the cartridge to collect the sample eluent.
8. Elute the adsorbed compounds with 3 mL methanol under gravity and then with the aid of a vacuum for a minimum of 30 s to dry the bed and achieve maximum recovery.
9. Evaporate the methanolic solution to dryness using oxygen-free nitrogen at 60°C.
10. Reconstitute the samples by adding 200 µL of LC mobile phase.
11. Vortex; transfer the reconstituted extract to a 0.2 mL tapered autosampler vial and cap the vial securely.
12. Examine 10 µL of the solution by LC-MS(-MS) for diuretics.

Gas chromatography and gas chromatography–mass spectrometry

The GC procedures referred to above detect a wide range of compounds in urine samples, at concentrations in the order of 0.1 mg/L. They depend on the fact that all the compounds of interest contain at least one nitrogen atom and produce a signal in an alkali flame-ionisation

detector. The methods of extraction and the selectivity of the detector ensure minimal interference from other compounds that do not contain nitrogen, although certain plasticisers that contain phosphorus, such as tributyl phosphate, may produce signals. In addition, other nitrogen-containing compounds that are not prohibited in human sport (e.g. antihistamines) produce interfering peaks.

Identification is based on the retention index; alternatively, retention time (relative to a standard) may be used. Details of retention indices or relative retention times of compounds in the systems described below are given in Chapter 40 and in the index of Gas Chromatographic Data.

The identity of a substance should be confirmed using derivative formation and GC-MS, comparing the data obtained with reference material analysed contemporaneously (see Criteria for identification below).

Liquid chromatography–mass spectrometry

With the development of atmospheric-pressure ionisation (API) techniques, LC-MS has found increasing application in doping control for both the qualitative and quantitative analysis of drugs. Screening methods have been developed for corticosteroids (Deventer, Delbeke 2003; Mazzarino, Botré 2006) and diuretics (Deventer *et al.* 2002; Ventura *et al.* 2008).

In human sports drug testing, LC-MS(-MS) has been used more frequently over the last 10 years. For example, Barrón *et al.* (1996) developed a direct method to determine anabolic steroids in human urine by on-line SPE LC-MS with a particle beam interface. Bean and Henion showed that it was possible to determine intact, i.e. conjugated, anabolic steroids using LC-electrospray ionisation (ESI)-MS(-MS) (Bean, Henion 1997). Thevis and colleagues used LC-MS(-MS) for the rapid screening of samples for beta-blockers (Thevis *et al.* 2001). Diuretics have been screened by LC-MS techniques (Ventura *et al.* 1991) and by LC-MS(-MS) (Thieme *et al.* 2001).

Recently, the use of sub-2 μm porous particles to enable faster separations and greater separation power has become possible (Mazzeo *et al.* 2005). High-pressure pumping systems (greater than the conventional 400 bar [40 MPa] limit) needed to obtain the linear velocities desired are now readily available. Although the frictional heating caused by the velocity of the mobile phase through the column can limit the benefit that can be obtained using small particles, the use of 2.1 mm and narrower internal diameter columns has minimised this potential difficulty. Thörngren and colleagues have used ultra-performance liquid chromatography (UPLC)-MS(-MS) to screen 130 different substances (diuretics, masking agents, central nervous system stimulants and opiates) in urine (Thörngren *et al.* 2008) in approximately 6 min.

Isotope ratio mass spectrometry

Combustion isotope ratio MS (CIRMS) is now used routinely by several WADA-accredited laboratories as an additional tool to help distinguish an individual whose testosterone : epitestosterone ratio may be naturally beyond the normal range from one who was administered testosterone. This technique relies on the fact that synthetic testosterone has a different proportion of ^{13}C to the more abundant ^{12}C than the normal endogenous steroid (de la Torre *et al.* 2001). The extracted steroids are separated by GC and then converted into CO_2 and the relative amounts of ^{12}C to ^{13}C as CO_2 is determined for each eluting steroid in turn. Typically, the testosterone metabolites androsterone and etiocholanolone or androstanediols are monitored (Aguilera *et al.* 2000), or the metabolites 5α-androstanediol and 5β-androstanediol (Aguilera *et al.* 2001; Shackleton *et al.* 1997b), often comparing the results with pregnanediol or pregnanetriol as endogenous internal standards (Aguilera *et al.* 1999; Shackleton *et al.* 1997a). Flenker and colleagues and Cawley and colleagues have published reference isotope ratios for endogenous steroids (Cawley *et al.* 2009; Flenker *et al.* 2008) and Cawley has also published a method for the direct analysis of testosterone rather than its metabolites (Cawley *et al.* 2009). Grosse and colleagues have shown that, in some urine samples, 19-norsteroids may be produced in small quantities from endogenous steroids (Grosse *et al.* 2005). Hebestreit and co-workers have published a method to distinguish this or the minute amounts that may be produced, especially in females, from the administration of nandrolone (Hebestreit *et al.* 2006). Buisson and colleagues (2009) have also used GC-CIRMS to detect exogenous hydrocortisone administration. Cawley and Flenker have published a tutorial article that reviews the use of CIRMS in doping control (Cawley, Flenker 2008).

Methods

In human sports drug testing, MS is essential for the definite identification of a prohibited substance, with the exception of peptide hormones and glycoproteins, such as human chorionic gonadotrophin (hCG) for which a validated immunoassay is required for detection and quantification. For confirmation of hCG, a second different immunoassay is required. Specific techniques and methodologies for other peptide hormones and glycoproteins such as EPO have been described by WADA (WADA 2009a) and one for recombinant hCG (rhGH) is currently being considered.

Criteria for identification

WADA requires laboratories to be accredited to ISO 17025 to be eligible for WADA accreditation. ISO/IEC 17025 : 2005 requires traceability of measurements and for sports drug testing this is considered to be met by WADA, when identifying a prohibited substance (WADA 2003), by the direct comparison with a reference material or reference collection analysed in parallel or in series with the test sample. A reference material is generally accepted as a homogeneous, stable chemical with a well-established structure. The material may be characterised structurally within the laboratory using appropriate techniques or validated against a certified reference material or by comparison with uncontroversial published data. WADA permits the use of a reference collection 'obtained from a verified administration study in which scientific documentation of the identity of metabolite(s) can be demonstrated' (WADA 2009b). Certified reference materials issued by organisations accredited for compliance with ISO Guide 34 : 2000 are often not available and hence there is the need to use authenticated administrations for comparison purposes. Many of the most common substances are now available with certificates of analysis, and thereby fully meet the generic traceability requirements of ISO/IEC 17025 : 2005. This is particularly important for quantitative analysis, where it is usually extremely difficult for an individual laboratory to determine the purity of a non-certified material to a sufficient standard to be able to establish the measurement uncertainty.

WADA generally expects a chromatographic retention time match between the analyte and a reference collection sample (see above) or reference material analysed using the same procedure in the same assay. This retention time difference must be not more than 1% or ±0.2 min, whichever is the smaller, and three diagnostic ions in the electron impact (EI) and chemical ionisation (CI) mass spectra must also match to within 20% of the relative abundance of each ion (Table 6.8). Figure 6.3 illustrates the relative abundance criteria that, paradoxically, show a step change for the data obtained using CI, LC or tandem MS. These standards generally meet or exceed those required by the Substance Abuse and Mental Health Services Administration (SAMHSA) for the US federal employment drug testing programmes (see also Chapter 3). Although library data may be useful in the early phase of substance identification, especially in generic screening procedures, they are not considered sufficiently reliable for the final identification. Similarly, published data are used more to assure reliability than directly for substance identification.

The required documentation for the analytical certificate is clearly set out in ISO/IEC 17025 : 2005 but merely requires a statement as to the substance found. However, WADA also sets out a

Table 6.8 Maximum relative ion intensity tolerances for substance identification using MS

Relative abundance (% of base peak)	*EI-GC-MS*	*CI-GC-MS; GC-MS^n; LC-MS; LC-MS^n*
>50%	±10% (absolute)	±15% (absolute)
25–50%	±20% (relative)	±25% (relative)
<25%	±5% (absolute)	±10% (absolute)

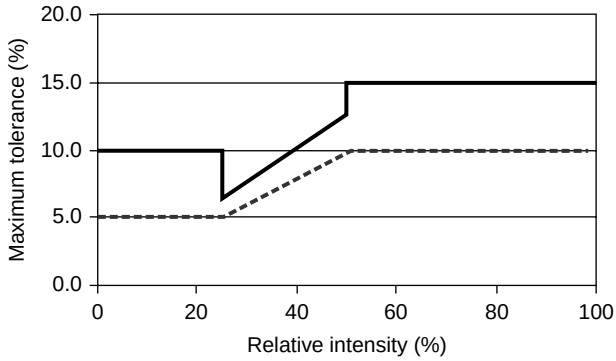

Figure 6.3 Graphical representation of WADA Maximum Tolerance Windows for relative abundances. Dashed line, EI-GC/MS data; solid line, CI-GC/MS, GC/MS^n, LC/MS and LC/MS^n.

standardised documentation package (WADA 2009e) to be provided in accordance with the International Standard for Laboratories (WADA 2009b) in support of a so-called Adverse Analytical Finding to avoid grounds for claims by lawyers that data are being concealed.

Threshold analysis

Thresholds may be set either in the rules for laboratory reporting (WADA 2009f) or as a penalty threshold (WADA 2009h). In either case, the laboratory needs a protocol to determine whether the specified threshold has been exceeded. Fully validated assays are used in these cases, with suitable standards and quality control samples run concurrently with the sample being assessed to assure the assay validity. Measurement uncertainty must be determined as part of the assay and validation (see Chapter 20 and Chapter 23). This uncertainty must be stated together with the mean result from three determinations whenever a quantitative result is included in the analytical report. Furthermore, the mean result must be greater than the reporting threshold, having taken into account the measurement uncertainty with the coverage factor, *k*, at a 95% confidence level. WADA has recently published a 'guard band' approach, whereby the group measurement uncertainty of its accredited laboratories has been assessed for the determination of 19-norandrosterone and used to determine whether a measured concentration exceeds the reporting threshold (WADA 2009g).

Drugs misused in sport

As described earlier, drugs misused in sport include anabolic steroids, stimulants, narcotics, corticosteroids and diuretics. Of particular interest are the anabolic steroids and corticosteroids; not only may synthetic analogues of endogenous substances be misused, but also testosterone or hydrocortisone (i.e. chemically or biosynthetically produced). This use of a pseudoendogenous compound that is either indistinguishable, or distinguishable with difficulty, from that which is produced naturally by an individual presents interesting analytical problems. Other examples of pseudoendogenous substances prohibited in sport include rhGH and rhEPO.

Dietary supplements

In recent years and probably since the passing of the Dietary Supplement and Health Education Act (DSHEA) by the United States Congress in 1994, which requires the US Food and Drug Administration to treat supplements as harmless food products, a large number of food supplements that contain anabolic steroids either deliberately or by contamination have become readily available. This may have given rise to inadvertent violation of the anti-doping rules. Nevertheless, most governing bodies of sport work on the principle of strict liability, and it is the responsibility of the competitor in human sport to avoid the administration of a prohibited substance.

Anabolic steroids

In human sport, anabolic steroids are used as bodybuilding drugs, sometimes in very large quantities, in events such as weightlifting and the shot-put. There are broadly two chemical types based upon the androstane and estrane ring systems: those with a 17α-alkyl group, which are active orally but are hepatotoxic, and 19-nor derivatives administered by injection. Although steroidal oestrogens and some stilbenes reputedly possess anabolic activity and are employed in beef production, they do not appear to be used as doping agents.

The metabolism of anabolic steroids in humans has been documented quite well, especially by Schänzer and co-workers (Schänzer 1996; Schänzer, Donike 1993). Synthetic anabolic steroids used in humans may be detected readily by the use of GC-MS analysis. Detection of the administration of pseudoendogenous compounds (i.e. compounds that are virtually identical to those of endogenous origin, such as testosterone) presents a more complex problem. There are several methods to indicate that testosterone has been administered to a male human. Natural testosterone production is controlled by a feedback mechanism that involves the pituitary gland, and administration of testosterone suppresses the natural production of pituitary hormones, such as luteinising hormone (LH) and follicle-stimulating hormone (FSH).

GC-MS analysis may be used to measure the testosterone concentration in urine, and immunoprocedures to determine LH and hence the urinary ratio of total (free plus conjugated) testosterone to LH. Testosterone is measured in nanomoles/litre, and LH in International Units of Human Menopausal Gonadotropin 2nd International Reference Preparation per litre (HMG-IR2/L). A ratio in excess of 200 is abnormal (Brooks *et al.* 1979).

In the human female, whose pituitary hormones may be suppressed by the use of oral contraceptives, the testosterone : LH ratio is of little evidential value. Instead, a method suitable for both males and females is to measure the ratio of testosterone (T) to epitestosterone (E) using GC-MS. In this method, the bis(trimethylsilyl) derivative is formed and the intensity of the molecular ions at *m*/*z* 432, under EI conditions for both of the steroid derivatives, is used to determine the ratio (Donike, Zimmermann 1980). WADA requires its accredited laboratories to report an 'atypical finding' whenever the measured ratio significantly exceeds 4. The increase in reported findings in 2005 reflects the reduction in the threshold for reporting from 6 to 4. Samples with a T/E greater than 4 may be submitted to CIRMS (see earlier). A method to detect the administration of dihydrotestosterone, the more active metabolite of testosterone, has also been proposed (Kicman *et al.* 1995) based on the perturbation of the endogenous hormone profile following administration. Isotope ratio MS, as described earlier, is also now used to assist detection of the administration of testosterone and related compounds.

Sampling carried out only at the time of competition has enabled the misuser to switch from using a preferred synthetic anabolic steroid to testosterone or to a synthetic anabolic steroid that is eliminated rapidly in sufficient time to escape detection. Thus sampling out-of-competition and with minimum notice as well as at competitions is now accepted as the optimal approach to detecting, and thereby limiting, the use of anabolic steroids in humans. A comprehensive

review of the detection of anabolic steroid administration has recently been published (Kicman *et al.* 2009).

Diuretics

Furosemide and hydrochlorothiazide are the diuretics most commonly reported by WADA-accredited laboratories. They are used in weightlifting and other competitions classified by weight such as boxing. The dilution of the urine, which results from diuretic use, can render detection of some other drugs more difficult. Diuretics have a wide variety of chemical structures, which makes it difficult to find a single suitable screening procedure. Diuretics can be detected in urine by HPLC using system HN (Chapter 41). A method applicable to human urine using extractive alkylation and GC-MS (Lisi *et al.* 1991, 1992), or LC with tandem MS (Thieme *et al.* 2001) may be used. A rapid screening method using automated SPE and LC-ESI-MS(-MS) that is capable of detecting 35 diuretics and related compounds at a concentration significantly below the WADA minimum required performance level in about 12 min per sample has been described (Goebel *et al.* 2004). Thörngren *et al.* (2008) have published a UPLC-MS(-MS) method that requires just 6 min per sample. The disadvantage of such rapid methods is that care needs to be taken to avoid ion suppression that might result in a false-negative result.

Protein hormones

Currently, in human sports drug testing, methods are accepted for the analysis of hCG and for EPO only. Tests for hCG are based on immunoprocedures (Cowan *et al.* 1991; Laidler *et al.* 1994). A method has been developed to identify the different isoform pattern of recombinant EPO from that of endogenous material using isoelectric focusing (Lasne 2001; Lasne, de Ceaurriz 2000), whereas a method based on the perturbation of a number of blood parameters (haematocrit, reticulocyte haematocrit, percentage macrocytes, serum EPO and soluble transferrin receptor [Parisotto *et al.* 2001]) was required by the IOC as part of the test. Subsequently, WADA accepted the isoelectric focusing method to be used alone to evidence EPO administration. New forms of EPO are now reaching the marketplace. Catlin and colleagues (2002) have published the detection of the administration of darbepoetin, a novel erythrocyte-stimulating protein, using the isoelectric focusing method of Lasne and de Ceaurriz (2000). This recombinant EPO-related substance has a half-life that is about three times longer than that of endogenous EPO. Recently a pegylated form of EPO (epoeitin-β) has been marketed that has an even longer half-life, and relatively little appears in urine. This foreign substance has a molar mass of about 60 kDa. Although an immunoassay may be used for screening purposes, the isoelectric focusing method is used for confirmation. WADA has recently updated a technical document that describes the confirmation of this and other forms of EPO that may include the use of sodium dodecylsulfate polyacrylamide gel electrophoresis (SDS-PAGE) (WADA 2009a). Interestingly, although natural equine and canine EPOs do not cross-react with the antibodies used to detect human EPO, so that the use of an immunoassay to detect EPO may be sufficient, confirmation using immunoblotting may be desirable and indeed has been undertaken (Bartlett *et al.* 2006).

A method has been published for detection of insulin administration in plasma (Thevis *et al.* 2005) and in urine (Thevis *et al.* 2006b), and also for detection of administration of the corticotrophin tetracosactide (Synacthen) in plasma (Thevis *et al.* 2006a).

A test to prove GH administration has been available since the Olympic Games in Athens in 2004. This test is based on the fact that, since recombinant GH does not contain the 20 kDa isoform, the absence of this isoform is the basis of the so-called isoform test (Bidlingmaier *et al.* 2009; Wu *et al.* 1999). An alternative biomarker approach is based on using a discriminant function with the GH-sensitive substance IGF-1 produced by the liver and procollagen type III (P-III-P) (Cowan, Bartlett 2009; Powrie *et al.* 2007; Sönksen 2001).

To support screening on the basis of immunochemistry methods, LC-MS(-MS) methods for IGF-1 determination in the horse have been developed (Bobin *et al.* 2001; De Kock *et al.* 2001). In addition, LC-MS has been shown to provide a viable approach for the quantification of IGF-1 in the horse (Popot *et al.* 2001). Recently, IGF-1 has been quantified from human serum (Bredehöft *et al.* 2008) and also compared with immunoassay data (Kay *et al.* 2009).

Blood doping

Tests for blood doping have been in place since the Olympic Games in Athens in 2004 based on the quantification of blood group antigens (Nelson *et al.* 2002, 2003). Currently, no method exists to evidence autologous blood transfusion. With the advent of blood substitutes based on cross-linked haemoglobin, methods have recently been developed also to detect their use (Goebel *et al.* 2005; Lasne *et al.* 2004; Thevis *et al.* 2003). A method to detect the use of efaproxiral (RSR13), an agent that enhances oxygen uptake, was published (Breidbach, Catlin 2001) even before the substance reached the market.

The future

Over the past few years, analytical methods to detect the use of more and more of the substances and methods prohibited in sport have been added to our armoury. Gaps still remain such as the detection of autologous blood transfusion and gene doping. The field is developing extremely rapidly, with many new analytical techniques and approaches being used. The use of high temperatures and high pressure with small-particle (sub-2 μm) LC columns seems likely to find increased use to provide fast chromatography with increased resolving power (Plumb *et al.* 2007). In addition, mass spectrometry is likely to be used more for the identification and quantification of protein hormones, e.g. IGF-1 and hCG, which is currently only possible using immunoassays. Furthermore, although the detection of many endogenous substances makes use of population data, there is a move towards a so-called athlete's passport (WADA 2010a) enabling the use of the individual athlete's normal data. A Bayesian approach to evaluating the data has been published (Sottas *et al.* 2008) and reviewed (Kicman, Cowan 2009).

CHAPTER

7 Drug Testing in Animal Sport

P Teale

Introduction

The use of drugs to affect the performance of horses in competition predates the twentieth century: so-called horse 'nobbling' was known well before this time. For example, the account of the famous trial of Daniel Dawson, publicly hanged at Cambridge, England, in 1812 for poisoning racehorses with arsenic, reveals that drinking troughs in some stables were padlocked. 'Exciting substances' were also banned in races in Worksop in 1666.

In human sport the abuse of drugs is almost entirely intended to enhance performance by one means or another. The effect of drugs on performance is often extremely difficult to determine, and there is little definitive published work for any species. Changes in performance of less than 1% cannot be demonstrated with statistical significance because of the many variable and uncontrollable factors, yet an improvement of only 1% represents a lead of about six lengths in a horse race over 1 mile (1.6 km).

While an improvement in performance through the use of drugs may be difficult to measure, or to achieve, there are other considerations in animal sports, particularly racing. Historically, the most important of these has been that gambling is central to the funding and, for many, to the enjoyment of horse and dog racing. There is no doubt that numerous drugs are available with the capability of adversely affecting athletic performance: sedatives, tranquillisers, anaesthetics and beta-blockers being some of the most obvious candidates. It is interesting to note that some of these classes of drugs could, at lower doses, have the contrary effect and potentially improve performance. This explains the relatively early introduction of drug testing into animal sports, which was well established in several European countries by the early 1920s and saw the establishment of the Association of Official Racing Chemists (AORC) in the USA by 1947.

While the prevention of the use of drugs to affect performance remains important to maintaining the credibility of animal sports, welfare considerations have become increasingly important. There is a clear need to allow veterinarians to administer legitimate medication to treat an animal so as to ensure its long-term well-being. At the same time, it must be ensured that such administrations have no effect on racing performance. In horseracing; this has led to a narrowing of the gap in the philosophy adopted by racing authorities across the world between those with a 'zero tolerance' of drugs (predominantly European and Asia/Australia) and those that allow certain medications under controlled conditions (predominantly the USA).

The result of these diverse requirements is that animal sports testing requires the capability of detecting a hugely diverse range of substances, from small molecules such as carbon dioxide, through conventional pharmaceutical drugs, to large molecules such as proteins. These requirements have led to a steady development in the testing technologies applied.

Rules

In horseracing, the International Agreement on Breeding and Racing, published by the International Federation of Horseracing Authorities (IFHA), provides guidance to maintaining the integrity of the sport for recognised racing and breeding authorities (IFHA 2001). Article 6 of this agreement addresses prohibited substances and provides guidance on sampling, sanctions, trainers' responsibilities, raceday regulations, prohibited substances, thresholds and laboratory services. The objective of Article 6 is to protect the integrity of horseracing through controlling the use of substances capable of giving a horse an advantage or making it disadvantaged in a race contrary to the horse's merits. Section 10 of Article 6 defines prohibited substances on the basis of pharmacological action (Table 7.1).

The finding of a prohibited substance means a finding of the substance itself or a metabolite of the substance or an isomer of the substance or an isomer of a metabolite. The finding of any scientific indicator of administration of or exposure to a prohibited substance is also equivalent to the finding of the substance.

As of 2010, 40 countries were signatory to Article 6 in full and use the above definitions as the basis for their national rules of racing. Another 16 countries are signatory in part to Article 6 with a further 2 non-signatories. The basis of such rules is to ban the use of any prohibited substance in racehorses at the time of competition – that is, a policy of 'zero tolerance' except for substances controlled by thresholds. Article 6 states that thresholds can only be adopted for:

- substances endogenous to the horse
- substances that arise from plants traditionally grazed or harvested as equine feed
- substances in equine feed that arise from contamination during cultivation, processing or treatment, storage or transportation.

The list of threshold substances taken from the 2009 publication of the International Agreement on Breeding and Racing is shown in Table 7.2.

Substances included in Table 7.2 detected below the thresholds are not actionable. For any finding of an endogenous substance above the threshold, the Horseracing Authority may decide itself or at the trainer's or owner's request to examine the horse further. In authorities applying the 'zero tolerance' approach, a positive finding of a drug or metabolite almost invariably results in disqualification.

In contrast to the policy of 'zero tolerance' of drugs currently adopted by racing authorities that are full signatories to Article 6, some other jurisdictions permit certain drugs at the time of racing. For example, in North America, in an attempt to harmonise sanctions, the Racing Commissioners International (RCI) produced *Uniform Classification Guidelines for Foreign Substances and Recommended Penalties and Model Rules* (RCI 2002). Drugs are placed in categories 1 to 5, with class 1 agents having a high potential to affect the performance of the horse. Class 1 agents, with a high potential to affect performance, have no place in racing and include opiates, central nervous system (CNS) stimulants and psychoactive drugs. Class 2 agents include psychotropics, certain stimulants, depressants, neuromuscular blocking agents and local anaesthetics that could be injected as nerve-blocking agents. These drugs also have the potential to affect racing performance, but less significantly than class 1 agents. Class 3 agents include some drugs registered for equine veterinary use and have less potential to affect performance than class 2 agents. Racing authorities in certain states in North America have set thresholds for some of the widely used non-steroidal anti-inflammatory drugs (NSAIDs): phenylbutazone, its major metabolite oxyphenylbutazone, flunixin and meclofenamic acid. The use of furosemide is subject to a threshold in many authorities in North and South America and other authorities have set 'decision levels' in urine for some

Table 7.1 Prohibited substances according to Article 6 of the International Agreement on Breeding and Racing (IFHA 20011)

Substances capable at any time of acting on one or more of the following mammalian body systems:

- Nervous system
- Cardiovascular system
- Respiratory system
- Digestive system
- Urinary system
- Reproductive system
- Musculoskeletal system
- Blood system
- Immune system except for licensed vaccines
- Endocrine system

Endocrine secretions and their synthetic counterparts
Masking agents

substances accepted for equine veterinary use (acepromazine, albuterol, atropine, benzocaine, mepivacaine, procaine, promazine and salicylates).

At the time of writing, both the 'zero tolerance' and 'allowed medication' approaches are under reconsideration. The 'zero tolerance' approach is largely dictated by the sensitivity of analytical methods used by laboratories to test for drugs in body fluids which has increased markedly over the past two decades. Major reasons for this increased sensitivity are enzyme-linked immunosorbent assays (ELISAs) and instrumental screening methods, such as mass spectrometry coupled to gas chromatography (GC-MS) and liquid chromatography (LC-MS). As a result of this available sensitivity, it is possible that some therapeutic medications may be detected in urine for periods of time beyond the point at which the drug continues to exert a pharmacological action. Various approaches have been adopted or proposed to address this issue. In Canada, the racing authorities have adopted a policy of the 'deliberate non-selection of unnecessarily sensitive testing methods for specific substances' (Stevenson 1995). Tobin *et al.* (1999) proposed the development of threshold values for therapeutic substances based upon the determination of the highest no-effect dose for their primary pharmacological effect, such as the use of the heatlamp–abaxial sesamoid block model for local anaesthetics (Harkins *et al.* 1996). Similarly, Smith (2001) questioned the continued adherence to the policy of zero tolerance for drugs registered for equine veterinary use and suggested the use of pharmacologically determined reporting levels. Smith drew an analogy with other fields – veterinary drug residues in feed, food packaging contaminants, and food additives in which the levels of chemicals of no concern for a biological effect have been determined using pharmacological (toxicological) and pharmacokinetic parameters. For example, maximum residue limits (MRLs) and the acceptable daily intake (ADI) have been determined for many drugs used in veterinary practice for the treatment of livestock.

This change in attitude to the 'zero tolerance' approach is being mirrored by modifications to the Uniform Classification Guidelines adopted in most of the USA. In particular the designation of anabolic steroids as class 4 drugs has been changed to class 3 drugs, the use of which is more tightly controlled or prohibited. Model rules recently proposed by the Racing Medication and Testing Consortium (RMTC) and supported by the RCI have banned the use of most of the synthetic anabolic steroids and limited the use of nandrolone, boldenone, testosterone and stanozolol. As of 2008, the majority of racing authorities in the USA have either introduced these rules or undertaken to introduce them in the near future.

In addition to horseracing, a wide range of other equine sports is popular around the world. Many of these, such as show jumping, eventing and dressage, are under the control of the Fédération Equestre Internationale (FEI). Drugs prohibited under FEI rules are broadly similar to those prohibited by the IFHA.

No internationally agreed list of prohibited substances exists for canine sports. Where testing is carried out in an organised manner, prohibited substances are specified locally or nationally. In most instances the substances prohibited are broadly similar to those banned in horseracing.

Table 7.2 List of internationally agreed threshold substances for horseracing

Substance name	*Threshold*
Arsenic	0.3 μg total arsenic per mL in urine
Boldenone	0.015 μg free and conjugated boldenone per mL from male horses (other than geldings)
Carbon dioxide	36 mmol available carbon dioxide per L in plasma
Dimethyl sulfoxide	15 μg dimethyl sulfoxide per mL in urine, or1 μg dimethyl sulfoxide per mL in plasma
Estranediol in male horse (other than geldings)	0.045 μg free and glucurono-conjugated 5α-estrane-3β, 17α-diol/mL in urine
Hydrocortisone	1 μg hydrocortisone per mL in urine
Methoxytyramine	4 μg free and conjugated 3-methoxytyramine per mL in urine
Salicylic acid	750 μg salicylic acid per mL in urine, or 6.5 μg salicylic acid per mL in plasma
Testosterone	0.02 μg free and conjugated testosterone per mL in urine from geldings, or 0.055 μg free and conjugated testosterone per mL in urine from fillies and mares (unless in foal)
Theobromine	2 μg theobromine per mL in urine

Reported analytical findings

The drugs most commonly detected in horseracing in Europe (France, Germany, the UK, Ireland and Italy) over the period 1993–1997 are shown in Table 7.3 and Table 7.4 (Smith 2001). The majority of the reported findings (77%) were for substances registered for equine veterinary use (Table 7.3). The NSAIDs accounted for 28% of the reported findings and isoxsuprine for 22%. Isoxsuprine, a vasodilator, is widely used in veterinary practice for the treatment of navicular disease and can be detected in urine for long periods of time after dosing has ceased (Pompa *et al.* 1994). Moreover, when used as a powder for oral administration through admixture with feed, it can produce serious contamination problems in the stable environment (Russell, Maynard 2001). Modifications to assay sensitivity along with changes in veterinary practice have largely eliminated the reporting of low levels of isoxsuprine in racing animals. For the drugs without market authorisation (Table 7.4), anabolic steroids accounted for 35% of the reported findings, xanthines for 24%, and CNS-stimulant active drugs for 12%.

It is interesting to compare these findings with those for reported findings in the USA and Canada over a similar period. If a prohibited substance is reported in a post-race sample from a horse, the International Agreement on Breeding and Racing recommends that the horse be disqualified. However, the USA and Canada are not signatories to this aspect of Article 6. Rather, the 'model rules' discussed in the previous section are applied. Carter (2001) summarised the combined reported findings of substances in classes 1, 2 and 3 over the period 1995–1999 for racing in California, Canada, Florida, Kentucky, Maryland, New York and Ohio in thoroughbred, standardbred and quarter horses (horses bred for maximum speed over a quarter of a mile). For comparison with the European findings, the results for quarter horses have been omitted. Findings for class 1 agents included morphine (15), cocaine (presumably as the major metabolite benzoylecgonine) (15), strychnine (3), oxymorphone

Table 7.3 Reported findings in Europe for prohibited substances with veterinary market authorisation (Smith [2001]; reproduced with the kind permission of Professor RL Smith)

Drug	*Number of reports*
Isoxsuprine	73
Phenylbutazone	66
Caffeine	28
Dexamethasone	25
Lidocaine	24
Procaine	22
Flunixin	14
Acepromazine	13
Clenbuterol	10
Dembrexine	9
Salicylate	8
Dipyrone	7
Furosemide	6
Hyoscine	5
Naproxen	4
Methylprednisolone	3
Altrenogest	3
Other drugs[a]	<3

[a]Other drugs with fewer than three reports each are diphenhydramine, detomidine, xylazine, prednisolone, mepivacaine, meclofenamic acid, ketoprofen, butorphanol and atropine.

Table 7.5 Findings of Class 3 agents in California, Canada, Florida, Kentucky, Maryland, New York and Ohio during the period 1995–1999 (Carter 2001)

Drug	*Number of reports*
Clenbuterol	55
Promazine	35
Pyrilamine	30
Albuterol	28
Procaine	22
Detomidine	12
Atropine	10
Bumetanide	10
Glycopyrrolate	10
Butorphanol	9
Phenylpropanolamine	6
Pentoxyfylline	4
Hyoscine	4
Acepromazine	3
Theophylline	3
Xylazine	3
Pentazocine	2
Other drugs[a]	1

[a]Drugs with one report each are ketorolac, metoprolol, nefopam and terbutaline.

(2), apomorphine (1), dextromoramide (1) and oxycodone (1). Findings for class 2 agents were lidocaine (28), caffeine (21), mepivacaine (8), buspirone (7), ephedrine (4), nalbuphine (3), imipramine (2), chlorprothixene (1), ketamine (1) and tramadol (1). The findings for class 3 agents are shown in Table 7.5.

Within Europe, 49 substances were detected a total of 431 times in a 4-year period with a total of 97 451 samples tested, an incidence of reported findings of 0.44%. Carter (2001) estimated that the number of samples tested per annum in Canada and seven states within the USA was 200 000. Thus, for class 1, 2 and 3 agents, within a 4-year period, 39 substances were detected a total of 389 times in an estimated 800 000 samples, an incidence of reported findings of 0.049%.

Table 7.4 Reported findings in Europe for prohibited substances without veterinary market authorisation (Smith [2001]; reproduced with the kind permission of Professor RL Smith)

Drug/drug type	*Number of reports*
Xanthines	24
Testosterone	16
Nandrolone	10
Boldenone	7
Morphine	6
Heptaminol	5
Promazine	4
Pyrilamine	3
Ketorolac	3
Propranolol	2
Nikethamide	2
Methandriol	2
Diclofenac	2
Cortisol	2
Chlorpromazine	2
Other drugs[a]	1

[a]Drugs with one report each are salbutamol, propionylpromazine, phenylpropanolamine, nalbuphine, mephenesin, hydroxyzine, bumetanide and amitriptyline.

The significant difference in the incidence of reported findings in the two geographical areas can almost certainly be explained by the absence of data for class 4 and 5 agents in the American study. Many of the substances reported in Europe would fall into these classes within the USA. For example, in the USA, NSAIDs and isoxsuprine are class 4 agents controlled by the application of threshold levels, the concentration of phenylbutazone and/or oxyphenylbutazone in the reporterd samples in Europe would be well below the US threshold. European racing authorities also place significant importance on the detection of anabolic steroids, whereas at the period covered by these findings anabolic steroids were class 4 agents in the USA and limited testing was applied. The difference in the incidence of reported findings reflects, in part, the difference in philosophical approaches to doping control currently adopted on the two continents at that time: 'zero tolerance' versus permitted medication.

It is interesting to note the influence that the introduction of new or more sensitive tests can have upon reporting statistics. Carter (2001) reported 24 findings of class 1 agents in standardbred racing in the USA over the period 1995–1999; 23 of the findings were for the drug metaraminol. These findings were all reported in one state, Louisiana, and occurred over a short period and resulted from the introduction of a new test. A similar situation arose with the drug clenbuterol (see Table 7.5) when a more sensitive test was introduced in 1998.

Sampling

Sample collecting procedures must take into consideration both scientific and legal aspects:

- The health of the animal being sampled must be safeguarded.
- Incorrect labelling, contamination or sample switching must be avoided.
- The rights of interested parties, generally the owner and trainer of an animal, must be safeguarded against error by the analyst.

Article 6 of the *International Agreement on Breeding and Racing* (IFHA 2009) states that a sample collected under a secure chain of custody shall be split into an A sample and a B sample, and this policy is adopted by racing jurisdictions worldwide. If the A sample is reported to contain prohibited substances, the B sample can be analysed for those substances, either automatically or at the trainer's request. The analysis is carried out either in the primary laboratory or in a nominated secondary laboratory. Within greyhound racing, a split sampling policy generally is not adopted because sometimes only a small volume of urine is available.

In animal sport the vast majority of samples taken are post event, with the majority being urine. In fact, until relatively recently, post-event sampling was the only approach applied to the control of drug misuse. This is entirely suitable for controlling agents, the presence of which could affect the outcome of the competition. However, it has been recognised that it is inappropriate for controlling the misuse of drugs that continue to offer a benefit after they become undetectable – anabolic steroids, erythropoietin (EPO), etc. For this reason many authorities now undertake additional sampling out-of-competition. Also, a number of authorities undertake pre-race testing, mostly for the presence of alkalising agents, but more extensive pre-race testing is undertaken by a small number of authorities, for example in Hong Kong.

Urine

Until relatively recently, urine was the preferred body fluid in all species. Its collection is non-invasive, it is generally available in sufficient quantity and the drugs or their metabolites tend to be present in relatively high concentrations. The disadvantages are that a drug may be present as its metabolites or in a conjugated form and the parent drug may be present only in a relatively low concentration or be entirely absent, as is the case with several protein-based therapeutic agents.

Urine is collected almost invariably by voiding naturally. Greyhounds urinate very readily after being released from their transporter and 96% of horses in Britain urinate within 1 hour of racing. Urine samples from greyhounds are caught directly in a bowl held under the animal. For horses, a container held on the end of an extending handle is generally used (e.g. a net held on a metal ring into which is inserted a polythene bag). Metal ladles are unsuitable because the noise produced by the urine that falls into them frequently inhibits the horse from urinating further.

Blood

The principal advantage of a blood sample in equine sport is the ease with which it can be collected. In addition, drug concentrations in blood are interpreted more easily than those in urine and certain drugs that are not excreted in urine in detectable quantities (e.g. reserpine) can be detected in blood. Blood is rarely collected from the greyhound because of the relative ease of urine sampling and the limited volume of blood available. Blood is sampled increasingly in horseracing as a second choice when urine is not obtainable or as an additional matrix for further testing. Blood is the body fluid of choice for pre-race and testing in training samples because of the relative ease of collection compared with that of obtaining urine samples.

Saliva

The principal disadvantages of saliva are that it is difficult to obtain a useful volume and few drugs are present at a concentration higher than that in plasma. Non-ionised drugs and drugs not protein bound in plasma diffuse passively into saliva. Thus, alkaline saliva (as in the horse) tends to concentrate acidic drugs but, because the percentage of unbound acidic drug in plasma is generally very low, concentrations remain lower than the corresponding total plasma concentrations. For drugs of low lipid solubility, and for high salivary flow rates, equilibrium is not established, which results in concentrations even lower than those predicted on theoretical grounds. The principal value of saliva, therefore, is in the detection of topical exposure that results from recent oral ingestion.

Hair

Hair analysis has value within animal sports in that it can provide a historical record of drug administrations; this information would be particularly useful for those drugs with no legitimate therapeutic use and long-lasting effects (e.g. anabolic steroids). Reported studies (Boyer *et al.* 2007; Jouvel *et al.* 2000; Popot *et al.* 2001b; Whittem *et al.* 1998) have addressed the detection of morphine, diazepam, clenbuterol and steroids in horse hair. The development of instrumental systems with ever-increasing sensitivity has the potential to further enhance the effectiveness and applicability of hair testing in animal sport.

Analytical approach

Screening methods

Drugs are generally administered at or near the therapeutic dose, which results in relatively low concentrations in biological fluids. There is usually no obvious outward evidence as to whether a drug has been administered, or what sort of drug it might be. Any drug used in human treatment or in veterinary practice may be found. Thus, screening procedures must be both sensitive and of wide coverage. However, the sports chemist enjoys the advantage of examining relatively constant material, usually in fairly fresh condition. He or she thus has a clearer picture of a normal sample than does the forensic or hospital chemist who may be required to examine a wide variety of materials in various states of decomposition. Any sample that fails a screening test is invariably submitted to rigorous confirmatory testing (see below) before an adverse report is issued.

Although the parent drug is the entity normally described in the rules, screening procedures rely upon the detection of either the unchanged drug or its metabolites. The identification of the corresponding metabolites is often useful supplementary evidence to support the identification of the parent drug. In addition, the presence of metabolites in the appropriate concentrations relative to the parent drug helps to support the conclusion that a drug has been administered. Occasionally, the parent drug is not excreted in urine at a detectable concentration and knowledge of the metabolic pathways in the particular species is thus essential. An example of this is the identification of 19-norepiandrosterone and 19-noretiocholanolone in the urine of dogs as evidence of the administration of the anabolic steroid nandrolone or a 19-norsteroid precursor. Some drugs are notable for being excreted in urine almost entirely in the conjugated form as are, for instance, apomorphine, fentanyl, nefopam and pentazocine in the horse. Hydrolysis or other appropriate pretreatment prior to extraction is therefore required if instrumental screening methods are to be effective. The use of hydrolysis significantly increases the complexity of the matrix, particularly in the case of horse urine.

No single analytical scheme will suffice to cover so many different types of compound; various approaches have, therefore, evolved in racing chemistry laboratories to address this challenge.

Immunochemical methods that cover glucocorticosteroids (Chakraborty *et al.* 1976; Dumasia *et al.* 1973) and anabolic steroids (Jondorf 1977; Jondorf, Moss 1978) were first introduced into equine drug-screening programmes in the 1970s. However, in the late 1980s, ELISAs were developed specifically for equine drug-testing programmes (e.g. Woods *et al.* 1988). A range of ELISA tests is now available and their use remains widespread, though far from universal. Many laboratories, primarily in the USA, make use of ELISA tests to provide coverage of a range of drugs.

For more general screening, liquid–liquid extractions designed for group separation of drugs followed by thin-layer chromatography (TLC) were almost universally employed, but their use is now in decline. In many laboratories around the world, while specific analytes are targeted using ELISA, broad coverage is increasingly provided by instrumental screening techniques. For this purpose the use of GC with nitrogen–phosphorus detection (GC-NPD) and high performance liquid chromatography using ultraviolet detection (HPLC-UV) was almost entirely superseded by GC-MS through the 1980s and 1990s. In the last decade, LC-MS has been increasingly used in animal sports drug testing

laboratories. This is reflected in the fact that the number of analytical papers submitted to the International Conference of Racing Analysts and Veterinarians (ICRAV) relating to the use of LC-MS increased from 11% in 1998 to 88% by 2006. The balance of use of immunoassays and instrumental methods is a complex equation between relative costs of consumables, staff and capital equipment that varies widely depending upon geography.

Confirmatory methods

In animal sports testing, substances detected using screening techniques are subsequently subjected to further analysis intended to unambiguously confirm the screening finding. This usually involves an analyst taking a second aliquot from the primary (A) sample and the use of a suitably selective technique to provide the required confidence in the analytical finding. Industry guidelines for horseracing laboratories state that, for regulatory identification, MS or a similarly definitive technique, if applicable to the analyte in question, must be included. An important aspect of this confirmatory analysis is that the chain of evidence must be maintained from the primary sample to the final analytical result. In most instances, a second confirmatory analysis is either required or available upon request. Where a B bottle sample has been obtained, this second confirmatory analysis is undertaken with that sample, normally in the presence of a witnessing analyst or at a second laboratory.

Laboratories are required to have established and documented chromatographic and mass-spectrometric criteria that the analyte of interest in the test sample must have in common with the reference material for identification purposes. Industry guidelines for low-resolution mass spectrometry have been introduced by the AORC. These are similar to those applied by World Anti-Doping Agency (WADA) laboratories. In the 1990s, discussions within the IFHA identified the desirability for accreditation to International Standards Organization (ISO) standard 17025. While many laboratories have attained accreditation, this is not universally applied. To assist in the process of accreditation, the racing industry, through the efforts of the AORC, has produced the guidelines *Accreditation Requirements and Operating Criteria for Horseracing Laboratories*, published by the International Laboratory Accreditation Co-operation (ILAC 1997). Further development of this document to maintain its applicability is ongoing. ISO 17025 (ISO 2003) requires traceability of measurements and in the sports fields this is considered to be met, when identifying a prohibited substance, by the direct comparison with a reference material analysed in parallel or in series with the test sample. A reference standard is generally accepted as a chemical with a well-established structure. The material may be characterised structurally within the laboratory using appropriate techniques or validated against a certified reference material or by comparison with uncontroversial published data. A reference material may also be an isolate from a urine or blood sample after an authenticated administration, provided that the analytical data from it is sufficient to justify fully its identity as a metabolite of the substance administered. Chemical reference standards are often not available and hence there is the need to use authenticated administrations for comparison purposes. Many of the most common substances are now available with certificates of analysis, and thereby fully meet the generic traceability requirements of ISO 17025 (ISO 2003).

Sample extraction

In many racing chemistry laboratories throughout the world, solid-phase extraction (SPE) has augmented or replaced liquid–liquid extraction for the isolation of drugs from the sample matrix. Based upon the studies of Shackleton and Whitney (1980), the early applications of SPE to racing chemistry involved the use of C_{18} bonded-phase cartridges in the isolation of anabolic steroids and their metabolites from equine urine (Dumasia *et al.* 1986). With the development of a range of more polar phases and, more importantly, ionic and particularly mixed-mode phases, the technique evolved to provide a simple, rapid, robust and efficient approach to the fractionation of drugs from biological fluids. In an early example of this, Dumasia and Houghton (1991) reported the application of lipophilic/cationic mixed-mode cartridges for the extraction of β-agonists, β-antagonists and their metabolites in horse urine prior to their analysis by GC-MS. Following the application of a urine sample at pH 6.0 to the cartridge, basic drugs are retained primarily by cation-exchange processes, whereas acidic and neutral drugs are retained by hydrophobic interactions. Washing the cartridge with acetic acid (1 mol/L) fortifies the ionic interaction for the basic drugs. The acid and neutral drugs can then be eluted with an organic solvent such as ethyl acetate or dichloromethane. As a result of the retention of basic drugs through ionic interaction, the cartridges can be washed with methanol to remove interfering substances. Subsequently, the basic drugs are eluted by suppression of ionisation using a solvent such as ethyl acetate containing concentrated ammonia solution or triethylamine (2–4%). The ability to use cationic mixed-mode cartridges to fractionate acid/neutral and basic drugs is widely exploited by many laboratories, although the details of the procedure often differ markedly.

Polymeric phases are now also available, the surface chemistry of which can provide a variety of advantages compared with the traditional silica-based phases. These properties can be further modified by combining two classes of polymeric sorbents or by using co-polymeric and functionalised polymers. The treatment of the functionalised polymer with sulfonic acid provides cation-exchange characteristics. These cartridges have been shown to be effective in the extraction of a number of basic drugs from equine urine (Stanley *et al.* 2001).

One of the major problems encountered in the SPE of horse urine, particularly if automated procedures are used, is cartridge blockage. This is primarily because of the viscous nature of horse urine and, to a lesser extent, suspended material. This problem has been addressed (Wynne *et al.* 2001a, 2001b) using non-conditioned SPE (NC-SPE). The sorbents used in this technique are highly cross-linked with a unique combination of hydrophilic and lipophilic moieties and thus do not require conditioning. They have good flow characteristics and can be applied to the extraction of a wide range of drugs. Wynne *et al.* (2001b) suggested the application of NC-SPE for the pre-extraction of horse urine before application of the recovered extract to mixed-mode cartridges. Other laboratories favour the use of a protease, which significantly decreases the viscosity of the urine sample. A comprehensive fractionation procedure using multiple SPE cartridges has been described (Wynne *et al.* 2004) and the application of SPE to veterinary drug abuse has been reviewed by the same author (Wynne 2000).

Gas chromatography–mass spectrometry

A major advantage of GC-MS for general broad-range screening has been the availability of extensive electron-impact mass spectral libraries. Typically, derivatisation is employed to render analytes containing polar and active functionalities amenable to chromatography. Derivatisation methods widely applied include trimethylsilylation, acetylation and alkylation, for example to form pentafluoropropionyl or methyl derivatives. No single procedure is appropriate for derivatising all analytes. However, it is possible to develop methods capable of detecting very large numbers of drugs and metabolites. Arguably, the major issue with full-scan GC-MS screening is the complexity of the resulting data-sets and difficulty of producing meaningful and accurate analytical reports in an automated manner.

GC-MS is also widely used for target analysis using selected-ion monitoring (SIM) approaches. An excellent example of the use of this approach is in the detection of anabolic steroids in urine. GC provides excellent separation of isomers, an important consideration in steroid chemistry where multiple isomers are possible, and SIM provides the required sensitivity to detect the target analytes in the low nanogram per millilitre range. The selection of derivatisation reagent is an important consideration in this application. For example, formation of *t*-butyldimethylsilyl derivatives where fragmentation results in the production of intense high-mass ions (Teale, Houghton 1991).

GC-MS has also been widely applied for confirmatory analysis, in which the identity of a substance should be confirmed using derivative formation and comparison of the data obtained with reference material analysed contemporaneously.

Liquid chromatography–mass spectrometry

An early application of LC-MS to drug testing in equine sports demonstrated the use of the moving belt interface in the confirmatory analysis of synthetic corticosteroids (Houghton *et al.* 1981). Other techniques employed in animal sports testing have included direct liquid introduction (Henion, Maylin 1980) and particle beam-MS (Stanley *et al.* 1995). With the development of atmospheric-pressure ionisation (API) techniques, LC-MS has found increasing application in doping control in animal sports for both the qualitative and the quantitative analysis of drugs. The technique has been applied to the analysis of intact steroid conjugates isolated from horse urine with particular reference to the quantification of testosterone sulfate (Dumasia *et al.* 1996). Methods developed for other individual drugs include hydrocortisone (Samuels *et al.* 1994), triamcinoloneacetonide (Koupai-Abyazani *et al.* 1994b), levodopa and its metabolites (Koupai-Abyazani *et al.* 1994a), clidinium bromide (Ryan *et al.* 1996) and glycopyrrolate (Matassa *et al.* 1992).

Many of the initial screening methods developed using API LC-MS were based upon ion-trap systems that were popular owing to their full-scan sensitivity and flexibility. Examples include methods for diuretics (Eenoo *et al.* 2001), also a broad screen detecting a range of diuretics, some cyclooxygenase-2 (COX-2) inhibitors and anti-ulcer drugs in a single analysis (Woodward *et al.* 2003). Product-ion scan MS-MS has facilitated the development of screening procedures for large numbers of compounds in a single analysis. Screening methods have been developed for corticosteroids (Tang *et al.* 2001), while You *et al.* (2003) developed a screening procedure for simultaneous analysis of 60 basic drugs isolated from horse urine with detection limits at low microgram per litre levels. The drugs were isolated from enzyme-hydrolysed urine by SPE and analysed by LC-MS in the positive-atmospheric-pressure chemical ionisation (APCI) mode. The method enabled the analysis of 60 drugs within 10 min using a combination of full-scan MS and product-ion MS-MS. LC-MS is also increasingly being employed in the analysis of anabolic steroids in equine blood (Guan *et al.* 2005) and urine (Ho *et al.* 2006).

With the development and commercial availability of high-sensitivity, triple-quadrupole, LC-MS systems, the application of LC-MS to screening has become increasingly important. The duty cycle of modern systems and the development of improved software systems for instrument control have significantly increased the number of analytes that can be included in a single screening run. Further advances include the development of hybrid triple-quadrupole/ion-trap systems that allow generation of full-scan data triggered by the detection of a multiple reaction monitoring (MRM) signal. However, triple-quadrupole screening is by its nature and definition a highly targeted approach. Significant interest in the application of full-scan, high-resolution, accurate mass techniques for general screening has been expressed by a number of laboratories around the world (Hewitt *et al.* 2007). Technological advances in appropriate analyser technologies, such as time-of-flight (TOF) and Orbit rap, are making this significant change in analytical approach more likely (Hudson *et al.* 2007). In addition, developments such as ultra-performance liquid chromatography and improvements in source design allowing the use of higher flow rates with greater reliability will serve to extend the applicability of LC-MS to sport testing.

Drugs misused in sport

As listed above, drugs misused in animal sports include the anabolic steroids, the corticosteroids, NSAIDs, diuretics, sedatives, bronchodilators, protein-based therapeutic agents and alkalinising agents. Of particular interest are the anabolic steroids and corticosteroids; not only may synthetic analogues be misused, but also testosterone or hydrocortisone. This use of a pseudo-endogenous compound that is either indistinguishable, or distinguishable with difficulty, from that which is produced naturally by an individual presents interesting analytical problems. Other examples include recombinant growth hormones and recombinant EPO.

Anti-inflammatory agents

The use of anti-inflammatory agents is considered a major welfare issue by many racing authorities. Loosely they can be categorised as steroidal (based upon the naturally occurring corticosteroid, hydrocortisone) or NSAID. A number of corticosteroids are available, and they have a range of uses and routes of administration including: topical treatment of skin conditions, inhalation for treatment of respiratory tract disorders, and intra-particular administration to treat joint inflammation. The high potency of the corticosteroids, combined with difficulties with derivatisation and extensive fragmentation in electron-impact ionisation, make their detection by mass spectrometry difficult, although confirmatory methods based upon negative-ion chemical ionisation GC-MS have been developed (Houghton *et al.* 1982). A number of commercial ELISAs capable of detecting either a range of corticosteroids or a specific corticosteroid are available. More recently, the introduction of API LC-MS has significantly simplified their analysis by instrumental techniques and a number of methods have been published (Guan *et al.* 2003; Ho *et al.* 2006; Tang *et al.* 2001).

The NSAIDs are a much more structurally diverse group of compounds, including acidic drugs such as ibuprofen and neutral to weakly acidic compounds such as phenylbutazone. Many of the NSAIDs are detectable using GC-MS following methylation and this is a common approach to screening in many laboratories. Many of these drugs are also administered at comparatively high doses. The relatively recent introduction of the COX-2 inhibitor class of NSAIDs has further complicated screening for NSAIDs as most of these are extensively metabolised and not readily amenable to detection by GC-MS, although LC-MS methods are available (Woodward *et al.* 2003).

Anabolic steroids

The use of anabolic/androgenic steroids (AASs), either at the time of racing or as a training aid, is banned by most racing authorities. In most European, Asian and Australasian jurisdictions, the use of these agents is completely prohibited. In the USA the use of selected AASs (nandrolone, testosterone, boldenone and stanozolol) is allowed for legitimate veterinary purposes; all other agents are subject to a complete ban. In addition to the expected improvement in musculature, AASs are said to improve a horse's appetite and to produce behavioural changes of a masculinising type in geldings and mares, though they may also be used in stallions.

In the greyhound, the use of AASs as anabolising agents is also banned. A complication in this arena was the use of testosterone and methyltestosterone as oestrus suppressants (Biddle *et al.* 2005). In many authorities this practice is now banned.

Structurally, there are broadly two chemical types of AASs based upon the androstane and estrane ring systems: those with a 17α-alkyl group, which are active orally but possess hepatotoxicity, and 19-nor derivatives administered by injection.

Studies have shown the metabolism of the veterinary anabolic agents nandrolone, testosterone, boldenone and trenbolone in the horse to be complex, with both phase I and phase II processes playing important roles (Dumasia, Houghton 1981, 1984; Dumasia *et al.* 1983; Houghton 1977; Houghton, Dumasia 1979, 1980). Nandrolone and boldenone have been shown to be endogenous to the male horse (Ho *et al.* 2004; Houghton *et al.* 1984) and along with testosterone are controlled by threshold values (see Table 7.2). A review of the presence and metabolism of endogenous steroid hormones in the horse has recently been published (Scarth *et al.* 2009). Radioimmunoassay and subsequently ELISA procedures have been developed for these veterinary anabolic agents (Jondorf 1977; Jondorf, Moss 1977) and commercial assays are currently available. Also, the identification of the major metabolites for these steroids has enabled the development of multi-residue GC-MS screening procedures (Dumasia *et al.* 1986; Houghton *et al.* 1986). Reduction of the 4-ene-3-one group and epimerisation at C-17 are major phase I pathways. Phase II processes also differ markedly, with sulfate conjugation playing an important role in horses but a minor role in dogs. Thus, the developed methods for screening and confirmatory analysis by MS methods require steps for cleavage of both glucuronic acid and sulfate conjugates.

Metabolism and detection of a number of synthetic steroids, including their esters, have also been studied in the horse (Ho 2005; Ho *et al.* 2007a, 2007b; Kim *et al.* 2000; Lampinen-Salomonsson *et al.* 2006; McKinney *et al.* 2001, 2004; Schoene *et al.* 1994) and both aspects have recently been reviewed (McKinney 2009; Teale, Houghton 2010). A number of studies have been carried out in the dog (Biddle 2008; Brockwell *et al.* 1992; Ralston *et al.* 1992; Stewart *et al.* 2009; Williams *et al.* 2000). These studies have thus been essential to identify key analytes for the development of screening and confirmatory analysis methods.

Diuretics

Furosemide, a loop diuretic, is widely used in horse racing due to the claimed efficacy in reduction of exercise-induced pulmonary haemorrhage (nose bleeds), a relatively common occurrence in some animals. Because of this, the diuretic furosemide is permitted at the time of racing by a number of racing jurisdictions around the world. Some concerns have been raised that the dilution of the urine that results from diuretic use could render detection of some other drugs more difficult. For this reason, in many countries, diuretic drugs are banned as potential masking agents. Diuretics have a wide variety of chemical structures, which make it difficult to find a single suitable screening procedure, although LC-MS is increasingly used. Many of the diuretics are neutral to weakly acidic compounds that are difficult to analyse by GC-MS as they cannot be derivatised reliably.

Basic drugs

A number of classes of drugs of interest to animal sports administrators fall into the general classification of basic drugs. These include, in no particular order, sedatives (such as the phenothiazines), antidepressants (tricyclics such as amitriptyline), local anaesthetics (lidocaine, procaine, etc.), β-agonists and antagonists (clenbuterol, propranalol, etc.). Immunoassays are available for a range of these analytes, particularly those that have high potency and offer particular threats to the sport. Instrumental screening methods offering the ability to detect a number of these substances in a single analytical method are popular and GC-MS is widely used, often following extraction using mixed-mode cartridges as described earlier. LC-MS is also highly applicable and offers the advantage of high sensitivity and rapidity, although this is frequently at the expense of breadth of coverage, particularly where triple-quadrupole systems are employed.

Protein hormones

Rumour concerning the abuse of growth hormone (GH) in horseracing has been circulating for a number of years, but interest in developing methods for its control intensified in 1998 with the approval, in Australia, of recombinant equine GH for veterinary use. Insulin-like growth factor-1 (IGF-1) has been confirmed as a universal marker to detect abuse of the three commercially available recombinant GH variants (equine, porcine and bovine GH) that were shown to be active in the horse (De Kock *et al.* 2001c). However, as IGF-1 is endogenous to the horse, the current international rules of racing would require its control through a threshold value.

In a collaborative study, IGF-1 levels in normal serum samples of horses in South Africa, Australia and the UK were determined by an immunoradiometric assay (IRMA) and were shown to have a close to normal distribution (De Kock *et al.* 2001a). Also, significant increases in IGF-1 levels in serum have been demonstrated after GH administration (De Kock *et al.* 2001c; Faustino-Kemp *et al.* 2001; Noble, Sillence 2001; Popot *et al.* 2001a, 2001d).

To support screening on the basis of immunochemistry methods, LC-MS methods for IGF-1 determination have been developed (Bobin *et al.* 2001; De Kock *et al.* 2001b). In addition, LC-MS has been shown to provide a viable approach for the identification and quantification of IGF-1 (Popot *et al.* 2001c, 2008). Means of directly detecting exogenous GH, based upon the difference in primary amino sequence, have also been reported (Bailly-Chouriberry *et al.* 2008b), as has the use of techniques to detect the immune response of the body to the exogenous protein (Bailly-Chouriberry *et al.* 2008a).

Misuse of recombinant human erythropoietin (rhEPO) in horses, supposedly to improve performance, has received wide publicity. However, the horse is a natural blood doper in that, under exercise, contraction of the spleen can increase the haematocrit by 33%. Thus, misuse of rhEPO presents a serious threat to the welfare of the horse, as its administration coupled with splenic contraction could result in a marked increase in blood viscosity. This increase in an animal undergoing severe exercise could have serious health implications. Some physiological implications of administration of rhEPO to horses were reviewed by (McKeever *et al.* 1996).

ELISA tests to detect rhEPO administration to horses and greyhounds have been evaluated and shown to be effective in serum (Tay *et al.* 1996) and in serum, plasma and urine (Roberts *et al.* 2003). The double western blotting technique developed by Lasne and de Ceaurriz (2000) for EPO analysis in urine has also been evaluated in the horse (Lasne *et al.* 2005) and shown to be effective. As the natural equine EPO does not cross-react with the antibody used in the test, the test provides a better distinction between positive and negative samples when applied to equine urine as opposed to human urine (Roberts *et al.* 2003). In addition an LC-MS method for detection of rhEPO and darbepoetin in equine plasma has been reported (Guan *et al.* 2007, 2008). A number of positive findings in racing horses have been confirmed using both of these techniques.

A further approach to the detection of the misuse of rhEPO has been to screen blood samples for the presence of antibodies, and several ELISA systems have been developed for this purpose (Birks *et al.* 2007). A number of animals with an immune response have been identified in the USA/Canada and subjected to the sanction of not being allowed to compete until the antibody titre decreases to normal levels.

New technologies and future threats

Modern animal sports testing laboratories employ many of the most up-to-date techniques and technologies to address the issues of drug use, including the detection of doping and maintaining the welfare of the athlete. These abilities are particularly well developed in the area of small-molecule drug analysis, but this has come at the cost of increasing complexity of the analytical processes and data handling requirements. A significant challenge facing testing laboratories is to simplify these processes while maintaining the required breadth of coverage. A further challenge in small-molecule analysis is addressing the possible use of 'designer drugs', such as tetrahydrogestrinone, specifically intended to evade detection. The emergence of affordable, robust, high-resolution ($>$20 000) and accurate mass LC-MS instrumentation is considered by many to offer the potential to address many of these issues. Screening based upon full-scan accurate mass LC-MS is potentially both broad ranging and highly selective and could replace more limited targeted screens such as those based upon triple-quadrupole systems. Inclusion of additional analytes is straightforward and, at least for the purpose of gathering information on previous use, retrospective. The use of chemometric tools either to directly detect novel agents or to identify metabolite patterns indicative of abuse may also offer a solution to designer drugs.

A potentially more serious threat is posed by the switch to biological drugs and therapies emerging from the pharmaceutical industrial and medical research laboratories. Development of methods to detect the misuse of GH and EPO presented both the analytical laboratories and the sporting authorities with significant challenges. Rumours of the abuse of more exotic protein-based agents such as snake and cone snail venoms have circulated around the world, although seized materials claiming to contain these materials have often proved to be counterfeit. While these challenges are far from trivial, developments in protein MS, transcriptomics and metabolomics provide the promise that detection methods will become available, either directly or indirectly via biomarkers (Teale *et al.* 2009). It should also be noted that, for the most part, animal sport testing laboratories have the advantage of dealing with protein therapeutics that are clearly endogenous. For example, all the pharmaceutical preparations of EPO currently available are based upon human EPO, the primary structure of which is significantly different from equine or canine EPO.

A more difficult area to address is likely to be the use of therapies that do not directly involve administration of a drug. Examples of these include shock wave therapy and gene doping. Direct detection of these therapies may prove difficult, although significant research into the detection of gene doping has been undertaken and various targets for detection have been identified. A highly attractive possibility is the use of biomarkers. If successful, appropriate biomarkers could provide evidence of misuse of a wide range of agents and possibly replace traditional means of screening.

CHAPTER

8 Drug-facilitated Sexual Assault

MD Osselton

Drug-facilitated assault (DFA) has emerged as a major area of forensic work during recent years as a consequence of media publicity attributed to a handful of drugs such as flunitrazepam, gamma-hydroxybutyrate (GHB) and ketamine. Although drug-facilitated sexual assault (DFSA) has attracted much attention, drug-related assault may also be encountered in cases of robbery or uncharacteristic and antisocial behaviour by an individual. DFSA has been loosely described by the popular media as 'date rape' and linked with drink spiking, particularly in club venues. Despite media publicity, drink-spiking cases probably make up only a small percentage of DFSA cases and the majority of cases are associated with recreational drug and alcohol use by the victim. In a typical drink-spiking scenario, a potential sexual offender surreptitiously spikes the drink of an unsuspecting person with a sedative substance for the purpose of 'drugging' and subsequently sexually assaults the victim while he or she is under the influence of this substance. Victims often report loss of memory during and after these incidents and may wake up in unfamiliar places, inappropriately dressed and often with the sense but not the actual recollection of having had sex. DFSA is not limited to male assaults on females but may involve female assault on males as well as homosexual assault. DFSA is not a new crime and appears to be documented in the Bible where Lot's daughters are recorded to have used wine to drug him before having sexual intercourse with him in order to procreate. Both daughters became pregnant and subsequently produced sons Moab and Benammi (Genesis 19 : 30-38).

This chapter will consider the terminology used in association with drug-related assault, the types of substances most frequently encountered, and the approaches that may be taken when investigating such cases.

Definitions

'Assault' may be defined as 'an intentional act by one person that creates an apprehension in another of an imminent harmful or offensive contact'. In the UK the Sexual Offences Act 2003 came into force in May 2004 and essentially repealed most of the existing statute law relating to sexual offences. Under the auspices of the UK Sexual Offences Act 2003 a person A is guilty of a sexual assault if: (i) he/she intentionally touches another person (B); (ii) the touching is sexual; (iii) B does not consent to the touching; and (iv) A does not reasonably believe that B consents. It is up to the court to decide whether 'belief' is reasonable after having regard to all the circumstances, including any steps A has taken to ascertain whether B consents. This law covers any kind of intentional sexual touching of another person without their consent. It includes touching any part of their body, clothed or unclothed, either with the body or with an object (www.homeoffice.gov.uk/crime/sexualoffences/legislation/act.html). The Act therefore makes it an offence for any male or female to intentionally touch another person sexually without his or her consent. Under the same Act, rape occurs if a male penetrates with his penis the vagina, or the anus or mouth of a female or male without their consent. The issue of consent is therefore a key issue. The Sexual Offences Act 2003 for the first time in UK law provides a clear definition of consent, making it easier for courts to decide upon evidence put before them. Section 74 of the Act defines consent as follows: 'A person consents if he/she agrees by choice and has the freedom and capacity to make that choice.'

Date rape, also referred to as 'acquaintance rape', defines a sexual assault/rape or attempted assault/rape by an acquaintance who may have been previously known to the victim or whom the victim has met socially for the first time. Although the terms 'date rape' and 'drug-assisted rape' have been used interchangeably, the two should not be confused. Drug-facilitated sexual assault occurs when a person is subjected to non-consensual sexual acts while their capacity to provide consent is impaired (or they are unconscious) owing to the effect(s) of ethanol, a drug and/or other intoxicating substance, and are therefore prevented from resisting and/or unable to consent. The drug can be any substance that induces changes to the physical state of the intended victim or that exerts mind-altering properties. While UK law has been cited above as an example of legislation, the definitions of rape, sexual assault and drug-facilitated sexual assault are not dissimilar in other countries. In the USA, sexual assault may be referred to in different terms in the laws of different states (sexual battery, criminal sexual assault, rape, etc.); however, the underlying principles of law remain essentially the same.

Frequency/statistics of DFSA

The extent of DFSA cases has not been officially recorded and only estimates of its prevalence are available in the literature. The extent of DFSA is difficult to gauge because some incidents are not reported to the police and others are not reported within a time frame that enables drug exposure to be identified by the analysis of blood or urine specimens. The European Monitoring Centre for Drugs and Drug Addiction stated that between 1997 and 2007 there had been a rise in the number of reports in which drugs and alcohol had been used to immobilise victims for the purposes of sexual assault (www.emcdda.europa.eu). It further reported that surveys in six European Union countries suggested that up to 20% of women had experienced some form of sexual assault in their adult lifetime. In 2001 the British Crime Survey estimated the total number of rapes of females to be between 11 000 and 39 000 (Walby, Allen 2004); however, the proportion of cases in which drugs were implicated is unknown. Figures taken from the British Crime Survey 2010 relating to male and female rape and sexual assault between 2004/2005 and 2009/2010 are summarised in Table 8.1, which shows an apparent decrease in the number of cases. The way the statistics have been collected has changed, however, and therefore the latest results are not directly comparable with those of earlier years. As with the earlier reported figures by Walby and Allen, there is no indication in the British Crime Survey 2010 of what proportion of cases were implicated as involving drug use. It is notable that during the same period the number of drug-related offences rose by 62% from 145 837 to 234 998. Only a small number of studies have been published in the scientific literature that provide information on the extent of alcohol and drug use in DFSA cases. For example, the number of reported sexual assaults in the USA according to the FBI Uniform Crime Report is presented in Table 8.2. Both the number and the rate of reported rapes declined throughout most of the 1990s, reaching a low in 1999. It is also well known that the number of reported rapes is significantly lower than the actual number. In 1999, for example, the Bureau of Justice Statistics estimated that there were over 141 000 cases of sexual assault, 58% more than the number actually reported to the police.

Table 8.1 Rapes and sexual assaults reported between 2005 and 2010, abstracted from the British Crime Survey 2010

Year	*Rape – female over 16 years*	*Rape – female under 16 years*	*Sexual assault on females over 13 years*	*Rape – males over 16 years*
2005/2006	8786	3153	17 158	460
2006/2007	8247	2853	16 883	431
2007/2008	7731	2413	15 780	344
2008/2009	7950	2538	15 503	339
2009/2010	9102	2926	15 713	372

Elsohly and Salamone (1999) surveyed 1179 urine samples from suspected DFSA victims collected from 49 states, Puerto Rico and the District of Columbia over a 26-month period. The urine specimens were screened using immunoassay for amfetamines, barbiturates, benzodiazepines, cannabinoids, cocaine metabolite (benzoylecgonine), methaqualone, opiates, phencyclidine and propoxyphene. In addition, samples were screened for flunitrazepam metabolites and GHB by gas chromatography–mass spectrometry and for ethanol by gas chromatography using a flame ionisation detector. No drug substances were detected in 468 of the samples; 451 specimens tested positive for ethanol, 218 for cannabinoids, 97 for benzoylecgonine, 97 for benzodiazepines, 51 for amfetamines, 48 for GHB, 25 for opiates and 12 for barbiturates. Of the samples shown to contain drugs, 35% contained multiple drugs. A similar study undertaken in the UK analysed the toxicology results from 1014 cases submitted to the Forensic Science Service London laboratory between January 2000 and December 2002 (Scott-Ham, Burton 2005). Alcohol was reported to be present in 470 of all cases (46%) either alone or in combination with drugs. Drugs of abuse were detected in 344 cases (34%), with cannabis being the most commonly detected in 260 cases (26%), cocaine in 110 cases (11%), MDMA in 47 cases (5%), amfetamine in 23 cases (2%), diamorphine in 12 cases (1%) and ketamine in 3 cases (0.5%). Potentially stupefying drugs were detected in 187 cases (18%), although in the vast majority of these cases the drugs had been taken therapeutically by the victim or taken after the incident. Only 21 cases (2%) were attributed to involuntary ingestion, i.e. as a result of deliberate drink spiking. During the 3-year period of the survey no evidence for the use of flunitrazepam was observed. As in the ElSohly study, only a few cases were encountered in which a sedative drug was detected and its presence could not be attributed to voluntary use by the complainant. Scott-Ham and Burton further analysed the blood and urine alcohol concentrations in cases of alleged DFSA (Scott-Ham, Burton 2006). Of the 1041 cases scrutinised, 391 had blood and/or urine samples collected within 12 h of an alleged incident. The authors back-calculated the alcohol concentrations in these 391 samples to estimate the possible alcohol concentration at the time of the alleged incident. Following back-calculation, 60% of cases were estimated to have a blood alcohol concentration in excess of 150 mg alcohol per 100 mL of blood at the time of the alleged incident. Hall *et al.* (2008) surveyed blood alcohol concentrations (BACs) determined in cases of alleged DFSA in Northern Ireland between 1999 and 2005 and reported that the estimated average BAC (218 mg/100 mL) remained broadly similar during the period of the study. Jones *et al.* (2008) analysed blood and urine specimens from 1806 female victims of alleged non-consensual sexual activity. No alcohol or drugs were reported to be present in 559 cases (31%) and ethanol alone was detected in 772 cases (43%). In 215 cases (12%) ethanol occurred together with at least one other drug. The mean, median and highest concentrations of ethanol in blood ($N = 806$) were 124, 119 and 370 mg/100 mL, respectively. Amfetamine and cannabinoids were reported to be the most common illicit drugs detected. Elliott and Burgess (2005) reported on 169 clinical requests relating to surreptitious drug administration over a 2-year period between 2002 and 2004. Approximately half of the cases analysed were negative for alcohol or drugs, but in the cases that were positive alcohol and common drugs of abuse were found to be present. Neither GHB nor flunitrazepam was detected in any of the cases. These studies indicate that the patterns of drug and alcohol use in DFSA cases is similar in different countries and that alcohol is the most frequently encountered substance in these cases.

Table 8.2 Number of reported sexual assaults – FBI Uniform Crime Report

Year	*Number of sexual assaults*	*Rate per 100 000*
1990	102 560	41.2
1991	106 590	42.3
1992[a]	109 060	42.8
1993	106 010	41.1
1994	102 220	39.3
1995	97 460	37.1
1996	96 252	36.3
1997	96 153	35.9
1998	96 144	34.5
1999[b]	89 411	32.8
2000	90 178	32.0
2001	90 863	31.8
2002	95 136	33.0
2003	93 433	32.1

[a] The highest.
[b] The lowest.

Toxicological approach to DFSA

Delay in collecting samples can be a critical factor for drugs that exhibit short elimination half-lives, e.g. GHB, as these may not be detectable at concentrations above endogenous levels after around 10–12 h of administration. In the UK, the Association of Chief Police Officers (ACPO) produced the report *Operation MATISSE – Investigating drug facilitated sexual assault* (Gee *et al.* 2006), which assessed the time periods between alleged incidents and the collection of urine samples. They found that, out of a total of 117 samples collected, 25.6% of samples had been collected within the first 6 h, 47.8% within 11.59 h, 84.5% within 23.59 h and 94.8% within 47.59 h.

It is essential that specimens for analysis should be collected as soon as possible after the victim becomes aware that a drug-related sexual assault has taken place. This of course depends on the victim reporting the incident to the appropriate authorities and is outside the toxicologist's control. Laboratories can, however, take a proactive role in working with their local authorities, colleges, health departments, police forces and forensic medical examiners to make them aware of the need to educate the population at large to report incidents and of the need to collect specimens as soon as possible after an alleged offence is suspected to have taken place. Urine specimens can be collected without the need for trained medical personnel to be present and without the need for observed supervised collection, thus facilitating the obtaining of an early evidence specimen while waiting for medical examiners to arrive and collect blood specimens. In order

- Name of subject
- Age
- Sex
- Weight
- Height
- Build (proportional/stocky or muscular/obese/slim etc.)
- Date of incident
- Time of incident
- Date samples taken
- Time samples taken
- Occupation of complainant
- Name and contact details of investigating officer
- Name and contact details of the doctor that examined the victim
- Details of the incident – full case history
- What led the victim to suspect that a DFSA offence had taken place?
- Did the victim fall unconscious? If so provide approximate times, e.g. how long was he/she unconscious?
- Does the victim suffer from any medical condition requiring treatment from a physician?
- Does the victim suffer from any medical condition, e.g. diabetes, depression?
- Did the victim empty his/her bladder prior to reporting the incident?
- Had complainant taken any alcohol, drugs or medication within 48 hours prior to the incident? If so what? How much? and when?
- If alcohol was consumed in the period leading up to the incident was this more than would have normally been consumed? If yes give details of times and amounts consumed.
- Were alcohol or any drugs consumed after the incident? If yes what, how much and when?
- Were any symptoms experienced, e.g. drowsiness, dizziness, nausea, vomiting, impairment of memory, thirst, sweating or shivering, unusual taste, hallucinations?
- Were any of the following symptoms observed by police officers or the medical examiner? Drowsiness, poor coordination, unsteadiness, shivering, sweating, nystagmus, hyperactivity, abnormal pupil size
- Is the complainant a known drug user? If so obtain details
- Is the identity of the suspect known? If so have blood or urine specimens been obtained from the suspect for analysis?
- What is the occupation of the suspect?
- What are the hobbies of the suspect, e.g. making model aircraft
- Have any other exhibits been collected and submitted for analysis, e.g. cups, glasses, tablets, etc.?

Figure 8.1 Information required in cases of suspected drug-facilitated sexual assault.

to avoid irretrievable loss of forensic evidence, it is recommended that a urine specimen should be collected before the commencement of any interviews with the victim. At least 20–25 mL urine should be collected as soon as possible after an incident has been reported. Ideally the urine should contain sodium fluoride as preservative at a minimum final concentration of around 1.5% w/v. There have been anecdotal reports of concerns being expressed in some areas of the USA that supervised collection should be enforced, as in workplace drug testing, to ensure that alleged victims do not add drug substances to their urine specimens in order to make malicious accusations against an innocent party.

As soon as the forensic medical examiner is available, a specimen of blood should be collected. The volume of blood collected should ideally be of a minimum volume of 10 mL and should be collected into a sealed glass container with a minimum final concentration of 1.5% w/v sodium fluoride as preservative. A second urine specimen (20 mL) should also be collected into a container with sodium fluoride preservative as above. All specimens should be clearly labelled with the name of the victim as well as the time and date that the specimen was collected. Specimen containers should not be over-filled. This avoids breakage if the sample is frozen at a later time. Once the early evidence specimens have been obtained, the case history and information regarding the events and circumstances should be recorded. Many police forces and clinics will have their own protocols for collecting details of the case circumstances. However, it is important that the case history should be as detailed and comprehensive as possible. The information that should be collected is summarised in Figure 8.1. Information can provide the toxicologist with important clues as to what, or what not, to look for and in cases where limited sample volumes have been submitted for analysis can make the difference between detection of an incapacitating agent and a negative finding.

In addition collection of a detailed case history and blood, hair and urine from the alleged victim, any suspected tablets, powders, drinks, containers or residues in cups, etc. should be collected and submitted for possible analysis. While this may be impracticable if the alleged drink spiking occurred in a bar, many alleged incidents take place in the home where exhibits are less likely to have been disposed of. The examination of drinking vessels may reveal drug or tablet residues. In cases where gelatin capsules have been added to hot drinks it is not uncommon to be able to see the melted capsule adhering to the base of the cup. If the subject has vomited and vomit stains are available, these may also be considered for analysis. Alleged incidents in public bars may be recorded on security video systems and examination of these can also provide useful evidence of an alleged incident.

Samples and sample collection

Blood, urine and hair are recommended for collection wherever possible, although each has its merits and limitations. Blood is the tissue of choice for analysis because it provides potentially interpretable results and helps place drug consumption within a fairly narrow time frame (up to 24–36 h depending on the drug consumed and the amount taken). Many drugs may be detected in blood for 24–36 h after consumption, although GHB is unlikely to be present in concentrations greater than endogenous concentrations approximately 6–8 h following consumption (Andresen *et al.* 2010). If it is suspected that GHB has been consumed, urine should be collected in addition to blood. Blood and urine should be stored in a refrigerator prior to submission to the forensic laboratory for analysis.

As well as being easy to collect, urine is usually plentiful and easy to analyse, contains higher concentrations of drugs or their metabolites than blood, and provides a wider window of detection than blood. Depending on the drugs consumed, urine may enable the detection of drugs of abuse, benzodiazepines, flunitrazepam metabolites, trichlorinated compounds and many basic drugs for up to 2–3 days after consumption and hence is particularly useful in cases where a long delay in reporting an incident has occurred. The window of detection for GHB in urine, although greater than that of blood, is still short and is unlikely to yield meaningful results for this compound if more than 12 h has elapsed between ingestion and specimen collection. Alcohol may usefully be analysed in urine and used for back-calculations up to around 24 h after consumption but after this time the results are likely to provide only limited information. The major flunitrazepam metabolite (7-aminoflunitrazepam) can be detected in urine for up to 72 h following the ingestion of a single therapeutic dose (Negrusz *et al.* 2000; Snyder *et al.* 2001). Table 8.3 summarises the approximate detection times for alcohol and some common drugs in blood and urine after single or therapeutic doses.

In cases where the time elapsed between an incident and reporting exceeds 24–48 h, hair analysis should be considered. Hair grows, on average, at a rate of approximately 1 cm per month and therefore a hair specimen should be collected at the time of the first examination and the victim advised to return to provide a second hair specimen after approximately 6 weeks. The first hair specimen taken after the incident may then be used as a control and any drugs taken around the time of the incident will hopefully show up in the second sample. Protocols for hair collection and analysis are provided in Chapter 19. If it is proposed to collect hair specimens, a clear explanation should be given to the alleged victim of the potential outcomes in terms of the results of the analysis. The subject should be advised that where he or she is a voluntary drug user but has not declared the fact, the ramifications of this being disclosed in court could be potentially damaging.

Table 8.3 Approximate detection times for alcohol and common drugs following the consumption of single or therapeutic doses

	Detection time (h)	
Drug	***Blood*[a]**	***Urine*[a]**
Alcohol	8–10	24
Amfetamines	12	24–48
Barbiturates	24	242–48
Benzodiazepines (including metabolites)	48	48–72
Cannabinoids	4–12[b]	12–48
Cocaine	12	12
Benzoylecgonine	12–24	24–48
Flunitrazepam	12–24	48–72
GHB	<8	10–12
Morphine/opiates	12	24–48
Methadone	24	24–48
MDMA	12–24	24–48
Ketamine	4–10	12–24

[a]Dependent on limit of detection of assay and quantity consumed.
[b]May not detect occasional use.

Sample analysis

Beverages, cups and tablets

Commercial 'Quick Test' kits have been marketed for use by the public to test drinks for adulteration *in situ* in a nightclub scenario. Beynon *et al.* (2006) reported on the evaluation of two such kits – 'Drink Guard' and 'Drink Detective' – and concluded that 'whilst drink spike testing kits may be a useful public health tool, neither kit demonstrated high levels of sensitivity, specificity or utility' under the laboratory protocols used for the evaluation. They further stated that 'in practice this could leave the public feeling falsely reassured or overplay the magnitude of drink spiking'.

Liquids submitted for analysis should be carefully examined against control samples for signs of adulteration, which might be indicated by cloudiness, opacity, colour changes (the manufacturers of flunitrazepam incorporated a blue dye into the tablets to provide an indication of drink spiking), particles floating on the surface or residues in the bottom of the container. If a liquid preparation of an adulterant such as GHB is added to a beverage there may be no easily recognisable sign of adulteration. However, if a liquid herbal preparation is added, e.g. valerian tincture, distinct colour changes may be observed. Herbal preparations such as crushed herbal sleep aid tablets often yield floating debris that is easily recognisable. The addition of coloured tablets or capsules containing oily drug formulations may be indicated by a coloured scum or immiscible oily globules floating on the surface of the drink. Most tablets comprise bulking agents in addition to the active pharmaceutical ingredient and these may sometimes be left as visible residues in the bottom of a drinking container. Figures 8.2–8.5 illustrate, respectively, a crushed tablet showing parts of coating prior to addition to a beverage, an Arthrotec tablet partially dissolved in water, a residue in a tea cup following removal of the beverage by decanting and floating waxy particles following the addition of crushed tablet with wax coating.

In some cases there may be sufficient residue present in a container that it can be scraped from the bottom and analysed directly using colour tests, ultraviolet spectrophotometry (UV), Fourier transform infrared spectrometry (FTIR), thin-layer chromatography (TLC), high performance liquid chromatography (HPLC) or gas chromatography–mass spectrometry (GC-MS). In cases where only a slight residue may be indicated, the receptacle should be washed with a small quantity of ethanol, which can be retrieved, evaporated and subsequently tested by immunoassay screening or instrumental analysis such as high

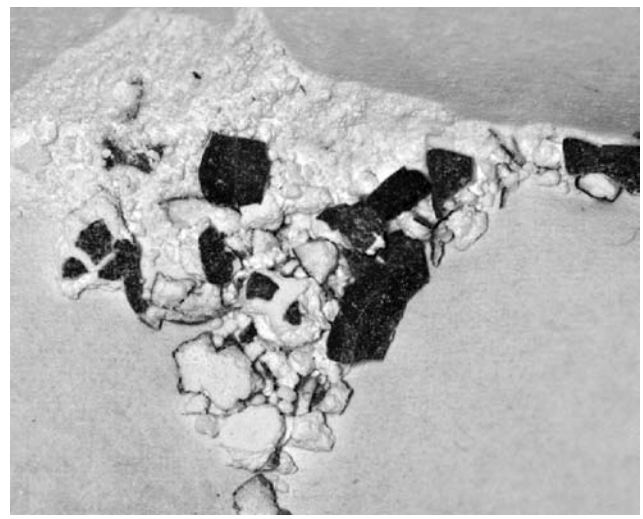

Figure 8.2 Crushed tablet material showing parts of tablet coating.

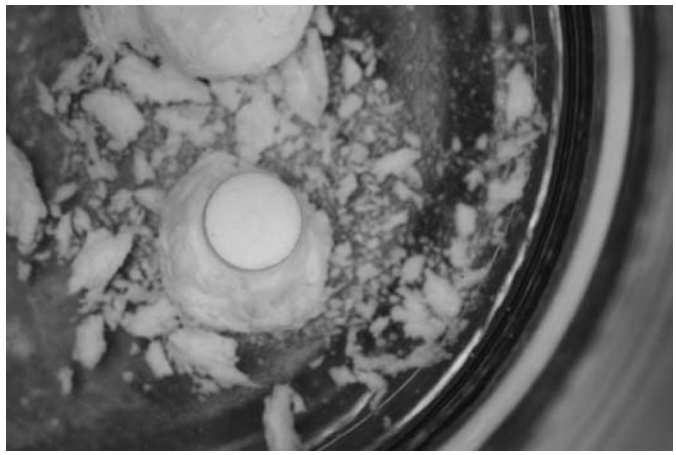

Figure 8.3 Arthrotec tablet added to water showing undissolved residue and inner tablet.

performance liquid chromatography–mass spectrometry (LC-MS). Procedures for the identification of intact tablets are given in Chapter 13 and colour tests are provided in Chapter 30. HPLC is a particularly valuable technique for the analysis of beverages suspected to have been adulterated with drugs since the beverage may be injected directly into the HPLC instrument and the elution profile compared against an unadulterated control. Figure 8.6 shows the HPLC analysis of Pepsi Max adulterated with ketamine following direct injection of the beverage into the HPLC diode array system. Figure 8.7 provides a checklist of points for consideration when analysing an exhibit suspected to contain an adulterated beverage. Olsen *et al.* (2005) added eight potentially sedating medicinal drugs (flunitrazepam, oxazepam, zopiclone, carisprodol, clonazepam, morphine, diazepam and alprazolam) to water, beer, Coca-Cola and 12% ethanol, and measured the drug concentrations at 5, 10, 20 and 40 min after adding the drugs. They concluded that, although a sufficient amount of each drug dissolved in the beverages to potentially cause impairment, adulteration would be likely to be apparent to the consumer from the altered appearance and/or taste of the beverages.

Figure 8.4 Residue of crushed tablet in bottom of cup that had contained tea.

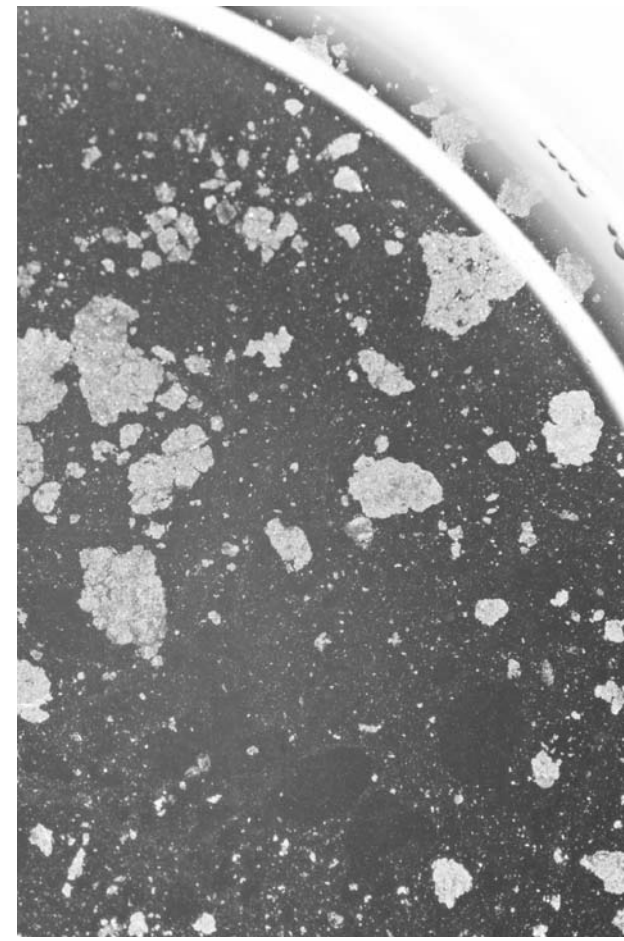

Figure 8.5 Wax film floating on the surface of adulterated tea.

Blood and urine

As a consequence of the wide range of drugs that may be used to facilitate DFSA there is no single analytical method that can be applied for the detection of possible adulterants. Blood and urine should always be analysed for the presence of alcohol (*see* Chapter 4) followed by immunoassay screening for the presence of drugs of abuse. At the time of writing, the availability of immunoassay screening tests for drugs other than common drugs of abuse is limited. However, suppliers of commercial immunoassay reagents are beginning to develop screening test panels for substances that may be encountered in DFSA cases, e.g. GHB, ketamine, meprobamate, the 'Z' drugs (zaleplon, zolpidem and zopiclone), flunitrazepam metabolites, phenothiazines and chloral metabolites. The Randox microarray technology (Figure 8.8) offers a sensitive means of screening up to 12 drugs simultaneously on a single drop of blood or urine (www.Randox.com). Immunoassay screening in DFSA cases should be carried out using appropriate 'cut-off' concentrations. Laboratories should strive to employ the lowest cut-off concentrations that are reliable and should recognise that the high cut-offs

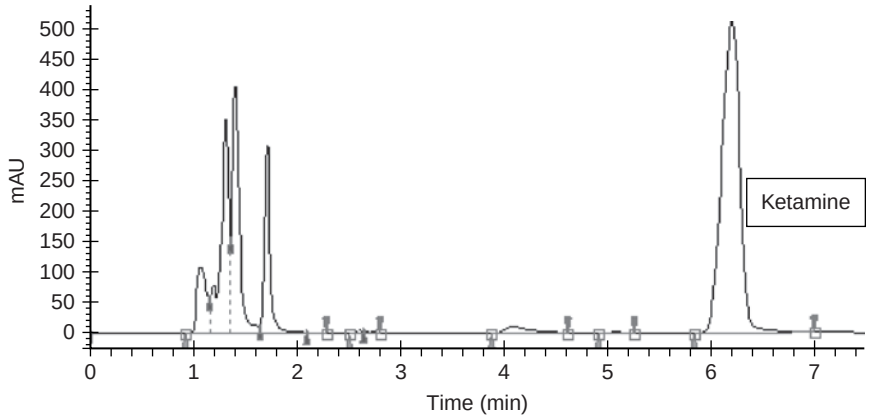

Figure 8.6 HPLC chromatogram of Pepsi Max adulterated with ketamine. Varian C_{18} column (150 mm × 2.1 mm); isocratic 5 mmol/L ammonium acetate–acetonitrile (50 : 50 v/v) monitored at 210 nm.

recommended by SAMHSA for workplace drug testing (see Chapter 3) are totally inappropriate for use in DFSA case screening. Analysts should also be aware of the limits of detection and quantification of their methods used in wider GC or HPLC screening procedures. The lower the limit of detection of an assay, the greater the window of drug detection will be. The Society of Forensic Toxicologists (SOFT) formed an expert committee to provide guidance for its members on the way cases should be approached. The SOFT expert committee published a list of recommended minimum

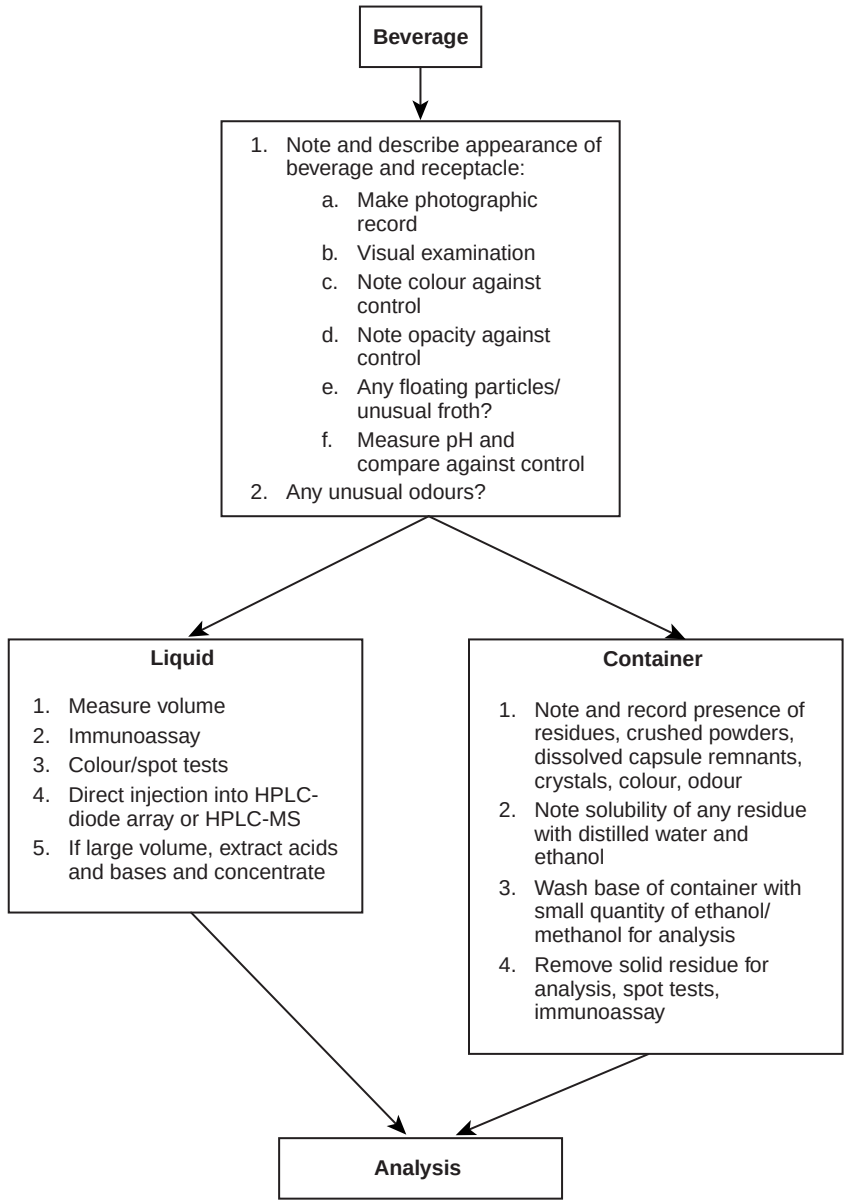

Figure 8.7 Examination checklist for adulterated beverages.

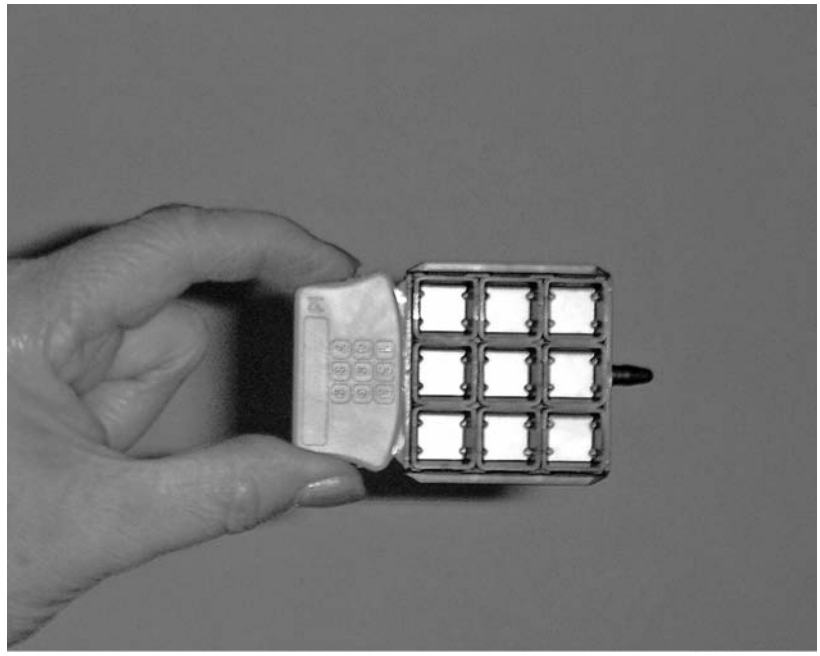

Figure 8.8 Randox Microarray for drug screening. Each of the nine squares shown in the figure is capable of detecting up to 12 different drugs from 1–2 drops of urine, blood or tissue suspension.

limits of detection for drugs that laboratory methods should achieve when screening DFSA cases. The list of recommended limits of detection is presented as Table 8.4 courtesy of SOFT. Comprehensive methods for drug screening of blood and urine can be found in Chapter 1.

A method described by Adamowicz and Kala (2010) for the simultaneous screening of 128 drugs associated with DFSA cases in urine using GC-MS is summarised as follows. To urine (2 mL) add diazepam-d_5 and methadone-d_4 internal standards to achieve final concentrations of 2.5 μg/mL for each internal standard. Add 1 mL of 0.1 mol/L acetate buffer (pH 5.5) and β-glucuronidase/arylsulfatase (50 μL). Incubate for 60 min at 55°C. Precondition Oasis HLB SPE cartridges using 2 mL of methanol followed by 2 mL of deionised water. Add the hydrolysed urine specimens to the preconditioned SPE cartridges and allow the urine to drain slowly through the column under a mild vacuum. Rinse the column with 2 mL of deionised water and discard the water wash before drying the columns under vacuum for 5 min. Elute retained analytes using 0.8 mL of methanol and 0.8 mL of a mixture of methanol–isopropanol (3 : 1) under gravity. Evaporate the eluate to dryness under nitrogen at 37°C. Derivatise the dry column eluates using 50 μL of BSTFA + 1%TMCS in 40 μL of ethyl acetate–acetonitrile (1 : 1) at 60°C for 30 min. Derivatised samples may be analysed by GC-MS.

If urine is available it should also be screened for trichlorinated compounds, e.g. trichloroethanol, which is formed in the body after the consumption of chloral/chloral hydrate using the Fujiwara test. To 2 mL of urine in a boiling tube add 2 mL freshly prepared 20% sodium hydroxide solution followed by 1 mL of pyridine. Place into a bath containing boiling water and leave for 5–10 min. The presence of trichlorinated substances is indicated by the formation of a pink/violet coloration in the upper pyridine layer. A blank sample should always be tested when using the Fujiwara test as the presence of chloroform vapour in the laboratory atmosphere can also give a positive result.

Drugs with potential for use in DFSA cases

The ideal drug properties for substances used in DFSA include rapid onset of action, reduced inhibitions, drowsiness, reduced ability to resist unwanted advances, anterograde amnesia, tastelessness, potency such that effects are obtained after consumption of low doses, short elimination half-life for rapid elimination from the body, and ease of administration. Substances that have been associated with DFSA are all psychoactive, sedative or hypnotic drugs exerting their action on the central nervous system (CNS). The list of drugs that may potentially be used in sexual assault is long and may include alcohol and sleep aids that are readily available in over-the-counter preparations in supermarkets and health shops, as well as medicinally prescribed hypnotics, anxiolytics, antidepressants, phenothiazines, antihistamines and illegal drugs of abuse. To make the analyst's role even more challenging, we must also be aware that, as a consequence of the high frequency of international travel, drugs that are not commonly encountered in the victim's country of residence may be obtained while individuals are on holidays or business trips abroad. Proprietary drug names used in different parts of the world may be obtained from sources such as *Martindale's Complete Drug Reference* (Sweetman 2007) and the *Physicians Desk Reference*.

Alcohol

Alcohol is the most commonly encountered substance in DFSA cases probably because it is taken voluntarily, is inexpensive and is easy to obtain. Alcohol misuse has drawn considerable attention in recent years because many young people engage in binge drinking. There are even venues in some major cities where alcohol may be purchased via intravenous administration to enable users to experience rapid and intense intoxication. Alcohol is a CNS depressant that in low doses may produce enhanced sociability, mild euphoria, talkativeness and relaxation of inhibitions. Higher BACs may induce drowsiness, impaired coordination, impaired information processing, impaired judgement, memory loss, reduced attention span, increased reaction times and impaired muscular function. The physical signs of alcohol intoxication include nystagmus, loss of balance and impaired coordination, impaired speech, vomiting and incontinence. A full account of alcohol abuse is provided in Chapter 4. Unlike most other drugs possessing psychoactive properties and inducing behaviour changes, it is possible to broadly estimate the effects that a given BAC might exert on a person (see Table 4.2, Chapter 4).

Antihistamines

Antihistamines are widely available as both prescription and over-the-counter products for the treatment of allergies, as cold remedies and as sleep aids. The most commonly encountered antihistamines include bromodiphenhydramine, brompheniramine, chlorpheniramine, cyclizine, diphenhydramine, doxylamine, ethopropazine and

Table 8.4 Recommended maximum detection limits for common DFSA drugs and metabolites in urine samples

Target analytes	*Parent drug*	*Trade names/ `street names'*	*Recommended maximum detection limit*
Ethanol			
Ethanol	Ethanol	Alcohol, ethyl alcohol, 'booze'	10 mg/dL
GHB and analogues			
Gamma-hydroxybutyrate	Gamma-hydroxybutyrate	Xyrem, 'GHB', 'Easy Lay', 'G', 'Georgia Home Boy', 'Grievous Bodily Harm', 'Liquid Ecstasy', 'Liquid E', 'Liquid G', 'Liquid X', 'Salty Water', 'Scoop', 'Soap'	10 µg/dL
	1,4-Butanediol	'1,4-BD', 'Enliven', 'Inner G', 'Revitalize Plus', 'Serenity', 'SomatoPro', 'Sucol B', 'Thunder Nectar', 'Weight Belt Cleaner', 'White Magic'	
	Gamma-butyrolactone	'GBL', 'Blue Nitro', 'G3', 'Gamma G', 'G.H. Revitalizer', 'Insom-X', 'Invigorate', 'Remforce', 'Renewtrient', 'Verve'	
Benzodiazepines			
Many benzodiazepines are biotransformed into glucuronide-conjugated metabolites. To improve detection limits and times, it is recommended that laboratories use hydrolysed urine specimens to free the conjugate before extraction. Instrumental techniques will detect the glucuronide metabolites *or* hydrolyse urine specimens to free the conjugate before extraction.			
Alprazolam	Alprazolam	Xanax, Nirava	10 ng/mL
α-Hydroxy-alprazolam			
Chlordiazepoxide	Chlordiazepoxide	Librium, Libritabs	10 ng/mL
Clonazepam	Clonazepam	Clonapin, Klonopin, Rivotril	5 ng/mL
7-Aminoclonazepam			
Diazepam	Diazepam	Valium, Diastat, Dizac	10 ng/mL
Flunitrazepam	Flunitrazepam	Rohypnol	5 ng/mL
7-Flunitrazepam			
Lorazepam	Lorazepam	Ativan	10 ng/mL
Nordiazepam	Diazepam, chlordiazepoxide		10 ng/mL
Oxazepam	Oxazepam, diazepam, chlordiazepoxide, nordiazepam, temazepam	Serax	10 ng/mL
Temazepam	Temazepam, diazepam	Normison, Restoril	10 ng/mL
Triazolam	Triazolam	Halcion	5 ng/mL
4-Hydroxy-triazolam			
Marijuana			
11-Carboxy-THC	Tetrahydrocannabinol (THC)	Marinol, Dronabinol, 'Marijuana', *Cannabis sativa*	10 ng/mL
Barbiturates			
Amobarbital	Amobarbital	Amytal	25 ng/mL
Butalbital	Butalbital	Esgic, Fioricet, Fiorpap, Fiorinal	
Pentobarbital	Pentobarbital, thiopental	Nembutal	
Phenobarbital	Phenobarbital, primidone		
Secobarbital	Secobarbital	Seconal, Tuinal	20 ng/mL
Over-the-counter medications			
Brompheniramine	Brompheniramine	Alatapp, Bromaline, Bromanate, Bromfed, Bromphen, Dimetane, Dimetapp, Myphetane, Polytine, Puretane	10 ng/mL
Desmethylbrompheniramine			
Chlorpheniramine	Chlorpheniramine	Aller Chlor, Chlor-Trimeton, Coricidin, Deconamine, Efidac, Kronofed, Teldrin	
Desmethylchlorpheniramine			
Dextromethorphan	Dextromethorphan	Benylin, Romilar, Delsym	
Diphenhydramine	Diphenhydramine	Banophen, Belix, Benadryl, Dermarest, Excedrin PM, Hydramine, Sleepinal, Sleep-Eze 3, Tylenol PM, Unisom Sleep Gels	
Doxylamine	Doxylamine	Unisom, Bendectin	
Desmethyldoxylamine			

Table 8.4 continued

Target analytes	*Parent drug*	*Trade names/`street names'*	*Recommended maximum detection limit*
Antidepressants			
Amitriptyline	Amitriptyline	Elavil, Endep	10 ng/mL
Nortriptyline			
Citalopram	Citalopram	Celexa, Cipramil	
Desmethylcitalopram			
Desipramine	Desipramine, Imipramine	Norpramin, Pertofrane	
Doxepin	Doxepin	Sinequan, Adapin, Zonalon, Prudoxin	
Desmethyldoxepin			
Fluoxetine	Fluoxetine	Prozac, Sarafem	
Norfluoxetine			
Imipramine	Imipramine	Tofranil	
Paroxetine		Asimia, Paxil	
Sertraline	Sertraline	Zoloft	
Norsertraline			
Narcotic and non-narcotic analgesics			
Codeine	Codeine		
Fentanyl	Fentanyl	Actiq, Duragesic, Sublimaze, Innovar	
Hydrocodone	Hydrocodone	Anexsia, Hycodan, Lorcet, Lortab, Norco, Panacet, Vicodin, Zydone	
Hydromorphone	Hydromorphone	Dilaudid, Palladone	
Meperidine	Meperidine	Demerol, Mepergan	
Normeperidine			
Methadone EDDP	Methadone	Dolophine	10 ng/mL
Morphine	Morphine	Avinza, Astramorph, Duramorph, Kadian, MSIR, MS Contin, Oramorph, Roxanol	
Oxycodone	Oxycodone	OxyContin, Oxyir, Roxicodone, Percodan, Percocet, Percolone, Roxicet, Tylox	
Propoxyphene	Propoxyphene	Darvocet, Darvon, Wygesic	
Norpropoxyphene			
Miscellaneous drugs			
Carisoprodol	Carisoprodol	Som	50 ng/mL
Clonidine	Clonidine	Catapres, Combipres, Clorpres, Duraclon	1 ng/mL
Cyclobenzaprine	Cyclobenzaprine	Flexeril	10 ng/mL
Ketamine	Ketamine	Ketalar	1 ng/mL
Norketamine			
Methylenedioxyamfetamine	Methylenedioxyamfetamine		10 ng/mL
Methylenedioxymethamfetamine	Methylenedioxymethamfetamine		
Meprobamate	Meprobamate, carisoprodol	Equagesic, Equanil, Micrainin, Miltown	50 ng/mL
Phencyclidine	Phencyclidine		10 ng/mL
Scopolamine	Scopolamine	Isopto Hyoscine, Scopace, Transderm Scop	
Valproic acid	Valproic acid	Depacon, Depakene, Valproate	50 ng/mL
Zolpidem	Zolpidem	Ambien	10 ng/mL
Stimulants			
While the drugs below do not possess the pharmacological effects typically associated with DFSA drugs, owing to their popularity it is recommended that screens for these drugs and metabolites be conducted at the detection limits listed or better.			
Amfetamine	Amfetamine, metamfetamine	Adderall	50 ng/mL
Cocaine	Cocaine		50 ng/mL
Benzoylecgonine			
Metamfetamine	Metamfetamine	Desoxyn	50 ng/mL

tripelennamine. Most antihistamines induce drowsiness or sleep and their sedative effects may be potentiated when taken in combination with alcohol, sedative hypnotics and narcotics.

Benzodiazepines

The benzodiazepines are the most widely used and prescribed class of sedatives, anxiolytics and hypnotics in medical practice. The benzodiazepines replaced the barbiturates as a consequence of their greater safety and lower toxicity. The first benzodiazepine to be synthesised was chlordiazepoxide, which was introduced into medical practice in 1960, followed in 1963 by the introduction of diazepam. Diazepam became the most commonly prescribed anxiolytic drug in the latter part of the 20th century and is still widely prescribed today. Over 3000 benzodiazepine compounds have been synthesised, although only around 35 are in use worldwide today. All benzodiazepines are capable of inducing sedation, memory impairment, reduced inhibitions, reduced anxiety, muscle relaxation, anticonvulsant and antidepressant activity, anterograde amnesia and reduced nocturnal gastric secretions. The properties of the benzodiazepines are governed by the dose administered, the half-life and the mode of administration. Benzodiazepines are classified either by their chemical structures or by their half-lives, i.e. short, intermediate and long half-life. Table 8.5 provides examples of benzodiazepines classified as either hypnotics or anxiolytics and Table 8.6 provides examples of benzodiazepines classified by half-life. Some benzodiazepines, e.g. diazepam and midazolam, are administered intravenously to facilitate anterograde amnesia during unpleasant short-term medical procedures, e.g. gastroscopy, endoscopy and dental treatment, that may require patient cooperation. There have been reports that some female patients may experience sexual fantasies when sedated with IV diazepam or midazolam, although these appear to be dose related (Brahams 1989; Dundee 1990). This observation is of potential importance since a number of allegations of sexual assault have been made against dentists and medical staff by female patients who have received IV benzodiazepine treatment. The benzodiazepines exert their pharmacological action by reacting with a benzodiazepine binding site on the $GABA_A$ receptor. The metabolism of most benzodiazepines is associated primarily with the cytochrome P450 system, and in particular with isoenzymes CYP2C19 and CYP3A4. Thus, adverse effects may be produced by use of benzodiazepines with drugs that inhibit, induce or are metabolised by these isoenzymes. Enhanced sedation may occur when benzodiazepines are taken in combination with other drugs that exert CNS-depressant properties, such as alcohol, antidepressants, sedative antihistamines, antipsychotics, other hypnotics or sedatives and, opioid analgesics. Despite widespread indications in the popular press, flunitrazepam has not been widely encountered in DFSA cases either in the UK or in the USA. Flunitrazepam is not available on prescription in the UK but can be obtained via internet sites.

Cannabis

After alcohol, cannabis is the most frequently encountered drug in DFSA cases and it is usually present as a consequence of the victim having smoked cannabis or cannabis resin prior to the alleged incident. Cannabis is most widely used for its euphoriant and psychotropic effects, the intensity and duration of which are influenced by susceptibility of the person taking the drug, the quantity of active components such as Δ^9-tetrahydrocannabinol (THC) reaching the brain, and the frequency of use. Cannabis induces a feeling of well-being, euphoria, relaxation and distortion in the perception of space and time. It can also cause deterioration in coordination and disturbance of judgement, loss of concentration, drowsiness, sleepiness, lethargy and slowed reactions. The perceived and euphoric effects of cannabis may last for between 2 and 4 hours after smoking a single cigarette. However, there is considerable evidence that some unwanted behavioural effects may persist for much longer. The term 'temporal disintegration' has been used to describe the inhibitory effects that cannabis exerts on short-term memory and the impairment of ability to undertake memory-dependent, goal-directed behaviour (Leonard 1992). Subjects suffering from temporal disintegration have a tendency to confuse the past, the present and the future, and to feel depersonalised. The sensation of depersonalisation is more pronounced after higher doses of cannabis are consumed. High doses of cannabis are also associated with hallucinations, anxiety, acute panic reactions, acute delirium (characterised by marked memory impairment), delusions, acute paranoia, schizophrenic behaviour and acute mania. The effects of cannabis may be enhanced when taken in combination with alcohol and the relaxant effects of cannabis might be expected to be enhanced when the drug is taken in combination with other CNS depressants.

The unknowing consumption of a pharmacologically significant quantity of cannabis via a 'spiked drink' is unlikely. The main active ingredient, Δ^9-THC, is insoluble in water; hence the addition of herbal cannabis or cannabis resin to a cold beverage such as beer or cola would not release into the liquid sufficient active drug to exert any pharmacological effect. Addition of herbal cannabis and crushed resin yields floating herbal material on the surface of drinks and resin also leaves a residue in the bottom of containers. Giroud *et al.* (2000) prepared water and milk decoctions from 5 g of cannabis containing 35 mg THC and administered them to two groups of six volunteers. The water decoction was found to contain approximately 1.6 mg free THC per 200 mL, while the milk decoction contained approximately 23.2 mg free THC per 200 mL, reflecting the greater lipophilic nature of milk. They demonstrated that the whole blood of volunteers who had consumed the water decoction of cannabis contained only trace quantities of THC and 11-hydroxy-THC and that only THC-carboxylic acid reached any significantly measurable concentration (~3 μg/L). The THC-acid remained detectable for approximately 10 h. After the consumption of the milk decoction, however, measurable quantities of both THC (~4 μg/L) and 11-hydroxy-THC (~4 μg/L) were present in whole blood and the whole blood concentration of THC-acid attained concentrations of approximately 25 μg/L. No subjective effects of cannabis were described for volunteers after consumption of the water decoction, but effects were noted after the consumption of the milk decoction. It should also be remembered that oral doses of cannabis must be significantly higher than smoked doses to obtain equivalent effects. Therefore the quantity of insoluble debris that would be needed to be added to a drink to achieve a pharmacological effect would not be disguisable. Cannabis oil would likewise not yield significant quantities of Δ^9-THC into solution and, although it might be easier to mask the presence colour-wise in a dark beverage such as cola, it would settle as a tar on the base of the receptacle to which it was added and would therefore be unlikely to be consumed.

Table 8.5 Examples of anxiolytic and hypnotic benzodiazepines

Anxiolytic	*Hypnotic*
Alprazolam	Estazolam
Chlordiazepoxide	Flunitrazepam
Clonazepam	Flurazepam
Diazepam	Nitrazepam
Lorazepam	Quazepm
Medazepam	Temazepam
Oxazepam	Triazolam

Table 8.6 Examples of short, intermediate and long half-life benzodiazepines

Short half-life	*Intermediate half-life*	*Long half-life*
Alprazolam	Lorazepam	Chlordiazepaoxide
Flunitrazepam	Temazepam	Diazepam
Midazolam	Oxazepam	Nordiazepam
Triazolam		Medazepam

Elsohly and Jones (1995) measured the Δ^9-THC content of cannabis teas and found that when 1 g of cannabis (total Δ^9-THC content of 2%) was boiled for 1 min in water and then allowed to steep for a few minutes, only 5% of the total Δ^9-THC content was released into the tea and that 85% of this was in the form of the acid precursor of Δ^9-THC. They further experimented by boiling cannabis for 45 min and still found only minute quantities of Δ^9-THC in the final solution. Elsohly and Jones reported that it is necessary to heat cannabis at 90–100° to achieve the quantitative conversion of THC-acids into free THC.

Cooking with cannabis has been well established in some cultures and there is no shortage of recipes for cannabis culinary practices. Elsohly and Jones (1995) conducted experiments by simmering cannabis in spaghetti sauce for 90 min and demonstrated that under these conditions Δ^9-THC was stable and hence could enter the body systems of individuals who consumed such preparations. Cone *et al.* (Cone *et al.* 1988; Cone 1990) measured the urinary concentrations of Δ^9-carboxy-THC in subjects who had consumed cannabis-laced brownies. Cone demonstrated that oral doses of THC equivalent to one and two cigarettes (approximately 28.5 and 57 mg THC, respectively) could produce peak urinary carboxy-THC concentrations between 108 and 436 µg/L. The peak urinary carboxy-THC concentrations measured in subjects who had smoked equivalent amounts of THC (one to two cigarettes) ranged between 9 and 152 µg/L. Cone (1990) also demonstrated that the time span for the detection of cannabis metabolites in urine was dependent upon the method of analysis and the cut-off or limit of detection used. Using EMIT and a cut-off of 20 µg/L the mean detection time for THC metabolites in urine was 121 h after consumption of a brownie containing THC equivalent to one cigarette (~28.5 mg THC) and 142 h after consumption of a brownie containing THC equivalent to two cigarettes (~57 mg THC). Using GC-MS with a cut-off of 5 µg/L the mean detection times increased to 149 and 156 h respectively. It follows therefore that THC metabolites may be present in urine at concentrations above the cut-offs normally used for workplace drug testing following the unknowing oral consumption of cannabis.

Hempen Ale is a proprietary beer brewed with hemp seeds. Although the seeds do not contain THC, they do contain other cannabinoids found in the cannabis plant. Kunsman *et al.* (1999) organised a study in which 10 subjects consumed Hempen Ale and subsequently provided urine specimens for analysis. Nine of the volunteers were allowed to drink Hempen Ale as desired throughout the day (the amount of the ale consumed varied between 5 and 14 bottles (12 ounce)) while the tenth volunteer drank two bottles each day over an 8-day period. A total of 146 urine specimens were collected and screened for cannabinoids using a selection of immunoassays including fluorescence polarisation immunoassay (FPIA), kinetic interaction of microparticles in solution assay (KIMS), enzyme immunoassay (EIA) and radioimmunoassay (RIA), and any immunoassay positives were further analysed by GC-MS for the presence of Δ^9-THC-carboxylic acid. With the exception of 10 specimens analysed by RIA all immunoassay results were negative and the 10 samples indicated to be positive by RIA were shown to be negative by GC-MS.

Chloral

Chloral, often known as the traditional 'Micky Finn' when mixed with alcohol, is available as chloral hydrate and chloral betaine. Chloral is an effective sedative hypnotic that produces only minimal respiratory and circulatory depression when administered in therapeutic doses. Although not widely used today, chloral hydrate and chloral betaine are used in the short-term treatment of insomnia, inducing sedation and as a premedicant in children. Chloral hydrate is rapidly converted into trichloroethanol in the body and may also be converted into trichloroacetic acid by the enzyme chloral hydrate dehydrogenase. Chloral hydrate is rapidly absorbed from the gastrointestinal tract and its effects begin to be noticed after approximately 30 min. The sedative hypnotic effects of chloral are potentiated by alcohol and other drugs with CNS-depressant properties, e.g. barbiturates and sedatives. Chloral is said to possess an unpleasant taste. Recorded side-effects associated with the consumption of chloral include drowsiness, light-headedness, ataxia, headache, paradoxical excitement, hallucinations, nightmares, delirium and confusion (sometimes with paranoia). Chloral is available as Chloraldurat (Germany), Chloraldurat, Nervifene (Switzerland), Welldorm (UK) and Somnote (USA).

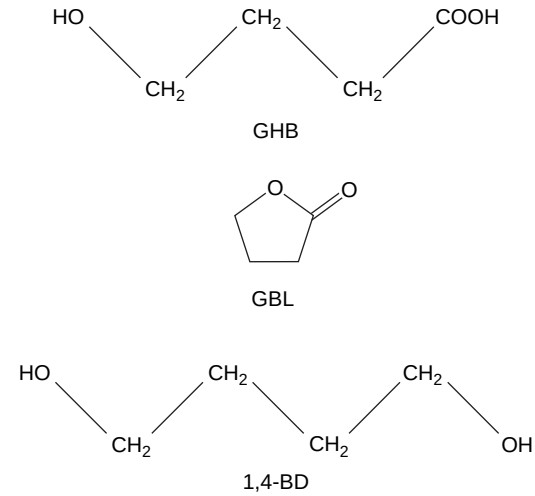

Figure 8.9 Chemical structure of gamma-hydroxybutyrate (GHB), gamma-butyrolactone (GBL) and 1,4-butanediol (1,4-BD).

Gamma-hydroxybutyrate

Gamma-hydroxybutyrate (synonym gamma-hydroxybutyric acid) and related compounds that are converted to GHB, such as gamma-butyrolactone and 1,4-butanediol (1,4-BD), are shown in Figure 8.9. Figure 8.10 shows the metabolic transformation of GBL and 1,4-BD to GHB by alcohol dehydrogenase, aldehyde dehydrogenase and lactonase. GHB is sold on the streets under names such as Salty Water, Scoop, Soap, Liquid X, Natural Sleep-500, Liquid Ecstasy. GHB is rapidly metabolised and eliminated from the body. The detection window for blood is about 6–8 h and for urine is about 8–10 h. GHB is endogenously produced in the human body and in some foods, and this needs to be taken into account when carrying out an analysis for GHB. It is used in DFSA because it is effective rapidly,

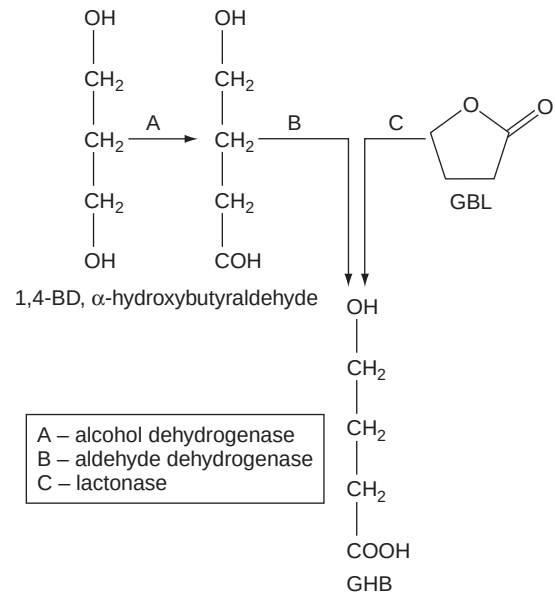

Figure 8.10 Metabolic transformation of GBL and 1,4-BD to GHB.

is relatively easy to manufacture and obtain, and is alleged to have aphrodisiac properties. Possession, sale and clandestine manufacturing of GHB are illegal in many countries including the USA, the UK and Japan. In 2003 GHB became a class C controlled drug in the UK, although it is approved for treatment of narcolepsy in the USA.

Ketamine

Ketamine has become increasingly popular as a drug of abuse in the 'club scene' owing to its ability to produce psychedelic effects. Ketamine is a dissociative anaesthetic that exerts potent analgesic, hypnotic and amnesic properties. These properties confer suitability on the drug for use as an anaesthetic in painful procedures where muscle relaxation is not essential, e.g. the manipulation of fractures, minor gynaecological surgery, dental procedures, changing burn dressings and cardiac catheterisation in children. Because ketamine is not a muscle relaxant, subjects under the effects of the drug do not require assisted respiration and the drug is therefore particularly useful in situations where anaesthesia has to be performed single-handedly by a surgeon with limited resources such as in disaster or battlefield conditions. Ketamine is structurally related to phencyclidine (PCP) and exerts activity at multiple sites in the brain. It acts primarily as a glutamate antagonist by non-competitive binding to the PCP receptor located in the ion channel of the *N*-methyl-D-aspartate (NMDA) receptor complex. Ketamine sterically blocks the cation channel gated by the NMDA receptor, impeding the flow of Na^+ and Ca^{2+} ions into the neuron, resulting in disruption of glutamate-mediated transmission at these sites throughout the brain. The *S*-isomer is more potent in displacing the NMDA ligand from its receptor than (*R*)-ketamine. In addition, ketamine facilitates monoamine transmission by inhibiting the reuptake of dopamine, noradrenaline (norepinephrine) and serotonin, resulting in an accumulation of these neurotransmitters in synapses. It also acts on the opiate system as an agonist at the μ-opiate receptor. When taken in low doses, ketamine may produce hallucinations and 'out-of-body' or 'near-death experiences'. A state of helplessness may be induced in which the user loses awareness of the environment and experiences severe loss of coordination, pronounced analgesia and total amnesia. Because of its ready solubility in water and alcohol, ketamine has the potential to be used in 'date rape' situations and should always be considered in the analysis of specimens from subjects claiming to have been victims of DFSA. Most street ketamine is prepared from diverted medical or veterinary preparations by heating the injectable solution to yield ketamine hydrochloride powder. Ketamine powder is most commonly taken by nasal insufflation in quantities of between 25 and 50 mg. Ketamine is readily water soluble and may also be injected, or taken orally or anally. It has an unpleasant taste and is usually mixed with a flavoured drink such as orange juice when prepared for oral consumption. The presence of ketamine in adulterated beverages may be readily demonstrated by HPLC with diode array detection – see Figure 8.6.

'Z' drugs: zopiclone, zolpidem and zaleplon

Zopiclone, zaleplon and zolpidem, known as the 'Z' drugs, are all potent, low-dose, short-acting hypnotics characterised by a fast onset of action and act in a similar way to the benzodiazepines. As with the benzodiazepines the 'Z' drugs induce drowsiness and sleep, as well as anterograde amnesia. All have very short elimination half-lives and users of these drugs are subsequently less likely to experience drowsiness and other after-effects the morning after they have been taken. The peak plasma concentrations of the 'Z' drugs are low (5 mg oral zaleplon ~10–20 μg/L; 20 mg oral zolpidem ~250 μg/L; 7.5 mg oral zopiclone ~ 60–90 μg/L). Zopiclone is extensively metabolised and undergoes *N*-demethylation, *N*-oxidation and decarboxylation in the liver. The metabolism of zaleplon is complex with the formation of a number of intermediate metabolites including desethylzaleplon prior to glucuronidation.

'Legal highs'

The term 'legal high' is used to describe a range of synthetic and plant preparations that are marketed primarily for the 'club scene' but for which, at the time they are sold, there are no legal controls relating to their sale or possession. These substance are claimed to offer users similar psychedelic and hallucinatory experiences to those of controlled drugs such as THC, methylenedioxymethylamfetamine (MDMA), methylamfetamine (MA) and phencyclidine (PCP), and may be encountered in DFSA cases. The use of the term 'legal high' implies to many who purchase these preparations that because there are no legal controls on the substance it is safe to use. This is a total misconception and many of the chemicals that have been marketed as legal highs have no legitimate use and may be orders of magnitude more potent than some of the substances that they are purported to mimic. Because of the unknown and untested properties of many of these substances, those who use them are putting their health at considerable potential risk.

It is a difficult task for legislators to control all newly introduced chemicals and their identification is difficult since there are often no control substances available for analysts to compare these newly introduced compounds against in order to ascertain their identity and composition.

Substances marketed as legal highs are wide ranging and include substances originating from herbal materials such as cathinones and *Salvia divinorum* to chemically synthesised substances such as mephedrone (4-methylmethcathinone), which was recently classified as a Class B drug under the Misuse of Drugs regulations in the UK, and the piperazines. All exert stimulant properties and many behave similarly to MDMA by also exerting enactogenic properties. The piperazines, *N*-benzylpiperazine (BZP), *m*-chlorophenylpiperazine (mCPP) act by elevating the serotonin and dopamine neurotransmitters in the brain by blocking synaptic reuptake of transmitters. Trifluoromethylphenyl-piperazine (TFMPP) acts as a substrate for dopamine and serotonin transporters, resulting in increased concentrations of serotonin and dopamine in the brain's synapses. The piperazines exert stimulant and euphoriant effects in users. Other stimulants marketed as 'legal highs' include naphthylpyrovalerone, also known as naphyrone and NRG-1.

Summary

Although much has been made of the drug-facilitated sexual assault problem in the popular media and, to some extent in the scientific literature, the true extent of the problem is not yet known. Literature surveys published to date suggest that although 'drink spiking' does occur, recreational consumption of alcohol and other drugs is the major contributor in the majority of reported cases. Numerous drug substances have properties that convey upon them the potential to be used in DFSA cases. There is, therefore, a clear need for toxicologists to keep informed about new products that might be used and to develop appropriately sensitive methods for detection of these drugs in the body fluids and/or hair of complainants.

Considerable progress has been made during recent years in the standardisation of sexual assault evidence collection protocols and devices. These efforts have been coordinated in many places by groups with representation from police, prosecutors, clinicians, victim support services, advocates and forensic laboratories. Continued education of, and communication between, those agencies involved with DFSA cases is essential, particularly with respect to the collection of appropriate evidence and dissemination of information concerning new drug findings. The DFSA committee of the Society of Forensic Toxicologists has taken an international lead in providing information for toxicologists by placing updated reports on the society's website (www.soft-tox.org). Toxicologists who might be involved with DFSA cases are encouraged to adopt the recommendations of professional groups such as SOFT and the International Association of Forensic Toxicologists (TIAFT) and to maintain current awareness of new trends by visiting the websites of these organisations on a regular basis.

CHAPTER

9 Forensic Toxicology

MD Osselton, AC Moffat and B Widdop

> Learning toxicology is easy! It only takes 2 lessons to become an expert; each lesson takes 10 years. Irving Sunshine (1910–2006)

Introduction

This chapter is dedicated to the memory of three of the most eminent toxicologists of the twentieth century: John Jackson (1924–1984), the author of this chapter in the first and second editions of 'Clarke'; Dr Allan Curry (1925–2007); and Dr Irving Sunshine (1910–2006). The basic principles of forensic toxicology have remained unchanged since the first edition of Clarke and accordingly much of John Jackson's original chapter has been retained. The content of this chapter has been bought up to date and integrated with the remaining chapters where appropriate. The philosophical style, attention to detail and excellent science taught by these eminent toxicologists have been preserved by the editors as a tribute to them.

The science of toxicology relates to the investigation of poisons and derives its name from the Greek words *τοξικόζ or toxikon (poison)* and *λογία* or *logia (a discourse or study)*.

Paracelsus (1493–1541) is attributed with stating that 'All substances are poisons: there is none which is not a poison. The right dose differentiates a poison and a remedy' (Amdur *et al.* 1991). Orfila (1787–1853) refined the definition of a poison as 'any substance which, when taken inwardly in a very small dose, or applied in any kind of manner to a living body, depraves the health, or entirely destroys life'. The first complete work of international importance on the subject of forensic toxicology was written by Orfila in 1813 (*Traité des poisons tirés des regnes minéral végétal et animal, ou toxicologie générale, considerée sous les rapports de la pathologie et de médecine légale*; see Orfila (1818)). It was an immediate success and won him the title of 'Father of Toxicology'. 'The chemist', said Orfila, 'horrified by the crime of homicidal poisoning, must aim to perfect the process necessary for establishing the case of poisoning in order to reveal the crime and to assist the magistrate punish the guilty'. It is interesting to note that he realised the necessity of adequate proof of identification, emphasised the importance of what we now call quality assurance (purity of standards, etc.) and anticipated the need for pharmaceutical, clinical, industrial and environmental toxicology.

The term 'forensic toxicology' covers any application of the science and study of poisons to the elucidation of questions that occur in judicial proceedings. The subject is usually associated with work for the police, the coroner and the criminal law courts. However, the analysis and identification of medicines and the maintenance of agricultural, environmental, industrial and public health legislation (to ensure clean air, pure water and safe food supplies) are all aspects of forensic toxicology, although associated with civil courts rather than criminal courts. Like the forensic toxicologist in criminal cases, analysts employed in these civil areas may at times find their work the subject of severe public scrutiny in a law court, and both groups should be aware of the strengths and limitations of each other's methodology.

During the first half of the twentieth century, accidental self-poisoning and attempted suicide cases used to fall largely within the domain of the forensic toxicologist, but as sensitive analytical methods such as ultraviolet (UV) spectrometry, gas chromatography (GC), high performance liquid chromatography (HPLC) and gas chromatography linked to mass spectrometry (GC-MS) became more widely available, such cases increasingly became the responsibility of the clinical toxicologist or the hospital biochemist. A small proportion of these cases is still referred to the forensic toxicologist, usually because of an allegation of malicious poisoning, or because the patient died under suspicious circumstances and a coroner's inquest is ordered. The preliminary analysis may have been carried out already, and close cooperation between the forensic and hospital laboratories is obviously desirable.

The rapid development of more sensitive methods in the latter part of the 20th century and since 2000 also resulted in a change to the types of samples that can now be analysed with a movement away from organs such as the liver, where large quantities of tissues were required. Improvements in analytical capabilities also enabled toxicologists to analyse alternative samples such as oral fluid (Chapter 18), eye fluid, sweat (Chapter 28) and hair (Chapter 19), thus widening the scope of analyses that toxicologists can offer to their customers. What follows is an account of the principles, methodology and special problems encountered in forensic toxicology for all workers in these related fields, and for chemists and pharmacists in more remote areas of the world who may be faced with the request 'test for poisons'.

Principles of forensic toxicology

The forensic toxicologist is expected to detect and identify poisons, but if 'poison' is defined as a chemical substance harmful to living organisms, it is obvious that 'harmfulness' is not a property that can be measured by any chemical method of analysis. Toxicity is a biological concept, usually determined by some form of bioassay, but bioassays are hardly ever used now in forensic toxicology. Chemical analyses are used to detect the presence of the poison, measure its concentration and relate this to its known toxicity. If the poison is not specified by name, the request to 'test for poisons' becomes a major problem for the chemist, because no single chemical method of analysis is able to detect all the various poisons. At least seven different analytical schemes are required to exclude even the most commonly encountered poisons (Figure 9.1). Compared with toxicologists in academic research or industry, the task of the forensic toxicologist is made more difficult because the analytical material, the available time and the resources are all severely limited. The forensic toxicologist has scarcely any control over the sampling time or the selection of material submitted for analysis, and has no certain knowledge that a poison is present. Dr Alan Curry was renowned for saying 'if you do not look for it you will not find it'.

Forensic toxicology demands an overall analytical system designed to exclude or indicate the presence of any poison in each of the chemical groups shown in Figure 9.1. Most of the numerous screening procedures reported in the literature are too limited to permit a confident negative report. All too often these procedures are drug oriented, even though many criminal poisonings result from compounds other than drugs. For example, Trestail (2000) estimated that out of 679 documented classical homicidal poisonings, 31% resulted from arsenic, 9% from cyanide, with only 6% from strychnine and 2% from morphine.

Apart from these analytical problems, the legal aspect of the work demands a scrupulous attention to detail. Failure to make full descriptive notes on the items received, a simple error in the date on which the analysis was performed, or neglecting to record weighings or to check

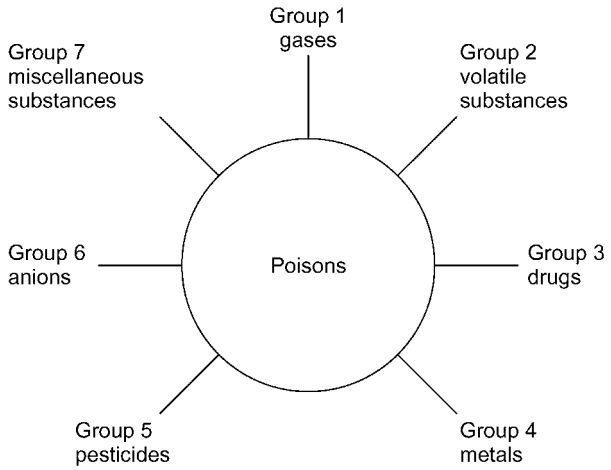

Figure 9.1 The seven major groups of poisons.

one's calculations or reagent purity can become evidence of careless work in the hands of an astute lawyer. The lawyer may, with justification, explore the extent of the toxicologist's experience and knowledge, demand a detailed account of the analytical methods and challenge the integrity of any opinion. The crucial evidence of identification and quantification of the poison may be faultless and the conclusions may be correct, but if the court's confidence in the forensic toxicologist as an unbiased scientific expert is destroyed, the case may be lost. A secure chain of custody of all the exhibits submitted also has to be demonstrated.

Orfila was well acquainted with this aspect of forensic toxicology, and the guiding principles he established nearly 200 years ago are still applicable. These may be summarised as follows:

- All chemists who undertake this work must have toxicological experience.
- The analyst must be given a complete case history that contains all the information available.
- All the evidential material, suitably labelled and sealed in clean containers, must be submitted and examined.
- All the known identification tests should be applied and adequate notes made at the time.
- All the necessary reagents used for these tests should be pure, and blank tests should be performed to establish this fact.
- All tests should be repeated, and compared with control samples to which the indicated poison has been added.

Strict adherence to these principles makes forensic toxicology one of the slowest and most expensive forms of analysis. However, this must be accepted not only to ensure justice for the alleged poisoning victim and for the accused, but also to protect the integrity and reputation of the analyst and the laboratory that he or she represents. In today's economic climate, where police or other customers are required to pay for analysis and where competitive tendering for suppliers of laboratory services is becoming commonplace, the toxicologist is often limited by what a prospective customer is willing to pay for and must therefore be cautious that the scope and quality of his work are not compromised. If such restrictions are imposed on the toxicologist, the case notes should be amended to reflect customer instructions. A comparison of the principles above with the modern requirements of quality control and quality assurance may be made by reference to Chapters 21 and 22.

Range of cases submitted

Historically, forensic toxicology gained notoriety because the cases that caught the public eye were invariably associated with allegations of murder – e.g. the cases of Dr William Pritchard (antimony; 1865), Mary Ann Cotton (arsenic; 1873), Eugene Chantrelle (opium; 1878), Dr Lamson (aconitine; 1882), Florence Maybrick (arsenic; 1884), Adelaide Bartlett (arsenic; 1886), Roland Molineux (mercury cyanide; 1899), Hawley Harvey Crippen (hyoscine; 1910), Donald Griggs (arsenic; 1928), John Christie (carbon monoxide; 1953), Kenneth Barlow (insulin; 1957), Graham Frederick Young (thallium; 1971), Harold Shipman (diamorphine; 1999) to name but a few. More details of historically interesting cases are provided in the Further reading list at the end of this chapter. The birth of forensic toxicology as a profession arose as a consequence of the widespread use of arsenic as a poison in the early nineteenth century during the Victorian era and much has to be attributed to the work of the early pioneers Mathiue Orfila (1787–1853), Robert Christison (1797–1882), James Marsh (1794–1846), Hugo Reinsch (1841) and Alfred Swaine Taylor (1806–1880), who were the founding fathers of this new field of medical science. During the early nineteenth century analytical techniques used in toxicology were limited to colour tests, crystal tests and taste tests. The twentieth century saw the advent of chromatography and mass spectrometry, although it was not until the introduction of the microchip that the boundaries of analytical toxicology suddenly opened up, permitting mass spectrometry to become the daily workhorse in most forensic toxicology laboratories (Figure 9.2). The scope of work undertaken by forensic toxicologists has since broadened and, in addition to the investigation of sudden deaths and cases of alleged criminal poisoning, forensic toxicology now extends to areas such as driving under the influence of drugs and alcohol (Chapters 4 and 5), drug-facilitated sexual assault (Chapter 8) and workplace drug testing (Chapter 3).

The ultimate objective of any forensic scientist is to attempt to provide answers to questions that may arise during coronial, criminal or tribunal investigations or in subsequent court proceedings. In cases

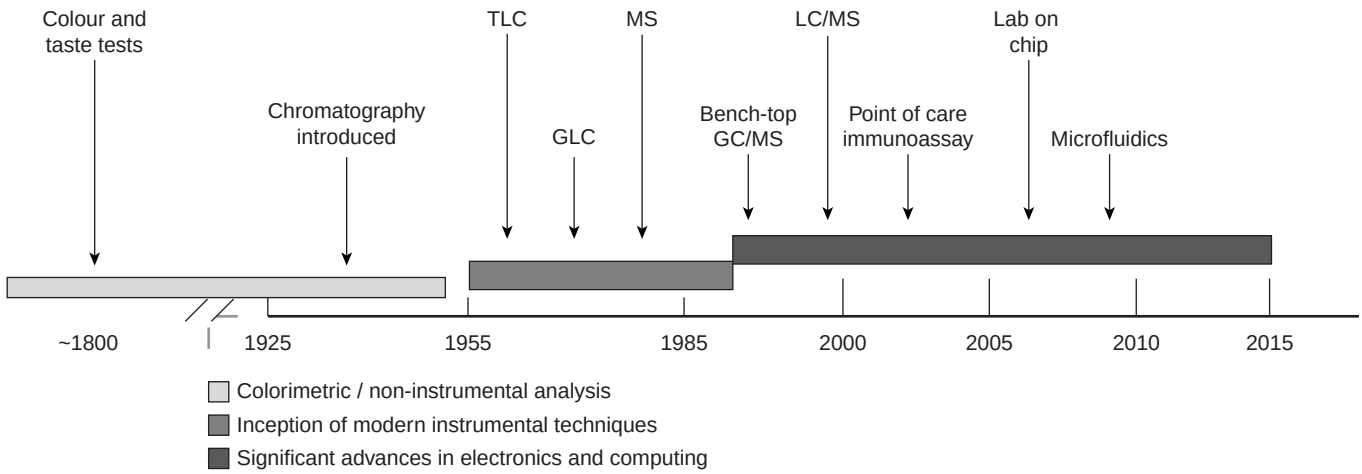

Figure 9.2 Landmarks in drug and poison analysis. (Reproduced with permission of MD Osselton.)

associated with criminal and coronial investigations the traditional question that must be answered is 'Has this person been poisoned?', together with the supplementary queries that follow if the result is positive, such as 'What is the identity of the poison?', 'How was it administered?', 'What are its effects?' and 'Was it a dangerous or lethal amount?'. Whereas early forensic toxicologists were largely employed as analysts, interpretation of results has become a firmly established part of their role in all types of cases and today's toxicologist consequently requires in-depth knowledge of analytical chemistry, pharmacology, pharmacokinetics and biochemistry.

Laws that govern the possession and use of narcotic and stimulant drugs, and legislation concerned with the influence of drink or drugs on driving skills, have increased the workload of many forensic laboratories. The widespread recreational use of psychoactive drugs has also led to a significant increase in allegations of drug-related sexual offences. In cases associated with drug use and the workplace, the principal challenges will be related to the analytical findings in relation to the workplace drug policy adopted by an employer (Chapter 3). These will often be focused around the screening and confirmation cut-offs, whether an analytical result may have been affected by attempts to dilute or adulterate the specimen submitted for analysis, and the analytical methods employed by the laboratory. Workplace drug testing, although not traditionally regarded as forensic work, has now become accepted as an area of forensic toxicology and has seen significant growth.

Modern analytical methods can give the forensic toxicologist the ability to answer questions that previously were considered either hopeless or not worth considering because the results were so often negative. Methods that are sensitive to nanogram or picogram amounts of drugs and poisons make it worthwhile to undertake an analysis, even when a plate, cup or container has apparently no food or drink left in it.

Drugs may be detected in blood and hair at therapeutic concentrations or lower, so it is possible to obtain clues to the clinical history of the deceased, the victim or the accused, even when they are unable or unwilling to provide this information themselves. Thus, the discovery of drugs used in the treatment of epilepsy, diabetes, etc., in a blood sample taken from an unidentified body may start a new train of enquiries that leads to successful identification of the body. Similarly, allegations of doping prior to rape or robbery may be refuted or confirmed.

A now routine area of forensic toxicology concerns the analytical checking of statements made by witnesses during the course of a police inquiry. Provided that a blood or urine sample is taken within about 12 hours of an event, there is a good chance of checking the truth of statements such as 'I don't remember what happened because I was high on drugs at the time', 'I used to be an addict, but I haven't taken anything for over a year' or 'I killed him in self-defence because after taking LSD he went berserk and attacked me with a knife'.

Stains can also be examined successfully for drugs and poisons (Hammond *et al.* 1979). For example, if the victim notices a nasty taste and spits out a drink, the allegation that someone tried to poison him or her can be investigated if the stained garment is submitted for analysis.

In most cases, the results obtained in the various types of cases mentioned above can be proved conclusively, i.e. the identity of the poison can be confirmed by more than one method and it can be quantified. Even when specific identification is not feasible, an opinion as to whether the suspect is most probably telling the truth or lying can be of value to the investigator.

Case investigation

Most cases that enter a forensic toxicology laboratory start with the suspicion that a drug or poison may be present. A fatality might be an accident, suicide or murder, but a toxicological examination must be carried out to assist the investigating officer to decide which of these it might be. Often the investigating officer will not know whether any offence has been committed until the results of the forensic toxicological analyses are available, so that forming the correct questions for him to ask is vital if accurate and useful answers are to be given. Details of the circumstances that lead to the conclusion that a criminal action might have taken place must be supplied to the toxicologist so that the analyses can be planned. There is no universal test for a poison and without the provision of relevant information intuitive considerations or 'guesswork' is likely to predominate. This is not only costly and time-consuming but may also result in valuable samples being used up before the drug(s) or poison(s) present can be identified. Information concerning possible access to drugs or poisons either by the deceased or by a suspect can provide a starting point for toxicological analysis. National information relating to death or prescription statistics may also be useful to toxicologists if it is available. For example, in England and Wales about 80% of fatal overdose poisoning cases are associated with 20 or fewer poisons; hence, in drug overdose cases, and in the absence of any other clues, these substances might provide a starting point for analysis. Table 9.1 lists the drugs associated with 80% of 2668 deaths attributed to poisoning in 1980 in England and Wales. Table 9.2

Table 9.1 Drugs associated with 80% of 2668 poisoning-associated deaths in 1980 (England and Wales)[a]

Drug	*Number of cases*
Paracetamol	559
Dextropropoxyphene	348
Amylobarbital	287
Secobarbital	237
Amytriptyline	172
Aspirin	141
Pentobarbital	92
Chlormethiazole	88
Diazepam	88
Butobarbital	77
Nitrazepam	77
Dothiepin	76
Flurazepam	75
Phenobarbital	60
Imipramine	48
Orphenadrine	40
Chlorpromazine	36
Dipipanone	31
Cyclizine	27
Trimipramine	27

Table 9.2 Drugs associated with 80% of 2928 drug-related poisoning deaths in 2008 (England and Wales)[a]

Drug	*Number of cases*
Diamorphine and morphine	897
All antidepressants	381
Methadone	378
Paracetamol	242
Cocaine	235
All benzodiazepines	230
All amfetamines	99
Tramadol	83
Dextropropoxyphene	48
Zopiclone/zolpidem	36
Aspirin	15

[a] From Wells C (2009). Deaths related to drug and poisoning in England and Wales, 2008. *Health Statistics Quarterly* 43: 48–55.

summarises the principal drugs associated with 80% of poisoning-related deaths in 2008 in England and Wales. Deaths associated with barbiturates, dextropropoxyphene and paracetamol (acetaminophen) have decreased markedly since 1980, while in 2008 there appears to be a trend associated with drugs of abuse (diamorphine, morphine, cocaine).

Knowledge of the apparent volume of distribution (V_d), the therapeutic index and the potentially lethal doses of drugs and poisons may also provide valuable assistance to the toxicologist in selecting appropriate tissues for analysis as well as suitable analytical methods. The *apparent volume of distribution* is defined as the volume of fluid that would be required to contain the amount of drug in the body if it were uniformly distributed at a concentration equal to that in the plasma. This provides an indication whether the drug is likely to be retained within the blood ($V_d < 1.0$) or distributed into tissues ($V_d > 1.0$). A list of potentially fatal doses for some common drugs and poisons is provided in Table 9.3, showing that the likely amounts of poisons ingested may vary by several orders of magnitude (grams to g $\times 10^{-12}$), so that screening methods must take this into account.

The *therapeutic index* of a drug is defined as the ratio of the toxic dose to the therapeutic dose. Hence, drugs with a low therapeutic index may require only a small increase in dose to produce toxic effects. Consideration of weight, body mass index (BMI), concomitant drug therapy, renal function or drug levels in the plasma is usually necessary before the prescribing of drugs with a low therapeutic index. As well as indicating that some therapeutic drugs are more inherently dangerous than others, knowledge of the therapeutic index can assist the analyst in selecting appropriate analytical methods. The lower the dose difference between therapeutic benefit and initiation of toxic effects, the more accurate and precise an assay must be to provide confidence in interpreting results. Drugs with low therapeutic indices include digoxin, phenytoin, warfarin, carbamazepine and ciclosporin.

Table 9.3 Likely fatal oral doses of some common drugs and poisons

Drug	*Possible oral fatal dose*
Alcohol	200 g (consumed over a short period of time)
Paracetamol	15 g
Carbon tetrachloride	10 g
Chlorate	10 g
Amylobarbital	1.5 g
Phenobarbital	1.5 g
Thallium	1 g
Amitriptyline	1 g
Codeine	800 mg
Amfetamine	200 mg
Fluoroacetate	700 mg
Dextropropoxyphene	500 mg
Amfetamine	200 mg
Cyanide	200 mg
Arsenic	200 mg
Morphine	200 mg
Strychnine	100 mg
Nicotine	80 g
Cantharadin	60 mg
Aconitine	3–6 mg
Ricin	1 mg
Botulinum toxin	50 ng
Polonium 210	1 pg

Table 9.4 The fatal/therapeutic dose ratios of some common drugs

Drug	*Fatal/therapeutic dose ratio*
Morphine	1
Cocaine	2
Digoxin	3
Strychnine	5
Amylobarbital	10
Aspirin	35
Paracetamol	70
Diazepam	100

Table 9.4 lists the fatal/therapeutic dose ratios for some common medicinal compounds. Pharmacokinetic information relating to therapeutic index and V_d is provided in the individual monographs where available.

Every case submitted should be accompanied by a form similar to that shown in Figure 9.3. This information will assist the toxicologist to use the most directly useful methods of analysis, and to interpret the results in the context of the case at a later stage.

The information required for each type of case will differ and various forms have been suggested for use and are reproduced in this book: information to be submitted with the exhibits in all cases where there is suspicion of poisoning or doping (Figure 9.3); drug-facilitated sexual assault request form (see Chapter 8); request form for toxicological analysis in hospital cases (see Chapter 1); and the postmortem toxicology request form (see Chapter 10, Figure 10.1). Every effort must be made to obtain the information requested on the relevant form. If possible, a personal consultation with the investigating officer should be arranged, either in person or by telephone. A few minutes talking with the investigating officer can save many hours, or even days, of analysis time.

Samples

It is essential that the appropriate samples be collected as soon as possible, and be correctly and informatively labelled and stored appropriately. Their acquisition, storage and transport to the laboratory should be documented adequately (with dates and times) to ensure a safe chain of custody. A list of suggested postmortem samples for routine toxicological screening is given in Chapter 10, those for drug-facilitated sexual assault in Chapter 8 and those for particular anions and metals in Chapter 17.

The containers used for the samples may vary depending on the analysis to be performed, and it is vital that the correct types are used. For example, a fluoride oxalate sample tube for blood is useless if a fluoride estimation is required and gamma-hydroxybutyrate (GHB) may be destroyed by citrate. Blood requiring analysis for alcohol should ideally contain fluoride as a preservative at a concentration of at least 1.5% and ideally 2% in the final sample volume. Glass containers with gas-tight seals should be used for collection of samples requiring analysis of volatile substances. If containers are to be examined for fingerprints, this should be carried out before any toxicological examination. In cases where the tissue may also be required for DNA analysis it is essential that the toxicologist and biologist communicate before any analysis is undertaken in case the sequence of analysis could interfere with the work of other experts; for example, the biologist might open the only available blood container before alcohol or volatiles have been analysed.

Victim's information

Name .....
Gender .....
Age .....
Weight or height .....
Nationality .....
Recent foreign travel? .....
Occupation (details of end-product of factory or firm) .....

Medical history

Did victim suffer from viral hepatitis or any other infectious disease? .....
Any recent illness or chronic disease? What drugs were prescribed? .....
Was victim an alcoholic, drug addict or smoker? .....
What poison is suspected? How much? (tablet bottles, syringes, etc., found near the body should be submitted) .....
Give names of any drugs or poisons to which victim or associates had access (apart from any mentioned above) .....

Timings

Date and time victim last seen to have been in normal health .....
Date and time of illness or death, and where victim found (e.g. at work, in bed, outdoors) .....
If these times are not known, when was the victim found? .....
Time and details of last meal .....

Treatment

Any medical attention given after the suspected poisoning or doping? .....
Time of hospital admission. Date and time discharged .....
Details of any treatment given (volume of stomach wash, time when blood/urine samples taken) .....
Hospital analysis: supplied/not done/not available .....
Tick any of the following symptoms that apply:

Diarrhoea	☐	vomiting	☐	thirst	☐	blindness	☐	constipation	☐	cyanosis (blue tinge to skin)	☐
jaundice	☐	loss of weight	☐	shivering	☐	convulsions	☐	eye pupils dilated	☐	eye pupils constricted	☐
delirium	☐	coma	☐	sweating	☐	renal failure	☐				

Name of pathologist or doctor .....
Autopsy report sent: Yes/No
Date of autopsy and possible cause of death .....
Any further information that could be useful to the laboratory, such as victim pregnant, details of suspect (especially occupation and end-product of factory or firm, comments made by victim, witnesses or suspect) .....

Samples required

If victim alive:
Vomit, stomach aspirate or wash, blood and urine

If victim dead:
Stomach contents. All available (no preservative); enquire if stomach wash or vomit is available. If no contents, submit stomach

Blood

Femoral vein	30 mL unpreserved and 5 mL preserved (for alcohol analysis); identify source; do not mix
Heart	All available from intact heart chambers; avoid body cavity samples; enquire if antemortem samples are available
Urine	All available, however small a volume (preserved); enquire if antemortem samples are available. If no urine, submit kidney and bile
Liver	250 g; gall bladder should not be included with this sample

If the suspected poison is a volatile substance, brain and lungs will be required. Bone and hair are needed if metal poisoning is suspected. Brain should always be submitted if the body is decomposed.
If in doubt, consult the laboratory.
Glass jars should be used whenever possible. Samples should be properly labelled and sealed. The label should include the name of the victim, signature of pathologist and the date. Antemortem samples should also specify time of sampling.

Figure 9.3 Information to be submitted with the exhibits in all cases in which there is suspicion of poisoning or doping.

Analytical approaches

General methodology

The forensic toxicologist should remember Orfila's maxim: 'The presence of a poison must be proved in the blood and organs before it can be considered as a cause of death.' There are five stages in any toxicological examination:

1. Detection – to detect any drugs or poisons in the samples submitted by means of screening procedures.
2. Identification – to identify conclusively any drugs, metabolites or poisons present by means of specific relevant physicochemical tests.
3. Use of corroborative tests, where available, to confirm the identify and amount of any substance found.
4. Quantification – to quantify accurately those drugs, metabolites or poisons present.
5. Interpretation and reporting – to interpret and report the analytical findings in (2) and (4) in the context of the case, the information given and the questions asked by the investigating officer.

The detection of the drug or poison is the most difficult part, since the nature of the poison may not be known. Screening tests for any possible drugs or poisons should be used where there is no information about the possible identity. Immunoassays are available for screening blood, urine and vitreous samples for a wide range of drug substances (Chapter 31). Immunoassays provide a sensitive means of testing for a wide range of drugs in small samples. However, it is important to ensure that appropriate 'cut-off' concentrations are selected for the types of cases under investigation. For example, the use of workplace drug testing cut-offs in drug-facilitated sexual assault cases would be inappropriate and could result in many potential drugs being undetected.

General screening methods are usually more flexible than special methods and can therefore be applied to a wide variety of materials. They are essential for the investigation of unknown poisonings and have some advantages even when the toxic agent is known or suspected. The bulk of this chapter gives the philosophy of applying such tests to the seven classes of poisons shown in Figure 9.1. Since the last edition of this book was published there has been growing awareness among toxicologists concerning bioterrorism and the use of chemical and radioactive threats against individuals or sectors of society. The notable case of Alexander Litvinenko (see http://archive.student.bmj.com/issues/07/09/education/324.php), who was poisoned with polonium in London in November 2006, the sarin gas attack on the Tokyo subway system (March 1995) and the anthrax attacks in the USA (in 2001) exemplify the need for toxicologists to maintain an open mind when dealing with the 'unknown' types of cases. Consideration should also be given to the growth in international travel for holidays and business since this opens the opportunity for the importation from different parts of the world of drugs or poisons that are not normally available in the home country.

Once a toxic agent has been detected, specific analytical procedures can be used to identify it conclusively. Such procedures are given in Chapters 1–19 in this book. Each of these chapters looks at the analysis of drugs and poisons from a different analytical standpoint, which depends on the area of toxicology being described. Particular techniques to be used in such analyses are given in Chapters 30–44, and the individual monographs of drugs and poisons in Part 2 give further physicochemical information to be used for identification, such as for mass spectrometric data. Methods for the quantification of groups of drugs and individual drugs and poisons are also given in Chapters 1–19 and each monograph also contains references to established quantitative methods in various tissues using a variety of techniques. The interpretation of the results is explained in Chapter 26 and use of the disposition and toxicity data, etc., given in the relevant monographs in Part 2.

General guidance

Analyses may be required to answer specific questions concerning, for instance, the amount of alcohol in blood. Alternatively, the enquiry may be more general, such as 'Was this food poisoned?'. This latter type of case is termed a 'general unknown' (i.e. those cases in which the analyst knows nothing about the nature of the poison or, indeed, whether any is present). All seven groups of poisons shown in Figure 9.1 should be excluded before a negative report can be given. Fortunately, group tests are available for five of these groups (i.e. gases, volatile compounds, drugs, metals and pesticides). Specific tests must be used to detect anions and miscellaneous compounds. Obviously, the choice of which group should be eliminated first is critical if a rapid answer is expected.

Most forensic toxicology cases involve substances that act on the central nervous system (e.g. alcohol, hypnotics, narcotics, sedatives, or tranquillisers). However, it may be that these are the most commonly identified poisons because they are sought more often than other toxic substances and because they are the poisons for which most comprehensive screening systems have been published. There are inherent dangers in this pragmatic approach because there is no differentiation between self-poisonings and criminal poisonings. On the other hand, a completely systematic and comprehensive analytical scheme that covers all the poison groups is extremely time-consuming and costly. Much will depend on the requirements of the investigating officer.

The first essential task of the analyst must be to ensure that the so-called 'general unknown' case is an authentic unknown poisoning. Only a small proportion of submitted cases have no guiding features; these cases consist mainly of unidentified drowned, burnt or decomposed bodies, or of the submission of some untasted, but allegedly poisoned, food samples. In most cases there are some facts available that provide clues to the most likely group of poisons to be excluded as a first action. Thus, if the time of onset of the symptoms was less than 1 hour, and there is no evidence of injected material, the sample should be examined for gases and volatile poisons before other groups. Severe vomiting and diarrhoea indicate possible metal poisoning, although food poisoning or too much alcohol should be ruled out.

The age and occupation of the victim or the site of the incident may guide the choice of the first group screen to be employed. For instance, few elderly people indulge in solvent abuse; farm workers have easier access to the more toxic pesticides; and a death in an electroplating factory certainly requires cyanide to be eliminated. These facts are not always freely available and therefore must be sought.

It is impossible to design a single analytical scheme that is both able to detect all the drugs and poisons now available and suitable for all the various purposes mentioned above. The forensic toxicologist needs a repertoire of standard methods that can be modified according to the nature of the investigation, the type and amount of material for analysis, and the time and resources available. This collection of standard methods should include about a dozen general screening methods and as many special methods as can be acquired and practised.

Special methods detect, or exclude, only a limited number of related chemical compounds. Their more limited purpose means that they can be made more efficient, rapid and selective than general methods, but in certain circumstances they waste both time and material. The temptation to screen for poisons by employing a whole series of special methods should be resisted. Some of the specialised methods designed to detect a particular poison or a chemically related group of drugs (e.g. benzodiazepines or phenothiazines) are not as selective as they purport to be. This is because the extraction procedures have been simplified for rapid processing, because they utilise a non-specific identification technique or, more frequently, because they are designed to quantify the drug rather than identify it. For example, many methods based on a colour reaction only require the preparation of a protein-free filtrate. Consequently, the drug or poison is not really separated from most of the endogenous material and the only evidence of identification involves the dangerous assumption that the positive response is from the compound sought. If possible, non-selective special methods should be avoided in forensic toxicology. Unfortunately, they are often the only types that the manufacturer of the compound can supply.

Classification of poisons

Drugs and poisons can be classified alphabetically, pharmacologically (antidiabetic, anticonvulsant, etc.) or by chemical structure (barbiturates, phenothiazines, etc.). However, for analytical purposes it is more useful to classify poisons according to the method used for extraction. Five major groups are usually considered:

- Gaseous and volatile substances isolated by diffusion or distillation
- Organic non-volatile substances isolated by solvent extraction (drugs and pesticides)
- Metallic poisons isolated by ashing, by wet oxidation of the organic matter or by enzymic hydrolysis of the tissue
- Toxic anions isolated by dialysis
- Miscellaneous poisons that require immunoassays or special extraction techniques, such as ion-exchange columns, formation of derivatives or ion pairs, freeze-drying and continuous extraction with a polar solvent.

Some of these groups have been subdivided because they are too large or because alternative methods of extraction are available. The seven groups so formed are illustrated in Figure 9.1.

Most analyses require several unit operations, namely separation of the poison and its metabolites from the biological material, isolation, purification, concentration, identification, confirmation of identity and quantification. The most useful methods are those that combine two or more of these unit operations. Thus, colour tests (see Chapters 1 and 30), which can be applied to the sample directly without the need for any isolation or purification processes, are indispensable in the initial stages of an analysis (e.g. Fujiwara and Reinsch tests). Immunoassay techniques (see Chapter 31) also eliminate the need for many separate operations and, like colour tests, can provide a tentative identification and approximate quantification of the poison. However, a disadvantage of both these methods is that a negative result eliminates only a few of the possible toxic substances. Consequently, additional colour tests or immunoassays are required before that particular group of poisons can be excluded. This type of sequential testing can waste much time.

A broad-spectrum screen, able to detect or eliminate most of the poisons in a group, usually requires a combination of three or more of the available techniques. For the drug and pesticide groups, the only combination potentially able to encompass all the required steps is mass spectrometry (MS) coupled with either GC or HPLC. However, a simple, direct solvent-extraction scheme is generally employed to eliminate endogenous substances that might otherwise reduce the efficiency of the system. Completion of the following analytical probing tests will, in many cases, provide clues to the nature of the poison.

Analytical probing

Medicaments and other materials near the body

Empty, or nearly empty, tablet containers found in the home or close to a body can provide a valuable first clue as to what to look for, particularly if accompanied by a suicide note. It is a common mistake, however, to spend too much time identifying every tablet or capsule found at the scene (they may have nothing to do with the event or may have been placed there to try to draw attention from another direction). However, a quick attempt at identification before analysing body fluids can be valuable (see Chapter 13) for the identification of solid dosage forms). Other materials may include containers of household or industrial products (e.g. cleaning agents, disinfectants, gas-lighter refills, pesticides) and syringes. Their chemical content is usually obvious from the container labels and in situations where a syringe is found it makes sense to analyse any residual content.

Food or drink residues near the body

The priority given to this aspect depends on the case history, but a rapid initial examination at an early stage is often useful (see Examination of food and drink below).

Body fluids

A number of preliminary tests should be carried out to confirm or exclude the most common toxic agents.

Urine The following tests, details of which are given in Chapter 1 (Fast limited screening), should be performed on urine samples: Trinder's test for salicylates; cresol–ammonia test for paracetamol; iron(III) chloride–perchloride acid–nitric acid (FPN) reagent for phenothiazines; and Fujiwara test for trichloro compounds. In addition, the content of alcohol should be determined by GC (see Chapter 4).

Stomach contents Stomach contents should be examined visually for colour and the presence of tablet residues or excipients (often maize starch). The odour should be noted as this may indicate the presence of alcohols, aldehydes, ketones, phenols, cyanide, ethchlorvynol, nicotine, etc. Caution should be applied when smelling stomach contents in case of the presence of HCN (approximately 50% of the population are unable to smell cyanide). The following tests, details of which are given in Chapter 1 (Fast limited screening) should be performed: Trinder's test for salicylates; cresol–ammonia test for paracetamol; FPN reagent for phenothiazines; and Fujiwara test for trichloro compounds. In addition, the diphenylamine test for oxidising agents and the Reinsch test for heavy metals (Chapter 30) should be carried out and a diluted, filtered extract examined by direct ultraviolet (UV) spectrophotometry for drugs with high absorbance (A_1^1) values. A small aliquot of stomach contents may also be rapidly screened by thin-layer chromatography (TLC) following alkaline solvent extraction to indicate the presence of basic drugs or alkaloids.

Blood In many laboratories, and in the light of human tissue legislation in the UK, blood may be the principal sample submitted for toxicological screening. Tests on the blood sample should include screening, a quantification of alcohol by GC (Chapter 4), and detection and quantification of carbon monoxide by spectrophotometry (Chapter 1). Visual examination of the blood may immediately indicate carbon monoxide poisoning (bright cherry-red specimen), and brown blood as a result of methaemoglobinaemia may signify poisoning by oxidising agents such as nitrite and chlorate. Immunoassay provides a rapid and efficient way of screening for the presence of many drugs using small tissue samples. New immunoassay technologies such as the Randox biochip enable a wide range of drugs to be screened on a single drop of blood, urine, vitreous and even homogenised tissue.

The precise order in which these tests are carried out depends on the information available, but most of them need to be done at some time, unless the evidence overwhelmingly indicates a specific poison (e.g. cyanide). Even in these cases, ancillary questions may arise in court. For instance, was the victim doped or drunk prior to the administration of the fatal poison? A toxicologist should, therefore, carry out most of the above plus a routine drug screen in every case. For example, not all carbon monoxide cases are suicidal or accidental, even if the circumstantial evidence seems to indicate a non-criminal cause of death.

The flow chart in Figure 9.4 shows how the information obtained from the questionnaire and the suggested analytical probing are combined to obtain a probable identity, or at least the type of poison involved. If the analytical probing suggested above is compared with the poison group classification shown in Figure 9.1, it can be seen that every group has been checked by at least one test designed to confirm or exclude one or more of the most common toxic agents within that classification, with the exception of group 7, miscellaneous substances.

A simple drug screen, such as those in Chapter 1, of the urine and stomach contents may be undertaken as part of this probing phase. Alternatively, a more traditional multi-fractional screen can be carried out (see Chapter 10). Both approaches are valid, depending on the type of case that predominates in the laboratory. If most of the work is undertaken for the coroner and pathologist and concerns mainly the investigation of suspected suicidal overdoses, the simple drug screen is probably better. However, if a large number of antemortem investigations (i.e. non-fatal doping, poisoning, traffic and drug offences) are undertaken, the traditional multi-fraction screen is more economic of both sample and time in the long term. Moreover, there is an increasing demand for the forensic laboratory to investigate the possibility of drug involvement in murder, manslaughter and rape cases. In these cases, proof is required of ingestion of a drug rather than of the consumption of an overdose, so that a simple drug screen might not suffice.

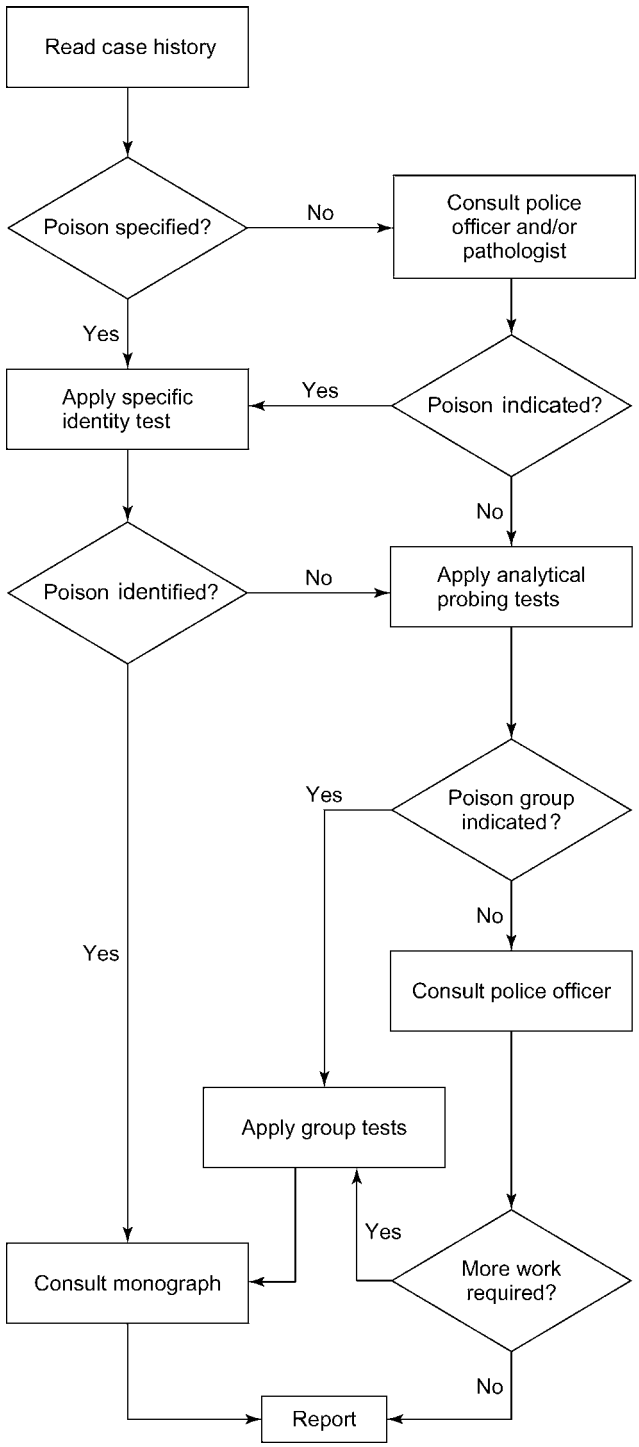

Figure 9.4 Analytical probing flow chart.

Only a small number of qualitative tests utilise the blood sample. This is because it is generally the most limited sample, its matrix is not compatible with simple tests, and it is also the most valuable for the confirmation and quantification phases of a toxicological analysis. The methods employed for drugs-driving cases (Chapter 5) may be of assistance here.

The analysis of tissue samples was formerly a prerequisite of any toxicological examination, but it is less important now provided that the laboratory has sensitive instrumental methods in routine use. However, analysis of the liver is essential when a full range of body fluids cannot be obtained, or if the detailed analysis of these fluids fails to provide an answer. For these reasons, liver should still be requested as a routine specimen in every postmortem case. It is doubtful whether the supply and analysis of a full set of body organs, advocated by many classic toxicology textbooks, can now be justified, for there is little evidence that such routines have uncovered homicidal poisonings that would otherwise have been overlooked. In general, the analysis of liver specimens need be considered only in those cases in which the circumstantial evidence conflicts strongly with the analytical results. For example, toxic concentrations of some drugs (e.g. thioridazine) in blood are not significantly higher than therapeutic concentrations. This is not generally true of liver concentrations, which, in postmortem specimens, may be over 10 times higher than those obtained from patients on therapeutic dose regimens. Liver analysis in these cases may provide a more certain indication of a fatal overdose. Liver tissue analysis is essential when analysing drugs that undergo postmortem redistribution. This term describes the movement of drugs within the body after death, resulting in postmortem blood concentrations far in excess of those present when death occurred. Major causes of this phenomenon are the release and diffusion of drugs from organs such as the liver and lungs into adjacent blood vessels and simple diffusion from gastric contents into the abdominal aorta and the iliac vein. A full discussion is given in Chapter 10 under Interpretation of postmortem toxicology results.

Tissue analysis is obviously a necessity for exhumed or decomposed bodies, or when the victim has survived for several days after ingestion of the poison. In all these cases the routine samples (stomach contents, blood and urine) may not be available or, if they are, may not produce meaningful results. In an exhumed body, thigh muscle and hair may be the most appropriate specimens to collect.

Group tests

In this section, each classified group of poisons is discussed in turn. The group tables summarise the type of circumstantial evidence usually characteristic for the majority of poisons, list possible spot or probing tests to confirm or refute the circumstantial indications, and indicate the analytical methods required for the group. A general method is suggested where this is available. Further details about specific groups of drugs and poisons are given in other chapters. The figure given under 'number of compounds to be excluded' is an estimate of the total number of poisons within that particular group.

Group 1 poisons: gases

The presence of this group of poisons is usually indicated by the circumstances of the incident (provided that they have been reported in full to the analyst). Furthermore, the identity of the actual gas involved is often indicated by the circumstantial evidence. This is fortunate, since no single-stage group test or analytical method is available for this group (Table 9.5). However, a few points need careful investigation. For instance, a portable heater may have been removed from the room where the death occurred. In one case, a devoted mother warmed her son's cold bedroom before he was awake using a defective paraffin heater, which was subsequently transferred to warm the bathroom before he took a bath. He was found dead in bed with no visible source of carbon monoxide in the room and so the laboratory was only requested to analyse for drugs. (The classic pink skin colour from carboxyhaemoglobin is not always apparent.) Fortunately, a routine test for carbon monoxide established the cause of death before too much time had been wasted looking for drugs. The analyst should also enquire whether oxygen was administered or artificial respiration was attempted before death, since these measures can bring about a significant reduction in carboxyhaemoglobin concentrations. As a result, carboxyhaemoglobin may be found in a postmortem blood sample at a non-fatal concentration, but no-one may think to inform the analyst of the first aid that had been given.

Some compounds that are gases at normal temperature and pressure can be detected by headspace GC using systems GA or GI (Chapter 40). In blood samples, system GI detects butane, ethane, methane, nitrous oxide, propane and also several of the fluorocarbons with low boiling points. In Chapter 14 a summary of the GC systems for gases and volatile compounds is given in Table 14.2 together with a description of the use of such systems.

Table 9.5 Group 1 poisons: gases

Indications	
Symptoms	Apnoea, asphyxia, dyspnoea, vomiting; pink or red skin colour (carbon monoxide or cyanide)
Onset of symptoms	Very rapid onset of illness or death
Scene	Hospitals and dental surgeries (anaesthetic gases), industrial sites, laboratories, mines
	Victims found in bathrooms, boats, caravans, cars, fires, kitchens
	Presence of fire extinguishers, gas fires, geysers, portable heaters
Occupation	Chemical industry, electroplating, fumigation, furnaces, glue factories, industrial tank cleaning, jewellery, metal treatment, mines, photography, sewers, tanneries
Additional investigations	
	Examination of equipment or vehicle
	Examination of clothing if stained or if odours are noted
	Postmortem examination of lung and brain specimens
Analysis	
Odour	Cyanide
Colour tests	Direct-reading colorimetric indicator tubes (Dräger tubes)
Group tests	Not available
General methods	Diffusion in Conway cell (cyanide), headspace GC
Most common poisons	Carbon monoxide, cyanide
Number of compounds to be excluded	30

Only two poisons in this group require routine exclusion: cyanide and carbon monoxide. The main exceptions to this general recommendation are cases that arise from incidents on industrial premises, or the use and abuse of compressed solvent fuels and aerosols. In the former case, a list of the industrial gases used or available on site should be requested. In the latter case, most of the relevant compounds are covered by headspace GC, as mentioned above.

Carbon monoxide

The detection and measurement of carbon monoxide in blood samples is necessary to investigate deaths in fires, cars, caravans, etc., and it is essential for all routine screening schemes. The forensic toxicologist infrequently undertakes scene visits and those that are most likely to require a visit tend to involve carbon monoxide accumulation linked to a blocked flue/chimney or faulty gas heating appliance. These visits often occur in the mid/late autumn when heating systems are fired up for the first time after a prolonged period of non-use over the warmer summer months and when birds have nested in the chimney stack or when an unserviced boiler is started. When visiting such a scene it is essential to have a qualified gas board or appliance engineer present as well as coloured smoke bombs. Placing a coloured smoke bomb in the fireplace or grate of a solid fuel burner will rapidly demonstrate a blocked chimney or flue. The gas appliance engineer will be able to safely inspect the appliance for evidence of faults or lack of servicing. The detection of carbon monoxide at the scene may be achieved by use of either colorimetric tests, e.g. the Dräger gas detection tubes or via electronic measurement devices that sample the atmosphere. The introduction of the catalytic converter into car exhaust systems has significantly reduced the number of carbon monoxide fatalities associated with the inhalation of vehicle exhaust fumes. The most rapid and convenient method to detect and quantify carbon monoxide in blood as a primary or secondary cause of poisoning is by a spectrophotometric method, preferably using a co-oximeter (Chapter 1) or by GC with flame ionisation detection (FID).

Cyanide

Cyanide is most frequently encountered in fire deaths or following the ingestion of sodium or potassium cyanide. In most cases where cyanide has been ingested the cyanide is self-indicating by its odour of bitter almonds. However, as previously stated, the ability among the population to detect cyanide by its odour is very variable, so a colour test is useful (Chapter 30). Ingestion of sodium nitroprusside is likely to be indicated by the presence of dark blue/black staining around the stomach wall. For blood and tissue specimens it is convenient to use quantitative methods that involve Conway micro-diffusion cells.

Group 2 poisons: volatile compounds

The rapid onset of symptoms followed by serious illness or death is the most valuable clue to the presence of this group. The probable identity of the particular poison may be indicated by the nature of the symptoms (Table 9.6). Physical evidence at the scene (bottles, residues in cups

Table 9.6 Group 2 poisons: volatile compounds

Indications	
Symptoms	Abdominal pain (especially with phenols), convulsions (especially with glycols), delirium, drunken behaviour (drowsiness, ataxia, speech and vision disturbance), jaundice (aniline, nitrobenzene), tremors, vomiting
Onset of symptoms	Rapid onset of illness or death when inhaled, slower if taken orally
Clinical history	Alcoholism; volatile substance abuse (more common in children and teenagers)
Scene	Domestic locations, hospitals and research laboratories, industrial locations
	Presence of liquor, methylated spirit or surgical spirit; glues or polishes associated with plastic bags; unusual siting of antifreeze or other domestic products
Occupation	Degreasing plants, dry cleaners, chemists, printers; manufacturers of adhesives, dyes, paints, petroleum products, plastics, polishes, perfumes, rubber
Additional investigations	
	Bottles or containers found near victim, even if empty
	Examination of clothing if stained or if odours are noted
	Antemortem examination of blood or urine samples
	Postmortem examination of lung and brain specimens; also vitreous humour, especially if the body is decomposed
Analysis	
Odour	
Colour tests	Dichromate test for ethanol, aldehydes and ketones; colorimetric indicator tube; Fujiwara test for trichloro compounds
Group tests	Headspace GC
General methods	GC
Most common poisons	Ethanol, methanol, toluene, hydrocarbons and halocarbons
Number of compounds to be excluded	120

etc., tubes of adhesives and plastic bags with characteristic odours) frequently leaves little doubt as to the nature of the intoxicant, if the material is submitted within 48 hours. If death has been delayed for several days by hospital treatment, it is imperative to obtain for analysis any antemortem samples taken on admission to hospital, no matter how small.

If several days have elapsed before the body is discovered, there is a tendency to think that analysis for volatile poisons would be futile, but in such cases it should be one of the first groups to be checked. The presence of alcohols, toluene and halogenated hydrocarbons has been shown in many such samples, although the interpretation of the detected concentrations may present problems. In all cases of suspected volatile substance involvement, it is essential that samples are collected and stored in glass containers with a gastight stopper, preferably lined with metal foil. It is also advisable to leave as little headspace as possible in the sample container. However, if the sample is to be stored in a freezer, care should be taken to leave sufficient space for expansion to avoid breakage of the tube.

Special care is needed if the samples have been frozen. Volatile poisons may be missed if the analytical material is not allowed to thaw, preferably at room temperature, before examination, although care must be taken to ensure that the container is properly sealed to avoid loss during warming.

Solvent abusers now turn their attention to a wide variety of industrial solvents. A list of products that may be abused by inhalation is given in Chapter 14. It follows that a good general screening method backed up with a large database is required to detect and identify the agent(s) involved. GC is the only way to achieve this coverage, since all other methods require the application of separate colour tests or chemical reactions for each volatile substance, although the Fujiwara test, which detects the presence of trichloro compounds remains a useful tool (Chapters 1 and 30).

Headspace GC (Chapter 40) is probably the most widely used method for the general screening of volatile poisons; systems GA or GI (Chapter 40) may be used. A comprehensive screening and identification system is given in Chapter 14, Table 14.3.

Group 3 poisons: drugs (solvent soluble)

In general, postmortem stomach contents, blood, vitreous, hair and urine samples may be analysed by immunoassay (see Chapter 31), and by the same methods as those detailed for patients' samples in Chapter 1, provided that the objective is identical, i.e. to obtain evidence of a drug overdose (Table 9.7). However, in some suspicious deaths or criminal cases, stomach contents, blood and urine samples cannot be obtained and alternative tissue samples have to be examined (Chapter 28). Most screening systems for biological fluids are modified easily by the introduction of a few additional clean-up procedures to permit the use of homogenates of liver or other tissues. There is much to be said for having a few routine extraction methods of general applicability, rather than a large number of detailed methods each designed for a specific purpose. The inherent defects of a few routine systems are soon discovered through constant use, but this is preferable to the unknown defects of a multiplicity of systems that are used rarely. Enzyme digestion allows the extension of stomach content, blood and urine extraction routines to samples of solid tissue.

Tissue analysis

Direct solvent extraction, or solid-phase extraction, before or after acidic or enzymatic digestion is the most widely used sample preparation method. The sensitive detection methods of GC and MS require only small amounts of tissue to be processed and any emulsion problems that arise are easily resolved.

Enzymatic digestion

Enzymatic digestion is usually the best choice for general screening of solid tissue (Osselton *et al.* 1978; Osselton 1979, 1981). It is simple, readily adaptable and gives a protein-free filtrate from which any drugs present may be extracted. It also gives enhanced extraction of many drugs compared with classic methods.

Table 9.7 Group 3 poisons: drugs (solvent soluble)

Indications	
Symptoms	Effects are variable, but the following information may be used as a guide:
Analgesics	Gastric irritation, haematuria, tinnitus, sweating, coma, convulsions
Opiates and synthetic narcotics	Contracted pupils, muscle twitching, slow respiration, hypotension, coma
Sedatives and hypnotics	Ataxia, slurred speech, drowsiness, stupor, coma
Stimulants and antidepressants	Dilated pupils, dry mouth, headache, tachycardia, tremors, convulsions
Onset of symptoms	Can be relatively slow unless injected (i.e. 1–48 h)
Age	Illicit drugs more common in the group 16–30 years of age; the elderly use their own prescribed drugs
Scene	Illegal lodgings, colleges, discos, clubs, residential homes
Additional investigations	
	Antemortem samples if the victim is admitted to hospital
	Postmortem examination of nasal swabs, injection marks and a control area of skin
Analysis	
Colour tests	No general tests, only selective tests for salicylates, phenothiazines, sulfonamides, etc.
Group tests	Direct solvent extraction and examination by TLC and immunoassay
	Confirmation and quantification by UV, GC, HPLC, MS
Number of compounds reported	200
Number of compounds to be excluded	>2000

A suitable procedure is as follows:

1. Macerate 10 g of liver or other tissue with 40 mL of 1 mol/L tris-(hydroxymethyl)methylamine.
2. Add 10 mg of Subtilicin A and incubate in a water bath at 50–60°C for about 1 h, with agitation.
3. Filter the digest through a small plug of glass wool to remove undissolved connective tissue.

Aliquots of this digest may be substituted for the specified biological fluid in most routine screening procedures. The filtered digest has a pH of 8.0–9.5.

This method is very useful for the analysis of sectioned injection marks. The superficial fatty skin layer is removed and the remaining muscle layer is analysed as above. If the injection was intramuscular and of recent origin, the drug concentrations should be greater than in a similar tissue sample that does not show an injection mark. If the injection was intravenous, such a distinction cannot be expected.

The method's superb ability to 'liquidise' solid tissue can be used for many purposes apart from drug analysis. The recovery of shotgun pellets and small bomb fragments in body tissues is one such application. The preparation of solutions for direct aspiration into atomic absorption spectrophotometry instruments to detect some metals is useful, as is their use in the detection of toxic anions and some pesticides.

General drug screens

A multipurpose drug screen may be applied to samples of body fluids, especially when there is a limited amount of sample. A suitable TLC screening procedure is given in Chapter 1 (Toxicological screening by thin-layer chromatography), as is a GC one (Gas chromatographic screening for drugs) and an HPLC one (HPLC screening using the systematic toxicological identification procedure).

Drug screening in non-fatal criminal cases and traffic offences

Many forensic enquiries entail analytical investigations that require detection of therapeutic drug concentrations rather than toxic concentrations. For example, in driving and sexual assault offences a screen is required for drugs that can impair memory, judgement and psychomotor activities (e.g. sedatives, tranquillisers, stimulants and narcotics). This type of analysis may also be needed to check allegations that the victim or accused is a drug addict or was under the influence of drugs at the time of the crime. The amount of blood and urine available for analysis in these cases is usually very limited and irreplaceable; additional blood or urine samples taken several days after the event are useless, although hair may be considered (Chapter 19).

Background information is of paramount importance, and the following should be requested as a matter of routine:

- Were there any drugs in the possession of the victim or the defendant?
- What was the subject's condition (e.g. drowsy, asleep, confused, agitated)?
- Did the police doctor certify impairment of driving ability?
- Was the subject prescribed any drugs by his or her own doctor and, if so, when was the last dose taken?
- Is the subject a known drug addict?

Further information on the analysis of such samples is given in Chapters 5 and 8.

Blood and urine samples should be obtained whenever possible in this type of investigation: when the blood sample is small, the chance of detecting and confirming residual traces of an antidepressant or stimulant drug may be low. If there is no urine sample, pre-screening by immunoassay methods is essential to provide an analytical guide to the nature of any drug present in the blood sample.

For forensic purposes, at least two uncorrelated methods of identification are required (e.g. HPLC and GC, HPLC and MS, or GC and MS). Immunoassay methods provide good exclusion evidence but poor confirmation of identity, although they are vital for the detection of insulin, lysergide and the cannabinoids.

When drug concentrations are liable to be low, the extraction of separate aliquots of urine or stomach contents is recommended for acidic and neutral drugs and for basic drugs (Chapter 10).

Group 4 poisons: metals

Historically, poisons in this group (Table 9.8) have been used frequently, probably because in general they are potent, tasteless, readily available and produce symptoms similar to many common diseases. Consequently, suspicion is rarely aroused until it is too late. For example, the substitution of arsenious oxide for the contents of one or two capsules of a prescribed medicine can have fatal results with all the appearance of a straightforward drug overdose suicide. A drug-screen analysis in these circumstances will result in a very perplexed analyst and much wasted time and case material.

Group 4 poisons should be checked as a matter of routine if vomiting and diarrhoea are noted as symptoms, no matter what other poisons may be suggested by medical opinion or circumstantial evidence. Simple qualitative tests should be applied first, e.g. the Reinsch test (Chapter 30). Although this test detects only seven toxic metals, it can be applied to almost any material (body fluids, homogenised tissue, food and drinks) without any elaborate preparation, and it is sensitive enough to detect toxic concentrations of the most common poisonous metals in a few minutes. However, it misses too many metals for it to be considered as a complete group-exclusion test. Another simple test is the Gutzeit test for arsenic (Chapter 30).

Table 9.8 Group 4 poisons: metals

Indications	
Symptoms	Anaemia, cramps, diarrhoea, gastric pain, hair loss (thallium and selenium), jaundice, metallic taste, paralysis, peripheral neuritis, salivation, urine retention, vomiting, weight loss
Onset of symptoms	Usually after several hours; death may occur within 24 h, but more commonly after several days (with acute rather than chronic poisoning)
Scene	Industrial locations, laboratories
Occupation	Electroplating, smelting; manufacture of agricultural chemicals, alloys, batteries, ceramics, glass, paint, petroleum products
Additional investigations	
	Antemortem examination of blood and urine
	Postmortem examination of kidney, intestinal contents, bone, hair, nails
Analysis	
Colour tests	Reinsch test, Gutzeit test
Group test	Atomic emission spectroscopy
Most common poisons	Arsenic, antimony, lead, lithium, mercury, thallium
Number of compounds to be excluded	20

A satisfactory routine metal-screening method must be able to analyse any biological material, without drastic modifications and with detection limits that provide reliable exclusion of minimum quoted toxic concentrations. Fortunately, for most metals the lower threshold of toxicity is at least an order of magnitude higher than the normal level.

The most widely used methods for the analysis of metals in biological fluids are electrochemical (anodic stripping voltammetry), electrothermal atomic absorption spectrometry, flame atomic absorption spectrometry, inductively coupled plasma emission spectrometry and inductively coupled plasma MS. Details of the identification and quantification of the most common metal poisons by these methods are given in Chapters 17 and 43.

Group 5 poisons: pesticides (solvent soluble)

Pesticides may be classified as insecticides, herbicides, rodenticides, molluscicides and acaricides, depending on their use. They may also be from a variety of chemical classes (e.g. organophosphorus compounds, carbamates, chlorinated hydrocarbons, pyrethroids and substituted ureas). Most of the published work on the analysis of pesticides makes the assumption that the analyst knows the identity of the actual compound or that they have some knowledge of the particular type of pesticide present in the analytical sample. This is rarely true in forensic work and, until this information has been obtained, many excellent published methods are not suitable. Indications associated with pesticide poisoning are provided in Table 9.9 and Chapter 16 gives detailed information on the analysis of pesticides.

In Western countries, pesticides are not used commonly by those with suicidal tendencies. However, this is not true of poisoners; in fact many of the chemicals used for homicidal poisoning have been pesticides. Arsenic, thallium, phosphorus and strychnine preparations have been used as rodenticides, and nicotine and mercury salts as insecticides and fungicides. The criminal use of the herbicides sodium chlorate and paraquat has been relatively common. The solvent-soluble pesticides should always be considered in the forensic investigation of a malicious food poisoning, sudden illness or suspicious death.

The detection of pesticides is best accomplished by applying simple presumptive colour tests as the preliminary screening tests followed by a

Table 9.9 Group 5 poisons: pesticides (solvent soluble)

Indications	
Symptoms (the additional symptoms below may be used as a guide)	Principal features are vomiting and convulsions
Chlorinated hydrocarbons	Dizziness, headache, muscular weakness, tremors
Chlorinated phenoxyacetic acids	Burning sensation, low blood pressure (convulsions are not a main feature for these substances)
Organophosphates	Contracted pupils, salivation, sweating, dyspnoea, anoxia, cyanosis
Phenols and cresols	Fever (main symptom), thirst, sweating, anoxia, haematuria, jaundice
Onset of symptoms	Rapid (within 30 min) if product contains a petroleum solvent or is inhaled; otherwise, slow (1–6 h)
Scene	Farms and horticultural nurseries, food-processing factories, domestic premises
Occupation	Manufacture of agricultural chemicals, farm workers, gardeners, pesticide officers
Additional investigations	
	Stained clothing, vomit, drink, stomach contents
Analysis	
Visual appearance	Abnormal colours in food, drink or stomach contents (pesticides often contain dyes)
Odour	Hydrocarbon solvents or odours that are fishy, sulfide or urine-like
Colour tests	Ammonium molybdate test for phosphorus and phosphides
	Furfural test for carbamates
	Phosphorus test for organophosphorus compounds
	Dithionite test for diquat and paraquat
	Test for cholinesterase inhibitors (Chapter 16)
Group tests	Colour tests, UV spectrophotometry, GC (Chapter 16)
General methods	Solvent extraction; most pesticides extract into acid and neutral groups
Common poisons	Chlordane, dichlorophenoxyacetic acid, dinitro-*o*-cresol, lindane, paraquat, parathion
Number of compounds to be excluded	>1000

comprehensive screening procedure by means of TLC or GC. GC-MS is the recognised standard technique for confirming identity (see Chapter 16 for details).

Group 6 poisons: anions

Poisoning from this group of poisons is fairly rare in Western countries, but cases still occur. Therefore, an attempt at isolation, identification and quantification in blood and tissues should be made to assist in the interpretation of an atypical case in which symptoms and circumstances do not provide the usual clues. Systematic analysis is difficult, and individual tests for anions are often necessary. Chapters 17 and 30 describe tests for individual anions.

The toxic dose of most of the chemicals in this group is relatively large, about one or two teaspoonfuls. This may explain why, with the exception of chlorates and fluorides, they have not featured in many homicidal poisonings. However, anions are used in malicious poisoning cases, so food, drink, vomit, stomach washings, gastric aspirates and urine should always be examined for their presence. In non-fatal cases, blood samples are usually inadequate and should be reserved until the results of the work on other samples are known. Table 9.10 summarises the common features of this group.

Table 9.10 Group 6 poisons: anions

Indications	
Symptoms	Violent vomiting, diarrhoea, abdominal pain, cyanosis (methaemoglobin formed with oxidising agents), stained skin and mucosa (permanganate, oxalate, iodide and bleaching agents)
	Exceptions to these symptoms are fluoride and bromide
Onset of symptoms	Usually within 1 h, death may occur within several hours (note that the toxic dose of this group is relatively large, >10 g)
Scene	Agricultural sites (nitrate, chlorate, fluoride and fluoroacetate)
	Industrial sites (nitrite, oxalate and sulfite)
	Domestic sites, drain and lavatory cleaners (hypochlorite and persulfate), weed killers (chlorate), insect powders (fluoride)
	Laboratories
Occupation	Sewer workers, rat catchers (fluoroacetate), factory workers
Additional investigations	
	Vomit, stained clothing, cups, etc., found near victim, stomach contents or washings, antemortem blood
Analysis	
Visual evidence	Chocolate-coloured blood, blood-stained vomit or urine, crystalline residues in food and drink
Colour test	Diphenylamine test for oxidising agents, which covers about 50% of the group
Group tests	Not available
Number of compounds to be excluded	15

The diphenylamine test for oxidising agents (Chapter 30) has a sensitivity of about 1 ppm and, if negative, excludes most of the toxic anions in this group.

In non-fatal poisoning cases, the sample of food, vomit, etc., may be very limited. If this is the case, the sequential method described next can be used.

Examination of food and drink

Most malicious poisoning cases, and many extortion attempts, involve the addition of toxic substances to food or drink. The analysis of suspected poisoned food or drink presents problems different from those in the detection of drugs and poisons in body fluids. The concentration of the toxic agent is usually higher than that found in blood, urine or postmortem tissue samples, but the available material for analysis is often more limited, and of much greater variety. The routine analysis of blood and urine samples soon ensures recognition of endogenous substances (e.g. urea, tryptamine, cholesterol) and of common exogenous chemicals (e.g. caffeine and nicotine) when they occur in extracts, spectra and chromatograms. But one scarcely knows what to expect from the analysis of chicken curry or chocolate gateau. Packet labels demonstrate that even simple foodstuffs may contain several unfamiliar chemical additives (e.g. so-called E numbers, see

Indexes of Analytical Data). The parallel analysis of a purchased sample of the same food may be necessary to check that inexplicable reactions or unfamiliar UV spectra are normal or abnormal for that type of material.

Before starting the analysis, every effort should be made to obtain details of the circumstances that led to the complaint or suspicion of doping or poisoning. As mentioned above, every case must be accompanied by an enquiry form relevant to the alleged crime. Figure 9.2 gives the information required in a general poisoning or doping case, and Chapter 8 the information required in a date-rape case. This information requirement may be compared with that in a postmortem toxicology request form (Chapter 10, Figure 10.1). The information should be supported, when possible, by an interview with the police officer involved. Was the suspect material tasted? If not, what aroused suspicion? Is the victim ill? What are the symptoms? Without clues to guide the selection of tests and screening systems, the sample is a 'general unknown'.

Depending on the case history, it is sometimes useful to request a urine and a blood sample from the victims; they may have been poisoned, but not by the food or drink submitted for analysis! Alternatively, the food may contain a poison, but there may be no evidence of the poison in their blood or urine. Fake poisonings are not uncommon, especially in marital cases or extortion attempts. Another type of fake poisoning is the misguided joke of putting some obnoxious material (e.g. urine, aloes, soap, mustard) into a person's food or drink.

In date-rape cases, the victim may not remember accurately what went on prior to the alleged incident. However, it is most likely that a hypnotic or sedative drug would have been used and the analysis should concentrate on those classes of drugs most likely to have caused unconsciousness. It is recommended that a urine specimen be collected as soon as possible after a victim of suspected date rape reports the incident, even before the police surgeon arrives. The UK Forensic Science Service has issued a special 'early evidence' kit for just this purpose, which includes a container with fluoride preservative in which to collect an early urine specimen. The reason for this is that victims of date rape often report the incident several hours after it has taken place and drugs with short half-lives (e.g. γ-hydroxybutyrate) may not be detectable after approximately 10 h. Blood and urine alcohol concentrations should be measured as well as those of drugs.

About 10 g of food or 10 mL of drink (which may be all that is available) is adequate, provided that there is some guide to the nature of the poison. However, this would not be sufficient for 20 or 30 individual colour tests. A drug screen alone is not sufficient, unless circumstantial evidence indicates that the intention was to dope rather than to poison the victim. The method must utilise techniques that are non-destructive and eliminate large numbers of compounds.

The method described below is designed to obtain the maximum amount of analytical data from the minimum quantity of material. It is very flexible and can be applied to tea, coffee, milk, alcoholic drinks, sandwiches, cakes, pies, sausages and numerous other types of food. Vomit and food stains may also be examined.

Analytical procedure

Make a full description of the exhibit, noting the type of container, labels, seals, stains or identification marks on the outer surface and total volume or mass of the contents. Note the colour, odour, possible presence of injection marks, presence or absence of suspended solids or sediment, pH and whether material has a tendency to form a stable froth on shaking. Note also the type and materials comprising the suspected container; one of the authors has encountered a case in which hydrofluoric acid had been placed in a plastic aftershave bottle.

Colour

The appearance of abnormal colours may indicate the presence of inorganic pigments (e.g. copper, nickel or cobalt salts) or dyestuffs from tablets, capsules, medicines, pesticides and rodent baits, especially those that contain warfarin, reserpine, chloralose or diphenadione. Common rat-bait colours are blue, green or red, and are usually associated with oatmeal or cereal grain.

Odour

Although odour is often very characteristic, and therefore smelling an exhibit can be very revealing, there is always the inherent danger of inhaling toxic vapours and this should be borne in mind when conducting such tests. Material taken straight from the refrigerator should be warmed gently prior to examination for odour. If possible, the opinions of several colleagues should be obtained on any abnormal odour. Many poisons can be detected in this way, but the test is very subjective, and some people have a poor sense of smell (e.g. cyanide detection by odour is an inherited ability). In favourable circumstances, smell is a very sensitive test, e.g. cyanide, chloroform and toluene can be detected at about 1 ppm.

Apart from the usual characteristic odours of sulfides, aldehydes, ketones, esters, etc., the analyst should be familiar with the smell of chloral hydrate, ethchlorvynol, methylpentynol, phenelzine, thiamine, penicillamine, penicillins and other common antibiotics.

These cases can be most frustrating to the analyst, for a negative report cannot be given when there is a most obvious detectable abnormal odour, the source of which has not been identified. If the material has a distinct odour, a headspace GC screen is indicated.

Sediments and suspensions

Sediments may result from insoluble or sparingly soluble tablet or capsule excipients (e.g. talc, starch or calcium phosphate), certain poisons (e.g. arsenious oxide) or sometimes from an interaction of the added contaminant with the beverage or drink (e.g. battery acid produces a coagulation of protein material). Microscopic examination of the sediment or filtered suspension may give a clue to the nature of the material, e.g. herbal or plant material.

The presence of insoluble inorganic crystalline sediments is often caused by the addition of cleaning powders (especially when accompanied by a faint odour of bleach or ammonia). Nevertheless, an analysis for metals should be undertaken at some stage (see group 4 poisons and Chapters 17 and 43). Gelatin capsules often remain as undissolved residue in the base of cups or drinking vessels. When crystalline material can be isolated from the material under examination, X-ray diffraction and infrared (IR) spectrophotometry are valuable non-destructive techniques if they are readily available and are backed up by good spectral libraries.

Frothing

The presence of a stable froth when the sample is shaken (with water if necessary) may indicate contamination with soap or detergents. Acidify the sample, shake again and, if froth still forms, a detergent rather than soap is present. Although of low toxicity, soap, detergents and cleaning powders are frequently the cause of complaints of poisoning or adulteration.

Direct ultraviolet spectrophotometry

In poisoned food or drink samples, concentrations of 0.1–10% of the toxic agent are not uncommon, so that direct UV spectrophotometry is often used. This is in contrast to biological samples, for which prior solvent extraction is required because of the very low concentrations (<0.01%).

If a sample of food contains a foreign substance with an A^1_1 >200, and it is present at a concentration of 0.1%, the material may be diluted 50 times and still show the characteristic spectrum for that substance when examined by direct UV spectrophotometry. This is a very useful, rapid and non-destructive exclusion method for the large number of drugs, disinfectants and pesticides with high specific absorbances.

Direct UV spectrophotometry is invaluable as an initial screening technique for all alcoholic drinks, and for beverages such as tea, coffee, milk and soup. It may also be applied to solid foods (cakes, sweets, bread, etc.) and to complete meals (meat, stews, vegetables), either by application to a diluted homogenate or by examination of a copious water-wash of the food material. The latter method is preferred, as most poisoners tend to sprinkle the poison on the surface of the food rather than add it during the cooking process. A note of the mass of the material used and the volume of added water should be made to facilitate calculation of the approximate quantity of poison present.

If possible, a control sample of the particular food or drink should be examined at the same time. If the spectra obtained with the control sample are similar to those obtained with the sample, a large number of substances are excluded without loss or destruction of what might be an extremely limited amount of original material.

Colour tests

After UV spectrophotometry, the diluted liquid or washing is available for further preliminary tests, using a small aliquot for each test:

1. Apply the Fujiwara test for trichloro compounds (Chapter 1, Fast limited screening).
2. Apply the diphenylamine test for oxidising agents (Chapter 30).
3. Test for the presence of halides with silver nitrate (Chapter 17).

Warm the main bulk of the sample on a water bath; note any odour and test the sample with appropriate test papers (pH, lead acetate, silver nitrate, starch). Apply the Reinsch test for metals (Chapter 30). After the application of the Reinsch test, filter the sample and retain the solids and the filter paper. Use small aliquots of the filtrate to test for borate and phosphate.

Extraction scheme

The preliminary observations often allow the tentative identification of a poison, so that specific tests can be made. If this is not so, the extraction procedure outlined in Figure 9.5 should be applied to the filtrate obtained above. Immunoassay screening may be undertaken on a small aliquot extract. Details of the TLC systems used to screen basic nitrogenous drugs are given in Chapter 39 (systems TA, TB and TC), as are those for three TLC systems used to screen acidic and neutral drugs (systems TD, TE and TF).

Analysis of tablets and capsules

Most tablets and capsules are complex mixtures that contain a small amount of one or more drugs together with a larger amount of excipients. A combination of visual and microscopic examination, colour tests, chromatography and UV and IR spectroscopy is employed in the analysis. Chapter 13 gives the details for these examinations. If the preparation is fairly common and does not contain a complex mixture of drugs, two or three of these techniques usually succeed in establishing the identity of the tablet or indicating the nature of the drug or drugs that it contains. The first step is to make careful notes about the container and its contents.

- The container may be a tube, envelope, folded paper packet, box or bottle. Note any seals and labels. Make full notes of the information given on the label.
- For the contents, note the total number of tablets or other preparation in the container, together with an estimate of the total number that the container could hold if full. Note the shape (flat, bevelled, biconvex, etc.), whether compression coated, film coated, enteric coated or sugar coated, markings (numbers, letters, symbols or score marks), exterior and interior colour, layered and core tablets, mean mass, diameter and thickness.

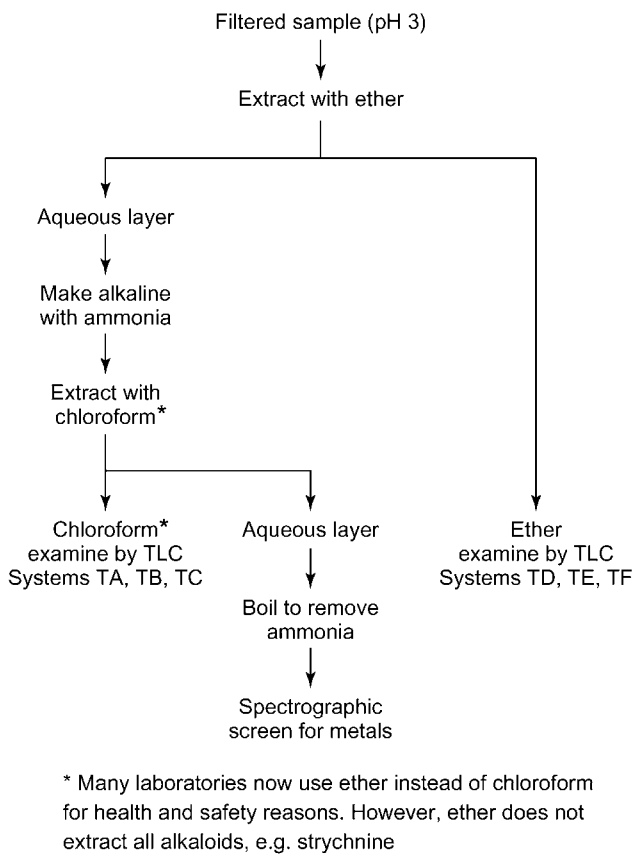

Figure 9.5 Scheme for the extraction of toxic substances in food and drink.

Visual recognition

Visual recognition can be regarded only as a useful clue; even tablets with well-known brand names may be faked, and placebo tablets are sometimes made. Chapter 13 gives methods for identifying solid dosage forms from their visual appearance. Especial care is required with capsules because their contents may be changed readily (arsenic, cyanide, strychnine and lysergide have been substituted in the past). Counterfeit preparations may occasionally be encountered (see Chapter 12, Counterfeit medicines).

Homoeopathic preparations

Homoeopathic preparations are usually round, flat–flat tablets with rough surfaces, 5–6 mm in diameter and contain mainly lactose.

Herbal remedies and health food preparations

Herbal remedies may contain active therapeutic compounds as well as some components that may be toxic. Health foods usually contain vitamins, minerals, herbal extracts, yeast, etc. Further information is given in Chapter 12, Herbal and homoeopathic products).

Sex-shop preparations

Sex-shop preparations usually contain substances reputed to be aphrodisiacs, such as vitamin E, ginseng and amyl nitrite (poppers).

Non-medicinal preparations

Non-medicinal preparations include a variety of preparations such as sweetener tablets, fertiliser tablets, stink bombs, indoor fireworks and slug pellets. Sweets may often be confused with medicinal products as they are often very similar in appearance.

`Legal highs'

A wide variety of chemicals are currently available via the internet purporting to be 'legal highs'. The term 'legal high' is used to describe substances that are designed to mimic the effects of recreational drugs such as cocaine, metamfetamine, amfetamine and MDMA but that are not controlled by legislation. The term 'herbal high' is also used, sometimes interchangeably with 'legal high' to describe products of herbal origin that are not controlled by legislation but may produce stimulant or psychotropic effects. These preparations are produced by chemists trying to stay ahead of drug control legislation and may contain a wide range of substances including synthetic cannabinoids and chemicals such as mephadrone (dimethycathinone), methylone, butylone and ephedrine, or herbal material such as 'Spice' (synthetic cannabinoids), *Salvia divinorum* and yohimbine. This is a constantly changing scene and toxicologists must ensure that they keep abreast of local developments in their country. One of the problems confronting forensic toxicologists in cases where so-called legal highs are involved is the ability to obtain reference standards. Although some reagent suppliers are responding to this need, there is inevitably a delay between a new substance becoming available and its identification and subsequent availability for use as a reference compound.

Analytical procedure

Chapter 12 gives details of the analysis of medicinal products with the identification of the active ingredient. If the identity of the drug is unknown, a screening procedure (TLC, GC, HPLC) followed by MS confirmation is often the most efficient method of analysis.

The presence of plant material indicates that the tablet is probably a herbal remedy. These are frequently very complex mixtures and are unlikely to be identified by simple methods. However, examination of an alcohol extract by UV spectrophotometry and TLC is worth attempting.

Odour

A few drugs have distinctive odours, which can provide a clue to the compound or at least to the type of preparation. A yeast-like or meaty smell may indicate a harmless vitamin preparation; an odour of peppermint may indicate a non-toxic indigestion remedy. Antibiotics, especially of the penicillin group, sometimes have a rather unpleasant sulfide-type smell. Other drugs with characteristic odours are clomethiazole, phenelzine, amitriptyline, chloral hydrate, methylpentynol and ethchlorvynol.

Size

The size of the tablet, which should be measured with callipers having a vernier reading to 0.1 mm, can provide a rough guide to the general class of preparation. Tablets of large diameter (i.e. >10 mm) are unlikely to contain potent alkaloids (except codeine); conversely, tablets with diameters less than 5 mm could not contain drugs with medicinal doses of 200 mg or more.

There is an approximate correlation between tablet diameter and the amount of drug contained in the tablet (Table 9.11), which may be used as a rough guide.

Extraction of tablets and capsules

Elaborate solvent-fractionation schemes are not usually necessary for solid dosage preparations. Most drugs are soluble in methanol and most of the excipients are not. Therefore, the preparation of a simple methanol extract is all that is required.

Thin-layer chromatography

The great majority of drugs present in pharmaceutical products are nitrogenous bases. The extract should be examined, therefore, using systems TA, TB or TC (Chapter 39). If these fail to reveal any positive reacting spots with the suggested location reagents, the possible identity of the unknown substance is reduced from a large number of basic drugs to a few hundred acidic and neutral drugs. The extract should then be examined using system TD, TE or TF (Chapter 39). Alternatively, one of the GC or HPLC screening procedures could be used, as given in Chapters 40 and 41, respectively.

Ultraviolet spectrophotometry

A portion of the methanol extract (see above) is diluted with water and examined at both acid and alkaline pH by UV spectrophotometry. The features of any resultant spectrum should be checked in the index to UV absorption data in Part 3. If the identity is suspected, the spectrum may be compared with that given in the appropriate monograph in Part 2.

Table 9.11 Relationship between tablet diameter and probable drug content

Tablet diameter (mm)	*Probable drug content (mg)*
<6	<5
<7	<15
<8	15–100
<9	30–200
<10	200–300
>11	250–500

Infrared spectroscopy

Extract a small portion of the crushed tablet or capsule contents with chloroform; to a portion of the chloroform extract add solid potassium bromide, dry under an IR lamp, prepare a compressed disc and examine by IR spectroscopy. Further details are given in Chapter 33. The features of any resultant spectrum should be checked in the index of IR peaks in Part 3. If the identity is suspected, the spectrum may be compared with that given in the appropriate monograph in Part 2.

For the majority of compounds, a mixture of 1 mg of drug with 150 mg of dry potassium bromide produces a good spectrum. It is not too difficult to obtain a rough estimate of the amount of sample needed to achieve this concentration if the product has been partially identified by other means. However, when the identity is completely unknown, it may require several attempts to obtain a disc with the correct concentration.

Mass spectrometry

Running the methanolic extract on a temperature-programmed gas chromatograph with a non-polar column connected to a mass spectrometer should detect most drugs present. Non-volatile drugs may be examined by LC–MS. The likely identity may then be found by using the index of MS data in Part 3. If the identity is suspected, the spectrum may be compared with that given in the appropriate monograph in Part 2.

Analysis of powders

The analysis of powders and similar articles suspected of containing drugs of abuse is described in Chapter 11.

Examination of syringes

A syringe found at the scene of an incident or in the possession of the victim or suspect should always be examined by the toxicologist, even if it has been stated that it is clean or empty. The usual safety measures regarding needlestick injury and possible microbial contamination should be taken.

If the syringe contains a few drops of an aqueous solution, remove a portion with a small TLC-spotting pipette and examine by the usual routine GC, GC-MS, LC-MS or TLC system. There is a high probability that a narcotic drug will be present, but amfetamine or methylphenidate may also be abused using a syringe. Wash the syringe with 1 mL of water and use this solution for UV spectrophotometry in acid and at pH 10. If a drug is indicated, a pure sample of the substance should be examined in conjunction with the original undiluted aqueous solution.

If the syringe is dry, introduce one or two drops of methanol into the syringe and proceed as described above.

The volumes of water used and any dilutions necessary for the UV examination must be noted to give a quantitative estimate of any drug present. Direct solvent extraction can be applied to the extracts and dilutions used for UV spectrophotometric analysis. This may also be necessary if the syringe is heavily blood stained. It is important to remember that some of the drugs encountered in syringes are susceptible to alkaline hydrolysis (e.g. diamorphine and methylphenidate). Thus, the addition of strong sodium hydroxide solution to the syringe should be avoided.

CHAPTER

10 Postmortem Toxicology

G Jones

Postmortem toxicology is used to determine whether alcohol, drugs or other poisons may have caused or contributed to the death of a person. It differs fundamentally from clinical toxicology, including therapeutic drug monitoring and emergency toxicology, which is used to assist in the clinical management of a living patient. While drug analysis in clinical toxicology shares some common approaches with postmortem analysis, such as the use of immunoassay, chromatography and mass spectrometry (MS), clinical assays usually need to be modified to give acceptable results with the unique fluids and tissues encounusuatered in postmortem cases. Compared with serum or plasma, and certainly with urine, whole blood contributes a large number of endogenous compounds that, although present in serum and plasma, are at much lower concentrations (e.g. fatty acids, cholesterol and other sterols). However, it is the greater difficulty of interpreting postmortem results that principally differentiates postmortem toxicology from clinical toxicology.

Specimens and other exhibits

Request, receipt and storage

It is the responsibility of the laboratory to advise its clients (e.g. coroner, medical examiner, lawyers, pathologist) what types and amounts of specimens are required for postmortem toxicology testing, and what preservative, if any, should be used. At least one tube of whole blood preserved with a minimum of 1% sodium fluoride should be provided, to be reserved for testing for ethanol and drugs such as cocaine. Stomach contents and most tissues are usually provided unpreserved. A recommended list of specimens is given in Table 10.1.

The laboratory should provide guidelines on specimen collection and storage as well as a requisition form to be completed by the submitter, which should be sent with the specimens to the laboratory. The requisition serves five primary purposes:

1. It identifies the deceased and gives appropriate demographic information and case history (e.g. circumstances of death, relevant medical history, autopsy findings).
2. It identifies the specific specimens and exhibits submitted.
3. It provides space to identify the testing required.
4. It identifies the submitter and serves as a chain-of-custody document.
5. It provides directions and information for packaging and transport of the specimens.

Each specimen must be labelled uniquely to identify the deceased from which the specimen was obtained (i.e. name or case number), and the specimen type. Figure 10.1 gives an example of a requisition for postmortem specimen analysis.

The extent of information requested depends on the jurisdiction in which the toxicologist is working. Where most samples are transferred internally within a medical examiner facility or department of forensic medicine, a less detailed case history or autopsy summary may be required if it can be readily obtained later.

Upon receipt in the laboratory, the specimens submitted must be checked against the information given on the requisition. Where there is more than one specimen of the same type, each container should be labelled uniquely (e.g. A, B, C, ...) since, with the exceptions of urine, vitreous humour and bile, postmortem specimens are not homogeneous and different containers of the same specimen type (e.g. blood) can sometimes have different drug concentrations. Receipt of the specimens must be recorded, on paper or electronically. That log should include appropriate demographic information, an adequate description of the specimen and its site of sampling (e.g. femoral blood), the approximate volume or mass, the type of container (e.g. grey-stoppered tube; tub) and any abnormal appearance of the specimen (decomposed, heat denatured, bloody urine, etc.).

All laboratories that undertake postmortem toxicology should document the chain of custody. At a minimum, the laboratory should document what was received, from whom, by what means (by hand, courier, mail) and when. Storage of the specimens and exhibits should be secure, and access to specimens and case files should be limited to authorised laboratory personnel. Blood and other tissue specimens should be stored under refrigerated conditions between receipt at the laboratory and analysis. Where there may be a significant delay between receipt and analysis, frozen storage should be considered, especially if potentially unstable substances may be involved. A record should be kept of each occasion on which the specimen is opened to remove an aliquot. The date when specimens are discarded or returned to the submitter should also be recorded. The length of time of retention of tissues by the laboratory may be a set period (e.g. 3–12 months agreed with the client), or the time required to complete any legal proceedings.

Specimen types

The specimens available for analysis in postmortem cases may be numerous or may be limited to blood or a single tissue, depending on the case history and preferences of the submitter. In a relatively recent death, blood, vitreous humour, at least one organ tissue (usually liver) and the gastric contents are commonly collected. However, in a severely decomposed case found outdoors, muscle, hair and bone may be the only specimens available. Although toxicology testing can theoretically be performed on almost any specimen, it is usually limited to those for which there is an appropriate database available to assist with interpretation of the results. Proper collection and preservation of postmortem specimens are critical, since there is usually no opportunity to go back for re-collection of specimens at a later date as the body may well have been cremated or buried.

Table 10.1 List of recommended postmortem specimens for routine toxicology examination

Specimen	*Quantity*
Heart blood	25 mL
Peripheral blood	10 mL
Brain	50 g
Liver	50 g
Vitreous humour	All available
Bile	All available
Urine	All available up to 50 mL
Gastric contents	All available (or 100 g and record total present in stomach)

Blood

In living patients the dose of a drug is most closely correlated with its concentration in blood or plasma. Historically, therefore, blood has been used as one of the primary specimens in postmortem toxicology. In most cases postmortem blood is relatively fluid and typically has numerous small clots. Sampling can usually be achieved with a syringe and large-gauge needle.

It used to be assumed that postmortem blood was more or less homogeneous: it is not. Postmortem blood concentrations of many drugs may vary from site to site (see later). As a result, much attention has been focused on the site of collection of postmortem blood samples. A word of caution may be appropriate about specimen labelling. Samples simply labelled 'blood' may have been collected from almost anywhere in the body. Even samples labelled as 'heart blood' may not have been collected from the heart itself but drawn blind through the chest wall, and may include pleural or chest fluid, pericardial fluid and even gastric contents if the death was traumatic. On occasion, it might be collected outside the body following a traumatic accident, as pooled blood in a body bag. As the awareness of postmortem redistribution grows, great faith is being placed in the analysis of subclavian and femoral blood rather than cardiac blood. However, the toxicologist should be wary of the anatomical purity of these specimens when large volumes are supplied, and should take this into account when offering an interpretation. Unless the femoral or subclavian veins are ligated, it is very likely that some blood will be drawn from other vessels. For example, a skilled pathologist or technician can sometimes draw as much as 50 mL of blood from the femoral vein. However, the femoral vein is relatively small and it is highly likely that much of that volume will be drawn down from the larger iliac vein and inferior vena cava. It is difficult to collect more than 5–10 mL from a ligated femoral vein, unless the leg is massaged. However, massaging the leg may promote release of drug from the skeletal muscle, potentially increasing the concentration of drug in the blood specimen.

Vitreous humour

Vitreous humour has been used for many years as the preferred specimen for postmortem confirmation of the ingestion of ethanol, since

Figure 10.1 Example of a postmortem toxicology requisition from a medical examiner office. CME, Chief Medical Examiner; C.O.D., cause of death.

postmortem formation of ethanol does not occur to any significant extent in vitreous humour. Even in the presence of elevated concentrations of glucose, fermentation does not occur because the interior of the eye is a sterile medium until the most advanced stages of decomposition. For this reason, vitreous humour is particularly useful for ethanol estimation in decomposing bodies. Vitreous humour has also been used increasingly for the measurement of drugs. For example, digoxin concentrations increase markedly in postmortem cardiac blood, but do not increase significantly in vitreous humour (Vorpahl, Coe 1978). Accordingly, vitreous digoxin concentrations give a better indication of perimortem concentrations than does heart blood. It has also been shown that monoacetylmorphine and cocaine may be more stable in vitreous humour than in blood (Lin *et al.* 1997). This presumably results from the relative lack of esterases in the eye, as compared with blood. The main disadvantage of vitreous humour is its relatively small volume – about 3 mL in each eye. Another disadvantage is that there is relatively little information in the literature on the concentrations expected after therapeutic doses for most drugs. While the vitreous : blood ratio for some drugs is close to unity, it is considerably less than unity for many drugs. The concentrations of highly lipid-soluble drugs, such as benzodiazepines, are relatively low in vitreous humour compared with whole blood; concentrations of highly protein-bound drugs, such as the tricyclic antidepressants, also tend to be much lower (Evenson, Engstrand 1989; Scott, Oliver 2001). The use of vitreous humour is therefore limited by the volume available, and the difficulty of interpretation of the results for many drugs.

Urine

Urine is a useful fluid for toxicology testing as it comprises more than 99% water and contains relatively few endogenous substances that interfere with chromatography or immunoassay tests. However, there are three disadvantages with urine in postmortem work. First, urine is available in only about 50% of deaths, as it is fairly common for the bladder to be voided during the dying process. It is therefore unwise to develop an analytical protocol for postmortem testing that relies solely on the presence of urine for the detection of drugs. Second, many drugs are metabolised so extensively that the parent drug is not detected in urine, or is present only at a relatively low concentration. However, if the metabolites are searched for, urine can be a useful fluid, especially for inexpensive methods such as thin-layer chromatography (TLC), in which the metabolite patterns of some drugs, such as the tricyclic antidepressants and phenothiazines, can be diagnostic. The third disadvantage of urine is that urinary concentrations of most drugs are difficult, if not impossible, to interpret. The correlation between the concentration of drugs in urine and blood is extremely poor. The primary reason for this is that urine is not a circulating fluid, but is a waste product collected in the bladder. The concentrations of drugs and metabolites in urine therefore depend on the time of urine formation relative to sampling and drug ingestion.

Liver

While many tissues are collected and analysed in postmortem toxicology, liver is the most important. The main reasons are the large amount of tissue available, its ease of collection and the relative ease of sample preparation compared with other tissues. There is also a relatively large database of liver drug concentrations available in the literature compared with the amount of data for other tissues. Concentrations of many basic drugs are also higher in the liver than in blood, making detection easier. For example, concentrations of the tricyclic antidepressants are roughly 10–50 times greater in the liver than in the blood, partly because of the absorption of drugs from the small intestines by the hepatic portal system. Today, with more sensitive analytical methods, the majority of drugs are detected readily in the blood, and it is not necessary to rely on the liver for their detection. However, liver is an extremely valuable tissue for the analysis of drugs that undergo postmortem redistribution because concentrations in the liver are relatively stable after death. As a result of the increased stability of drugs in liver, analysis of this tissue can be a valuable aid in the interpretation of postmortem toxicology results. Liver concentrations can fall slightly after death through diffusion, although this effect is quantitatively minor (Hilberg *et al.* 1994). It has also been demonstrated that some local increases in drug concentration can occur because of postmortem diffusion of drugs from the stomach (Pounder *et al.* 1996a, 1996b). The only major disadvantage of the liver as a specimen is that it tends to be fatty and can putrefy faster than blood. It is therefore important that analytical methods incorporate some type of clean-up step and are robust enough to minimise the matrix effect of the tissue.

Stomach contents

Stomach (or gastric) contents are valuable for two primary reasons. After overdosage, drug concentrations in the stomach may be quite high, even after the majority of the drug has passed into the small intestine. Analysis of the stomach contents is uncomplicated by metabolism, so drugs that are metabolised extensively in the body may be detected unchanged. Similarly, drugs that may be difficult to detect in the blood because of extensive distribution in the body might be detected readily in the stomach. The disadvantage of stomach contents is their composition, which varies from a thin watery fluid to a semi-solid, depending on the amount and type of food present. The interpretative value of stomach contents is in confirming the consumption of an oral overdose. If the total amount of drug detected in the stomach contents is significantly greater than the prescribed dose, the possibility of drug abuse or an overdose should be considered. There are, however, two important caveats. First, stomach contents are rarely homogeneous, and therefore it is difficult to measure accurately the representative concentration of drug in the volume of stomach contents received, unless the contents are homogenised. Most chromatographic assays are based on volumes as small as 1 mL or less, and therefore the potential for sampling errors is great. The second reason for the difficulty of accurate estimation of a dose in gastric contents is that the total stomach contents are often not sent to the laboratory. Results should therefore be reported as the amount of drug present in the volume or mass of stomach contents received. Specimen collection guidelines should therefore encourage pathologists to submit the complete stomach contents rather than an aliquot.

There are two misconceptions regarding interpretation of drug concentrations in the stomach. First, the concentration (as distinct from the amount) of a substance in the stomach contents is virtually meaningless by itself. Shortly after a therapeutic dose, the concentration of a drug in the stomach may be very high, even if the total amount is not. Second, the absence of a large amount of residual drug in the stomach does not necessarily rule out an oral overdose. It may take several hours to die from a drug overdose, during which most or all of the drug could have passed from the stomach to the small intestine, or even have been largely absorbed. On the other hand, consumption of an oral overdose of medicine can result in a formation of a medicine 'mass' or bezoar in the stomach, which may take several hours or even a day or more to dissipate (Ong, Achkar 2001). High concentrations of some drugs can delay gastric emptying. It must therefore be accepted that gastric drug concentrations should never be interpreted on the same basis as those for blood. The detection of a drug or metabolite in the stomach contents does not necessarily mean that the drug was taken orally. Gastric juice is constantly being secreted into the stomach; it in turn is formed from extracellular fluid, which may contain significant amounts of basic drugs and metabolites circulating in the blood. Active back extraction of basic drugs from the circulation into the acidic environment of the stomach may also occur. It is also important to bear in mind that gastric juice may have been contaminated with bile from retching or vomiting. In overdose patients administered oral charcoal, large amounts of charcoal in the stomach lead to an underestimation of the total amount of drug present.

Other fluids, tissues and organs

Bile has been collected historically, although its usefulness is limited. Previously, bile was valuable because it contains high concentrations of drug conjugates, most notably morphine. Detection of morphine and many other drugs (e.g. benzodiazepines, colchicine and buprenorphine) is therefore more likely in the bile than in the blood, in which

concentrations may be as much as 1000 times lower. The possibility that drugs in the bile may undergo enterohepatic re-circulation should not be overlooked. With the widespread use of sensitive immunoassays and other techniques, the use of bile as a screening specimen is therefore less valuable than it once was. In addition, bile, like urine, is a waste fluid and, with the possible exception of ethanol, the correlation between blood and bile concentrations of drugs is generally poor.

Brain, kidney and spleen have been used to determine and interpret the concentrations of drugs or other toxins. Brain, and indeed other organ tissues, can be useful in assessing the overall body burden of the drug, although the database of reference values that may assist interpretation is limited. The brain offers the additional advantage that it is a relatively isolated organ and should be unaffected by trauma to the abdomen and chest, although concentrations of some drugs vary considerably from one region of the brain to another (Jones, Pounder 1987; Pounder, Jones 1990). The measurement of drugs in the brain may therefore be misleading unless the origin of the tissue analysed is identified and there is an adequate database regarding concentrations in that anatomical region.

Drug concentrations in the kidney and spleen have little intrinsic significance, other than as part of the overall assessment of the body burden of a toxin, although the kidney has been found to be useful in determining heavy metal concentrations. Spleen has been used as a secondary specimen for toxins such as carbon monoxide and cyanide that bind to haemoglobin.

Injection sites

Forensic folklore indicates that injection sites may be valuable for determining whether or not someone has been injected with a drug or poison. However, proof of intravenous injection through the analysis of excised tissue around the suspected injection site is unlikely to be convincing, because the drugs will probably be swept away rapidly by the blood circulation. Arguably, a botched injection might leave an extravascular residue. Subcutaneous injection sites offer a better chance of detection, since absorption is considerably slower. In either case, it is critical that a control site be excised, for example from the opposite side of the body. It is easily forgotten that most drugs and other toxins are distributed to virtually every tissue and fluid in the body.

Nasal swabs

Some pathologists collect intranasal samples using cotton-tipped swabs in an attempt to demonstrate nasal administration. However, the same principles apply as those for proving that a drug was injected at a particular site, and interpretation should be undertaken with caution. Using cocaine as an example, if the drug is used one would expect to find small amounts of cocaine, and certainly cocaine metabolites such as benzoylecgonine, in the nasal passage, just through normal secretions. Therefore, without a difficult quantitative assessment, the simple detection of cocaine or its metabolites in nasal swabs does not prove that cocaine was snorted.

Syringes and other items

Detection of some drugs, and particularly non-drug poisons, may be considerably easier in items found at the scene than through analysis of blood alone, and might also assist interpretation of the results. For example, residues of partially dissolved medications found in a drinking glass at a scene of death can be a strong indicator of suicidal intent. Other containers used to mix poisons prior to suicidal consumption (or homicidal administration) can also be useful to the toxicologist. Some pesticides are not detected readily in blood using routine screening procedures but can be detected much more easily in the concentrated residue in a container. Similarly, some potent drugs that are difficult to detect in blood or tissues may be detected in syringes. For example, the interpretation of blood morphine concentrations may be influenced by whether they resulted from use of morphine or diamorphine (heroin). Since diamorphine rapidly breaks down in blood, and monoacetylmorphine is only slightly more stable, proof of the use of diamorphine may depend on circumstantial evidence, such as detecting a residue in a syringe. Similarly, the finding of insulin in a syringe near a person who was not a known diabetic is useful circumstantial evidence of insulin administration. It is otherwise extremely difficult to prove hypoglycaemia in a dead person.

Antemortem specimens

Not infrequently, victims of an accident or overdose may be admitted to hospital, albeit sometimes surviving only briefly before they die. When that occurs, it is common for blood and sometimes urine and gastric contents to be collected as part of the medical evaluation and treatment. There are at least two reasons why collection and analysis of antemortem specimens can be invaluable, even if death occurs fairly soon after admission to hospital. First, analysis of hospital admission specimens gives a good idea of the circulating blood concentration at the time of admission to the hospital, which by definition is unaffected by postmortem redistribution and may provide the only reliable indicator of dosage. Second, the antemortem specimen may provide the sole opportunity to perform meaningful toxicology if the person survives long enough for alcohol or drugs to be cleared from the body prior to death or to be diminished to a concentration of limited or no forensic value. Even if blood or plasma collected on admission is not available, clearly timed specimens drawn several hours later may still be useful if allowance is made for clearance and for the presence of drugs administered as part of treatment.

There are some caveats. Blood collected for clinical purposes is usually centrifuged to separate serum or plasma for testing on clinical analysers. However, once separated, the serum or plasma may not be resealed after analysis, and this will allow ethanol and other solvents to evaporate. This should be taken into account if the sample is analysed subsequently for forensic purposes, sometimes several days later. Another problem that can occur with clinical samples is the deterioration of some drugs in unpreserved serum, most notably cocaine. Intuitively, a serum or plasma specimen collected in the casualty or emergency department might be expected to contain higher concentrations of unchanged cocaine than a postmortem blood sample collected later. However, this is often not the case, because postmortem blood is often collected in tubes that containing sodium fluoride, which inhibits cocaine hydrolysis, whereas clinical samples are typically unpreserved.

Analytical toxicology

Scope of testing

One of the reasons why postmortem toxicology is so challenging is that it can require a search for any drug or poison of toxicological significance. However, this approach, while idealistic, is not practical for any laboratory that receives many hundreds or thousands of cases each year. A more practical approach includes a search for the common drugs of abuse, prescription and non-prescription drugs, followed, as necessary, by specific analyses as indicated by the case history. Any laboratory that claims to perform general 'drug screening' should, at a minimum, have protocols that include gas chromatography (GC) and/or liquid chromatography (LC) combined with MS and that are not just limited to a panel of immunoassay assay screens (e.g. for drugs of abuse). Other substances may be included, depending on the history. Carbon monoxide should be tested for in garage-related deaths, or circumstances in which malfunction of fossil-fuel devices is a possibility (e.g. house furnace, propane-powered devices). Deaths caused by cyanide are often occupationally related (e.g. metal plating, geology, agriculture, academic chemistry staff or students).

In practice, the laboratory investigation is directed by information received from the submitter of the specimens, including basic details of the circumstances of death and the key autopsy findings. No matter how good the laboratory is, some relatively common prescription and non-prescription drugs are not readily detected by commonly used methods. Also, in some geographical regions, particularly those devoted to large-scale agriculture and with relatively limited access to drugs, deaths caused by pesticides and rodenticides may be common, which necessitates a modified approach to drug screening (see Chapter 16). The scope of laboratory testing may vary considerably with case history and is often progressive. Initial negative findings after preliminary testing

may prompt further discussions with investigators or pathologists. The death may involve drugs or other poisons that are not detected readily by the screening methods used by the laboratory.

Specimen preparation and extraction

The first stage of the analytical process involves separation of the drug or compound of interest from the biological matrix in which it is contained. Urine and other non-viscous fluid specimens do not usually require treatment prior to extraction. However, even for relatively fluid blood samples, volumetric measurement with a positive displacement pipette designed for viscous samples, or gravimetric sampling, is preferred. The use of standard glass pipettes is discouraged as being inaccurate with viscous samples. Liquid–liquid extraction or solid-phase extraction (SPE) are both appropriate procedures for extracting drugs from urine and blood. Clotted blood may be homogenised in water or buffer prior to analysis. A typical analytical scheme for the screening of drugs in blood is given in Chapter 1.

The extraction of drugs from solid tissues requires that the tissue matrix be broken down to release drugs into an environment from which they are accessible for solvent extraction or SPE. This can be achieved by homogenisation, acid or alkaline hydrolysis, or enzyme digestion. Direct solvent extraction, with or without acid or enzymatic digestion, has almost superseded the classic protein-precipitation methods. The more sensitive detection methods of GC-MS and LC-MS mean that much smaller amounts of tissue can be processed. Consequently, any emulsion problems that arise are resolved more easily than in the past, when several hundred grams of liver and large volumes of solvent were required. The use of protein-precipitation reagents, such as barium chloride, zinc sulfate and tungstic acid, is discouraged for quantitative work because a significant portion of the analyte may be co-precipitated with the coagulated protein and therefore lost to the analysis.

Homogenisation

Tissues may be homogenised in water or buffer (e.g. Tris [(hydroxymethyl)methylamine] buffer). A dilution of one part tissue plus three parts water is common and gives a homogenate sufficiently thin to be pipetted easily, although some laboratories use one part tissue to nine parts water. Use of an efficient homogeniser, such as those that have a 'probe' design that blends, shears and cuts, is preferable. Older-style Waring (food-processor style) blenders or 'stomachers' are less efficient. Tissue homogenates may be analysed without further treatment if they have been prepared with an efficient homogeniser and the assay uses a good internal standard. Care should be taken to prevent operator exposure to aerosols that might be formed during the homogenisation process.

A typical procedure is as follows. Weigh 5 g liver or other tissue, and cut into small pieces with scissors or a scalpel. Place the tissue in a suitable tube or small beaker and add 15 mL distilled water. Homogenise the tissue to a uniform consistency. For liver and most other tissues, 1–2 mL of whole homogenate can subsequently be extracted directly using the protocol shown in Figure 10.2 for basic drugs. The protocol will extract basic drugs but leave behind lipids and sterols such as cholesterol. The protocol described in Figure 10.3 may be applied for acidic and many neutral drugs. For difficult tissues, e.g. those with a large amount of connective tissue, the enzymatic digestion described later may be useful. It is important to emphasise that, for quantitative work, whole homogenate must be extracted, not just the supernatant. Drugs that are protein bound are typically present at much higher concentrations in the uncentrifuged homogenate than in the supernatant.

Enzymatic digestion of tissues

Enzymatic digestion involves the use of a robust proteolytic enzyme, such as subtilisin Carlsberg, to digest the tissue to yield an essentially aqueous matrix for extraction; it is suitable for general screening as well as for more specific analysis (Osselton 1977, 1979; Osselton *et al.* 1978). It is simple, readily adaptable and provides a protein-free filtrate from which any drugs present may be extracted. It also provides enhanced extraction of many drugs compared with the tungstate, ammonium sulfate or Stas–Otto methods.

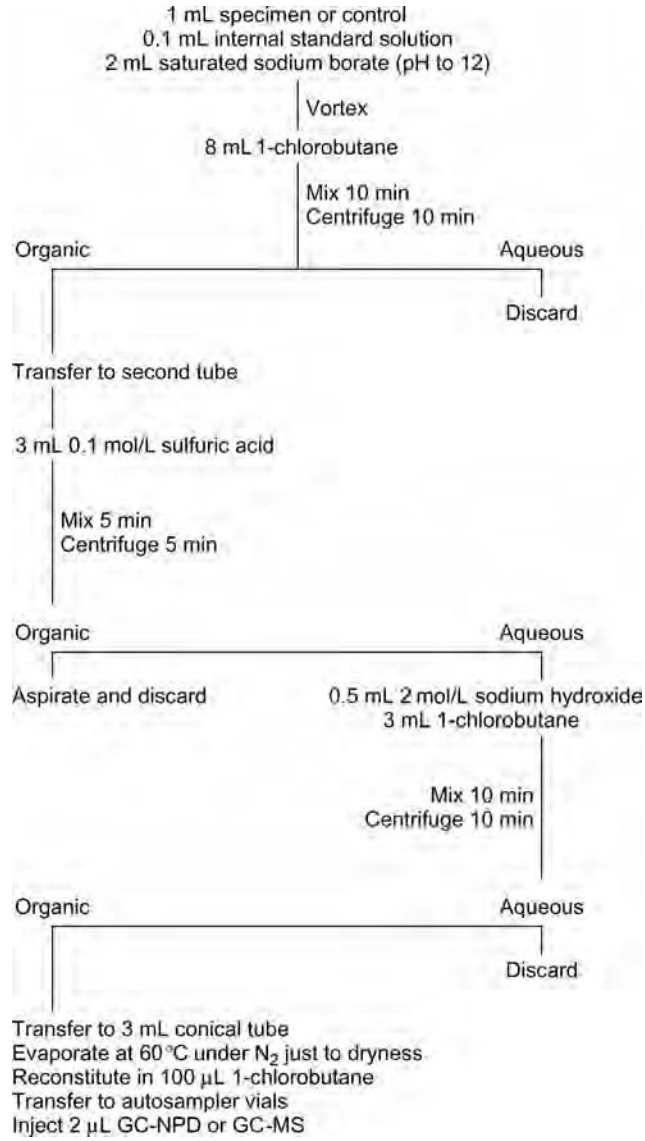

Figure 10.2 Extraction pathway for strong bases.

A suitable procedure is as follows. Macerate 10 g of liver or other tissue with 40 mL of 1 mol/L Tris; add 10 mg of subtilisin Carlsberg and incubate in a water bath at 50–60°C for about 1 h, with agitation. Filter the digest through a small plug of glass wool to remove undissolved connective tissue. Aliquots of this digest may be substituted for the specified biological fluid in most routine screening procedures. The filtered digest has a pH of 8.0–9.5.

This method is very useful for the analysis of sectioned injection marks. The superficial fatty skin layer is removed and the remaining muscle layer analysed as above. If the injection was intramuscular and of recent origin, the drug concentrations should be greater than in a similar tissue sample that does not show an injection mark. If the injection was intravenous, such a distinction cannot be expected. The method's superb ability to 'liquidise' solid tissue can be used for many purposes apart from drug analysis. The recovery of shot-gun pellets and small bomb fragments in body tissues is one such application. The preparation of solutions for direct aspiration into atomic absorption instruments for the detection of some metals has also been studied (Lock *et al.* 1981), and its use for the detection of toxic anions and some pesticides also seems feasible.

Hydrolysis of glucuronide conjugates

Drugs that form glucuronide conjugates may be hydrolysed with β-glucuronidase prior to extraction. For example, the determination

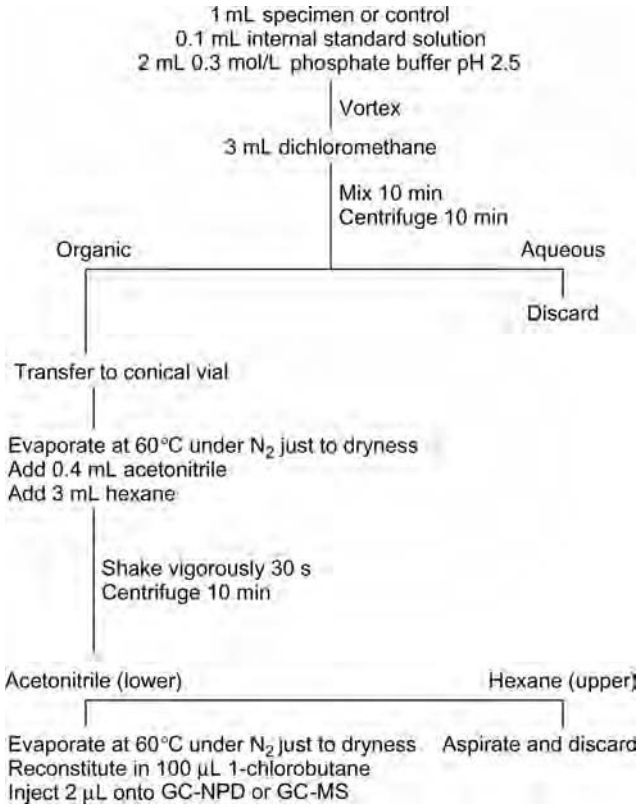

Figure 10.3 Extraction pathway for acids and neutrals.

of morphine in blood is often performed with and without the addition of β-glucuronidase to estimate the unconjugated (free) and 'total' (conjugated plus unconjugated) drug present, and therefore to aid interpretation. Other applications include enhanced detection of benzodiazepines and other drugs in blood and urine.

A typical procedure for the enzymatic hydrolysis of glucuronides is to mix 1 mL blood or urine with internal standard and 1.5 mL buffer and then to add 100 µL of β-glucuronidase obtained from *Helix pomatia*. Mix the solution and allow to incubate at 37°C overnight (~16 h). After incubation, the pH of the solution is adjusted appropriately for solvent extraction or SPE of the drugs of interest.

Acid hydrolysis may be used to cleave glucuronide conjugates; however, this method is restricted to acid-stable analytes such as morphine in urine. Acid hydrolysis of blood dramatically increases the amount of potentially interfering substances and may produce a denatured protein mass that reduces analyte recovery.

Extraction

Liquid–liquid extraction still predominates in most laboratories. The choice of an appropriate solvent is often a matter of experience or tradition. The chosen solvent should ideally extract as much of the target analyte as possible, while minimising the extraction of endogenous substances. Ideally, a solvent should extract the target analyte with an efficiency of at least 50%, and preferably much higher.

The pH of the specimen influences the extent to which acidic and basic drugs are extracted. Addition of a weakly basic buffer, such as sodium borate (pH 9), favours the extraction of weakly basic drugs, as well as most neutral substances. Similarly, the addition of an acidic buffer, such as sodium dihydrogenphosphate, favours the extraction of acidic as well as neutral drugs. The majority of drugs of forensic interest are 'basic' in character, but are often present at relatively low concentrations in blood. It is therefore desirable to have an extraction scheme that incorporates a back-extraction step to eliminate or minimise the extraction of endogenous molecules. An example extraction scheme is shown in Figure 10.2. The sodium hydroxide will force the basic drugs into the lipid-soluble unionised form, allowing extraction into the chlorobutane. The chlorobutane is transferred to a fresh tube and the drugs back extracted into sulfuric acid. Neutral or acidic substances will remain in the upper chlorobutane layer, which may be pipetted or aspirated to waste. The remaining acid layer is then made basic by addition of sodium hydroxide, and the now unionised basic drugs re-extracted with chlorobutane. The upper solvent layer may then be removed and concentrated under nitrogen, prior to analysis by a suitable chromatographic method. This extraction scheme will give extracts that are relatively free of interfering substances. However, it should be noted that morphine and other amphoteric drugs cannot be detected by this method since the phenolic functional group will ionise at high pH, therefore precluding extraction into the solvent. For amphoteric drugs, the basic phase should be less than pH 9.0, and preferably pH 8.0–8.5.

While a similar extraction scheme to that used for basic drugs (but with the additions of acid and base reversed) could be used for strongly acidic drugs, such a method does not efficiently extract weakly acidic drugs, such as the barbiturates, and neutral drugs, such as meprobamate. Conversely, simple addition of an acidic buffer to whole blood and extraction with a solvent results in the co-extraction of large amounts of endogenous lipid substances. Such extracts may be 'cleaned up' by partitioning between immiscible solvents of different polarities, such as acetonitrile and hexane, as shown in Figure 10.3. The more polar drugs tend to partition into the acetonitrile, whereas the endogenous lipids (fatty acids, sterols) tend to partition into the hexane.

SPE has been used for many years in clinical toxicology, although to a lesser extent for postmortem work. SPE usually results in better extraction efficiencies than liquid–liquid methods, especially for more polar analytes. One of the major obstacles to general acceptance in this field has been the difficult nature of postmortem specimens, which are often clotted and laden with solid material that can easily plug the fine material in SPE columns. However, improved sample preparation techniques and SPE column technology have largely overcome these problems. Use of a good internal standard, appropriate dilution of the sample and centrifugation of residual solid material usually results in a solution that does not plug the column and for which quantitative determination has not been compromised. Despite the inclusion of wash steps, the higher extraction efficiency of SPE columns compared with liquid–liquid extractions can sometimes result in dirtier extracts, although this need not be a problem if specific (e.g. MS) detection methods are used. Manufacturers of SPE columns readily provide sample extraction protocols.

Screening and detection

Postmortem toxicological analysis usually starts with a drug screen. Certainly, a drug screen can never be a single test, and most commonly is an open-ended panel of tests designed to detect the maximum number of substances of toxicological interest. This approach has often been called a search for the 'general unknown' (see Chapter 9). Careful distinction must be made between this open-ended approach and a panel or targeted approach, in which the testing protocol detects only specific substances or classes of substances (e.g. drugs of abuse). Such an approach should not be referred to as a drug screen because this misleads the reader of a report into believing that a broader range of substances has been tested for than can possibly be the case.

Targeted testing is sometimes justified where the case history strongly indicates that a specific substance is involved, particularly where that substance is not detected by the methods usually employed in the 'general unknown' approach. However, most experienced toxicologists have encountered instances in which the suspected drug was not found, with an entirely different substance detected in a clearly fatal amount. There can be several reasons for this. It may be that the person has consumed someone else's medication. Or it may be that the medications reportedly found at the scene were not those taken. In suicidal deaths, it is not uncommon for the victim or family to try to hide evidence of the overdose.

In most forensic laboratories a drug screen consists of a panel of immunoassay tests and headspace analysis for alcohol and other

volatiles, combined with one or more broad-based GC or high performance liquid chromatography (HPLC) procedures, and sometimes TLC and other techniques. The GC screening tests frequently use a nitrogen–phosphorus detector (NPD), since the vast majority of drugs contain nitrogen and therefore give a response in the detector, whereas non-nitrogenous compounds, such as fatty acids, cholesterol and other lipids, do not. Similarly, most HPLC systems use ultraviolet (UV) or diode array detectors, since the vast majority of drugs absorb light in the region between 210 and 350 nm. However, increasingly, as technology improves and prices decrease, MS is replacing NPDs and electron-capture detectors in GC and even in HPLC systems.

Forensic identification and confirmation

The forensic toxicology profession and the courts have increasingly demanded that the identification of a substance be beyond reasonable scientific doubt. The principle has long been established that forensic identification of an analyte requires the use of two techniques that employ different physical and chemical principles (SOFT/AAFS Guidelines Committee 2006). This approach has the advantage that two completely different scientific techniques are used that are supportive in arriving at a positive result. It has been argued that forensically acceptable detection and identification of an analyte can be achieved by a single extraction of a postmortem sample followed by GC-MS or LC-MS analysis of that extract. The argument is that GC-MS (or LC-MS) methods are a combination of two very different analytical methods – separation of the mixture and determination of retention time being one, and production of the mass spectrum being the other. While this approach is reasonable, it produces a forensically acceptable confirmation only if laboratory contamination and, if possible, contamination of the original specimen can be ruled out. Therefore, at a minimum, the drug should be detected using two different extracts of the same specimen. This is often accomplished incidentally, because separate extracts may be prepared for the initial drug screen and for a subsequent quantitative analysis. Even better is detection and identification of the substance in two different specimens. An example might be detection and identification in a urine specimen, followed by quantification in blood and one or more other tissues. This latter approach increases confidence in the result by ruling out a false-positive finding through contamination from glassware or, indeed, one of the specimens.

Identification of a drug by the use of two similar methods, such as two different immunoassays, is not acceptable, even though such tests may employ different endpoint reactions (e.g. fluorescence polarisation immunoassay (FPIA) and enzyme immunoassay (EIA)). The reason is that the antibodies used may have similar cross-reactivities, even though the designs of the immunoassays as a whole differ. Similarly, identification of a substance on the basis of different retention times (or different relative retention) on two different GC columns is rarely acceptable unless it can be shown clearly that the columns differ markedly in their retention and discrimination characteristics.

A caveat to this approach is simultaneous detection and quantification of ethanol and other specific analytes, such as carbon monoxide. Although the use of two independent methods may be used to identify ethanol, it is still generally accepted that a single GC method is forensically acceptable. Analysis of alcohol using two different non-correlating column-packing materials and internal standards provides much greater confidence. The quality of GC methods used in most laboratories and the fact that few other compounds are likely to be present at such a high concentration mean that erroneous identification of ethanol is unlikely. The few other compounds include methanol, isopropanol and acetone, for which separation from ethanol in the analytical system must be demonstrated. Similar arguments can be made for carbon monoxide, especially when the history clearly indicates that carbon monoxide poisoning is likely. However, in rare circumstances grossly elevated carbon monoxide concentrations may be detected where there is not an obvious source of the toxin. In such instances, confirmation by an independent technique is highly desirable (e.g. headspace GC or palladium chloride via a Conway diffusion cell).

Specific analytical techniques

The principal analytical techniques used to screen, confirm and quantify drugs that have been isolated from tissues include immunoassay, GC, HPLC, TLC and MS. All of these are described in detail in other chapters of this book and the reader is recommended to refer to these chapters as appropriate.

Quantification of drugs and other toxins

The vast majority of drugs, metabolites and other toxins are quantified by GC or HPLC, increasingly in combination with MS detection. Simple GC or HPLC detection is usually based on the total peak area produced by the detector (e.g. NPD, flame ionisation detection (FID), UV). MS quantification, while it can be based on the total ion signal, is more usually based on the peak area for specific ion fragments – called selected-ion monitoring (SIM). By its nature, SIM GC-MS quantification is considerably more specific and often more sensitive than use of the more traditional GC or HPLC detection. This is of particular importance in postmortem work, in which endogenous lipids and putrefactive products can produce significant interference. Increasingly, LC-MS and especially LC-MS(-MS) methods are being used for the quantification of drugs and metabolites in postmortem specimens. LC-MS(-MS) methods in particular can be highly specific and produce very clean chromatograms. The quantification of benzodiazepines creates many problems for some laboratories because of large differences in the blood concentrations and the thermal instability of some drugs and metabolites. Use of LC-MS (MS) allows all benzodiazepines and the major metabolites to be confirmed and quantified in a single run (Smink *et al.* 2004; Marin *et al.* 2008).

Other than detection techniques, there are two other major considerations in quantitative postmortem work. The first is the reproducibility and robustness of the extraction procedure. The second is the choice of an appropriate calibration method. Use of an appropriate assay design and sound extraction and calibration methods can minimise the effect of the matrix, especially if the calibrators are prepared in a similar matrix to that being analysed.

Calibration methods

Choice of an appropriate calibration method is critical to obtaining reliable results. Single-point calibrations are generally unacceptable for postmortem toxicology, unless it can be shown that the calibration is stable and linear over the desired range, and that appropriate controls are used to validate the calibrations when specimens are being analysed. Multipoint calibrations are preferred, unless the calibration is known to be very stable and linear (e.g. GC-FID headspace ethanol analysis). A minimum of three calibration points is usually recommended, although five or more are preferred, depending on the linearity and precision of the method. An appropriate internal standard is considered almost essential for all GC- or HPLC-based methods to help minimise matrix effects and also to correct for other variables, such as slight differences in transfer volumes when using liquid–liquid extraction or SPE. An internal standard should ideally be similar in chemical structure to the target analyte (e.g. an alkyl analogue). Use of stable isotope analogues (e.g. deuterated analogues) is becoming quite common, where available. A good internal standard can provide much greater accuracy and precision than would be possible otherwise with difficult postmortem specimens. Quantitative results are only acceptable if the analyte concentration lies within the validated calibration range. If the concentration lies outside that range, it may be reported as either greater than or less than the calibration range, as appropriate, or additional calibrators or controls could be run to validate the calibration in that range. Standard curves should not be extrapolated and, if an accurate result is required when the initial quantification lies outside the scope of the standard curve, the specimen should be diluted and re-analysed.

Ideally, an assay calibration should be linear and produce a good correlation coefficient (e.g. better than 0.98). Not infrequently the calibration line will be non-linear and may require a quadratic fit.

Some GC or HPLC assays are inherently non-linear. For example, at very high or low concentrations, ions common to both the analyte and internal standards may cause a deviation from linearity. A large deviation from linearity usually indicates the use of an inappropriate internal standard, poor chromatography or poor analyte recovery during the extraction, or that the dynamic range of the detector has been exceeded.

The method of standard addition can be useful in quantitative postmortem analysis. In essence, the specimen being analysed is used as the matrix to prepare calibrators. Multiple calibrators are prepared by adding known amounts of the analyte to tubes that contain the target specimen. An internal standard should be used; if possible, these should be deuterated analogues in MS techniques. The analyte : internal standard ratio for the sample can be read off the *y*-axis and the concentration of the analyte calculated. This method can be used with some success for difficult matrices. The concentrations of the spiked calibrators should not be too high above the anticipated concentration of the analyte since linearity of the procedure cannot be guaranteed much below the concentration of the lowest calibrator. Ideally, another person in the laboratory should also independently prepare a control (in the same sample matrix).

Method validation

It is almost universally accepted that any method used in forensic work must undergo some type of validation (see Chapter 20). However, there is considerable disagreement as to the extent of validation required. Perhaps, arguably, the extent of validation depends on the specificity and sophistication of the assay, whether the assay is in routine use and the potential consequences of producing an inaccurate result. For example, the legal consequences of a quantitative error in measuring an endogenous analyte, such as adrenaline (epinephrine), in a homicide case are obviously more serious than for, say, strychnine, which ordinarily should not be present in any amount. Similarly, to report an amfetamine analogue as present instead of a decongestant such as pseudoephedrine can have serious consequences.

Qualitative methods, such as immunoassay, should be validated for specificity and limit of detection (LOD). It is accepted that most immunoassays cross-react to some extent with analytes other than those targeted, and it is important to know the extent of that cross-reactivity, particularly for structurally related compounds. LOD is important because a class assay (e.g. opiates, amfetamines) may be far less sensitive for some drugs than for others, which allows the possibility of a false negative. Where an assay is used to analyse matrices other than those for which it was designed, appropriate validation should be performed. For GC-based and other chromatographic drug screens, it is not usually practical to determine the LOD for every analyte expected to be detected, but the LOD for representative examples can be determined. If the laboratory is asked to determine whether a particular drug is present in a specimen, the laboratory should have some idea what the sensitivity of the assay is, and that it can at least detect potentially toxic concentrations.

A quantitative assay should be validated for accuracy, precision, linearity and LOD. However, it can be argued that some assays are, by their design, self-validating. For example, if a GC-MS-SIM assay uses a good internal standard, numerous (e.g. six) matrix-matched calibrators, at least one independently prepared matrix-matched control and appropriate acceptance criteria for the calibrators, the calibration as a whole and to the control, the assay could be described as self-validating. If the assay was not accurate, the control result would be out of range. If the assay has poor precision, one or more of the calibrators would not read within an acceptable percentage when read against the calibration. Specificity can be demonstrated by the appropriate choice of ion ratio qualifiers and lack of chromatographic interference with those ion chromatograms. For some analytes, determination of LOD or limit of quantification (LOQ) is irrelevant if a cut-off is used, or where the analyte concentration is accepted only if within the valid calibration range. Demonstration of that cut-off may be satisfied if it represents the value of the lowest calibrator or control.

Quality control and quality assurance

Quality assurance (QA) deals with all aspects of laboratory practice that might influence the accuracy of the final analytical result, and is dealt with elsewhere (see Chapter 22). Quality control (QC) refers to the inclusion of material spiked with a known amount of a target analyte. The independently prepared material should be included in an assay to verify that the calibration is accurate within acceptable, defined limits. However, while the routine inclusion of proper QC material should be considered essential, the practice has not been adopted widely in postmortem toxicology testing. With the exception of some very common analytes, such as ethanol and a few therapeutic drugs, control material has not been available commercially; when it is available, it is only by custom order, tends to be relatively expensive and is often available only in serum or plasma rather than whole blood. Although time-consuming, spiking analytes into drug-free whole blood with storage at $-40^{\circ}C$ is an acceptable practice. Ideally, if the control material is prepared in-house, it should be prepared by a person other than the one running the assay, and from different stock material or at the very least from a different weighing of the same powdered stock material. It is not acceptable for an analyst to spike calibrators and then spike the same solution into separate tubes and call these the controls. Any errors made in the preparation of the standard solution or in spiking calculations would not be uncovered using this approach. It is important for quantitative work that acceptance criteria for controls be set and that they be realistic – neither too loose nor unrealistically strict. Failure to meet these criteria should invariably result in corrective action and, as necessary, repeat of the assay. Generally, controls for drugs and other toxins should read within 20% of their nominal value. For some analytes, such as ethanol, criteria such as $\pm 10\%$ or tighter are more appropriate. If a control is targeted close to the LOQ for the assay, $\pm 30\%$ may be acceptable for drugs and other toxins.

Participation in at least one suitable proficiency-test programme is another vital component of a good-quality assurance programme and goes a long way to demonstrating competence, as is the accreditation of a laboratory; these inevitably enhance the quality of postmortem toxicology analyses.

Unusual specimen matrices

One of the unique aspects of postmortem toxicology work is that often specimens are received in various states of decomposition or putrefaction. Specimens may be denatured by heat, or mummified. All of these sample types create problems. Samples that are heat denatured are probably the easiest to deal with because the lipid content and concentrations of any putrefactive amines are not much higher than those in relatively fresh postmortem specimens. Heat-denatured samples usually require homogenisation, and for accurate quantitative work may require some type of protease treatment, since a proportion of the analyte may be occluded by coagulated protein. Decomposed and mummified tissues probably create the biggest challenge, because the presence of high concentrations of lipids and putrefactive amines may obscure or interfere with the detection or accurate quantification of target analytes. Even if there is no obvious interference using a specific MS method, there may be a sufficient matrix effect to influence quantitative measurement adversely. Overcoming the effects of specimen decomposition is very difficult and often has limited success. Finding a matrix-matched sample to act as a blank for the preparation of calibrators or controls is difficult, because samples vary tremendously in the nature or extent of decomposition. The quantitative determination of analytes in decomposed or other deteriorated samples is invariably less accurate than that in fresher samples. Robust, well-validated methods inevitably produce more reliable results than those that are not.

Other matrices, such as bone, nails and hair, have been analysed successfully for a variety of substances (Drummer 2008; Garside 2008; Kintz 2008). As with any other matrix, the appropriate use of internal standards (at least for chromatographic assays) and calibrators is important. The more difficult issue may be interpretation of the quantitative results. More detailed discussion concerning oral fluid and hair are given in Chapters 18 and 19.

Limited specimen volume

For a variety of reasons, the volume of postmortem material available for analysis may be very limited. The problem faced by the toxicologist is how to make the best use of that material. With the widespread use of sensitive MS techniques, or even other GC and LC detection methods, it should seldom be necessary to base a single assay on more than 1 mL of specimen. However, even if the volume of specimen used per sample used per test does not exceed 1 mL, the total amount of specimen available for a case may not permit the usual range of tests, or allow the normal level of sensitivity. Therefore, when such results are reported, it is important to reflect any such shortcomings in the final report, such as a higher LOD, or the inability to perform certain screening tests that otherwise might imply a false-negative result.

Interpretation of postmortem toxicology results

When attempting to interpret drug concentrations, forensic toxicologists traditionally have placed a great deal of faith in the assumption that the postmortem concentration of the substance at least approximates that present at the moment of death. Over the years, we have learned that such faith is often misplaced. Even for ethanol, we continue to learn more about its kinetics and disposition during life and changes that occur after death. A thorough understanding of what happens to drugs in the body after death is still lacking, and even for living patients there is a poor correlation between blood concentration and effects. So-called 'therapeutic ranges' have been established for only a relatively small number of drugs, and patient-to-patient variability can be considerable even for these. Some patients exhibit unacceptable side-effects with drug plasma concentrations well within the therapeutic range, whereas plasma concentrations above the therapeutic range are necessary to obtain the desired control with minimal side-effects in others. The problems of interpretation are even greater with postmortem specimens.

Ethanol

Although ethanol is a common and relatively well-understood intoxicant, interpretation of postmortem results can be complex. Ethanol can be formed by postmortem fermentation, degraded by bacterial action and redistributed within the body through trauma and other processes.

The postmortem formation of ethanol in the blood, urine and tissues has been well described (Corry 1978). Under appropriate conditions, ethanol can be formed in concentrations up to, and exceeding, those set as the statutory limit for driving a motor vehicle in many countries (e.g. 50–100 mg/100 mL blood). What is poorly understood is that concentrations as high as 200–400 mg/100 mL can be formed in exceptional circumstances (Harper, Corry 1988). Conversely, ethanol can also serve as a substrate for many microorganisms such that ethanol concentrations in blood and tissues may initially increase and later decrease. There is no known correlation between the degree of putrefaction of a specimen and the production of postmortem ethanol. Many severely decomposed specimens may contain no ethanol at all, whereas others that appear less severely decomposed may contain concentrations of 80 mg/100 mL or higher.

Other factors can also cause ethanol to be present in postmortem blood as an artefact. It has been demonstrated that, when the stomach contains a sufficiently large amount of ethanol, the ethanol may diffuse through the stomach wall and diaphragm and eventually enter into the heart and central blood vessels (Backer *et al.* 1980; Pounder, Smith 1995; Iwasaki *et al.* 1998). Severe trauma, sufficient to rupture the stomach and diaphragm, may allow gastric contents to pass into the chest cavity. In such cases it may be difficult to obtain blood from the usual peripheral vessels. The presence of a small amount of beer or wine, such as might be left after a single drink with lunch, could produce an enormously elevated, but artefactual, chest blood ethanol concentration. Another mechanism by which blood alcohol may be elevated is the agonal, or postmortem, movement of gastric contents into the trachea and lungs (Pounder, Yonemitsu 1991). This can lead to elevated blood ethanol concentrations in the major central pulmonary and cardiac vessels and subsequently to erroneous interpretation.

For these reasons, analysis of a second alternative specimen in postmortem cases is recommended. Vitreous humour is the specimen of choice because it remains sterile for a period of days after death and therefore postmortem fermentation does not take place. Only in the case of very severe putrefaction, in which the eye dries out and little fluid is available, is a slight increase in ethanol concentration seen, but the extent of this effect is rarely, if ever, above 20 mg/100 mL (Zumwalt *et al.* 1982; Gilliland, Bost 1993). Although an equilibrium between ethanol in the vitreous humour and that in blood is attained quickly, there may be a lag period during absorption when the vitreous ethanol concentration is slightly lower than that in the blood (Fernandez *et al.* 1989). After equilibrium has been attained, the concentration of ethanol in vitreous humour is about 1.15 times higher than that in blood (Garriott 2008). This is because ethanol is distributed in the body according to water content and, while vitreous humour contains more than 98% water, whole blood contains on average approximately 85–88% water. Cerebrospinal fluid may be similarly useful, but is more difficult to collect and therefore is less often available for analysis than vitreous humour.

Urine is also a useful fluid for the corroboration of ethanol concentrations in blood. Although concentrations of ethanol in urine average about 1.3 times those in blood, there is considerable variability. Urine is a waste fluid stored in the bladder and, once formed, is largely unaffected by the circulating blood ethanol concentration, unlike ethanol in vitreous humour, which is in equilibrium with the circulating blood. Ethanol can be present in urine and not in blood if sufficient time has elapsed between its consumption and death to allow for clearance from the blood into the bladder. Ethanol can also be detected in urine (sometimes at high concentrations) but not in blood if the donor is a poorly controlled diabetic and if high concentrations of glucose are present. The coexistence of a urinary tract infection (yeast or bacterial) can allow considerable *in vitro* postmortem fermentation to occur in the bladder (Alexander *et al.* 1988; Saady *et al.* 1993). It is virtually impossible to have significant concentrations of ethanol in blood, but not in the urine, except as an artefact caused by postmortem fermentation or contamination.

Other postmortem specimens are less useful for ethanol measurement. Bile ethanol concentrations are roughly comparable to those in blood for uncontaminated specimens (Winek *et al.* 1983). However, because of the proximity of the gallbladder to the stomach and liver, bile is of little value where postmortem fermentation or postmortem diffusion is of concern. Similarly, liver and other tissues can undergo postmortem fermentation when bacteria are present. In relatively fresh postmortem tissue, concentrations of ethanol are approximately 50–85% of the corresponding blood concentrations, because of the lower water content of solid tissues. The average liver : blood ratio for alcohol is approximately 0.6 (Jenkins *et al.* 1995).

Other alcohols and volatiles

The presence of volatiles other than alcohol in postmortem specimens generally, but not always, indicates exposure to, or ingestion of, such compounds. An example is acetone, which can be present in poorly controlled diabetics at concentrations up to, and sometimes exceeding, 80 mg/100 mL. Acetone is also sometimes present at lower concentrations (e.g. below 10 mg/100 mL) in chronic alcoholics, malnourished individuals and those who suffer from severe stress. Isopropanol can also be present in trace amounts, and is probably formed as a postmortem artefact from acetone (Davis *et al.* 1984). The presence of both isopropanol and acetone can also result from solvent ingestion (acetone is the major metabolite of isopropanol).

In more northerly climates, methanol is readily available and accidental or suicidal methanol poisonings are common, but methanol can also be present as an artefact of postmortem change. Methanol is a major ingredient in many embalming fluids, and therefore is present in most embalmed bodies. Some forensic examinations take place in funeral homes, especially in rural areas, and blood or other fluids collected may be contaminated inadvertently with embalming fluid. Less obvious is contamination of motor vehicle accident victims with methanol contained in windshield washer fluid, in which concentrations can be 30%

or higher. Blood collected from any site other than from an intact blood vessel has the potential for contamination. It is even possible for the vitreous fluid to be contaminated after the eye has been splashed with windshield washer fluid (Jones *et al.* 2007).

Drugs and other toxins

The interpretation of the concentrations of drugs in postmortem blood and tissue specimens is complicated because many drugs are unstable *in vivo* and *in vitro*. Interpretation may also be affected by tolerance, inter-individual variation in pharmacological response, drug interactions, the presence or absence of natural disease, and the circumstances under which death occurred. For example, cocaine is hydrolysed readily before and after death. It is thought that serum cholinesterase is responsible for the hydrolysis of cocaine to ecgonine methyl ester, while the formation of benzoylecgonine may arise from spontaneous non-enzymatic hydrolysis (Isenschmid *et al.* 1989). Interpretation must therefore depend not only on the concentration of cocaine measured but also that benzoylecgonine and ecgonine methyl ester. Even when postmortem blood is collected into a tube that contains sodium fluoride (to retard *in vitro* hydrolysis of the cocaine), the degree of hydrolysis that occurs *post mortem* compared with that prior to death is almost impossible to determine. In other words, if relatively high concentrations of cocaine metabolites are detected, it can be difficult to determine whether they resulted from an acute overdose of cocaine or from chronic heavy consumption (bingeing) over a period of several hours or even days. Even if that question could be answered, it is known that cocaine can cause serious and even fatal cardiac arrhythmias at high concentrations, but it is also known that regular cocaine users can snort or inject large doses of cocaine without apparent, serious, short-term toxicity. Some individuals can develop excited delirium syndrome and die after relatively small doses of cocaine (Wetli, Fishbain 1985; Pollanen *et al.* 1998).

Some benzodiazepines (e.g. flunitrazepam, nitrazepam and clonazepam) are known to be unstable *in vitro* and back calculation of the perimortem concentration is not practical (Robertson, Drummer 1995, 1998). Many other drugs are known to have poor stability in postmortem blood (e.g. chlordiazepoxide, phenelzine, olanzapine, zopiclone). Morphine glucuronide may be converted back into unconjugated morphine in postmortem blood in circumstances in which sufficient bacterial contamination is present to release glucuronidase (Carroll *et al.* 2000). The extent to which glucuronide metabolites can be formed is poorly understood for most drugs. For example, while it is well known that morphine readily undergoes glucuronidation, it is much less well known that codeine also forms a glucuronide metabolite that can be found abundantly in both blood and urine (Wang *et al.* 2006). While glucuronide formation is thought to occur primarily on functional groups that have active hydrogens (e.g. phenols, alcohols), extensive glucuronide formation of tertiary amines such as amitriptyline is rarely appreciated (Breyer-Pfaff 2004).

One of the most important factors to affect the interpretation of postmortem drug concentrations is the phenomenon of postmortem redistribution. The term 'postmortem redistribution' has been used to describe the movement of drugs within the body after death with the result that the blood concentration of a drug is significantly higher at autopsy than that immediately after death. Postmortem redistribution is a complex phenomenon, and probably involves at least three mechanisms to a greater or lesser degree. The first, and probably major, contributor in most cases is the release and diffusion of the drug after death from tissues or organs that contain high concentrations (usually the lungs and liver) into nearby cardiac and pulmonary blood vessels. This mechanism has been clearly identified for several drugs, including amitriptyline, for which the concentration in the liver and lungs may be 20–100 times that in the blood. The exact mechanism at a molecular level has not been identified, but it is known that changes in pH and protein structure occur after death, and thereby disrupt the protein-binding characteristics of drugs. Therefore, drugs such as the tricyclic antidepressants, which concentrate in the major organs through binding to protein and other molecules, are more likely to undergo redistribution by diffusion along nearby blood vessels. It is worth noting that, although toxicologists have referred to postmortem redistribution from the heart, the bulk of the redistribution occurs from the lungs and liver (Hilberg *et al.* 1994). In contrast to the tricyclic antidepressants, the benzodiazepines undergo very little postmortem redistribution because they are not highly concentrated in the major organs relative to blood. In one case study in which blood was collected from 10 separate ligated venous and arterial sites, the marked site dependence in the concentrations of

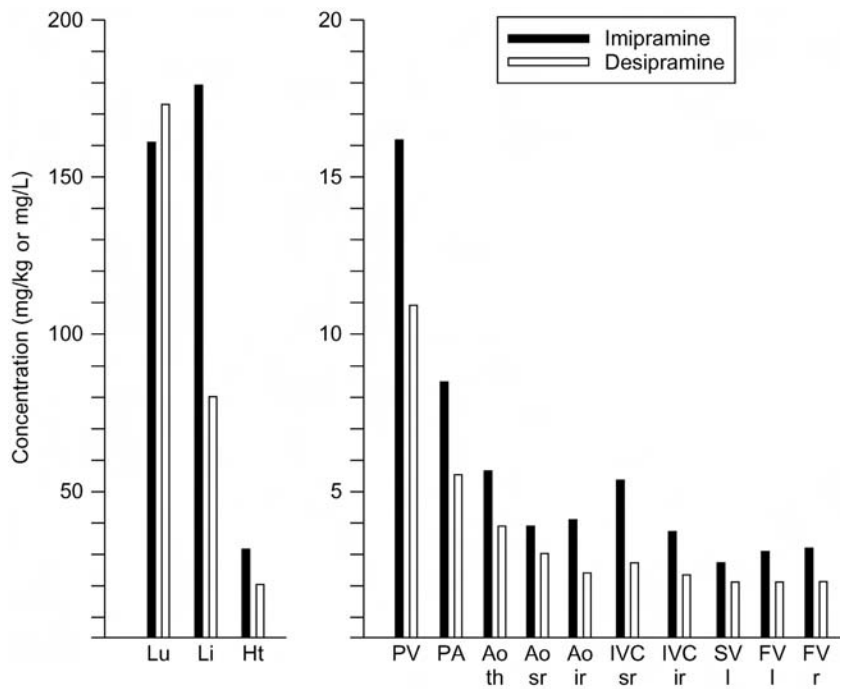

Figure 10.4 Comparison of concentrations of imipramine and the metabolite desipramine in several specimens from the same case. Lu, lung tissue; Li, liver tissue; Ht, heart tissue; PV, pulmonary vein blood; PA, pulmonary artery blood; Ao th, thoracic aorta blood; Ao sr, suprarenal aorta blood; Ao ir, infrarenal aorta blood; IVC sr, suprarenal inferior vena cava blood; IVC ir, infrarenal vena cava blood; SV l, left subclavian vein blood; FV l, left femoral vein blood; FV r, right femoral vein blood. Based on data from Jones and Pounder (1987).

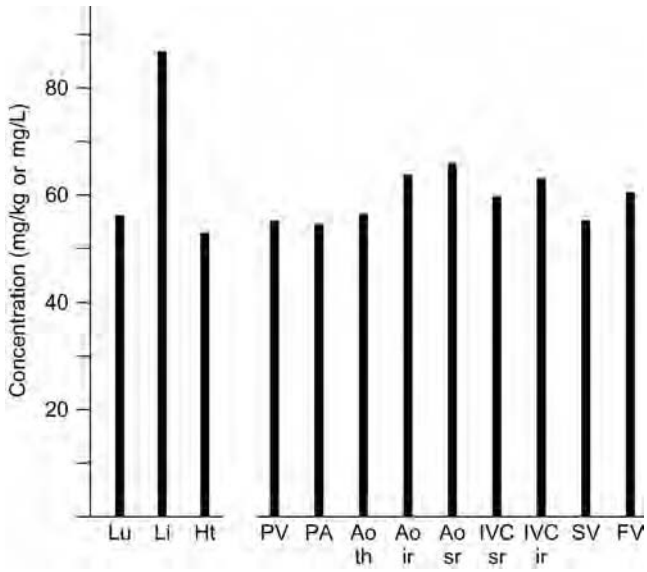

Figure 10.5 Comparison of concentrations of paracetamol in several specimens from the same case. Lu, lung tissue; Li, liver tissue; Ht, heart tissue; PV, pulmonary vein blood; PA, pulmonary artery blood; Ao th, thoracic aorta blood; Ao sr, suprarenal aorta blood; Ao ir, infrarenal aorta blood; IVC sr, suprarenal inferior vena cava blood; IVC ir, infrarenal vena cava blood; SV, subclavian vein blood; FV, femoral vein blood. Based on data from Jones and Pounder (1987).

some drugs, but not others, was demonstrated clearly (Jones, Pounder 1987). Figure 10.4 shows the marked site dependence of imipramine and desipramine in the case study, and Figure 10.5 shows the relative lack of site dependence of paracetamol in the same case.

The second mechanism is simple diffusion after death from a drug depot such as the gastric contents. This is unrelated to release from the major organs because of changes in protein binding. At least two, and possibly three, situations have been identified where this can occur: diffusion or traumatic release from the stomach, agonal aspiration of the stomach contents into the lungs and continued release from a drug-delivery system. If a drug is present in sufficient concentration in the stomach, diffusion through the stomach wall can occur. Such diffusion can potentially elevate concentrations of drugs in the abdominal blood vessels, such as the abdominal aorta and iliac vein, as well as in tissues such as the liver and kidney (Parker *et al.* 1971; Pounder *et al.* 1996a, 1996b). The extent of postmortem diffusion is directly related to both the concentration and the total amount of drug in the stomach. Rupture of the stomach in a traumatic accident or suicide can cause artificially elevated drug concentrations by allowing gastric contents to spill into the chest cavity. Under such circumstances even the residue of a single therapeutic dose could produce an erroneous chest blood concentration equivalent to 10–100 times that expected after therapeutic doses. In many jurisdictions a postmortem examination is not performed if the cause of death is obvious, and a less-experienced coroner or medical examiner might attempt to draw blood from the heart by a blind stick through the chest wall (Logan, Lindholm 1996). Agonal or postmortem movement of the gastric contents into the trachea and lungs can occur after vomiting at the time of death, or as a consequence of handling of the body after death. Marked increases in the concentration of ethanol and drugs can occur through this mechanism, especially into the pulmonary and aortic blood (Pounder, Yonemitsu 1991). In the third situation, markedly increased blood concentrations can occur with at least two different drug delivery devices. Transdermal patches left on a body after death give rise to locally high concentrations of the drug (e.g. fentanyl, nicotine). Transdermal devices rely on passive diffusion across a rate-limiting membrane for drug delivery and therefore, if not removed, concentration of the medication in the local area of the patch continues to rise after death, albeit at a slower rate. As there is no blood circulation through the skin after death, the drug is no longer transported away (except by diffusion), which results in a local accumulation of the drug. The concentration gradient between the drug-containing medium (e.g. gel, adhesive) that contains the medication in the patch and the skin is so high that even modest postmortem diffusion can raise postmortem tissue and blood concentrations up to several centimetres away from the patch. The magnitude of such effects depend on the proximity of the patch to the site from which blood was drawn and the postmortem interval. Perhaps more obvious is the situation in which someone dies while receiving analgesics or other medication from an intravenous delivery device (e.g. syringe driver). Intravenous solutions may continue to be pumped into the patient after death, and potentially cause a large local increase in blood concentration (Jenkins *et al.* 1999). While most of these devices are external and readily switched off, some are internal and not obvious until the autopsy is conducted.

The third mechanism is incomplete distribution at the time of death. Even for drugs for which little or no redistribution is thought to occur, marked site-to-site differences in blood drug concentration can occur following an overdose. Since clinical pharmacokinetic studies have shown that a significant arterial–venous difference in concentrations can occur after therapeutic doses, it is reasonable to conclude that even larger differences are likely after massive oral or even intravenous overdoses. In the case of an oral overdose, localised high concentrations are likely in the portal vein, inferior vena cava, and right heart and pulmonary vessels. The existence of this phenomenon has been suggested as an explanation for site-to-site differences in unconjugated blood morphine concentrations in diamorphine-related deaths, even though morphine was shown by the same work not to undergo redistribution as such (Logan, Smirnow 1996). It is therefore important to bear in mind that demonstrating site-to-site differences in the blood concentrations of a particular drug does not necessarily prove that the drug undergoes postmortem redistribution. The distinction is an important one. By the nature of postmortem redistribution and postmortem diffusion, increases in blood concentration are time dependent. However, simply to demonstrate that blood samples from two different sites in the body contain different concentrations of a particular drug does not prove that redistribution is likely to occur for that drug in all circumstances. The reader is also referred to more detailed reviews of the possible mechanisms of postmortem redistribution (Pelissier-Alicot *et al.* 2003; Yarema, Becker 2005).

Blood and/or plasma distribution

One issue that is often overlooked in comparing postmortem data with that from living patients is that most postmortem laboratories analyse whole blood, whereas clinical laboratories invariably analyse serum or plasma. Many drugs are not evenly distributed between plasma and erythrocytes, and therefore concentrations may be misrepresented by a factor of up to 2 or more. For example, digitoxin is primarily distributed into plasma, with virtually none in the red cells, with a blood : plasma ratio of 0.5, whereas digoxin has a blood : plasma ratio of close to 1.0 (Abshagen *et al.* 1971; Lukas, Peterson 1966). Similarly, Δ^9-tetrahydrocannabinol (THC) has a blood : plasma ratio approaching 0.5, which indicates that most of the drug is distributed in the plasma, with little in the erythrocytes (Mason, McBay 1985). The significance of this is again that most postmortem measurements are conducted on whole blood, whereas much of the pharmacokinetic data are based on plasma measurement. Although the blood : plasma distribution is not likely to have as big an influence on interpretation as postmortem redistribution for some drugs, it is a factor that should not be overlooked, particularly if the analytical results are being compared with those obtained from plasma and/or serum specimens.

Blood and/or tissue distribution

Liver and brain have been used extensively for the postmortem measurement of drugs. Initially, tissues were used because many drugs are present at concentrations up to 10–50 times that in blood, and because tissues provided a large volume of material for extraction and analysis. This was essential in the days when physical isolation of the poison, crystallisation and pharmacological testing were a goal. As analytical methods improved, analyses for most drugs could be performed on blood, leading to a trend in the analysis of blood alone. However, with

the recognition that redistribution and related phenomena could seriously decrease confidence in postmortem blood drug concentrations, analysis of tissues is regaining importance. While concentrations of some drugs can increase by as much as 2- to 10-fold after death in postmortem blood, concentrations in tissues such as liver remain relatively stable. The problem lies with the interpretation of tissue drug concentrations. Unlike in blood, reference ranges for drugs in tissues are not obtainable from clinical studies, and animal data are not directly transferable to humans. Forensic toxicologists have to rely on empirical data from other cases in their own laboratories, or on published material. To be useful, the postmortem data must include cases in which drugs are likely to have been taken in therapeutic doses, not just overdose cases.

The question can be posed., 'How do you convert a tissue concentration into a blood concentration?' You do not. Organs are anatomically distinct entities with different kinetics from blood. Although it is generally true that very high blood concentrations tend to be associated with high tissue concentrations and that a useful relationship can be demonstrated, there is too much variation to attempt mathematical conversion for any single case. Although virtually no studies have examined the dose–time–concentration relationship in tissues, and certainly none in humans, some studies have demonstrated marked variation in drug concentrations within an organ, such as the liver and the brain. This further demonstrates why caution must be exercised in attempting to convert tissue concentrations into an equivalent blood concentration. A tissue concentration provides an additional piece of the puzzle. Multiple tissue concentrations provide additional pieces, and help to build a picture of the body burden of the drug in a qualitative sense. This information, together with blood concentrations, information from the autopsy and the circumstances of death, can help formulate informed conclusions about the role of the drugs (if any) in a death.

Pharmacokinetics

Postmortem toxicologists tend to interpret drug concentrations simply in terms of 'What role, if any, did these substances play in the death of this person?'. While this question is important, lawyers, judges and the public frequently ask 'How many tablets did the person take and when did they take them?' The non-scientist readily understands the concept of 'dose' (the number of tablets a person took, compared with the prescribed dose). However, the concept of 'blood concentration' and its relationship (or lack thereof) with time and dose is more difficult to understand. Pharmacokinetics is, in theory, a scientific tool that could bridge the link between the concentration of a drug in the blood and dosage. However, pharmacokinetics can be misapplied in postmortem cases.

Pharmacokinetics is an invaluable tool to help understand the time course of drugs in the body. In the living, it can be used to determine duration of action, inter-individual differences in peak plasma concentrations and clearance, and the likely effectiveness of different pharmaceutical formulations. However, rarely can pharmacokinetics be applied successfully to postmortem toxicology. When clinical pharmacokinetic studies are performed, the dose and time of dose are controlled, and often multiple plasma samples are collected to determine the pharmacokinetic parameters for a drug. For living persons, determining the dose from a single plasma or blood concentration is fraught with uncertainty. The problem is even more complex for postmortem cases. The most common equation applied is:

$$\text{Dose (g)} = C\,(\text{g/L}) \times \text{body mass (kg)} \times V_d\,(\text{L/kg})$$

where C is the concentration of drug in plasma or blood and V_d is the volume of distribution. For postmortem cases, only the body mass of the deceased can be ascertained with certainty. The V_d for any given drug typically varies over a range of at least two fold in the general population, and frequently more. Theoretically, the concentration of a drug can be determined with reasonable accuracy in the blood sampled. In postmortem cases, there is always uncertainty whether the concentration of drug in the sample was the same, or similar, at the time of death. Furthermore, the use of calculations that involve V_d assumes that absorption of the drug is complete and the drug is in equilibrium throughout the body. In postmortem cases this assumption may be invalid, especially when dealing with acute intoxications or overdoses. As a result, dose calculations may overestimate a dose by as much as 10-fold or more.

Forensic toxicologists have occasionally used analysis of multiple tissue samples from various organs in the body in attempt to overcome the errors inherent in the use of V_d calculations. The approach requires quantitative analysis of tissue from multiple organs and sites to estimate the total body burden of a drug – that is, the total amount in the body. At the very least, the major organs such as liver, lungs and brain must be analysed, in addition to skeletal muscle and adipose tissue. Masses measured at autopsy can be used to calculate the total drug in the organs sampled. However, the masses of skeletal muscle and adipose tissue can be estimated realistically only from historical data (Butler 1971; Diem, Lentner 1971) and may poorly reflect the actual tissue masses in the victim. As previously discussed, the concentration of a drug in the piece of organ or other tissue measured may or may not reflect the average for all of that organ or tissue. Another often overlooked factor is that, after chronic dosing, steady-state levels for some drugs, especially those with a large V_d and long half-life, may be several-fold higher after chronic therapeutic dosing than after a single dose. To summarise, therefore, pharmacokinetic calculations should be attempted with extreme caution, if at all, and any assumptions made should be stated clearly. In most instances, pharmacokinetic calculations using postmortem blood measurements are rarely defensible forensically.

Metabolism and pharmacogenetics

Although the primary pathways of drug metabolism have been understood for at least 20–25 years, the extent and mechanisms of drug interactions and pharmacogenetic influences on blood concentrations have really been elucidated only in the past few years. A detailed discussion of pharmacogenetics and drug metabolism is beyond the scope of this chapter; however, some aspects should be highlighted. It is known that 7–8% of the white population is deficient in cytochrome P450 2D6 (CYP2D6), one of the major enzymes responsible for many important oxidative pathways, such as alkyl hydroxylation. That deficiency is determined genetically. As a result, the ability of those affected to metabolise and clear many drugs may be affected seriously. In many instances, even though drug clearance is significantly slower than for those not deficient in CYP2D6, it is not as slow as might be predicted because other pathways may compensate. Even if a person is not specifically identified as being deficient in CYP2D6, the person or physician may be indirectly aware of it because of an unusual sensitivity to some drugs and the higher prevalence of side-effects. Even in people without deficiencies in drug-metabolising enzymes, drug–drug interactions can result in dangerously elevated concentrations. It has also been recognised that many drugs can inhibit their own metabolism by saturating the primary metabolising enzyme systems. For example, the dose–plasma concentration curve for phenytoin can rise almost exponentially at high therapeutic doses. These variabilities in the relationship between dose and plasma or blood concentration can therefore introduce even more error into any attempt to apply conventional pharmacokinetics to estimate dosage (Richens 1979).

There is a great temptation to categorise blood levels in black-and-white terms as being the result of therapeutic doses, or of a suicidal overdose, or perhaps of abuse. Other possibilities are sometimes overlooked when high concentrations of drugs are encountered. One of the simplest ways to determine compliance with prescribed dosage, although not foolproof, is to conduct a medication count. Knowing when the medication was prescribed, how much was dispensed, the dose and the number of days between dispensing and death can often provide a powerful indicator of patient compliance, and whether an overdose is likely or not. Information regarding compliance over a longer period may often be obtained by a review of the pharmacy or medical records.

The slowing of drug metabolism with age has been well documented, but this can be overlooked as an explanation for elevated postmortem drug concentrations in the elderly.

Caution against using reference tables

Interpretation of postmortem toxicology results can be very challenging and should be done only with a thorough knowledge of the case history, including autopsy findings, information from the scene and relevant medical history. It is not difficult to interpret a high blood strychnine concentration in a person found dead in a farmhouse together with an open container of strychnine-containing rodent poison and a suicide note. However, how should the toxicologist interpret a moderately high blood concentration of imipramine in an adolescent prescribed the drug for attention-deficit disorder. Could the drug have accumulated? Was the subject suffering from depression? Was he or she complaining of side-effects? Can any medication that remains be accounted for by the time since the prescription was filled and dosage (i.e. a medication count)? Did the autopsy reveal any significant natural disease? Was the behaviour of the subject observed in the immediate period leading to death? Was the death a sudden, witnessed collapse? Was there a period of emergency hospitalisation leading up to death? If so, what did the medical assessment reveal? Are there any antemortem plasma or blood specimens still available? These are the types of questions that the forensic toxicologist should ask in cases that are anything less than straightforward.

There is a great temptation for forensic toxicologists and others to refer to tables of therapeutic, toxic and fatal concentrations. While these tables may be of some use in clinical toxicology, they are of very limited value for the interpretation of postmortem toxicology results and can be very misleading. Such tables are often drawn extensively from clinical data, seldom take into account tolerance and do not allow for phenomena such as postmortem redistribution. For example, interpretation of morphine and other narcotic concentrations may be very dependent on how long the person has been prescribed the drug and at what dosage. The inappropriate use of tables can result in over- and underestimation of the potential toxicity of a drug depending on the degree of tolerance developed, natural disease and whether other substances are present. The ranges given may not take into account the circumstances of drug use. For example, the therapeutic range for fentanyl when used intravenously as an adjunct to anaesthesia may be greater than 10-fold that after use for analgesia via a transdermal patch. Data compendia may also include cases in which there was a prolonged survival time and the person died from the sequelae of the intoxication (e.g. hypoxia, organ failure), but after medical intervention had prolonged life, resulting in lower blood concentrations. Specific references to case data and further information are lacking in most instances. Experienced postmortem toxicologists rely first on their own case experience, supplemented by compilations of drug monographs, where references to the original published work are available, and the circumstances of the case (Baselt 2008).

CHAPTER

11 Drugs of Abuse

SD McDermott

Introduction

Definitions

One definition of the term 'drug of abuse' is any substance that, because of some desirable effect, is used for some purpose other than that intended. The intended use of the substance could be for a therapeutic effect with, for example, benzodiazepines, or a practical use in the case of the solvent abuse by 'glue-sniffing'.

Another definition of 'drug of abuse' is any substance whose possession or supply is restricted by law because of its potential harmful effect on the user. Such drugs are known as controlled or scheduled substances. For example, in the United Kingdom (UK), such 'Controlled Drugs' are those listed in Schedule 2 of the Misuse of Drugs Act 1971. The Schedule is divided into three parts (or classes) largely on the basis of decreasing order of harmfulness: Part I (Class A), Part II (Class B) and Part III (Class C). This division into three classes is solely for the purpose of determining penalties for offences under the Act. The drugs comprise licit materials (i.e. those manufactured under licence), the illicit products of clandestine factories and some natural products. Although many plant-based drugs have been self-administered for thousands of years (e.g. coca leaf, cannabis (marijuana and hashish), opium, peyote cactus), the imposition of criminal sanctions is mostly a product of the 20th century. Many of the drugs currently abused were once not only on open sale but often promoted as beneficial substances by the food and pharmaceutical industries. A pattern developed whereby initial 'misuse' of pharmaceutical products such as heroin, cocaine and amfetamine led to increasing legal restrictions and the consequent rise of an illicit industry. Nowadays, nearly all serious drug abuse involves illicit products. Most abused drugs fall into just a few pharmacological groups, e.g. central nervous system (CNS) stimulants, narcotic analgesics, hallucinogens and hypnotics. It is still true that the most prevalent drugs are plant-derived or semi-synthetic substances (e.g. cannabis, cocaine and heroin), but the view of the United Nations (UN) Drug Control Programme is that wholly synthetic drugs (e.g. amfetamine, 3,4-methylenedioxymetamfetamine (MDMA) and related designer drugs) are likely to pose a more significant social problem in the future.

This limited definition of drug abuse excludes those pharmaceutical products that may be misused in the sense that they could lead to accidental or deliberate overdose or that they could contribute to vehicle accidents or are banned by sporting organisations. Also excluded are drugs such as alcohol, tobacco and caffeine, which either are foodstuffs, with or without nutritional value, or whose use is socially acceptable. According to the World Health Organization (WHO), scheduled drugs are 'abused' rather than 'misused'. Drugs of abuse may or may not lead to physical or psychological 'dependence', a term used by WHO in preference to 'addiction'.

Legislation

Drug laws have been a common feature of human law for several hundred years. Today's 'war on drugs' bears many similarities to earlier drug laws, particularly in motivation. The motivation behind many earlier drug laws was based on religious observance, allegations of violence related to the consumption of the drug and concern for public health. The first law prohibiting outright the use of a specific drug in the United States of America (USA) was a ban on the smoking of opium in San Francisco in 1875. Cocaine was prohibited in the first part of the 20th century. In 1914 The Harrison Act was passed in the USA. This law required sellers of opiates and cocaine to have a licence. While originally intended to require paper trails for drug transactions, it soon became a prohibitive law. The Marijuana Tax Act of 1937 was introduced in the USA to counter the loss of revenues associated with the purchase of the drug from an unlicensed source as no legal licence to sell the drug was in existence.

Narcotic drugs are classified and placed under international control by the 1961 UN Single Convention on Narcotic Drugs, as amended in 1972. The Single Convention limits 'exclusively to medical and scientific purposes the production, manufacture, export, import, distribution of, trade in, use and possession of drugs' (Table 11.1).

Psychotropic substances are placed under international control by the 1971 UN Convention on Psychotropic Substances. The objectives of this Convention are again to limit the use of these substances to medical and scientific purposes (Table 11.2). While some psychotropic substances may have therapeutic value, they also present a dangerous risk of abuse.

The Controlled Substances Act (CSA, 1970) in the USA places all substances that were in some manner regulated under existing federal law into one of five schedules. This placement is based upon the substance's medical use, potential for abuse, and safety or dependence liability. The Act also provides a mechanism for substances to be: controlled, or added to a schedule; decontrolled, or removed from control; and rescheduled or transferred from one schedule to another.

The following items are indicators within the terms of the CSA that a drug or other substance has a potential for abuse:

- There is evidence that individuals are taking the drug or other substance in amounts sufficient to create a hazard to their health or to the safety of other individuals or to the community.
- There is significant diversion of the drug or other substance from legitimate drug channels.
- Individuals are taking the drug or other substance on their own initiative rather than on the basis of medical advice from a practitioner licensed by law to administer such drugs.
- The drug is a new drug so related in its action to a drug or other substance already listed as having a potential for abuse as to make it likely that the drug will have the same potential for abuse as such drugs, thus making it reasonable to assume that there may be significant diversions from legitimate channels, significant use contrary to or without medical advice, or that it has a substantial capability of creating hazards to the health of the user or to the safety of the community. Of course, evidence of actual abuse of a substance is indicative that a drug has a potential for abuse.

In determining into which schedule a drug or other substance should be placed, or whether a substance should be decontrolled or rescheduled, certain factors are required to be considered. The body with the responsibility for this in the USA is the Drug Enforcement Agency (DEA) and the factors to be considered include:

1. The drug's actual or relative potential for abuse.
2. Scientific evidence of the drug's pharmacological effects. The state of knowledge with respect to the effects of a specific drug is, of course, a major consideration. For example, it is vital to know whether or not a

Table 11.1 1961 UN Single Convention on Narcotic Drugs

Schedules	*Harmfulness*	*Degree of control*	*Examples of listed drugs*
I	Substances with addictive properties, presenting a serious risk of abuse	Very strict; 'the drugs in Schedule I are subject to all measures of control applicable to drugs under this Convention' (Article 2.1)	Cannabis and its derivatives, cocaine, heroin, methadone, morphine, opium
II	Substances normally used for medical purposes and given the lowest risk of abuse	Less strict	Codeine, dihydrocodeine, propiram
III	Preparations of substances listed in Schedule II, as well as preparations of cocaine	Lenient; according to the World Health Organization, these preparations present no risk of abuse	Preparations of codeine, dihydrocodeine, propiram
IV	The most dangerous substances, already listed in Schedule I, which are particularly harmful and of extremely limited medical or therapeutic value	Very strict, leading to a complete ban on 'the production, manufacture, export and import of, trade in, possession or use of any such drug except for amounts which may be necessary for medical and scientific research' (Article 2.5.b)	Cannabis and cannabis resin, heroin

drug has a hallucinogenic effect if it is to be controlled because of that effect. The best available knowledge of the pharmacological properties of a drug should be considered.

3. The state of current scientific knowledge regarding the substance. Criteria (2) and (3) are closely related. However, (2) is primarily concerned with pharmacological effects and (3) deals with all scientific knowledge with respect to the substance.
4. Its history and current pattern of abuse. To determine whether or not a drug should be controlled, it is important to know the pattern of abuse of that substance, including the socio-economic characteristics of the segments of the population involved in such abuse.
5. The scope, duration and significance of abuse. In evaluating existing abuse, the DEA administrator must know not only the pattern of abuse but also whether the abuse is widespread. In reaching a decision, the administrator should consider the economics of regulation and enforcement attendant on such a decision. In addition, the administrator should be aware of the social significance and impact of such a decision upon those people, especially the young, who would be affected by it.
6. What, if any, risk there is to public health. If a drug creates dangers to the public health, in addition to or because of its abuse potential, then these dangers must also be considered by the administrator.
7. The drug's psychological or physiological dependence liability. There must be an assessment of the extent to which a drug is physically addictive or psychologically habit forming, if such information is known.
8. Whether the substance is an immediate precursor of a substance already controlled. The CSA allows inclusion of immediate precursors on this basis alone into the appropriate schedule and thus safeguards against possibilities of clandestine manufacture.

After considering the factors listed above, the administrator must make specific findings concerning the drug or other substance. This will determine into which schedule the drug or other substance will be placed.

In the European Union (EU), when a new psychoactive substance is first detected, the European Monitoring Centre for Drugs and Drug Addiction (EMCDDA) together with Europol conduct a risk assessment on the health and social risks, caused by the use of, the manufacture of and traffic in the new psychoactive substance, the involvement of organised crime and the possible consequences of control measures. An early warning system exists to fast track the collection of information and the subsequent control of the substance.

Various offences are defined under the legislation, and in the UK offences under the Act include:

- Possession of a controlled substance unlawfully.
- Possession of a controlled substance with intent to supply it.
- Supplying or offering to supply a controlled drug (even where no charge is made for the drug).
- Allowing premises you occupy or manage to be used unlawfully for the purpose of producing or supplying controlled drugs.

Drug trafficking (supply) attracts serious punishment including life imprisonment for Class A offences. To enforce this law the police have special powers to stop, detain and search people on 'reasonable suspicion' that they are in possession of a controlled drug.

Legal status of cannabis

The legal status of cannabis for personal use is one of the most controversial policy issues in the EU and indeed worldwide. Although cannabis is a classified narcotic drug placed under control by the UN and by all EU Member States, the measures adopted to control it at national level vary considerably. Cannabis extracts – marijuana, hashish and cannabis oil – are classified as narcotic drugs under both Schedules I and IV of the UN Single Convention on Narcotic Drugs

Table 11.2 1971 UN Convention on Psychotropic Substances

	Harmfulness	*Degree of control*	*Examples of listed drugs*
I	Substances presenting a high risk of abuse, posing a particularly, serious threat to public health which are of very little or no therapeutic value	Very strict; use is prohibited except for scientific or limited medical purposes	Lysergide (LSD), MDMA (ecstasy), mescaline, psilocybin, tetrahydrocannabinol (THC)
II	Substances presenting a risk of abuse, posing a serious threat to public health which are of low or moderate therapeutic value	Less strict	Amfetamines and amfetamine-type stimulants
III	Substances presenting a risk of abuse, posing a serious threat to public health which are of moderate or high therapeutic value	These substances are available for medical purposes	Barbiturates, including amobarbital, buprenorphine
IV	Substances presenting a risk of abuse, posing a minor threat to public health with a high therapeutic value	These substances are available for medical purposes	Tranquillisers, analgesics, narcotics, including allobarbital, diazepam, lorazepam, phenobarbital, temazepam

(1961). Article 36 requests State Parties to 'adopt such measures as will ensure that . . . possession . . . of drugs contrary to the provisions of this Convention . . . shall be punishable offences when committed intentionally'. The active principles of cannabis, the cannabinoids THC (tetrahydrocannabinol) and specifically dronabinol (Δ^9-THC) are classified as psychotropic substances under Schedules I and II respectively of the UN Convention on Psychotropic Substances (1971). Article 22 of this convention echoes the terms of the 1961 Convention mentioned above, stating that 'each Party shall treat as a punishable offence, when committed intentionally, any action contrary to a law or regulation adopted in pursuance of its obligations under this Convention. . .'. The EU Member States have transposed the UN precepts concerning the penal or administrative control of cannabis, and have applied them according to their own local or regional circumstances. This has resulted in a heterogeneous 'legal map' regarding cannabis offences: some countries or regions tolerate certain forms of possession and consumption; other countries apply administrative sanctions or fines; and still others apply penal sanctions. A study of the decriminalisation of cannabis in Switzerland also examined the situation in Australia and the USA and found varying applications of the law relating to cannabis use (Magg 2003).

Fines, cautions, probation, exemption from punishment and counselling are favoured by most European justice systems. It is of interest to note that cannabis in particular is frequently distinguished from other substances and given special treatment in these cases, in the law, by prosecutorial directive, or by the judiciary. Nevertheless, police arrests for drug offences, mainly those involving cannabis and mainly use-related offences, are increasing in several countries.

Legal status of hallucinogenic mushrooms

Mushrooms containing psilocin or psilocybin are known as hallucinogenic or 'magic' mushrooms. Psilocin and psilocybin are controlled substances under Schedule 1 of the 1971 UN Convention on Psychotropic Substances, so all Member States control them accordingly. However, the control of the mushrooms themselves is interpreted in many different ways across Europe – this may reflect the extent to which they grow freely in certain conditions, and the fact that they appear to be a somewhat regional phenomenon.

In some countries, the law specifically lists hallucinogenic mushrooms themselves as a controlled substance and forbids their sale or possession. Some will simply treat the mushrooms as being the controlled substances of psilocin or psilocybin in compound form. Some look at the intent of the act; they ban cultivation, possession or sale only when for the purposes of abuse. Their condition is also considered – fresh mushrooms might not be considered illegal, but prepared or treated mushrooms are illegal – again perhaps reflecting the intent. Interpretation of the term 'prepared' or 'treated' may become a complex matter for the courts. Others use a catch-all phrase in the law ('cultivation of any plant for the purposes of making a psychoactive substance'). Finally, a number of countries remain with unclear legislation, simply because so few cases have come to court.

Penalties for drug offences

Penalties for drug offences vary considerably across the world. There is generally a distinction between possession for personal use (smaller quantities) and possession with intent to supply to others.

In Europe, in general, the penalty associated with possession of a small quantity of a controlled drug for the first time is a fine. Further convictions even for possession of a relatively small quantity can lead to jail sentences, and possession of large quantities of controlled drugs generally attracts a jail sentence. Some countries have mandatory minimum jail sentencing for drugs above a certain quantity or monetary value.

In the USA the Anti-Drug Abuse Act of 1988 allows the government to punish minor drug offenders without giving the offender a criminal record if the offender is in possession of only a small amount of drugs. This law is designed to impact the 'user' of illicit drugs, while simultaneously saving the government the costs of a full-blown criminal investigation. Under this Act, the government has the option of imposing only a civil fine on individuals possessing only a small quantity of an illegal drug. Possession of this small quantity, identified as a 'personal use amount' carries a civil fine of up to $10 000. In determining the amount of the fine in a particular case, the drug offender's income and assets will be considered. This is accomplished through an administrative proceeding rather than a criminal trial, thus reducing the exposure of the offender to the entire criminal justice system, and reducing the costs to the offender and the government.

Congress has imposed two limitations on this Act's use. It may not be used if (1) the drug offender has been previously convicted of a Federal or state drug offence or (2) the offender has already been fined twice under this Act.

Analysis of seized drugs

Items suspected of containing drugs occur in four principal forms: (i) powders; (ii) tablets and capsules; (iii) living plants or dried vegetable matter; and (iv) liquids. Apart from situations where the analyst has made extracts from clothing or other matrices, the last category could include solvents, aqueous solutions (e.g. γ-hydroxybutyric acid (GHB)), injection solutions, alcoholic solutions (e.g. cocaine in liquor) and hash oil, many of which will have a characteristic appearance or packaging. Powders are unlikely to show any clear visual clues to their identity and will often be presented in paper or plastic wrapping. Although the analytical approach to each may differ, there are six basic components, not all of which will be needed in every case: physical examination; sampling; screening; qualitative analysis; quantitative analysis; profiling/comparison (Fig. 11.1). The particular techniques used will depend on available equipment, staff skills and the objectives of the analysis, but there are certain minimum criteria that need to be satisfied, particularly when the results are presented as evidence in court.

Physical examination

A natural starting point in any analysis procedure is the physical examination of the item in question. This may involve making a sketch or taking a photograph of the item. It will invariably involve either taking some physical measurements such as length or diameter, or making a record of the number of items (e.g. number of tablets) or the weight of the item in question. It may involve taking detailed notes on the type of wrapping material used. On many occasions, details such as these can take on a large significance.

While the physical appearance of a suspect material can sometimes give an early indication of the possible drug(s) present, it is only after chemical analysis that the full picture can emerge.

Sampling

Drugs submitted to forensic science laboratories can vary enormously in the manner of presentation. One exhibit may be a quantity of ecstasy tablets that are well made and essentially clean to handle; the next exhibit may be packs of heroin or cocaine that had been concealed internally by a drug user. The initial approach to each scenario will depend on such matters as:

- Health and safety
- Linking of packaging material
- Fingerprint analysis
- Other evidence.

It is also true that, because of time constraints and costs, not all of the items submitted will be analysed and therefore a sampling policy must be established.

The number of items tested will be determined by a number of factors such as the number of items seized, their physical appearance and the need to satisfy a court of law.

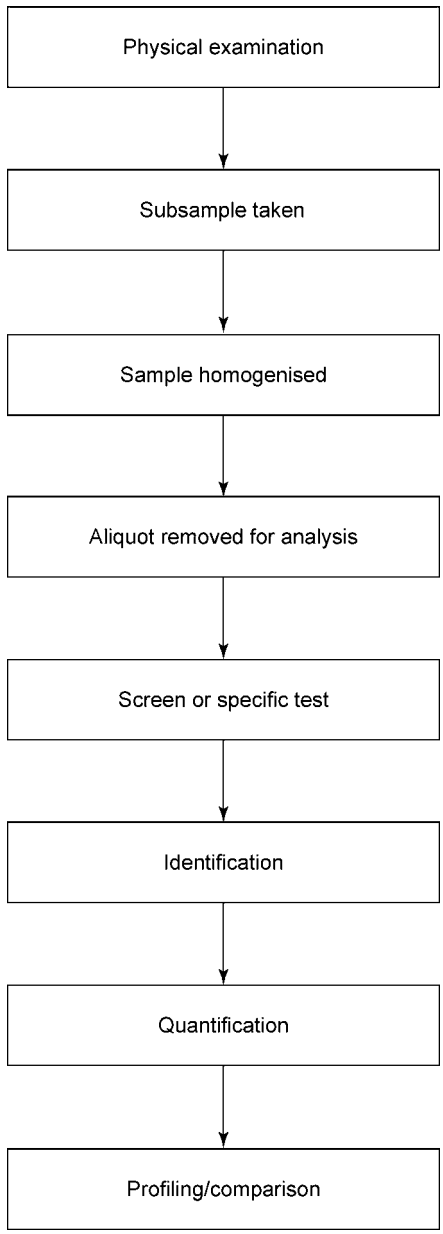

Figure 11.1 Flowchart for the examination of an unknown substance.

Exhibits of controlled substances are received by forensic laboratories in large numbers and a representative sampling plan must be established. The benefits of a sampling plan are to

- Reduce the number of analytical determinations.
- Reduce overall workload.
- Decrease exposure to controlled substances.
- Reduce handling of biologically contaminated evidence.

With any sampling plan, an initial visual examination of all the units in the population is conducted. If all the units are similar in appearance, the population can be considered as homogeneous and a sampling plan can be implemented (Aitken 1999; Clarke, Clark 1990; Colon *et al.* 1993; Frank *et al.* 1991; Tzidony, Ravreby 1992).

The most frequently used sampling procedures are as follows:

(1) Take a sample of size equal to the square root of the population size ($n = \sqrt{N}$); e.g. from a population of 400 take a sample of 20.
(2) Take a sample equal to 10% of the population size ($n = N/10$); e.g. from a population of 400 take a sample of 40.

Although experience has shown that the square-root method produces reliable results, it does not provide a statistical foundation to the sampling problem.

(3) Another popular method of sampling is the use of a hypergeometric distribution. This procedure involves statistical tables that can be used to determine how many samples should be taken for analysis. Table 11.3 is an example of such a table. If these analysis tests are positive, an inference can be made for the whole population. For example, if 1000 suspect tablets are seized and sent to the laboratory, by testing 28 tablets and if the tests are positive for MDMA, then there is a 95% probability that 90% of the tablets contain MDMA.

In relation to sampling from single items, it is important that a correct sampling procedure be put in place. The principal reason for a sampling procedure is to produce a correct and meaningful chemical analysis. Most methods – qualitative and quantitative – used in forensic science laboratories for the examination of drugs require very small aliquots of the material, so it is vital that these small aliquots are entirely representative of the bulk from which they are drawn.

However, because of various legal requirements, it may not always be possible to render a sample into a homogeneous state before sampling. This could be the case if the sample was to be separately tested by another laboratory or if keeping the sample in its original 'heterogeneous' state was an important piece of physical evidence.

As a rule, though, items should be in a homogeneous state prior to sampling, and this is especially important in quantitative analysis. This might involve the simple grinding of a small amount of powder (or tablet) in a mortar with a pestle, or might involve taking numerous samples from a larger quantity of powder and grinding them together.

In many instances the amount of drug submitted to the forensic analysis is too large to get an accurate weight of the total and therefore an estimate of the weight may be used. The simplest way to get such an estimate is to accurately weigh a subsample and get average/standard deviation information and extrapolate this from the subsample to the total population. The forensic report produced should reflect the fact that the total weight of the drug is based on an estimate. Generally the court will accept this as a legitimate scientific practice.

Table 11.3 Hypergeometric sampling table (UN 1998)

>1600	29

Screening tests

Colour/spot tests provide a valuable indication of the content of any particular item tested, but it must be stressed that positive results to colour tests are only presumptive indications of the possible presence of the drug. Colour tests have the advantage that they can be used as field tests by unskilled operators, with the obvious need for follow-on analysis in the laboratory. One of the most important and widely used colour tests is the Marquis reagent test.

Another important screen is thin-layer chromatography (TLC). This has many advantages as an analysis/screening tool. It is quick, easy to use and has a low cost; it is relatively sensitive and can give a good degree of discrimination.

Solvent systems TA and TB are suitable for many drugs (see Table 11.4 and Chapter 39).

Visualisation of many of the drugs may be achieved by a variety of methods. However, spraying with acidified potassium iodoplatinate reagent is suitable for many drugs.

Qualitative analysis

Using a capillary column gas chromatograph and a suitable temperature programme coupled to a mass spectrometer (GC-MS; see Chapter 37), the drug components of most samples can be separated and identified. Because of the reduced capital outlay of such instruments in recent times, it is not uncommon for laboratories to have several such instruments working with automatic samplers (possibly on a 24-hour basis). The use of GC-MS has become the routine method of identification of most drugs. A general GC-MS screen method (GAK, Table 11.4) can be used to separate and/or identify most of the drugs encountered in exhibits. Figure 11.2 shows the separation achieved, by this method, of a mixture of the main drugs described in this chapter.

Identification of the various components of a suspect mixture can be made by library searching against commercial libraries but it is important to run a standard of the specific drug being tested, e.g. pure heroin. This obviously will need to give a retention time and mass-spectral match.

High performance liquid chromatography (HPLC) is a simple and reliable method of analysis of most drugs. It is both accurate and precise and thus lends itself to quantitative analysis. It is especially useful for compounds that are thermally labile. HPLC has some advantages over GC because of the variety and combinations of mobile phases that can be chosen. There is also a choice of detectors available for specific applications. HPLC can, however, involve significantly more method development than GC and the resolution of GC is greater.

No one system is suitable for optimum separation of all the different drug types, so different systems are used to give optimum separations for specific analysis. The system that is best for the separation of heroin/acetylcodeine/noscapine/papaverine (Huizer 1983) will not be the same as that which separates cocaine from its impurities and processing by-products (Moore, Casale 1994).

A general screening method such as HBC (Table 11.4) can be used for the separation of heroin (diamorphine), cocaine, amfetamine and metamfetamine (Fig. 11.3).

Using this system, metamfetamine and MDMA co-elute. However, by changing the method to HBD, amfetamine, metamfetamine, MDMA and methylenedioxyethamfetamine (MDEA) may be separated (Fig. 11.4). This illustrates the versatility of HPLC. Separations can occur between compounds that co-elute by altering the elution system. A system such as the above could be used as a screen, but identification would necessitate some spectroscopic method such as MS or infrared (IR) spectroscopy.

Most modern laboratories are now equipped with Fourier transform IR (FTIR) spectrometers (see Chapter 33). These have many advantages over traditional IR instruments. They are faster and can work with smaller samples. When they are coupled with a microscope, tiny samples can be analysed. The difficulty with IR analysis of drug samples is the presence of other material that will interfere with the spectrum. These interfering compounds could be other drugs that occur naturally in the samples (or from the synthetic process) or could be adulterants such as caffeine and paracetamol. IR analysis can, however, give valuable information on chemicals that are not suitable for GC-MS analysis.

Another technique that is popular is GC-FTIR. Because of the speed of scanning of the FTIR it can be used to obtain a spectrum of the compounds that have been separated by GC.

In practice, neither spectra nor pure reference samples may be available for comparison for the more unusual substances. In this situation, nuclear magnetic resonance (NMR) spectroscopy (see Chapter 36) is the method of choice.

Quantitative analysis

For most controlled drugs there are no minimum quantities below which an offence does not occur. The quantitative analysis of drugs is therefore not carried out routinely on all exhibits. The main reason for determining purity/drug content of powders and tablets is to enable a court to establish a monetary value of the seizure or when sentencing structures are based on equivalent pure drug content. In some countries the death sentence can apply if one is convicted of possession/supply of greater than a specified quantity of a substance.

In some situations, information on drug purity will be used for intelligence purposes such as to assess trends in the illicit drug market or for use in drug comparison and profiling.

Having already identified the powder as, for example, heroin, quantitative analysis may be carried out by GC using flame ionisation detection (FID) or by HPLC. In performing quantitative analysis it is always desirable to include an internal standard in the analysis. This has the advantages of ease of use, increased accuracy, no need for volumetric glassware, no need to measure injection volume and easy determination of reproducibility, and can be used as a monitor for GC or HPLC systems.

An internal standard must meet the following criteria: it must be absent from the sample; it must be readily available (and not too costly); and it must be pure, show good chromatographic behaviour, be reproducible and be soluble in the solvent used. Straight-chain hydrocarbons (for GC) fulfil all of these requirements and they elute as a homologous series, so they are a popular choice as internal standard. It has been suggested that the internal standard that one chooses should be chemically related to the compound being analysed. However, provided that it fulfils the above criteria, any compound can be chosen.

A general approach to quantification by GC could be as follows. The GC conditions for the qualitative analysis can again be used. A standard curve is established by preparing up to five standard solutions of the drug being quantified. A range from 1 mg/mL to 5 mg/mL is prepared using solvent containing an internal standard. A concentration of internal standard of 0.5 or 1 mg/mL will normally be adequate. A test sample is prepared that will have a concentration between 1 and 5 mg/mL, i.e. within the range of the standard curve. If the test sample is outside the range, a second sample is prepared based on the information from the first sample. In general it is suggested that at least two samples of the powder being tested be taken for quantitative analysis and an average of these be taken as the true result. The amount of the drug in the test sample can now generally be calculated by the data-analysis function of the instrument.

Both GC and HPLC are used extensively for quantitative analysis and it is useful to compare the results obtained by one method with the other, for a given drug.

Profiling and comparison

A more detailed analysis of drug samples can be used to provide 'collective' information. This is generally called profiling when it involves the chemical analysis of powders, or is known as characterisation when the physical properties of tablets and other dosage forms are measured. Chemical profiling has been the technique most widely used and is often based on the chromatographic separation of impurities and precursors (as in the case of amfetamine and metamfetamine) or other naturally occurring components and adulterants (e.g. heroin, cocaine,

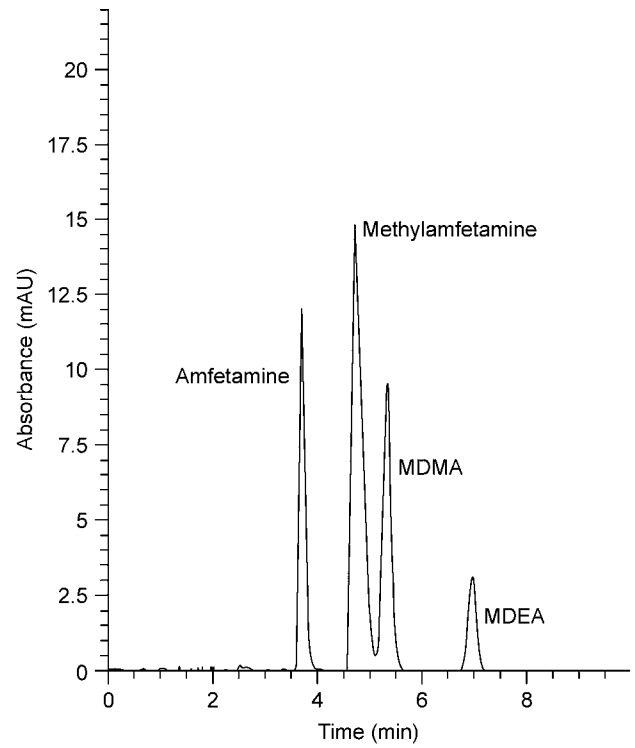

Figure 11.4 HPLC separation.

cannabis resin). Detection may range from flame-ionisation to isotope-ratio mass spectrometry. Non-separation methods, for example using IR, Raman or X-ray diffraction spectroscopy, have only limited scope.

Drug profiling may be used for two quite separate purposes. In the first case, it can establish connections between a number of exhibits that are suspected of being linked as part of a local distribution chain. This is known as comparison or tactical profiling and may be carried out as a routine requirement in forensic casework. A second stage (intelligence or strategic profiling) exists where answers to wider questions may be sought. These will depend on the drug concerned, but include estimating the number of different profile types in circulation and relating them to the number of active laboratories and how long they have been in operation; determining the extent of importation by comparing the profiles of police and customs seizures; identifying the route of synthesis and types of precursors used; creating large-scale maps of drug distribution and identifying the country or region of origin.

Tablet comparisons using general physical features, gross drug content and microscopic examination of defects and punch marks (so-called ballistic analysis) can be of some value, but they suffer from the fact that at any one time a large fraction of illicit tablets in circulation may be almost identical. Such small differences as may exist could simply reflect inherent differences in the punches and dies of a multiple-stage tabletting machine. This can be illustrated by the Mitsubishi logo (Fig. 11.5), which was found on over half of all MDMA tablets seized in Europe in the late 1990s. A similar pattern was also found in the UK for amfetamine in the early 1990s, when nearly half of all samples belonged to one profile type. In these circumstances, any connection between two separate seizures of otherwise identical tablets or powders may be purely fortuitous.

This, in turn, raises other problems with profiling. It is necessary to maintain a database of profiles such that the significance of any 'match' or 'non-match' can be critically assessed. However, in a situation where profiles may change with time, what constitutes a 'current' database is not always clear. In the case of determination of country of origin, authentic samples are required in order to provide a statistical 'training set', yet such samples may be difficult to obtain and their true provenance uncertain.

A general approach to the analysis of unknown substances

A general approach to the analysis of unknown substances has been outlined in Fig. 11.1. Different approaches will be required depending on whether the exhibit is a powder, vegetable matter, tablet/capsule or liquid.

Powders

When a powder is submitted for analysis, the most likely drugs to be present include heroin, cocaine, amfetamine and metamfetamine. Although others may be present, these are the most common. Initial examination will involve describing/detailing of the packaging material. If there are multiple packs present then a subsample may be removed for analysis. The powder must be weighed before analysis.

The powder is then homogenised and an aliquot is taken for analysis. A screen (colour test, TLC, HPLC, GC) will indicate the drug(s) present. Identification of the drug can be achieved using GC-MS or FTIR spectroscopy. GC-MS has an advantage over FTIR spectroscopy because of retention time and a mass-spectral comparison with a known standard.

Figure 11.5 Impressions on illicit MDMA tablets.

Identification of the other components in the powder can be achieved by using a range of analytical techniques including FTIR, X-ray fluorescence (XRF), X-ray diffraction (XRD), NMR spectroscopy and others.

The drug content can be quantified by GC or HPLC by preparation of a curve using a range of concentrations of the drug in question. In some circumstances comparison may be required between powders for links in a specific case or for intelligence purposes, and GC and HPLC can be employed to examine some of the minor ingredients of the powder.

Vegetable material

This includes cannabis plants, cannabis resin, khat and psilocybe mushrooms. A physical examination would include a description of the material followed by a measurement of the weight of material or the height of the plant. A subsample of the population may be chosen and an aliquot taken for analysis. Homogenisation may be necessary depending on the material. The physical appearance will generally give a very good idea of the drug present, for example cannabis plant or psilocybe mushrooms. We can therefore go directly to a specific test rather than use a screening technique. Identification can be carried out by a combination of microscopic and chemical techniques.

The drug content can be quantified by GC or HPLC and comparison/profiling carried out by chemical and physical comparisons.

Tablets and capsules

Tablet or capsules submitted to the laboratory include ecstasy (MDMA, MDEA, etc.), benzodiazepines, steroids, LSD squares and others. An initial examination will include a description of any markings or logos, counting of the items, measurement of the tablet/capsule and possibly a weight. An examination of a tablet/capsule identification database such as TICTAC may give an indication of the drug present (see Chapter 13). Subsampling followed by homogenisation will lead to essentially a powder sample and the procedure for analysis of powder samples may then be followed.

For comparison/profiling a physical comparison of the logo or mark may be the most informative piece of information available.

Liquids and other forms

These include GHB, steroid oils, cocaine liquor and others. A physical examination may give an indication of the drug likely to be present. The physical measurements to be noted would include the volume, colour, odour and general appearance of the liquid. A subsample may be taken and an aliquot removed for analysis. It may be necessary to (base) extract the drug from the liquid into an organic solvent prior to analysis. The physical examination may allow the analyst to proceed to the identification stage, otherwise a screen may be used to indicate the presence of a certain drug. Identification, quantification and comparison/profiling can be carried out along the lines outlined for powders.

Clandestine laboratories

Because of the increase in abuse of synthetic drugs, clandestine laboratories have become an increased part of forensic investigations. The investigation of such sites is very interesting as they reveal (*in situ*) the synthetic processes, intermediates, and often notes and chemical equations describing the various reactions used. These laboratories, however, are also very hazardous sites to investigate. The use of the word 'laboratory' disguises the more usual scenario of a garage, shed or kitchen.

Forensic scientists frequently become involved in an advisory capacity in the initial stages of a clandestine laboratory investigation. Information may come to light about certain chemicals being used at a premises and the scientist is responsible for formulating an opinion as to whether a controlled substance is being produced. The police can then act on the basis of this opinion.

Many countries have specially trained police and scientists to deal with the specific problems that clandestine laboratories pose. These problems could be in the form of hazardous chemicals (acids, bases, solvents and reagents) and fire and explosion potentials.

Ultimately, if the seizure results in a court case, the testimony in these cases can be technically demanding for the scientist. In many situations, only a small amount (or none) of the final product (i.e. the controlled substance) may be found. In these instances, detailed explanations of the synthetic routes may be required. An explanation of the role of each of the chemicals found at the scene could be required. The scientist must also be aware of alternative explanations for the presence of the chemicals, as this is the likely defence in such cases. In many instances the precursor chemicals themselves are controlled. The forensic investigation of clandestine laboratories has been well documented (Christian 2003) and many of the complications associated with such laboratories have been explored.

In the USA, the number of clandestine metamfetamine laboratories has increased enormously in recent times. Illegal seizures increased from 7438 in 1999 to 12 484 in 2005. The hazards and contamination issues associated with such laboratories pose difficulties for those involved in the process and for public health in general (Martyny *et al.* 2007). Capillary electrophoresis (CE) has been employed to characterise phosphorus species used in the manufacturing process (Knops *et al.* 2006).

Concealment of drugs

The internal concealment of illicit drugs to smuggle quantities across borders has been a phenomenon for decades (Fineschi *et al.* 2002; Gill, Graham 2002; Takekawa *et al.* 2007). The 'body packer' or 'mule' carries quantities of drugs that are generally well wrapped to withstand the biological hazards of internal concealment. Deaths related to such activities are not uncommon. However, it is not known how widespread the practice is as the detection is frequently associated with instances that have adverse medical consequences.

Impregnation of items with cocaine is also a novel method of concealment. Cocaine-impregnated silicone in baseball cap parts were detected and chloroform was used to extract the cocaine (Microgram 2003). Items of clothing impregnated with cocaine were extracted with methanol (McDermott, Power 2005) and in this instance 'moth balls' containing camphor were added to the suitcase to deter detection by dogs. An unusual way of smuggling cocaine is the use of a cocaine–poly (methylmethacrylate) solid solution (Gostic, Klemenc 2007).

Analysis of the main drugs of abuse

In this section, methods are described for the analysis of the main drugs of abuse. In all cases a number of analysis methods are described. The methods chosen will depend on the aim of the analysis, the apparatus/equipment available, legal aspects and the number of analyses to be performed, and may depend on other details associated with the specific drugs seizure.

The analytical data for the various drugs are shown in Tables 11.5 and 11.6.

Amfetamine and metamfetamine

Amfetamine (α-methylphenethylamine; 1-phenylpropan-2-amine) and metamfetamine (*N*-methyl-α-methylphenethylamine; *N*-methyl-1-phenylpropan-2-amine) in free base form are both liquids. Amfetamine is normally produced as amfetamine sulfate or phosphate and is common in Europe. Metamfetamine is normally produced as metamfetamine hydrochloride and is more popular in North America and Japan.

Street-level amfetamine and metamfetamine are normally submitted to the laboratory as white/off-white powders with relative low purity (e.g. 5%).

Synthesis of amfetamine and metamfetamine

Many methods are available for the illicit synthesis of amfetamine, but the Leuckart reaction has been the most popular. This method is simple and rapid, gives a good yield and does not involve any particularly hazardous chemicals or procedures. It may be considered as a three-step reaction involving the condensation of phenyl-2-propanone (P-2-P) with formamide followed by a hydrolysis of the *N*-formylamfetamine and finally purification by steam distillation.

[(a)] k values.

Metamfetamine can be made by the Leuckart reaction using methylamine and formic acid or *N*-methylformamide in the condensation step.

Analysis of amfetamine and metamfetamine

Because many of the street-level samples submitted to the laboratory are relative low in purity (5%), pre-concentration of samples may be required for the analysis to be successful. This may be achieved by base extracting the amfetamine/metamfetamine into ether and evaporating to dryness in an airflow without heat. A few drops of methanol can then be added and the methanolic solution transferred to a plastic insert prior to analysis.

Colour test Marquis test gives an orange colour for both amfetamine and metamfetamine.

TLC

- TA: amfetamine $R_f = 0.43$; metamfetamine $R_f = 0.31$
- TB: amfetamine $R_f = 0.15$; metamfetamine $R_f = 0.28$
- Visualisation is with acidified iodoplatinate solution.

Separation/identification

(For analytical data see Tables 11.5 and 11.6.)

In addition, it is common practice with primary amines to prepare derivatives such as *N*-methylbis(trifluoroacetamide) (MBTFA) or trifluoroacetic anhydride (TFAA) derivatives. It is good practice to analyse both derivatised and underivatised samples since *N*-hydroxylamines may give the same product as the parent amines.

Using a concentrated/base-extracted sample, the molecular ion peaks *m/z* 134 and *m/z* 148 for amfetamine and metamfetamine, respectively, can readily be achieved in an underivatised sample.

Both amfetamine and metamfetamine have one asymmetrical carbon atom, resulting in a pair of enantiomers in each case. Depending on the synthetic route *l*-, *d*- and *dl*-amfetamine or metamfetamine could be encountered in samples submitted to the laboratory for analysis. These optical isomers differ in their pharmacological activity and are subject to different regulatory measures in certain countries. In those countries where the specific optical isomer needs to be identified, chiral analysis can be undertaken by derivatisation/GC, by the use of chiral columns (GC and HPLC) and by the use of CE (Anastos *et al.* 2005; Fanali *et al.* 1998; Lebelle *et al.* 1995; Sellers *et al.* 1996). Enantiomeric analysis of metamfetamine samples (Lee *et al.* 2007) showed that up until 1997 the vast majority of the metamfetamine encountered in the Republic of Korea was the *S*-(+)-enantiomer, but from 1997 onwards the *R*-(−)-enantiomer began to appear and increased continuously until 2005 when 50% of the metamfetamine samples seized contained the *R*-(−)-enantiomer.

Quantitative analysis and profiling of amfetamine/metamfetamine

Amfetamine and metamfetamine can be quantified by HPLC or GC. Normally if GC is used the samples are base extracted into an organic solvent and either run directly or derivatised and then run. Using HPLC there is no need to extract and, in many cases, this is the preferred method for quantitative analysis of amfetamine/metamfetamine.

Amfetamine produced illicitly often contains impurities that are a result of the manufacturing process. The presence of these impurities can be used to compare and distinguish samples of amfetamine since material used in the same manufacturing batch would almost certainly have the same number and relative amount of identical impurities. Samples from the same illicit laboratory produced at different times may show strong similarities, whereas samples from unrelated laboratories are expected to show major qualitative and quantitative differences.

Basic extracts into organic solvents are subjected to GC or GC-MS analysis. Samples are compared by visual inspection of the GC trace and by quantitative comparisons.

Metamfetamine impurity profiling is also carried out by GC analysis, with the impurities also giving information on the synthetic route (Seta *et al.* 1994). A recent study (Lee *et al.* 2006) of the impurities present as a result of the synthetic process showed that the selected impurity peaks may be utilised as the indicators of synthetic conditions and analysis of their patterns can supply valuable information for understanding the

conditions of clandestine synthesis of metamfetamine. The use of thermal desorption followed by GC-MS was found to be an efficient method for impurity profiling of metamfetamine (Kuwayama *et al.* 2007).

The purpose of the comparison/profiling is: to identify dealer–user links; to establish possible sources, i.e. the clandestine laboratory; and to build up databases to allow interpretation in comparison casework. This approach has been used in Australia to examine samples over the period 1998–2002 (Qi *et al.* 2006).

A series of studies were undertaken to develop a harmonised method for the profiling of amfetamine synthesised by three different methods. The study covered the sample preparation, extraction procedure, optimisation of GC-MS method, selection of target compounds and numerical comparison of amfetamine impurity profiles (Aalberg *et al.* 2005a, b; Andersson *et al.* 2007a,b,c; Lock *et al.* 2007). This inter-laboratory study found that the variation from laboratory to laboratory was affected by such factors as homogeneity of samples and concentration effects due to dilution.

Cannabis, cannabis resin and cannabinoids

Herbal cannabis (marijuana) means all parts of the plant *Cannabis sativa L.*, but excludes the seeds and mature/woody stalk material. *Cannabis sativa L.*, which can be grown in all parts of the world, is an annual plant and attains a height of 1–5 m. When it is planted for the production of hemp fibre, the stalks are crowded and without foliage except near the top. The wild growing plant, in contrast, has numerous branches. The resin of the plant occurs mainly in the flowering area, the leaves and the stem, particularly at the top of the plant. The highest amount of resin is found in the flowering part. Up to the time of flowering, the male and female plants produce resin almost equally. After shedding their pollen the male plants soon die. The resin is found in the glandular trichomes.

The leaves of *Cannabis sativa L.*, are compound and consist of 5 to 11 separate leaflets. Each leaflet is characteristically hair covered and veined and has serrated edges (Fig. 11.6).

Cannabis herbal material may be encountered in blocks of dried flowering tops and dried leaves. Cannabis resin (hashish) is a compressed solid made from the resinous parts of the plant and is usually produced in 250 g blocks. Herbal cannabis imported into Europe may originate from West Africa, the Caribbean or South East Asia, but cannabis resin derives largely from either North Africa or Afghanistan. Cannabis and cannabis resin are normally mixed with tobacco and smoked, but can be ingested. The average 'reefer' 'joint' cigarette contains around 200 mg of herbal cannabis or cannabis resin.

The main psychoactive compound in cannabis and cannabis resin is Δ^9-THC. Cannabinol (CBN) and cannabidiol (CBD) are among the other main components.

Analysis of cannabis/cannabis resin

Colour test The presence of cannabinoids in suspect material can be indicated by the Duquenois–Levine test.

Figure 11.6 Cannabis plant.

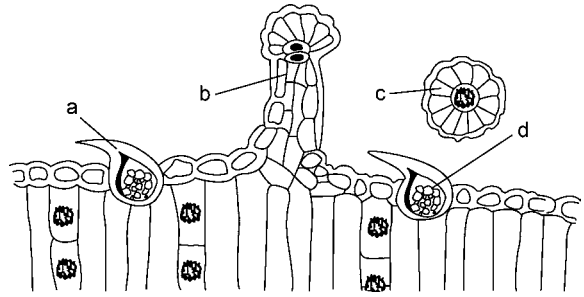

Figure 11.7 Microscopic examination of cannabis: (a) cystolith hair; (b) large glandular hair with several cells in the head and stalk; (c) head of one of the large glandular hairs; (d) calcium carbonate.

A sample of the material is extracted with petroleum ether. The petroleum ether is removed and evaporated to dryness. The addition of Duquenois reagent followed by concentrated hydrochloric acid will yield a purple colour after a few minutes. The addition of chloroform should result in a purple colour in the chloroform layer. This result can be taken positive for cannabinoids.

TLC

- TAH: THC $R_f = 0.50$; CBD $R_f = 0.60$; CBN $R_f = 0.45$
- Visualisation is by fast blue BB with THC showing a red colour, CBD showing an orange colour and CBN showing a purple colour.

Microscopic examination of cannabis/cannabis resin

The most characteristic botanical feature visible under the microscope is the hairs. There are two types of hair:

- Cystolithic hairs
- Glandular hairs.

The cystolithic hairs contain a deposit of calcium carbonate at their base. These hairs are mostly single celled. The glandular hairs are most important since they contain and secrete the resin. They are short and may be unicellular or multicellular. The bigger glandular hairs have a multicellular stalk with heads containing 8–16 cells (Fig. 11.7).

The microscopic test is carried out by putting a small portion of the dry material (cannabis herbal material or cannabis resin) on a microscope slide. A few drops of Duquenois reagent are added followed by a few drops of concentrated hydrochloric acid. The cystolithic hairs contain a deposit of calcium carbonate at their base and a characteristic effervescence can be observed. The heads at the end of the glandular hairs will become a red/purple colour.

An alternative method is to add a few drops of chloral hydrate solution to the dry material. This is particularly useful for getting more detailed information on the structure of the plant tissue since it removes coloured materials such as chlorophyll.

Quantitative analysis and comparison of cannabis/cannabis resin

As already stated, cannabis resin is normally produced in 250 g blocks. Frequently these blocks carry an impression, e.g. a number or a letter or a symbol. Comparison can be made between different blocks on the basis of similar impressions, though unrelated blocks often have the same impression. The street-level deal of cannabis resin is typically a finger-sized portion (normally 1–10 g) possibly wrapped in tinfoil or plastic. It may be possible to link a smaller piece of cannabis resin to its original block by a physical fit between the smaller and larger pieces.

GC or HPLC may be used to obtain a chemical profile of the cannabis/cannabis resin (see Tables 11.5 and 11.6). The THC content can be calculated and comparison can be made on that basis. It must be noted that variations can occur in the THC content of a single block of cannabis resin as the THC content decreases with age and storage conditions. The outer material in a block of cannabis resin can differ from that in the centre. The variation of distribution of cannabinoids within blocks of resin was studied and it was noted that composition of the resin changed even within a 12-month period (Lewis *et al.* 2005). The main chemical constituents of cannabis have been well documented (Elsohly, Slade 2005).

The THC contents of the various forms of cannabis can vary enormously. For example, recent seizures of cannabis in the UK had the following THC contents: sensemilla (indoor intensively cultivated herbal cannabis), mean 16.2%, range 4.1–46%; imported herbal material, mean 8.4%, range 0.3–22%; resin (mostly from North Africa), mean 5.9%, range 1.3–28% (Hardwick, King 2008).

Short tandem repeat (STR) DNA markers have been used to indicate the likely origin of a cannabis crop and STR markers can permit the identification of hydroponically propagated clonal drug lines, providing evidence to link illegal operators (Gilmore *et al.* 2007).

Cocaine

Cocaine is a naturally occurring alkaloid found in certain varieties of plants of the genus *Erythroxylum*. Coca cultivation is distributed throughout the central and northern Andean Ridge, with approximately 60% in Peru, 30% in Bolivia, and the remainder in Columbia, Ecuador, Venezuela, Brazil, Argentina and Panama.

Cocaine production

Production of illicit natural cocaine involves three steps:

1. Extraction of crude coca paste from the coca leaf.
2. Purification of the coca paste to cocaine base.
3. Conversion of cocaine base to cocaine hydrochloride.

Cocaine is normally encountered in the laboratory in paper or plastic packs of white powder and can be analysed without extraction.

Analysis of cocaine

Colour test Cobalt thiocyanate test or modified cobalt thiocyanate test (Scott test): a blue colour indicates the presence of cocaine.

Odour test A 5% methanolic solution of sodium hydroxide added to the test sample and warmed gives a characteristic odour in the presence of cocaine.

TLC

- TA: $R_f = 0.65$; TB: $R_f = 0.47$
- Visualisation is with acidified iodoplatinate solution.

Separation/identification

(For analytical data see Tables 11.5 and 11.6.)

In addition to GC and HPLC, IR spectroscopy is routinely used in cocaine cases if a distinction is to be made between cocaine as a salt, e.g. cocaine hydrochloride, and cocaine in base form. The cocaine base is known as crack and, unlike cocaine hydrochloride, can be consumed by smoking. The differences in their IR spectra are shown in Fig. 11.8.

The differences in the spectra at 1736 and 1709 cm^{-1} for the base and 1729 and 1711 cm^{-1} for the hydrochloride are explained (Elsherbini 1998) by the effect of the hydrochloride ion on the C=O stretching bands.

A simple laboratory test also exists for the determination of the chemical form of cocaine (Logan *et al.* 1989).

Quantitative analysis and profiling of cocaine samples

Quantitative analysis of cocaine samples may be carried out by GC or HPLC. The general quantitation method previously described may also be used for cocaine. In some jurisdictions, preparations containing less than 0.1% cocaine base are exempt from certain controls and analytical procedures must be designed to accommodate this.

Because of the unsophisticated nature of the cocaine manufacturing process, a multitude of trace-level alkaloid impurities are present in illicit cocaine. Many of these impurities are naturally occurring alkaloids that originate from the coca leaf and are carried through the manufacturing process. In addition, cocaine is also contaminated with a variety of manufacturing by-products. The relative amounts of these compounds can be used to compare cocaine samples (Moore, Casale 1998).

The alkaloid impurities, which originate in the coca leaf, include *cis*- and *trans*-cinnamoylcocaine, tropacocaine, truxillines and hydroxycocaines.

Manufacturing by-products found in illicit cocaine include hydrolysis products such as benzoylecgonine, ecgonine methyl ester, ecgonine and benzoic acids.

Oxidation by-products also arise and these include *N*-norcocaine and *N*-norecgonine methyl ester. New impurities arising from the oxidation of crude cocaine base have been reported recently (Casale *et al.* 2007).

In addition to the above, solvent residues may be detected by NMR or headspace GC. The solvents detected include acetone, methyl ethyl ketone, benzene, toluene and diethyl ether (Cole 1998).

A comparison of cocaine samples can be achieved by a combination of qualitative analysis for the presence/absence of certain trace impurities and by quantitative analysis of the cocaine and other ingredients. Isotope ratio analysis has also been used in the profiling of cocaine (Benson *et al.* 2006). A recent study explored the optimisation and harmonisation of a profiling method for cocaine in two separate laboratories using eight main alkaloids as the comparators (Lociciro *et al.* 2007).

Heroin

Street-level heroin (diamorphine, diacetylmorphine) is normally encountered in the laboratory in paper or plastic packs containing typically 100–200 mg of brown (and sometimes white) powder. The street-level purity varies depending on availability and other factors, but values of 40–60% are common.

Production of heroin

The raw material for the production of heroin is opium. Opium is a naturally occurring product of the plant *Papaver somniferum* L. (opium poppy).

Opium is purified to form crude morphine. The morphine is acetylated with acetic anhydride to produce diacetylmorphine, the primary constituent of illicit heroin samples. Sometimes known as 'Chinese heroin', heroin from south east Asia is a white powder consisting of heroin hydrochloride and minor amounts of other opiate alkaloids, but adulterants are unusual. This material is ideally suited to injection. Heroin from south west Asia is a much cruder product. Typically seen as a brown powder containing heroin base, it has variable amounts of other opiate alkaloids (e.g. monoacetylmorphine, noscapine, papaverine and acetylcodeine) as well as adulterants such as caffeine and paracetamol. It is believed that these cutting agents are added to heroin either at the time of manufacture or during transit. Brown heroin may be 'smoked' by heating the solid on a metal foil above a small flame and inhaling the vapour. Those intending to inject brown heroin must first solubilise it with, for example, citric acid or ascorbic acid.

Analysis of heroin

Colour test Marquis reagent gives a purple/violet colour.

Other opiate alkaloids (morphine, codeine, monoacetylmorphine and acetyl codeine) give the same positive reaction to the Marquis test.

TLC

- TA: $R_f = 0.47$. TB: $R_f = 0.15$
- Visualisation is with acidified iodoplatinate solution.

Separation/identification

(For analytical data see Tables 11.5 and 11.6.)

Quantification and profiling of heroin

Heroin may be quantified by either GC or HPLC. A problem associated with GC analysis is that heroin may hydrolyse to 6-*O*-monoacetylmorphine and/or transacetylation may occur of the common cutting agent paracetamol by heroin in the injection port of the GC column. The use of fresh samples and of chloroform as solvent can avoid these problems.

By examining the amount of heroin, papaverine, noscapine and acetylcodeine in the samples it is possible to discriminate between or show a link between samples (Besacier, Chaudron-Thoxet 1999; Dufey *et al.* 2007; Seta *et al.* 1994; Stromberg *et al.* 2000). This method of comparison was used successfully on 500 heroin samples that were divided into nine groups (Zhang *et al.* 2004). It may be further possible to examine heroin samples and show potential links between samples by the presence (and amount) of adulterants such as caffeine or by the presence of less common adulterants such as diazepam, phenobarbital

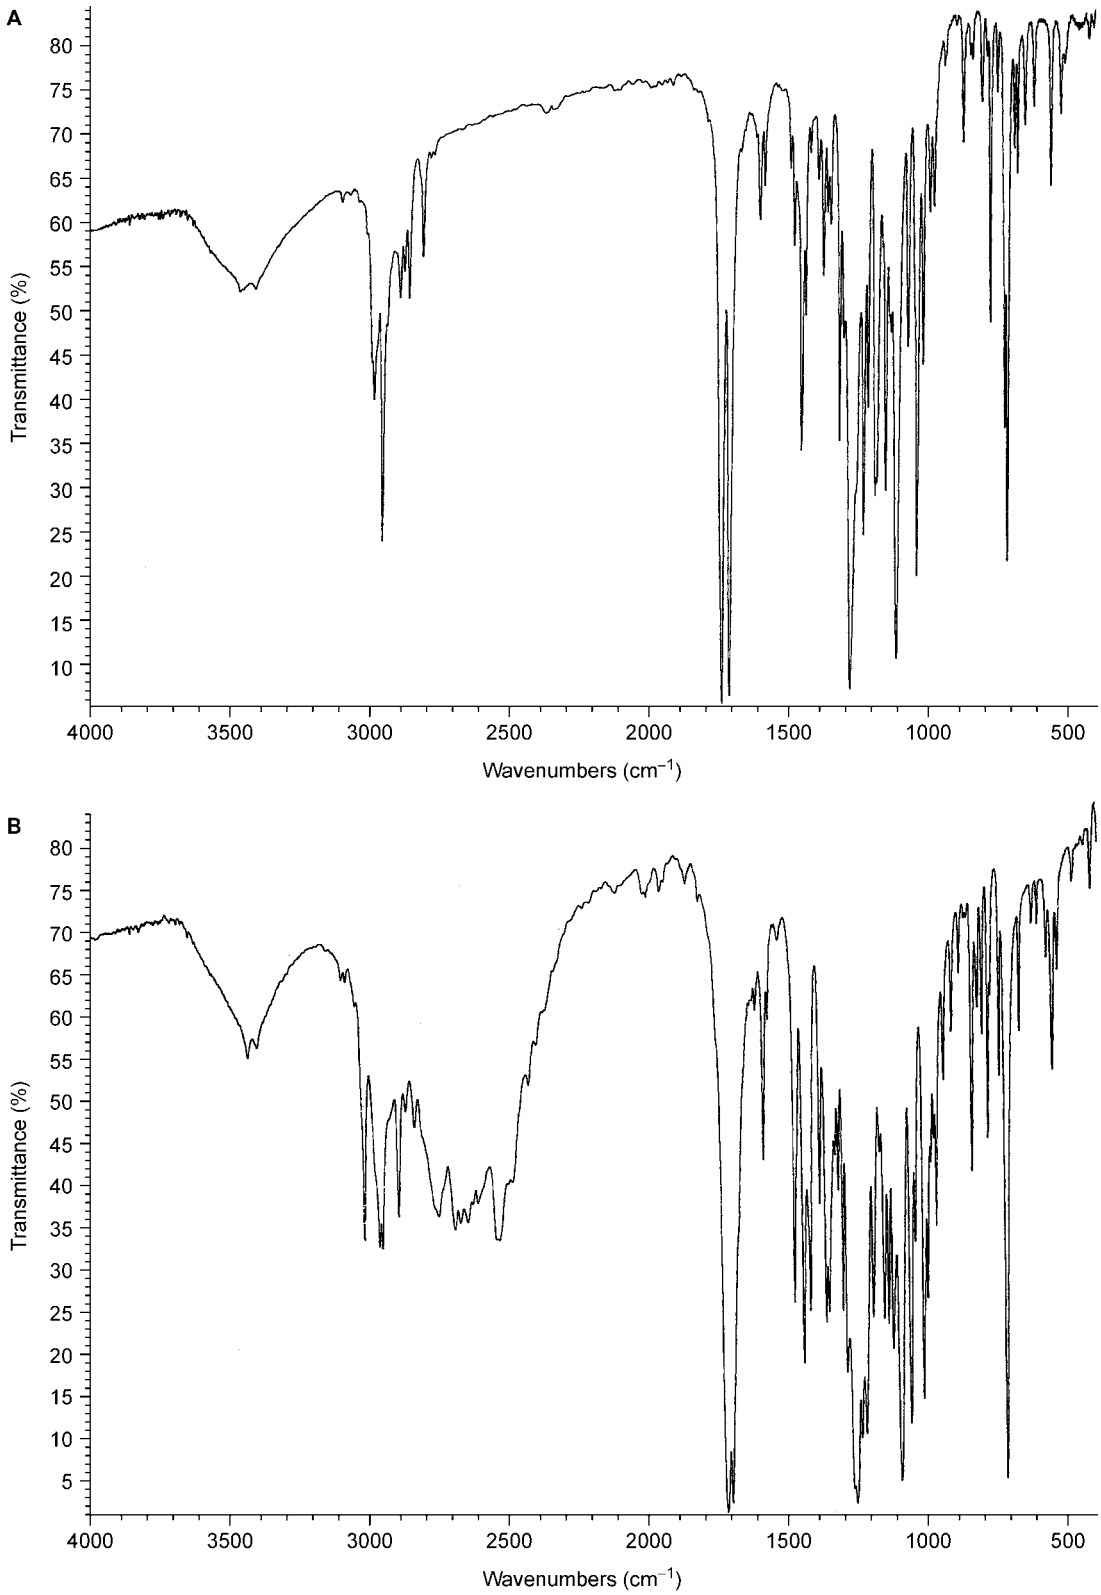

Figure 11.8 Infrared spectra of (A) cocaine base and (b) cocaine hydrochloride.

or mannitol hexa-acetate (El Haj *et al.* 2004). In large seizures, differences may be found between various samples originating from the seizure that indicate that it includes more than one batch of heroin. Chemical profiling was used to determine the country of origin of heroin samples in Australia (Collins *et al.* 2006) and stable isotope analysis was used to complement the chemical profiling on the same samples (Casale *et al.* 2006). Isotope ratio analysis has increasingly been used as a comparison tool for heroin (Carter *et al.* 2005; Zhang *et al.* 2005).

In addition to examining the relative ratios of the main components, it is possible to analyse for solvent residues (Cole 1998; Dams *et al.* 2001).

LSD

LSD is one of the most potent hallucinogenic substances known. Its properties were first discovered in the 1930s and its popularity as a drug of abuse was very high during the 1960s and 1970s when it was associated with the hippy movement.

Synthesis of LSD

LSD can be produced by several different methods, the majority of which use lysergic acid as the starting material. Lysergic acid itself is also produced in clandestine laboratories using, most commonly, ergometrine or ergotamine tartrate as the starting material. Ergotamine refluxed with potassium hydroxide and hydrazine in an alcohol–water mixture produces lysergic acid.

The methods used for the production of LSD yield a crude product, which is then cleaned up and converted to a more stable form, e.g. the tartrate salt.

In the past, LSD was encountered in a variety of substrates including powder in gelatine capsules, gelatine squares, sugar cubes and 'microdots'. Nowadays LSD is encountered mostly in paper dose form. The paper dosages are produced by soaking pre-printed paper in a solution of LSD. These sheets are then perforated into squares (typically 5×5 mm) with each square ('tab') containing approximately 50 µg of LSD.

The designs on the paper can vary from one design per square to one large design covering many squares (Fig. 11.9).

Analysis of LSD

The only analogue of LSD to receive widespread interest is lysergic acid *N*-(methylpropyl)amide (LAMPA) and any analytical technique should be capable of separating LAMPA from LSD.

The presence of LSD may be signalled early by placing the suspect paper under long-wavelength UV light. The presence of LSD is indicated by a blue fluorescence.

Colour test Van Urk reagent gives a purple colour.

TLC

- TAI: LSD $R_f = 0.58$; LAMPA $R_f = 0.49$
- Visualisation: observe the plate under UV light (254 and 365 nm)
- Spray with Van Urk reagent and heat to give a blue spot.

Separation/identification

(For analytical data see Tables 11.5 and 11.6.)

Some difficulty may be encountered in obtaining an unequivocal identification of LSD is because of its low dosage (50 µg or less). However, if the sample is concentrated, a satisfactory analysis can be achieved.

Place a suspect LSD square in a glass vial and cover with methanol. After soaking (or sonication) for 10–20 min, the methanol can be transferred to a plastic insert for analysis. Another method is to add concentrated ammonia (~2 drops) to the methanol.

In addition to chromatographic separation, LSD can be discriminated from other ergot alkaloids by its MS fragmentation pattern; for example, the presence in the LSD spectrum of a *m/z* 100 fragment nearly as intense as the as the *m/z* 111 fragment differentiates LSD from other di-substituted amides (Clarke 1989).

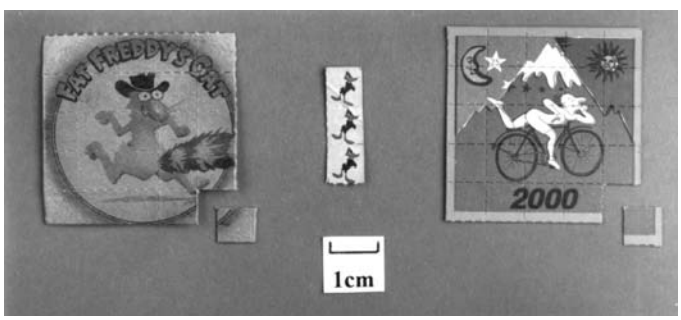

Figure 11.9 Examples of LSD paper squares.

Quantitative analysis and comparison of LSD

HPLC is the method of choice for quantitative analysis of LSD. Using the solvent mixture methanol–water (1 : 1), quantitative extraction of LSD from paper squares is normally achieved after sonication for 20 min (McDonald *et al.* 1984).

In some instances, a comparison is requested between one square of LSD and a large sheet of perforated squares. This can be an easy matter if the design on the large sheet spreads over the whole sheet and the 'missing' square fits neatly into the pattern. In other instances, the design may be on each individual square (or there may be no design). In such a case it is necessary to examine the colour/design/dimensions of the squares and the perforation pattern.

Chemical comparisons can also be undertaken, but squares from the same larger sheet can vary in the amount of LSD on each square.

MDMA

MDMA is the prototypical member of a large series of phenethylamine designer drugs and has become one of the main drugs of abuse in many countries in northern Europe. Clandestine production is largely centred in Europe. A number of homologous compounds with broadly similar effects, e.g. MDA (methylenedioxyamfetamine), MDEA (methylenedioxyethamfetamine) and MBDB (*N*-methyl-1-[1,3-benzodioxol-5-yl]-2-butanamine) have also appeared, but have proved less popular. These substances are collectively known as the 'ecstasy' drugs.

MDMA is the most common drug encountered in 'ecstasy' tablets. The tablets are typically 10 mm in diameter, either flat or biconvex, and weigh approximately 300 mg. The MDMA content varies but is generally in the range 80–100 mg per tablet. The tablets normally carry a characteristic logo/imprint. These designs are not restricted to MDMA tablets, but may be found on amfetamines and other illicit products. In other words, the logo and other physical characteristics provide no reliable information on the drug content. Many hundreds of different impressions have been found and several examples are shown in Fig. 11.5.

Synthesis of MDMA

Several methods of synthesis can be employed including:

1. Amine displacement method using safrole as the starting material.
2. Via the intermediate 1-(3,4-methylenedioxyphenyl)-2-propanone (MDP2P) with isosafrole or a nitrostyrene as starting material.

Analysis of MDMA

Colour test Marquis test gives a blue/black colour.

TLC

- TA: $R_f = 0.31$; TB: $R_f = 0.23$
- Visualisation is with acidified iodoplatinate solution.

Separation/identification

(For analytical data see Tables 11.5 and 11.6.)

Base extraction into an organic solvent and/or derivatisation prior to GC-MS analysis is common with MDMA.

Quantitative analysis and profiling/comparison

In order to perform a quantitative analysis on 'ecstasy' tablets they must first be ground to produce a homogeneous powder and the MDMA content determined by either GC (either directly or base extracted) or HPLC.

Chemical profiling of tablets containing MDMA involves the examination/quantification of the drug and main adulterants present such as caffeine, sugars and binding agents. In addition to the main ingredients, many trace-level impurities from the synthetic process can be present and these can be used for comparison (Bohn *et al.* 1993; Renton *et al.* 1993). A cross-laboratory study on organic impurity profiling of MDMA tablets based on 46 organic impurities yielded separation between population of samples from the same synthesis batch and samples from different batches (Weyermann *et al.* 2008). Trace metal analysis has proved to be a useful method for comparing MDMA tablets (Koper *et al.* 2007; Waddell *et al.* 2004). The metals arise in the tablets as a result of the catalyst or reducing agent in the synthesis. Isotope ratio analysis has also been used to discriminate between different tablets

containing MDMA (de Korompay *et al.* 2008; Palhol *et al.* 2004). Recent advances in impurity profiling in MDMA tablets have employed a variety of techniques, with multiple techniques being used in many situations (Waddell-Smith 2007).

As already mentioned, tablet comparisons can also be made using (so-called) ballistic analysis. In this, general physical features and microscopic examination of defects and punch marks are used for comparison. The difficulty is that, at any one time, a large fraction of illicit tablets in circulation may be almost identical.

Anabolic steroids

Anabolic steroids may be abused by 'body builders' and athletes. In the UK, 48 steroids are listed specifically and generic legislation covers certain derivatives of 17-hydroxyandrostan-3-one or 17-hydroxyestran-3-one. Methandienone, nandrolone, oxymetholone, stanozolol, and testosterone and its esters account for most cases. Further non-steroidal anabolic compounds are also controlled, i.e. human chorionic gonadotrophin (HCG), clenbuterol, non-human chorionic gonadotrophin, somatotropin, somatrem and somatropin. Certain anabolic steroids are scheduled in the US Controlled Substances Act, but these drugs are not listed in the UN Conventions. A large number of the anabolic steroids encountered in seizures have been found in counterfeited packaging and the drug content may differ qualitatively or quantitatively from what is indicated in the information on the product label. This mislabelling can be particularly frustrating to the forensic chemist trying to identify the particular steroid in the product. Formulations may be either as tablets or as steroid esters dissolved in vegetable oil suitable for injection. The oils may be extracted using a steroid : hexane : methanol ratio of 1 : 2 : 1 (Chiong *et al.* 1992) with the methanol layer being used for analysis.

Because of the large number of steroid products available, analytical information is presented here on only four: fluoxymesterone, nandrolone, testosterone and methyltestosterone. Further information on the analysis of anabolic steroids in urine is to be found in Chapters 6 and 7 on Drugs in sport.

Analysis of steroids

TLC

- TP: fluoxymesterone $R_f = 0.51$; nandrolone $R_f = 0.87$; testosterone $R_f = 0.60$; methyltestosterone $R_f = 0.70$
- TQ: fluoxymesterone $R_f = 0.09$; nandrolone $R_f = 0.48$; testosterone $R_f = 0.07$; methyltestosterone $R_f = 0.16$
- Visualisation is with ethanol–sulfuric acid or *p*-toluene sulfonic acid solution.

Separation/identification

(For analytical data see Tables 11.5 and 11.6.)

Benzodiazepines

There are 34 benzodiazepines listed in Schedule 4 of the UN 1971 Convention. Most are now rarely prescribed and abuse is largely restricted to pharmaceutical preparations containing diazepam, flunitrazepam, nitrazepam, flurazepam and temazepam. They may be used in conjunction with opiates (e.g. heroin) or in their own right. A particular problem occurred in Scotland during the mid-1990s when the contents of gel-filled temazepam capsules were injected. Abuse of temazepam declined following the withdrawal of capsules from the market and their replacement with tablets. In other countries, flunitrazepam became the most widely abused benzodiazepine. This drug also gained a certain notoriety for its association with 'date-rape'. For these reasons, flunitrazepam was moved to Schedule 3 of the UN 1971 Convention and is therefore subject to more stringent controls.

Analytical information is presented here only for diazepam, flunitrazepam, nitrazepam and flurazepam.

Analysis of benzodiazepines

Colour test Zimmerman's test: reddish-purple or pink indicates the possiblility of some of the benzodiazepines.

TLC

- TA: diazepam $R_f = 0.75$; flunitrazepam $R_f = 0.63$; nitrazepam $R_f = 0.62$; flurazepam $R_f = 0.68$
- TB: diazepam $R_f = 0.23$; flunitrazepam $R_f = 0.10$; nitrazepam $R_f = 0.30$; flurazepam $R_f = 0.00$
- Visualisation is with acidified iodoplatinate solution.

Separation/identification

(For analytical data see Tables 11.5 and 11.6.)

GHB and analogues

γ-Hydroxybutyric acid (GHB) was originally developed as an anaesthetic drug and is still used for that purpose in some countries. It acts as a central nervous system depressant and hypnotic, and is chemically related to the brain neurotransmitter GABA (γ-aminoxybutyric acid). Synonyms include sodium oxybate, γ-OH, somatomax, 'GBH' and 'liquid ecstasy'. The effects of GHB have been likened to those produced by alcohol and there are claims that it has anabolic properties. GHB is easily manufactured by adding aqueous sodium hydroxide to γ-butyrolactone (GBL) to leave a weakly alkaline solution. Not only is the precursor GBL widely used as an industrial solvent, it can also be ingested directly to produce the same effects as GHB. Illicit GHB is normally sold in solution as a clear liquid in 30 mL opaque plastic bottles. The typical dose is around 10 mL equivalent to about 1 g or more of GHB. The sodium and potassium salts of GHB are hygroscopic. This property mean that GHB is almost never found as a powder or in tablets.

Analysis of GHB

The legal distinction between GHB and GBL, coupled with the potential for GBL to undergo interconversion with GHB, raises important issues in the analytical approach to GHB analysis. The potential exists for aqueous-based GBL products to undergo conversion to GHB in the time between manufacture and consumption. Some of the factors affecting this interconversion have been explored (Ciolino *et al.* 2001).

Colour test With 1% cobalt nitrate a pink to violet colour is indicative of GHB.

Separation/identification

(For analytical data see Tables 11.5 and 11.6.)

GC analysis of GHB samples will result in conversion of GHB to GBL, thus necessitating the need for derivatisation prior to analysis (Blackledge, Miller 1991).

Test samples are taken to dryness under a stream of dry air. Samples are then derivatised with 99 : 1 *N*,*O*-bis(tri-methylsilyl)trifluoroacetamide (BSTFA) : trimethylchlorosilane (TMCS) in the presence of pyridine and incubated at 70°C for 30 min.

GHB is detected as the di-trimethylsilyl (TMS) derivative and GBL does not form a silyl derivative.

HPLC can be used without derivatisation (Mesmer, Satzger 1998).

In a study of the reaction of GHB with alcohol it was found that an ester was formed under certain conditions and this can be separated from both GHB and GBL by HPLC and GC (Hennessy *et al.* 2004). Capillary electrophoresis has been used to separate GHB, GBL and 1,4-butanediol (Dahlen, Vriesman 2002). Carbon isotope ratio analysis has been used to examine the discrimination between endogenous and exogenous GHB (Saudan *et al.* 2007).

Khat

Catha edulis is a flowering evergreen shrub cultivated in East Africa and the Arabian Peninsula. The leaves and fresh shoots are commonly known as khat, qat or chat. Khat can be used by chewing the leaves or by brewing as a 'tea' and daily consumption can be up to several hundred grams. Khat has stimulant effects similar to those of amfetamine. Alcoholic extracts (tinctures) of khat have been noted especially in 'herbal high' sales outlets and at music festivals.

The active components of khat, cathinone ((−)-1-aminopropiophenone) and cathine ((+)-norpseudoephedrine), are usually present at around 0.3–2.0% (Lee 1995). Both substances are close chemical

relatives of synthetic drugs such as amfetamine and methcathinone. Khat must be used fresh as the more active cathinone begins to deteriorate rapidly after harvesting. Both cathine and cathinone are scheduled under the UN 1971 Convention, but khat itself is only specifically listed in a few jurisdictions.

Analysis of khat

Approximately 5–6 g of plant material is cut into small pieces. Methanol (15–20 mL) is added and sonicated for 15 min. The green methanolic solution is filtered/decanted and condensed to near dryness. Approximately 20 mL of 0.2 mol/L sulfuric acid is added and the solution acquires a reddish hue. A chloroform extract will remove the neutral organic compounds. The aqueous layer (red layer) is basified with saturated sodium bicarbonate solution. Methylene chloride (20 mL) is added to extract the cathinone and cathine. A stream of air is used to reduce the volume to approximately 1 mL.

Colour test Cathinone gives no reaction with Marquis reagent, but does produce a slow-forming yellow/orange colour with Chen's reagent.

TLC

- TE: cathinone $R_f = 0.46$; cathine $R_f = 0.25$
- Visualisation: UV (254 nm) and 0.5% ninhydrin with cathinone showing an orange colour and cathine a purple colour.

Separation/identification

(For analytical data see Tables 11.5 and 11.6.)

Psilocybe mushrooms

The hallucinogenic substances psilocin and its phosphate ester psilocybin occur in a number of fungi, particularly those of the genus *Psilocybe*. These are small grey mushrooms which grow wild over large areas. Although such material is not in itself controlled, and neither is its cultivation, it has been held in UK case law that the deliberate drying or processing of these mushrooms constitutes preparation of a controlled drug.

Analysis of psilocybe mushrooms

A small quantity (approximately 1 g) of the dried mushrooms is sonicated with methanol (approximately 5 mL) for 10 min. The liquid is removed and reduced in volume at room temperature in an air flow. Psilocybin can be converted to psilocin by heating. This conversion can also occur if the mushrooms are not dried prior to or when they arrive into the laboratory.

Colour test Ehrlich reagent: a violet colour is indicative of psilocybin and psilocin

TLC

- TAN: psilocybin $R_f = 0.34$; psilocin $R_f = 0.59$
- TA: psilocybin $R_f = 0.05$ psilocin $R_f = 0.39$
- Visualisation is with Van Urk's reagent, with both compounds showing a blue/violet colour.

Separation/identification

(For analytical data see Tables 11.5 and 11.6.)

Direct injection of psilocybe mushroom extracts onto a GC column will convert psilocybin to psilocin by thermal dephosphorylation and only psilocin will be detected. Thus prior derivatisation is necessary if psilocybin is to be detected.

To eliminate sugars that may interfere with derivatisation, 1 mL of acetone is added to the methanolic solution and the mixture allowed to stand for 30 min and then filtered. The solution is taken to dryness in a stream of air. Pyridine (15 µL), TMCS (15 µL) and BSTFA (100 µL) are added and heated at 100°C for 30 min.

Psilocin is converted to psilocin di-TMS and psilocybin to psilocybin tri-TMS. LC-MS and LC-MS-MS have also been used to analyse the constituents of magic mushrooms (Kamata *et al.* 2005).

'Designer Drugs'

Although a few ring-substituted phenethylamines (e.g. 2,5-dimethoxy-4-bromoamfetamine (DOB), 4-bromo-2,5-dimethoxyamfetamine) had been subject to limited abuse since the 1960s, it was not until the 1980s that the phenomenon of so-called designer drugs was fully recognised.

Starting in the late 1980s, a large series of designer drugs began to appear, all of which were based on the phenethylamine nucleus. Just as with the production of the major illicit phenethylamines (e.g. MDMA), much of this synthetic activity took place in Europe.

Table 11.7 lists a number of designer drugs that have appeared in Europe and the USA since the mid-1990s. This list, which may not

Table 11.7 Designer drugs reported in Europe and the USA since the mid-1990s

Compound/drug	*Acronym*	*UN/UK*
Ring-substituted phenethylamines		
3,4-Methylenedioxyamfetamine	MDA	+/+
3,4-Methylenedioxymetamfetamine	MDMA	+/+
3,4-Methylenedioxyethylamfetamine	MDE(A)	+/+
4-Bromo-2,5-dimethoxyamfetamine	DOB (Bromo-STP)	+/+
4-Methoxyamfetamine	PMA	+/+
N-Hydroxy-MDA	N-OH MDA	+/+
3,4-Methylenedioxypropylamfetamine	MDPA	−/+
N-Methyl-1-(1,3-benzodioxol-5-yl)-2-butanamine	MBDB	−/+
1-(1,3-Benzodioxol-5-yl)-2-butanamine	BDB	−/+
4-Bromo-2,5-dimethoxyphenethylamine	2C-B	−/+
3,4-Methylenedioxydimetamfetamine	MDDM	−/P
2,5-Dimethoxy-4-(*n*)-propylthiophenethylamine	2C-T-7	−/+
4-Allyloxy-3,5-dimethoxyphenethylamine	AL	−/+
3,5-Dimethoxy-4-methylallyloxyphenethylamine	MAL	−/+
N-Hydroxy-MDMA	FLEA	−/P
2,5-Dimethoxy-4-chloroamfetamine	DOC	−/+
4-Methylthioamfetamine	4-MTA	−/P
2,5-Dimethoxy-4-ethylthiophenethylamine	2C-T-2	−/+
4-Methoxy-*N*-metamfetamine	Me-MA	−/+
6-Chloro-MDMA	—	−/+
N-(4-Ethylthio-2,5-dimethoxyphenethyl)-hydroxylamine	HOT-2	−/+
2,5-Dimethoxy-4-iodo-phenethylamine	2C-I	−/+
4-Methoxy-*N*-ethylamfetamine	—	−/+
***N*-Substituted amfetamines without ring substitution**		
N-Hydroxyamfetamine	N-OHA	−/P
N,N-Dimetamfetamine	—	−/−
N-Acetylamfetamine	—	−/−
Di-(1-phenylisopropyl)amine	DIPA	−/−
Tryptamines		
N,N-Dimethyl-5-methoxytryptamine	5-MeO-DMT	−/+
N,N-Di-(n)-propyltryptamine	DPT	−/+
4-Acetoxy-*N,N*-di-isopropyltryptamine	—	−/−
α-Methyltryptamine	α-MT	−/−
Other phenylalkylamines and miscellaneous		
1-Phenethylamine	1-PEA	−/−
N-Methyl-1-phenethylamine	N-Me-PEA	−/−
4-Methyl-1-phenethylamine	4-Me-PEA	−/−
1-Phenyl-3-butanamine	—	−/−
N-Benzylpiperazine	BZP	−/−
Methcathinone	—	+/+

necessarily be complete, shows that the phenethylamines comprise the largest group. Ring-substituted compounds were more common than *N*-substituted homologues without ring substitution. The substances shown in Table 11.7 have appeared both as powders and as tablets, often manufactured, packaged or marked in such a way that they may appear to the user to be amfetamine or MDMA. Considerable scope exists to develop further series of phenethylamine-related 'designer drugs'. Thus ring-substituted analogues of cathinone and methcathinone might have MDMA-like activity.

As mentioned earlier, the EU, via Europol and EMCDDA, carry out risk assessments on new synthetic drugs. Since 1997 ten risk assessments have been undertaken on the following drugs: MBDB, 4-MTA, GHB, ketamine, *p*-methoxymethamphetamine (PMMA), 2C-1, 2C-T-2, 2C-T-7, TMA-2 and benzylpiperazine (BZP). Various studies have outlined the analytical methods available to separate and identify these and other designer drugs (Blachut *et al.* 2002; Furnari *et al.* 1998; Poortman, Lock 1999; Tsai *et al.* 2006) A detailed chemical identification of DOB has been described using CE, IR spectroscopy and GC-MS (da Costa *et al.* 2007). Raman spectroscopy has been used as a screen for tablets containing DOB (Bell *et al.* 2007).

Piperazines have increasingly become an alternative to amfetamine-derived drugs of abuse (EMCDDA 2005). Among the most prominent of these have been *N*-benzylpiperazine (BZP), 1-(3-trifluoromethylphenyl) piperazine (TFMPP) and 1-(3-chlorophenyl)piperazine (mCPP). The legal status of piperazines is very inconsistent and many European countries are considering control measures, while others already control mCPP (EMCDDA 2005). In the USA, BZP and TFMPP were temporarily placed into Schedule 1 of the Controlled Substances Act in 2002 followed by final placement of BZP into Schedule 1 2004. In 2003 both BZP and TFMPP were controlled in Japan.

The analysis of aryl-piperazines has been carried out by HPLC and GC-MS with and without derivatisation (de Boer *et al.* 2001; Tsutsumi *et al.* 2005). Analytical profiles covering a range of techniques have been reported for a number of tryptamines (Spratley *et al.* 2005).

The approach to the analysis of these compounds, especially the phenethylamine-related 'designer drugs', could be in line with the general procedure outlined for powders and with specific reference to the analytical procedures employed to analyse MDMA or amfetamine.

Those substances listed in UN 1971 or which are controlled in UK by the Misuse of Drugs Act 1971 are shown by (+) in Table 11.7. Substances pending control in the UK are shown by 'P'. In the USA, unscheduled substances may still be deemed to be controlled by virtue of the Controlled Substances Analogue Enforcement Act 1986.

Conclusion

Many other compounds are encountered in the laboratory as 'drugs of abuse' such as opium, phencyclidine and analogues, tryptamines, barbiturates, methadone, morphine, dihydrocodeine, ephedrine, ketamine and alkyl nitrites. However, the general approach to the analysis of an unknown substance previously outlined should pose no difficulty to the identification of any of these drugs. Analytical information and background information on many of the drugs can be found in some of the general texts in the area (CND Analytical 1994; Cole, Caddy 1995; Gough 1991; Karch 1996, 1998; Klein *et al.* 1989; Redda 1989; Shulgin, Shulgin 1991; Smith 2005; UN 1994; Weaver, Yeung 1995).

CHAPTER

12 Medicinal Products

AC Moffat and AG Davidson

Introduction

Medicinal products should be safe and efficacious. Manufacturers of medicinal products are required by law to possess marketing authorisations from government regulatory agencies in countries in which their products are marketed and to manufacture their products in compliance with current Good (Pharmaceutical) Manufacturing Practice (cGMP) standards. These requirements include conducting appropriate quality control tests to check that the product conforms to a specification that assures its safety and efficacy. Typical specifications include tests to verify the chemical composition and physical properties of the medicine and to ensure that the medicine is not contaminated by microorganisms or other substances.

Although authentic medicinal products are subject to quality control testing by the manufacturer, they may have been counterfeited, adulterated or stored poorly, and therefore need to be checked for the following purposes:

- Determine or confirm their composition
- Assess their suitability for use
- Investigate defects
- Identify unknown medicinal products
- Identify contaminants
- Determine whether the products have been adulterated
- Establish whether the products are counterfeit.

Independent quality checks of medicinal products may be carried out by official medicines control laboratories as part of a government surveillance programme, and by hospital quality control laboratories, public analyst laboratories and forensic laboratories.

This chapter describes the philosophies, strategies and methodologies for the analysis and testing of medicinal products by laboratories that may not have access to the manufacturers' research and development data or to the manufacturers' test methods, specifications and reference materials for the products. It focuses on the information about the medicinal product that can be derived from other sources and on the conclusions that can then be made about the quality of the product.

Submission of samples and choice of tests

A wide range of tests that utilise a variety of analytical techniques are available to laboratories. Samples submitted for testing should therefore be accompanied by a clear written request about the nature of the investigation required. The provision of relevant background information about the sample, including the reason for the request, allows the laboratory to choose the most appropriate tests, analytical techniques and, where relevant, acceptance criteria (i.e. criteria that allow an objective assessment to be made about the quality of the product).

In most cases that involve checking of the quality of a medicinal product, it is preferable to use the test methods in the product specification defined in the manufacturer's marketing authorisation for the product. This is because the product specifications, including the test methods and acceptance criteria, have been assessed by the relevant government regulatory agency as being valid and justified. Some manufacturers publish their analytical methods in the scientific literature. Consequently, it may be worthwhile to check the literature or maintain a library of published methods for widely used medicinal products. Alternatively, in certain circumstances, manufacturers may provide the laboratory with the test methods, acceptance criteria and reference materials.

If the laboratory does not have access to the authorised finished product specification, including the test methods and acceptance criteria, pharmacopoeial monographs can be used, where applicable (see later). In the absence of a pharmacopoeial monograph, alternative approaches are required to obtain as much information as possible about the quality of the medicinal product. This requires the development of valid test methods to measure relevant quality parameters and the application of generally accepted criteria to assess the quality. However, if the laboratory uses analytical techniques different from those used by the manufacturer (e.g. a high performance liquid chromatographic (HPLC) technique instead of an ultraviolet (UV) spectrophotometric technique), the results may differ significantly from those obtained by the manufacturer, particularly if high levels of impurities are present. This is because analytical techniques differ in their accuracy, precision, selectivity, and/or specificity and sensitivity. It is therefore important to consider the findings in relation to the technique used.

This chapter describes the tests that should be carried out to provide information about different aspects of medicinal products. A summary of the principal tests and techniques for checking known products and investigating unknown products is given in Table 12.1.

Counterfeit medicines

The World Health Organization (WHO) describes counterfeit medicines as part of the broader phenomenon of substandard pharmaceuticals – medicines manufactured below established standards of quality and therefore dangerous to patients' health and ineffective for the treatment of diseases. The difference is that counterfeits are deliberately and fraudulently mislabelled with respect to identity or source. Counterfeiting occurs with both branded and generic products.

Counterfeit medicines may:

- contain no active ingredient
- contain the wrong active ingredient (e.g. a cheap antibiotic instead of an expensive antibiotic)
- contain an incorrect (usually low) quantity of the active ingredient
- be in low-quality packaging
- be manufactured using low-quality active ingredient or excipients
- be manufactured under poor standards of cGMP compliance.

Counterfeit products that contain no active ingredient and those that contain the wrong active ingredient or the correct active ingredient in the wrong amount can be detected by carrying out appropriate identification and quantitative tests (see below). In situations where resources for accurate and precise quantitative testing are limited, for example in developing countries, basic tests, including semi-quantitative tests, may be sufficient to detect these types of counterfeit medicines (see below).

It may also be possible to identify products as being counterfeit by their general appearance (colour, markings, etc.), particularly when the appearance differs from a genuine batch of the product. For this reason, laboratories that regularly undertake checks for counterfeit medicines maintain a stock of genuine reference products for comparison. Examination of the labelling should also be carried out to check the

Table 12.1 Summary of tests and techniques

Purpose	*Test(s)*	*Analytical technique(s)*[a]	*Comment*
1. General check of quality	Test to full specification		Refer to typical monographs for dosage forms in pharmacopoeias
	Identity	See 2 below	
	Assay	See 5 below	
	Homogeneity	Uniformity of content	
	Contaminants	HPLC, GC, TLC, CE, etc.	
	Release of active ingredient	Dissolution test	
	Microbial quality	TVAC, specific microorganisms, sterility test	
2. Confirm identity of product	Instrumental tests for active ingredient (s)	NIR, IR or combination of UV, HPLC, TLC, colour reaction, melting point, etc.	Instrumental checks provide greater assurance about identity
	WHO basic tests	Colour reactions, TLC	
3. Rapid identification of unknown product	Visual comparison of physical characteristics (size, colour, shape, etc.) against library	TICTAC, Identidex, etc.	See Chapter 13
	Simple screening tests	UV, TLC, HPLC, colour tests	See Chapters 32, 39, 41 and 30
4. Unambiguous identification of unknown products	Specific identification tests	IR, NMR, LC-MS, GC-MS, CE, chiral HPLC (for enantiomeric substances), AAS (for inorganic moieties)	See relevant chapters on these techniques
5. Quantification of active ingredient(s)	Assay	HPLC, GC, UV, CE	See relevant chapters on these techniques
6. Homogeneity of active ingredient	Uniformity of content (or mass)	Assay of several (e.g. 10) dosage units or subsamples of the product	Uniformity of content preferred, particularly for unit doses with a content of active substance <25 mg or 25% of the total mass
7. Investigation of reduced efficacy	Assay Dissolution	HPLC, GC, CE	Stability-indicating assay[b] and discriminating dissolution test[c] required
8. Investigation of side-effects or contamination	Drug-related impurities	HPLC, GC, CE, TLC, etc.	
	Solvent residues	GC, GC-headspace	
	Non-drug-related contaminants	Screening techniques, e.g. HPLC, GC, TLC, LC-MS, GC-MS	
	Dissolution (to detect 'dose-dumping' of the active ingredient)[d]		
	Microbial contamination	TVAC, specific microorganisms	
9. Investigation of counterfeit medicines	Rapid identification test	See 3 above	
	NIR and impurity profiling	See 2 above	
	Identification of unknown drugs	See 4 above	
	Identification of manufacturer		

AAS, atomic absorption spectroscopy; CE, capillary electrophoresis; GC, gas chromatography; HPLC, high performance liquid chromatography; IR, infrared; LC, liquid chromatography; MS, mass spectrometry; NIR, near infrared; NMR, nuclear magnetic resonance; TLC, thin-layer chromatography; TVAC, total viable aerobic counts; UV, ultraviolet.
[a]Most tests require extraction of the active ingredient before application of the analytical technique.
[b]A stability-indicating assay is selective for the active ingredient in the presence of decomposition products.
[c]A discriminating dissolution test distinguishes between batches with different bioavailability.
[d]Dose-dumping is release of the active ingredient at a rate faster than intended.

accuracy of the information presented. Labels of products made by counterfeit manufacturers may contain errors that are evident to an expert. The quality of the packaging materials and of the printing should also be inspected carefully and, if possible, compared with that of a genuine batch of the product. Genuine products may contain anti-counterfeiting devices (e.g. holograms) that are difficult to copy.

Many counterfeit products are manufactured under unsatisfactory conditions, which may result in defects that are detectable visually. For example, black marks on sugar-coated tablets may arise from the use of an excessive temperature during the coating process, which chars the sugar. A high level of particulate matter or fibres in parenteral and ophthalmic preparations may indicate poor environmental control during the manufacturing process. Inadequate or faulty sealing of the container or packaging may indicate the use of inappropriate equipment. Physical defects alone may not prove that the product is counterfeit, but their presence may corroborate other indicators of the counterfeit nature of the product.

Direct comparison of products

The direct comparison of an authentic sample and the questioned product is a quick and easy way to detect counterfeit medicines. In this respect, near-infrared (NIR) spectroscopy (see Chapter 34) is rapidly becoming an indispensable analytical technique used by many manufacturers to detect counterfeits of their products. The power of the technique lies in its ability to fingerprint intact products qualitatively and, in favourable circumstances, quantitatively. Anti-counterfeiting application of the technique involves the preparation of a library of

NIR spectra of genuine batches of the product within a pre-defined range of variables. With the correct mathematical transformations, NIR spectra are specific for the medicinal product. This is because NIR spectra depend not only on the active ingredient but also on the nature of the excipients. It may be possible to put the correct amount of active ingredient in a product, but getting the right grade and percentage of excipients in the product is very difficult. The spectra are also very sensitive to changes in particle size, moisture levels and other variables. The authenticity of a batch of a product can be proved by obtaining a good spectral match with the reference library within the defined range of variables. Conversely, failure of a suspect sample to provide a good spectral match indicates that it may be a counterfeit product.

Figure 12.1 shows an example of the use of NIR spectroscopy to compare two questioned batches of Plavix tablets 75 mg (containing clopidogrel as hydrogensulfate) with tablets from an authentic batch. Figure 12.1a shows the authentic and the first questioned batch to be the same, whereas Fig. 12.1b clearly shows the second questioned batch to be very different from the authentic batch and therefore counterfeit.

NIR spectroscopy is not very good for aqueous samples, but ultraviolet (UV) spectrophotometry can easily be used for direct comparison of medicinal products in these cases. Figure 12.2 shows a comparison of an authentic and a question batch of Cosopt Eye Drops which contain: dorzolamide as the hydrochloride 2%, timolol as the maleate 0.5% and benzalkonium chloride 0.0075%. Both spectra show peaks for the two active pharmaceutical ingredients and are almost superimposable, demonstrating that the questioned product is almost certainly authentic.

The usual questions concerning a medicinal product are: does it contain the correct active ingredient and is it at the right amount? Methods to answer these questions are given in the next two sections and basic tests are covered in the following section. Methods for

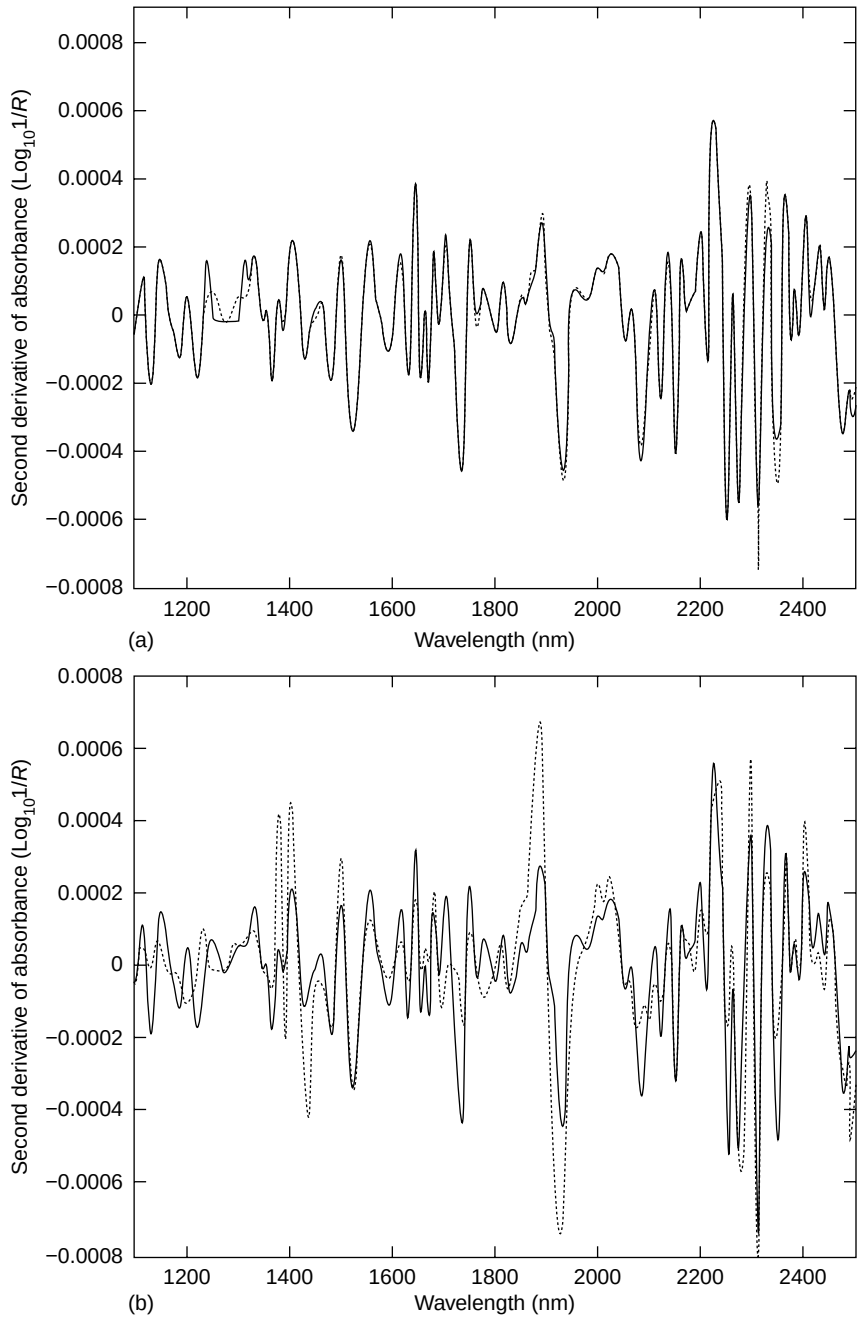

Figure 12.1 Second derivative near-infrared spectra of Plavix tablets 75 mg. (a) Authentic tablets (solid line) and questioned tablets of a different batch which turned out to be authentic (dotted line); correlation coefficient 0.970. (b) Authentic tablets (solid line) and counterfeit tablets (dotted line); correlation coefficient 0.718.

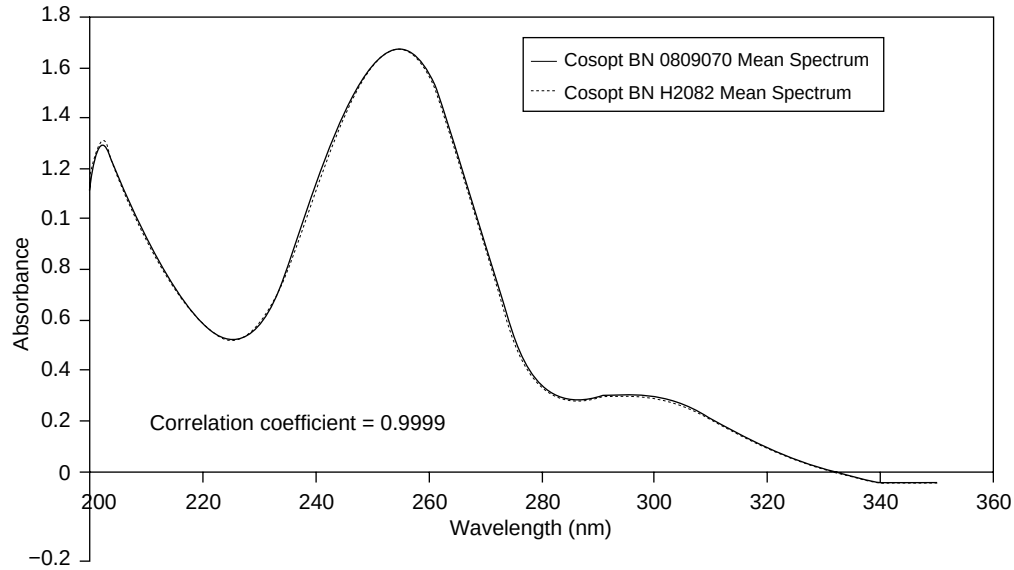

Figure 12.2 Ultraviolet spectra of Cosopt Eye Drops diluted 1 : 1000 in ethanol: authentic eye drops (solid line); questioned eye drops of a different batch which turned out to be authentic (dotted line), correlation coefficient 0.9999; the two spectra are therefore almost totally superimposable. Cosopt Eye Drops contain dorzolamide as the hydrochloride 2%, peak at 255 nm; timolol as the maleate 0.5%, peak at 295 nm; and benzalkonium chloride 0.0075%, no significant absorption due to its low concentration.

profiling medicines in order to compare them, e.g. to substantiate a charge of trafficking, follow.

Identification of active ingredients

The first step in the analysis of a medicine is usually to verify that it does contain the correct active ingredient(s). A visual examination of the medicine should be made (colour, size, shape, marking, etc.) to verify the identity of the product and the label should be examined for information about the active ingredient(s) (see Chapter 13).

The identity tests in the registered finished product specification or pharmacopoeial specification generally are suitable for verifying the identity of the active ingredient. Identity tests in pharmaceutical specifications are not necessarily intended to be absolutely specific, but should be able to distinguish between similar active ingredients. For example, the identity tests in the European Pharmacopoeia (Ph. Eur.) monograph for glycerol now include a test for refractive index to differentiate glycerol from diethylene glycol (DEG). An incident in Haiti in the mid-1990s, in which DEG had been substituted for glycerol in a paediatric product, resulted in the deaths of over 100 children. In 2007 the Food and Drug Administration (FDA) reported the detection of batches of counterfeit toothpaste containing DEG.

Infrared (IR) spectroscopy is one of the most commonly applied analytical techniques for identification. The IR spectrum of the drug substance extracted from the medicinal product should be concordant (in terms of the position and relative intensities of the absorption bands) with a reference spectrum of the substance or with the spectrum of a reference substance (see Chapter 33). For substances with a highly characteristic 'fingerprint' spectrum in the 1600–400 cm^{-1} region, concordance of the spectra provides a high level of assurance about the identity of the active ingredient. Alternatively, a combination of non-selective identity tests can provide a similar level of assurance. For example, in the Ph. Eur. monograph for the drug substance atenolol, verification of the identity of the drug is carried out by IR spectroscopy alone or, alternatively, by a combination of melting point test, thin-layer chromatography (TLC) and UV spectrophotometry. When using these three tests, none of the tests alone is sufficiently selective, but the combination of the three tests provides the level of assurance required. The British Pharmacopoeia (BP) monograph for atenolol injection uses only an IR spectrophotometric test carried out on the residue obtained by extracting the active ingredient from the injection into chloroform followed by drying and evaporation of the solvent. It is more difficult to obtain a pure residue of atenolol from atenolol oral solutions (e.g. syrups) because colouring and flavouring agents in the formulation may co-extract with atenolol and interfere in the IR spectrum. The BP monograph for atenolol oral solution, therefore, uses both TLC and HPLC to verify the identity of the active ingredient.

Identity tests should also be able to distinguish optical isomers and different salts and polymorphic forms of the drug substances. An optical rotation test often suffices to distinguish enantiomers from each other and from a racemic mixture of the two enantiomers. Chiral HPLC (see Chapter 41) may be used to verify the enantiomeric nature of the wanted enantiomer and quantify the unwanted enantiomeric impurity.

The presence of counter-ions of acidic and basic drugs can be confirmed in the bulk substance by standard pharmacopoeial tests for chloride, phosphate, citrate, sodium, calcium, aluminium, etc. When IR and/or melting point tests do not distinguish different polymorphic forms of a drug substance, it may be necessary to use a radiographic diffraction technique.

When the identity of the medicinal product is not stated on the label or on documentation that accompanies the sample, or when the appearance of the medicine does not correspond to that stated on the label, its identity might be determined in a number of ways.

The combination of colour, size, shape, breakbars, markings, etc., of solid oral dosage forms is reasonably characteristic of the medicine, and several systems are available to identify the medicine based on its physical characteristics (see Chapter 13).

When it is not possible to identify the medicine from its appearance (e.g. because of the absence of distinctive colour, shape and markings), physicochemical tests should be carried out to determine the qualitative and quantitative composition of the active ingredients. The chromatographic screening techniques described in this book (TLC, HPLC and gas chromatography (GC)) are particularly useful for this purpose.

Identification of 'rogue' tablets in a container may help to determine whether the rogue tablets are the result of poor manufacturing practices or of malicious adulteration of the product after it has been released onto the market. If the rogue tablets prove to have been manufactured at the same site as the 'correct' tablets, a breakdown of manufacturing standards is indicated. However, if another producer made the rogue tablets, malicious contamination may be more likely.

Medicinal products that are simple aqueous solutions containing active ingredients, with or without excipients, may be injected directly,

or after appropriate dilution with the mobile phase, into a liquid chromatograph. The relative retention time or retention index may allow the active ingredient(s) and excipients to be identified tentatively. Excipients in solid dosage forms and semi-solid dosage forms (e.g. creams and ointments) and in viscous liquids, which are likely to be present in high concentrations in relation to the amount of active ingredient, can interfere in identification tests. Consequently, separation of the active ingredient(s) from the excipients should be carried out to 'clean up' the sample prior to analysis. The choice of solid-phase extraction (Chapter 29) or solvent extraction depends on the relative polarities of the active ingredients and excipients. Extraction of drugs from solid dosage forms can often be carried out with aqueous acid, aqueous alkali or methanol alone, followed by filtration of the extract.

If the extracts show absorption bands in the UV or visible region, reference to the wavelengths of maximum absorption in the individual drug monographs or the Index of Ultraviolet Absorption Maxima may provide a rapid tentative identification of the active ingredient. Confirmatory identification tests should then be carried out by other test methods such as IR spectroscopy, TLC, HPLC and melting point determination.

For viscous liquids and semi-solid dosage forms, it may be necessary to carry out a liquid–liquid extraction to separate the active ingredient(s) from the excipients. The screening extraction procedure described in Chapter 29 (solvent extraction procedure) should be used, followed by a range of screening spectroscopic and/or chromatographic tests.

If forensic standards of proof of identity are required, for example to support litigation or regulatory or enforcement action, a specific identification test should be employed, such as mass spectrometry (MS; see Chapter 37).

Quantification of active ingredients

The content of the active ingredient(s) in a medicinal product is one of the most important quality parameters that assure its efficacy. As with other tests in a specification, if the laboratory does not have access to the assay method specified in the marketing authorisation or if there is no relevant pharmacopoeial monograph for the product, a suitable assay should be developed. It may also be necessary to quantify excipients that have a critical bearing on the safety or efficacy of the product (e.g. preservatives).

Commonly used techniques for the assay of pharmaceuticals that offer the optimum combination of accuracy, precision, selectivity, sensitivity, robustness, speed and accessibility are HPLC (Chapter 41), GC (Chapter 40) and UV spectrophotometry (Chapter 32). Capillary electrophoresis (CE; Chapter 42) and NIR spectroscopy (Chapter 34) are used increasingly for certain applications. Although NIR methods are usually published for the assay of active ingredients in intact proprietary medicines, there is an increasing use of NIR applications for generic medicines, e.g. paracetamol tablets (Shek *et al.* 2006) and ibuprofen tablets (Lo *et al.* 2007). Reference should be made to the relevant chapters in this book and to the Further reading list of this chapter.

As stated previously, the selectivity of different spectrometric and chromatographic techniques may differ markedly, particularly when there are high levels of impurities that are chemically related to the active ingredient. Consequently, care is required in the interpretation of results in relation to the test method employed.

Basic tests for drug substances and products

Some developing countries do not have access to fully equipped laboratories and the use of rapid, basic tests offers a cost-effective alternative approach to the detection of substandard medicines, including counterfeit products. The WHO has published two books to assist such laboratories: *Basic Tests for Drugs* (WHO 1998), which includes pharmaceutical substances, medicinal plant materials and dosage forms, and *Basic Tests for Pharmaceutical Substances* (WHO 1986). The basic tests described, which are designed to verify the identity of drug substances and medicinal products and to detect gross contamination, use a limited range of readily available reagents and equipment.

Tests to verify identity are based on a combination of organoleptic checks and simple physicochemical tests, such as colour reactions ('test-tube methods') and melting point determinations.

Basic tests for degradation products should be carried out for drug substances and drug products that are unstable (e.g. adrenaline (epinephrine) and ampicillin), particularly under conditions of high temperature and humidity, which may occur during transportation and storage. These tests, which are generally based on simple colour reactions, detect only gross contamination.

Semi-quantitative TLC methods have been developed as basic tests using a limited number of solvent systems and detection systems. References to these tests are given in the WHO (1998) text. The tests involve the extraction of one unit dose of the product. For quantification, the spots are compared with reference spots that represent acceptable upper and lower limits (e.g. 80% and 120% of the nominal strength). A single test is, therefore, sufficient to verify (or disprove), with reasonable certainty, the identity of the product and to indicate whether its content is within acceptable limits. Portable test kits based on this principle have been developed for use under non-laboratory conditions (e.g. for testing at importation centres).

It should be emphasised that basic tests are intended not to replace pharmacopoeial requirements but to provide a rapid, inexpensive means to verify identity and strength and possibly detect poor-quality counterfeit and other substandard products. When suspect products are detected, they should be tested for compliance with pharmacopoeial requirements (see below).

Profiling

The intention of this kind of analysis is to compare two medicinal products to show that they have a common origin, identify the synthetic route or determine the site of manufacture. NIR spectroscopy is particularly good at comparing medicinal products because it looks at the whole matrix of the product and not just at the active ingredient. It is relatively easy to compare authentic and counterfeit products (see above), but it is also possible to differentiate generic products containing the same amount of active ingredient (Fig. 12.3) or to identify the site of manufacture of proprietary products (Yoon et al. 2004).

'Impurity profiling' involves the determination of the pattern of drug-related impurities present in a medicinal product. The impurity profile (e.g. by HPLC or GC) of the active ingredient in a genuine product is reasonably consistent from batch to batch because of the consistency of the manufacturing process. If a sample of a product shows a different impurity pattern, this may be through the use of drug substance produced by a different synthetic route and/or active ingredient manufacturer and may indicate that the product is counterfeit.

Impurity profiling may also allow the manufacturer of the drug substance to be identified. This involves developing a separation method that distinguishes ('fingerprints') the impurity profiles of a drug substance from different manufacturers. The chromatographic profiles from a number of genuine batches from each manufacturer are expressed quantitatively by an appropriate mathematical technique, such as cluster analysis. The same technique can also be applied to products that contain the drug substance, provided that the excipients do not significantly interfere with the impurity pattern of the drug substance. If a sample of a medicinal product has an impurity profile that does not match that of the authorised manufacturer for the product, it may be a counterfeit product or may have been manufactured using a non-authorised source of the active ingredient.

In an actual case that involved antibiotic oral preparations from different manufacturers, the drug-related impurity profiles were similar because all the manufacturers used the same synthetic route. However, the 'fingerprint' of solvent residues detected by headspace-GC with a nitrogen–phosphorus detector was sufficiently characteristic to allow the synthetic process and the manufacturer to be identified.

When the use of a single technique is insufficient to differentiate all the manufacturers of a drug substance, a combination of analytical

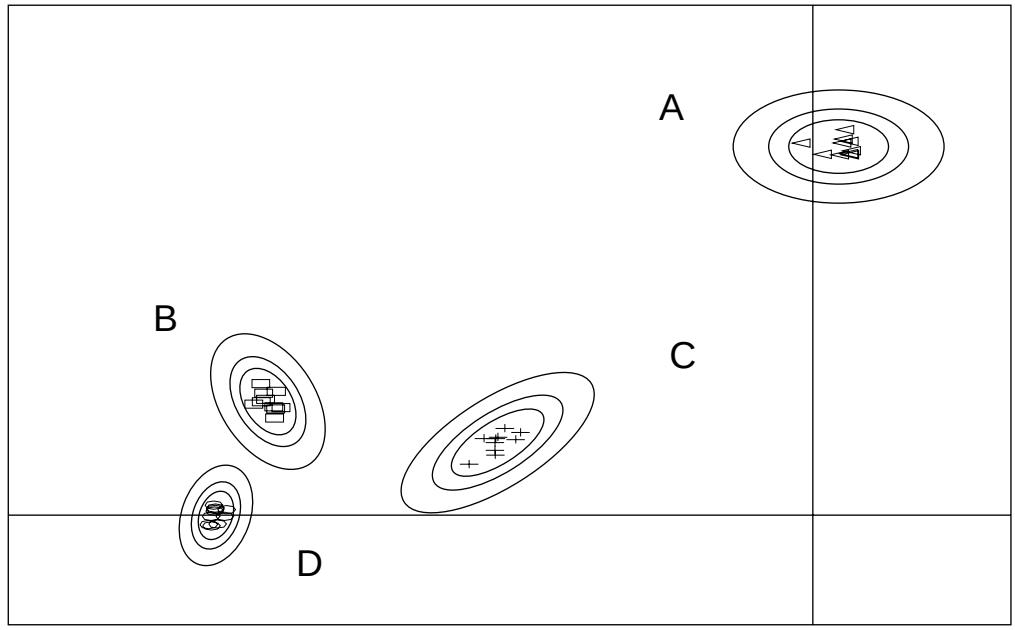

Figure 12.3 Near-infrared centre of gravity plots of four different manufacturers of allopurinol tablets 100 mg. The equal frequency ellipses for a given manufacturer are 0.95, 0.99 and 0.999 (inner, middle and outer respectively). The scales for the axes are $X_{min} = -0.015\,760$, $X_{max} = 0.073\,238$; $Y_{min} = -0.027\,013$, $Y_{max} = 0.108\,089$. Range = 1750–850 nm.

techniques may be used, for example HPLC for drug-related impurities and headspace-GC for volatile impurities. When the drug substance contains inorganic elements, inductively coupled plasma (ICP) spectroscopy and/or atomic absorption spectroscopy (AAS) can be used to quantify the pattern of inorganic impurities.

General tests

In addition to tests for identity and assay (see above), and for contaminants (see below), specifications may include tests to check the uniformity of the batch of medicinal product and its fitness for use. Examples of these tests include:

- Uniformity of mass and uniformity of content of solid dosage forms
- *In vitro* disintegration and dissolution testing of tablets and capsules
- Particle size testing of medicines in which particle size of the active ingredient can affect the bioavailability of the product
- Viscosity tests on creams and ointments
- Sterility tests for parenteral and ophthalmic products
- Tests for microbiological quality of non-sterile products
- Friability testing of tablets to ensure that they will withstand normal handling during transportation of the product and use by the patient
- Aerodynamic assessment of fine particles in inhalation products (e.g. pressurised metered-dose inhalation preparations).

These tests are described in pharmacopoeias (see below).

Defective samples

Defective medicines may be reported to a laboratory because they do not work as they should, or the tests described above may indicate a counterfeit or substandard medicine. Medicines may be defective in their chemical composition, physical properties (which may affect the safety and efficacy of the product) or microbiological quality. When medicines are suspected of being defective, appropriate tests should be carried out to investigate the defect.

Low potency

If a batch of a medicine is suspected to have reduced efficacy, it should be tested for content (see above) and release of active ingredient by a suitable dissolution test. The assay should be able to indicate stability (i.e. it should be selective in the presence of degradation products, to detect loss of potency that arises from decomposition of the active ingredient in the dosage form).

The pharmacopoeias describe dissolution tests for tablets, capsules, suppositories and transdermal patches. These may be used to compare a complaint sample suspected of having low efficacy with a sample from a 'good' batch of the medicinal product. Immediate-release tablet and capsule preparations that comply with the general criteria of a pharmacopoeia (e.g. the BP requirement of not less than 75% of the content of active ingredient being released within 45 min) are usually satisfactory. A significant difference in dissolution rates between a complaint sample and the 'good' sample may explain the observation of reduced efficacy, particularly if the complaint sample releases less than 75% in 45 min.

If the results of the assay and dissolution test do not confirm the suspicion of reduced potency, then further tests should be carried out to investigate:

- Polymorphism of the active ingredient
- Uniformity of the content of the active ingredient
- Particle size of the active ingredient.

Contaminants

Products with a high incidence of unwanted side-effects should be investigated initially for their content of active ingredient and impurities, as high concentrations of these may result in an unacceptable toxicity and account for the observed effects.

Impurities arise in medicinal products from a variety of sources, which include the synthetic starting materials, reagents, reaction by-products, synthetic intermediates and decomposition products. These are often referred to as 'related substances' and can usually be detected chromatographically (HPLC, GC, CE or TLC) using suitable detection systems. If samples of the impurities are not available from the manufacturer or other sources, it may be possible to synthesise them. For example, decomposition products of the active ingredient can be generated by hydrolytic, oxidative or photochemical reactions. Process-intermediate impurities can be synthesised if the synthetic route of the active ingredient is known. Alternatively, a comparison of the chromatographic profile of the complaint sample can be made with

that of a sample of a 'good' batch of the product. Unknown impurities found to be present may be identified by coupling the chromatographic separation with mass spectrometry (Chapter 37).

Residual solvent impurities may be present as a result of incomplete solvent removal during synthesis and recrystallisation. The presence of some solvent residues (e.g. isopropyl ether) may impart an unpleasant taste or smell to the medicinal product, which may discourage patient compliance. Some solvents are toxic even at very low levels, or are environmental hazards, and are controlled to very low concentrations in medicinal substances. For example, benzene and other International Conference on Harmonisation (ICH) Class 1 solvents (see Further reading) should be avoided in pharmaceutical manufacture. If their use is unavoidable, they should be controlled to very low levels in drug substances (e.g. benzene, 2 ppm; carbon tetrachloride, 4 ppm; and 1,1-dichloroethene, 8 ppm). Less toxic solvents (Class 2) and those with low toxic potential (Class 3) should still be controlled to a level that depends on the permitted daily exposure of the solvent. GC, with or without a headspace analyser, is used frequently to determine residual solvent residues (see Chapter 40).

A much more difficult analytical problem is the identification of organic impurities, present in small quantities, that are unrelated to the active ingredient and its synthetic route. These may arise from accidental cross-contamination with other drug substances or products manufactured at the same site (an indication of poor compliance with cGMP) or, in extreme cases, by malicious adulteration or contamination of the active ingredient or finished product. A full screening programme, involving chromatographic and spectrometric instrumentation, including 'hyphenated' techniques (e.g. HPLC-MS), should be used to isolate, identify and quantify the unknown contaminant.

Mineral impurities, including simple inorganic ions and heavy metals, may give rise to problems of safety and quality if they are present in certain types of products. For example, heavy metals and certain other ions (e.g. aluminium and nickel) may be toxic when administered parenterally in high doses or over long periods. Metallic ions (e.g. Fe^{3+}, Cu^{2+}, Co^{3+}) may catalyse oxidative decomposition reactions of the active ingredient (e.g. adrenaline, morphine and phenothiazine drugs), which can result in the formation of toxic and/or coloured impurities.

Inorganic impurities are determined by flame atomic emission spectrometry or AAS, or by the general pharmacopoeial test methods for heavy metals and sulfated ash. For more selective and/or sensitive measurements, electrothermal AAS, ICP spectroscopy, ion chromatography or atomic fluorescence spectrometry may be employed. (see Chapter 17).

Acceptable limits for impurities that assure the drug's safety depend on the toxicity of the impurity, daily dose and duration of treatment of the drug, and its route of administration. The very wide range of toxicities means that acceptable limits vary from the parts per million level to several per cent. For example, the limit for the highly toxic impurity hydrazine in povidone BP is 1 ppm. In contrast, the total limit for related impurities in vincristine sulfate BP is 5%. Typical limits for individual impurities are 0.1–0.5% and for total impurities 0.2–1%.

If an unknown impurity is found in a significant quantity, say greater than 0.1% expressed on an area percentage basis by HPLC or GC, an attempt should made to identify it. HPLC or GC, coupled with MS, may be used for this purpose (see Chapter 37).

For samples in which there are high levels of known impurities or in which new impurities or contaminants have been identified, it may be necessary to carry out a toxicological assessment of the impurities before the reported side-effects can be attributed conclusively to the impurities. If the results of the assay and tests for impurities do not explain the observation of side-effects, the dissolution profile of the complaint sample should be compared with that of a 'good' batch of the product. In some products, for example digoxin tablets (Beckett, Cowan 1973) and carbamazepine tablets (Davidson 1995), the use of micronised active ingredients resulted in very fast dissolution rates of the active ingredient ('dose dumping') and in reported incidents of adverse reactions in patients.

Physical defects

The laboratory should undertake a thorough visual examination for physical defects as part of the sample receipt procedure. If one or more physical defects are detected in a batch of medicinal product, the batch is usually withdrawn or recalled from the market, even if the visual defect does not directly affect the safety and efficacy of the product. If visual defects are observed, appropriate tests should be carried out to investigate the cause. Some examples are given below.

If the colour of a batch of a medicinal product differs from that of other batches of the product, or if the colour is uneven throughout the batch, the most likely explanations are the use of the wrong active ingredient or colouring agent (which indicates a serious breakdown of the manufacturer's quality management system), formation of coloured decomposition products, lack of homogeneity or microbiological contamination.

Verification of the identity of the active ingredient and/or colouring agent can be checked as described above. The formation of coloured decomposition products should be investigated by chromatographic tests for related impurities and a stability-indicating assay of the medicinal product. The former test is likely to yield the greater amount of information because even trace amounts of some intensely coloured decomposition products can impart a significant colour to medicinal substances and products.

Gross microbial contamination may be evident visually from microbial growth in aqueous or semi-solid products or from the appearance of light or dark areas on solid products. The pharmacopoeial tests for total viable aerobic counts (TVACs) and specified microorganisms are much more sensitive than visual detection and should be carried out whenever microbial contamination is suspected or as a general check of microbiological quality. If significant numbers of organisms are found, it may be necessary to carry out microbial identification tests to determine whether the microorganisms are harmful.

A significant proportion of broken tablets may indicate a manufacturing defect. The pharmacopoeial test for friability of uncoated tablets is intended to determine the extent of breakage or surface damage under defined conditions of tumbling the tablets in a drum. A maximum loss of 1% of the tablet mass after 100 revolutions is considered acceptable for most products.

The pharmacopoeial test for resistance to crushing of tablets (hardness) can also be used to measure the force needed to disrupt the tablets by crushing. The hardness of tablets is a property of the tablets, but the value measured depends on the type of instrument used to measure the hardness. Acceptable limits, expressed in newtons, are wide. Nevertheless, a comparison of the hardness of the complaint batch with a 'good' batch of the same product may indicate significant differences, which may account for the damage observed.

Breakage of the tablets may also be the result of the ingress of moisture. This can be investigated by comparison of the moisture level in the complaint sample with that of a 'good' batch of the product. If a significantly higher moisture level is found, the effect on the stability of the active ingredient should be investigated by using a chromatographic test for decomposition products (see Contaminants).

Foreign bodies

Visual examination of the medicine may reveal the presence of extraneous matter, which may be inorganic, organic or biological in origin. The appearance of the extraneous matter, including its microscopic appearance, may give a clue to its general identity. Visible fragments of glass, metal and entomological parts are generally easy to isolate from the sample, which allows a more specific identification to be carried out.

To investigate the origin of glass or metal fragments, the inorganic composition should be compared with that of the container and, if possible, the equipment used in the manufacture of the medicinal product (e.g. mills, tablet presses).

Vegetable, animal and insect fragments can usually be identified microscopically, which may also indicate the source of the contamination. In an actual case that involved the presence of insect fragments in a

medicinal product manufactured in the UK from vegetable drugs imported from Asia, the insect was entomologically identified as one indigenous only to Asia. This proved that the source of the extraneous matter was the vegetable drug ingredient and not the local environment at the UK manufacturing site.

The identity of organic extraneous matter can be determined by the usual techniques for the identification of contaminants (see under Contaminants). The task is relatively straightforward if crystals of the organic contaminant can be isolated from the bulk of the sample prior to identification.

Pharmacopoeial specifications and methods

Pharmacopoeias are good sources of the specifications and standards with which a wide range of commonly used drug substances, excipients, packaging materials and finished products must comply throughout their shelf-life. The principal pharmacopoeias are the European Pharmacopoeia (Council of Europe 2007), British Pharmacopoeia (Medicines and Healthcare products Regulatory Agency 2008) and the United States Pharmacopeia (USP; US Pharmacopeial Convention 2006). National pharmacopoeias of some countries, for example Japan, China and individual European countries, may provide specifications for pharmaceuticals that are available only in those countries. The International Pharmacopoeia (Ph. Int.) published by the World Health Organization (WHO 2006) is intended for use by WHO member states that wish to establish pharmacopoeial requirements for pharmaceuticals used in their country.

The specifications in monographs of pharmacopoeias are intended to be applicable to drug substances, excipients and finished products from different producers. Although the monographs contain the essential tests that provide verification of the suitability of the product for use, the monographs do not attempt to control unique aspects of individual products. Consequently, drug substance and finished product specifications in marketing authorisations of individual products may be based on the requirements of a relevant pharmacopoeia, but may also contain additional tests or tighter acceptance criteria. This is particularly true of finished product specifications for the release of batches of products onto the market (release specifications are used in Europe, but not in the USA). For these, tighter acceptance criteria may be required at the time of release to ensure that the product remains within specification during its shelf-life. Since samples tested by a laboratory are often obtained from the marketplace, the shelf-life acceptance criteria in pharmacopoeias provide a suitable means by which the quality of medicinal products can be judged.

Pharmacopoeial monographs for medicinal products provide good models upon which the testing of non-pharmacopoeial products should also be based when a general check of their quality is required. Typical pharmaceutical specifications for dosage forms include the following types of tests to provide assurance of their quality, safety and efficacy:

- Identity test to confirm the identity of the active ingredient(s) and, if appropriate, other important constituents (e.g. preservatives)
- Assay of the active ingredient(s) and, if appropriate, other constituents
- Homogeneity (e.g. uniformity of content for tablets and capsules)
- Release of the active ingredient from the formulation
- Drug-related impurities and other contaminants
- Microbiological tests (e.g. sterility tests for injectable and ophthalmic products
- Other relevant tests that assure quality.

Sources of information

Pharmacopoeias contain useful chemical, physical and microbiological information about drug substances, excipients and dosage forms. Examples include molecular structures and formulae, relative molecular masses, melting and boiling points, spectroscopic data and solubilities in various solvents.

The appendices in the Ph. Eur. and BP and the general chapters in the USP are useful texts that provide information on, for example:

- Methods of sterilisation
- Production of vaccines
- Containers
- Materials for the manufacture of containers
- Storage conditions to ensure stability of the product.

Supplementary chapters of the BP and general information chapters of the USP provide information on a range of diverse subjects, such as:

- Pharmacopoeial philosophy on the control of impurities
- Systems for nomenclature
- Guidance on the interpretation of results of microbiological assays
- *In vivo* bioequivalence guidelines
- Biotechnology-derived articles.

Reference standards

Approximately 3000 different pharmaceutical reference materials are available from the BP, Ph. Eur., USP and WHO for a variety of different purposes. Chemical reference substances (CRSs) are used, for example, for the following:

- Comparison of spectra in identification tests
- Standards in comparative assays
- Identification and quantification of specific impurities
- Calibration of instruments (e.g. dissolution apparatus and melting point apparatus).

The suffix CRS (e.g. BPCRS, EPCRS, USPCRS or ICRS (International Pharmacopoeia)) indicates that the CRS has been issued by the relevant pharmacopoeia. Similarly, certain biological reference preparations (BRPs) are available (e.g. from the Ph. Eur. as European Pharmacopoeia Biological Reference Preparations (EPBRP)) for the biological assay of antibiotics (microbiological assay) and hormones, blood products, and immunological and other biological products.

It is important to emphasise that a pharmacopoeial reference substance should be used only for the purpose for which it is described in the pharmacopoeia. For example, a pharmacopoeial CRS used only to confirm the identity of a drug substance in the bulk material or in dosage forms by IR spectroscopy or TLC may not have been purified exhaustively, although it will be satisfactory for use in the identity test. Such a standard should not be used in a selective assay (e.g. an HPLC assay) without first assigning a purity value by an appropriate method.

Sources of chemical and biological reference materials are listed at the end of this chapter.

Test methods

Pharmacopoeial methods should always be considered when the testing of pharmacopoeial articles is required. Even if the test methods in the marketing authorisation differ from those in the relevant pharmacopoeia, the article must also comply with the standards of the pharmacopoeia, including the use of the pharmacopoeial test methods, if it is covered by a monograph in the pharmacopoeia.

In most circumstances, pharmacopoeial methods can be assumed to be valid for the materials covered by the monographs. This is because they are intended for use by a wide variety of laboratories, sometimes on an infrequent basis. One of the criteria for the selection of the methods is that they should be robust. Nevertheless, it is good practice to carry out additional tests (e.g. a recovery test) to demonstrate that the method is suitable for the sample.

If a test method is required for a pharmaceutical product for which there is no pharmacopoeial monograph, it may be possible to use or adapt the test methods in a monograph of a similar material. In these circumstances, however, relevant validation tests should be carried out, such as recovery, precision, robustness, selectivity and/or specificity and (for trace amounts, e.g. impurities) limits of detection and quantification, to provide confidence in the suitability of the adapted method.

Pharmacopoeial monographs generally do not rely on a single analytical technique, but instead contain a number of tests based on different analytical methodologies (e.g. identity tests that use spectroscopic techniques and colour reactions, tests for impurities using chromatographic techniques and assays using a non-selective titrimetric or UV spectrophotometric technique). Pharmacopoeial authorities consider that this approach provides the optimum level of assurance about the quality of the product. For many substances and products it is possible to combine the identity test, tests for impurities and assay into a single chromatographic test. Indeed, many manufacturers, including those of pharmacopoeial products, adopt this approach for economic reasons. For similar reasons, a laboratory may choose to develop a single chromatographic test to check identity, impurities and assay in surveillance programmes that involve large numbers of samples. However, it is important to weigh the cost benefits of this approach against the risks of failure to detect substandard products (e.g. those that contain impurities not detected by the single test).

Pharmacopoeial monographs may contain, in addition to product-specific test methods, a number of general tests applicable to a wide variety of materials in the pharmacopoeia. Examples of these are melting point and boiling point determination, heavy metals test, sulfated ash test (test for residue on ignition in the USP), disintegration testing of solid dose products, tests for microbial contamination, preservative efficacy tests, sterility tests and the Karl Fischer determination of moisture. These pharmacopoeial methods have been accepted as standard test methods and, consequently, can be applied by laboratories to a wide range of non-pharmacopoeial materials, provided that appropriate validation has been carried out.

Instrument performance standards

Pharmacopoeial standards for the performance of analytical instruments and testing equipment in most circumstances provide adequate assurance about the general suitability of the equipment for the testing of non-pharmacopoeial products also. These standards include:

- Wavelength, absorbance and resolution checks for spectrophotometers
- Accuracy of pH meters
- Repeatability and symmetry factors in HPLC and GC.

Acceptance criteria

Acceptance criteria in some pharmacopoeial tests are specific to the article covered by the monograph; for example, limits for specific, named impurities in drug substances and dosage forms and limits for water in hydrated substances. However, the acceptance criteria in many other tests are general and are not dependent on the article; for example:

- Limits of 95–105% for the content of active ingredients in medicinal products that are not subject to significant decomposition
- A disintegration time of not more than 15 min for uncoated tablets
- A limit of not less than 75% of the content of active ingredient released after 45 min from tablets or capsules under the conditions of a discriminating dissolution test
- Limits for uniformity of mass for tablets, capsules, suppositories and powders for injection
- Limits for microbial contamination of different types of pharmaceutical preparations
- Limits for the efficacy of antimicrobial preservatives.

These general limits are useful for assessing the quality of non-pharmacopoeial articles as well.

Biological and biotechnological products

Biological products are medicines that contain biological substances that cannot be characterised fully by physicochemical tests. Consequently, in addition to physicochemical tests, biological tests (e.g. a biological assay) are needed to characterise the product. Biological medicines are classified according to their modes of activity:

- Vaccines
- Hormones
- Antisera
- Coagulation factors.

Biotechnological medicinal products are proteins, polypeptides or their derivatives generated by living organisms. They are classified according to their mode of preparation:

- Monoclonal antibodies derived from the fusion of homologous or heterologous cells
- Products derived from recombinant DNA (rDNA) technology
- Products derived from transformed continuous cell lines.

Examples of biotechnological products are human insulin, erythropoietin and growth factor (which are natural products), and novel products (e.g. proteins with modified sequences and gene therapy).

Biotechnological and biological products are generally more complex than chemically synthesised small-molecule drugs, which have a well-defined structure and can be characterised readily by physicochemical tests in terms of their composition, purity and content. The production of biological and biotechnological products from living systems requires very careful control to ensure safety, homogeneity throughout the batch and batch-to-batch consistency. Factors such as the type and stability of the cell systems, culture conditions, the use of continuous or batch processes, and purification conditions are critical to assure the safety, quality and efficacy of the product. Even minor changes in the production process can have profound effects, for example the introduction of potent contaminants or changes in the stability of the product. The use of a new strain of microorganism and a minor process change in the fermentation production of L-tryptophan resulted in over 30 deaths and hundreds of cases of eosinophilia–myalgia syndrome in 1989. The process change introduced a new, highly toxic impurity, 1, 1-ethylidene bis-tryptophan (Belongia *et al.* 1990), which was not controlled by the specification in use at that time.

The pharmacopoeias contain monographs for several biological and biotechnological substances and products including:

- Alteplase for injection (a tissue plasminogen activator)
- Erythropoietin (a mixture of glycoproteins indistinguishable from naturally occurring erythropoietin)
- Human insulin and interferon alfa-2.

All of these are derived from rDNA technology. In a case study, a batch of somatrophin (a protein produced by rDNA technology, having the same structure as the main component of the growth hormone produced by the human pituitary) was shown to be counterfeit by application of the Ph. Eur. monograph for somatrophin (Charlton *et al.* 1998).

Characterisation of biological and/or biotechnological products includes the determination of physicochemical properties, biological activity, immunological properties, tests for purity and impurities, and quantity.

Physicochemical tests used to characterise biological substances and products include:

- Determination of amino acid sequence
- Amino acid composition
- Terminal amino acid sequence
- Peptide mapping
- Number and position of sulfhydryl groups and disulfide bridges
- Carbohydrate structure.

Other physicochemical tests may provide additional information about the properties of the materials, including determination of relative molecular mass, isoform pattern (e.g. by isoelectric focusing), molar absorptivity, and electrophoretic, liquid chromatographic and spectrometric profiles. Identity tests in specifications should be highly specific and focus on unique aspects of the molecular structure and other physicochemical, biological and/or immunochemical properties.

The biological character of the material should be defined in terms of its biological effects and, for antibodies, its immunochemical effects. Biological activities are measured by bioassays, such as animal-based bioassays (which measure the response of an organism to the product), cell culture-based bioassays (which measure biological responses at the cellular level) or biochemical assays (e.g. measurement of enzymatic reaction rates).

The potency (expressed in units) of the material, as determined by bioassay, is calculated relative to the biological response of an official reference preparation (e.g. EPBRP) or a well-characterised in-house reference preparation.

Tests for process impurities and other contaminants include immunoassay for protein impurities derived from the host organism. For the control of product-related impurities, including degradation products, tests based on chromatographic, electrophoretic, MS and circular dichroism techniques may be employed. An appropriate combination of tests to control impurities should be included in the specifications.

Testing of biological and biotechnological medicines requires special instrumentation and analytical expertise that may not be available in laboratories normally engaged in the testing of conventional medicines. It may be necessary, therefore, to refer the testing of such products to specialist institutes that have the ability to undertake the appropriate tests. Further information on biological testing is contained in the BP and the USP.

Herbal and homeopathic products

Herbal remedies have seen a revival in recent years. They comprise a wide range of botanical materials (roots, leaves, seeds, bark, etc.), herbal preparations (extracts, tinctures, oils, resins, etc.) and herbal medicinal products (tablets, creams, etc.).

Herbal remedies are difficult to characterise fully because the production of the active constituents is dependent on natural processes. Genetic and environmental factors, therefore, may result in a wider variation of the constituents of herbal products compared with those of biotechnological products, the manufacturing processes of which are strictly controlled.

As few herbal products have been subjected to rigorous safety (toxicological) and efficacy (clinical) studies, protection of the public depends on adequate measures to control the quality of the products. Monographs of quality standards for herbal products are now included in the *British Pharmacopoeia* 2010 (Medicines and Healthcare products Regulatory Agency 2008) and have been published in the *British Herbal Pharmacopoeia* (British Herbal Medicine Association 1996), the *European Pharmacopoeia* (Council of Europe 2007) and the *Escop Monographs* (European Scientific Co-operative on Phytotherapy 2003). Regulatory guidance on the setting of specifications for herbal medicinal products has been published by the European Medicines Agency Committee on Herbal Medicinal Products (2007). These monographs should be used whenever possible.

Identification tests

Identification tests for herbal products should discriminate between related botanical species and potential adulterants, and should include verification of the microscopic and macroscopic characters, chromatographic (e.g. TLC or HPLC) tests and chemical reactions.

Tests for potential contaminants

General pharmacopoeial tests for foreign matter in vegetable drugs, ash and acid-insoluble ash are useful for determining the presence of adulterants such as inorganic matter and dirt. A test for water content should be included when the herbal drug is known to be hygroscopic. Pesticide residues should be checked using the method described in the European Pharmacopoeia.

Microbial contamination levels generally are higher in herbal products than in synthetic materials because plants have their own microbial flora and are able to sustain microbial growth. It is important, therefore, to carry out tests for total viable organisms (bacteria, yeasts and moulds). The limits given in guidelines for microbiological quality of pharmaceutical preparations (category 4) in the Ph. Eur. can be used to assess this aspect of the quality. The microorganisms detected by the test for TVAC generally are not pathogenic, but the number provides an indication of the general microbiological 'cleanliness' of the product. From a safety point of view, the presence of specific pathogenic microbes, such as *Escherichia coli*, *Salmonella* spp. and enterobacteria, may be more relevant. The test methods for these organisms and the acceptance criteria of the Ph. Eur. should be used to assess this parameter.

Although high levels of bacteria and of yeasts and moulds generally do not present a health risk, their presence under certain circumstances can lead to contamination by microbial toxins. Bacterial endotoxins, which are released from the cell walls of Gram-negative bacteria during the sterilisation of parenteral products by autoclaving, can induce pyrogenic symptoms such as fever, pain and headache. High levels of certain mycotoxin-producing fungi, in particular aflatoxin-producing strains (e.g. *Aspergillus spp.*), may lead to high levels of the mycotoxins being formed during storage under warm, humid conditions. Aflatoxins are particularly dangerous as they are mutagenic and carcinogenic and can cause hepatitis. Tests for bacterial endotoxins (limulus amoebocyte lysate (LAL test)) are described in the pharmacopoeias.

Quantitative tests

The active chemical constituents of herbs vary widely and include alkaloids, glycosides, tannins and volatile oils. However, the active chemical constituents of some medicinal herbs (e.g. valerian) have not been elucidated fully. Most herbs contain several active constituents that vary in composition, depending on the cultivation conditions. To ensure that herbs are of an appropriate quality, quantitative tests should be sufficiently selective and sensitive for the active constituents, requirements usually met by TLC or HPLC.

Ethnic herbal remedies

The availability of ethnic herbal remedies, for example traditional Chinese medicines (TCMs) and ayurvedic medicines, presents additional challenges to the regulatory authorities and to laboratories. The problems associated with controlling TCMs result mainly from the large number of ingredients in many TCM formulae and from the risk of contamination and confusion about nomenclature, which may result in the accidental or deliberate substitution of one herb by another. Substitution is particularly important when a relatively non-toxic herb can be confused with, or substituted by, a more toxic herb. The incorporation of herbal ingredients into products should be subject to adequate quality control, including identification tests, to ensure the use of the correct ingredient and the absence of adulteration.

In a serious incident in Belgium in 1993, over 100 women who had been prescribed a TCM at a slimming clinic developed progressive renal failure, which resulted in renal replacement therapy in 60% of the women and in renal carcinomas. The nephrotoxicity of the slimming treatment was traced to inadequate quality control: 80–90% of the *Stephania tetranda* powder (Pin Yin name *han fang ji*) in the slimming preparation was inadvertently substituted by *Aristolochia fangchi* powder (Pin Yin name *guang fang ji*). The toxic elements of *Aristolochia* species are aristolochic acids (substituted nitrophenanthrene carboxylic acids), which are potent immunostimulant, mutagenic, carcinogenic and nephrotoxic agents (Vanherweghem 1998). Many countries have now banned the use of *Aristolochia spp.* and other botanical species, such as certain *Stephania* spp. and *Akebia* spp., with which *Aristolochia* may be confused.

Another problem encountered is the deliberate addition of synthetic drug substances to TCMs, an example of which is the addition of potent corticosteroids (e.g. triamcinolone, dexamethasone and fluocinolone acetonide) to Chinese herbal cream formulations used for eczema. These can be investigated by a HPLC screening test for corticosteroids using UV detection at 240 nm (see Chapter 41).

A particular problem with ayurvedic medicines and some TCMs is the presence of high levels of toxic heavy metals. These may arise from the general contamination of the environment with pollutants (cadmium, lead, mercury), but more usually from the deliberate addition of heavy metals and/or arsenic to the formulation. Tests for these elements can be carried out by a multielement technique, such as ICP spectroscopy (see Chapter 17).

Homeopathic preparations

The nature of homeopathic products precludes tests for the identity and content of the active ingredient because of their high dilution. Consequently, only general tests can be performed on homeopathic products (e.g. uniformity of mass of solid dosage forms and tests for microbial contamination). However, quality standards and tests for the homeopathic stocks and mother tinctures from which these products are made are increasingly becoming available in pharmacopoeias, e.g. the BP 2010. Identification tests rely predominantly on macroscopical description and TLC. Tests for foreign matter are included where there is a hazard for contamination.

CHAPTER

13 Solid Dosage Form Identification

J Ramsey

Introduction

History

Tablets and capsules are a surprisingly modern development. Thomas Brockedon was granted a patent in 1843 'for manufacturing pills and medicinal lozenges by causing materials, when in a state of granulation, dust or powder, to be made into form and solidified by pressure in dies'. In 1884, Burroughs Wellcome & Co. applied for the term 'tabloid' to be made a registered trademark. It is said that Henry Wellcome (1853–1936) derived this word from 'tablet' and 'alkaloid' and used it to mean highly effective drugs in a compressed, concentrated form. The British Pharmacopoeia (BP) of 1885 included a monograph for Glyceryl Trinitrate Tablets. No others appeared until 1945 when the Seventh addendum to the BP of 1932 still contained only 35 tablets. Tablets and later dosage forms, such as gelatin or starch capsules, and sugar-coated tablets (dragées), proved to be particularly well suited to mass production.

Tablets and capsules are now commonplace and a large number of consumer products are available in this form, not only medicines but also products such as sweeteners (sugar substitutes), confectionery (mints), detergents and even toys (indoor fireworks, jumping beans).

Legitimate medicines supplied as tablets and capsules, such as the barbiturates (Tuinal, Seconal), methaqualone (Mandrax, Quaalude) and amfetamines (Drinamyl) were commonly misused in the 1960s. Legitimate capsules were also emptied and used to conceal heroin in the 1970s. Illicit drugs were rarely seen as tablets or capsules until the early 1990s, when the drugs now commonly known as ecstasy flooded the club–dance scene, first in Europe and later the USA. Currently, many millions of illicitly made tablets that contain methylenedioxymetamfetamine (MDMA) or its homologues and analogues are consumed each week. This 'normalisation' of tablets as an illicit dosage form has resulted in an expansion of illicitly produced tablets that contain other drugs, principally amfetamine and metamfetamine, in other countries, particularly in South East Asia (Thailand, Myanmar).

The need for tablet and capsule identification arises for many reasons in both health care and law-enforcement practice. Treatment of the poisoned patient may be assisted by identification of the product responsible, even though most patients are treated symptomatically. The agent responsible for the poisoning, if a tablet or capsule, may often be identified more rapidly than the diagnosis can be made by the analysis of body fluids. However, the tablets found alongside the patient are not necessarily the same as those that were taken. Pharmacy practice generates many identification enquiries, such as the rogue tablet found in a tablet bottle or the customer who wants 'some more of these' but does not know what they are. In Europe, 'parallel imports' are common, because it is cheaper to import some medicines from other countries. The imported drugs, even if manufactured by the same company, usually have a different physical appearance from the familiar native product. Patients, when prescribed a generic form of a medicine, might receive an unfamiliar product of foreign origin and request confirmation that an error has not been made. A constantly changing melange of products in circulation also results from takeovers and mergers within the pharmaceutical industry (when the physical appearance of products is changed to meet new corporate identity standards). Consequently, patients, pharmacists and law officers are continually faced with unfamiliar products.

Changes in legislation may also generate new reasons to perform identifications; for example, when anabolic androgenic steroids came under the Misuse of Drugs Act in the UK in 1996 both the Police and Her Majesty's Customs and Excise (now HM Revenue and Customs) were suddenly required to be able to recognise them.

The misuse of pharmaceutical products, such as the benzodiazepines (particularly temazepam and diazepam), and an illicit drug scene in which users like to experiment, results in solid dosage forms being much more prevalent. Drug-facilitated sexual assault may also involve drugs supplied as tablets and capsules (e.g. flunitrazepam). The trading across national boundaries via the Internet of so-called 'lifestyle drugs' used to treat obesity (e.g. phentermine, orlistat), impotence (sildenafil, vardenafil, tadalafil), baldness (finasteride) or smoking cessation (bupropion) also results in enquiries to identify unfamiliar products.

The emergence of 'herbal highs' or 'party pills' sold on the Internet and containing mostly piperazine derivatives, many of which are not subject to legal controls, has resulted in many more recreational drugs available as tablets or capsules.

The current 'harm minimisation' strategy to counteract drug misuse, which involves informing users, potential users and parents honestly about the risks of drug misuse, has alerted parents and those responsible for the welfare of youngsters (e.g. teachers) to the possibility that those in their charge might be in possession of illicit (illegal) drugs. In turn, this has meant that many more enquiries are made to health care professionals regarding the identification of suspect materials. Many enquiries are made to community (retail) pharmacists regarding 'tablets' found in the possession or proximity (bedrooms, school playgrounds) of young people.

Some confectionery may coincidentally resemble medicines and some may even be deliberately designed to resemble drugs (such as sugar cigarettes). Small white tablets marked with a P, an O or an L purported to be the holes from the centre of Polo Mints caused much concern when they were found out of context, such as in school playgrounds (Ramsey 2001; Young 1997).

Dosage forms

Pills

Pills are an outdated dosage form seldom encountered in modern pharmacy practice. Technically, a pill is a small rounded mass, usually handmade, and is intended to be swallowed whole. However, the word is in common usage as a generic term for all solid dose forms, e.g. ecstasy pills, slimming pills or contraceptive tablets ('the pill'). Some branded products still use the word, but usually referring to small sugar-coated tablets (Beechams Pills, Ex-Lax Pills).

Tablets

Tablets are compressed dosage forms that contain both active ingredients and inactive materials called excipients, which include diluents, adhesives, binders, fillers, lubricants, disintegrants and colours. Tablets need to be strong enough to withstand transport and handling yet still disintegrate and release the active ingredients when consumed. The behaviour of the tablet depends on the production methods, the various excipients and their effect on the active ingredient. The physical form of the active ingredient (particle size) and the particular salt are also important.

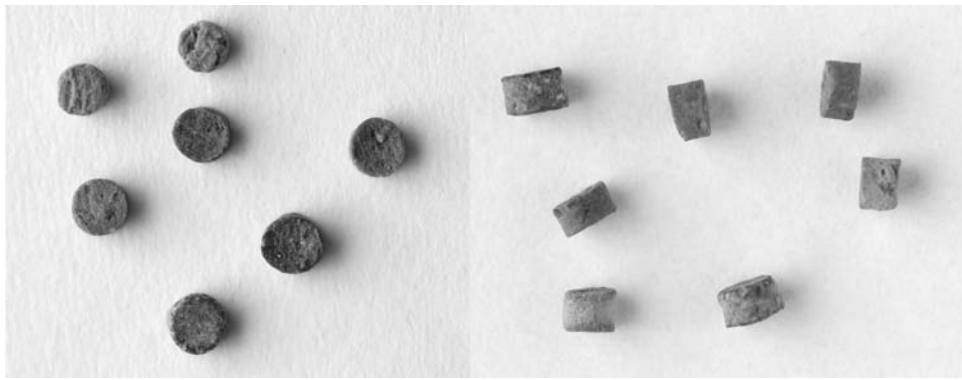

Figure 13.1 LSD 'microdots' made using perforated metal sheet. Reproduced with permission from TICTAC Communications.

The identification of a tablet is usually based on the physical appearance or the analytical determination of the active drug and seldom depends upon the nature of the excipients. However, examination of the gastric contents, after gastric lavage (now less favoured) or *post mortem*, with a polarising microscope for the presence of starch granules may indicate the recent consumption of tablets or capsules.

Illicit tablets

Seizures of millions of illicit tablets, mostly of the drug 'ecstasy', have been made in many countries, (e.g. the UK, The Netherlands, USA, China, Poland). These tablets are usually marked with distinctive logos that often belong to large commercial organisations (automobile manufacturers, mobile phone makers, fashion designers), or represent cartoon characters or simple text or currency symbols.

The investigation of the illicit production of the synthetic phenethylamines (MDMA, amfetamine) may require the examination of the clandestine 'laboratories' that produce the active ingredient as well as tablet-making facilities. Information may be gleaned on the synthetic route to the active substance and batch characteristics by analysis of the impurity profile of the finished tablet.

Moulded tablets

Small numbers of tablets may be made by moulding, a similar process to that once used in pharmacies. The active ingredient, a diluent and some form of binder (gum or adhesive) are pressed into a mould and allowed to set. Perforated metal sheet or even pegboard may be used as the mould. This dose form was common for lysergide (LSD) in the UK in the 1970s. Small 'microdots' (2.4 mm in diameter and 1.3 mm thick, weighing 5 mg: Fig. 13.1) were produced in large numbers using sheets of perforated metal.

The product shown in Fig. 13.2 is from a London club's 'amnesty bin'. The tablet is made from plaster-of-Paris to resemble an ecstasy tablet, but it contains no active ingredients.

Figure 13.2 Fake ecstasy tablet made from plaster-of-Paris, taken from a London club's 'amnesty bin'. Reproduced with permission from TICTAC Communications.

Compressed tablets

Legitimate products

Modern commercial compressed tablets are made by highly automated machines that use multiple sets of dies and punches in clean-room conditions. Strict quality-assurance procedures ensure that the product is manufactured to close tolerances, so there is little variation in physical appearance (size, weight, colour), content of active ingredient and bioavailability.

Illicit tablets

Small numbers of tablets may be made using drilled metal plates and hammer-driven punches or by screw-driven hand presses. Most illicit tablets are made by similar machines to those used by the legitimate manufacturers, but in very different conditions (Fig. 13.3). The equipment needed to satisfy the demand for ecstasy tablets (estimated at one

Figure 13.3 Commercial tablet machine used to produce illicit tablets. Reproduced with permission from TICTAC Communications.

Figure 13.4 Diazepam tablets that appear to be professionally made but are of unknown origin. Reproduced with permission from TICTAC Communications.

million each week in the UK) has to be highly automated. The machines may be in poor condition and the dies and punches may be damaged and leave characteristic visible imperfections on the tablets that they produce, which may provide valuable intelligence. The so-called 'ballistic' examination of tablets for these imperfections (using techniques like those for the examination of firearms and ammunition) by forensic laboratories was once common, but is no longer carried out routinely (in the UK).

The variability of dimensions and dose of illicitly produced tablets is often much greater than that found in legitimate tablets, despite the use of similar machinery. Tablets pressed in the same die must all have the same diameter, but can vary greatly in thickness depending on the fill weight and the degree of compression. This may affect both the dose and the disintegration time and hence the bioavailability of the active compound.

Coated tablets

Tablet cores may be coated with layers of sucrose, a thin film of resin or a soluble wax. This may be: to make the medicine more palatable; to protect the active ingredient from exposure to air, light or moisture; to delay the absorption until it reaches the small intestine; or to extend the duration of action. Products may also be coated to give them a more attractive appearance. Sugar-coated tablets vary more in dimensions (both size and weight) than uncoated or film-coated products. Markings printed on sugar-coated tablets may often rub off quite easily. The sugar coating also tends to 'round off' the edges of the core, so that sharp edges become rounded. Sugar-coated tablets may closely resemble confectionery in both appearance and taste, at least initially, and may be consumed inadvertently by children who believe them to be sweets (candy).

Counterfeits

There are many examples of counterfeit or substandard pharmaceutical products that are fraudulently labelled with respect to their source or content. Their use has resulted in failure of treatment or even poisoning (Reidenberg, Conner 2001). Less surprisingly, products of uncertain origin appear on the drug-abuse scene. Diazepam tablets that appear to be professionally made and of foreign origin are commonly in circulation in the UK (Fig. 13.4), but neither the manufacturer nor the importer is known.

Anabolic agents in ampoules and tablets, purportedly from reputable manufacturers, have been detected that do not contain the active ingredient stated on the packaging. For example, the counterfeit product shown in Fig. 13.5 was found to contain testosterone and not boldenone as stated on the packaging, where the word steroid was incorrectly spelled.

Illicit tablets of similar appearance, probably made in the same machine, may also contain different active ingredients. Examples of the tablet shown in Fig. 13.6 have been found to contain methyltestosterone, methandrostenalone or clenbuterol.

Individual legitimate pharmaceutical tablets may also be modified by hand to look like other products and so increase their value. The half-scored tablet in Fig. 13.7 had a Y-shaped marking (similar to the Mercedes motor manufacturer's logo) carved on to make it resemble an ecstasy tablet.

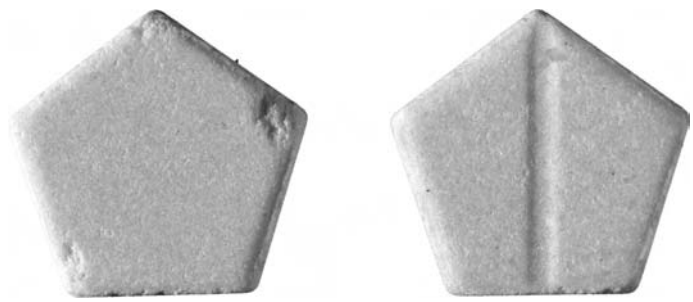

Figure 13.6 Illicit tablet seen with different active ingredients (methyltestosterone, methandrostenalone or clenbuterol). Reproduced with permission from TICTAC Communications.

Figure 13.5 Counterfeit anabolic steroid (Boldebal-H) packaging with a spelling mistake. Reproduced with permission from TICTAC Communications.

Figure 13.7 A legitimate tablet modified to look like an ecstasy tablet. Reproduced with permission from TICTAC Communications.

Capsules

Capsules are a popular consumer dosage form because their slender shape makes them easy to swallow, and they effectively mask any unpleasant taste or odour of their contents. Most capsules consist of two parts, a cap and body, and are made from gelatin. These shells are made using precision-machined moulds, to which the liquid gelatin adheres, forming both the cap and body sections. High-speed machinery removes the gelatin shell layers from the moulds and then joins, prints and packages them. The two parts may be the same or different colours, or may be transparent.

Capsule filling

Small numbers of capsule shells may be filled by hand; highly automated filling machines are able to fill many thousands of capsules per hour. The contents may be powder, controlled-release granules, herbal material or, less commonly, liquid.

Capsule printing

Capsules are usually marked, although the printing may rub off, particularly on oil-filled soft gelatin products. The printing may not be consistently on the cap or body (Fig. 13.8). This is particularly noticeable when the cap and body are different colours.

Special capsules

Special capsules made from cellulosic (hydroxypropylmethylcellulose) raw materials and printed with natural printing inks satisfy vegetarian and cultural (e.g. kosher) needs. Wider-diameter capsules are designed for double-blind clinical trials to allow containment and blinding of large-diameter or uniquely shaped tablets.

Very small gelatin capsules are used for oral dosage to rodents in preclinical studies and are specially designed for performing preclinical trials, such as pharmacokinetic, pharmacodynamic and safety studies.

Liquid-filled capsules

Soft gelatin capsules are commonly used to contain liquid or semi-liquid preparations (Fig. 13.9). Some have abuse potential. Encapsulated liquid preparations of temazepam had to be modified and subsequently discontinued because the contents were being withdrawn with a syringe and needle and injected intravenously, intramuscularly or even intra-arterially, which caused severe lesions (Dodd *et al.* 1994).

Figure 13.8 Examples of capsule showing marking reversed on cap and body. Reproduced with permission from TICTAC Communications.

Figure 13.9 Soft gelatin capsule containing liquid. Reproduced with permission from TICTAC Communications.

Special two-piece hard gelatin capsules may be sealed for secure containment of liquids and semi-solids. The overlapping portion is moistened during the filling process and the cap and body effectively weld together as they dry. Two-piece capsules (Fig. 13.10) may be secured with a sealing band of shellac to prevent leakage of, or tampering with, the contents.

Transdermal devices

Potent drugs, with suitable solubility characteristics, that require extended dosing may be given in preparations designed to deliver the drug through the intact skin (transdermally; Table 13.1). The dosage forms may be creams, sprays or patches that resemble adhesive wound dressings (Elastoplast, Band Aid). Patches are usually either transparent or in colours to match skin tones. Some are marked with names or codes, while others are completely unmarked.

The misuse of transdermal patches that contain fentanyl has been reported; fentanyl may be extracted from these patches and used as a source of the drug for injection or they may even be dried and smoked (Marquardt, Tharratt 1994; Purucker, Swann 2000).

Novel preparations

There are many novel dosage forms, some of which are used when the fast or slow controlled release of an active ingredient is required.

Melts

The product Maxalt Melt Wafer 10 mg contains the antimigraine drug rizatriptan. Although approximately 13 mm in diameter, it weighs only 64 mg and is intended to be taken without water (Fig. 13.11).

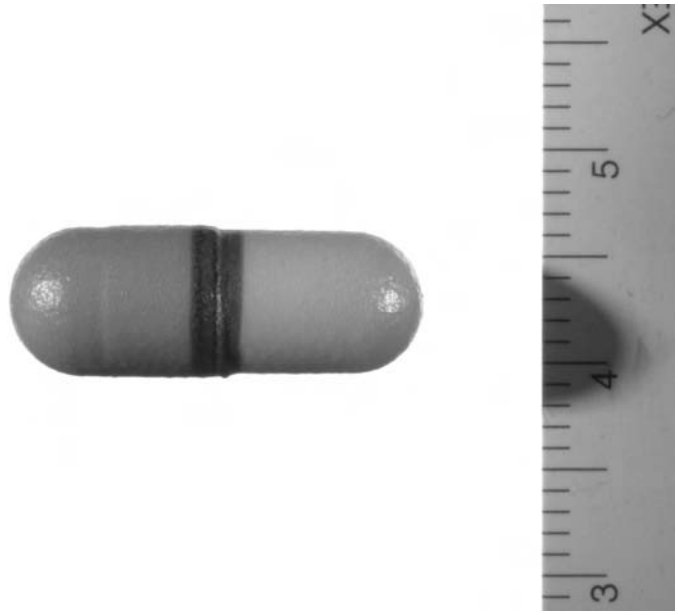

Figure 13.10 Cap and body capsule with sealing band (scale in centimetres). Reproduced with permission from TICTAC Communications.

Table 13.1 Preparations designed to deliver the drug through the intact skin

Preparation	*Function*
Drugs delivered in transdermal devices	
Estradiol	Hormone replacement
Testosterone	Hormone replacement
Norethisterone (norethindrone)	Hormone replacement
Nicotine	Tobacco withdrawal
Glyceryl trinitrate (nitroglycerin)	Antianginal
Fentanyl	Analgesic
Hyoscine (scopolamine)	Motion sickness
Other compounds in patches	
Citronella oil	Insect repellent
Tropical orchid aroma	Appetite control
Capsicum (cayenne pepper)	Counter irritant
Arnica montana (leopard's bane)	Counter irritant
Methyl salicylate	Analgesic
Ferrite magnet	Pain relief?

Figure 13.11 Maxalt Melt Wafers, anti-migraine treatment designed to be taken without water. Reproduced with permission from TICTAC Communications.

Slow-release products may have cores that do not disintegrate in the gut and may be found intact at postmortem examination in stomach contents. These cores are also found in other circumstances, such as in homes for the elderly and psychiatric institutions, with the outer coating removed (presumably after having been spat out).

The Adalat tablet (Fig. 13.12) has such a core (Fig. 13.13); it is a complex device with a laser-drilled hole that is clearly visible in a yellow layer. The core is revealed when the coating, which is pink, is removed; this is a common identification enquiry.

Figure 13.13 The Adalat tablet shown in Fig. 13.12 with coating removed. Reproduced with permission from TICTAC Communications.

Figure 13.14 LSD-impregnated paper sheet with a pattern that covers multiple doses (the small square is a single dose). Reproduced with permission from TICTAC Communications.

Veterinary products

Relatively few veterinary medicines for use in large animals are supplied as tablets or capsules because it is usually easier for a veterinary practitioner to administer an injection to an animal. However, treats and worming preparations and medicines for domestic animals are commonly sold as tablets. Animal treats may have markings reminiscent of those on ecstasy tablets.

Some products may be very large: Coppinox 27 copper supplement capsules for cattle are 24 mm long and weigh over 25 g.

Impregnated paper

LSD is commonly supplied impregnated into small absorbent paper 'stamps', which usually carry a distinctive marking. Large sheets are perforated so that they may be torn into individual doses on quarter-inch or 7 mm squares. They are impregnated by dipping the sheet into a solution of the drug in a solvent, often vodka or ethanol. More rarely the solution of the drug may be applied to the individual paper squares on the sheet with a dropper. The pattern may be complete for each square or may extend across multiple squares or the whole sheet (Fig. 13.14). The patterns are classified by law enforcement agencies by a Prototype number. LSD has also been impregnated in gelatin squares (window panes) or on sugar lumps and supplied as moulded tablets.

Other very potent illicit drugs (e.g. 4-bromo-2,5-dimethoxyamfetamine (DOB)) may also be seen, though rarely, impregnated into paper.

Confectionery

Some confectionery is commonly mistaken for illicit drugs. Sweets, mainly mints, may look like medicines or illicit drugs, particularly when out of the original packaging (Fig. 13.15).

Figure 13.15 Confectionery that resembles ecstasy tablets. Reproduced with permission from TICTAC Communications.

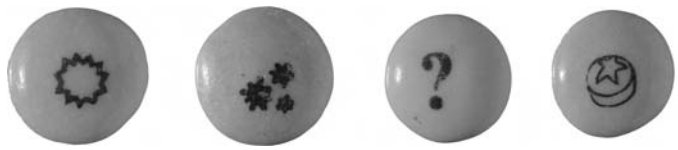

Figure 13.16 Sugar-coated chocolate drops. Reproduced with permission from TICTAC Communications.

Figure 13.17 Sweeteners that are mistaken for drugs. Reproduced with permission from TICTAC Communications.

Sugar-coated chocolate drops (Smarties, M&Ms) may also be confused with sugar-coated tablets, particularly when they bear markings for special promotions (Fig. 13.16). The TICTAC database (see later) contains 120 different Smarties.

Sweeteners (sugar substitutes) in tablet form regularly result in identification enquiries when they are found in or near food or out of context in schools or public places (Fig. 13.17).

Examination of unknown products

Unnecessary submissions and expensive laboratory time may be saved if solid dosage forms can be recognised from their physical appearance. They may be identified with a high degree of confidence if they have sufficiently characteristic features, if the appearance can be accurately described and if an appropriate database is available.

The method of identification used depends upon why the identification is required, the speed with which a result is needed, the nature of the unknown and the resources available. When a rapid identification is required for clinical purposes, and if the unknown is likely to be a legitimate pharmaceutical, it is usually sufficient just to locate it in a commercial database, particularly if it carries a distinctive marking. The treatment of the patient is likely to be symptomatic and is unlikely to depend solely on the identification of the product. In contrast, if the identification is for forensic purposes and the product is likely to be illicit or has no distinctive features, a chemical analysis is required. However, a preliminary search of a database can save much time and expense and can guide the subsequent analysis.

Solid dosage form identification databases

History

The legitimate pharmaceutical products available vary greatly from country to country. National pharmacopoeias define medicines available in each country, but generally do not provide much data on physical appearance. The physical appearance of branded medicines usually differs when marketed in different countries and manufacturers are seldom familiar with their own products from other countries. Several identification systems have been developed in the UK over the years. There are no international databases of the physical appearance of legitimate solid dosage forms. Paradoxically, there is more uniformity in illicit tablets found in different countries – the same designs and logos on ecstasy tablets are seen all around the world.

TICTAC (The Identification CD-ROM for Tablets And Capsules)

TICTAC (http://www.tictac.org.uk) is a UK commercial database supplied every 13 weeks on CD-ROM, with interim updates provided via the Internet. It is used by both health care and law-enforcement professionals. TICTAC includes data on over 23 000 solid dosage forms from the UK and Eire and contains both legitimate and illicit drugs. It includes over 65 000 pictures of the products, chemical structures of the active ingredients and their reactivity with immunoassay reagents. An index of street slang for drugs and drug-related activities is also included (1992; Ramsey, Woolley 2001).

IDENTIDEX

IDENTIDEX is a commercial text-only database of largely American products. It is supplied as part of the Micromedex suite of medical information programmes on CD-ROM (IDENTIDEX System 2001).

Drug Identification Bible

The *Drug Identification Bible* has an alphabetical index of markings (imprints) on almost 14 000 American tablets and capsules; it also has almost 900 pictures of controlled prescription drugs. It is published annually (Marnell 2001). The data on American marked tablets and capsules is also available on CD-ROM as RxID, which is updated quarterly.

The Compendium of Pharmaceutical Specialities

The *Compendium of Pharmaceutical Specialities* (CPS) is a Canadian compendium with pictures of most pharmaceuticals (Canadian Pharmacists Association 2001). It is available in hard copy and on CD-ROM.

Identification for clinical purposes

Community

Community pharmacy practice sometimes requires the identification of tablets and capsules. Customers may become anxious when dispensed unfamiliar generic products, particularly when they are dispensed mixed batches. Parallel imported products may also cause anxiety and confusion. Patients on large amounts of medication may become confused and may report the presence of 'rogue' tablets.

Anxious parents may also rely on community pharmacists for advice on suspected 'drugs' found around the home. While abused drugs are more likely to be in tablet form than ever before, many such enquiries result from the discovery of confectionery and sweeteners in unlikely circumstances.

Residential nursing homes for elderly people often receive medications in drug trays containing all the medication required daily for each resident. The quality management of dispensing these trays is often carried out with the aid of a database that contains details of the physical appearance of the medicines.

Hospital

The treatment of acute poisoning rarely depends upon the identification of a tablet or capsule. However, confirmation of the identity of medicines brought in with the patient may be of value. Those who treat drug abusers also frequently require identifications. Many abused drugs are in tablet form and most drug abusers use multiple drug types. Enquiries for identification of the benzodiazepines (particularly temazepam and diazepam) and opiate/opioid analgesics (codeine and dihydrocodeine in the UK; dihydrocodeinone in the USA) are particularly common.

Pharmaceuticals

The pharmaceutical manufacturers need to be able to recognise their own products as a public service and also, from time to time, to check proposed markings for new products to ensure that they are not currently in use. They also need to investigate allegations that batches of their products contain 'rogue' tablets.

The practice of workplace drug testing requires Medical Review Officers to investigate whether the medication declared by the testee is consistent with the results of the subsequent laboratory analysis of a urine sample. The medication is frequently declared in insufficiently precise terms that require clarification (e.g. 'Anadin', or is described as 'pink headache tablets'). Suspicious tablets may also be found in the workplace (e.g. gymnasia, food production plants, off-shore oil rigs).

Forensic

Identifications are carried out in the law-enforcement sector for many reasons by many different agencies. HM Revenue and Customs need to be able to recognise suspected contraband in luggage, particularly now that controls on anabolic agents are in force. Prisons need to be able to screen drugs in the possession of remand prisoners and to investigate contraband and enforce the status of drug-free wings. Police benefit from ready access to identification resources to make decisions about items discovered during searches and to prevent unnecessary submissions for laboratory analysis.

The international proliferation of ecstasy (MDMA and similar compounds) has created the requirement to investigate the illicit production of these tablets. This is an international trade in which the same or similar tablets are found all over the world. They are commonly marked with logos from all manner of consumer products and companies, particularly those that produce trendy products of appeal to the youth market. The TICTAC database currently has over 1300 logos, most from illicit products.

New synthetic drugs sold as 'legal' alternatives to the amfetamines or 'ecstasy' sold openly on the Internet and in 'head shops' as tablets or capsules have recently emerged as an international problem. Initially piperazine derivatives (BZP, *N*-benzylpiperazine; TFMPP, 1-[3-trifluoromethylphenyl] piperazine; mCPP, 1-[*m*-chlorophenyl]piperazine) were seen, but as legal controls have been introduced other novel compounds (glaucine; D2PM, diphenyl-2-pyrrolidinemethanol, diphenyl prolinol) have emerged. Tablets containing these compounds are usually marked with logos similar to, or the same as, those found on ecstasy tablets.

Another aspect is the identification of solid dosage forms from the scene of a fatality at which death by an overdose of drugs is suspected.

The identification process

The identification process is illustrated using the UK TICTAC CD-ROM database. Examples using the other databases are given when appropriate. The software–user interface uses a filing card analogy (Fig. 13.18), with a card appropriate for each type of identification enquiry. The procedure to identify an unknown tablet or capsule is shown in Fig. 13.19.

If a product is distinctively marked or is unusual in some way, an unambiguous identification may be achieved, but there are limitations if the product has few distinguishing features. For example, a plain white unmarked tablet is unlikely to be identified from a physical description

Figure 13.18 The TICTAC user interface showing the filing card analogy. Reproduced with permission from TICTAC Communications.

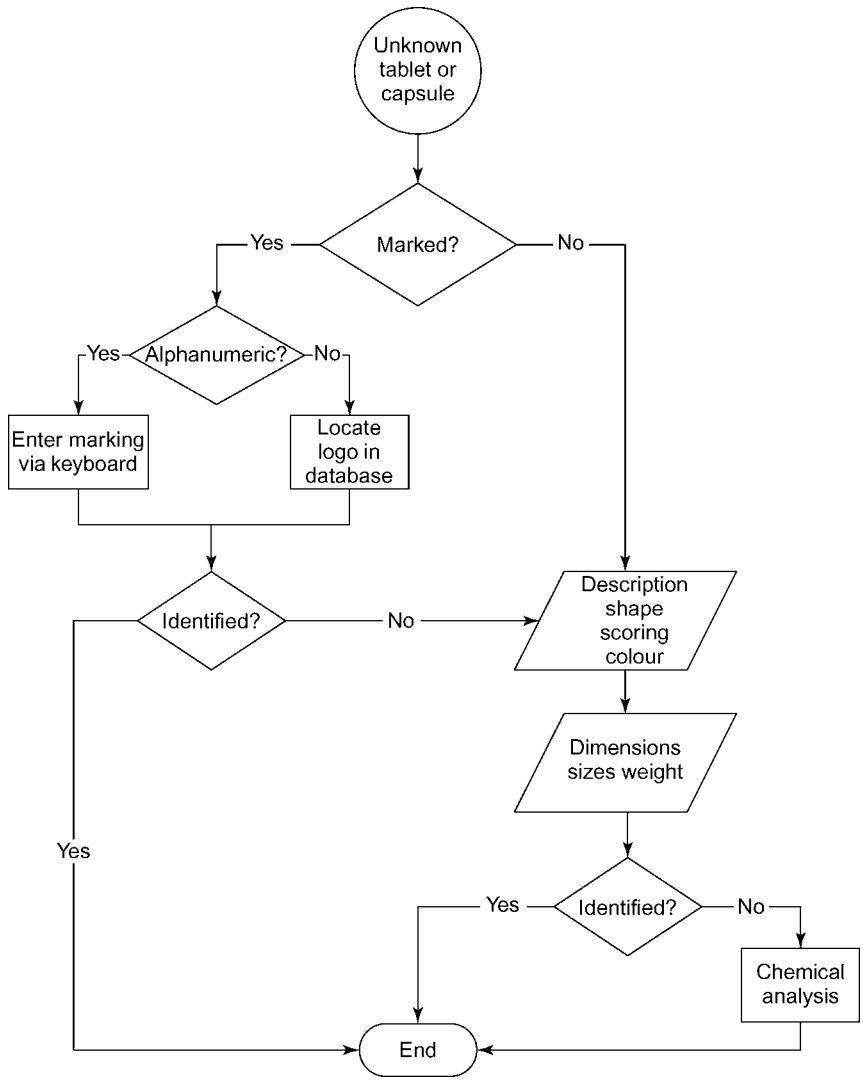

Figure 13.19 Flow diagram showing the procedure to identify an unknown tablet or capsule. Reproduced with permission from TICTAC Communications.

unless it is unusually large or small, so chemical analysis will be required. If a unique identification is not possible, TICTAC can present candidates in order of best fit to the data entered. It may be necessary to confirm the tentative identification made from a physical description by chemical analysis if the identification is required for legal purposes.

Distinctively marked product

TICTAC

Although the product shown in Fig. 13.20 is actually pink and quarter scored, it is also distinctively marked and can be identified simply by entering the marking 4Z1 into the appropriate card (*Product, Tablet*).

The software retrieves information on any products that match the description. The pictures and sizes and weights are presented to confirm that the identification is correct (Fig. 13.21). Further details of the ingredients (chemical structure, therapeutic category) and the supplier (contact details, website) can be obtained by pressing the appropriate button.

The TICTAC database contains alternative markings for products for which the marking might be considered ambiguous. Examples of marking that require care are shown in Table 13.2.

Figure 13.20 Example of a distinctively marked tablet. Reproduced with permission from TICTAC Communications.

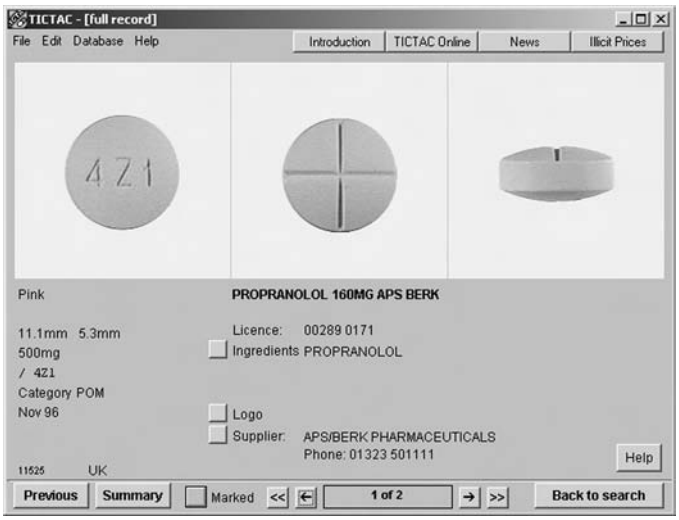

Figure 13.21 TICTAC output screen showing the result of a successful identification. Reproduced with permission from TICTAC Communications.

Table 13.2 Examples of markings that are easily confused

Numbers or letters		*Lower case L or upper case I*		*Depending which way up the product is viewed*	
1	0	L	u	Z	W
I	O	I	n	N	M

Figure 13.22 IDENTIDEX data input screen.

IDENTIDEX

The same identification may be performed using the IDENTIDEX database from Micromedex. The marking is entered in the *Enter Search Term* box and the *Search* button pressed (Fig. 13.22). A list of markings that match or are similar to those in the query is retrieved (Fig. 13.23). The matching entry is double clicked to retrieve the final detailed data; there are no images of the products (Fig. 13.24).

Unmarked product

TICTAC is the only database available to address the identification of unmarked products. Plain unmarked products may be located by entering the description in the appropriate card (*Tablet, Capsule, Patch* or *Stamp*). The *Patch* card deals with the identification of transdermal devices, and the *Stamp* card with illicit drugs supplied impregnated in paper 'stamps'.

Figure 13.23 IDENTIDEX intermediate data output screen.

Figure 13.24 IDENTIDEX final data output screen.

Figure 13.25 Example of an unmarked white tablet. Reproduced with permission from TICTAC Communications.

The tablet in Fig. 13.25 is 6.4 mm in diameter and 2.6 mm total thickness, and it weighs 90 mg. In this case the data entered need to be quite detailed:

- Unmarked (no alphanumeric marking or logo)
- Half-scored no marking (no marking other than a break-line which divides it in two)
- Shape in elevation – biconvex
- Shape in plan – round
- Colour – white
- Colour type – solid (as opposed to mottled or layered)
- Dimensions (measured in millimetres with a ruler or digital calipers).

The data are entered by selecting options using checkboxes or pull-down menus (Fig. 13.26). The dimensions are entered in order, largest first. Pressing the *Retrieve* button initiates a search for products in the database that match the data within the specified precision (10% by default) and, if the sort box is checked, the products found are sorted in order of best fit to the data entered. The default precision is appropriate unless the product is damaged or the measurements are imprecise. Sugar-coated and illicit tablets vary more in size and weight, so the precision may be widened when searching for these.

This enquiry retrieves about 20 similar products sorted in order of best fit to the sizes and weights entered. Many have the same active ingredient (prednisone) and may be identical products marketed by different companies, or may be manufactured to the same British Pharmacopoeia specification.

This identification cannot be achieved using IDENTIDEX, which deals with marked products only.

Products marked with a logo

TICTAC

A different strategy is required for products marked with a logo (defined as a marking that cannot be entered from a computer keyboard). The product in Fig. 13.27 may be identified by first searching the *logo database* for all the logos that have the description *cat* (Fig. 13.28), selecting the appropriate one and then searching the *products database* for those that bear the cat marking (Fig. 13.29).

Figure 13.27 Example of a tablet marked with a logo. Reproduced with permission from TICTAC Communications.

Products that are an unusual shape (those not shown in the shapes on the tablet or capsule forms) are also located in a similar manner, for example the cat's head shape in Fig. 13.30.

Capsule identification

Capsules are identified in a similar manner to tablets, but using the *Capsule* form. This form, although similar to the tablet form, has the appropriate descriptors for shape and allows two colours to be chosen (Fig. 13.31). As discussed above, the printing on capsules may not be consistent on the cap or body.

Unsealed capsules should be checked to ensure they have not been tampered with. It is useful to check the total weight of any capsule during identification, as this will almost certainly be different from that of the intact product if it has been interfered with. The capsule in Fig. 13.32 has had its contents removed and replaced with a crushed ecstasy tablet.

Confirmation of identity

Confirmation of identity may be required if the product is not identified uniquely or if the consequences of an error demand that identification be confirmed. The analysis can be quite challenging for some products,

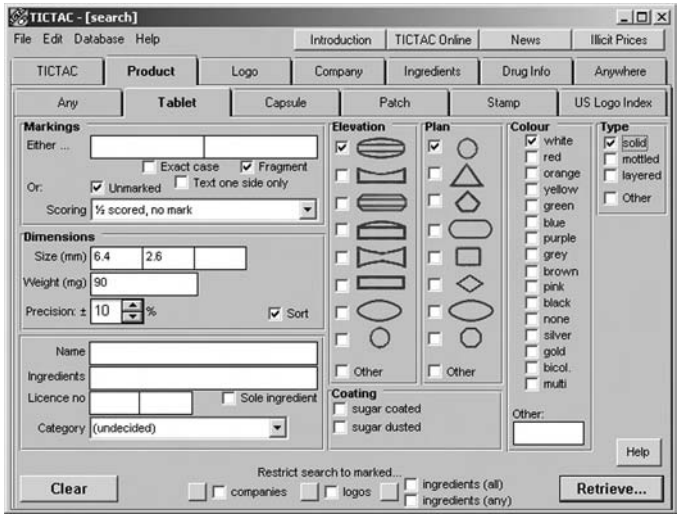

Figure 13.26 TICTAC data input screen with information required for the unmarked white tablet in Figure 13.25. Reproduced with permission from TICTAC Communications.

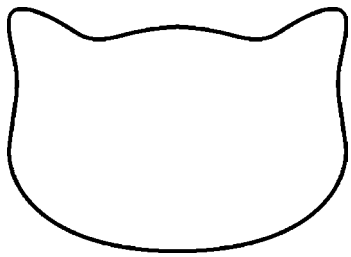

Figure 13.30 An example of a tablet that is an unusual shape. Reproduced with permission from TICTAC Communications.

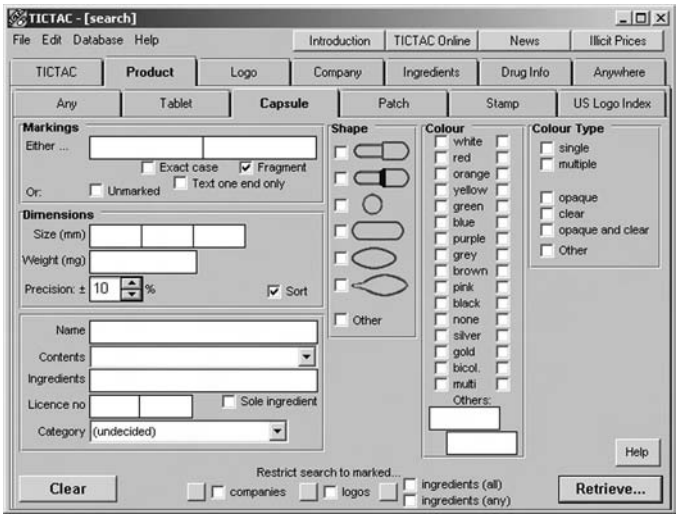

Figure 13.31 TICTAC data-input screen used to identify capsules. Reproduced with permission from TICTAC Communications.

such as multivitamins and minerals, herbal products, homeopathic remedies and steroids

Colour tests have been promoted for use by purchasers of ecstasy tablets at dance venues, either by organisations that offer a service or by the users themselves (Spruit 2001; Winstock *et al.* 2001). The Marquis reagent and more recently the Mecke or modified Mecke reagent and Mandelin's reagent are available to the public for this purpose on the Internet (Spruit 2001; Winstock *et al.* 2001).

Figure 13.32 A capsule that has had the contents removed and replaced with a tablet. Reproduced with permission from TICTAC Communications.

Confirmation of identity may be required for a variety of reasons:

- Identification of illicit products
- Unequivocal identification for forensic purposes
- Detection of adulteration
- Detection of the substitution of capsule contents
- Identification of products not in commercial databases
- Investigation of counterfeit or substandard products.

This may often be achieved by suspending a whole tablet or a scraping from a tablet or a portion of a capsule contents in a solvent, such as ethanol or methanol, and analysing it by spectroscopic methods (UV, IR, MS) or chromatographic methods (TLC, GLC, HPLC, CE or a combination of both (GC-MS, HPLC-diode array, UV). Commercial or in-house libraries of IR and mass spectra may be of great value in identifying unknown products. However, new synthetic illicit drugs, particularly when reference materials are not available, such as 4-methylthioamfetamine and those described in *PiHKAL* (e.g. 2C-T-7) (Shulgin, Shulgin 1991) can present significant analytical challenges and may require structural elucidation using NMR spectroscopy. Identification by diamond attenuated total reflectance (ATR) IR of the scrapings of a tablet or the contents of a capsule may be achieved providing the active ingredients are present as major components.

The analysis of legitimate pharmaceutical products is discussed in Chapter 12.

The analysis of non-active ingredients (excipients in legitimate medicines or diluents in illicit drugs) may be of value in investigating counterfeit medicines or the origin of illicit drugs. Near-IR spectroscopy, particularly when linked with microscopy, is a valuable technique for this purpose (see Chapter 34). Visible polarised-light microscopy may be used to identify excipients such as the starches (e.g. maize, potato) used as disintegrants.

The confirmation of identity of herbal products is difficult and may require microscopic examination for plant fragments by a specialist and chromatographic analysis (often TLC) for indicator compounds (Barnes *et al.* 2007). The genetic characteristics of traditional Chinese herbal drugs are under investigation at the Royal Botanic Gardens at Kew and may be of value for the confirmation of their identity in the future.

CHAPTER

14 Volatile Substances

RJ Flanagan

If anaesthesia is excluded, acute poisoning with volatile substances usually follows the deliberate inhalation of gas or solvent vapour in order to become intoxicated ('glue sniffing', solvent abuse, volatile substance abuse (VSA)). Solvents from adhesives, notably toluene, and from certain print-correcting fluids and thinners, hydrocarbons such as those found in cigarette lighter refills, halocarbon aerosol propellants and fire extinguishers, 'air dusters', and anaesthetic gases are among the products/compounds that may be abused in this way (Table 14.1).

Those who ingest, or more rarely inject, solvents or solvent-containing products, and the victims of clinical, domestic and industrial accidents, may also be poisoned by volatile substances. In addition, chloroform, diethyl ether and other volatiles are still used occasionally in the course of crimes such as rape and murder (Flanagan, Fisher 2008). Ingestion of the solvent γ-butyrolactone (GBL), and also of 1,4-butanediol, which are converted rapidly in the body into γ-hydroxybutyric acid (GHB), has become prevalent in recent years. A further volatile compound, chlorobutanol (chlorbutol), sometimes employed as a sedative, a plasticiser and a preservative, has been used in doping greyhounds. Inhalation of asphyxiant gases such as helium has been used as a means of suicide (Field-Smith *et al.* 2009).

Inhalation of a range of other volatile substances ranging from mothball vapour (naphthalene or 1,4-dichlorobenzene) to overtly toxic gases such as chlorine in order to experience particular effects has also been reported, but such practices are very uncommon. Isobutyl and isopentyl ('amyl') nitrites ('poppers', 'snappers') may also be inhaled in order to experience their vasodilator properties. In the USA, abuse of these compounds is discussed along with abuse of other volatiles under the term 'inhalant abuse' (Williams *et al.* 2007), but in other countries these substances are normally discussed separately. Isobutyl nitrite is now listed as a Class 2 carcinogen.

Solvents and many other volatiles can produce dose-related central nervous system effects similar to those of ethanol. Small doses can lead rapidly to euphoria and other behavioural disturbances, and may also induce more profound effects such as delusions and hallucinations. Heightened sexual (self-) gratification may also be a feature, sometimes in association with partial asphyxia (Musshoff *et al.* 2006). Once exposure ceases, rapid recovery normally ensues – rapid recovery after exposure may be a factor in the continuing popularity of VSA among children of high-school age (13–18 years old) in some countries. On the other hand, psychological dependence is common in chronic users. VSA has now been reported from most parts of the world, mainly among adolescents, individuals living in remote communities and those with occupational access to abusable volatiles.

The major risk associated with VSA is that of sudden death and, although the UK is the only country to collect VSA-related mortality data systematically, there have been many reports of 'sudden sniffing deaths' worldwide. There were at least 2308 (1967 male) UK sudden VSA-related deaths in the period 1971–2007, with some 47% in youngsters aged 7–17 years (Field-Smith *et al.* 2009). Some 5% of all VSA-related deaths were thought to have been suicides. Deaths occurring from 'indirect' causes such as inhalation of vomit (14.2% of deaths), asphyxia associated with use of a plastic bag (11.1%), and trauma (10.9%) were frequently associated with abuse of products containing toluene, usually adhesives (glue). However, most deaths (60.3%) were attributed to 'direct toxicity' (Field-Smith *et al.* 2009). Nine hundred and twenty-three deaths (40 per cent of all USA-related deaths) were associated with abuse of liquefied petroleum gas (LPG) cigarette-lighter refills. Annual numbers of deaths have been decreasing in the UK in recent years (58 deaths, 2007).

Chronic toxicity from exposure to volatile substances has also been described both in abusers and after occupational use of certain compounds. Although sale of adhesives and spray paints containing more than 0.1% (v/v) toluene to the general public was prohibited within the European Community from June 2007, industrial use of toluene remains unaffected. Deposition of titanium-containing granules in the lung after presumed inhalation of a toluene-based spray paint has been noted (Byard *et al.* 2007). Chronic toxicity such as lead poisoning from abuse of leaded gasoline has been reported in less developed countries or societies (e.g. among aboriginal populations, but is much less common nowadays). In addition to the risk of fire and explosion from abuse of LPG in confined spaces, hydrofluoric acid burns have been observed following ignition of 1,2-difluoroethane from compressed air cleaners (Foster *et al.* 2003).

Role of the analytical toxicology laboratory

The analytical toxicology laboratory may be asked to perform analyses for solvents and other volatile compounds in biological samples and related specimens for the following purposes:

1. To assist in the diagnosis of acute poisoning including the investigation of deaths where poisoning by volatile compounds (including anaesthetic agents and asphyxiant gases) is a possibility.
2. To confirm a suspicion of chronic VSA in the face of denial from the patient and/or a person responsible for the care of the patient such as a parent or guardian.
3. To aid investigation of rape or other assault, or other offences such as driving a motor vehicle or operating machinery, which may have been committed under the influence of volatile substances, or in which volatile substances may have been administered to a victim.
4. To help investigate fire or explosion where VSA might have been a contributory factor.
5. To assess occupational or environmental exposure to anaesthetic or solvent vapour. However, other techniques such as ambient or expired air monitoring or, in some instances, the measurement of urinary metabolite excretion may be more appropriate in this context.

The analysis of volatile substances presents particular problems. First, collection, storage and transport of biological samples must be controlled as far as practicable in order to minimize loss of analyte – quantitative work is futile if very volatile compounds such as propane are encountered unless precautions are taken to prevent losses from the sample prior to the analysis. Second, many of the compounds of interest occur commonly in laboratories and this necessitates precautions against contamination/interference. Third, many volatile compounds are excreted unchanged via the lungs and thus blood (and/or other tissues in fatalities), and not urine, is usually the sample of choice. Finally, the interpretation of results can be difficult, especially if legitimate exposure to solvent vapour is a possibility.

A diagnosis of VSA should be based on a combination of circumstantial, clinical and analytical evidence rather than on any one factor alone. It is especially important to consider all circumstantial evidence in cases of possible VSA-related sudden death since suicide or even homicide cannot be excluded simply on the basis of the toxicological

Table 14.1 Some products/compounds that may be abused by inhalation[a]

Product	*Major volatile components*
Adhesives	
Balsa wood cement	Ethyl acetate
Contact adhesives	Butanone, hexane[b], toluene and esters
Cycle tyre repair cement	Toluene and xylenes[c]
Polyvinylchloride (PVC) cement	Acetone, butanone, cyclohexanone, trichloroethylene
Woodworking adhesives	Xylenes[c]
Aerosols	
Air freshener	Purified LPG[d], dimethyl ether (DME) and/or fluorocarbons[e]
Deodorants, antiperspirants	Purified LPG[d], DME and/or fluorocarbons[e]
Fly spray	Purified LPG[d], DME and/or fluorocarbons[e]
Hair lacquer	Purified LPG[d], DME and/or fluorocarbons[e]
Paint	Purified LPG[d], DME and/or fluorocarbons[e] and esters
Anaesthetics/analgesics	
Inhalational	Nitrous oxide, cyclopropane[f], diethyl ether[f], halothane, enflurane, desflurane, isoflurane, methoxyflurane[f], sevoflurane, xenon
Topical	Ethyl chloride, fluorocarbons[e]
Cigarette lighter refills	Purified LPG[d]
Commercial dry cleaning and degreasing agents	Carbon tetrachloride[g], dichloromethane, methanol, 1,1,2-trichlorotrifluoroethane (FC 113), 1,1-dichloro-1-fluoroethane (FC 141b), methanol, propylene dichloride[g], 1,1,1-trichloroethane[g], tetrachloroethylene, toluene, trichloroethylene
Domestic spot removers and dry cleaners; surgical plaster/chewing gum remover	Carbon tetrachloride[g], dichloromethane, 1,1,1-trichloroethane[g], tetrachloroethylene, trichloroethylene
Dust removers ('air brushes', 'air dusters')	DME, fluorocarbons[e],[g]
Fire extinguishers	Bromochlorodifluoromethane (FC 12B1, BCF)[f], trichlorofluoromethane (FC 11)[f], dichlorodifluoromethane (FC 12)[f]
Hydrocarbon fuels/solvents	Acetylene, 'butane'[h], petrol (gasoline)[i], petroleum ethers[j], 'propane'[k]
Industrial/laboratory solvents	Chloroform[f], methyl acetate, methyl isobutyl ketone (MIBK), methyl *tert*-butyl ether (MTBE)
Injected oxidant (drag racing, blow torches)	Nitrous oxide
Paint/paint thinners	Acetone, butanone, esters, hexane[b], toluene, trichloroethylene, xylenes[c]
Paint stripper	Dichloromethane, methanol, toluene
Starting fluid	Diethyl ether, hydrocarbons (heptane, LPG[d]), DME
Typewriter correction fluids/thinners (some)	1,1,1-Trichloroethane[f]
Vasodilators	Butyl nitrite, isobutyl nitrite ('butyl nitrite'), isopentyl nitrite (isoamyl nitrite, 'amyl nitrite')[l]
Whipped cream dispenser bulbs/cylinders	Nitrous oxide

[a]The composition of some products varies with time and country of origin.
[b]Commercial 'hexane' mixture of hexane and heptane with small amounts of higher aliphatic hydrocarbons.
[c]Mainly *m*-xylene (1,3-dimethylbenzene).
[d]Liquified petroleum gas (LPG; butane, isobutane, propane; if unpurified also butenes, propenes, sulfur compounds, etc.).
[e]Nowadays often 1,1,1,2-tetrafluoroethane (FC 134a), but chlorodifluoromethane (FC 22), 1,1-difluoroethane (FC 152a), difluoromethane (FC 32), pentafluoroethane (FC 125), perfluoropropane (FC 218) and 1,1,1-trifluoroethane (FC 143a) might also be encountered.
[f]Rarely used for this purpose nowadays.
[g]May also contain denatonium.
[h]LPG.
[i]Mixture of aliphatic and aromatic hydrocarbons with boiling range 40–200°C.
[j]Mixtures of pentanes, hexanes, etc. with specified boiling ranges (e.g. 40–60°C).
[k]Propane, butanes, etc.
[l]Commercial 'amyl nitrite', mainly isopentyl nitrite but other nitrites also present.

examination. There have been a number of reports of the use of inhalational anaesthetics for suicidal purposes, and there has been one example in the UK of a serial homosexual rapist who murdered his victims and disposed of the bodies by setting fire to them in garden sheds in circumstances that suggested that the victim had caused the fire accidentally while indulging in VSA (Flanagan, Fisher 2008). The possibility of VSA should also be considered in individuals giving very high readings on evidential breath alcohol instruments (Gill *et al.* 1991). A result of 333 µg alcohol in 100 mL breath has been recorded in one instance after alcohol ingestion and butane inhalation; a contemporary specimen for blood ethanol measurement was not available for analysis (Flanagan, Fisher 2008). Modern instruments may be less prone to such interference, however.

Analytical methods

The analysis of biological samples for solvents and other volatiles that may be abused by inhalation has similarities to the analysis of methanol, ethanol and 2-propanol. Static headspace gas chromatography (GC) often provides a convenient and easily automated mode of analysis for

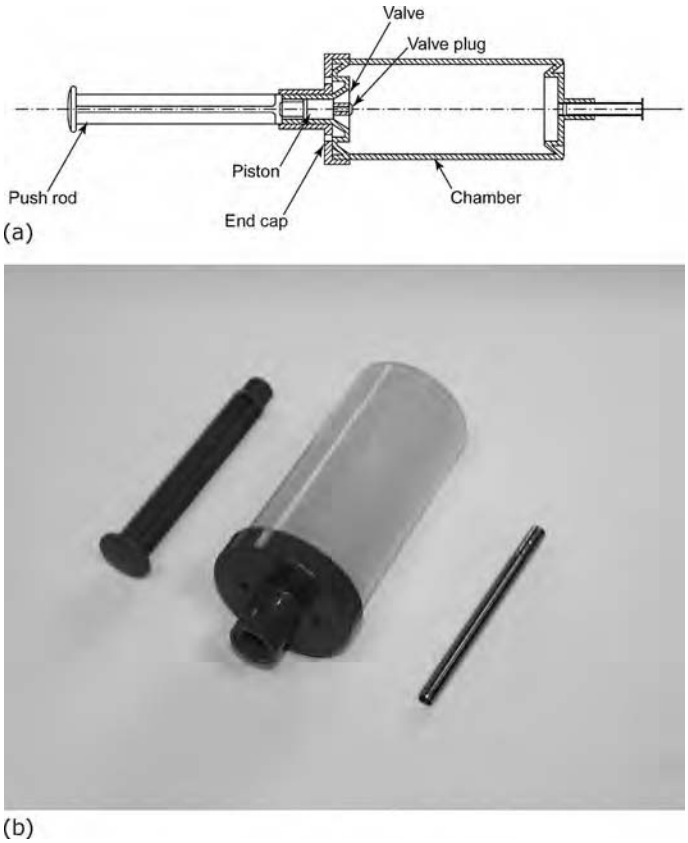

Figure 14.1 Device for capturing breath samples for solvent analysis: (a) schematic; (b) components. (Dyne *et al.* 1997; illustrations courtesy of Dr J Cocker, Health & Safety Laboratory, Buxton, UK.)

blood and other biological specimens that may be obtained without using special apparatus in order to collect the sample (Kolb, Ettre 1997). Many analyses can be accomplished using flame ionisation and/or electron capture detection (FID and/or ECD). Nitrous oxide and most halogenated compounds give a response with ECD, although thermal conductivity detection (TCD) may be used as an alternative if nitrous oxide poisoning is suspected. GC methods for xenon would require TCD or mass spectrometry (MS) (Miyano *et al.* 1993).

Use of expired air collected into either a Tedlar (polyvinylfluoride, PVF) bag or via a special device constructed from a polytetrafluoroethylene (PTFE)-like polymer (Fig. 14.1) (Dyne et al. 1997) with subsequent GC or GC-MS analysis can facilitate the analysis of a number of compounds. Direct MS of expired air can also detect many compounds several days post exposure. However, the use of these techniques is limited by the need to take breath directly from the patient and the specialist equipment required. This being said, helium has been detected in gas samples from the lungs of a helium-related suicide by GC-MS using nitrogen as carrier gas (Auwaerter et al. 2007). Vapour-phase infrared (IR) spectrophotometry may be useful in the analysis of abused products or ambient atmospheres. High performance liquid chromatography (HPLC) is useful in the analysis of polar metabolites of certain solvents.

Sample collection, transport and storage

If the analyte is very volatile (e.g. helium, propane, butane) direct sampling, for example of air in the lungs, may be indicated. If a quantitative analysis is required, a blood sample should be collected directly into the vial in which the analysis will be carried out (Gill *et al.* 1992). Many other volatile compounds are relatively stable in blood and other tissues if simple precautions are taken. In the case of blood, the container used for the sample should be glass, preferably with a cap lined with metal foil; greater losses may occur if plastic containers are used. The tube should be as full as possible and should be opened only when required for analysis and then only when cold (4°C) (Gill *et al.* 1988). If the sample volume is limited it is advisable to select the container to match the volume of blood so that there is minimal headspace. An anticoagulant should be used (sodium ethylenediamine tetraacetate (EDTA) or lithium heparin). Specimen storage between 2 and 8°C is recommended and 1% (w/v) sodium fluoride should be added to minimise enzymic activity.

If a necropsy is to be performed, tissues (approximately 10 g each of brain, lung, liver, kidney and subcutaneous fat) should be obtained in addition to standard toxicological specimens (femoral blood, urine, stomach contents, vitreous humour). Tissues should be stored before analysis in the same way as blood. No preservative should be added. Products implicated in the incident (and stomach contents if ingestion is suspected) should be packed, transported and stored entirely separately from (other) biological specimens to avoid cross-contamination. Investigation of deaths occurring during or shortly after anaesthesia should include analysis of the inhalational anaesthetic(s) used in order to exclude an administration error (Uyanik 1997). The stability of chloroform, diethyl ether, ethanol and toluene in formalin-fixed rabbit tissue (brain, lung, liver, kidney and skeletal muscle) has been studied (Takayasu *et al.* 1994). It was concluded that these compounds could be detected for up to 14 days after fixation even though there was marked loss of toluene, especially from brain (84%), even after 1 day.

Gas chromatography

Summary details of some GC methods for volatile compounds in biological specimens are given in Table 14.2. Packed columns, for example 2 m × 2 mm i.d. 0.3% (w/w) Carbowax 20M on Carbopack C programmed from 35°C to 175°C, have been used with headspace sample preparation (Ramsey, Flanagan 1982). Disadvantages include the poor resolution of some very volatile substances, a long total analysis time, and variation in the peak shape given by alcohols between batches of column packing. Retention index data for a range of solvents and other volatile compounds of interest on both 0.3% and 6.6% (w/w) Carbowax 20M are available (De Zeeuw et al. 1992).

Porous layer open tubular (PLOT) columns give good retention and thus resolution of compounds with similar relative molecular mass, but peak shapes of polar compounds are poor and it is difficult to screen for compounds of widely different volatility in one analysis. However, bonded-phase wide-bore capillary columns permit relatively large-volume septum injections and can offer advantages of improved efficiency, reproducibility and reliability. A 60 m × 0.53 mm i.d. fused silica capillary coated with the dimethylpolysiloxane SPB-1 (5 µm film) programmed from 40°C to 200°C offers many advantages over packed column and PLOT systems (Flanagan *et al.* 1997). Improved resolution of very volatile compounds is obtained and, even with an initial temperature of 40°C, the total analysis time can be reduced to 26 min, and good peak shapes can be obtained, even for alcohols. Moreover, splitless septum injections of up to 300 µL headspace can be performed with no noticeable effect on column efficiency; hence sensitivity is at least as good as that attainable with a packed column. Retention data on this system for some commonly used compounds are given in Table 14.3.

The use of a capillary column together with two different detectors (FID and ECD) confers a high degree of selectivity, particularly for low-molecular-mass compounds where there are relatively few alternative structures. If more rigorous identification is required, GC combined with MS or Fourier transform IR spectrometry (FTIR) may be used. However, GC-MS can be difficult at high sensitivity when the fragments produced are less than *m/z* 40, particularly if the instrument is used for other purposes as well as solvent analyses. In particular, the available sensitivity and spectra of the low-molecular-weight alkanes renders them very difficult to confirm by GC-MS. Inertial spray MS allows introduction of biological fluids directly into the mass spectrometer without prior chromatographic analysis and has been used in the analysis of halothane in blood during anaesthesia.

GC-FTIR may be more appropriate than GC-MS in the analysis of volatiles, but sensitivity is poor particularly when compared with ECD.

Table 14.2 Summary of some GC methods for volatile compounds in biological fluids published 1989–1998 (adapted from Pihlainen, Ojanpera 1998)

[a]HS, headspace; HS-FE, headspace full evaporation; HS-SPME, headspace solid-phase microextraction; HST, headspace low-temperature trapping; PH, pulse heating; PT, 'purge and trap'.
[b]LoD, limit of detection (in some cases limit of identification or limit of accurate measurement).
[c]1,1,1-Trichloroethane.
[d]Nitrous oxide.
[e]Toluene (3 µL sample).
[f]Isoflurane.
[g]Methyl *t*-butyl ether (30 mg sample).

Moreover, the apparatus is expensive and not widely available. In addition, interference, particularly from water and carbon dioxide in the case of biological specimens, can be troublesome. 'Purge and trap' and multiple headspace extraction offer ways of increasing sensitivity and, although not needed for most clinical and forensic applications, 'purge and trap' has been used in conjunction with GC-FTIR and FID in forensic case work (Ojanpera *et al.* 1996, 1998). Pulse heating has also been employed in the analysis of volatiles in biological specimens (see Table 14.2). This method involves the use of a Curie point pyrolyser employing a ferromagnetic alloy that can accurately attain temperatures in the range 150–1040°C very rapidly (4 s or so) (Nagano et al. 1989;Saito et al. 1995;Takayasu et al. 1995). Advantages of this latter technique include use of a small sample volume (0.5–5 µL), short extraction time and lack of matrix effects. Headspace solid-phase microextraction (HS-SPME) has also been used in the analysis of volatile compounds in biological samples (Junting et al. 1998; Walker et al. 2006).

Chiral GC methods are available should enantiomer separation of anaesthetics prove important (Schurig, Grosenick 1994; Shitangkoon *et al.* 1993).

Qualitative analysis

The procedures described below are based on those of Flanagan *et al.* (1997) using a 60 m × 0.53 mm i.d. fused-silica capillary coated with the dimethylpolysiloxane SPB-1 (5 µm film) with split FID/ECD detection and manual sample preparation and headspace injection. Note that the

[a]RT, retention time (min); RRT, retention time relative to 1,1,2-trichloroethane (on the ECD channel for compounds responding on that channel); ECD, relative ECD response (0 = nil, 1 = poor, 2 = good); Calc., calculated retention index on the SPB-1 system; Lit., literature retention index on SE30/OV-1/OV-101; M_r, relative molecular mass; BP, boiling point (°C, atmospheric pressure); CAS, Chemical Abstracts Registry number.
[b]Compounds injected as liquids.

pulsed discharge (PD) detector (Forsyth 2004) can be used as an ECD. A few per cent of an additional gas ('dopant') is added, which is ionised and provides electrons to produce a standing current. Several dopants have been tested – the best appear to be methane and xenon. The PD-ECD has a sensitivity (minimum detectable quantities of 10^{-15} to 10^{-12} g) similar to, or better than, ^{63}Ni-ECD, but does not require licensing, wipe tests, and other administrative or safety requirements.

Preparation of internal standard solution Approximately 50 mg ethylbenzene and 50 mg 1,1,2-trichloroethane (both checked for purity by gas chromatography before use – common impurities are toluene in ethylbenzene and 1,1,1-trichloroethane in 1,1,2-trichloroethane) are measured into 50 mL glass volumetric flasks containing outdated, 'volatile-free', blood-bank whole blood. After thorough mixing, 1.0 mL of the 1,1,2-trichloroethane solution and 2.5 mL of the ethylbenzene solution are diluted to 100 mL using outdated, blood-bank, whole blood–deionised water (1 + 24) to give the working internal standard solution. The final ethylbenzene and 1,1,2-trichloroethane concentrations are approximately 25 and 10 mg/L, respectively. This solution remains usable for not less than 2 years if stored in 3 mL portions at −5°C to −20°C in screw-topped glass vials (3.5 mL, Merck 215/0073/23) or equivalent.

Sample preparation

Blood and urine Internal standard solution (200 µL) is added to a 12 mL glass septum vial (Chromacol 12-CV or equivalent) using an air displacement pipette. The vial is then sealed with a crimped-on, Teflon-lined, silicone rubber septum (Chromacol 20-ST3 or equivalent) and disposable aluminium vial cap. The vial is incubated (65°C, heating block) and, after 15 min, a portion (100–300 µL) of the headspace is withdrawn using a 0.5 mL gas-tight glass syringe (Supelco 500F-GT or equivalent) that has been warmed by being placed on the heating block (10 min), and injected onto the gas chromatography column over 2–3 s.

Subsequently, the sample (whole blood, plasma, serum or urine) (200 µL) is added via the septum to the same vial using a 1.0 mL hard plastic (polystyrene) disposable syringe fitted with a 2.5-cm (1-inch), 25-gauge Luer needle and, after at least 15 min, a further portion of the headspace is taken using the 0.5 mL gas-tight syringe described above and injected onto the GC column. After each injection, the plunger should be removed from the gas-tight syringe and the assembly placed on the heating block until the next injection to ensure evaporation of any remaining analyte. The syringe should also be rinsed occasionally with methanol to remove deposits and dried by purging with compressed air.

Tissues A 'blank' internal standard analysis should be performed as described above. Samples of solid tissues should be analysed in a separate vial after adding a proteolytic enzyme to the incubation mixture to digest the sample. Thus, 20–50 mg wet weight of tissue is dissected from the centre of the frozen specimen. Duplicate portions of the specimen are incubated (65°C, 15 min) with internal standard solution (200 µL) and approximately 1 mg of solid protease (Sigma Type VIII (Subtilisin Carlsberg; Subtilopeptidase A; EC 3.4.21.62), P 5380) or equivalent, prior to the analysis of 100–300 µL headspace as described above.

Products Aerosols and fuel gases can be analysed after releasing a portion of the product into a headspace vial, and then transferring a few microlitres of the vapour to another vial for analysis. Liquids can be analysed in the same way except that it is often possible to withdraw a portion (5–50 µL) of the headspace directly from the container. In this latter case, however, the result may not be representative of the composition of the liquid as a whole. Adhesives and other liquid or semi-liquid products can be introduced into a glass vial. The vial is sealed and, after incubation (65°C, 15 min), a portion (50–100 µL) of the headspace is transferred to a sealed pre-incubated vial (65°C, 15 min) containing internal standard solution. After re-equilibration (65°C, 5 min) 100–200 µL of headspace is taken for analysis.

Quantitative analysis

Quantitative assays should be performed in duplicate either isothermally or on a temperature programme using the appropriate detector. If concentrations of ECD-responding compounds are very high, it is sometimes more convenient to use FID. Assay calibration should be by analysis of standard solutions prepared as described below; the same solutions are used in the analysis of blood and of tissue digests. Analyte concentrations in the ranges 0.1–10 or 0.5–50 mg/L are usually adequate in cases of acute poisoning. Calibration graphs of peak height or area ratio to the internal standard are usually used, although absolute calibration in terms of amount of analyte injected should be possible, especially if an automated headspace analyser is employed. Such apparatus not only permits unattended operation, but also gives much better reproducibility in quantitative work.

Liquid and solid analytes Calibration solutions are prepared by adding a known volume of the liquid analyte to a volumetric flask containing 'volatile-free' blood by using a positive displacement pipette and ascertaining the exact amount added by weighing. Solid analytes are weighed in directly. After allowing time for equilibration, appropriate dilutions are performed, taking care to minimize loss of analyte by handling reagents and glassware at 4°C and storing samples and standards at 4°C with minimal headspace. Small (3.5 or 7.0 mL) glass vials (Merck 215/0073/23 or 25, or equivalents) with screw caps lined with aluminium foil are convenient for performing standard dilutions. Portions of the standards are transferred to headspace vials for analysis as described above and a calibration graph of peak height or area ratio of analyte to internal standard against analyte concentration is prepared. Often, either 1,1,2-trichloroethane or ethylbenzene can be used as the internal standard.

Gaseous analytes Calibration solutions of gaseous analytes have been prepared from a solution of the analyte in methanol with subsequent dilution in blood (Broussard *et al.* 2001). Alternatively, calibration mixtures for gaseous analytes may be prepared directly into headspace vials (Gill *et al.* 1992). Septum vials of approximately 30, 50 and 100 mL nominal capacity (Supelco 33106, 33108-U, 33110-U; or equivalent) are calibrated by weighing when filled with deionised water. Each vial is then dried and filled with nitrogen. A piece of aluminium foil (approximately 1 cm^2) is added to aid mixing and the vial is sealed with a crimped-on, Teflon-lined, silicone rubber septum identical to those used in sample analyses. A 125 mL gas sampling bulb fitted with two grease-free Teflon stopcocks and a central cylindrical septum (Supelco 2-2146 or equivalent) is filled with pure analyte, usually purchased in a small cylinder ('lecture bottle'), at atmospheric pressure. The selected volume of vapour is then taken from the gas sampling bulb via the septum using a gas-tight syringe and added through the septum of a calibrated, nitrogen-filled, sealed septum vial. Care should be taken to ensure that the contents of this latter vessel remain at atmospheric pressure. Thus, if the volume of gas transferred is greater than 0.1 mL, a short vent needle should be inserted through the septum well away from the point of the gas-tight syringe needle. After thorough mixing of the gas transferred to the septum vial, further dilutions into additional calibrated, nitrogen-filled, sealed septum vials may be prepared as required. Finally, measured volumes of diluted analyte vapour are transferred using a gas-tight syringe into headspace vials containing the same volume of 'blank' blood as used in sample analyses. A constant volume of appropriately diluted internal standard vapour (2,2-dimethylpropane in the case of butane) prepared as above is also added to the sample headspace vial and to the headspace vials containing the calibration mixtures prior to the analysis.

Pharmacokinetics and the interpretation of results

The UK maximum exposure limit (MEL) or occupational exposure standard (OES; Table 14.4) provides information on the relative toxicities of different compounds after chronic exposure to relatively low concentrations of vapour. Inhaled compounds may rapidly attain high concentrations in well-perfused organs (brain, heart) while concentrations in muscle and adipose tissue may be very low. Should death occur, this situation is 'frozen' to an extent, but if exposure continues the compound will accumulate in less-accessible, poorly perfused tissues, only to be slowly released once exposure ceases. Thus, the plasma concentrations of some compounds may fall monoexponentially, while others may exhibit two (or more) separate rates of decline (half-lives).

The solubility of a volatile compound in blood is an important influence on the rate of absorption, tissue distribution and elimination of the compound. The partition coefficients of a number of compounds between air, blood and various tissues have been measured *in vitro* using animal tissues, and some *in vivo* distribution data have been obtained from postmortem tissue measurements in humans (Table 14.4). However, these latter data must be used with caution since there are many difficulties inherent in such measurements (sampling variations, analyte stability, external calibration, etc.). Published data on the plasma half-lives of volatile substances (Table 14.4) are not easily comparable, because either too few samples have been taken or the analytical methods used did not have sufficient sensitivity to measure the final half-life accurately.

Many volatile substances, including butane, dimethyl ether, most fluorocarbon refrigerants/aerosol propellants, isobutane, nitrous oxide, propane, tetrachloroethylene and 1,1,1-trichloroethane, are largely eliminated unchanged in exhaled air. Others are partly eliminated in exhaled air and also metabolised in the liver and elsewhere, the metabolites being eliminated in exhaled air or in urine, or incorporated into intermediary metabolism. After ingestion, extensive hepatic metabolism can reduce systemic availability ('first-pass' metabolism) of certain compounds. Table 14.5 gives details of examples where blood or urinary metabolite measurements have been used to assess exposure to volatiles.

Interpretation of qualitative results

The likelihood of detecting exposure to volatile substances by headspace-GC of blood is influenced by the dose and duration of exposure, the time of sampling in relation to the time elapsed since exposure, and the precautions taken in the collection and storage of the specimen (Broussard 2000; Gill *et al.* 1988; Willie, Lambert 2004). In a suspected VSA- or anaesthetic-related fatality, analysis of tissues (especially fatty tissues such as brain) may prove useful since high concentrations of volatile compounds may be present even if very little is detectable in blood.

Analysis of metabolites in urine may extend the time after which exposure may be detected but, of the compounds commonly abused, only toluene, the xylenes and some chlorinated solvents, notably trichloroethylene, have suitable metabolites (Table 14.5). Chronic gasoline 'sniffing' has been diagnosed by the measurement of blood lead concentrations or detection of aromatic components such as toluene and ethylbenzene. With some petrols and other complex mixtures such as petroleum ethers (see Table 14.1), however, the blood concentrations of the individual components are often below the limit of detection of HS-GC methods even after significant inhalational exposure. Abuse of methoxyflurane has been detected by measuring serum and urine fluoride ion concentrations.

Detection of a volatile compound in blood does not always indicate VSA or occupational/environmental exposure to solvent vapour. Acetone and some of its homologues may occur in high concentrations in ketotic patients. Large amounts of acetone and butanone may also occur in blood and urine from children with acetoacetyl-coenzyme A thiolase deficiency, for example, and may indicate the diagnosis. In addition, acetone is the major metabolite of 2-propanol in humans. Conversely, 2-propanol has been found in blood from ketotic patients. Other ketones may also give rise to alcohols *in vivo* (Table 14.5). Other volatile compounds such as halothane or chlorobutanol may be used in therapy or inadvertently added to the sample as a preservative.

Use of aerosol disinfectant preparations when collecting specimens may contaminate the sample if an aerosol propellant is used. Contamination of blood samples with ethanol or 2-propanol may also occur if an alcohol-soaked swab is used to cleanse skin prior to venepuncture. In 20 subjects studied after drinking alcohol, 2-propanol (0.13 g/L) was detected in one sample by HS-GC, while in two others the measured ethanol concentration increased from 0.58 g/L (dry cotton swab or 70% 2-propanol swab) to 1.2 g/L (pure ethanol swab) and from 0.12 g/L (dry swab and 2-propanol swab) to 1.26 g/L, respectively, with the swab being used to exert pressure on the venepuncture site upon withdrawal of the needle (Carter, McConnell 1990). Higuchi *et al.* (2005) also reported a definite risk of sample contamination from use of ethanol-containing swabs during sample collection from hospital patients, an extreme blood ethanol concentration of 9.6 g/L being recorded if the swab was used to wipe the syringe needle after sampling. Other studies in volunteers have, however, found at worst minimal contamination using either ethanol- or 2-propanol-soaked swabs (Goldfinger, Schaber 1982; Malingre *et al.* 2005; McIvor, Cosbey 1990; Peek *et al.* 1990). It seems likely that variation in sampling technique underlies these differences, the danger being that blood not drawn

initially for blood ethanol measurement and with due precautions is later used for this purpose.

Gross contamination with technical xylene (a mixture of *o*-, *m*- and *p*-xylene together with ethylbenzene) has been found in blood collected into Sarstedt Monovette Serum Gel blood collection tubes; contamination with toluene (up to 22 mg/L), 1-butanol, ethylbenzene and xylene has been found in more recent batches of these same tubes (Dyne *et al.* 1996). Contamination with 1-butanol or 2-methyl-2-propanol occurs commonly in blood collected into tubes coated with EDTA. Carbon disulfide has been detected in blood collected in tubes sealed with soft-rubber stoppers (Weller, Wolf 1989). Care should be taken when handling frozen tissues prior to analysis as any compounds present in ambient air may condense on the cold surface and give rise to false positives. Processing blank frozen tissue can control for this possibility.

The interpretation of case data involving chloroform is particularly difficult, especially since this compound is still sometimes used with criminal intent (Flanagan, Pounder 2010). In addition to sometimes being present in drinking water at low concentrations as a result of chlorination, chloroform is found in a variety of medicinal preparations, in cigarette smoke, soft drinks, margarines, and in swimming pools if a chlorination plant is in operation. A further possible source of chloroform on HS-GC is from thermal decomposition of trichloroacetic acid (Aggazzotti *et al.* 1987). Trichloroacetic acid is a metabolite of several

Table 14.5 Metabolites of some solvents and other volatile substances that may be measured to assess exposure

Compound	M_r	*Parent compound*	*Fluid*[a]	'*Normal*'[b]	'*High*'[c]	*Comment*
Acetaldehyde	44.1	Ethanol	Blood	0.2 mg/L	(Not known)	
Acetone	58.1	2-Propanol	Blood	10 mg/L	—	Blood/urine acetone concentrations can rise to 2 g/L in ketosis. 2-Propanol also acetone metabolite
			Urine	10 mg/L	80 mg/L	
4-Aminophenol	109.1	Aniline	Urine	—	10 mg/L	
Bromide ion	79.9	Bromomethane, other organobromines	Serum	10 mg/L	40 mg/L	The bromide concentrations associated with toxicity are lower after exposure to organobromines than when bromide salts given orally
Butoxyacetate	132.2	2-Butoxyethanol	Urine	—	100 mg/L	
Carbon monoxide	28.0	Dichloromethane	Blood	<5% HbCO	>20% HbCO	Carboxyhaemoglobin blood half-life 13 h breathing air, atmospheric pressure (carboxyhaemoglobin half-life 5 h after inhalation of CO). Blood carboxyhaemoglobin useful indicator of chronic exposure
Cyanide ion	26.0	Acetonitrile, acrylonitrile, other organonitriles	Blood	0.2 mg/L (non-smokers)	2 mg/L	Cyanide metabolised to thiocyanate; both compounds may accumulate during chronic exposure
Cyclohexanol	100.2	Cyclohexane, cyclohexanone	Urine	—	5 mg/L	Additional cyclohexane metabolites: *t*-1, 2-cyclohexanediol, *t*-1, 4-cyclohexanediol (alcohol metabolites excreted mainly as glucuronides in adults)
Cyclohexanone	98.2	Cyclohexane, cyclohexanol	Urine	—	0.5 mg/L	See entry for cyclohexanol above
2,5-Dichlorophenol	163.0	1,4-Dichlorobenzene	Urine	—	100 mg/L	
Dimethylsulfone	94.1	Dimethylsulfoxide (DMSO)	Urine	—	(Not known)	
Ethanol	46.1	Ethyl acetate	Blood	0.1 g/L	0.8 g/L	0.8 g/L legal UK driving limit
Ethoxyacetate	104.1	Ethoxyethanol, 2-ethoxyethyl acetate	Urine	—	50 mg/L	
β-Hydroxyethoxyacetate (HEAA)	120.1	1,4-Dioxane	Urine	—	0.5 g/L	Dioxane-2-one also found in urine
Fluoride	19.0	Methoxyflurane and some other organofluorines	Serum	0.2 mg/L	2 mg/L	
			Urine	1 mg/L	2 mg/L	
Formate	46.0	Formaldehyde, methanol, methyl formate	Urine	20 mg/L	30 mg/L	
2,5-Hexanedione + 4, 5-dihydroxy-2-hexanone	—	Hexane, 2-hexanone (MBK)	Urine	—	5 mg/L	2-Hexanol and 2-hexanone additional hexane metabolites
Hippurate	179.2	Toluene	Urine	0.2 g/L	2 g/L	Not ideal indicator of toluene exposure as there are other (dietary, pharmaceuticals) sources of benzyl alcohol/benzoate hence hippurate
Mandelate	152.1	Ethylbenzene, styrene	Urine	0.005 g/L	2 g/L	Phenylglyoxylic acid also urinary metabolite
Methanol	32.0	Methyl acetate, methyl formate	Urine	—	30 mg/L	
N-Methylacetamide (NMA)	73.1	*N*,*N*-Dimethylacetamide (DMAC)	Urine	—	65 mg/L	

table continued

Table 14.5 continued

Compound	M_r	*Parent compound*	*Fluid*[a]	'*Normal*'[b]	'*High*'[c]	*Comment*
N-Methylformamide (NMF)	59.1	*N*,*N*-Dimethylformamide (DMF)	Urine	—	15 mg/L	Hydroxymethyformamide and formamide additional metabolites
4-Methyl-2-pentanone	100.2	Methyl isobutyl ketone	Urine	—	3.5 mg/L	
2-Methylphenol (*o*-cresol)	108.1	Toluene	Urine	—	3 mg/L	Hippurate and other methylphenols additional toluene metabolites
t,*t*-Muconate (*t*,*t*-MA)	142.1	Benzene	Urine	—	2 mg/L	Phenol and *S*-phenylmercapturic acid additional benzene metabolites
Nitrite ion	46.0	Butyl nitrite, isopentyl nitrite, other organonitrites	Plasma	2.5 mg/L	(Not known)	
			Urine	—	10 mg/L	
Oxalate	90.0	Ethylene glycol	Urine	2.5 mg/L	4 mg/L	Glycolate and glyoxylate also plasma and urinary ethylene glycol metabolites
Phenol	94.1	Benzene	Urine	0.1 mg/L	50 mg/L	Excreted as sulfate and glucuronide conjugates. Other metabolites include catechol and hydroquinone. Urinary phenol excretion not a reliable indicator of benzene exposure. *t*,*t*-Muconic acid and *S*-phenyl-mercapturic acid excretion have been used to assess exposure
S-Phenylmercapturate (*S*-PMA)	239.2	Benzene	Urine	—	45 µg/L	*t*,*t*-Muconic acid and phenol additional benzene metabolites
2-Propanol	60.1	Acetone	Blood	—	2.5 g/L	Acetone also 2-propanol metabolite
Thiocyanate ion	58.1	Acetonitrile, acrylonitrile, other organonitriles	Plasma	4 mg/L (non-smokers), 20 mg/L (heavy smokers)	120 mg/L	Cyanide/thiocyanate may accumulate during chronic exposure.
2-Thiothiazolidine-4-carboxylate (TTCA)	163.2	Carbon disulfide	Urine	—	8 mg/L	TTCA glutathione conjugate of carbon disulfide. Urinary TTCA excretion reliable indicator of exposure
Tolurates (methylhippurates)	193.2	Xylenes	Urine	0.01 mg/L	1.5 g/L	
Trifluoroacetate	114.0	Halothane and some other fluorinated anaesthetics	Urine	—	2.5 mg/L	
Trichloroacetate	163.4	Trichloroethylene	Urine	—	100 mg/L	Metabolite of 2,2,2-trichloroethanol
2,2,2-Trichloroethanol	149.4	Trichloroethylene	Plasma	10 mg/L	50 mg/L	Also metabolite of chloral hydrate, dichloralphenazone and triclofos

[a]Urinary excretion often expressed as a ratio to creatinine.
[b]Upper limit of normally expected or 'non-toxic' concentration.
[c]Lower limit of concentration associated with toxicity/occupational exposure action limit.

compounds, including the solvent trichloroethylene and the drugs chloral hydrate, dichloralphenazone and triclofos. Trichloroacetic acid has a half-life in blood of 3–5 days and thus may be detected for a relatively long time after exposure to, or ingestion of, a precursor. Trichloroacetic acid plasma concentrations of up to 40 mg/L have been reported after occupational exposure to trichloroethylene vapour.

In 25 adult white women in Florida, USA, over a period of 6 months average plasma chloroform concentrations were generally less than 25 µg/L, but in two plasma chloroform concentrations of 2.9 and 4.0 mg/L, respectively, were found during routine sampling (Pfaffenberger, Peoples 1982). All subjects were carefully screened to exclude occupational and recreational exposure to chloroform and other compounds that could give rise to chloroform on headspace-GC. Nevertheless incidental acute exposure to chloroform or a trichloroacetic acid precursor must have occurred to give rise to these results. At the other extreme, postmortem blood chloroform concentrations in fatalities involving this agent have been reported as 5–800 mg/L (Baselt 2004).

It is well known that ethanol may be both produced and metabolised by microbial action in biological specimens. Propanols and butanols may also be produced by microbial action. 'Congener alcohols' such as methanol, propanol, butanol, 2-butanol, 2-methylpropanol, 2-methylbutanol and 3-methylbutanol (and ketone metabolites of secondary alcohols) may arise from ingestion of alcoholic drinks (Bonte 2000). Methanol or 2-methyl-2-propanol (*t*-butanol) may be used together with pyridine or denatonium benzoate (Bitrex, Aversion) to denature alcohol, although this may not stop the abuse of products containing denatured alcohol (Carnahan *et al.* 2005). Butyraldehyde, dimethyl disulfide, isovaleraldehyde and valeraldehyde may arise from putrefaction (Weller, Wolf 1989). Small amounts of hexanal may arise from degradation of fatty acids in blood on long-term storage even at −5°C to −20°C (Gill *et al.* 1988). Hexanal may co-elute with toluene on some GC systems, but interference from this source is only likely to be important if very low concentrations of toluene (0.1 mg/L or less) are to be measured.

In some deaths attributed to the abuse of LPG, only butane, isobutane and propane are detected on headspace-GC of postmortem samples. In other cases 2-propanol, acetone, 2-methyl-2-propanol, 2-butanol and/or butanone is also present. These latter compounds probably arise from the metabolism of the butanes and propane; using HS-SPME butanol, 2,3-butanediol, 3-hydroxy-2-butanone and 2,3-butanedione have also been detected in postmortem samples from LPG abusers (Walker *et al.* 2006).

The alkyl nitrites that can be abused by inhalation (isobutyl nitrite, isopentyl nitrite) are a special case in that (i) they are extremely unstable and break down rapidly *in vivo* to the corresponding alcohols (Kielbasa *et al.* 1999; Tytgat, Daenens 1996), and (ii) they usually also contain other isomers (butyl nitrite, pentyl nitrite) (Baselt 2004; Osterloh 1984). Any products submitted for analysis will usually contain the corresponding alcohols as well as the nitrites. The profound methaemoglobinaemia arising particularly from ingestion of these compounds can be detected easily.

Interpretation of quantitative results

In very general terms, soon after acute exposure, blood concentrations of volatile substances of 5–10 mg/L and above may be associated with clinical features of toxicity. In other words, pharmacologically effective concentrations of volatile substances are similar to those of inhalational anaesthetics (Baselt 2004; Flanagan 1998), and are thus an order of magnitude lower than those observed in poisoning with relatively water-soluble compounds such as ethanol.

There may be a considerable overlap in the blood concentrations of volatile compounds attained after workplace exposure and as a result of deliberate inhalation of vapour. In the occupational setting, blood toluene concentrations after exposure to up to 127 ppm toluene (the UK occupational exposure limit at the time was 100 ppm) for 8 h ranged between 0.4 and 6.7 mg/L (Campbell *et al.* 1987). After brief exposure only signs of moderate intoxication (e.g. slurred speech, unsteady movements) have been associated with blood toluene concentrations as high as 30 mg/L (Garriott *et al.* 1981). However, blood toluene concentrations above 9.2 mg/L were associated with impairment or probable impairment in car drivers arrested in Norway in 1983–87 (Gjerde *et al.* 1990).

Blood toluene concentrations in samples from 132 patients who were thought to have engaged in VSA ranged from 0.2 mg/dL to 70 mg/L, and were above 5 mg/L in 22 of 25 deaths (Meredith *et al.* 1989). On the other hand, 13 patients with blood toluene concentrations greater than 10 mg/L were either asymptomatic or only mildly intoxicated (headache, nausea, vomiting and/or drowsiness), although these manifestations of toxicity sometimes prove fatal. Similar findings have been reported from Japan (Miyazaki *et al.* 1990). Aside from individual differences in tolerance and possible loss of toluene from the sample prior to analysis, sample contamination, etc., the lack of a strong correlation between blood concentrations and clinical features of poisoning is probably due to rapid initial tissue distribution.

Some 80% of a dose of toluene is converted to hippuric acid, which is excreted in urine. Similarly, more than 90% of a dose of xylene is metabolised to methylhippuric (toluric) acids. The principal isomer found in urine is 3-methylhippurate since *m*-xylene is the principal component of technical-grade xylene (see Table 14.1). Methylhippurates are not normal urinary constituents, but hippuric acid may arise from the metabolism of benzoates used as preservatives in foods and medicines. Hippurate and methylhippurate excretion is often expressed as a ratio to creatinine since this obviates the need for 24-h urine collections. Occupational exposure to toluene can give rise to ratios of up to 1 g hippurate per g creatinine or more; in patients suspected of VSA a ratio of more than 1 g hippurate per g creatinine strongly suggests, but does not prove, toluene exposure (Meredith et al. 1989).

Conclusion

The analysis of volatile substances falls into two main areas: the diagnosis of acute poisoning and monitoring of occupational/environmental exposure to solvents and other volatiles. The Montreal Protocol and subsequent legislation aimed at limiting the use of certain chlorinated and brominated hydrocarbons has had a marked impact on the range of volatile substances available in many Western countries. The next few years are likely to see far fewer changes. As regards assessing occupational/environmental exposure, use of breath analysis via simple collection devices such as that of Dyne *et al.* (1997) and/or urinary metabolite excretion (see Table 14.5) in conjunction with ambient air monitoring is probably the best way forward. However, analysis of blood, and other tissues if available, will remain important in other applications. HS-GC or variants thereof used with appropriate detectors is ideally suited to the analysis of unchanged volatiles and is likely to remain predominant except when the analysis of polar metabolites possessing an appropriate chromophore suggests the use of HPLC.

CHAPTER

15 Natural Toxins

J F de Wolff and F A de Wolff

Introduction

The term 'natural toxins' usually refers to potentially toxic organic compounds of natural origin, in contrast to mineral poisons and synthetic drugs. Sources of these toxins range from simple microorganisms to highly developed vertebrates, and their chemical structures are correspondingly diverse. Exposure to natural toxins may lead to acute as well as long-term symptoms that affect almost any organ system. The highly varied chemical, biological and clinical nature of this class of poisons means that the contribution of the analytical toxicologist to the diagnosis, therapy and follow-up of 'naturally poisoned' patients is limited.

An extensive number of substances that comply with the definition of natural toxins have been used for therapeutic purposes. Classic examples are ergotamine, salicylic acid and the cardiac glycosides, such as digoxin, and penicillin. More recent examples are ciclosporin and botulinum toxin. Most of these are not discussed in this chapter. Similarly, commonly abused substances of natural origin, such as cannabis, cocaine and morphine, are covered elsewhere in this book.

The diversity in chemical composition of natural toxins prevents an arrangement according to chemical structures. Therefore, a biological classification has been chosen. Substances are discussed that originate from:

- Bacteria
- Fungi
- Higher plants
- Invertebrates
- Vertebrates.

Bacteria

The impact of pathogenic bacteria on human health mostly, if not always, results from their ability to produce microbial toxins. For this chapter, a selection has been made of three common potent bacterial toxins: tetanus toxin, botulinum toxin and verotoxin. The former two are related neurotoxic proteins produced by several *Clostridium* spp. strains; verotoxin is produced by certain *Escherichia coli* strains.

Bacteria may also be the source of toxins previously attributed to other organisms, such as tetrodotoxin (TTX), which is found in puffer fish but is most probably produced by commensal microorganisms. For reasons of convention, TTX is discussed in the section on fish poisoning. The same holds for those freshwater cyanobacteria that produce saxitoxins, which are described in the section on mollusc poisoning.

Clostridia (botulinum and tetanus)

Botulinum and tetanus neurotoxins are produced by strictly anaerobic bacteria belonging to the genus *Clostridium* and cause the neuroparalytic syndromes of botulism and tetanus. The botulinum toxins consist of at least four peptides with molecular sizes that range from 150 kDa to 900 kDa. The tetanus toxin has two disulfide-linked peptide chains of molecular size 50 kDa and 100 kDa. The clostridial neurotoxins are the most potent toxins known, with an estimated median lethal dose of about 1 ng/kg intravenously. Botulinum toxins are food poisons, whereas the tetanus toxin is not. Tetanus follows the contamination of necrotic wounds with spores of *Clostridium tetani*. Tetanus is rare in countries with immunisation programmes, but it has a high case fatality rate of 24%. An estimated 800 000 newborns die from neonatal tetanus worldwide each year. Treatment with antitoxin and intravenous administration of penicillin soon after infection may reduce mortality. Generally applicable analytical methods for the identification and quantification of tetanus toxin have not been reported (Cherington *et al.* 1995).

Classic food-borne botulism occurs after ingestion of food contaminated by preformed toxin of *C. botulinum*. The clinical presentations are stereotypical. Within 12–36 h of ingestion, the patient develops diplopia and ptosis, followed by a descending pattern of weakness that affects the upper and then the lower limbs, and respiratory paralysis in severe cases. There is no specific treatment for botulism; recovery is not uncommon but it requires the regeneration of new motor endplates, which takes weeks. Food-borne botulism remains a matter of concern. Effective treatment depends on provision of intensive care and rapid administration of botulinum antitoxin based on clinical presentation, and should not await the results of time-consuming laboratory diagnosis (Sobel 2005). Owing to its extreme neurotoxicity and easy production, botulinum toxin has also been suggested as a possible agent in bioterrorism (Villar *et al.* 2006).

Laboratory proof of botulism requires the detection of the toxin or bacterial deoxyribonucleic acid (DNA) in the patient's blood or stools. If it is still available, the suspected food should also be tested for the toxin. With an old toxin identification method using a mouse toxicity test with antitoxin neutralisation, laboratory results are not always confirmatory. A number of immunoassay methods have been reported for the detection of botulinum toxins. A radioimmunoassay has been replaced by a more sensitive 'double sandwich' enzyme-linked immunosorbent assay (ELISA) method based on application of three antibodies. An ELISA amplification technique may generate a 10-fold increase in sensitivity, rendering it suitable for diagnostic purposes (Hatheway and Ferreira 1996). A promising new method for the detection of bacterial spores and toxins uses a biosensor based on electrochemiluminescence. Toxins and bacterial spores are captured on antibody-conjugated micrometre-sized magnetic beads, followed by binding of ruthenium(II)-trisbipyridal chelate-labelled reporter antibodies. Immunomagnetically captured target materials are then collected on a magnet. Electrochemiluminescence is evoked from the Ru-tagged reporter antibodies by application of an electric potential. Using a commercially available analyser (ORIGEN), a femtogram sensitivity level is obtained for a number of toxins, including botulinum toxin. For *Bacillus anthracis*, this method yields a limit of detection of 100 spores (Gatto-Menking *et al.* 1995). Even more promising are laboratory methods based on the measurement of clostridium DNA by polymerase chain reaction (PCR) in combination with capillary or gel electrophoresis or other detection methods. Combined with ELISA or probe hybridisation, detection limits as low as 0.1 spore per gram of faeces or food have been reported (Lindström and Korkeala 2006).

Escherichia coli

Several strains of the common intestinal bacterium *E. coli* may cause diarrhoeal disease in humans. One such strain, which occurs naturally in the gut of cattle and other animals, produces a potent cytotoxin: verotoxin or verocytotoxin. This *E. coli* strain, usually referred to as VTEC, is

geographically widespread and is associated with life-threatening human diseases that range from bloody diarrhoea to the haemolytic uraemic syndrome and thrombocytopenic purpura. Young children, especially those from urban areas, are a particularly vulnerable group because of their age and immunological naivety to farmhouse infections (Chattopadhyay *et al.* 2001; Parma *et al.* 2000; Pritchard *et al.* 2000).

The chemical nature of verotoxin has not yet been elucidated. Verotoxin-producing *E. coli* strains are characterised through PCR and DNA hybridisation, and by a Vero-cell cytotoxicity assay (Leung *et al.* 2001).

Other *E. coli* strains (O157:H7) and other bacterial species produce Shiga toxins, which may produce disease in humans after consumption of undercooked contaminated beef. In humans these toxins may cause haemorrhagic colitis and haemolytic uraemic syndrome. Enzyme immunoassays are available that detect Shiga toxins in diarrhoeal stool samples from humans and in contaminated beef (Atalla *et al.* 2000; Hyatt *et al.* 2001).

Fungi

Mycotoxins are a group of potentially toxic substances produced by species of the botanical class Fungi. Remarkably, only a very few mushroom species are deadly after ingestion. Many more fungi that grow on food may produce toxins that do not, generally speaking, cause symptoms of acute intoxication, but that may cause adverse effects after chronic ingestion of small quantities. In this section, a selection is made of fungal toxins from *Aspergillus*, *Fusarium* (*Gibberella zeae*) and *Claviceps* genera that have a possible impact on human health, where the analytical toxicologist may have an important role in the prevention of food-borne diseases. In addition, the toxic principles from some of the most common toxic mushroom species are described.

Aspergillus

Aflatoxin

Aflatoxin (Fig. 15.1) is a family of mycotoxins, produced by the mould *Aspergillus flavus*, that are found as contaminants in both human foodstuffs and animal feed, particularly in maize, groundnuts and other nuts such as pistachios. The aflatoxin-producing *Aspergillus* species are ubiquitous in areas with a hot, humid climate. Foodstuffs may be contaminated with aflatoxin both pre- and post-harvest. Exposure occurs through consumption of contaminated food and also during the handling and processing of aflatoxin-contaminated crops. Aflatoxins have been detected in human milk, urine and blood samples (IARC 1993a).

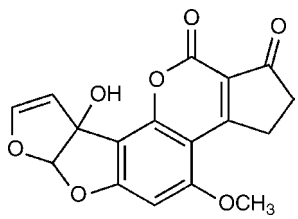

Figure 15.1 Aflatoxin-M_1.

Aflatoxin-B_1 is a very potent human carcinogen that reacts with DNA once it has been bioactivated to the epoxide. It is thought to cause hepatocellular carcinoma.

Aflatoxins have been measured in human blood by high performance liquid chromatography (HPLC) with fluorescence detection (Abdulrazzaq *et al.* 2002). In 201 samples of umbilical cord blood, aflatoxins were detected in 110 and there was a significant negative correlation between birth weight and the aflatoxin concentrations found. Kussak *et al.* (1995) applied a liquid chromatography–tandem mass spectrometry (LC-MS[-MS]) system to measure aflatoxins in spiked urine samples and achieved detection limits of 2–10 pg. A number of analytical methods have been described for the analysis of aflatoxins G_1, G_2, B_1 and B_2 in foodstuffs. High performance thin-layer chromatography (HPTLC) and ELISA procedures have been described, but HPLC with fluorescence detection is considered to be the method of choice (Boenke 1998; Gilbert 1993; Holcomb *et al.* 1992; Kok 1994). A review of these methods is presented in Jaimez *et al.* (2000). Sample preparation and extraction depend greatly on the physicochemical properties of the infected matrix; aflatoxins are soluble in slightly polar solvents, such as a mixture of acetone, chloroform or methanol. Non-polar solvents can be applied for fat extraction. Further purification can be accomplished by solid-phase extraction followed by concentration for chromatographic analysis. Reversed-phase HPLC with methanol–water or acetonitrile–water results in a good separation of the aflatoxins; a disadvantage of these aqueous media is that the natural fluorescence, which renders them so readily detectable by TLC, is quenched. This can be overcome by post-column derivatisation with iodine, a procedure finally adopted as an official method by the Association of Analytical Communities (AOAC) and the International Union of Pure and Applied Chemistry (IUPAC) in 1991 (AOAC 1991). Although much more is known about aflatoxins, ochratoxin is gradually being recognised as a fungal toxin of equivalent importance (Bayman and Baker 2006).

Ochratoxin

Ochratoxin-A (OTA, Fig. 15.2) is a widespread mycotoxin produced mainly by the fungi *A. ochraceus* and *Penicillium verruculosum* during the storage of cereals, cereal products, herbs, spices (IARC 1993b; Petzinger and Ziegler 2000) and other plant-derived products such as coffee (Viani 1996). OTA is chlorinated, which is unusual for a natural product. Ochratoxin-B, which is not chlorinated, and ochratoxin-C, the ethyl ester of OTA, are less toxic. OTA has been reported to be nephrotoxic, immunosuppressive, carcinogenic and teratogenic in animal studies. However, as with aflatoxins, it is often not clear to what extent animal studies are applicable to toxicity in humans.

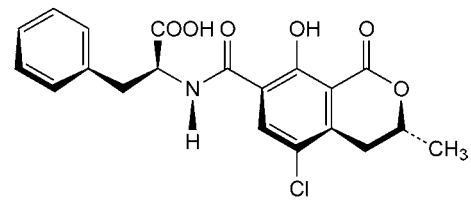

Figure 15.2 Ochratoxin-A.

Ochratoxin-A has been found primarily in northern temperate barley- and wheat-growing areas, but the presence of OTA in green and processed coffee has received much attention recently. As the list of OTA-producing fungi has expanded, so has the list of foods that can be contaminated with ochratoxins (Bayman and Baker 2006).

Consumption by pigs of mouldy pig feed may result in detectable levels of OTA in pork-derived products. Since OTA is hydrolysed rapidly by ruminal flora, it is unlikely to be found in milk or meat from cattle (Scudamore 1996). When ingested by humans, OTA is very persistent, with an elimination half-life of about 35 days attributed to very strong binding to plasma proteins. During the 1950s, a fatal chronic renal disease was identified in several countries in the Balkans and became known as Balkan endemic nephropathy (BEN). BEN has a striking similarity to porcine nephropathy induced by OTA. The causative factor is thought to be high OTA levels in the diet. The toxin is also a possible carcinogen, a teratogen and an immunotoxic agent. It appears to exert its toxic effects by promoting an increased level of lipid peroxidation, by inhibition of an amino-alkylation reaction and possibly by conversion into metabolites that are capable of binding DNA (Marquardt *et al.* 1990).

For the analysis of OTA in blood, serum and milk samples, Zimmerli and Dick (1995) used immunoaffinity column clean-up and HPLC with fluorescence detection and were able to obtain a limit of quantification (LOQ) of 5 pg/g. In a more recent report, Vatinno *et al.* (2007) applied solid-phase microextraction (SPME) to samples of human urine and analysed the extracts by HPLC with fluorescence detection. The LOQ and limit of detection (LOD) values were 0.05 μg and 0.01 μg respectively.

Several analytical procedures have been proposed for the identification and measurement of OTA in food products, as reviewed by Van

Egmond (1991) and Valenta (1998). Although TLC analysis gives satisfactory results in the absence of sophisticated instrumentation, C_{18} reversed-phase HPLC with fluorescence detection is the method of choice, with an excitation wavelength of 330 nm and an emission wavelength of 460 nm. More recently, Noba *et al.* (2009) have described a method based on immunoaffinity clean-up followed by LC-MS(-MS) for the analysis of OTA in ready-to-drink coffee. The LOQ was reported as 0.0065 ng/mL. OTA was detected in 30 samples of coffee available commercially in Japan. A review of LC-MS methods for the analysis of OTA and related substances has been given by Zollner and Mayer-Helm (2006), and it is likely that LC-MS will be the method of choice for ochratoxins in the near future.

Fusarium

Deoxynivalenol

Deoxynivalenol (DON) is a mycotoxin belonging to the trichothecene type of toxins produced by *Fusarium graminearum* (*Gibberella zeae*) and *F. culmorum*. These fungi grow on cereal crops, mainly wheat and maize (IARC 1993c). As wheat and maize products form a considerable part of the diet in many regions, the toxicity and the content of DON are important issues in food safety control.

Deoxynivalenol can affect the immune system, and both suppression and activation have been reported, but the toxin is not considered to be mutagenic or carcinogenic.

Two outbreaks of human disease related to trichothecenes have been reported, one in China in 1984 to 1985 and one in India in 1987. Consumption of mouldy wheat or maize results within 5–30 min in nausea, vomiting, abdominal pain, diarrhoea, dizziness and headache. DON has been detected in the cereals in a range of 0.34–92.8 mg/kg, together with 0.004–0.587 mg/kg zearalenone (IARC 1993c) (see later). The tolerable daily intake (TDI) in humans is considered to be 0.5 μg/kg body mass per day (Health Council of The Netherlands 2001). An overview of some of the major mycotoxins, including DON, has been given by Richard (2007).

Black *et al.* (1986) developed a gas chromatography–mass spectrometry (GC-MS) procedure for the measurement of trace quantities of trichothecene mycotoxins in samples of blood and urine. The method involved purification by reversed-phase Sep-Pak C_{18} cartridges and derivatisation to the heptafluorobutyl esters. LODs for a range of mycotoxins ranged from 2 ppb to 7 ppb. Meky *et al.* (2003) explored urinary measurement of DON as a potential biomarker of human exposure. Urine samples were treated with β-glucuronidase and sulfatase enzymes to release conjugated DON, which was then analysed by an immunoaffinity-column–HPLC technique. Positive results were confirmed by LC-MS. Urine samples collected from females living in a potentially high-exposure region of China and a low-exposure region were compared. Mean levels in samples from the suspected high- and low-exposure regions were 37 ng/mL (range 14–94 ng/mL) and 12 ng/ml (range 4–18 ng/ml), respectively.

A method for the quantification of DON in wheat using immunoaffinity-column isolation and HPLC with ultraviolet (UV) detection has been published (Cahill *et al.* 1999). It compares very well with the GC–electron capture detection (ECD) method published by Tacke and Casper (1996). Nowadays, HPLC with UV detection is the recommended method for residue analysis in food (Stroka *et al.* 2006). However, a more sophisticated method combining LC-MS with atmospheric pressure photoionisation has been recently described by Tanaka *et al.* (2009) for the detection of nivalenol and DON in wheat. This reduced the matrix effects seen with other methods and gave LODs of 0.2 and 0.39 ng/g for nivalenol and DON, respectively.

T-2 toxin

Another cereal mycotoxin, the trichothecene congener T-2 toxin, is produced by *F. sporotrichiodes*. T-2 toxin has been suggested as a potential chemical warfare agent (Hodgson *et al.* 1998). A disease known as alimentary toxic aleukia is associated with T-2 toxin. In severe outbreaks of poisoning this disease has a fatality rate as high as 50%. Aleukia is characterised by hyperaemia of the oral mucosa, weakness, fever, nausea and vomiting, and in severe cases by gastroenteritis. In later stages of the disease leukopenia, granulopenia and progressive lymphocytosis occur, followed by severe haemorrhagic diathesis, necrotic pharyngitis and laryngitis, and anaemia. In an outbreak in Kashmir in 1987, T-2 toxin concentrations in flour samples were found to be 0.55–0.8 mg/kg (IARC 1993d). The analytical aspects of T-2 toxin are discussed in the next section, which describes general methods for the analysis of trichothecenes

Zearalenone

Zearalenone is a benzoxacyclotetradecin derivative produced in *F. graminearum* (*Gibberella zeae*) and related species, and is primarily associated with maize (*Zea mais*). It is among the most widely distributed mycotoxins. Toxic effects in humans are extremely difficult to assess as, in cases of contaminated cereals, several mycotoxins are present simultaneously. Endocrine-disrupting effects occur in animals, but these were not reported in the two outbreaks described above, in which both DON and zearalenone were involved (IARC 1993c). A recent review on zearalenone toxicity was published by Zinedine *et al.* (2007).

Zearalenone is a metabolite of zeronal, a non-steroidal oestrogenic growth promoter that is banned for use in food-producing animals in the European Union. Consequently, methods have been devised for determination of the parent compound and its metabolite in bovine urine. Schmidt *et al.* (2008) applied LC-MS(-MS) to screen for stilbenes and zeronal and zearalenone in urine, and were able to detect and quantify these substances at levels below 1.5 μg/L.

As humans are usually exposed to a number of fusarium toxins through contaminated cereals, most analytical methods for use on these foodstuffs have been developed to identify and quantify a number of mycotoxins in a single procedure. The application of TLC in mycotoxin analysis has been reviewed (Lin *et al.* 1998). TLC is useful for the rapid screening of mycotoxins in food with detection limits as low as 1 ng/kg for aflatoxin-B_1 in feed, 0.3 μg/kg ochratoxin-A in pork kidney and 20 μg/kg zearalenone in cereals. Most quantitative methods have been based on GC-ECD, but HPLC has also been applied. Krska (1998) described clean-up procedures for the analysis of zearalenone in maize and trichothecenes in wheat in the microgram per kilogram range, based on immunoaffinity and multifunctional clean-up columns. A method for the direct qualitative and quantitative GC-MS analysis of eight different mycotoxins, including DON, T-2 toxin and zearalenone, was described by Onji *et al.* (1998), with limits of detection of 0.1–0.5 μg/kg and recoveries of around 90%. Analytical methods for the fusarium toxins DON and T-2 toxin were reviewed by Koch (2004). With the considerable advances in LC-MS technology since that time, the latter is becoming the major technique for multianalysis of mycotoxins in foodstuffs. For example, Sulyok *et al.* (2006) were able to develop a LC-MS (-MS) method for the determination of 39 mycotoxins in wheat and maize, including zearalenone and related derivatives. Because of the chemical diversity of the analytes, both positive- and negative-ion electrospray ionisation (ESI) modes were applied in two consecutive chromatographic runs. It was possible by extracting samples with a mixture of acetonitrile, water and acetic acid (79 : 20 : 1) to inject raw extracts diluted 1+1 without further clean-up. More recently, Diana Di Mavungu *et al.* (2009) reported on the use of LC-MS(-MS) with positive-ion ESI for the multianalysis of mycotoxins in foodstuffs such as soy isoflavones, St John's wort, garlic, *Ginko biloba* and black radish. They found the optimum extraction solvent to be a mixture of ethyl acetate and formic acid (95 : 5) and purified the extracts by a combination of liquid–liquid partition with hexane and solid-phase extraction cartridges. LODs and LOQs were in the range 0.3–30 and 1–100 ng/g, respectively.

Claviceps purpurea

Poisoning by ergot alkaloids produced by the mould *Claviceps purpurea* is usually referred to as *ergotism*, and is probably the oldest recorded food-borne disease of fungal origin. *Cl. purpurea* grows on food grain, particularly rye, during wet seasons. Symptoms of ergotism include erythema, diarrhoea, vomiting, a burning sensation of the limbs and, eventually, gangrene. Central nervous system (CNS) effects are

convulsions, catalepsy, dullness or maniacal excitement. These symptoms can be explained by the pharmacological properties of the ergot alkaloids, which may cause an α-adrenergic blockade, as well as serotonin antagonism. The ergot alkaloids ergotamine (the best known, Fig. 15.3) and ergometrine, or ergonovine, have been used for centuries as therapeutic agents to stimulate uterine contractions and in the treatment of migraine attacks. Overdose with these agents, and intoxication with ergot alkaloids from other sources, can be treated symptomatically with potent vasodilator drugs, such as sodium nitroprusside, and by maintaining adequate circulation.

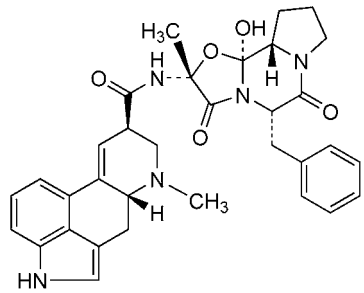

Figure 15.3 Ergotamine.

The method of choice for analysis of ergot alkaloids in serum is HPLC with fluorescence detection after liquid–solid extraction (Moubarak *et al.* 1996). The structural chemistry and a comparison of the available analytical techniques for ergot alkaloids have been reviewed extensively by Flieger *et al.* (1997).

Krska *et al.* (2008) published a review on the analysis of ergot alkaloids in cereal samples by means of LC with diode array detection and LC-MS(-MS).

Mushrooms

Amanita muscaria

A number of basidiomycetes contain hallucinogenic principles, the best-known examples being the *Amanita muscaria* and the *Psilocybe* species types. The fly agaric (*Am. muscaria)* is the European archetypical 'mother of all mushrooms' in legends and fairy tales, with a red hood and white spots. It is indigenous to the northern hemisphere, but is also found in some parts of South Africa, South America, Australia and New Zealand. Despite popular belief, no fatalities have been reported in humans. The most important toxin in *Am. muscaria* is *not* muscarine (which does occur in trace amounts) but ibotenic acid and its decarboxylation product muscimol. Poisoning with *Am. muscaria* usually results from deliberate ingestion to obtain a psychoactive response and symptoms occur within 20–180 min. Muscimol (Fig. 15.4) is a γ-aminobutyric acid (GABA) receptor agonist. It causes CNS depression that results in drowsiness and dizziness, followed by elation, increased motor activity, tremor, agitation and hallucinations. There are no specific antidotes and recovery is complete upon awakening.

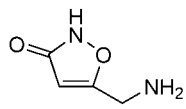

Figure 15.4 Muscimol.

There is no validated procedure available for analysis of ibotenic acid and muscimol in blood or urine. For their determination in mushrooms, an ion-pair HPLC method with UV detection after methanol extraction has been described (Tsunoda *et al.* 1993). More recently, methods have been published for the analysis of ibotenic acid in dried mushrooms using GC-MS (Tsujikawa *et al.* 2006) and LC-MS (Tsujikawa *et al.* 2007).

Psilocybe type

The 'psilocybe syndrome' is caused by consumption of one of the many species of the cosmopolitan genera *Psilocybe*, *Panaeolus*, *Copelandia*, *Gymnophilus* or *Stropharia.* These mushrooms contain the indole-alkylamine hallucinogen psilocybin (Fig. 15.5) and its dephosphorylated congener psilocin, which is about 1.5 times as potent as psilocybin. These hallucinogens are about 100 times less potent than lysergic acid diethylamide (LSD, lysergide). Intoxication with psilocybin-containing mushrooms is almost always intentional. Some of the somatic reactions to psilocybin resemble anticholinergic effects, for example mydriasis and urinary retention, which may be reversed successfully with physostigmine (De Wolff and Pennings 1995). An 18-year-old man who used *Psilocybe semilanceata* developed seizures, Wolff–Parkinson–White syndrome, arrhythmia and myocardial infarction (Borowiak *et al.* 1998).

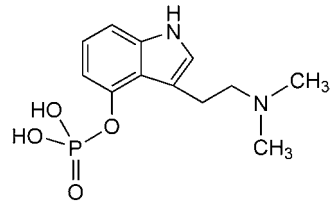

Figure 15.5 Psilocybin.

Measurement of psilocybin and related indole alkaloids in mushroom samples or patient material may assist the diagnosis and treatment of patients with suspected poisoning. A TLC method has been described (Stienstra *et al.* 1981). A 20 mL urine sample is made alkaline with 25% ammonia to pH 10, concentrated on an Extrelut column, and eluted with 30 mL diethyl ether. The dried residue is dissolved in 50 µL ethanol and chromatography is carried out on F_{254} silica gel plates with methanol–ammonia 25%. Psilocybin and psilocin are visualised under 254 nm UV light and after spraying with Van Urk's reagent for indole groups (grey–violet and faint blue, respectively). Quantitative procedures have been described using HPLC (Christiansen and Rasmussen 1983; Hasler *et al.* 1997; Koike *et al.* 1981; Kysilka and Wurst 1989; Lindenblatt *et al.* 1998) or ion-mobility spectrometry and GC-MS (Keller *et al.* 1999). In clinical and forensic practice, the HPLC method with electrochemical detection, as described by Hasler *et al.* (1997), seems to be most useful. The high instability of the analytes requires special measures to prevent oxidation during the clean-up procedure. Solid-phase extraction with reversed-phase material gives unsatisfactory results. Microdialysis yields lower recoveries, but improved reproducibility. Psilocin concentrations in human plasma can be measured in the microgram per litre range.

Amanita phalloides

Toxins from *Amanita phalloides* and related Agaricales are among the most lethal natural substances. In countries where the consumption of wild mushrooms is popular, as in middle and eastern Europe and some Mediterranean countries, hundreds of fatalities are reported every summer and autumn. The toxic principles are cyclic polypeptides: the phallotoxins are bicyclic heptapeptides; the virotoxins are monocyclic heptapeptides; and the amatoxins are bicyclic octapeptides (Fig. 15.6).

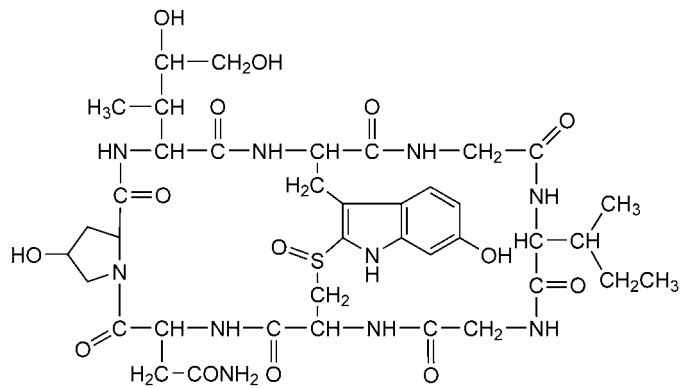

Figure 15.6 α-Amanitin.

The most important biochemical effect of the amatoxins is an irreversible inhibition of ribonucleic acid (RNA) polymerase II; the phallotoxins stimulate the polymerisation of G-actin and stabilise the F-actin filaments (De Wolff and Pennings 1995; Vetter 1998).

Symptoms of *Am. phalloides* poisoning can be roughly divided into three phases, the first appearing over 6 h after mushroom consumption and characterised by violent emesis and cholera-like diarrhoea. This phase is ascribed to the action of the phalloidins, and can usually be treated successfully with fluid and electrolyte replacement. The second phase occurs after 2–3 days as a transient remission, which is, however, fallacious, since the most dangerous third phase may then begin to take place. This is characterised by hepatorenal symptoms from the effect of amatoxins on RNA polymerase. Liver injury is evident by immensely elevated serum aminotransferase activities. Numerous antidotes against amatoxins have been proposed, but none has been proved to be successful, as hepatorenal symptoms appear only after irreversible binding of the toxins to its target enzyme. Liver transplantation seems to be an option for effective symptomatic treatment (De Wolff and Pennings 1995).

Identification and measurement of the toxins in blood for diagnostic purposes have proved a considerable challenge because of their complicated chemical structures and the low plasma concentrations. A rapid radioimmunoassay with a detection limit of 3 ng/mL was published by Faulstich *et al.* (1982). Since then, a number of HPLC methods have been described, as reviewed by Dorizzi *et al.* (1992), but most often with complicated sample pretreatment procedures. Electrochemical detection can achieve a sensitivity of 2 μg/L. An LC-MS procedure for α- and β-amanitin described by Maurer (1998) has a detection limit of 10 μg/L. Filigenzi *et al.* (2007) have reported a method for quantifying α-amanitin in serum and homogenised liver samples which involves precipitation of proteins with acetonitrile and subsequent cation-exchange SPE and analysis on a linear ion trap LC-MS system. The method has a limit of detection of 0.26 μg/kg in serum and 0.50 μg/kg in liver. In 11 of a series of 45 patients admitted to hospital with *Am. phalloides* intoxication, plasma levels ranged from 8 μg/L to 190 μg/L for α-amanitin and from 15.9 μg/kg to 162 μg/kg for β-amantin. Amatoxins were generally detectable in plasma samples taken within 36 h of admission, but were still present in urine samples for up to 4 days (Jaeger *et al.* 1993).

Higher plants

In this section a limited selection of lesser-known plant toxins has been made. For the more familiar toxins, such as atropine and hyoscine from the Jimson weed *Datura stramonium*, or digoxin from the foxglove *Digitalis purpurea*, the reader is referred to the monographs section in this book and to the specialist pharmacognostic literature. For an extensive overview of the analysis of plant toxins, see Gaillard and Pepin (1999).

Ricinus communis

The beans of *Ricinus communis* are the source of castor oil and consist mainly of the triglyceride of ricinoleic (12-hydroxyoleic) acid. Castor oil is well known for its purgative action, which is so strong that it may lead to colic and dehydration. *R. communis* also contains the extremely toxic peptide ricin, which is present in the seed husks. Ricin is a lectin that consists of two polypeptide chains of 34 kDa each, connected through a disulfide bond. One of the chains (the A-chain) is toxic because it inhibits protein synthesis. The B-chain is a galactose- or *N*-acetylgalactosamine-binding lectin and is responsible for the binding of ricin to cell surface receptors (Narang *et al.* 1997; Wellner *et al.* 1995). Ricin is insoluble in lipids; it therefore does not occur in medicinal castor oil. Ricin may have a therapeutic use as an immunotoxin in the treatment of leptomeningeal carcinomatosis (Muraszko *et al.* 1993; Woo *et al.* 1998, 2001).

Animal experiments indicate that the liver is the primary target organ in ricin poisoning (Balint and Halasz 1972). Intravasal aggregation of erythrocytes, and acute adrenocortical and renal insufficiency have also been demonstrated (Balint 1978).

The extreme toxicity of ricin first came to public attention after the Markov case in 1978 in the UK. Georgi Markov, a Bulgarian journalist in exile, was stabbed in the thigh with an umbrella and within a few hours developed high fever and a high leukocyte count. This was followed by a fall in blood pressure and body temperature, and he died on the third day. At the postmortem examination, a small platinum–iridium sphere with tiny holes was found in the subcutaneous tissue. Although the presence of ricin in the bullet was not confirmed analytically, the symptomatology led to the conclusion that ricin was the poison responsible. Oral ingestion of ricin is also very dangerous and may cause erythrocyte agglutination, haemorrhagic gastrointestinal irritation, vomiting, profuse watery or bloody purging, fever, convulsions and death. Death after the consumption of a single castor bean has been reported (Knight 1979), although others have survived ingestion of as many as 10–15 beans (Aplin and Eliseo 1997). There is evidence that ricin has been recommended for use in terrorist attacks. The fact that ricin can be absorbed through the lungs and its lethal inhalatory toxicity estimated at only 5–10 μg/kg mean that ricin presents a serious threat in this regard. Ricin toxicity has been reviewed by Bradberry *et al.* (2003) and Audi *et al.* (2005). Vaccines to treat ricin poisoning are currently being developed. The most promising approach has been to genetically engineer the A-subunit to eliminate both its enzymatic activity and its ability to induce vascular leaking. The non-toxic subunit is reported to elicit antibodies in animals, subsequently protecting them against the effects of large doses of ricin.

Administration of the vaccine is planned to be by an oral or intranasal route (Doan 2004). Godal *et al.* (1981) devised a radioimmunoassay for ricin that was applied subsequently in a patient who ingested 30 castor beans in a suicide attempt. The maximum plasma level on the first day was 1.5 μg/L, with a biological half-life of approximately 8 days. In urine, ricin became detectable only on the third day in low concentrations – around 0.3 μg/L (Kopferschmitt *et al.* 1983). Methods for the identification and quantification of ricin in tissues based on ELISA have also been reported (Griffiths *et al.* 1986; Leith *et al.* 1988). With avidin–biotin immunoperoxidase complex amplification, a limit of detection as low as 0.2 μg/L of tissue extract could be reached. Using a similar immunological procedure with chemiluminescence detection, Poli *et al.* (1994) achieved a limit of quantification in the 0.1–1.0 μg/L range.

A sensitive and accurate method to measure ricin in fluids is that of Narang *et al.* (1997), using a fibreoptic fluorescence biosensor and an avidin–biotin sandwich immunoassay scheme. The linear quantification range is 0.1–200 μg/L. A recent review on the analysis of potential warfare agents including ricin, staphylococcal toxin B and T-2 toxin has been published by Ler *et al.* (2006). The mechanistic, historical and analytical aspects of ricin have been reviewed by Musshoff and Madea (2009).

Lawsonia inermis (henna)

Henna is a greenish-brown vegetable colouring made from the leaves of *Lawsonia inermis*, a flowering plant from the family of the Lythraceae. The main pigment is the aromatic compound 2-hydroxy-1,4-naphthoquinone, also known as lawsone or hennotannic acid, and this can cause adverse reactions after application of henna to the skin.

Severe intravascular haemolysis has been reported following the topical application of henna in children with glucose-6-phosphate dehydrogenase deficiency (Katar *et al.* 2007).

Reactions to lawsone are uncommon, however, and most adverse effects from henna application result from reactions to *p*-phenylenediamine (PPD), which is sometimes added to henna to increase the intensity and longevity of a tattoo and to accelerate its drying. The most common reaction is type IV cutaneous hypersensitivity causing a contact allergy. Sensitisation to PPD is lifelong, and PPD may cross-react with a number of pharmacological compounds, such as the sulfonylureas and the thiazides. PPD sensitivity can be determined by patch testing. There have been calls to restrict the use of PPD in henna products (Jacob *et al.* 2008). Oral ingestion causes severe mucosal oedema, rhabdomyolysis and haemolysis (Anuradha *et al.* 2004).

Lawsone can be assayed in henna by HPTLC (El Shaer *et al.* 2007); for the analysis of PPD the reader is referred to the monographs section.

Catha edulis (khat)

Khat is a small evergreen shrub that grows in the horn of Africa and in the western Arabian peninsula. The chewing of khat leaves is practised in Ethiopia, Somalia and Yemen as well as in immigrant communities elsewhere in the world (Pennings *et al.* 2008). Regulatory control is not consistent around the world. The predominant active compounds in khat are the alkaloids (2*S*)-2-amino-1-phenylpropan-1-one (cathinone) and (1*S*,2*S*)-2-amino-1-phenylpropan-1-ol (norpseudoephedrine or cathine); both bear a structural relationship to amfetamine and have predominantly sympathomimetic effects. Cathinone produces more of the positive effects, while the negative systemic effects are attributable to cathine (Cox and Rampes 2003). Khat use has an anorexic effect similar to that of amfetamines (Pennings *et al.* 2008).

Khat use has been linked to physical and mental illness. Cox and Rampes (2003) found an increased risk of schizophreniform and manic psychosis, usually in brief episodes, and depression was more common after cessation of frequent use. Khat also has a number of systemic effects, which include cardiac arrhythmias, hypertension, constipation, and an increased risk of head and neck cancer as well as upper gastrointestinal tract cancer. The risk of myocardial infarction is markedly increased in heavy users (Pennings *et al.* 2008). In absolute terms, the health risk of khat is fairly low (Pennings *et al.* 2008).

Khat metabolites may be detected in urine as norephedrine up to 48 h after consumption, by immunoassay or GC (Cox and Rampes 2003). Quantification of cathinone along with eight other herbal phenalkylamines in plasma has been described by Beyer *et al.* (2007) using SPE and analysis by a LC-MS(-MS) system. The LOQ was 10 µg/L for all the analytes.

Umbelliferae

The Umbelliferae or Apiaceae family (named after their umbrella-shaped inflorescence) includes a large number of extremely toxic species, together with many species that are fit for human consumption, such as carrot, parsley and parsnip. The most best-known toxic species are the water hemlock *Cicuta virosa* and the poison hemlock *Conium maculatum*. The former contains the polyin cicutoxin as the active principle, whereas the latter contains the piperidine alkaloid coniine (Fig. 15.7). *C. maculatum* was the source of the poison used for the execution of Socrates in 399 BC. Cicutoxin affects primarily the CNS causing seizures, whereas coniine affects the neuromuscular junction and may lead to respiratory failure. Both plants have a very high mortality rate after ingestion. In both cases, treatment is symptomatic and does not depend on the result of toxicological analysis. Beyer *et al.* (2009) published a review of methods for the analysis of a number of alkaloids, including coniine, in biological samples.

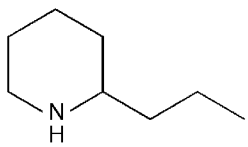

Figure 15.7 Coniine.

Another class of toxins produced by umbellifers are the furocoumarins or psoralens, the active principles of the hogweed or common cow parsnip *Heracleum sphondylium* which may cause serious dermal phototoxicity after skin contact with the juice of this plant and exposure to sunlight. The best-known psoralen from hogweed is 8-methoxypsoralen (8-MOP; Fig. 15.8), which is also used in the therapy of psoriasis in combination with UV-A irradiation (De Wolff and Thomas 1986). Psoralens can be measured in biological matrices with HPLC (Herfst *et al.* 1980; Stolk *et al.* 1987). Both the toxic and therapeutic action is based on binding of reactive products from 8-MOP, formed by irradiation with UV light, to DNA in the basal cells of the epidermis.

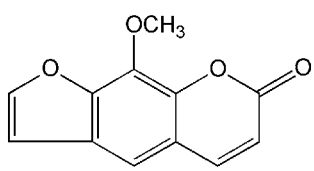

Figure 15.8 8-Methoxypsoralen.

A very recent application of psoralen phototoxicity is the inactivation of pathogens in donated blood as pretreatment for transfusion of blood products. The furocoumarin used for this application is amotosalen (Wollowitz 2001).

Lathyrus sativus

Lathyrus sativus contains the excitatory amino acid β-*N*-oxalylamino-L-alanine (L-BOAA), which is the cause of a neurodegenerative disorder, lathyrism, that occurs in many parts of the world. A likely mechanism of action of L-BOAA is that as an excitant amino acid of motor neurons it causes neurotoxicity by overstimulation of glutamate receptors. This action is stereospecific: D-BOAA and the α-isomer of BOAA seem to lack a neurotoxic effect.

Human consumption of 400 g *L. sativus* daily of seeds ground to flour to make bread for a prolonged period leads to symptoms of lathyrism, which is characterised by spastic paresis of the lower limbs and, in a more advanced stage, by loss of control of the bladder and rectum, and by impotence. Young males form the most sensitive part of the population. Treatment is limited to reduction of muscular spasm, with some success. For reviews on lathyrism, see Spencer (1995) and Barceloux (2009), which includes data on the analysis of the toxin.

Cycas circinalis

Toxins from the false sago palm *Cycas circinalis* have been associated with a neurodegenerative disorder that occurs on the Western Pacific island of Guam, on the Japanese Kii peninsula and in Irian Jaya (West Papua). The female cones of this tree have been used as a dietary source of starch for centuries and consumption is thought to be related to the incidence of a peculiar neurological disease, Guamanian motor neuron disease (GMND), which occurs in two clinical forms. The first form resembles amyotrophic lateral sclerosis and the second form is characterised by dementia and extrapyramidal manifestations. Cycad seed contains two classes of substances with a neurotoxic potential – amino acids and azoxyglycosides. As a result of its chemical analogy with BOAA (see above) and the clinical similarities between lathyrism and cycadism, the amino acid β-*N*-methylamino-L-alanine (BMAA) has long been thought to be causal in GMND, but this has been questioned in recent years. Excitotoxic amino acids such as BOAA have a dicarboxylic structure in common, which does not occur in BMAA. A more likely candidate for the instrumental neurotoxin is cycasin (methylazoxymethanol-β-D-glucoside), which is metabolised to methylazoxymethanol by β-glucosidase. Methylazoxymethanol is a direct alkylating agent with hepatotoxic, mutagenic, carcinogenic and teratogenic properties. It may also alter the function of post-mitotic neurons and so precipitate a slowly progressive degeneration of cells (Spencer *et al.* 1991). There is strong epidemiological support of a role for cycasin in the pathogenesis of GMND, probably in combination with inherited susceptibility (Roman 1996). Methods for the analysis of both BMAA and cycasin in cycad flour have been published (Kisby *et al.* 1992). For a review of cycadism, see De Wolff and Bruyn (1995).

Blighia sapida

Jamaican vomiting sickness affects mainly young children and is a form of toxic hepatitis associated with ingestion of the arilli of the unripe fruit of the ackee tree, *Blighia sapida* (Sherratt 1995). The ackee tree was imported into the West Indies, but is native to West Africa and deaths among children have been reported in the Ivory Coast (Foungbe *et al.* 1986) and in Burkina Faso (Meda *et al.* 1999). The disease presents with severe vomiting and hypoglycaemia followed by neurological symptoms, which include convulsions, coma and death (Tanaka 1979). The toxin responsible is hypoglycin, L-(*S*)-2-amino-3-methylenecyclopropylpropionic

acid. Seeds of the common sycamore (*Acer pseudoplatanus*) and of the lychee fruit (*Litchi sinensis*) also contain hypoglycin. Most of the metabolic effects of hypoglycin are caused by its metabolite, methylenecyclopropylacetyl-coenzyme-A (MCPA-CoA). It inhibits the β-oxidation of fatty acids, induces organic aciduria and inhibits gluconeogenesis. Sherratt (1995) has reviewed the biochemical mechanism of hypoglycin in detail.

Administration of intravenous glucose immediately after diagnosis may help to prevent a fatal outcome, and administration of riboflavin, glycine and L-carnitine might also be effective (Sherratt 1995). Kupfer and Idle (1999) have suggested methylene blue as an antidote to hypoglycin poisoning. No methods are available that detect hypoglycin in body fluids to confirm a suspected intoxication. However, hypoglycin exposure may be confirmed indirectly by measuring dicarboxylic acids in urine (ethylmalonic, glutaric and adipic acids) by GC with flame-ionisation detection (FID) after derivatisation with bis (trimethylsilyl)trifluoroacetamide (Meda *et al.* 1999). A rapid HPLC method for the analysis of hypoglycin-A in ackee fruit was described by Golden *et al.* (2002).

Invertebrates

Many species of animals without backbones produce venoms or contain toxins that may be harmful to humans, either externally by stinging or after ingestion (Mebs 2002). A selection of the most relevant types of toxins has been made here, with emphasis on mollusc species that usually cause human food poisoning by transmitting accumulated toxins produced by protozoal organisms. Analytical toxicology may be instrumental in the prevention and management of these food-borne diseases. Animals often reported to cause envenomation (representatives of the Cnidaria and Arthropoda) are also mentioned briefly.

Cnidaria (formerly Coelenterata)

Cnidaria may be stationary creatures (e.g. 'fire coral' or *Millepora alcicornis*, which is associated with reefs in, for example, the Caribbean and Australia) or free swimming (e.g. jellyfish, such as the Portuguese man-of-war or *Physalia physalis*). They have stinging cells or nematocysts (40 μm spheres that contain a viscous fluid composed of multiple toxins) and a long thread-like coiled tube (nema). When physical, osmotic or chemical stimuli trigger the nematocyst, its internal pressure produces an explosive inversion of the nema and the contents of the capsule are injected into the victim (Schwartz and Meinking 1997).

The Portuguese man-of-war jellyfish is particularly dangerous and can cause death. Its nemocysts contain a wide range of biologically active substances, including histamine, haemolytic toxins, phospholipases, proteases and a powerful neuromuscular toxin – hypnotoxin. Acute reactions involve stinging and burning, followed by the development of painful and pruritic linear papules and weals. Acute systemic reactions to physalia envenomation may include hypotension, shock, seizures, ataxia, haemolysis and acute renal failure. Other possibly lethal jellyfish include *Stomolphus nomurai*, which occurs in the waters around China; eight deaths from pulmonary oedema or cardiac arrest following envenomation by this species have been recorded (Burnett *et al.* 1996). The box jellyfish *Chironex fleckeri*, found in the Indo-Pacific region, is reputed to be the world's most venomous marine animal and has been responsible for at least 80 recorded deaths in Australia. The venom has a range of autonomic effects, such as vasospasms, cardiac irregularities, peripheral neuropathy, aphonia, ophthalmic abnormalities and parasympathetic dysautonomia. Related species, such as *Carukia barnesia*, produce a toxin that mimics extensive catecholamine release and targets the myocardium (Burnett *et al.* 1998). For purification of coelenterate venoms, capillary electrophoresis (CE), followed by binding to high-titre commercial ovoid hyperimmune serum, is the technique of choice (Burnett *et al.* 1996). For some jellyfish stings, rapid treatment of the affected area with household vinegar, which inactivates the toxins, is recommended, followed by administration of an antivenom (Tibballs 2006).

Molluscs

Mollusc poisoning or 'shellfish poisoning' is caused by the consumption of bivalve molluscs that accumulate toxins of protozoal or algal origin. Toxins from algal sources are also referred to as phycotoxins (Quilliam 1999), analogous to the mycotoxins from fungal sources (see above). Mollusc poisoning caused by algal toxins is usually classified according to the symptoms that they cause in humans (Baden 1983, 1995; Daranas *et al.* 2001; Sierra-Beltran *et al.* 1998):

- Paralytic shellfish poisoning (PSP, saxitoxins)
- Diarrhoetic shellfish poisoning (DSP, e.g. okadaic acid)
- Neurotoxic shellfish poisoning (NSP, brevetoxin)
- Amnestic shellfish poisoning (ASP, domoic acid).

Intoxication with venoms (the conotoxins) from snails belonging to the genus *Conus* is another form of mollusc poisoning.

Paralytic shellfish poisoning

Paralytic shellfish poisoning (PSP) is caused by saxitoxins (STX; Fig. 15.9) produced by marine 'red tide' dinoflagellates and freshwater blue–green algae such as *Alexandrium* spp., *Gymnodinium catenatu* and *Pyrodinium bahamense*. The chemistry and biosynthesis of the STX group of toxins have been described by Moore (1999) and Daranas *et al.* (2001). STX are potent agents that can block sodium channels in nerves and muscles at the extracellular side of the channel, which leads to conductivity disturbances and paralysis. About 1600 cases of poisoning are estimated to occur every year. In severe cases, the neurological symptoms spread to the extremities and respiratory muscles and, without ventilatory support, patients die between 2 and 12 h after ingestion. STX has become both an invaluable research tool and an internationally regulated chemical weapon. Apart from its activity as a calcium channel blocker, in recent times STX has also been found to bind to potassium channels, neuronal nitric oxide synthase, STX-metabolizing enzymes and two circulatory fluid proteins, namely a transferrin-like family of proteins and a unique protein found in the blood of pufferfish (Llewellyn 2006). Lawrence *et al.* (1996) described a fast and reliable analytical method to detect STX in molluscs, based on HPLC with fluorescence detection after pre-chromatographic oxidation. Shellfish samples were extracted by boiling with 0.1 mol/L HCl and purified by solid-phase extraction on C_{18} and strong ion-exchange cartridges, respectively. The samples were then oxidised with periodate and separated on a Supelcosil LC_{18} column. A number of PSP toxins, including STX, can be detected and quantified using fluorimetric detection at wavelengths of 330 nm (excitation) and 400 nm (emission). Garcia *et al.* (2004) applied a HPLC method with post-column derivatisation and fluorescence detection to the quantitative analysis of STX in a wide range of tissues and biological fluids taken from two fishermen who died 3–4 h after consuming a small number of toxic mussels. A comprehensive list of the findings is to be found in the STX monograph.

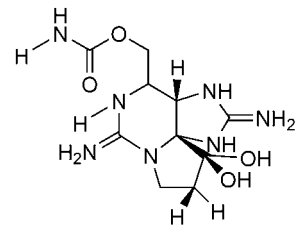

Figure 15.9 Saxitoxin.

Diarrhoetic shellfish poisoning

The major causative agent of diarrhoetic shellfish poisoning (DSP) is okadaic acid (Fig. 15.10), which is produced primarily by 'red tide' dinoflagellates belonging to the genera *Dinophysis* and *Prorocentrum* (Aune 1997; Daranas *et al.* 2001). DSP toxins are lipophilic and accumulate in the digestive gland of mussels. Okadaic acid is a potent inhibitor of protein phosphatases 1 and 2A. In humans, consumption of contaminated molluscs leads almost exclusively to gastrointestinal

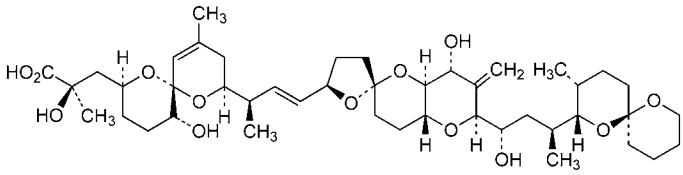

Figure 15.10 Okadaic acid.

symptoms – diarrhoea, nausea, vomiting and abdominal pain – which appear between 30 minutes and a few hours after the meal and can be caused by as little as 40 μg of toxin. Treatment is supportive and recovery is complete after a few days. Several methods for the analysis of okadaic acid in shellfish have been reported by, for example, HPLC (Quilliam 1995), LC-MS (Paz *et al.* 2007) and CE (Consoli and Damerval 2001). However, no simple analytical methods are available as yet to detect okadaic acid in these materials (Quilliam 1999).

Neurotoxic shellfish poisoning

Neurotoxic shellfish poisoning (NSP) is caused by a toxin produced by another 'red tide' dinoflagellate, *Gymnodinium breve*, which has been observed on the west coast of Florida, in the Gulf of Mexico, Japan and New Zealand.

The active principle is the lipid-soluble polyether brevetoxin (Fig. 15.11), which has a molecular weight of around 900 and is one of the most potent neurotoxins known. The mode of action of brevetoxin resembles that of ciguatoxin (CTX; see later). It is a depolarising substance in the cholinergic system that opens membrane channels permeable to sodium ions. This alters the membrane flow of excitable cell types, and results in an increase in inward flow of sodium ions, which can be blocked by tetrodotoxin (TTX; see later).

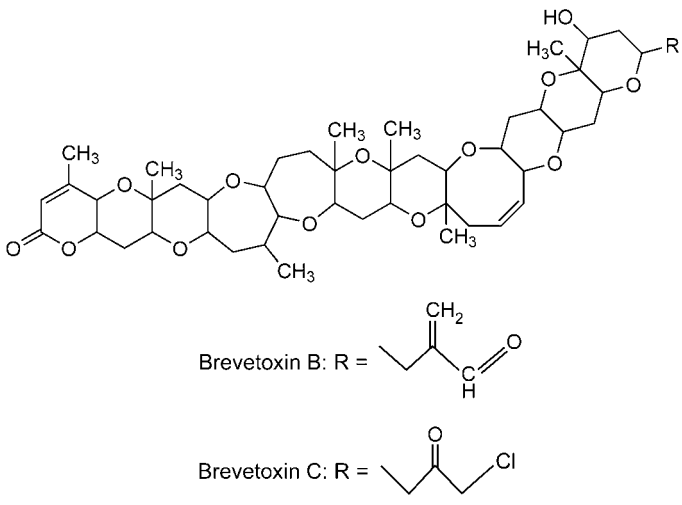

Figure 15.11 Brevetoxin.

In humans, ingestion of brevetoxin-contaminated shellfish can result in gastroenteritis with neurological symptoms. Within 3 h, nausea and vomiting, paraesthesias, reversal of hot/cold sensation, throat tightness and ataxia may occur. There is no paralysis. There is complete recovery from these symptoms within 2 days without specific treatment. No human deaths have been reported with brevetoxin poisoning. No simple and rapid analytical techniques for the detection of the toxins from *G. breve* have been described, although ELISA methods offer some promise (Quilliam 1999). Brevetoxin may also be detected with the LC-MS(-MS) method for CTX described by Lewis *et al.* (1999) (see later). Recent developments in the toxicology and analysis of brevetoxins have been reviewed by Watkins *et al.* (2008).

Amnestic shellfish poisoning

Amnestic shellfish poisoning (ASP) was identified as a marine toxin disease in 1987 in Canada, when more than 150 people were affected by the consumption of cultured blue mussels, which resulted in the deaths of three patients. The toxin responsible is domoic acid, a tricarboxylic acid that is formed by certain species of the diatom genus *Pseudonitzschia*. Domoic acid (Fig. 15.12) is a neurotoxic agent that binds competitively to the kainic acid and α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA)-subtype glutamate receptors in the CNS, leading to an elevation of intracellular free calcium and resulting in cellular damage.

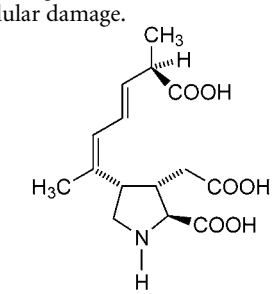

Figure 15.12 Domoic acid.

An estimated concentration of 200 μg domoic acid per gram of mollusc flesh may produce symptoms in humans. Acute symptoms include vomiting and diarrhoea and, in some cases, are followed by confusion, memory loss, disorientation, coma or death. Permanent neurological sequelae, especially cognitive dysfunction, are most likely in patients who develop neurological illness within 48 h (Baden *et al.*1995).

A large number of different analytical methods have been described for domoic acid, probably because of its relatively straightforward chemical structure. Quilliam *et al.* (1998) analysed domoic acid semi-quantitatively in shellfish using TLC. Tissues were extracted and concentrated using a strong ion-exchange resin. The extracts were applied to silica-gel TLC plates and developed with a butanol–acetic acid–water mixture (3 : 1 : 1, $R_f = 0.45$ for domoic acid). As little as 10 μg domoic acid per gram of tissue can be detected in this way. Several HPLC methods for domoic acid have been described. Lawrence *et al.* (1994) compared a reversed-phase HPLC method with an existing radioimmunoassay. Both methods appeared to be useful for the measurement of domoic acid in seafood, spiked rat serum and urine. A new pre-column derivatisation reagent, 6-aminoquinolyl-*N*-hydroxysuccinimidyl carbamate, was applied by Sun and Wong (1999) before reversed-phase HPLC with fluorescence detection. This method, which was employed in phytoplankton samples, has a mass limit of detection as low as 0.001 ng.

James *et al.* (2000) described another fluorimetric HPLC method for the determination of domoic acid in seafood and marine phytoplankton. The analyte was derivatised with 4-fluoro-7-nitro-2,1,3-benzoxadiazole (NBD-F) prior to isocratic reversed-phase HPLC with fluorescence detection with excitation at 470 nm and emission at 530 nm. Using a strong ion-exchange solid-phase extraction column for clean-up, the method detection limit is 6 ng domoic acid per gram of mussel tissue. This detection limit seems high when compared with the indirect competitive enzyme immunoassay published by Kawatsu *et al.* (2000). With this procedure, based on an anti-domoic acid monoclonal antibody, domoic acid concentrations were found in Japanese blue mussels in the range 0.11–1.81 ng per gram of tissue.

Capillary electrophoresis with UV absorbance detection has also been described for the analysis of domoic acid (Zhao *et al.* 1997). This has advantages over HPLC in that, in addition to domoic acid, several of its isomers can be separated. The method detection limit of 150 ng per gram of tissue, however, is higher than those obtained with HPLC and enzyme immunoassay (EIA). A new, sensitive method for the measurement of domoic acid in seawater and plankton based on HPLC was described by Mafra *et al.* (2009), with detection limits as low as 42 ng/L with UV detection and 15 ng/L by LC-MS. Domoic acid has been measured in serum by LC (Blanchard and Tasker 1990).

Conotoxin snails

Gastropods (snails) of the genus *Conus* feed on other molluscs, fish or worms, which they hunt by injecting venoms through a harpoon and proboscis. Stings of some species of these molluscs are known to cause

human fatalities. There are about 50 000 different conotoxins present in species of the genus *Conus*; about 1% have been pharmacologically characterised. The venom of *Conus geographus* contains several peptides. α-Conotoxin is a 13-amino-acid peptide with two disulfide bonds, which has a potent nicotinic receptor antagonist activity; μ-conotoxin is a sodium channel blocker, like tetrodotoxin. The neurotoxins from *Co. textile neovicarus*, which feeds specifically on molluscs, have been reviewed by Spira *et al.* (1993). A peptide that causes a characteristic tremor in experimental animals (*ω*-conotoxin GVIA) is now used as a pharmacological tool in neuroscience (Olivera and Cruz 2001). Conotoxin peptide toxins can be isolated from snail extracts by Sephadex G-50 column extraction followed by HPLC purification on C_{18} columns (Spira *et al.* 1993). The conotoxin ziconotide is now approved by the US FDA for the treatment of severe chronic pain by intrathecal administration (Williams *et al.* 2008).

Arthropods

Ticks, spiders and scorpions (Arachnids) and bees, wasps and ants (Hymenoptera) are part of this group; they usually transmit their toxins by stinging. Their venoms form a diverse group of chemicals with a wide range of toxicological mechanisms: for a review, see Piek and Leeuwin (1995). The role of the analytical toxicologist in the management of stinging incidents is limited and, therefore, only a small selection of the most important venomous arthropods is included in this section.

Hymenoptera

Isolated stings from bees, wasps and ants are usually not life threatening, although death may occur through anaphylactic shock. Mass stinging events do take place and are life threatening via the toxic action of the venom injected in large amounts. The rapid spread of the very aggressive Africanised subspecies of the honey bee *Apis mellifera* – which is held responsible for hundreds of human deaths – may become responsible for an increase in mass stinging. The major bee venom fractions consist of peptides (peptide-401, apamin and mellitin) and enzymes (phospholipase A_2 and hyaluronidase). Mellitin, which is able to hydrolyse cell membranes, is the primary cause of pain after a honey bee sting. Allergic reactions, mainly through phospholipase A_2 as the antigen, are IgE mediated. A sting interval of less than 2 months is a risk factor for the development of hymenoptera allergy. Wasp venom contains similar enzymes to bee venom, but with additional cholinesterases and phospholipase A_1 instead of A_2. The major peptides in wasp venom are the mastoparans, which induce histamine release. The enzymes, however, are responsible primarily for allergic reactions; they are usually not cross-reactive with bee venom allergens. The venom from the fire ant *Solenopsis invicta* also contains phospholipase A_1 and other allergens related to vespid venom.

Systemic clinical signs caused by multiple hymenoptera stings include acute renal failure, rhabdomyolysis, optic neuritis, atrial flutter, hepatic dysfunction, diffuse intravasal coagulation and respiratory distress. Wasp and ant stings may cause neurological symptoms as well. About 150–1000 bee stings and 20–200 wasp stings are thought to induce a critical situation. In all cases of allergic and mass stinging events, the victim should be transported to the emergency ward of the nearest hospital (Ewan 1998; Gelder *et al.* 1996; King and Spangfort 2000; Vetter *et al.* 1999).

Arachnids

Although tick bites are nowadays most notorious as transmitters of bacterial infections (*Borrelia* causes Lyme disease), several tick species, such as *Ixodus holocyclus* (Australia) and *Dermacentor andersoni* (North America), produce holocyclotoxins, which can result in a lethal paralysis through acetylcholinesterase inhibition at the neuromuscular junction.

A serious bite from the black widow spider *Latrodectus mactans* produces α-latrotoxins. These are proteins of about 1000 amino acid residues that bind irreversibly with presynaptic cell membranes, to produce cation-sensitive channels and interfere with the endocytosis of vesicle membranes. Local clinical signs are negligible; systemic clinical signs range from pain and muscle cramps to hypertension, pulmonary oedema and CNS involvement. Specific antivenom and muscle relaxants are administered in treatment (Piek and Leeuwin 1995; ME Peterson 2002, personal communication). Constituents of the black widow spider venom are now under investigation for possible use as insecticides (Rohou *et al.* 2007). The Australian funnel web spider *Atrax robustus*, found around Sydney, is far more dangerous, with a bite capable of causing death within 15 min. The toxin, robustotoxin, acts by opening sodium channels in axons of the victim. Administration of an antivenom has been shown to be life saving and, since its introduction, no more fatalities have been reported. The related species *Hadronynche versutus*, which is found in the southern regions of Queensland, Australia, produces versutoxin, the effects of which can also be treated with *At. robustus* antivenom (Hawdon and Winkel 1997). A different symptomatology is caused by the brown recluse spider *Loxosceles* spp., of which five species are known in the southern United States. Their venom contains a range of enzymes which are responsible for necrotic arachnidism at the biting site and a wide range of systemic symptoms, from fever and arthralgia to diffuse intravasal coagulation and renal failure (ME Peterson 2002, personal communication).

Scorpions constitute a serious public health concern in warm climates. Worldwide, 30 species produce potentially fatal toxins; the estimated yearly number of human fatalities that result from scorpion stings is 5000. Examples of scorpion species are: *Centruroides infamatus*, which is responsible for the highest envenomation rate in Mexico; *Tityus serrulatus*, which causes thousands of envenomations each year in Brazil; and *Buthus occitanus*, the most venomous scorpion, which is common in North Africa. Scorpion venom contains at least 85 different peptide neurotoxins. These disrupt sodium channel function (Becerril *et al.* 1997; Possani *et al.* 1999), which causes an increased activity of the pre-synaptic neuromuscular junction, and so affects the parasympathetic, adrenergic and adrenal medulla system. This explains the wide range of clinical symptoms in human victims. The sting site is usually very painful; pain may migrate proximally and hyperaesthesia may occur. Systemically, the cardiovascular system is affected predominantly, which results in hypertension, arrhythmias, myocardial damage, pulmonary oedema and respiratory failure. Other symptoms include hyperthermia, mydriasis, salivation, opisthotonus and roving eye movements. CNS dysfunction is seen in children, but rarely in adults, and may be secondary to cerebral hypertension (Gueron *et al.* 1992; Ismail 1995). Antivenom administration and treatment of hypertension are the recommended treatment (Ismail 1995). Murthy and Hase (1994) have suggested that insulin and glucose should be given to counteract the inhibition of insulin secretion brought about by the massive release of catecholamines during envenomation.

Vertebrates

Fish

Poisoning by the consumption of fish flesh (ichthyosarcotoxism) usually occurs in warm climates but is also observed in moderate climate zones when hygiene measures are ignored (Lipp and Rose 1997). Tetrodotoxic and ciguatoxic fish poisoning are caused by ingestion of fish that accumulate toxin-producing organisms, such as bacteria or protozoa, without being affected themselves. Scombroid poisoning is an example of a toxin produced by improper storage after death, and other fish produce poisonous stings; for a review, see Mebs (2002).

Ciguatera fish poisoning

Ciguatera fish poisoning (CFP) is caused by two groups of toxins, of which the principal one includes the lipid-soluble ciguatoxin (CTX) (Fig. 15.13) and gambierol, produced by the epiphytic dinoflagellate *Gambierdiscus toxicus.* The other group comprises the water-soluble maitotoxin. CTX is a group of heat-stable, lipid-soluble, highly oxygenated cyclic polyether molecules, which appear in the food chain through coral reef-fishes that have become toxic through their diet (Baden 1995; Daranas *et al.* 2001; Lehane 2000; Lewis 2001; Rein and Borrone 1999). CTX-containing dinoflagellates live on solid surfaces of macroalgae and are consumed during fish grazing. The mechanism of CTX toxicity is through its direct effects on excitable membranes. Its potent depolarising action, caused by a selective increase in sodium

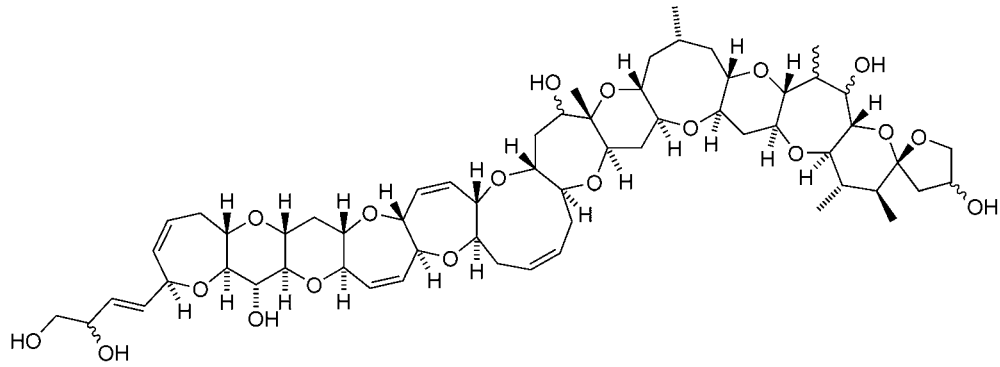

Figure 15.13 Ciguatoxin.

permeability in nerve cells and striated muscle, is based on its affinity to the 'polyether ladder toxin-binding site' of the ion channel receptor, through which sodium and calcium channels are activated. CTX activity can be counteracted by calcium ions and tetrodotoxin (see below). The ciguatera poisoning syndrome is a direct result of the stimulation of both the sympathetic and parasympathetic nervous system through opening of the voltage-dependent sodium channels in nerve cell membranes. Consumption of contaminated fish leads to gastrointestinal disturbances (nausea, vomiting and diarrhoea) within a few hours, followed by neurological symptoms. The latter include paraesthesias, tooth pain and reversal of hot/cold temperature sensation. The third symptom is pathognomonic for CFP. Paraesthesia and weakness may persist for months after the acute illness (Baden 1995). In some cases, the neurological sequelae may last for years (Lewis 2006).

Ciguatera fish poisoning is the most common cause of poisoning with marine toxins. Of those who live in or visit subtropical and tropical areas, an estimated 10 000–50 000 people per year suffer from ciguatera. The fatality rate, however, is probably less than 1%.

There is no specific therapy for CFP; prevention of consumption of contaminated fish is essential, and a simple and sensitive assay for CTX would be useful in this context. Analysis is difficult because of the low toxin level in fish and the complex structure of the CTX group of toxins. A method based on HPLC and tandem electrospray MS offers the required sensitivity (less than parts per billion; Lewis *et al.* 1999). This assay measured the Caribbean type of CTX (C-CTX) in fish flesh in concentrations of around 2.0 ng per gram of tissue. Non-toxic flesh samples spiked with C-CTX, Pacific-CTX (P-CTX) and brevetoxin yielded limits of detection of 0.2, 0.1 and 0.5 ng per gram of tissue, respectively. However, this method is unlikely to be cost-effective for routine screening. A membrane immuno-bead assay appears to be a simple, rapid, sensitive and specific detection method for CTX and its related polyethers, but further validation of this test is required (Hokama *et al.* 1998; Lehane and Lewis 2000; Lewis 2001); for a review, see Quilliam (1999).

Puffer fish poisoning

Puffer fish poisoning (PFP), or tetrodotoxin (TTX) (Fig 15.14) intoxication, causes gastroenteritis with severe neurological manifestations similar to those of PSP or saxitoxin intoxication. TTX intoxication constitutes a public health problem in subtropical and tropical regions. It is not limited to Japan, where consumption of Fugu – a local puffer fish – is popular. Fugu is harmless if prepared by a qualified chef who discards the organs in which TTX accumulates – the ovaries, roe, liver, intestines and skin. TTX can also be found in *Tetraodontiformes* spp., but these can usually be distinguished by their peculiar morphology and their ability to inflate themselves when in danger (Baden 1995; de Kom 2001). In recent years, it has been shown that a large variety of organisms besides puffer fish possess TTX (Noguchi and Arakawa 2008). TTX is produced by bacteria that colonise the gut and skin mucosal layers of the fish, and the toxin is sequestered in the gonads and the liver and, in some species, in muscle. Other marine organisms, such as the Japanese ivory shell, the trumpet shell and the blue-ringed octopus, may contain TTX. The toxin is also found in the skin of certain frogs.

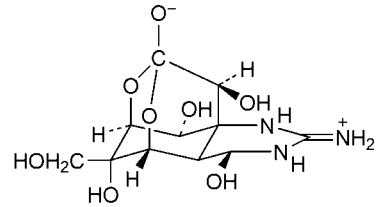

Figure 15.14 Tetrodotoxin.

Tetrodotoxin is a neurotoxic agent that blocks axonal excitability by reducing the inward flow of sodium ions, much like the saxitoxins (see above). It acts on conduction of both somatic and sensory nerves and it affects the emetic chemoreceptor. As opposed to saxitoxin, it causes hypotension through paralysis of the blood vessels. TTX is one of the most potent of the natural toxins; the lethal ingested dose for humans is 5–30 mg/kg wet tissue. The symptoms of TTX poisoning are comparable to those of PSP (see above), except for marked hypotension, and are apparent within 5–30 min after consumption. They include gastroenteric effects, paraesthesias, motor paralysis, hypotension and respiratory paralysis. In Japan the mortality rate is reported to be about 60%. Therapy consists of supportive measures, such as artificial ventilation and management of hypotension. Bioassays for PSP and PFP have been reported (Yasumoto 1991, cited in de Kom 2001). In addition, an HPLC method with fluorimetric detection has been described (Yotsu *et al.* 1989). TTX and its analogues are separated after clean-up on a Develosil ODS-5 column with 0.06 mol/L heptafluorobutyric acid in 0.001 mol/L ammonium acetate buffer (pH 5.0). The eluate is mixed with 4 mol/L aqueous NaOH solution and passed through a stainless steel column in an oil bath at 135°C. The fluorescence emission of the reaction products is measured at 500 nm, after excitation at 375 nm. The limit of detection is reported to be of the order of 2 µg/g, which is claimed to be sufficiently sensitive to measure TTX and its analogues in puffer fish liver. Tsai *et al.* (2006) have measured TTX in blood by GC-MS and by LC-MS; the latter method had a limit of sensitivity of 15.6 nmol/L. Using LC with post-column derivatisation with sodium hydroxide and fluorescence detection, O'Leary *et al.* (2004) were able to quantify TTX in serum with an LOQ of 5 µg/L. Yu *et al.* (2010) described a rapid method for measuring TTX in urine and plasma samples from poisoned patients by use of commercial SPE cartridges (C_{18} and weak cation-exchange columns) followed by analysis by HPLC with UV detection. The detection limit for both urine and plasma was 10 µg/L. They made the interesting observation that urine TTX levels measured during the first 24 h of admission to hospital showed a better correlation with the severity of poisoning when adjusted according to variations in concomitant creatinine excretion. TTX has also been measured in serum and urine samples as well as in puffer fish tissues by LC-MS(-MS). The detection limit in both urine and serum was 0.1 µg/L (Akaki and Hatano 2006). Examples of cases of puffer fish poisoning where TTX was measured in specimens of blood, serum and urine are described in detail in the tetrodotoxin monograph.

Scombroid fish

Scombrotoxin poisoning is the most commonly reported fish poisoning and occurs in many parts of the world. Scombrotoxin is formed in improperly stored fish, and its name derives from the type of fish in which it was described originally. Scombroid fish (*Scombridae*) are dark-fleshed migratory species, such as mackerel and tuna. Cases of poisoning have also been described after ingestion of non-scombroid species, such as herring, sardines and salmon.

'Scombrotoxin' is generally thought to be identical to histamine. The flesh of scombroid fish has a high histidine content, which is readily decarboxylated to histamine by enteric bacteria (*Proteus morgani*, *P. vulgaris*, *Clostridium* spp., *Escherichia coli*, *Salmonella* spp. and *Shigella* spp.) when fish stored for as little as 2–3 h at temperatures above 20°. Despite a widely reported association between histamine and scombroid food poisoning, histamine alone appears to be insufficient to cause food toxicity. Putrescine and cadaverine have been suggested to potentiate histamine toxicity (Al Bulushi *et al.* 2009). Prolonged cooking does not effectively destroy scombrotoxin and, therefore, it may also be present in canned products.

Clinical manifestations of the disease occur rapidly (10–30 min) after ingestion, and include acute gastrointestinal symptoms (vomiting, cramps, diarrhoea) associated with erythema, urticarial patches and oedema. The disease is distressing but seldom, if ever, fatal and recovery is spontaneous within 24 h. Treatment with intravenous cimetidine resolves most symptoms very quickly.

In suspect fish samples, histamine concentrations can be measured with standard methods for the analysis of histamine in food (Clark *et al.* 1999; Grant 1997; Trevino 1998).

Pfiesteria-*associated syndrome*

An illness that affects fish and humans was recently observed in the mid-Atlantic region and shown to be caused by a dinoflagellate, *Pfiesteria piscicida.* It is lethal to fish; in humans, it causes deficiencies in learning and memory, acute respiratory and eye irritation, and acute confusional syndrome (Grattan *et al.* 1998; Morris 1999). The toxins from *P. piscicida* have been identified as ligated copper compounds (Moeller *et al.* 2007).

Stonefish and weeverfish

Several species of fish with venom containing spines have been reported to cause fatalities. The stonefish *Synanceja horrida*, *S. trachynis* and *S. verrucosa*, belonging to the family Scorpaenidae, are located in temperate and tropical seas that extend across South Africa, Japan, the Pacific and Indian Oceans, Australia and New Zealand. Their venoms contain cholinesterase, alkaline phosphatase and phosphodiesterase. Stonefish stings are severely painful and patients may suffer collapse, cyanosis or pulmonary oedema (Burnett 1998).

Weeverfish (*Trachinus draco*, *T. vipera*, *T. radiatus* and *T. araneus*) occur in European coastal waters. Their venom contains serotonin, a kinin-like substance, adrenaline (epinephrine) and histamine, as well as several enzymes. Weeverfish sting causes an intense burning pain and death can occur rapidly through severe pulmonary oedema (Borondo *et al.* 2001).

Haff disease

Haff disease, a muscular condition, was first described in Germany in 1924. Lentz described muscular rigidity and some of the classic features of rhabdomyolysis in people who had consumed fish from the Haff coast off the Baltic Sea (Lentz 1925). Over subsequent years, about 1000 cases were described. There have been few reports of Haff disease since then, although scientists based at the US Centers for Disease Control described a small cluster of six cases discovered in 1997; they were able to trace the source to buffalo fish (*Ictiobus cyprinellus*) from Louisiana or Missouri. The toxin could not be isolated, could not be inactivated by cooking and was soluble in hexane, and fish from the same source fed to mice produced myopathy (Buchholz *et al.* 2000).

Amphibians

Of the amphibians, the toads are of major interest to the toxicologist because a number of species produce noxious substances in their dermal glands. These compounds include amines, peptides, proteins, steroids, and both water-soluble and lipid-soluble alkaloids. With the exception of the last, these substances are produced by the toad itself rather than bio-accumulated; for reviews, see Daly (1995) and Mebs (2002). The genus *Bufo* exudes the alkaloid bufotenine (*N*,*N*-dimethyl-5-hydroxytryptamine; Fig. 15.15), and there have been reports of attempts to gain psychedelic effects by licking the toad or smoking its venom, although Lyttle *et al.* (1996) point out that the psychedelic effects of bufotenine cannot be confirmed by objective studies. The substance may also be abused by intravenous injection, which has led to death (Kostakis and Byard 2009). Bufotenine is also a product of the 5-hydroxytryptamine (serotonin) degradation pathway, and its presence in urine has been suggested as a diagnostic indicator of psychiatric disorders (Takeda *et al.* 1995). These workers devised a three-dimensional HPLC method with electrochemical detection to measure bufotenine in urine. A method for the determination of bufotenine and other potentially hallucinogenic *N*-dimethylated indoleamines in human urine has also been described by Forsström *et al.* (2001). This used SPE followed by LC-MS, with identification based on retention data and two fragment ions produced by triple-quadrupole MS. Quantification was based on ESI and multiple reaction monitoring (MRM) to improve the sensitivity.

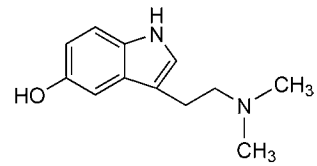

Figure 15.15 Bufotenine.

Reptiles

Gila monsters

These venomous lizards belong to the genus *Helodermatidae* (*Heloderma suspectum*, the Gila monster, *H. horridum*, the Mexican bearded lizard and their subspecies) and are indigenous to the south-western USA and Mexico. They have venom glands on the mandible and deliver the venom along grooved teeth into a bite. The venom contains hyaluronidase and proteases, in addition to gilatoxin, a 35 kDa glycoprotein with serine protease and kallikrein-like activity. The bite can lead to anaphylactoid syndrome (Hooker *et al.* 1994).

Snakes

Three main families of poisonous snakes exist – the Elapidae (cobras), the Viperidae (vipers) and the Crotalidae (pit vipers). The elapids comprise about half the world's species of venomous snakes and include the cobras and the mambas. Genera of the elapid family are found in Asia, the Pacific, the Americas and Africa (Mebs 2002). The true vipers (Viperidae), of which the common viper is the best known, inhabit Europe, Asia and Africa. The pit vipers (Crotalidae) are mainly found in North, Central and South America and include the rattlesnake genera *Crotalus* and *Sistrurus.* An estimated 30 000 lethal cases of snakebite occur annually in Asia and 1000 in Africa and South America (WHO 1995). The role of the analytical toxicologist in the diagnosis and management of snakebites is limited and the selection of information presented here aims to provide some basic data to facilitate consultative tasks.

The effects of snake venoms can be divided roughly into two major groups – neurotoxic and coagulotoxic. The neurotoxins from Elapidae and Viperidae act either at the postsynaptic level (α-neurotoxins) by preventing the binding of acetylcholine on its receptor, or at the presynaptic level by affecting neurotransmitter release. These are either non-enzymatic potassium channel blockers or β-neurotoxins, which are characterised by phospholipase A_2 activity (Bon *et al.* 1994); see also the Hymenoptera above. The dendrotoxins are small proteins from mamba venom with such specificity to potassium channels that they have become a probe for studying the physiological function of these channels (Harvey 2001). Mamba venom has also been shown to contain

toxins with high specific affinity for muscarinic acetylcholine receptors (Bradley 2000).

The haematotoxic principles of snake venoms may interfere with a number of components of the haemostatic system. These proteins and peptides are usually found in the venom of the Viperidae and Crotalidae. There are enzymes that cause fibrinogen coagulation, and enzymes that degrade fibrin or fibrinogen, there are factor V and factor X activators, substances with haemorrhagic activity, and platelet aggregation inducers and inhibitors. The haemorrhagins are of special interest; these are zinc-containing metalloproteases that act by degrading the component proteins of the basement membrane underlying capillary endothelial cells. Two reviews on snake haematotoxicity are by Markland (1997) and Hati *et al.* (1999).

The symptoms of snakebites in humans vary greatly depending on the species, but in general consist of local pain, oedema, blistering and necrosis. Systemic effects of neurotoxic species include blurred vision, ptosis and respiratory paralysis. Haemostatic toxins, such as the haemorrhagins, cause spontaneous bleeding in the gingival sulci, nose, skin and gastrointestinal tract. Fatalities result from cerebral haemorrhage or massive retroperitoneal bleeding (Warrell and Fenner 1993). Renal lesions include glomerulopathy, vasculopathy, tubular necrosis and interstitial nephritis, and often accompany snakebites with haematotoxic and neurotoxic venoms (Sitprija and Chaiyabutr 1999).

The only specific and effective treatment for systemic and severe local envenomation is the administration of antivenom, a hyperimmune immunoglobulin (Moroz 1998; Warrell and Fenner 1993). For administration of the proper antivenom, the species that has bitten the patient must be known, and panacea antivenom is not and will not be available. Purification and characterisation of snake venoms is not only important for the elucidation of their mechanism of action, but also for the preparation of these antivenoms (Bhat *et al.* 1991; Chang *et al.* 1997; Gasanov *et al.* 1997; Stiles *et al.* 1994). A future development in reducing snakebite fatalities may be active immunisation of populations at risk (Chippaux and Goyffon 1998). An exhaustive state-of-the-art review on available antivenoms, not only against snake bites but also against bites by spiders and scorpions, was recently published by Espino-Solis *et al.* (2009).

Birds

Coturnism is a peculiar type of poisoning, resulting in the development of rhabdomyolysis and acute renal failure after the ingestion of quail (*Coturnix coturnix*). Reactions to the consumption of quail have been known since antiquity, especially in the Middle East. Some authors attribute the death after ingestion of quail of the Israelites in the Bible (*Numbers*, chapter 11) to coturnism (Rizzi *et al.* 1991). It has been presumed that a toxin ingested by the birds during migration is directly toxic to striated muscle. The toxin has been postulated to be coniine from hemlock (*Conium maculatum*) (Rizzi *et al.* 1991) or red hempnettle (*Galeopsis ladanum*) (Tsironi *et al.* 2004).

CHAPTER

16 Pesticides

M Kała

More than a thousand pesticides are available and widely used in the world today. In addition, several hundred compounds that are no longer manufactured or marketed for crop protection still remain in people's houses. Both these groups of substances play an important role in clinical and forensic toxicology as causes of suicidal, homicidal and accidental poisonings. The immense variety of chemical compounds with pesticidal properties means that the identification of an unknown substance is complicated. The screening procedure presented is based on three methods: thin-layer chromatography (TLC), gas chromatography (GC) and gas chromatography coupled to mass spectrometry (GC-MS). Gas chromatography with tandem mass spectrometry (GC-MS[-MS]), high performance liquid chromatography (HPLC) and liquid chromatography combined with single-stage or tandem mass spectrometry (LC-MS or LC-MS[-MS]) are also used as confirmation and quantification methods. These methods can be used to identify the active component(s) in commercial preparations and household products and cosmetics, and to examine waters, drinks and foodstuffs to which a pesticide has been added either for criminal purposes or accidentally. They are also used to determine these compounds in biological samples and other materials taken from or found near a patient or body – so-called scene residues.

Classification of pesticides

The term 'pesticide' encompasses a wide variety of substances used to destroy unwanted life forms. Pesticides are applied in agriculture for crop protection and pest control, and in human and animal hygiene. They are classified as insecticides, herbicides, rodenticides, fungicides, nematocides, molluscicides and acaricides on the basis of their field of use. Commercial formulations can be mixtures of pesticides from different classes. It should be noted that some superseded materials are known to be still in use for non-agricultural purposes.

Most pesticides have common names agreed by the International Organization for Standardization (ISO) through its Technical Committee 81 (ISO/TC 81), for which the secretariat is the British Standards Institution (BSI). The principles for coining these common names are explained in ISO 257 : 2004. If the molecule is, for example, an acid, it may be used in a salt or ester form. Usually the common name is assigned to the parent acid; from this name, the salt or ester name can be derived in a straightforward manner by adding the name of the ester or ion (e.g. dichlorprop and dichlorprop, methyl). These common names are used throughout this chapter for convenience and brevity, but their equivalent systematic chemical names can be ascertained easily according to the rules of the International Union of Pure and Applied Chemistry (IUPAC) and the Chemical Abstracts Service Registry Number (CAS RN) (Merck Index 2006; Tomlin 2006). Approximately 880 active substances are currently formulated in pesticide products (Tomlin 2006). These substances belong to more than 100 chemical subclasses. Often the type of chemical is also indicated by a stem in the common name (e.g. 'uron' for ureas, and 'carb' for carbamates).

Structures of various pesticides are given in Fig. 16.1. Table 16.1 gives an alphabetical list of approximately 500 compounds together with their uses, chemical classification and analytical data.

Insecticides

Insecticides may be classified into eight chemical groups, of which the following five are the most important:

- Organophosphorus (OP) compounds, which have the general structure **1** in Fig. 16.1 with subclasses listed in Table 16.2
- Carbamates (structure **2** in Fig. 16.1 where R^1 = methyl, R^2 = H or methyl and R^3 = aryl, heterocyclic or oxime groups) (e.g. aldicarb, structure **3** in Fig. 16.1)
- Chlorinated hydrocarbons, which include dichlorodiphenyltrichloroethane (DDT) and its analogues (e.g. methoxychlor), hexachlorocyclohexane isomers (e.g. lindane) and bridged polycyclic chlorinated compounds (e.g. endosulfan, structure **4** in Fig. 16.1)
- Pyrethroids, both natural (e.g. pyrethrin II, structure **5** in Fig. 16.1) and synthetic (e.g. deltamethrin, structure **6** in Fig. 16.1)
- Substituted ureas (e.g. diflubenzuron, structure **7** in Fig. 16.1)

Other insecticide groups are organotin (e.g. cyhexatin, structure **8** in Fig. 16.1) and heterocyclic compounds (e.g. dazomet, structure **9** in Fig. 16.1).

Herbicides

Herbicides may be classified into at least 12 groups, but the seven most important are:

- Chlorinated phenoxy acids (e.g. 2,4-dichlorophenoxyacetic acid (2,4-D), structure **10** in Fig. 16.1)
- Substituted ureas (e.g. metobromuron, structure **11** in Fig. 16.1)
- Triazines (e.g. atrazine, structure **12** in Fig. 16.1)
- Uracils (e.g. lenacil, structure **13** in Fig. 16.1)
- Quaternary ammonium compounds (e.g. paraquat, structure **14** in Fig. 16.1, and diquat)
- Carbamates, which include not only the carbamates (e.g. propham), but also thiocarbamates (e.g. tri-allate, structure **15** in Fig. 16.1)
- Carboxylic acids and esters (e.g. dicamba).

Other herbicides include amides, chloroacetanilide, OP and organoarsenic compounds.

Fungicides

Chemicals from many groups belong to this class: benzimidazoles (e.g. carbendazim), dithiocarbamates (e.g. thiram, structure **16** in Fig. 16.1), acylalanines (e.g. metalaxyl) and OP compounds (e.g. pyrazophos). The most important are:

- Dithiocarbamate complexes with manganese, nickel and zinc.
- Organic and inorganic compounds of copper and mercury.

Rodenticides

Three types of compounds are notable in this category:

- Phosphines (derived by the reaction of moisture with magnesium, aluminium and zinc phosphides)
- Thallium salts, usually sulfates
- Coumarin anticoagulants (e.g. brodifacoum, bromadiolone, coumatetralyl, difenacoum; Fig. 16.2).

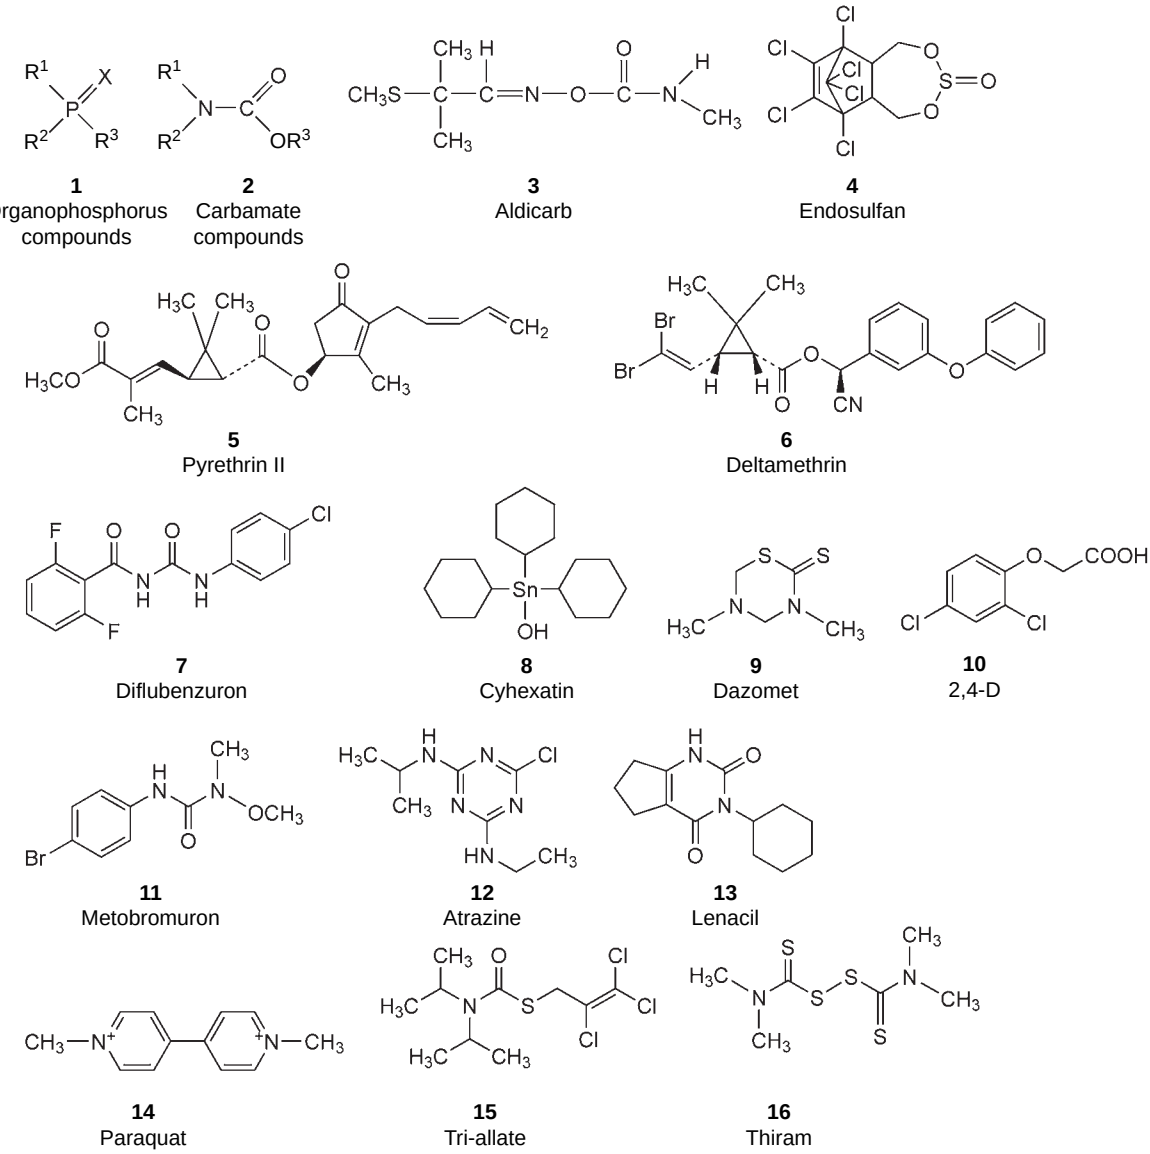

Figure 16.1 Structures of pesticides.

Acaricides, molluscicides and nematicides

These include organotin (acaricide), niclosamide (molluscicide) and phorate (nematicide). Some of these compounds that have more than one application can be found among those mentioned above.

Toxicity

The large variety of chemical compounds that show pesticide properties means that there is a very wide range of toxicity in humans. It is believed that an oral dose of only several drops (100 mg) of terbufos is fatal to most adults, whereas another pesticide (amitrole) is non-toxic in humans even when several hundred grams are ingested. Within a particular class of pesticide the lethal dose may vary considerably. Moreover, the metabolites of many pesticides (e.g. oxygen analogues of phosphorothionates) are much more toxic than the parent compounds. The commercially available preparations usually contain an active substance mixed with filler (solids) or dissolved in an organic solvent (liquids). Although certain pesticides are unlikely to cause acute toxicity, the vehicle in which they are formulated (toluene, xylenes, butan-1-ol, cyclohexanone, farbasol and solvent naphtha) (Chłobowska *et al*. 1996) may itself be toxic and, in some cases, can be the main causative agent for the symptoms observed.

The pesticides have been classified into five groups according to the World Health Organization (WHO) toxicity classification for estimating the oral acute toxicity of pesticides (Tomlin 2006) (Table 16.3). Toxicity was determined on the basis of the LD_{50} of the active ingredient for the rat and the estimated lethal doses related to a 70 kg person. However, realistic human lethal doses of pesticides can be estimated only on the basis of well-documented cases of poisoning.

Ideally, all the toxicological data for each formulation should be available from the manufacturer. However, if such data are not obtainable, then the classification may be based on proportionate calculations from the LD_{50} values of the technical ingredient(s) according to the following formula (WHO 2004):

$$\frac{LD_{50}\text{ active ingredient} \times 100}{\text{percentage of active ingredient in formulation}}$$

If the formulation contains more than one ingredient (including the solvent, wetting agents, etc.) that has significant toxicity-enhancing properties, then the classification should correspond to the toxicity of the mixed ingredients.

Analytical techniques

The chemical and physical properties of pesticides may differ considerably. There are several acidic pesticides; others are neutral or basic. Some

[a]AC, acetylated for GC analysis; -C_2H_3NO, desmethylcarbamoyl GCDP; -CO_2, GCDP formed by decarboxylation; ET, ethylated for GC analysis; -HCl, GCDP formed by the elimination of hydrochloric acid; -H_2O, GCDP formed by dehydration; HY, acid hydrolysed; M, metabolite; M (HO-), hydroxy metabolite; M (HOOC-), carboxy metabolite; ME. methylated for GC analysis; TFA, trifluoroacetylated for GC analysis.
[b]Classification of pesticides according to use: A, acaricide; F, fungicide; H, herbicide; I, insecticide; Mol, molluscicide; N, nematicide; R, rodenticide.
[c]According to chemical classes: CA, coumarin anticoagulant; CB, carbamate; CH, chlorinated hydrocarbon; CP, chlorinated phenoxy acid; GCDP, gas chromatography decomposition product; Misc., miscellaneous; OM, organometallic; OP, organophosphorus; PY, pyrethroid; QA, quaternary ammonium compound; SU, substituted urea; TR, triazine; UR, uracil.
[d]See Table 14.3.
[e]The R_f values were taken from Erdmann *et al*. (1990), De Zeeuw *et al*. (1992b) and Osselton and Snelling (1986) with kind permission of the authors and publishers.
[f]The retention indices and the typical ions and their intensities were taken from Pfleger *et al*. (2007) and De Zeeuw *et al*. (1992a) with kind permission of the authors and publishers.
[g]col., column; c, index is measured on capillary column; p, index is measured on packed column.
[h]Retention times relative to caffeine in system GK were taken from Fysh and Whitehouse (1986) with kind permission of the authors.
[i]HPLC data were taken from Osselton and Snelling (1986) with kind permission of the authors and publishers.
[j]Superseded entries.
[k]Relative molecular mass.
[l]Toxicity class according to Environmental Protection Agency (EPA).
[m]Compound without nitrogen.
[n]This compound could not be detected by GC.
[o]The transition ions and the typical ions were taken from Alder *et al*. (2006) and from www.bfr.bund.de/cd/5832 with kind permission of the author and publishers.
[p]Recorded ions were taken from Adamowicz and Kała (2009) with permission of the authors and publisher.

Table 16.2 Subclasses of organophosphorus compounds (structure 1 in Fig. 16.1)

Subclass	R^1	R^2	R^3	*X*	*Example*
Phosphorodithioates	*O*-alkyl	*O*-alkyl	*S*-alkyl, *S*-aryl	S	Phosalone
Phosphorothionates	*O*-alkyl	*O*-alkyl	*O*-alkyl, *O*-aryl	S	Fenitrothion
Phosphorothioates	*O*-alkyl	*O*-alkyl	*S*-alkyl, *S*-aryl	O	Omethoate
Phosphates	*O*-alkyl	*O*-alkyl	*O*-alkyl, *O*-aryl	O	Dichlorvos
Phosphonates	*O*-methyl	*O*-methyl	alkyl, aryl	O	Trichlorfon
Phosphonodithioates	alkyl	*O*-alkyl	*S*-aryl	S	Fonofos
Phosphoroamidothioates	*O* or *S*-alkyl	*O*-alkyl	amine	O or S	Methamidophos

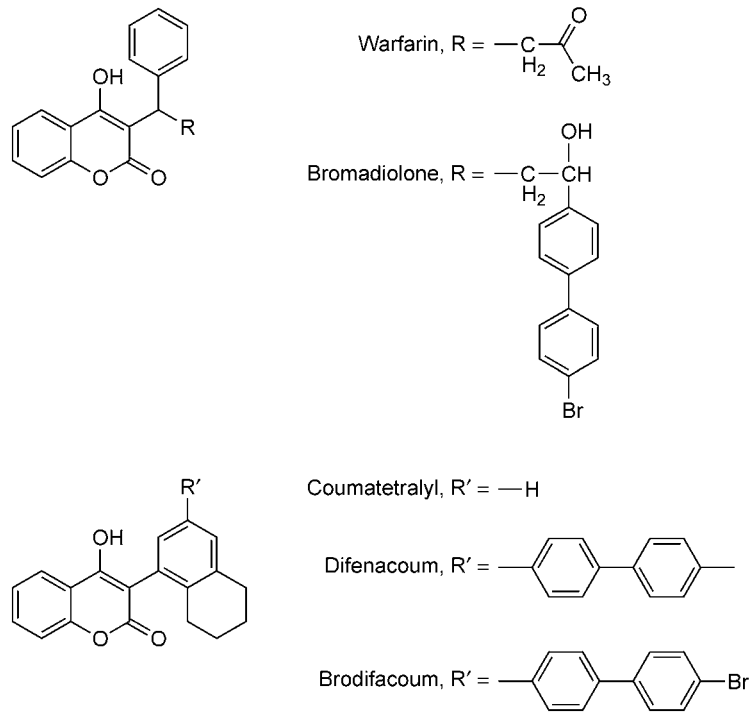

Figure 16.2 Chemical structures of the 4-hydroxycoumarin anticoagulant rodenticides. Reproduced with permission from Felice *et al*. (1991).

Table 16.3 WHO toxicity classification (Tomlin 2006)

Class	*Description*	*Oral LD_{50} for the rat (mg/kg body mass)*		*Estimated lethal dose (for a 70 kg person)*
		Solids	**Liquids**	
Ia	Extremely hazardous	≤5	≤20	≤30 drops, a taste
Ib	Highly hazardous	5–50	20–200	≤a tablespoon
II	Moderately hazardous	50–500	200–2000	≤a teacup
III	Slightly hazardous	≥501	≥2001	≥a teacup
U	Product unlikely to present acute hazard in normal use	≥2000	≥3000	

compounds contain halogens and others phosphorus, sulfur, or nitrogen. These heteroatoms may have relevance for the detection of pesticides. A number of compounds are very volatile, but several do not evaporate at all. This diversity causes serious problems in the development of a universal analytical method, which should have the widest scope possible.

The next sections describe a range of methods that can be applied to the detection of pesticides, from simple presumptive colour tests and TLC through to complex instrumental techniques. These can form part of a systematic analytical protocol that uses standardised extraction techniques and chromatographic conditions.

Preliminary screening tests

Primary references to particular methods are given, sometimes to the original methods even though many tests have been modified over the years.

Colour tests

Some colour tests can be very useful preliminary indicators of the class of compound and can confirm the constituents of a proprietary formulation. Simple quantification of compounds that belong to specific groups is also possible. To reduce false positives from artefactual sources,

a blank solution should be subjected to the same procedure as the sample. It is also essential to check the viability of the reagents by analysing a reference compound.

Ammonium molybdate test

The ammonium molybdate test is used for phosphorus and phosphides in stomach contents and non-biological materials (Flanagan *et al.* 1995). Impregnate a strip of filter paper in a saturated methanolic solution of silver nitrate and dry. Impregnate a second strip of filter paper in 10% (w/v) lead acetate solution and dry. Place 5 mL of sample in a test tube fitted with a cork with two slits cut on opposite sides. Insert the test paper into the slits, close the tube and heat in a water bath at 60°C for 20 min. If only the silver nitrate paper is blackened, phosphorus or phosphides may be present. If both papers are blackened, sulfides may be present and the result is inconclusive.

To test more specifically for phosphorus, place the silver nitrate paper on a glass microscope slide and cover with calcium hypochlorite powder. Leave in a moist chamber for 15 min to allow oxidation of phosphide to phosphate. Remove excess hypochlorite by careful washing with a small amount of water and dry the test paper by blotting with absorbent tissue. Add 50 µL of 0.05% (v/v) *o*-toluidine solution in 10% (v/v) glacial acetic acid and expose the paper to ammonia fumes from concentrated ammonium hydroxide in a fume cupboard. A blue colour confirms phosphorus.

Furfuraldehyde test

The furfuraldehyde test is used for carbamates in stomach contents and non-biological materials (Flanagan *et al.* 1995). Dissolve the dry residue after carrying out a standard liquid–liquid extraction (LLE; see the section Liquid–liquid extraction below) in 0.1 mL of methanol, apply a spot of the solution to a filter paper and allow to dry. Apply 0.1 mL of freshly prepared furfuraldehyde solution in methanol (1 : 10 v/v) to the spot, allow to dry and expose the paper to concentrated hydrochloric acid fumes for 5 min in a fume cupboard. Carbamates (pesticide and non-pesticide) give a black spot.

Phosphorus test

The phosphorus test is used for organophosphorus compounds. Extract each sample (several drops of proprietary preparation or 2 mL of other specimens) with 5 mL of a mixture of toluene–hexane (1 : 1 v/v). After separation, the organic layer is dried over sodium sulfate for 10 min and evaporated to dryness. To the dry residue add concentrated acids (1 mL nitric and 0.2 mL sulfuric acid), heat at 120°C in a heating block for 30 min, allow to concentrate and then cool. Add 1 mL of 10% (w/v) solution of ammonium molybdate in 5 mol/L nitric acid and replace in the water bath at 100°C for 10 min. A bright yellow solution or precipitate indicates the presence of phosphate ions, which may derive from an OP pesticide. The test has a sensitivity of approximately 5 µg per sample and is therefore not able to detect OP compounds in blood.

Sodium dithionite test

The sodium dithionite test is used for diquat and paraquat (Tompsett 1970). To 1 mL of urine or stomach contents add 1 mL of a freshly prepared 1% (w/v) solution of sodium dithionite in 1 mol/L sodium hydroxide solution. A blue colour indicates the presence of paraquat. A green colour is given by diquat, but paraquat may also be present. The limit of detection (LOD) for paraquat is 1.0 mg/L. Diquat may be differentially extracted from examined samples in the presence of paraquat using butan-1-ol (Minakata *et al.* 1990). Kuo *et al.* (2001) described a quantitative method for measuring paraquat and diquat in biological fluids and tissues that involved protein precipitation with trichloroacetic acid and subsequent purification of the supernatant by solid phase extraction. When both paraquat and diquat were present, their concentrations could be determined by the peak amplitudes of their respective second-derivative spectra after the addition of alkaline dithionate reagent. Interference was negligible when the diquat/paraquat concentration ratio was within the range 5.0–0.2 (Kuo *et al.* 2001).

Test for cholinesterase inhibitors in plasma or serum

To each of three tubes add 2 mL of 0.02% (w/v) dithiobisnitrobenzoic acid in 0.1 mol/L sodium dihydrogenphosphate buffer, pH 7.4 solution and 1.0 mL of 0.5% (w/v) aqueous acetylthiocholine iodide solution (Flanagan *et al.* 1995). To the first tube add 20 µL of control plasma and to the second 20 µL of sample plasma. To the third tube add 20 µL of 20% (w/v) aqueous pralidoxime chloride solution (reverses the inhibitor activity) and 20 µL of test plasma. Vortex mix the contents of all three tubes and allow to stand at room temperature for 2 min. If a cholinesterase inhibitor is present the yellow colour in the control tube will be deeper than that in the sample tube. Further confirmation is provided if the depth of colour in the pralidoxime tube is similar to that in the control tube.

Comprehensive screening procedure

This procedure consists of two initial screens by means of TLC or GC. TLC is a very useful screening and identification technique for pesticides in commercial preparations added to beverages or foodstuffs and in body fluids (stomach contents, urine) and tissues. Testing blood samples for these compounds requires the use of a more sensitive GC technique. The method of choice, regarded as the reference method for identification and confirmation of the presence of pesticide(s) in different materials, is GC-MS. More recently, GC-MS(-MS), LC-MS and LC-MS(-MS) methods have been developed for screening and determination of particular classes of pesticides in biological and non-biological matrices (Botitsi *et al.* 2007; Fernandez Moreno *et al.* 2008; Frenich *et al.* 2007; Pang *et al.* 2009; Walorczyk 2007). All these instrumental methods need special sample preparation procedures for biological materials.

Reference materials

For all the methods described it is very important to use good-quality reference materials, although in some situations, such as when using TLC screening methods, commercial preparations can be an adequate substitute. Many pesticide standards are available prepared in sealed ampoules from LGC Standards (http://lgcstandards.com/home/home_en.aspx), which is Radian's international distributor of certified analytical reference materials. Although an expiry date is provided with each reference material, dilute solutions of many pesticides will not remain stable for more than a few months after the ampoules are opened.

Sample preparation

A broad spectrum of pesticides in heterogeneous matrices (non-biological and biological samples) may be submitted for toxicological analysis. Depending on the pesticide class, biological sample preparation may involve denaturation of proteins with either organic solvents (methanol, acetonitrile) or acids (acetic, formic, trichloroacetic or perchloric), addition of solid urea, zinc salts, saturated sodium chloride solution or mixing with sodium sulfate, cleavage of conjugates, isolation from the matrix, volume reduction, clean-up steps and/or derivatisation of the pesticides and/or their metabolites. For some derivatives antioxidants, e.g. sodium disulfite, can be used (Ueyama *et al.* 2006). Each step can be a source of artefacts or decomposition products as a result of light sensitivity, atmospheric oxidation, hydrolysis and heat. The major metabolites of many pesticides (e.g. carbamates and organophosphates) are sulfate and glucuronide conjugates. Cleavage of conjugates by enzymatic or acid hydrolysis is necessary before extraction. Analytical data for pesticides after acid hydrolysis are given in Table 16.1. However, deconjugation of pesticides by acid hydrolysis drastically increases the formation of artefacts and can destroy analytes completely. Therefore, the gentle enzymatic method is recommended. The extraction of body fluids is further complicated because certain pesticides are decomposed readily by acids or alkalis. Moreover, the decomposition products of some subclasses of pesticides (e.g. substituted ureas) can react with the extraction solvent (e.g. ethanol or acetone) used for reconstitution of the dried residue after extraction. Many pesticides can undergo degradation during the chromatographic process. Accordingly, the possibility of formation of artefacts during all these processes must always be taken into account and minimised wherever possible. Derivatisation of pesticides can often improve chromatographic separation. Moreover, in

some cases, chromatography of the extract before and after derivatisation increases the identifying power of GC, and for GC-MS methods changes in the fragmentation pattern can yield additional information for characterisation.

Standard and special sample preparation procedures are described below. Pesticides can be isolated either by LLE and manual or by automated SPE. LLE is still regarded as the more universal method for screening, whereas SPE is preferred for quantification of certain pesticides in blood samples or for extraction of a particular chemical class of pesticides, such as coumarin anticoagulants (Maurer, Arlt 1998).

Other methods that should be considered include LLE followed by purification by gel permeation chromatography; this has been developed for the analysis of 660 pesticides in various tissues (Pang *et al.* 2006). Solid-phase microextraction (SPME) and headspace solid-phase microextraction (HS-SPME) have been used for the isolation of organophosphorus compounds from blood (Wollersen, Musshoff 2007) and Hernández *et al.* (2004) have described the direct injection of human urine samples for the determination of free, glucuronide and sulfate metabolites of parathion, methyl-parathion and fenitrothion by LC-MS(-MS).

Previously reported methods for extraction dialkylphosphate metabolites of organophosphorus pesticides as lyophilisation or azeotropic distillation were extremely time consuming and labour intensive.

The quantity of the sample taken for extraction depends on its type and is restricted by its availability. Samples may be proprietary formulations (solid or liquid in an amount of several drops to several millilitres or grams), beverages or foodstuffs, soil samples (20 g), river or lake water (up to 500 mL) and body fluids – stomach contents, urine (5 mL), blood (1–2 mL, but more often less than 1 mL) or tissues (5 g). Sundberg *et al.* (2006) described an extraction procedure followed by GC–electron-capture detection (ECD) for the analysis of organochlorine pesticides and polychlorinated biphenyls from 0.1 to 1 mL samples of avian serum with absolute recoveries of 74–101%.

It should be remembered that many pesticides are not stable during storage even when refrigerated. Moreover, when collecting samples to detect organophosphorus compounds, sodium fluoride should not be added to liquid specimens. For example, the presence of this common preservative in drug-free fresh blood samples (pH 7.4) caused complete degradation of dichlorvos over 15 min, and chlorpyrifos-methyl also became very unstable (Moriya, Hashimoto 1999).

Enzyme hydrolysis (urine)

To 5 mL of urine specimen are added 1 mL of 1 mol/L acetate buffer (pH 5) and 40 µL of β-glucuronidase plus arylsulfatase (30 U/mL plus 60 U/mL), and the mixture is incubated overnight at 37°C in a closed test tube. Incubation for 45 min at 56°C is less time-consuming, but the quantitative results are more variable – this shorter process can be used in emergency cases.

Liquid–liquid extraction

Solid or semi-solid samples are homogenised with an equal mass of water. Foodstuffs, stomach contents (especially with undigested food residues) or stomach tissues homogenised with water are treated with saturated calcium chloride solution, allowed to stand overnight, and filtered or centrifuged.

An aliquot of the filtered sample or homogenate is shaken for 5 min with an equal volume of a mixture of hexane–toluene (1 : 1, v/v) without adjusting the pH. After organic layer separation by centrifugation, the organic phase is retained. The aqueous fraction is adjusted to pH 2 by the addition of 1 mol/L sulfuric acid and then extracted with an equal volume of diethyl ether. The aqueous fraction is retained for later examination.

The hexane–toluene and ethereal fractions are combined and then divided into three equal portions. Each portion is evaporated to dryness at 40°C under a stream of nitrogen. One dry residue is reconstituted in 50 µL of toluene or hexane. A 5–10 µL aliquot is spotted on a TLC plate and a 1–2 µL aliquot is injected into the GC or the GC-MS apparatus. The two other residues and the aqueous phase are retained for derivatisation and/or additional tests, which are a part of screening or confirmation procedures.

Derivatisation procedures Table 16.1 gives retention indices, typical ions and their abundances for methyl (ME in Table 16.1), trifluoroacetyl (TFA in Table 16.1) and acetyl derivatives (AC in Table 16.1) of pesticides. Trifluoroacetylation and acetylation processes can be carried out for 5 min under microwave irradiation at about 400 W (Kraemer *et al.* 1997).

Acetylation Acetylation can be used interchangeably with trifluoroacetylation; 100 µL of pyridine and 100 µL of acetic anhydride are added to the second part of the dried extract (see above). The samples are vortex mixed, heated at 70°C for 20 min in a heating block, dried under nitrogen and reconstituted in 50 µL of ethyl acetate. Then, 1–2 µL are injected into the GC or the GC-MS apparatus. Alternatively, the acetylation process can be carried out with 50 µL of an acetic anhydride–pyridine mixture (3 : 2, v/v) for 5 min under microwave irradiation (Kraemer *et al.* 1997).

Methylation Methylation is used for System GK (see later) (Fysh, Whitehouse 1986). The third retained portion of extract, dissolved in 50 µL of methanol, is methylated for 2 h at room temperature with 200 µL of an ethanol-free solution of diazomethane in diethyl ether (Eistert *et al.* 1968) and then the methylation mixture is evaporated to dryness. The residue is dissolved in 50 µL of methanol and 1–2 µL are injected into the GC or the GC-MS apparatus. It should be noted that Diazald, a reagent for preparing diazomethane, is available (Sigma-Aldrich Co. Ltd.).

Methylation is also used for system GA (see later) (De Zeeuw *et al.* 1992a). The dried residue is dissolved in 0.5 mL of toluene and 0.5 mL of dimethyl sulfoxide. After addition of 50 mg of sodium hydride and 0.5 mL of methyl iodide, the sample is derivatised for 10 min at room temperature. After addition of 2 mL of hexane, the sample is shaken for 1 min. To remove the excess dimethyl sulfoxide, 2 mL of water is added and gently shaken, and then the organic layer is transferred and the aqueous phase is extracted again with 2 mL of hexane and then with 2 mL of ethyl acetate. The combined extracts are dried over sodium sulfate for 15 min and then concentrated to 0.1 mL (Rüssel 1986).

Trifluoroacetylation Trifluoroacetylation can be used interchangeably with acetylation. The trifluoroacetate derivative is prepared by reconstituting the dried extract with 50 µL of trifluoroacetic anhydride and 50 µL of ethyl acetate, and incubating at 60°C for 15 min (Catlin *et al.* 1987). After evaporation of the derivatisation mixture, the residue is dissolved in 50 µL of ethanol and dried ethyl acetate (1 : 1, v/v) and 1–2 µL are injected into the GC or the GC-MS apparatus.

Special procedure for quaternary ammonium herbicides A portion of the previously retained aqueous phase, filtered stomach contents or urine sample can be tested for the presence of paraquat and/or diquat by the colour test described above. Other assays to confirm the presence of paraquat or diquat can be carried out as follows (Draffan *et al.* 1977). The remaining aqueous phase after LLE or filtered stomach contents or urine sample is adjusted to pH 10 by the addition of 5% (v/v) ammonia solution and then mixed with 50 mg of sodium borohydride. After allowing to stand at room temperature for 30 min, the reaction mixture is extracted with an equal volume of diethyl ether. The ether extract contains the monoene and diene reduction products, which can be analysed by GC and/or GC-MS.

Thin-layer chromatography

Four TLC systems are used; each consists of an independent mobile phase and a sequence of different spray reagents, widely used for pesticide visualisation. General systems TZ and TAA (Kała, Chacia 1994) are used to reveal any pesticide in an examined sample and to enable presumptive chemical classification. Two more systems, TX and TY (De Zeeuw 1992b; Erdman *et al.* 1991; Erdmann *et al.* 1990), are used to identify the type of pesticide. The TX and TY systems give good reproducibility of R_f values with an error window of 7 calculated on the basis of interlaboratory results. The R_f values of the reference compounds chosen for the four screening systems are derived using 5–10 µg of each substance. Each extract is spotted onto a TLC plate in an amount corresponding to 2 g of the biological material being analysed. For

additional information, two other solvent systems (TAB and TAC) can be applied (Osselton, Snelling 1986).

The chromatographic process uses silica-gel plates of 0.25 mm layer thickness (e.g. Art. No 5721 from Merck), without fluorescent indicator and four mobile phases in saturated chambers in ascending mode. Seven spray reagents are suggested, which produce a variety of colours to facilitate differentiation. A large number of pesticides react with more than one reagent. The reagent sequences chosen allow the plates to be oversprayed (Kała, Chacia 1994). The LOD for most pesticides is 10 µg after reagent overspraying and 2–5 µg after single-reagent spray detection. After drying, all the chromatograms are first examined under ultraviolet (UV) light (366 and 254 nm) and then sprayed successively with the location reagents appropriate for each system. The plate is sprayed with a location reagent and dried, and a note is taken of any colours. The plate is then oversprayed with another reagent and again any changes are noted.

In addition to the spray reagents indicated below, useful individual detecting agents include anisaldehyde, 4-aminopyridine, 2-methylthioacridone or the Griess reagent (Patil, Shingare 1993) for organophosphorus compounds and also, used separately, trichlorobenzoquinoneimide and zinc hexacyanoferrate for the identification of carbamates. A sequence of 4-aminoantipyrine followed by potassium ferricyanide is recommended especially for carbaryl, propoxur and carbofuran as intense red spots develop (Sevalkar *et al.* 2000). Other reagents reported as selective and very sensitive are: tautomeric phloroglucinol for methomyl (Mali *et al.* 2006) and 2% diphenylamine and 5% formaldehyde in alcoholic solutions, which detect carbaryl and 1-naphthol as blue-green spots on heating (Daundkar *et al.* 2006).

Spray reagents

Silver nitrate ($AgNO_3$) The plates are sprayed with a 0.1 mol/L aqueous solution of $AgNO_3$. After spraying, the dry plates are exposed to UV radiation (254 nm) for 10 min. Many pesticides give white, grey and brown spots on a bright brown background.

Rhodamine B and sodium hydroxide (RHB-NaOH) A 0.02% (w/v) solution of rhodamine B (RHB) in ethanol and a saturated solution of NaOH in ethanol are used as the spray. After both the RHB and NaOH solutions have been sprayed, compounds are located as navy-blue spots by examination under UV light.

Diphenylamine and zinc chloride (DPA-$ZnCl_2$) The spray comprises 0.7% (w/v) diphenylamine (DPA) and 0.7% (w/v) $ZnCl_2$ solution in acetone. After spraying, the plates are exposed to UV radiation for 10 min and then heated at 100°C until no further colour change is observed. Light blue, blue, green and pink spots are observed on a white background.

2,6-Dibromoquinone-4-chlorimide and sodium hydroxide (DBQ-NaOH) A 0.2% (w/v) solution of 2,6-dibromoquinone-4-chlorimide (DBQ) in acetone and a saturated solution of NaOH in ethanol are used to spray the plates. After spraying, the plates are heated at 100°C for 10 min. Navy blue, pink and violet spots on a light blue background are observed.

Palladium chloride ($PdCl_2$) To make the spray, dissolve 0.5 g of $PdCl_2$ in 2.5 mL of 35% (v/v) hydrochloric acid and carefully dilute with water to 100 mL. After spraying, yellow and brown spots are observed.

4-(4-Nitrobenzyl)pyridine and tetraethylenepentamine (NBP-Tetren) To make the spray, dissolve 5 g of 4-(4-nitrobenzyl)pyridine (NBP) in 100 mL of acetone and dilute 1 : 5 (v/v) of tetraethylenepentamine (Tetren) with acetone (Brose *et al.* 1992). Spray the plate with the NBP solution and dry at 110°C for 10 min. After cooling, spray the plate with the dilute Tetren solution and observe the blue–violet spots on a white background. The colours are not stable. The stability of the colours can be enhanced by spraying the plate with a 20% (v/v) solution of acetic acid and drying at room temperature and at 110°C before using Tetren (Fodor-Csorba, Dutka 1986). The reagents should be freshly prepared.

Dragendorff spray, ferric chloride, iodine and hydrochloric acid The reagents are Dragendorff spray, a 5% (w/v) solution of $FeCl_3$, 1 g of iodine and 4 g of KI dissolved in 100 mL of ethanol, and finally a 25% (v/v) solution of concentrated hydrochloric acid made up in ethanol. Spray the reagents consecutively and examine any spots and colour changes.

Chromatography systems

System TX
- Mobile phase: hexane–acetone (4 : 1).
- Reference compounds: trichlorfon (hR_f 7), carbofuran (hR_f 17), methoxychlor (hR_f 43), dieldrin (hR_f 65) and quintozene (hR_f 84).
- Location systems: DPA-$ZnCl_2$, NBP-Tetren and DBQ-NaOH.

System TY
- Mobile phase: toluene–acetone (95 : 5).
- Reference compounds: thiophanate (hR_f 8), 2,4-D (hR_f 10), desmedipham (hR_f 22), captan (hR_f 42), tetramethrin (hR_f 52) and fenitrothion (hR_f 76).
- Location systems: $AgNO_3$ and $PdCl_2$.

System TZ
- Mobile phase: chloroform–acetone (9 : 1).
- Reference compounds: trichlorfon (hR_f 15), dimethoate (hR_f 37), propoxur (hR_f 66) and DDT (hR_f 90).
- Location systems: $AgNO_3$, RHB-NaOH, DBQ-NaOH and $PdCl_2$.

System TAA
- Mobile phase: chloroform.
- Reference compounds: methomyl (hR_f 9), dichlorvos (hR_f 36), chlorfenvinphos (hR_f 42), methoxychlor (hR_f 65) and fenvalerate (hR_f 75).
- Location system: Dragendorff-$FeCl_3$-I_3 in KI–HCl.

System TAB
- Mobile phase: dichloromethane.
- Reference compounds are any compounds examined in the TAB system from Table 16.1.

For location systems, see later.

System TAC
- Mobile phase: ethyl acetate–isooctane (15 : 85).
- Reference compounds are any compounds examined in the TAC system from Table 16.1.

For location systems, see later.

Location reagents for TAB and TAC Compounds are located with the DPA-$ZnCl_2$ reagent. A second spray system is as follows:
- Reagent A (fluorescein in dimethylformamide): dilute 1 mL of a 0.25% (w/v) solution of fluorescein in dimethylformamide to 50 mL with ethanol.
- Reagent B (silver nitrate and phenyl cellosolve): dissolve 1.7 g of silver nitrate in 5 mL of water and mix with 10 mL of phenyl cellosolve and 185 mL of acetone.
- To develop the colours, expose the developed plates to an atmosphere of bromine vapour for 1 min and then spray sequentially with reagents A and B. Yellow spots on a pink background appear which, after exposure to UV radiation, produce yellow spots on a black background.

Other spray reagents

The following reagents can provide additional confirmatory information.

Chlorine and *o*-toluidine Dissolve 1 g of *o*-toluidine in 10 mL of anhydrous acetic acid and 4 g of potassium iodide in 10 mL of distilled water. Mix the two solutions and dilute with distilled water to 1 L. To develop the colours, put the plate in a closed tank with chlorine gas (prepared by adding 2 mL of concentrated hydrochloric acid to 1 g of potassium permanganate) for 1 min. Remove excess chlorine from the plate under a stream of air in a fume cupboard. Dip the plate in the reagent for about 3 s. Yellow-orange spots appear against a white–blue background.

***N*,*N*-Dimethyl-*p*-phenylenediamine hydrochloride** Dissolve 0.1 g of *N*,*N*-dimethyl-*p*-phenylenediamine hydrochloride (MPA) in 10 mL of ethanol, and mix with 10 mL of sodium methoxide just before spraying. Spots develop against a grey–black background when the plate is irradiated with UV light at 366 nm for 10 min.

Ammonium molybdate with sodium antimony tartrate and ascorbic acid

- Reagent A (ammonium molybdate with sodium antimony tartrate): dissolve 10 g of ammonium molybdate in 40 mL of 2 mol/L H_2SO_4. Separately, dissolve 0.1 g of sodium antimony tartrate in 50 mL of 2 mol/L H_2SO_4. Mix both reagents and make up to 500 mL with the same acid.
- Reagent B (ascorbic acid): dissolve 2 g of ascorbic acid in 100 mL of water. This reagent can be used for 1 week if stored at 4°C.
- To locate any spots, remove the plate from the solvent chamber, air dry and heat for 2 h at 110°C. After cooling, lightly spray the plate first with reagent A and then with reagent B. The decomposition product of OP compounds (inorganic phosphate) reacts with ammonium molybdate and then phosphomolybdate is reduced to a blue complex by ascorbic acid (Murty *et al*. 1980).

Chromatographic data

The hR_f values for 167 pesticides in the TX, TY, TAB and TAC systems are listed in Table 16.1. Detection characteristics and limits of detection for chemical classes of pesticides with the spray reagents are given in Table 16.4.

Gas chromatography

Two GC systems are described. In both systems GC should be carried out with temperature programming and with an effluent splitter fitted to a dual flame ionisation–nitrogen-phosphorus detection (FID-NPD) system. Separation on the GA system (see below) can be carried out using packed or capillary columns, but for the GK system only packed columns are used. Nitrogen at a flow rate of 50 mL/min is used as a carrier gas. As reference substances, for calculation of the retention index (RI) of an unknown substance and for daily checking of the chromatographic performance, a mixture of *n*-alkanes with an even number of carbon atoms or other mixtures of typical drugs that cover a broad range of RI or retention time values should be used. One hundred nanograms of each substance in an aliquot of 1 µL of a reference mixture should be easily detectable by FID and 10 ng/µL of each using NPD. Peaks should be sharp and clearly separated (De Zeeuw *et al*. 1992a).

System GA

For packed columns

- Column: 3% SE-30 or 3% OV-1 on 80/100 mesh Chromosorb G HP.
- Temperature: 200–280°C.
- Reference compounds comprise 1 µL of methanolic solution of the following compounds (name, RI): barbital, 1489; pentobarbital, 1735; diphenhydramine, 1870; phenobarbital, 1953; methaqualone, 2135; codeine, 2375; morphine, 2445; nalorphine, 2572; quinine, 2800; haloperidol, 2930; strychnine, 3116.

For capillary columns

- Column: dimethylsilicone, fused silica, 10–15 m × 0.32 or 0.53 mm i.d., 1.5–3.0 µm.
- Temperature programme: 135°C for 4 min, to 200°C at 13°/min, to 240°C at 8°/min and to 312°C at 6°/min for 6 min.
- Reference compounds comprise 1 µL of ethyl acetate solution of each of the following compounds (name, RI): ethosuximide, 1205; ethinamate, 1365; barbital, 1489; aprobarbital, 1618; secobarbital, 1786; phenobarbital, 1953; heptabarbital, 2055; primidone, 2250; phenylbutazone, 2367; bis-(ethylhexyl)phthalate, 2507; prazepam, 2648.

System GK

- Column: 3% OV-17 on 80/100 mesh Gas Chrom Q, 1 m × 6 mm i.d.
- Temperature programme: 100°C to 260°C at 10°/min.
- Reference compounds comprise 1 µL of a solution of caffeine in ethyl acetate containing 1 mg/mL. Inject 1–5 µL of the sample extract, together with 1 µL of the caffeine solution.

Identification of pesticides

Gas chromatography–mass spectrometry

GC-MS is the recognised standard for systematic toxicological analysis and the GC-MS system described below is part of the most comprehensive GC-MS screening procedure for the detection of drugs and poisons, among which are pesticides (Pfleger *et al*. 2007). GC-MS systems are equipped with comprehensive libraries that contain reference spectra for many pesticides, their metabolites and decomposition products. The latest, most up-to-date library is the Wiley Registry, 8th edition/NIST 2008 which is a combination of the Wiley Registry of Mass Spectral Data and the NIST 2008 Library. The W8/N08 contains 562 000 EI spectra, 5308 precursor ions for MS-MS and, in addition, more than 2 million chemical names and synonyms, 350 000 searchable structures and 43 000 entries of GC retention indices. An integrated part of this library is the Automated Mass Spectrometry Deconvolution and Identification System (AMDIS) (http://eu.wiley.com). The most useful library for use in analytical toxicology is the Pfleger, Maurer and Weber library (3rd edn, 2007), which contains more than 7800 entries (Pfleger *et al*. 2007; Maurer 2006). Both of these libraries contain data for many pesticides, their metabolites and artefacts derived from different sources. For screening, the best GC-MS strategies are based on full-scan spectra in EI mode, reconstructed mass chromatography, and identification via library searches. Although evaluation of the data is greatly facilitated by the use macros, the final decision on the identity of a given compound

Table 16.4 Detection and limits of detection (µg) for chemical classes of pesticides with spray reagents

Spray reagent[a]	*Chemical class of pesticides*[b]							
	CB	*CH*	*CP*	*OP*	*PY*	*SU*	*TR*	*Misc.*
$AgNO_3$	5	2	5	2	5	5	5	±
RHB-NaOH	5	5	5	5	5	10	5	±
DPA-$ZnCl_2$	2	2	5	5	5	–	–	±
DBQ-NaOH	1	–	–	3	–	–	–	±
$PdCl_2$	–	–	–	1	–	–	+	±

[a]RHB-NaOH, rhodamine B with sodium hydroxide; DPA-$ZnCl_2$, 2,6 dibromoquinone-4-chloromide and sodium hydroxide; NBP-Tetren, 4-(4-nitrobenzyl)pyridine and tetraethylenepentamine; FDF-$AgNO_3$ + PC, fluorescein in dimethylformamide and silver nitrate with phenyl cellosolve; MPA, *N,N*-dimethyl-*p*-phenylenediamine hydrochloride; AMSA, ammonium molybdate with sodium antimony tartrate and ascorbic acid.
[b]+, positive; –, negative; ±, positive and negative; CB, carbamates; CH, chlorinated hydrocarbons; CP, chlorinated phenoxy acids; Misc., miscellaneous; OP, organophosphorus compounds; PY, pyrethroids; SU, substituted ureas; TR, triazines.

should always rest in the hands of the experienced toxicologist or analyst who undertakes a visual comparison between the EI full mass spectrum of the measured compound and the reference spectra and at the same time considers other chemical, analytical and toxicological evidence to support the identification. For forensic purposes ultimate identification should be performed by analysis of the analyte and the reference substance under the same analytical conditions. GC-MS methods can be used not only for simultaneous screening of pesticides and polychlorinated biphenyl compounds in biological samples, but also for solid environmental media (Liu, Pleil 2002).

System GC-MS

- Column: cross-linked methylsilicone capillary HP-1, 12 m × 0.2 mm i.d., 0.33 µm.
- Temperature programme: 100°C for 3 min to 310°C at 30°/min for 5 min.
- Injection port temperature, 270°C.
- Carrier gas: He, 1 mL/min.
- Ionisation mode, electron impact (EI).
- Ionisation energy, 70 eV.
- Ion source temperature, 200°C.
- Scan rate, 1 scan/min.
- Reference compounds comprise 1 µL of a methanolic solution containing 50 ng/mL of each of following compounds (name, RI): metamfepramone, 1355; acetylated amfetamine, 1505; pentobarbital, 1740; diphenhydramine, 1870; phenobarbital, 1935; methaqualone, 2155; codeine, 2375; morphine, 2455; nalorphine, 2620; quinine, 2800; haloperidol, 2940; strychnine, 3120; and the hydrocarbon C_{40}, 4000.

Analytical data The relative retention times for pesticides in the GK system (Fysh, Whitehouse 1986), the retention indices for the GA system (De Zeeuw *et al*. 1992a) and the GC-MS system (Pfleger *et al*. 2007), and the typical ions and their intensities are listed in Table 16.1. Despite different chromatographic conditions for the GA system with capillary column and the GC-MS system, in most cases the RI values do not differ by more than 50–60 RI units for the same pesticide.

No chromatographic conditions can ensure complete separation of all pesticides and therefore the possibility of peaks overlapping should be considered, even among the standards (Fig. 16.3).

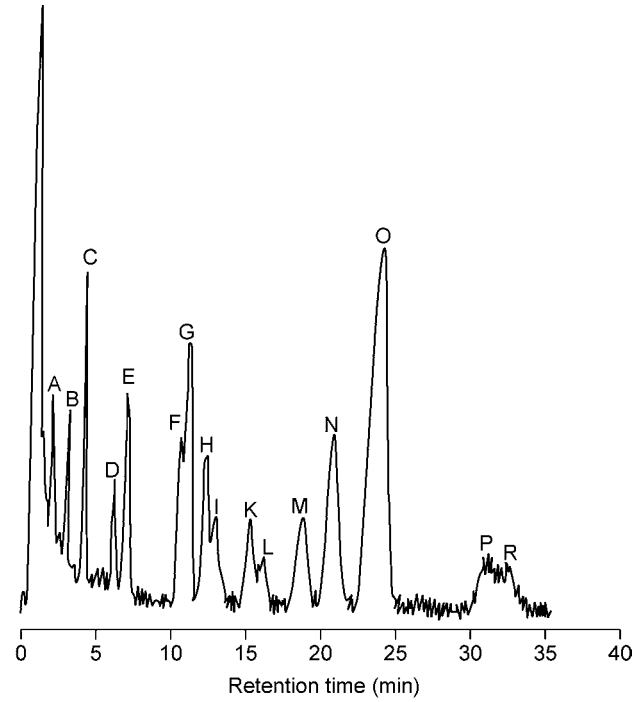

Figure 16.3 Gas chromatogram of some pesticides using an FID detector (column 10% SE-30 on Gas Chrom Q, column temperature 230°C). Relative retention times (RRTs) are given in parentheses: A, diuron (0.13); B, chloroneb (0.19); C, propachlor (0.27); D, hexachlorobenzene (0.40); E, diazinon + lindane + quintozene (0.45); F, fenchlorphos (0.69); G, fenitrothion + tetrachlorvinphos (0.72); H, fenthion (0.80); I, dicofol (0.85); K, captan (external standard, 1.00); L, chlorfenvinphos (1.05); M, α-chlordane (1.22); N, γ-chlordane (1.36); O, *pp′*-dichlorodiphenyldichloroethylene (DDE) + dieldrin (2.03); P, *op′*-dichlorodiphenyltrichlorethane (DDT); R, tetrasul (2.11). Reproduced with permission from Chłobowska *et al*. (1996).

High performance liquid chromatography

HPLC is less useful than GC for screening, since it tends to have less sensitivity and the retention times are not as reproducible. This technique can be used for those pesticides that are not stable at higher temperatures or are too polar for GC analysis. Several HPLC methods have been described, either for a specific pesticide (Meyer *et al*. 1998) or for a group of pesticides, e.g. dialkylphosphates, dialkylthiophosphates (Abu-Qare, Abou-Donia 2000, 2001; Aprea *et al*. 2002; Bardarov, Mitewa 1989). Spectrophotometric detection (UV or diode array detection [DAD]) is useful for aryl organophosphate esters, which show good UV absorption at higher wavelengths, whereas the corresponding alkyl derivatives have their absorption maxima below 250 nm. Fluorescence detection is suitable only for a few compounds that show natural fluorescence after alkaline hydrolysis, which can enhance fluorescence, and/or after derivatisation. Maximum native fluorescence intensity was observed at basic pH solutions for 3-indolyl acetic acid (Calatayud *et al*. 2006) and for asulam (Súbová *et al*. 2006). The effect of native cyclodextrins upon the UV-Vis and fluorescence properties of poorly fluorescent *N*-methyl carbamates such as bendiocarb and promecarb has been examined (Pacioni, Veglia 2007).

Five carbamate pesticides (aldicarb, carbaryl, 3-hydroxycarbofuran, carbofuran, methiocarb) were analysed by HPLC with fluorescence detection after *o*-phthalaldehyde derivatisation (King, Zhang 2002). Propoxur, carbofuran and carbaryl were coupled after alkaline hydrolysis with diazotised sulfanilic acid (Tena 1992). The application of *m*-periodate transgenic tobacco peroxidase, as a chemiluminescent label, and subsequent coupling to 2,4-dichlorophenoxyacetic acid (2,4-D) allowed determination of the conjugate by ELISA within the range 30 pg and 500 ng/mL (Dzgoev *et al*. 1999). Data for two HPLC systems are given in Table 16.1 and the chromatographic conditions are described below (Osselton, Snelling 1986).

System HAO

- Column: ODS-Hypersil, 160 × 5 mm stainless steel, 5 µm.
- Mobile phase: acetonitrile–water (60 : 40, v/v), 2 mL/min.

System HAP

- Column: Spherisorb S5W silica, 250 × 5 mm.
- Mobile phase: dichloromethane–isooctane (60 : 40, v/v), 2 mL/min.

Analytical data

In Table 16.1 retention data are expressed as capacity factors *k*, which are defined by $k' = (t_R - t_0)/t_0$, where t_R and t_0 are the retention times of the substance under investigation and a non-retained compound, respectively.

Liquid chromatography–mass spectrometry

HPLC has become a valuable technique for the screening, identification and/or multianalyte quantification of pesticides when coupled with single-stage or tandem mass spectrometry with electrospray ionisation (ESI) or atmospheric pressure chemical ionisation (APCI). The best LC-MS strategies for screening are based on tandem MS in multiple-reaction monitoring (MRM) mode. Only few LC or LC-MS(-MS) libraries have been developed so far because of the rather poor inter-apparatus reproducibility of ESI spectra. Therefore, before applying data from different sources, the apparatus should be standardised using certain test compounds. The ESI and APCI mass spectra library for identification of pesticides developed by Schreiber is commercially available (www.chemicalsoft.de.index-ms.htm). Another source of ion transitions from precursor to product ions for LC-MS(-MS) in SIR mode is the review by Alder *et al*. (2006). Complete acquisition parameter sets for positive

and negative electrospray, using an API 2000 mass spectrometer, in combination with single-quadrupole mass spectra and product ion scans are available from the Federal Institute for Risk Assessment in Berlin and can be downloaded from www.bfr.bund.de/cd/5832. These data are also available as a CD-ROM free of charge from the institute. All tuning parameters were also tested for a triple-quadrupole API 4000 apparatus. Tuning of other types of instruments may be assisted by product ion spectra, which were recorded at three fixed collision energies. The sensitivity of LC-MS(-MS) instruments was assessed by the injection of 20 μL of an analytical standard on a reversed-phase column (Phenomenex Aqua, 50 × 2 mm, 5 μm), using a gradient of methanol–water containing 5 mmol/L ammonium formate. Two ion transitions and collision energies obtained under the above-mentioned conditions have been added to the list of pesticides in Table 16.1.

Quantification of pesticides

Measurements of pesticide concentration in biological samples from acutely poisoned patients can have an immediate bearing on treatment, particularly when active elimination procedures, such as diuresis or haemodialysis, are contemplated. In fatal cases of suicidal or homicidal poisoning, it is easier to detect and identify pesticides by examining suspect materials, such as liquids, food, clothing and soil, in which the concentrations are likely to be quite high. Thereafter, if there is strong evidence that the substance detected may have been responsible for the death, quantitative examination of postmortem tissues may provide conclusive proof of poisoning.

Quantitative analyses also have an important role in monitoring pesticide concentrations in soil, water supplies, rivers, lakes and foodstuffs; in some countries, legislative control of permissible levels has been introduced. Their application is likely to increase with the growing public concern about the release of pesticides into the environment. GC-MS and LC-MS(-MS) are the techniques most commonly applied in multianalyte methods for pesticides at present. Many guidelines for quality assurance and method validation have been developed by individual scientists (Peters *et al.* 2007; Simonelli *et al.* 2007) and scientific organisations and several national and international proficiency testing schemes are now in operation. Numerous analytical procedures for the quantitative analysis of pesticides in various media are described in the National Institute for Occupational Safety and Health (NIOSH) *Pocket Guide to Chemical Hazards* (available on-line at www.cdc.gov/niosh/npg). Other publications have described original and sensitive GC-MS and LC-MS methods using standardised sample preparation procedures for the detection and quantification in human biological matrices of 61 pesticides of toxicological significance (Lacassie *et al.* 2001); a GC-negative chemical ionisation (NCI)-MS method for determining 37 organophosphorus pesticides in human tissues (Russo *et al.* 2002); and a multianalyte method for the quantification of 29 contemporary pesticides in human serum and plasma using isotope dilution gas chromatography–high-resolution mass spectrometry (Barr *et al.* 2002). More recently, validated methods for 229 pesticides in fruits and vegetables using GC-MS and LC-MS have been reported (Lehotay *et al.* 2005), and details of LC-MS(-MS) with MRM transitions for the determination of 660 pesticides in animal tissues have been published (Pang *et al.* 2006).

Both GC-MS- and LC-MS-based methods reveal a significant variation of sensitivity, covering a range of at least three to four orders of magnitude, depending on the pesticide. On the basis of review of the literature, it can be concluded that GC-MS achieves better performance only for one substance class, the organochlorine pesticides.

Capillary electrophoresis with titania-based columns has also been used to determine phosphorus-containing amino acid-type herbicides and their metabolites, e.g. glyphosate, aminomethylphosphonic acid, gluphosinate and 3-methylphosphonico-propionic acid, in human blood (Tetsuya *et al.* 2007).

Stability experiments for pesticides during the various stages of analysis (including storage prior to analysis) are essential. Ageda *et al.* (2006) studied the effect of temperature on the stability of 14 organophosphorus insecticides in fresh blood. Short- and long-term stability studies have been carried out for various chemical classes of pesticides by Simonelli *et al.* (2007). Moriya *et al.* (1999) found that the addition of sodium fluoride to blood samples caused the complete degradation of dichlorvos within 15 min and that chlorpyrifos-methyl also became very unstable. Organophosphates are degraded more rapidly by esterase activity than by chemical mechanisms, whereas organophosphorothioates are hydrolysed chemically in aqueous solutions but are very stable in biological specimens and not affected by esters.

Specific pesticides

Organophosphorus compounds

Organophosphorus compounds are by far the most important class of pesticides, in terms of both worldwide usage and their toxicity to humans. They act by the irreversible inhibition of cholinesterases, which are responsible for hydrolysing, and thereby deactivating, the neurotransmitter acetylcholine (ACh). Build-up of ACh at the neural junction leaves the muscles, glands and nerves in a constant state of stimulation, which produces a wide range of acute symptoms. These include dizziness, confusion and blurred vision, excessive salivation and sweating, nausea and vomiting, and muscular weakness. Severe poisoning leads to coma, flaccid paralysis, breathing difficulties, cyanosis and cardiac arrhythmias. Atropine and pralidoxime are effective antidotes in severe cases. In acute clinical poisoning, diagnostic tests for depressed cholinesterase activity are the most crucial. Detecting, identifying and quantifying the particular agent responsible has less bearing on immediate treatment, although some of the lipophilic diethyl phosphothiolates can be sequestered in the tissues for several days and patients who appear to have recovered may suffer a recurrence of toxic effects. Identification of the agent involved can alert clinicians to this possibility.

Quantification of cholinesterase activity in plasma or serum and whole blood Two types of cholinesterases exist in the body. Acetylcholinesterase (AChE), which is also known as true cholinesterase, is found in red cells, nerve endings, lungs and brain tissues. Its main function is to hydrolyse ACh at cholinergic nerve endings. The second type is usually known as pseudocholinesterase (ChE) and occurs in the plasma in addition to other body tissues. The exact physiological function of ChE is unknown, but it has the ability to hydrolyse a variety of esters in addition to cholinesterase. Depression of ChE can also be caused by non-pesticide chemicals, liver diseases and other factors (physiological, pharmacological or genetic). Measurement of red-cell AChE is therefore a more specific indicator of cholinesterase inhibition caused by OP or carbamate pesticides. Moreover, the depression of red-cell AChE activity can be demonstrated for up to 2–6 weeks after exposure, whereas that of plasma ChE returns to normal much more quickly. Nevertheless, in practice, plasma ChE activity is a useful indicator of exposure, since normal values effectively exclude acute poisoning by these substances.

Some carbamate herbicides and fungicides, such as the dithiocarbamates, do not inhibit cholinesterases to any significant degree and are relatively non-toxic in humans. Postmortem specimens for AChE assay must be kept in cold storage and analysed as soon as possible to minimise the effects of spontaneous reactivation of the enzyme (Geldmacher-v.Mallinckrodt *et al.* 1974).

It must be emphasised that the normal ranges for AChE activity are highly dependent on the type of assay system used and wide variations exist.

Determination of plasma or serum cholinesterase activity Adjust the temperature of 3 mL of 0.02% (w/v) dithiobisnitrobenzoic acid in 0.1 mol/L sodium dihydrogen phosphate buffer solution (pH 7.4) to 25°C; add 20 μL of sample serum and 0.1 mL of 5% (w/v) acetylthiocholine iodide solution, mix well, and record the absorbance of a 1 cm thickness at 405 nm at 0.5 min intervals for 2 min. If the change in absorbance value exceeds 0.2 when developing within 30 s, dilute the sample (one in ten) with normal saline and repeat the measurements (the readings must then be multiplied by 10). The cholinesterase activity is calculated as:

$$\text{Cholinesterase (munits/mL or mU/mL, at 25°C)} = \text{change in absorbance in 30 s} \times 23\,400$$

Normal values of ChE activity in serum range from 1900 mU/mL to 4000 mU/mL. Commercial kits for the determination of ChE activity in plasma and serum are available (Sigma Chemical Co., St Louis, MO, USA; Biotron Diagnostics, Inc., Hemet, CA, USA; Lovibond, Tintometer GmbH, Dortmund, Germany; Dade Behring, Paris).

Determination of whole-blood acetylcholinesterase activity The reagents for this are (Fleisher, Pope 1954):

1. Phosphate buffer (0.134 mol/L, pH 7.2), prepared by mixing 7 parts by volume of a solution of 23.752 g of $Na_2HPO_4{\cdot}2H_2O$ per litre and three parts of a solution of 18.156 g of KH_2PO_4 per litre; pH adjusted to 7.2 if necessary.
2. ACh (0.04 mol/L), prepared by dissolving 0.7266 g of acetylcholine chloride in 100 mL of 0.001 mol/L acetate buffer (pH 4.5); stable indefinitely in the cold.
3. ACh (0.004 mol/L), prepared by diluting Solution 2 with 9 volumes of phosphate buffer (Solution 1); made daily in the quantity required for the analyses.
4. Hydroxylamine hydrochloride (2 mol/L), made by dissolving 27.8 g in water to 200 mL.
5. NaOH (3.5 mol/L), made by dissolving 28 g in water to 200 mL.
6. Alkaline hydroxylamine prepared from equal volumes of Solutions 4 and 5, mixed shortly before use in a quantity required for the samples being analysed, and made up freshly for each set of samples analysed.
7. HCl (concentrated acid, specific gravity 1.18), diluted with 2 volumes of water.
8. Ferric chloride ($FeCl_3$, 0.37 mol/L), made with 10 g of $FeCl_3{\cdot}6H_2O$ dissolved in 100 mL of 0.1 mol/L HCl.

Prepare three test tubes. To the first tube (E), add 0.95 mL of 0.01% (v/v) saponin solution, 50 µL of heparinised blood sample and then 1 mL of 0.004 mol/L ACh; mix well and incubate at 25°C for 10 min. For the control, 1 mL of 0.004 mol/L ACh solution is incubated in a second tube (C) alongside the experimental sample. After exactly 10 min the reaction is stopped by the addition of 4 mL of alkaline hydroxylamine reagent (with vigorous shaking) to both experimental and control samples. After a wait of at least 1 min, 0.95 mL of saponin and 50 µL of blood sample are added to the control solution of ACh. Then 2 mL of HCl reagent is added to each sample, followed by 2 mL of $FeCl_3$ reagent, with mixing after each addition. The solutions are filtered through Whatman filter paper, and the absorbance of a 1 cm layer at 520 nm is recorded 10 min after the addition of the $FeCl_3$. The absorbance (A_E, in mmol/L) is measured against a reagent mixture that consists of 4 mL of alkaline hydroxylamine, 2 mL of HCl and 2 mL of $FeCl_3$ reagent. The measured value of absorbance of the control sample (A_C) should be in the range 0.3–0.4. The activity of AChE in blood is calculated as follows:

$$4 - (4A_E/A_C) \times 2000$$

= AChE activity in international units per millilitre (IU/mL)

The precision of the method is 210 IU/mL.

Normal values for AChE activity in whole blood range from 3500 IU/mL to 8000 IU/mL. Commercial kits for the determination of AChE activity in red blood cells, whole blood and plasma are available (EQM Research, Inc., Cincinnati, OH, USA).

Determination of organophosphates in urine Most compounds of this chemical class are hydrolysed rapidly by plasma and tissue enzymes with the production of many metabolites. Metabolites and their conjugates are excreted in urine and are known to be unstable in stored specimens. To derive data that accurately represent the true degree of exposure, as indicated by the concentration of OP compounds, it is essential to obtain and analyse samples as soon as possible after an incident. Urine samples should be analysed within a week of obtaining the sample and kept at −20°C prior to analysis (Comer *et al.* 1976).

Colorimetric procedure In the colorimetric procedure (Namera *et al.* 2000), to 1 mL of urine (pH 5–8) add 0.1 mL of 45% (w/v) of 4-(4-nitrobenzyl)pyridine (NBP) solution in acetone, vortex for 30 s and heat at 100°C on a heating block for 20 min. After cooling to room temperature, add 0.1 mL of Tetren and 1 mL of diethyl ether, then close the tube and vortex mix for 3 min. Measure the absorbance of the ethereal layer at 520 nm against a reagent mixture. Construct a calibration graph for the analysis of the standard OP compound solutions and calculate the concentration in the sample. The limits of detection range from 0.1 mg/L to 3.0 mg/L for 24 OP compounds and 10 mg/L for acephate, isofenphos and vamidothion.

Chromatographic analysis ?A3B2 twb=.28w?>The OP compounds can be analysed without prior derivatisation. Screening for these compounds by GC is assisted greatly by a dual FID–NPD system. Detection by NPD gives a 10-fold increase in sensitivity for phosphorus-containing compounds compared with those detected using nitrogen only. This is very important because many OP pesticides are highly toxic and their concentrations in biological samples are low. Mass fragmentation of these compounds to typical ions (which vary widely in intensity) allows the chemical class to be determined. Molecular ions of OP compounds can be monitored using the thermospray LC-MS technique (Niessen 1999). Both protonated and ammoniated molecules are detected in the positive-ion mode without any fragmentation. Phosphates and phosphorodithioates appear to give a better response than other chemical classes. Phosphorothioates with chlorine, bromine or nitrate substitution on the ring are especially intense. The thermospray mass spectra obtained by operating in the negative-ion mode are more compound dependent.

Human exposure to OP pesticides is often assessed by measuring general dialkyl phosphate metabolites of OPs in urine. Six common urinary dialkyl metabolites can be quantified by GC-MS to confirm cumulative exposure to OP pesticides (De Alwis *et al.* 2006).

An experiment on animals demonstrated the possibility of using hair analysis by GC-NCI-MS for monitoring low-level exposure to diazinon (Tutudaki, Tsatsakis 2005). Hair was also shown to be a promising material by documenting non-fatal intoxication in two men, one exposed to alachlor a year before sampling and the other exposed to carbofuran 14 days before sampling. The concentrations of alachlor in five analysed hair segments were between 12 and 136 pg/mg. Carbofuran and its main metabolite (3-hydroxycarbofuran) were detected in the hair strand (global analysis) at concentrations of 207 and 164 pg/mg, respectively (Dulaurent *et al.* 2008).

Blood and tissue levels Pre-treatment plasma concentrations (mg/L) in cases of non-fatal organophosphate poisoning are summarised below (Kłys *et al.* 1989, 1991, 1992).

Chlorphenvinphos	Fenitrothion	Phosalone
n = 20	*n* = 15	*n* = 16
0.1–10.6	0.096–0.35	0.005–0.39

Many studies have been carried out on the distribution of organophosphate in cases of fatal poisoning with this group of pesticides. Their concentrations (mg/L or mg/kg) in various body fluids and tissues can help to determine the specimens of choice in postmortem toxicological analysis. The following data have been reported:

For chlorphenvinphos (Kłys *et al.* 1989):

Blood	Liver	Kidney	Lung	Brain
n = 7	*n* = 7	*n* = 5	*n* = 7	*n* = 6
0.30–15.0	0.32–15.94	0.16–15.0	0.80–15.94	0.1–4.3

For fenitrothion (Kłys *et al.* 1992):

Blood	Liver	Kidney	Brain
n = 6	*n* = 5	*n* = 2	*n* = 5
1.9–14.8	0.8–11.5	3.9–4.5	0.04–1.15

Values reported in single cases are given below.
For dimethoate (Tarbah *et al.* 2007):

Blood	Urine	Brain	Liver	Lung	Myocardial muscle	Skeletal muscle	Kidney	Gall bladder	Stomach contents
38	0.47	2.2	4.6	7.6	7.6	21	55	31	104

In this case the blood alcohol concentration was 2.85 g/L and the blood was also positive for cyclohexanone and cyclohexanol, a mixture used as a vehicle in the commercial product.

For omethoate (Pavlic *et al.* 2002):

Cardiac blood	Urine	Bile	Liver	Kidney	Stomach contents
208	225	524	341	505	48 223

For dichlorvos (Moriya *et al.* 1999):

Thoracic aorta blood	Thoracic inferior vena cava blood	Cerebro-spinal fluid	Peri-cardial fluid	Vitreous humour	Bile	Spleen	Stomach contents
0.043	0.082	0.027	0.438	0.067	8.99	0.542	2929

In this case no dichlorvos was detected in blood from the left and right cardiac chambers, the pulmonary arteries and veins or the right femoral vein. Dichlovos was also absent from the urine, cerebrum, lung, kidney and right femoral muscle.

For chlorpyrifos-methyl (Moriya *et al.* 1999):

Blood						
Left cardiac chambers	Right cardiac chambers	Pulmonary arteries	Pulmonary veins	Thoracic aorta	Thoracic inferior vena cava	Right femoral vein
1.01	1.71	4.15	2.83	0.99	2.24	0.62
Cerebrospinal fluid	Pericardial fluid	Vitreous humour	Lung left hilus	Myocardium	Right kidney	Right femoral muscle
0.01	0.01	0.01	8.60	0.49	0.47	0.39
Liver deep right lobe	Spleen	Cerebrum	Stomach contents	Bile	Urine	
1.41	0.666	0.38	2041	ND	ND	

ND – not detected.

Concentrations of other OP compound in postmortem blood have also been reported:

Compound	Concentration (mg/L)	Reference
Chlorpyrifos	0.21–2.05 ($n = 6$)	(Park *et al.* 2009)
Diazinon	0.24–2.82 ($n = 4$)	(Park *et al.* 2009)
Diazinon	0.4–277 ($n = 3$)	(Poklis *et al.* 1980)
Malathion	0.35–1.32 ($n = 4$)	(Park *et al.* 2009)
Malathion	175–517 ($n = 6$)	(Jadhav *et al.* 1992)
Parathion	0.21–19.64 ($n = 17$)	(Park *et al.* 2009)
Phosalone	0.024–0.19 ($n = 3$)	(Kłys *et al.* 1991)

Carbamates

Analysis These compounds can be divided into various subclasses, characterised by their different thermal stabilities. *N*-Methylcarbamates give thermal decomposition products, mainly substituted phenols. The molecular ions that arise from these products are more abundant in mass spectra. The compounds from other subclasses are more thermally stable. The molecular ions are of low intensity, but together with diagnostic fragments they enable identification to be made. In LC-MS methods, the carbamates do not present a serious problem. Positive ion detection with a soft ionisation technique is the method of choice (Niessen 1999). Some compounds, e.g. carbofuran and promecarb, can be determined by a chemiluminescence method (on-line conversion into methylamine by irradiation with UV light, and then reaction with tris(2,2′-bipyridine)ruthenium(III), which was generated through the on-line photooxidation of tris-2,2′-bipyridineruthenium(II) with peroxydisulfate) (Perez-Ruiz *et al.* 2002).

Toxicity Carbamate pesticides have a similar action to that of the OP compounds in causing a decrease in cholinesterase activity, but the binding to the active site of the cholinesterase enzyme is reversible. Consequently, although the symptoms are practically identical to those of organophosphorus poisoning, they have a shorter duration.

Blood and tissue levels Blood carbofurane concentrations in 15 non-fatally poisoned patients ranged from 0.15 to 2.78 mg/L, and in seven fatal cases concentration ranges were as follows (Kłys, Bialka 1990):

Blood	Liver	Kidney
0.31–3.90	0.09–9.34	0.54–6.29

In a case of oral ingestion of thiodicarb (which is unstable under acidic condition and rapidly hydrolysed to methomyl), the parent compound was detected only in gastric contents at a concentration of 24.3 mg/L. In all other fluids and tissues, various concentrations of methomyl – its metabolite – were detected. Methomyl concentrations (mg/L or mg/kg) were as follows (Hoizey *et al.* 2008):

Stomach contents	Peripheral blood	Urine	Bile	Liver	Kidney	Lung	Brain	Heart
19.9	0.7	8.5	2.7	0,7	1.7	1.5	9.3	3.6

Traces of methomyl were also detected in vitreous humour. Moreover, blood concentrations (mg/L) of zolpidem (2.87), bromazepam (2.39), nordazepam (4.21) and levopromazine (0.64) were above their common therapeutic ranges. In contrast to this case, blood and liver methomyl concentrations following methomyl ingestion in several published fatal case reports varied between 0.003 and 63.5 mg/L, and between 'not detectable' and 1.2 mg/kg, respectively (Hoizey *et al.* 2008). Blood methomyl levels in nine fatal cases ranged from 8 mg/L to 56 mg/L (Baselt 2004, pp. 700–701).

Blood methomyl concentrations (mg/L) in a case reported by Moriya and Hashimoto (1999) were site-dependent as shown below:

Blood						
Left cardiac chambers	Right cardiac chambers	Pulmonary arteries	Pulmonary veins	Thoracic aorta	Thoracic inferior vena cava	Right femoral vein
4.89	1.08	4.75	4.09	7.00	0.56	3.91

ND, not detected.

In three cases involving fatal ingestion of carbaryl, concentration ranges in blood and urine (mg/L) and tissues(mg/kg) were as follows (Baselt 2004, pp. 167–169):

Blood	Liver	Kidney	Brain	Urine
6–27	12–29	1.9–25	4.6	31

In a lethal poisoning with ethiofencarb and ethanol, concentrations of the parent carbamate compound and its two major metabolites (mg/L) in antemortem (taken on admission to hospital) and postmortem biological fluids (death occurred 3 h after admission, samples were taken at autopsy 2 days after death) were measured with the following results (Al Samarraie *et al.* 2009):

	Antemortem blood	Postmortem peripheral blood	Postmortem urine
Ethiofencarb (mg/L)	18.8	26.4	1.7
Ethiofencarb sulfoxide (mg/L)	25.6	37.9	41.2
Ethiofencarb sulfone (mg/L)	0.5	0.9	0.4
Ethanol (g/kg)	Not analysed	1.2	2.6

Chlorinated hydrocarbons

Analysis The chlorinated hydrocarbons chemical class of pesticides may be analysed intact using chromatography with a dual FID-NPD detection system, but greater sensitivity can be achieved using an ECD. Among hyphenated techniques, GC-MS is the method of choice for this class of pesticide. The methods applied in clinical and forensic cases do not need to be highly sensitive because most compounds that belong to this class are only slightly toxic and severe symptoms of poisoning are observed only after ingestion of large quantities (several grams). Moreover, the symptoms often result from the solvents in which the chlorinated hydrocarbons are formulated. Useful references for the determination of chlorinated hydrocarbons in human or avian serum are Brock *et al.* (1996) and Sundberg *et al.* (2006) using GC after SPE, and López *et al.* (2007) using GC-MS or GC-ECD.

Toxicity Chlorinated hydrocarbons are neurotoxins that also damage the liver and kidneys. Major clinical features of poisoning are headache, disorientation, paraesthesia and convulsions.

Blood and tissue levels A blood lindane concentration of 0.13 mg/L was measured in a patient who developed seizures after ingesting about 250 mg (Burton *et al.* 1991). An adult male who ingested 57 g of 1% lindane lotion and became comatose had a blood lindane concentration of 1.3 mg/L on the first day of admission to hospital and died 7 days later with a postmortem blood concentration of 0.02 mg/L (Kurt *et al.* 1986).

In a fatal case of endosulfan poisoning in a woman, the blood endosulfan concentration was 30 mg/L (Bernardelli, Gennari 1987).

In a case of endrin suicide poisoning, its concentrations (mg/L or mg/kg) in different postmortem materials were as follows (Moriya, Hashimoto 1999):

Blood					
Left cardiac chambers	Right cardiac chambers	Thoracic aorta	Thoracic inferior vena cava	Right femoral vein	Kidney
0.615	0.568	0.542	0.453	0.353	ND
Cerebrospinal fluid	Pericardial fluid	Vitreous humour	Lung left hilus	Lung right hilus	Myocardium
0.515	1.00	1.67	6.20	1.19	0.467
Liver deep right lobe	Urine	Cerebrum	Stomach contents	Bile	Right femoral muscle
13.8	ND	1.93	1100	2.06	2.08

ND, not detected.

Pyrethrins and pyrethroids

Analysis The term 'pyrethrins' is used collectively for the six insecticidal constituents present in extracts of the flowers of *Pyrethrum cinerariaefolium* and other species. Pyrethrins comprise esters of the natural stereoisomers of chrysanthemic acid (pyrethrin I, cinerin I and jasmolin I) and the corresponding esters of pyrethric acid (pyrethrin II, cinerin II and jasmolin II). Their low photochemical stability leads to synthetic analogues (pyrethroids), which are highly toxic to insects. In recent years pyrethroids have been manufactured and used in large quantities. These contain no nitrogen and therefore both GC-FID and GC-MS are appropriate detection systems. The compounds can be analysed easily by chromatography, either without derivatisation or after methylation (Bissacot, Vassilieff 1997; Cherstniakova *et al.* 2006; Fernández-Gutiérrez *et al.* 1998).

Toxicity Pyrethrins and pyrethroids have relatively low toxicity to humans, but exposure to these compounds by inhalation can cause localised reactions to the upper and lower respiratory tract, which leads to oral and laryngeal oedema, coughing, shortness of breath and chest pain. In acutely exposed sensitised patients a serious asthmatic-type reaction can be triggered that can prove fatal within a few minutes.

Nitrophenols and nitrocreosols

Analysis Dinitro-*o*-creosol (DNOC) can be measured in blood specimens by colorimetry (Smith *et al.* 1978).

Toxicity Dinitrophenol, dinitro-*o*-creosol and dinoseb stimulate oxidative metabolism in the mitochondria and cause profuse sweating, headache, tachycardia and fever.

Blood levels Blood and urine measurements are useful as an aid to diagnosis and treatment. Symptoms of headache and malaise are noted with DNOC blood concentrations of around 40 mg/L and serious intoxication has been observed in workers with concentrations of 44–60 mg/L (Bidstrup *et al.* 1952). In a fatal case, the postmortem blood concentration was 75 mg/L (Bidstrup *et al.* 1952). In two deaths attributed to the

use of dinitrophenol, its concentrations in blood were 28 and 36.1 mg/L (Miranda *et al.* 2006). In another case involving ingestion of dinitrophenol together with medicinal drugs, the postmortem blood contained 48.4 mg/L of dinitrophenol, 1.2 mg/L of 2-amino-4-nitrophenol, citalopram and its desmethylated metabolite (in toxic concentrations), and olanzapine, desalkylflunitrazepam and nordiazepam (in therapeutic or subtherapeutic concentrations) (Politi *et al.* 2007).

Chlorinated phenoxy acids

Analysis Substituted phenoxy acids occur in commercial products as salts or esters. Conversion of salts by extraction and derivatisation to the corresponding methyl esters improves their chromatographic properties. The presence of isooctyl (2,2,4-trimethylpentyl) esters of chlorinated phenoxy acid herbicides can be indicated using mass chromatography with ions of *m/z* 41, 55, 57, 69, 71 and 85, as well as high-mass ions of significant intensity (Fysh, Whitehouse 1986).

Toxicity Chlorinated phenoxy acids are corrosive chemicals that damage the skin, eyes, and respiratory and gastrointestinal tracts. Ingestion of large doses causes vomiting, abdominal pain, diarrhoea, metabolic acidosis, pulmonary oedema and coma. Some herbicide preparations of 2,4-dichlorophenoxyacetic acid (2,4-D) and 2,4,5-trichlorophenoxyacetic acid (2,4,5-T) have been shown to contain a contaminant, dioxin (2,3,7,8-tetrachlorodibenzodioxin), which is a potent teratogenic agent. Alkalinisation of the urine to increase the excretion of 2,4-D and other chlorophenoxy compounds after poisoning has proved an effective therapy.

Blood and tissue levels A patient who survived after taking 7 g of 2,4-D had an initial plasma concentration of 400 mg/L (Park *et al.* 1977). In another non-fatal case, a maximum 2,4-D plasma level of 1031 mg/L was recorded (Rivers *et al.* 1970). In five fatal cases, blood 2,4-D concentrations have ranged from 58 mg/L to 826 mg/L (Baselt 2004, pp. 323–325). A patient who died 30 h after taking a mixture of 2-(2-methyl-4-chlorophenoxy)propionic acid (MCPP; 44 g), 2,4-D (39 g) and chlorpyrifos had blood concentrations of 389 µg/g MCPP and 325 µg/g 2,4-D. Postmortem tissue concentrations were also reported (Osterloh *et al.* 1983).

Ingestion of 4-chloro-2-(methylphenoxy)acetic acid (MCPA) led to the following concentrations of MCPA and its metabolite, *p*-chloro-*o*-cresol (mg/L or mg/kg) in postmortem materials (Takayasu *et al.* 2008):

	Heart blood	Peripheral blood	Urine	Brain	Left lung	Right lung	Liver	Left kidney	Right kidney	Stomach contents
MCPA	888.3	578.1	52.2	770.9	2864	1 362	1 135	867.1	755.5	10 200
p-Chloro-*o*-cresol	2.16	1.92	0.24	1.64	9.06	7.41	10.36	5.56	4.85	16.45

Triazines

Analysis Triazines contain several nitrogen atoms and show enhanced NPD and FID ratios. Most triazines, which are readily amenable to GC-MS, exhibit highly characteristic mass spectra of the parent compounds and yield the important degradation products hydroxy- and desalkyl triazines. By using LC-MS with APCI and ESI, and optimising the in-source parameters, the protonated triazine molecule can be seen without fragmentation (Niessen 1999). Quantification of atrazine metabolites, e.g. atrazine mercapturate, desethyl and desisopropyl atrazine, as markers of atrazine exposure, in urine has been achieved using isotope-dilution calibration of an LC-MS(-MS) method (Nguyen *et al.* 2007).

Toxicity Ingestion of about 100 g of atrazine can lead to coma, circulatory collapse, metabolic acidosis and gastric bleeding. This may be followed by renal failure, hepatic necrosis and a disseminated intravascular coagulopathy that may prove fatal. Haemodialysis is recommended for severe cases.

Blood levels An adult died 3 days after taking approximately 100 g of atrazine together with ethylene glycol and formaldehyde; 1 h after ingestion the plasma concentration was 2 mg/L (Pommery *et al.* 1993).

Quaternary ammonium compounds

Analysis Paraquat and diquat are not extractable by conventional LLE. A recently published comparison study of different extraction procedures showed that a chloroform–ethanol 7 : 3 (v/v) solvent mixture was the most effective extraction solvent (Baeck *et al.* 2007). The diene or monoene reduction products of paraquat and diquat produced by sodium borohydride can be extracted by diethyl ether from alkaline solution for chromatography (Draffan *et al.* 1977). Very limited data are available for the mass spectral characterisation of these compounds (de Almeida, Yonamine 2007). Colorimetric determination of paraquat and diquat after reduction with sodium dithionite under alkaline conditions is probably the most widely used technique. Both of the bipyridylium reduction products have absorbance maxima at 396 and 379 nm. Using an ion-pairing extraction technique, a lower limit of measurement of 50 µg/L can be achieved (Jarvie, Stewart 1979). However, it is not possible to include an internal standard in this method. Radioimmunoassay (Fatori, Hunter 1980) and fluorescence polarisation immunoassay (Colbert, Coxon 1988) methods for the determination of paraquat in serum are very sensitive and require only small sample volumes, but they are not widely available. Paraquat can also be determined in serum by HPLC-UV after extraction onto a disposable cartridge of end-capped octadecyl silica (Fig. 16.4) (Croes *et al.* 1993) down to a concentration of 25 µg/L. Diquat may be analysed in biological specimens by most of the procedures described for paraquat. Specific HPLC procedures for paraquat and/or diquat have also been described (Ameno *et al.* 1995; Arys *et al.* 2000; Hara *et al.* 2007).

Difenzoquat, diquat and paraquat can be quantified in human whole blood in addition to other quaternary ammonium compounds by LC-MS(-MS) with positive ESI following SPE and ion-pair chromatography (Ariffin, Anderson 2006).

Toxicity Ingestion of concentrated paraquat formulations causes burning of the mouth, oesophagus and stomach, and after massive absorption patients die of multiple organ failure. Absorption of smaller amounts can lead to renal damage followed by a progressive pulmonary fibrosis that causes death from respiratory failure, in some cases after 2–3 weeks of ingestion. Treatments to reduce absorption or increase elimination have not been effective. A strongly positive urine test with the dithionite test in a sample collected more than 4 h after ingestion indicates a poor prognosis. Measurement of the plasma paraquat concentration is a more accurate prognostic guide. Diquat is also an irritant poison that causes vomiting, diarrhoea and epigastric pain. In severe cases, liver and renal failure, convulsions and coma may ensue, but diquat ingestion does not lead to progressive pulmonary fibrosis.

Blood levels A fatal outcome is usually associated with plasma paraquat concentrations greater than 0.2 mg/L at 24 h after ingestion and 0.1 mg/L at 48 h after ingestion (Scherrman *et al.* 1983). In a fatal case of accidental paraquat poisoning a blood concentration of 0.64 mg/L of paraquat was reported (Ariffin, Anderson 2006). In fatal cases of diquat poisoning, plasma diquat concentrations ranging from 0.45 mg/L to 4.5 mg/L have been recorded (Vanholder *et al.* 1981).

Phosphides

Analysis The ammonium molybdate test and commercially available detector tubes (Guale *et al.* 1994) may be used as qualitative and quantitative procedures for stomach contents and non-biological materials. Phosphine can also be determined in biological samples using GC and NPD detection (Chan *et al.* 1983; Musshoff *et al.* 2008).

Toxicity Hydrogen phosphide is widely used as an insecticide and rodenticide (agricultural fumigant) and is usually generated by the action of water on metallic phosphides (aluminium, magnesium or zinc). Inhaled

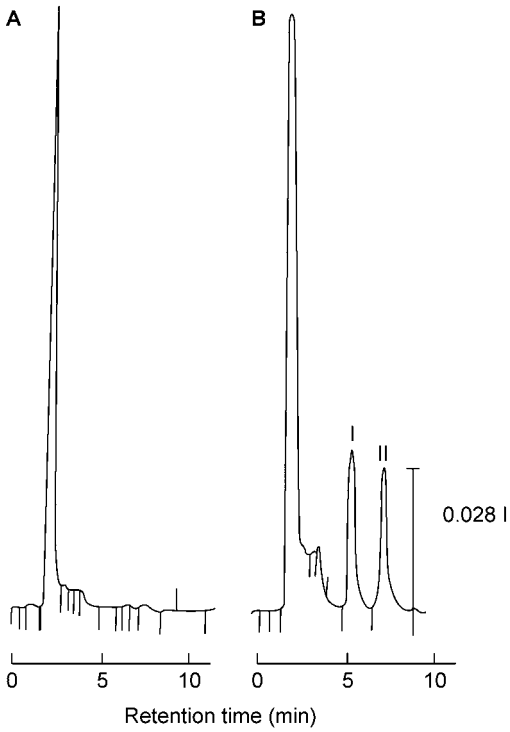

Figure 16.4 HPLC chromatograms of extracted human serum with UV detector (Microspher C18 column, λ = 258 nm). A, blank serum; B, spiked serum sample with (I) 500 µg/L paraquat, RRT 0.75, and (II) 2500 µg/L 1,1-diethyl-4,4′-bipyridyl chloride (internal standard), RRT 1.00. Reproduced with permission from Croes *et al*. (1993).

phosphine is readily absorbed by the lungs. Following the ingestion of metallic phosphides, phosphine is generated in the stomach and the gas acts on the gastrointestinal and central nervous systems. In severe cases abdominal pain, vomiting, convulsions and coma develop rapidly and death usually ensues within 2 h.

Blood and tissue levels Postmortem blood in a man who ingested an unknown number of aluminium phosphide tablets contained 0.5 µg/L of phosphine. The tissue phosphine concentrations were 3 µg/kg in liver and 3000 µg/kg in stomach contents (Chan *et al.* 1983). In another case after accidental ingestion of novel rodenticide pills also containing aluminium phosphide, the following phosphine concentrations (mg/kg) were found:

Stomach contents	Nose smear	Small intestine
0.2	0.56	0.28

Urine, femoral and heart blood, liver, kidney, bile and brain samples tested negative (Musshoff *et al.* 2008).

Thallium

Analysis Several convenient colorimetric methods can be applied to determine thallium in urine, stomach contents and suspect preparations. One of these methods (Flanagan *et al.* 1995) is based on measuring the absorbance of a chloroform-extractable pink–red thallium–dithizone complex from an alkaline solution that contains potassium, sodium and cyanide ions to mask interference from other metal ions. It indicates the presence of thallium in urine at concentrations of 1 g/L or more. However, the method is not specific and atomic absorption spectrophotometry is a much more reliable technique (see Chapter 43).

Toxicity Poisoning with thallium salts leads to delayed damage to the peripheral and central nervous systems. The cardiorespiratory system is also affected. Loss of body hair 1–2 weeks after ingestion is a characteristic sign of thallium poisoning. The most reliable diagnostic procedure is a quantitative thallium determination in serum and/or urine. Treatment with potassium ferrohexacyanoferrate (Prussian or Berlin blue) to absorb thallium re-circulated in the bile is effective if instituted early enough; serum and urine thallium measurements are useful in monitoring the progress of the therapy.

Blood levels Blood thallium concentrations in fatal cases of poisoning have ranged from 0.5 mg/L to 11 mg/L (Baselt 2004, p. 1092). The following tissue concentrations (mg/kg) of thallium were determined in three people who died after ingestion of this poison (Sadlik 1997):

	Woman, age 63	Man, age 58	Boy, age 17
Liver	81.0	59.2	12.1
Kidney	62.5	38.5	11.8

In a 15-year-old boy who survived the intentional ingestion of thallium sulfate, blood and urine concentrations (mg/L) examined during treatment were as follows (Lech, Sadlik 2007):

	Day 14	Day 24	Day 31
Blood	0.88	0.44	0.36
Urine	2.35	3.35	5.00

Uracils

Analysis Uracils are pyrimidine herbicides that can be analysed intact and also after derivatisation. HPLC with UV detection is a good technique for confirmation (Lawrence, Turton 1978). Quantities of 200 ng or 20–50 ng of these compounds at 254 nm or 270–280 nm, respectively, give a response equivalent to 0.01 absorbance units (Lawrence, Turton 1978). The use of HPLC and atmospheric pressure ionisation (API, both ESI and APCI) MS in positive- and negative-ion mode for qualitative analysis of uracils (e.g. bromacil) has also been published (Schreiber *et al.* 2000).

Toxicity No serious cases of human poisoning with these compounds have been reported.

Substituted ureas

Analysis These herbicides, especially phenyl- and sulfonylureas, contain nitrogen and respond to both FID and NPD. They are very thermolabile and cannot be derivatised readily. Analysis by GC is complicated, as it is impossible to avoid the formation of their numerous decomposition products because of the high injection port temperature. To reduce the formation of additional artefactual products, inert solvents (ethyl acetate or hexane) should be used to reconstitute the extracts. Protonated substituted ureas without fragmentation have been observed by LC-MS in APCI mass spectra. The appearance of spectra obtained by thermospray LC-MS is highly dependent on the analytical conditions (Niessen 1999).

LC-MS(-MS) methods with positive ion and MRM modes for measurement of dichlorophenyl urea, dichlorophenylmethyl urea, diuron and linuron as markers of phenylurea herbicide exposure and of dimethoxypyrimidine, dimethylpyrimidine and methoxymethyl triazine as markers for sulfonylurea herbicide exposure in urine have been developed by Nguyen *et al.* (2007).

Toxicity No serious cases of human poisoning as a result of ingesting this class of pesticides have been reported.

Coumarin anticoagulants

Analysis Warfarin and the superwarfarin anticoagulant rodenticides (brodifacoum, bromadiolone, coumatetralyl and difenacoum; Fig. 16.5) can be analysed either intact or after derivatisation, by either GC or GC-MS methods, these being the most sensitive and selective. For biological samples (plasma and urine), extractive methylation using the phase-transfer reagent tetrahexylammonium hydrogensulfate, methyl

iodide and then SPE has been developed as part of a systematic toxicological system (Maurer, Arlt 1998). Using MS with ions of *m/z* 291, 294, 295, 309, 313, 322, 324, 336, 343 and 354, the presence of 4-hydroxycoumarin anticoagulants and even the hydroxy metabolites of coumachlor, coumatetralyl and warfarin can be detected (Maurer, Arlt 1998). Five of the 4-hydroxycoumarin anticoagulants (brodifacoum, bromadiolone, coumatetralyl, difenacoum and warfarin) can also be resolved and determined in serum by HPLC with fluorimetric detection (Felice *et al*. 1991), using the following method.

1. To 2 mL of serum add 4 mL of acetonitrile, vortex for 10 s and then centrifuge for 5 min at 700*g*.
2. Decant the supernatant liquid to another test tube, add 8 mL of diethyl ether and vortex mix for 2 min and then centrifuge.
3. Separate the ethereal phase (approximately 7 mL); evaporate to dryness at 50–55°C under a stream of nitrogen.
4. Dissolve the residue in 150 µL of methanol and add 50 µL of mobile phase.
5. Inject an aliquot of 50 µL into the HPLC apparatus:
   - Detector: fluorescence (λ_{ex}=318 nm, λ_{em}=390 nm).
   - Column: C_{18} Ultrasphere, 250 × 4.6 mm.
   - Mobile phase: gradient mixture of 0.05 mol/L ammonium acetate buffer (with addition of 2 mL of glacial acetic acid and 2 mL of triethylamine in 1 L of aqueous phase) and methanol (38 : 62 for 2 min to 18 : 82 at 5 min for 8 min to 10 : 90 at 13.5 min for 1.5 min to 38 : 62 at 17 min).

Recoveries average from 68% (warfarin) to 98% (bromadiolone). Bromadiolone and warfarin can be quantified with a precision of at least ±10% at serum concentrations of 20 µg/L, and brodifacoum, coumatetralyl and difenacoum at serum concentrations of 10 µg/L.

A series of procedures for the screening, confirmation and quantification of superwarfarin anticoagulant rodenticides in serum or blood by LC-MS(-MS) has been published recently. Grobosch *et al.* (2006) developed a method for the simultaneous determination of five superwarfarins (brodifacoum, bromadiolone, difenacoum, difethialone and flocoumafen) and five other vitamin K antagonists (acenocoumarol, coumatetralyl, coumachlor, phenprocoumon and walfarin) in 0.5 mL serum samples. Jin *et al.* (2007) determined bromadiolone in 0.2 mL whole blood specimens.

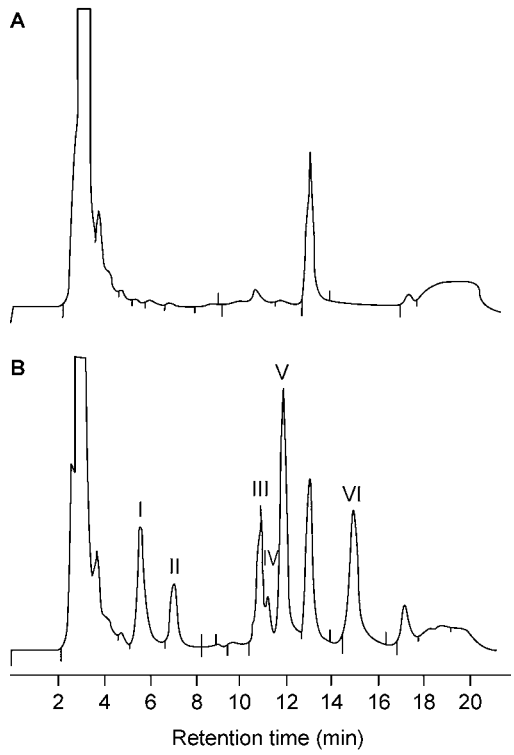

Figure 16.5 HPLC chromatograms of extracted canine serum (fluorescence detector, Ultrasphere C_{18} column). A, blank canine serum; B, canine serum spiked with 50 µg/L of coumatetralyl (I), difenacoum (V) and brodifacoum (VI) and 100 µg/L of warfarin (II) and bromadiolone (III, IV). Reproduced with permission from Felice *et al*. (1991).

Extraction Adamowicz and Kała (2009) evaluated the following LC-ESI-MS method for the detection and quantification of six anticoagulants:

1. To 1 mL of blood add 50 µL (10 µg/mL) of nimesulide (IS), 1 mL of acetate buffer (pH 5.5) and 6 mL of chloroform–acetone (1 : 1, v/v).
2. Shake the mixture for 20 min and then centrifuge for 5 min at 6000*g*.
3. Transfer 5 mL of lower organic layer to a clean tube and evaporate to dryness at 50°C on a heating block under a stream of nitrogen.
4. Reconstitute the dry residue in 100 µL of mixture consisting of acetonitrile–water (1 : 1, v/v).
5. Inject an aliquot of 20 µL into the HPLC using an autosampler.

Chromatography

- Column: LichroCart Purospher RP-18e, 125 × 3 mm, Merck.
- Mobile phase, gradient mixture of 0.1% (v/v) of formic acid in water–acetonitrile (90 : 10 to 0 : 100 at 10 min for 5 min to 90 : 10 at 16 min for 4 min).
- Detector, triple-quadrupole mass spectrometer, operated in ESI negative-ion and selected-ion recording (SIR) modes
- Recorded ions (*m/z*): warfarin, 161 and 250; nimesulide (IS), 229; coumatetralyl, 291 and 292; bromadiolone, 525 and 527; difenacoum, 443 and 444; brodifacoum, 523 and 521; difethialone, 539 and 537.
- Validation parameters: 9-point (0, 10, 50, 100, 200, 500, 1000, 2000 and 5000 µg/L) calibration curves were linear from limit of quantifications (LOQs) up to 5000 µg/L; LOQs (S/N>10) (µg/L) were 10 for coumatetralyl, 15 for warfarin, 50 for bromadiolone, 60 for brodifacoum and difenacoum, and 200 for difethialone.
- Retention times are shown in Fig. 16.6.

Other parameters were determined at blood concentrations of 100 µg/L. Recoveries averaged from 65% (warfarin) to 81% (brodifacoum). Within-day and between-day precision was less than 15% RSD. Specificity was checked using ten blank blood samples (including post-mortem samples) from different sources and no interfering peaks were observed.

The same extraction procedure and HPLC-DAD method was successfully applied for the identification of above-mentioned active anticoagulant components in commercial rodenticide preparations and waters, drinks and foodstuffs (soups, sausages, ground coffee) to which a rodenticide has been added for criminal purposes, and in stomach contents taken from animals (dogs, seals, spoonbills) suspected of having been poisoned and stomach washings in emergency cases of severe poisoning (Adamowicz, Kała 2005).

Toxicity Accidental and intentional ingestion of 4-hydroxycoumarin rodenticides can lead to serious poisoning manifested by bleeding in multiple organ sites. Treatment consists of supplements of vitamin K (mild cases) and, for serious cases, infusions of fresh frozen plasma or purified clotting factors until the prothrombin time returns to the normal range.

Blood and tissue levels Cases of serious poisoning are generally associated with serum concentrations greater than 5 mg/L, but for some derivatives (e.g. acecoumarol and brodifacoum) toxicity appears at much lower concentrations (Geldmacher-v.Mallinckrodt 1997).

A limited number of cases of non-fatal intoxications by coumarin anticoagulants have been reported where serum concentrations (µg/L) were measured. These can be summarised as follows (Grobosch *et al.* 2006):

Brodifacoum	Difenacoum	Bromadiolone
n = 3	*n* = 2	*n* = 2
630, 710, 731	600, 970	40, 440

In a case of bromidiolone, poisoning the whole-blood concentration was 51 µg/L (Jin *et al.* 2007). In a fatal poisoning following ingestion of a

rodenticide containing 0.005% of brodifacoum, its concentrations (μg/L or μg/kg) were as follows:

Heart blood	Femoral blood	Bile	Liver	Spleen	Lung
2240	3919	4276	50	34	31

Brodifacoum was not detected in vitreous humour or in brain tissue. It is worth adding that in liver preserved by formalin and in formalin solution after preservation concentrations of brodifacoum were 820 μg/kg and 5440 μg/L, respectively. The most reasonable explanation for such high levels of brodifacoum in the fixed liver and formalin fixative was significant release of brodifacoum from hepatic tissues (Palmer *et al.* 1999).

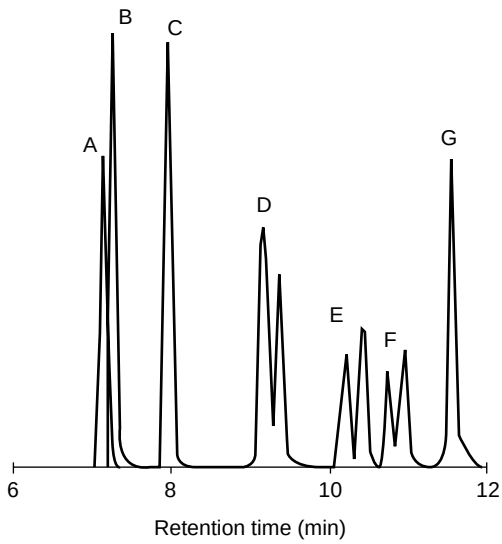

Figure 16.6 LC-MS chromatogram (mass detector, operated in ESI negative-ion and SIR modes; Purospher RP-18e). The extract of control blood spiked with: A,100 μg/L of warfarin; B, 500 μg/L of nimesulide (IS); C, 100 μg/L of coumatetralyl; D, 200 μg/L of bromadiolone; E, 200 μg/L of difenacoum; F, 200 μg/L brodifacoum; G, 400 μg/L of difethialone. Reproduced with permission from Adamowicz and Kała (2009).

Organic and inorganic metallic compounds

A wide range of organic and inorganic metallic compounds is found in agricultural use. Inorganic and organometallic compounds are used as acaricides (organotin), herbicides (organoarsenic), fungicides (dithiocarbamate compounds of nickel and dithiocarbamate complexes with manganese and zinc, organic and inorganic compounds of copper and mercury) and rodenticides (magnesium, aluminium and zinc phosphides, and thallium sulfate). For some compounds, exposure to the organic form results in more serious toxicity and the features of poisoning may differ significantly from those of the inorganic compound. For example, whereas inorganic tin compounds are relatively innocuous, the organic forms (ethyl, butyl or phenyl derivatives), used mainly as molluscicides, present a serious hazard because of their lipid solubility, which allows rapid uptake into the central nervous system. This can lead to partial paralysis, visual and psychic disturbances, convulsions and death from respiratory or cardiac failure. Ingestion of inorganic mercury compounds causes gastrointestinal problems (vomiting, diarrhoea) and renal failure, whereas the lipid-soluble organic mercurials (e.g. the dimethyl and diethyl derivatives) concentrate in the central nervous system and lead to ataxia, chorea and convulsions. Numerous techniques, based on atomic absorption spectrophotometric detection and colorimetric detection, can be used to analyse these compounds (see Chapters 30 and 43). Since most methods require prior destruction of the organic matrices (wet or dry), LC-MS techniques have evolved, in particular for the analysis of organotin compounds (Niessen 1999).

CHAPTER

17 Metals and Anions

R Braithwaite

General introduction

Metals and anions form an important, but disparate, group of agricultural, household and industrial poisons that present many difficulties in their systematic chemical analysis (Baldwin and Marshall 1999; Yeoman 1985). Severe acute poisoning with these agents is rare in most developed countries, but remains common in many developing parts of the world. Chronic poisoning, as a result of occupational or environmental exposure to heavy metals and pesticides, occurs in many countries and can be a cause of ill-health in both adults and children.

The signs and symptoms of acute poisoning may differ from those associated with chronic toxicity. Some metallic (e.g. arsenic) and anionic (e.g. cyanide) substances undergo extensive metabolism after ingestion. These factors have a significant bearing on analytical investigations applied to biological materials and their interpretation. It is important in individual cases, therefore, to know whether poisoning resulted from acute, chronic or acute-on-chronic exposure. Of equal importance is the time of specimen collection in relation to the alleged time of ingestion or exposure.

The wide range of metallic or anionic poisons that might be involved in any case of suspected poisoning means that great care is required in the collection of appropriate specimens and the selection of toxicological and other tests. There is no simple systematic way to investigate cases for which the history is uncertain and the identity of the poison unknown. The investigation is often led by a process of elimination of the more likely causes of poisoning (e.g. pharmaceuticals and illicit drugs), and then a careful examination of the detailed history of the patient or deceased, in particular any access to compounds associated with industrial and agricultural use, or specific household products.

Considerable advances in analytical techniques for measuring metals in biological fluids have been made since the early 1980s, particularly in electrothermal atomic absorption spectrometry (ETAAS) (Halls 1984; Slavin 1988) and inductively coupled plasma–mass spectrometry (ICP-MS) (Hsiung *et al.* 1997). These techniques are discussed in detail in Chapter 43. The use of ICP-MS has expanded rapidly in the last 5 years and it is now the technique of choice for sensitive multi-element analysis, particularly in the investigation of suspected poisoning of 'heavy metals' or less common inorganic poisons. When investigating chronic exposure to toxic metals, great care must be taken to control the accuracy and precision of biological analyses. This calls for ready access to a supply of reliable internal quality-control materials and regular participation in external quality-assurance programmes. These are often not available in developing countries, but much can be done at relatively low cost with cooperation between laboratories (Braithwaite and Girling 1988; Halls 1984).

The development of analytical techniques for anions in biological fluids has historically been limited. The increased availability of liquid chromatography–mass spectrometry (LC-MS) techniques has greatly improved matters. However, a number of simple methods for measuring selected poisons remain valid and have a role to play where access to more sophisticated equipment is restricted (Flanagan *et al.* 1995).

Specimen collection and analysis

In cases of suspected poisoning admitted to hospital, specimens of blood and, where possible, urine should be taken (see Chapter 1). These should be labelled carefully (full name of patient, admission number and date and time of collection) and stored in a refrigerator (4°C) pending any delay in transport to the laboratory. When blood specimens are received in the laboratory and analyses are not required immediately, it is useful to separate off plasma or serum from red cells, prior to deep freezing. However, for toxins that have a significant distribution into the red cells (e.g. lead, cadmium, mercury and cyanide), it is essential to conserve samples of anticoagulated whole blood. In postmortem examinations it is important to undertake a more systematic specimen collection and great care is required in the selection of sampling sites, method of collection and use of appropriate specimen containers (see Chapter 10).

Where an industrial accident has occurred there may be access to 'scene residues' or materials used in a chemical process. Analysis of these materials can yield invaluable clues when the precise nature of the chemical agent is unknown. However, prior to transportation to the laboratory, separate packaging from any biological specimens is advisable to avoid the risk of contamination.

Stomach contents

Vomit, stomach aspirate and washout fluid are now rarely available from cases of acute poisoning admitted to hospital. Stomach washout procedures (except in rare cases) have been replaced by the administration of oral activated charcoal in most developed countries. In fatal cases, the whole stomach and its contents can be removed *post mortem* for detailed examination.

When dealing with the initial examination of stomach contents, or vomitus, it is helpful to note any unusual smell, colour or other appearance, such as the presence of fresh or altered blood (coffee grounds; see Chapter 1). Great care should be taken when dealing with cases that involve the oral ingestion of cyanide salts or phosphides, as the contents of the stomach may represent a serious hazard and risk of secondary poisoning (a fume cupboard or safety cabinet must be used in these circumstances). The total volume of the stomach contents should be recorded. These can then be homogenised in a blender to allow two or three representative smaller specimens to be taken for both qualitative and quantitative analysis.

Homogenised specimens can be filtered directly using a coarse-grade filter paper or diluted with distilled water. The clear supernatant or a representative sample of the homogenised stomach contents can be used for analysis. Quantitative analysis of the stomach contents is generally of interest only in medicolegal cases in which the quantity of chemical poison present in the stomach contents may provide useful forensic evidence.

Blood

Venous blood (10 mL) should be collected in all cases of suspected poisoning; for metallic poisons and anions, such as cyanide, a potassium ethylenediamine tetraacetic acid (K-EDTA) container is the most appropriate. A wide range of blood-collection tubes is available commercially; to avoid the possibility of contamination, the use of products certified as suitable for trace-element analyses is strongly recommended, particularly when dealing with environmental or subclinical exposure to agents such as lead and cadmium. Blood-collection tubes that contain gel separation barriers should not be used. Alternatively, the laboratory can purchase relatively large batches of standard blood-collection tubes

(all with the same batch number) and carefully test a few tubes from each batch to ensure that they are free of contamination with those metals of clinical interest (e.g. lead, cadmium and aluminium). When blood specimens are received in the laboratory in an unusual container, it may be useful to request a 'blank' container that can be analysed for the presence of any contaminating substance.

It is equally important to ensure that reliable blood-specimen containers are used for postmortem examinations. These can be supplied to the pathologist ahead of any postmortem examination as part of the standard specimen collection kit. It is recommended that, at any postmortem examination, blood should be taken from an identified anatomical site (preferably the femoral vein) for quantitative analysis, since after death significant diffusion or redistribution of poisons may occur (see Chapter 10). Other sites (e.g. the heart) may be useful for qualitative 'screening' purposes.

Blood should never be taken from the body cavity at the end of the postmortem examination. The main problem is that blood samples taken from different sites, e.g. femoral, subclavian, aorta, at postmortem examination show different concentrations. In cases of rapid death, where there may be large quantities of unabsorbed poison present in the stomach, or aspirated into the lungs, this can undergo significant diffusion after death, leading to very high concentrations in adjacent blood vessels.

Urine

An early specimen of urine (20 mL in a plain Sterilin-type container with no preservatives added) should be collected, with care taken to ensure that the sample is not contaminated during the collection process. If patients are undergoing chelation therapy, it can be useful to collect sequential 24 h urine specimens into acid-washed plastic urine containers. The total volume of urine should be recorded carefully prior to taking aliquots of specimens for analysis to determine the excretion of chelated elements and the efficacy of treatment.

Other specimens

Hair analysis for trace elements has often been used for diagnostic purposes in cases where an individual complains of symptoms for which no cause can be found by routine medical or pathological investigations. However, experience and published studies show that the results can sometimes be misleading (Poon *et al.* 2004; Seidel *et al.* 2001; Taylor 1986). Hair analysis has more application in surveys of population exposure and in investigations of suspicious deaths, such as those that involve arsenic or mercury. The long persistence of metals and many other chemical poisons in hair and nail samples compared with their relatively short duration in blood or urine specimens can be a major advantage in forensic cases (Daniel *et al.* 2004). Analysis of hair and nail sections can also sometimes yield an important chronological forensic record of when doses were administered.

Specimens such as tissues and bone may sometimes be collected at postmortem examination as part of the investigation of complex medicolegal cases (Benes *et al.* 2000; Lech and Trela 2005; Warren *et al.* 2002). As with blood specimens, great care is required in selecting the site of collection and to avoid contamination. In addition, interpretation of the results without access to comparable reference specimens can be very difficult.

Quality assurance

Access to appropriate 'internal' control or other reference materials is very important for the analysis of trace metals. A wide variety of certified reference materials, including blood, serum, urine and bone, is available commercially. Where these cannot be obtained easily, an inexpensive alternative is to prepare such materials from bovine blood, or any suitable large animal as a cooperative effort between experienced laboratories (Braithwaite and Girling 1988). This entails the preparation of large batches of samples with trace metal concentrations at, for example, normal, borderline toxic levels and toxic levels, which can then be analysed repeatedly by the laboratories so that the pooled results can be used to assign concentration ranges. It is equally important for laboratories to subscribe to national or international external quality-assurance schemes where these are available.

Table 17.1 Common methods of analysis for trace elements in biological fluids and tissues

Colorimetric
Fluorimetric
Electrochemical (anodic stripping voltametry and ion-selective electrodes)
Flame atomic absorption spectrometry
Electrothermal atomic absorption spectrometry
Inductively coupled plasma–emission spectrometry
Inductively coupled plasma–mass spectrometry

Metals

Methods of analysis

A wide range of techniques is available to laboratories for metals analysis (Table 17.1) and these are described in Chapter 43. A few simple qualitative and quantitative tests (e.g. the Gutzeit and Reinsch tests) can be useful, particularly where laboratory resources are severely limited (Flanagan *et al.* 1995).

Aluminium

Introduction

Aluminium is the most abundant non-essential element in the earth's crust, but its role in human health and disease became understood only recently (Krewski *et al.* 2007; Martin 1986). The normal intake of aluminium from food, water and beverages is probably 2–3 mg per day, but its absorption from the gut is relatively poor and depends on the speciation of the element and the presence of other substances (e.g. phosphate and citrate) in the diet (Klein 2005). Aluminium is a powerful neurotoxin, and it is well established that excessive intravenous exposure in patients undergoing dialysis results in its significant accumulation in the body, particularly in the brain, which can cause 'dialysis dementia', a type of encephalopathy that can be rapidly progressive and lead to death within a few months (Alfrey *et al.* 1976). Use of aluminium sulfate as a flocculating agent in domestic water supplies is the major source of the metal in these patients, particularly if the water used for dialysis is not purified. The large quantities of oral aluminium salts that may be given to some renal patients to reduce the intestinal absorption of phosphate may also cause toxicity. Aluminium may also be a suspected risk factor in Alzheimer's disease (Flaten 2001; Miu and Benga 2006). More recently, concern has developed about the harmful effects of occupational exposure to aluminium (Akila *et al.* 1999; Iregren *et al.* 2001; Meyer-Baron *et al.* 2007; Polizzi *et al.* 2002; Rifat *et al.* 1990). Attention has also been drawn to the possible harmful effects of aluminium present in infant formulae (Freundlich *et al.* 1985; Sedman *et al.* 1985).

Specimen collection

Specimens are collected as follows:

- Blood/serum/plasma – 5 mL, plain or lithium–heparin tube
- Water – 20 mL, plastic universal container
- Dialysis fluid – 20 mL, sterile plastic universal container
- Urine – 20 mL, sterile plastic universal container.

It is important to check that all specimen containers are 'aluminium free'. Glass containers should never be used to collect specimens for aluminium analysis.

Analysis

Constant vigilance is required to avoid contamination of specimens, reagents, tubing and equipment from aluminium in dust in laboratory areas. Cleaned glass containers should be used only to prepare concentrated stock solutions of aluminium salts. Great care is required to avoid

Table 17.2 Recommended water and dialysate aluminium concentrations

Solution	*Concentration*
Maximum allowable concentration (MAC) for potable water	200 µg/L (7.4 µmol/L)
Guideline concentration for potable water	50 µg/L (1.9 µmol/L)
MAC for water for preparation of dialysis fluid	10 µg/L (0.4 µmol/L)
Recommended upper limit for dialysis fluid	30 µg/L (1.1 µmol/L)

contamination when separating plasma or serum from blood specimens. Storage conditions of specimens are important (Wilhelm and Ohnesorge 1990). Aluminium is most commonly measured in plasma using ETAAS with background correction. The use of matrix-matched calibration standards and control material is essential (Taylor *et al.* 1994). Other methods have been described based on colorimety and fluorimetry but these are more suitable for water analysis. More recently there has been the increased use of ICP-AES and ICP-MS to measure aluminium in plasma, water and dialysate or other more complex matrices (Murko *et al.* 2007; Zhang *et al.* 2000, 2002).

Interpretation

The recommended (European) guidance values for water and dialysate aluminium concentrations are shown in Table 17.2. In patients on haemodialysis, in which a water purification system (such as reverse osmosis) is in operation, it is important to monitor aluminium in pre- and post-water samples to detect any breakdown in the purification process that would allow contamination of the dialysis solution used to treat the patient (Berend *et al.* 2001).

Plasma aluminium concentrations should be monitored routinely in all patients in end-stage renal failure who receive dialysis therapy, to ensure that absorption of aluminium is kept to an absolute minimum. In addition, regular testing is needed of water supplied to patients who have home dialysis. European guidelines for plasma aluminium concentrations in patients who receive dialysis therapy are given in Table 17.3. The body burden of aluminium in dialysis patients can be obtained from the measurement of plasma aluminium concentration before and after the administration of a standard dose of an aluminium-chelating agent such as desferrioxamine (Chazan *et al.* 1989; Marumo *et al.* 1987).

Where renal function is normal, aluminium is excreted rapidly from the body and there is little possibility of accumulation. The reference value for urine aluminium in non-exposed healthy adults is less than 15 µg/L (0.5 µmol/L). In situations of acute or chronic occupational or environmental exposure to aluminium, measurement of blood (plasma) and/or urine aluminium is an effective way to assess the degree of exposure (Ljunggren *et al.* 1991; Pierre *et al.* 1995). Where occupational exposure involves inhalation of fine particles or dusts, aluminium may be stored in the lung tissue and leach out very slowly over several months. As a result, plasma and urine aluminium concentrations can remain elevated for several weeks or months (Ljunggren *et al.* 1991).

Table 17.3 Recommended action limits for plasma aluminium concentrations

Situation	*Concentration*
Normal (no history of chronic renal failure)	<10 µg/L (<0.4 µmol/L)
Desirable in chronic renal failure	≤60 µg/L (<2.2 µmol/L)
Excessive accumulation	>60 µg/L (>2.2 µmol/L)
Cause for concern; high risk of toxicity in children	>100 µg/L (>3.7 µmol/L)
Urgent action required; high risk of toxicity in all	>200 µg/L (>7.4 µmol/L)

There is also evidence of a dose-dependent association between increased aluminium body burden and central nervous system effects in these workers (Akila *et al.* 1999). Suggested thresholds for these effects in aluminium welders are 108–160 µg/L (4–6 µmol/L) in urine and 7–10 µg/L (0.25–0.35 µmol/L) in plasma (Riihimaki *et al.* 2000).

Aluminium accumulates in the bone of dialysis patients and bone biopsy samples can be analysed to estimate the body burden (Tang *et al.* 1996). Extensive data are available on the aluminium content of bone in dialysis patients with aluminium-related bone disease. Bone aluminium concentrations of up to 300 mg/kg have been reported in these patients, whereas concentrations in non-exposed reference populations are very low (<13 mg/kg). De Wolff *et al.* (2002) recently reported blood and tissue aluminium concentrations in four patients who had died as a result of the use of dialysate contaminated with aluminium, which subsequently resulted in the criminal prosecution of hospital staff who had been involved in the incident (Berend *et al.* 2004). A major chemical incident involving the contamination of public drinking water by aluminium occurred in north Cornwall, in the UK, in 1988. Approximately 20 000 people were exposed to very excessive amounts of aluminium over a relatively short period of time. Although there were no fatalities, or apparent serious toxicity, the long-term consequences of this exposure were uncertain. However, a recent postmortem examination carried out on a woman who was exposed to aluminium and subsequently developed a rare form of Alzheimer's disease showed elevated brain concentrations of aluminium (Exley and Esiri 2006).

Antimony

Introduction

Various salts of antimony (e.g. tartar emetic, antimony potassium tartrate) have a long history of use as medicines (McCallum 1999) and continue to be used to treat tropical parasitic diseases such as schistosomiasis (bilharziasis) and leishmaniasis. Antimony compounds are also used industrially in the manufacture of lead batteries, semiconductors, paints, ceramics and pewterware. Other modern industrial compounds include antimony oxychloride ($Sb_6O_6Cl_4$), widely used as a fire retardant on fabrics and mattresses. It was postulated by Richardson in 1994 that the formation of antimony hydride (stibine, SbH_3) might be a cause of sudden infant death syndrome (SIDS) in babies who sleep on mattresses with polyvinyl chloride (PVC) covers manufactured using antimony-based fire retardants. It was claimed that fungal growth (*Scopulariopsis brevicaulis*) on older soiled mattresses converted the antimony fire retardant into stibine, which was inhaled by the babies and led to unexpected death. This was subsequently disproved by a government enquiry that showed that this hypothesis had been based on erroneous experimental work (Cullen *et al.* 2000; Delves *et al.* 1997; Warnock *et al.* 1995).

The fatal dose of antimony in the form of tartar emetic is about 1 g in an adult, but there is much inter-individual variability. The signs and symptoms of acute antimony poisoning include metallic taste, dysphagia, epigastric pain, violent vomiting, diarrhoea, abdominal pain and circulatory collapse (Stemmer 1976). These symptoms are almost indistinguishable from those of acute arsenic poisoning, but larger doses are required. Similarly, the effects of exposure to stibine are similar to those of arsine (AsH_3). Chronic effects of occupational antimony exposure include 'antimony spots' on the skin and pneumoconiosis (Stemmer 1976).

Specimen collection

Specimens are collected as follows:

- Bloods – 10 mL, K-EDTA tube
- Urine – 20 mL, sterile plastic universal container.

Analysis

A number of methods have been described for measuring antimony in biological fluids, including the use of hydride generation and ETAAS. ICP-MS has been applied to the analysis of a wide range of fluids and tissues, particularly those from young infants and babies (Delves *et al.* 1997; Dezateux *et al.* 1997; Miekeley *et al.* 2002).

Interpretation

Reference values for antimony in body fluids and tissues are below 1 µg/L (8 nmol/L). In a study reported by Smith *et al.* (1995) concerning the analysis of urine antimony concentrations in occupationally exposed battery workers, values of up to 150 µg/L (1.2 µmol/L) were reported. A male AIDS patient who received by accident 10 times the prescribed dose of sodium stibogluconate for treatment of visceral leishmaniasis (6.5 g instead of 650 mg) and survived had a blood antimony concentration of 1.38 mg/L 20 h after dosing (Reymond and Desmeules 1998). A female patient who died 48 h after ingesting antimony trichloride solution had tissue concentrations of 4.6 mg/L (blood), 6 mg/kg (brain), 6 mg/kg (lung), 45 mg/kg (liver), 404 mg/kg (bile) and 32 mg/kg (kidney) (Baselt 2005).

Arsenic

Introduction

Arsenic is widely distributed in the environment, particularly in rocks, sediments and some water supplies. A number of inorganic arsenicals have a particularly long historical use as drugs and poisons. In the eighteenth century, Fowlers solution (1% w/v potassium arsenite) was used as a 'cure all' and remained in use until the twentieth century. Many thousands of arsenic-containing organic compounds were synthesised in the late nineteenth and early twentieth centuries as pigments (e.g. Emerald, or Paris Green, copper aceto-arsenite), chemical warfare agents (Lewisite, chlorovinyldichloroarsine) and pharmaceuticals (Salvarsan, arsphenamine; Gorby 1994). Arsenic trioxide (white arsenic or sugar of arsenic) was particularly popular as a homicidal poison up until the late nineteenth century, but its use declined following the development of sensitive techniques for its detection in body fluids and tissues such as the Marsh, Reinch and Gutzeit tests (Rosenfeld 1985). In most countries arsenic compounds are now rarely encountered in cases of suspected murder or suicide, but they have not disappeared from use (Duenas-Laita *et al.* 2005; Gorby 1988; Lech and Trela 2005; Mackell *et al.* 1985; Poklis and Saady 1990). It has been shown to be useful to screen for the presence of arsenic and other inorganic poisons where there are signs and symptoms of unexplained gastrointestinal illness in unexplained or suspicious deaths.

Organic forms of arsenic (e.g. arsenosugars, arsenobetaine, arsenocholine) occur naturally in seaweed, fish and shellfish, but are relatively non-toxic (Francesconi *et al.* 2002; Le *et al.* 1994). Arsenic is metabolised in the liver to mono- and dimethylated species as a means of detoxification, but the various enzymes and pathways are far from being fully understood (Aposhian and Aposhian 2006) Different forms of arsenic have widely differing human toxicity. They are also handled by the body in different ways, which causes problems in their determination and in the interpretation of laboratory findings, particularly when the source of arsenic is unknown (Aposhian and Aposhian 2006; Buchet *et al.* 1981; Johnson and Farmer 1991; Lovell and Farmer 1985; Pott *et al.* 2001; Vahter 1994).

Arsenic has three common valence or oxidation states: 0 (metalloid), 3+ (arsenite) and 5+ (arsenate). The trivalent inorganic salts of arsenic (e.g. sodium arsenite; $NaAsO_2$) are the most toxic and may cause serious toxicity or death after acute ingestion of relatively small doses (<200 mg). Inhalation of arsine gas (AsH_3) may cause massive haemolysis, renal and other organ failure and rapid death, as in industrial accidents (Pakulska and Czerczak 2006). In such cases plasma exchange appears to be the only effective method of treatment, but should be applied as soon as possible (Song *et al.* 2007). The signs and symptoms of chronic arsenic poisoning are extremely complex, affect different organ systems (Table 17.4) and differ from those of gastroenteritis, with bloody diarrhoea, vomiting, excruciating abdominal pain, circulatory collapse and coma associated with acute poisoning (Fowler and Weissberg 1974). In addition, some of the early cutaneous signs, such as melanosis, may go unnoticed (Saha 2003). Skin, liver and respiratory cancer is another major feature of chronic arsenic exposure; huge populations are affected in parts of India, Bangladesh and Vietnam because of the consumption of contaminated well-water (Ahsan *et al.* 2000; Berg *et al.* 2001; Chowdhury *et al.* 2000; Piamphongsant 1999; Smith *et al.* 2000; Yoshida *et al.* 2004). The main sources of the problem are wells sunk into land that contains rocks with a high content of arsenic salts, with subsequent contamination of the underground aquifers, although the precise mechanism of release of arsenic into water is not fully understood.

Table 17.4 Signs and symptoms of chronic arsenic poisoning (arsenic oxide)

Anorexia
Weight loss
Malaise
Hyperpigmentation of skin (diffuse or spotted melanosis)
Hyperkeratosis
Mee's white transverse lines on nails
Peripheral neuropathy
Liver damage
Haematological change (pancytopenia)
Hypertension
Ischaemic gangrene (black foot)
Increased risk of cancer (skin, liver lung)

Specimen collection

Specimens are collected as follows:

- Blood – 10 mL, K-EDTA tube
- Urine – 20 mL, sterile plastic universal container.

Analysis

Simple tests such as the Reinsch test may identify the presence of arsenic in stomach contents tissue digests or 'scene residues'. The Gutzeit test may also be applied to the quantitative analysis of arsenic in stomach contents, water, food and other materials (Crawford and Tavares 1974; Kneip *et al.* 1977). This technique is relatively specific because it is based on the conversion of arsenic into arsine. Other simple spectrophotometric methods to measure arsenic in biological fluids, and other materials such as water, have been described (Lakso *et al.* 1979; Pillai *et al.* 2000). However, the most popular modern approach involves hydride generation following acid digestion and then ETAAS, which can be applied to the measurement of arsenic in a variety of matrices. Analysis of arsenic in urine can be problematic in view of the presence of several different inorganic and organic species (Feldman 1991) (Table 17.5). A major issue is the removal of dietary sources of organic arsenic compounds, particularly those that result from the recent ingestion of fish or shellfish. The limit of detection of this procedure is 5 µg/L (67 nmol/L) of arsenic. More sophisticated techniques include ICP-MS or the separation and measurement of individual arsenic species using gas chromatography (GC)-MS (Claussen 1997) or ion-exchange chromatography linked to ICP-MS (Brima *et al.* 2006; Hughes 2006;

Table 17.5 Measurement of arsenic species in biological fluids

Sequence	*Arsenic species*	*Group*
1	Arsenite (As^{3+})	Inorganic arsenic species
2	Arsenate (As^{5+})	
3	Monomethyl arsonic acid (MMAA)	Methylated arsenic metabolite species
	Methyl arsenate	
4	Dimethyl arsinic acid (DMAA; cacodylic acid)	
5	Complex organo-As compounds (e.g. arsenobetaine, arsenocholine)	Dietary organic species (e.g. fish)

Lindberg *et al.* 2007; Milstein *et al.* 2003). However, the separation of different species of arsenic can be very time-consuming in the investigation of acute or chronic arsenic poisoning, although reference materials are available for urine analysis (Yoshinaga *et al.* 2000).

Interpretation

Normal values for arsenic are <10 μg/L (0.1 μmol/L) in blood and urine. Elevated values can be obtained, depending on the type of methodology and the ingestion of seafood prior to specimen collection or occupational exposure (Apostoli *et al.* 1999). The current American Conference of Government Industrial Hygienists (ACGHI) Biological Exposure Index (BEI) for arsenic (at the end of the working week) is 50 μg/g creatinine (as inorganic arsenic or its metabolites; note that creatinine correction has recently been abandoned because arsenic is excreted by diffusion). Special care is required in the interpretation of results in situations of chronic occupational or environmental exposure. However, in cases of acute symptomatic inorganic arsenic poisoning, concentrations above 2000 μg/L (28 μmol/L) may be seen in blood and urine (Duenas-Laita *et al.* 2005; Lech and Trela 2005). Hair and nail analysis has also been used in the diagnosis and evaluation of chronic arsenic poisoning, particularly suspected homicides (Poklis and Saady 1990). However, there may be problems distinguishing external contamination from ingested arsenic (Hindmarsh 2002).

Barium

Introduction

The inorganic compounds of barium are very widely used as welding fluxes, pigments and glazes in industry and in the manufacture of paint, glass, explosives and ceramics. Soluble salts are used as pesticides and depilatory agents. The insoluble sulfate salt is widely used as radiographic contrast medium. Most (insoluble) barium salts are relatively non-toxic. However, pneumoconiosis related to the inhalation of barium dusts (baritosis) has been recognised in the mining industry. By contrast, the soluble salts of barium, particularly the acetate, hydroxide and chloride, are extremely toxic if ingested orally or given intravenously. Less-soluble salts, such as the carbonate, may be converted to the chloride at low pH in the stomach. Toxicity is associated with the ingestion of as little as 200 mg of soluble barium salts and the oral fatal dose of soluble salts may be as little as 800 mg (Boehnert 1988; Deng *et al.* 1991). Signs and symptoms of barium poisoning may show within 1 h of ingestion and include abdominal pain, diarrhoea, vomiting, muscular weakness and a tingling around the mouth (Johnson and VanTassell 1991; Schorn *et al.* 1991). Severe hypokalaemia may also develop from a shift of extracellular potassium into muscle. This may cause cardiac rhythm disturbances, which require close monitoring, and the administration of large doses of potassium chloride intravenously to correct the hypokalaemia. Haemodialysis has been used successfully in the treatment of barium poisoning (Bahlmann *et al.* 2005).

Specimen collection

Specimens are collected as follows:

- Blood – 5 mL, K-EDTA tube
- Urine – 20 mL, sterile plastic universal container.

Note that some gel-containing blood tubes may be contaminated with barium.

Analysis

Barium can be measured in plasma, urine and tissue digests using ETAAS or ICP-MS (De Boer *et al.* 2004; Dinya *et al.* 2005).

Interpretation

Reference concentrations of barium in plasma are less than 1 μg/L (<7 nmol/L) and urine excretion is below 10 μg/24 h (<0.70 nmol/24 h). In non-fatal cases of barium poisoning, plasma barium concentrations of up to 8 mg/L (58 μmol/L) have been reported (Boehnert *et al.* 1985). Other useful investigations in cases of acute barium poisoning include radiography of the abdomen for the presence of radiopaque material in the gut. Careful monitoring of serum potassium concentrations in any case of suspected barium poisoning is of vital importance. A death in a 49-year-old pharmacist who deliberately ingested barium chloride was associated with a postmortem blood concentration of 10 mg/L (site of collection unknown). Barium concentrations in bile and urine were 8.8 mg/L and 6.3 mg/L, respectively (Jourdan *et al.* 2001). Analytical data from other poisoning cases are given in the barium monograph.

Beryllium

Introduction

Beryllium is used in the manufacture of corrosion-resistant and high-strength alloys. Such products are commonly used in the nuclear, aerospace and weapons industries. Beryllium alloys with other metals, such as aluminium, copper, magnesium and nickel, are used in diverse products such as springs, gears, electrical contacts and other engine components.

Beryllium itself is a highly toxic element and is associated with a characteristic occupational disease (Kolanz 2001). However, chronic occupationally related disease associated with beryllium exposure may go unrecognised (Infante and Newman 2004) The major target organ is the lung, where it causes granulomatous disease (berylliosis) and an increased risk of lung cancer. The pathological and clinical features of chronic beryllium disease may resemble those of sarcoidosis (Infante and Newman 2004). Other organ systems may also be affected, including the lymphatic system, liver, heart, kidney, skin and bone (Stiefel *et al.* 1980).

Most of an absorbed dose of beryllium is excreted in urine over a period of several days, but lung deposits may leach beryllium so slowly that urine excretion continues for several years.

Specimen collection

Specimens are collected as follows:

- Blood – 10 mL, K-EDTA tube
- Urine – 20 mL, sterile plastic universal container
- Lung – postmortem examination of beryllium-related deaths.

Analysis

Beryllium is most often measured in urine using ETAAS. Newer procedures based on ICP-MS are increasingly being used, particularly when dealing with low-level exposure (Apostoli and Schaller 2001; De Boer *et al.* 2004; Xia *et al.* 2004).

Interpretation of results

Normal values for beryllium in urine are generally accepted as less than 1 μg/L (0.1 μmol/L). A recent large study of urine beryllium concentrations in a group of 65 exposed workers reported values in the range 0.12–0.15 μg/L (13–17 nmol/L), with control subjects having values below 0.63 μg/L (70 nmol/L) (Apostoli and Schaller 2001).

Beryllium has also been measured in lung tissues from workers who were known to have had beryllium-related lung disease.

Bismuth

Introduction

Bismuth, a heavy metal, produces toxicity that can sometimes mimic that associated with lead and mercury. For this reason, it can be useful to include bismuth in any heavy-metal screening procedure undertaken in patients with unexplained neurological symptomatology or acute renal failure. Bismuth salts have been used in medicine for more than 200 years as topical salves and in the treatment of gastrointestinal (GI) disorders, and are available in over-the-counter preparations. Because most orally administered inorganic salts of bismuth are relatively insoluble in water and are poorly absorbed from the GI tract, they cause minimal toxicity. Other compounds, particularly lipid-soluble organic compounds, are known to accumulate in the body after excessive dosing and can cause severe neurotoxicity, such as a progressive encephalopathy (Playford *et al.* 1990). Water-soluble compounds of bismuth are more likely to cause renal damage, including oliguria and acute renal failure (Huwez *et al.* 1992). A number of deaths have been reported after acute and chronic overdose with various bismuth medicinal products.

Specimen collection

Specimens are collected as follows:

- Blood – 10 mL, K-EDTA
- Urine – 20 mL, sterile plastic universal container.

Analysis

Historically, there have been problems with the reliable measurement of bismuth in biological fluids. The method of choice is ETAAS, which may be carried out by direct determination or following hydride generation (Froomes *et al.* 1988). Methods based on ICP-MS have also been reported (Mauras *et al.* 1993; Vanhoe *et al.* 1993).

Interpretation

Reference values for bismuth in blood are extremely low (<1 μg/L [5 nmol/L]). Acceptable 'therapeutic concentrations' are generally up to 50 μg/L (239 nmol/L) and concentrations in excess of 100 μg/L (480 nmol/L) are generally associated with toxicity (Serfontein and Mekel 1979; Slikkerveer and De Wolff 1989). Extremely high (>1000 μg/L [4.8 μmol/L]) blood bismuth concentrations may be found in patients with severe neurological symptoms such as encephalopathy. Monitoring of blood bismuth concentrations is useful in patients who develop acute renal failure as a result of bismuth toxicity. Reference concentrations of bismuth in urine are <1 μg/L (5 nmol/L). Measurement of urinary bismuth concentrations may be useful diagnostically or after treatment of poisoning using oral chelating agents, which can greatly increase urinary clearance of bismuth (Basinger *et al.* 1983; Slikkerveer *et al.* 1993).

Cadmium

Introduction

Cadmium and its salts and alloys are used in the manufacture of nickel–cadmium batteries, pigments, anticorrosion coatings and special alloys. Acute or chronic ingestion of cadmium salts is extremely rare, but reported signs and symptoms include nausea, vomiting, haemorrhagic gastroenteritis and general organ failure.

Most of the toxicological problems associated with cadmium are the result of occupational and environmental exposure and have been known for many years. These include pneumonitis and emphysema from the acute inhalation of cadmium fumes and, more long term, renal impairment (Jarup *et al.* 1988; Nordberg 2004). Water supplies contaminated with industrial cadmium in Japan led to accumulation of the metal by rice and other dietary sources, with subsequent human poisoning on a vast scale. Those affected developed renal damage, skeletal deformities caused by disturbances of calcium and phosphate metabolism, and severe back and leg pain (Friberg *et al.* 1971; Nordberg 2004). This painful condition became known as 'itai-itai' ('ouch-ouch') disease. For those not occupationally exposed, the major source of cadmium remains the diet, although it is absorbed poorly from the gut. However, inhalation of tobacco smoke is an important source of cadmium exposure, as the bioavailability of cadmium via the lung is very high. Following oral or pulmonary absorption, cadmium is stored mainly in the liver and kidney, where it is bound to metallothionein and stays in the body for decades. The most important toxic effect is on the kidney, with proximal renal tubular necrosis; this can be detected by a characteristic increase in the excretion of low-molecular-weight proteins (Lauwerys and Bernard 1986; Lauwerys *et al.* 1994). Both occupational and environmental exposure to cadmium now appears to be a determinant for the subsequent development of end-stage renal disease (Hellstrom *et al.* 2001).

Specimen collection

Specimens are collected as follows:

- Blood – 5 mL, K-EDTA
- Urine – 20 mL, sterile plastic universal container.

It is very important to ensure that specimen tubes are free from cadmium contamination; use of certified trace element tubes is strongly recommended. Strict precautions against contamination should be taken when handling and processing specimens.

Analysis

Routine flame AAS techniques lack sufficient sensitivity for cadmium analysis in blood and urine, but techniques employing special specimen introduction devices, such as the Delves cup, have proved successful, particularly in the assessment of occupational exposure or high levels of environmental exposure (Delves 1977). Most current methods are based on ETAAS with Zeeman background correction (Halls *et al.* 1987). ICP-MS has increasingly become a more suitable approach to analysis particularly in the assessment of occupational cadmium exposure (Botta *et al.* 2006).

Interpretation

Reference values for cadmium in blood and urine are extremely low. Blood cadmium concentrations in non-smokers are generally less than 1 μg/L (9 nmol/L) and in smokers less than 6 μg/L (53 nmol/L). Urine concentrations of cadmium are generally below 1 μg/L in both smokers and non-smokers. Recent occupational guidance values for cadmium in the assessment of cadmium exposure are 5 μg/L (45 nmol/L) in both blood and urine or 10 nmol/mmol creatinine in urine. Thus, heavy smokers may have blood cadmium concentrations at the limit of current occupational guidance values. Cadmium-induced renal tubule impairment is generally related to urine cadmium concentrations in excess of 15 μg/L (134 nmol/L) but these may be much lower for those who were exposed to cadmium many years earlier (Bernard 2004). Blood cadmium concentrations are an index of both recent and past exposure. Individuals who have a long history of excessive occupational cadmium exposure can have a high body burden, which persists into old age (Mason *et al.* 1999). Elevated blood and urine cadmium concentrations may be observed many years after the cessation of exposure in such individuals. Large amounts of cadmium are stored in the liver and kidney, and this can result in a marked redistribution of cadmium into blood after death. This may result in significantly raised postmortem blood cadmium concentrations, depending on the site of blood collection, which could be mistaken for the presence of 'suspiciously elevated' blood cadmium concentrations prior to death.

Copper

Introduction

Copper is an essential, but potentially very toxic, trace element with a recommended intake of approximately 1.53–3.0 mg per day in adults (Aggett 1999; Piscator 1979). The concentration of copper in drinking water may vary greatly, depending on the source of water and the use of copper piping. Recommended concentrations are usually <1.0 mg/L. Copper can be tasted in water at concentrations above 1 mg/L, and there may also be a blue–green coloration at water concentrations >5 mg/L. Copper salts, particularly the water-soluble sulfate, are still used as fungicides and algicides, and may sometimes be found in children's chemistry sets. Total body concentrations of copper are relatively low, with the highest quantity found in the liver, which controls copper homeostasis. Most (~95%) of the circulating copper found in blood is bound to a specific copper-binding protein, ceruloplasmin. Generally, only small amounts of copper are excreted in urine, unless there is the presence of disease. Wilson's disease (hepatolenticular degeneration) is an important genetically inherited disorder of copper metabolism in which there is an inability to transport and excrete copper from the liver into bile (Aggett 1999). This leads to 'copper overload' and associated liver and neurological damage that can cause death unless treated early. It is also known that a deficiency of copper in the diet is associated with pathologically 'low' plasma copper concentrations, which may cause anaemia and low white cell counts, particularly in patients receiving long-term enteral feeding, or taking excessive amounts of zinc, or copper-chelating agents (Lang *et al.* 2004; Oliver *et al.* 2005; Todd *et al.* 2004).Thus copper measurements may be useful in investigating certain types of unexpected death in patients receiving enteral feeding or taking medication that reduces copper absorption.

There is some evidence that excess environmental exposure to copper in drinking water or diet (from copper or brass cooking pots)

may lead to copper-related liver disease in babies and young children (Müller *et al.* 1996; Sethi *et al.* 1993; Spaziano *et al.* 2002; von Muhlendahl and Lange 1994). Copper toxicity has also been found in patients who undergo dialysis with defective copper-containing dialysis membranes (O'Donohue *et al.* 1993). Occupational exposure to copper compounds is relatively rare. The main risk is associated with copper fumes in smelting furnaces that lead to respiratory illness and metal-fume fever. Copper-related liver and respiratory disease has also been reported in vineyard workers who spray copper-containing fungicides (Bordeaux mixture). Toxicity has also been reported following occupational exposure during the application and removal of antifouling paints in ship repair facilities.

Acute copper poisoning may sometimes be seen in cases of accidental and suicidal ingestion of copper salts and solutions, particularly water-soluble salts, such as the sulfate, chloride or acetate (Saravu *et al.* 2007). The signs and symptoms of acute (oral) copper poisoning are metallic taste, GI irritation, abdominal pain, nausea, vomiting, diarrhoea and GI bleeding (Chuttani *et al.* 1965; Patel *et al.* 1976; Saravu *et al.* 2007). In severe cases this can lead to hypotension, shock, liver failure, jaundice, cardiac and multiorgan failure, and death (Gulliver 1991; Walsh *et al.* 1977). The fatal dose of copper sulfate is thought to be approximately 0.2 g/kg body mass.

Specimen collection

Specimens are collected as follows:

- Blood – 2 mL, K-EDTA tube
- Urine – aliquot of 24 h collection in acid-washed urine container for the investigation of copper-related disease and assessment of chelation therapy
- Stomach contents – may be useful in cases of fatal accidental or suicidal poisoning, particularly if they have a blue coloration
- Water – 20 mL, sterile plastic universal container for the investigation of suspected contaminated drinking water.

Analysis

In the investigation of acute copper poisoning, measurement of plasma copper may be useful to assess the severity, although it is unlikely to change clinical management. Analysis can be carried out using colorimetric analysis, or by flame AAS (Taylor 1996) or ICP-MS (De Boer *et al.* 2004; Venelinov *et al.* 2004).

Urine copper can be measured by ETAAS, ICP-AES or ICP-MS, and is generally only of value in the investigation of chronic copper-related liver disease (da Costa *et al.* 1991; Taylor 1996). Measurement of copper in liver biopsy specimens is best undertaken using ICP-MS.

Interpretation

The reference range for plasma copper is wide and depends on age, pregnancy and any underlying disease state. In healthy adults the reference range is 0.8–1.6 mg/L (12–25 μmol/L). Lower values are seen in neonates, copper deficiency and Wilson's disease. Somewhat higher reference values are seen in pregnancy or in patients with inflammatory or neoplastic disease (up to 2.8 mg/L [44 μmol/L]) (Taylor 1996).

The urinary excretion of copper in healthy adults is less than 50 μg/day (0.8 μmol/24 h). Significantly raised values are associated with patients with hepatobiliary disease (50–100 μg/day) or Wilson's disease (>100 μg/day). Much higher values for copper excretion are seen after a challenge with a chelating agent (penicillamine) in both healthy adults (<760 μg/day) and patients with Wilson's disease (>1600 μg/day) (da Costa *et al.* 1991). Other investigations of chronic copper-related liver disease include standard liver function tests and the measurement of plasma ceruloplasmin (Walshe 2003). Copper may also be measured in liver tissue samples after needle biopsy in the investigation of certain types of liver disease. In cases of fatalities following ingestion of soluble copper salts there may be large differences between ante- or perimortem blood/plasma copper concentrations and postmortem blood copper concentrations. These may be caused by postmortem diffusion of unabsorbed copper remaining in the stomach (Gulliver 1991).

Iron

Introduction

Iron poisoning was historically often seen in young children after the accidental ingestion of iron tablets and was until recently one of the leading causes of death in those under 6 years of age (Bosse 1995; Robotham and Lietman 1980). The introduction of unit-dose packaging of iron supplements in 1997 lead to a significant fall in fatalities (Tenenbein 2005). Accidental or suicidal ingestion of iron preparations in adults is relatively rare. Most over-the-counter products contain various ionic iron salts (e.g. sulfate, fumarate, gluconate) and many are slow-release preparations. More recently a number of non-ionic iron preparations have been introduced (e.g. carbonyl iron and polysaccharide iron) that contain a much greater proportion of iron, which is only slowly converted to ferrous iron. The amount of elemental iron in any particular brand of tablet can range from 12% w/v to 98% w/v, which makes assessment of the actual dose of iron ingested very difficult, particularly if the formulation is unknown (Chyka and Butler 1993). The signs and symptoms of iron poisoning can be difficult to assess if the time of ingestion is uncertain. Peak plasma levels of iron are generally seen within about 5 h of ingestion, but this is strongly influenced by the formulation. Initial signs and symptoms include nausea, vomiting and abdominal pain. In more severe cases of overdosage this may lead to intestinal ulceration, small-bowel infarction, haematemesis and melaena. In the most severe cases there may be the subsequent development of metabolic acidosis, hepatic failure and coma. GI symptoms are generally associated with the ingestion of >10–20 mg/kg body mass elemental iron. Serious toxicity after acute ingestion is generally seen at doses of more than 50 mg elemental iron/kg. Life-threatening signs and symptoms and fatalities are more common when the ingested dose of iron is above 100 mg/kg. The clinical presentation of iron poisoning and its time course can be quite complex and go through different phases, particularly when dealing with young children if the ingested dose is very high.

Measurement of serum iron can be useful in the diagnosis and management of patients, but it is not an infallible guide. Early single measurements may be difficult to assess, particularly when iron is still being absorbed from the gut. Measurement of serum iron is of greatest value when considering the intravenous use of chelation therapy with desferrioxamine (Cheney *et al.* 1995; Schauben *et al.* 1990). The measurement of iron in urine is mainly used to assess the efficacy of iron removal using chelation therapy, but it can be of interest in dealing with cases of acute poisoning and in the management of iron overload. In cases of suspected fatal iron poisoning, measurement of iron in body fluids and tissues can be helpful.

Specimen collection

Specimens are collected as follows:

- Blood – 5 mL, plain tube
- Urine – aliquot of 24 h collection of value in the assessment of chelation therapy
- Vomit/stomach contents – generally only of value in forensic cases.

Analysis

Iron is traditionally measured in unhaemolysed serum by colorimetric assay. The two major approaches are coloured complex formation followed by spectrophotometry or AAS. Colorimetric procedures to quantify serum iron are usually available in hospital pathology departments and are suitable for rapid emergency analyses, although they are not reliable if desferrioxamine has been administered. More sensitive and specific ETAAS and ICP-MS procedures can be applied to the analysis of iron in serum, plasma, whole blood and urine, particularly in postmortem cases

Interpretation

Interpretation of serum iron concentrations in acute poisoning can be quite complex, particularly as the absorption of iron from the gut may be delayed or prolonged because of the ingestion of a sustained-release formulation.

Reference ranges for serum iron are dependent on age and sex, but typical values are:

Males 0.6–1.7 mg/L (10–30 μmol/L).

Females 0.5–1.5 mg/L (9–27 μmol/L).

On initial presentation a serum iron concentration above 3 mg/L (54 μmol/L) is associated with the presence of GI symptoms; clear signs and symptoms of toxicity are associated with concentrations between 3 and 5 mg/L (54–90 μmol/L); pronounced systemic toxicity is seen at concentrations between 5 and 10 mg/L (90–180 μmol/L); significant morbidity and mortality are associated with concentrations >10 mg/L (>180 μmol/L). However, if chelation therapy has been carried out using desferrioxime, it is not possible to interpret subsequent plasma iron concentrations. A range of serum iron concentrations of 2.8–25.5 mg/L (50–457 μmol/L) has been reported in children who survived the ingestion of up to 10 g ferrous sulfate (Baselt 2002). Children who died 3–5 days after ingesting 6–15 g of ferrous sulfate had serum iron concentrations of 19–50 mg/L (340–900 μmol/L) on the first and second days (Baselt 2002).

Lead

Introduction

The toxic effects of (inorganic) lead have been known since antiquity, but this metal still presents a significant public health problem in many parts of the world (Laraque and Trasande 2005; Needleman and Gatsonis 1990; Tong *et al.* 2000). Lead compounds (and other heavy metals) continue to be used as components of some traditional medicines (Bayly *et al.* 1995; Fisher and Le Couteur 2000; Hardy *et al.* 1998; Moore and Adler 2000). Acute lead poisoning is relatively uncommon, however, and most symptomatic cases result from chronic ingestion, or inhalation of lead fumes or dusts during occupational exposure, or use of lead-containing 'traditional' medicines and ingestion of lead paint chips or dust from old or substandard housing in children with pica (Braithwaite and Brown 1988; Carton *et al.* 1987). Other sources include the ingestion of lead objects such as fishing sinkers by children or adults with psychiatric or learning difficulties (Newton *et al.* 2005; St Clair and Benjamin 2008; Treble and Thompson 2002). Lead poisoning can also arise from retained bullets or lead fragments from gunshot wounds (McQuirter *et al.* 2001). Lead and its compounds are very rarely involved in suspected homicides, which may therefore go unrecognised, or the signs and symptoms may be confused with those of natural disease (Lech 2006).

In adults, barely 10% of ingested lead is absorbed from the GI tract; in children this proportion may be much higher. However, the bioavailability of ingested lead may be influenced substantially by the individual's diet and nutritional status (for example, iron and calcium deficiency will increase lead absorption from the GI tract). Lead absorbed by inhalation has a much greater bioavailability, but this may depend on factors such as respiratory rate, particle size, the atmospheric concentration of lead and the duration of exposure. Thus there can be a significant risk of lead poisoning in demolition workers using cutting tools, or those refurbishing old houses or other buildings by burning off lead paint, without using appropriate protection.

The clinical diagnosis of lead poisoning can be difficult when there is no clear history or apparent source of exposure, since many of the signs and symptoms of chronic lead poisoning are relatively non-specific (e.g. tiredness, abdominal pain, anorexia) (Cullen *et al.* 1983; Newton *et al.* 2005; Visvanathan 2001). Wider ranging laboratory investigations, therefore, play an essential part in the diagnosis and management of lead poisoning and also in the assessment of occupational and environmental lead exposure (Delves 1998).

Specimen collection

The recommended specimen collection for lead analysis is:

- Blood – 5 mL, K-EDTA tube (2 mL in children); check that the tube is lead free (certified lead-free tubes are commercially available)
- Urine – 20 mL, sterile plastic universal container (only useful after organolead exposure)
- Urine – 24 h collection (aliquot) only in the case of chelation therapy
- Water –20 mL, plain universal container.

Analysis

Published procedures to determine lead in blood, urine and other fluids, such as tap water or tissues (bone, teeth), are numerous. One of the most successful historical methods for blood lead measurement used flame AAS with the blood specimen introduced into the air–acetylene flame in a small nickel cup (Delves cup), and is still in routine operation in several parts of the world (Delves 1970). This has been superseded by ETAAS methods, which can determine blood lead concentrations accurately (<100 μg/L [0.5 μmol/L]) in 'non-exposed' populations (Bannon *et al.* 1994; Shuttler and Delves 1986). More recently, ICP-MS has been employed to measure lead in situations of low-level lead exposure. ICP-MS techniques are able to determine blood lead concentrations below 10 μg/L (0.05 μmol/L); also by measuring lead isotope ratios in biological specimens it is possible to correlate these with the likely sources of exposure that might be found in a chemical incident or poisoning from an unusual source of lead (Delves and Campbell 1988, 1993).

Interpretation

As mentioned, symptoms of lead poisoning are relatively non-specific and this can make its clinical diagnosis very difficult, particularly where the source of lead exposure is not known (Braithwaite and Brown 1988). Anaemia (haemoglobin <110 g/L) may be present at high blood lead concentrations (>1 mg/L [50 μmol/L]). Children with blood lead values of this order due to the ingestion of lead paint or use of traditional medicines may also develop severe symptoms of encephalopathy, although this is uncommon.

The best-understood toxic effect of lead is its influence on haemoglobin synthesis. leading to anaemia. Lead inhibits the enzyme ferrochelatase, which is involved in iron transport in the bone marrow and catalyses the introduction of ferrous iron (Fe^{2+}) into the porphyrin ring to form haem (Sakai 2000) (this is the last stage of haemoglobin synthesis). Chronic lead exposure leads to the incorporation of zinc (rather than iron) into the porphyrin ring to produce erythrocyte zinc protoporphyrin (ZPP). The assay of ZPP is relatively simple and is used as an inexpensive screening test for chronic lead exposure. However, raised levels of ZPP may also be found in those with iron deficiency anaemia (Solé *et al.* 2000). Monitoring the reduction in blood haemoglobin and the elevation in erythrocyte ZPP helps to assess chronic lead poisoning (Braithwaite and Brown 1988).

About 98% of the lead in blood is associated with the erythrocytes and has a half-life of a few months. Constant exposure results in the accumulation of lead in blood and tissues until a 'steady state' is reached. Provided that the degree and type of exposure are relatively constant, blood lead concentrations in environmentally, as well as in some occupationally, exposed individuals may be stable over long periods of time. Although lead can be found in most tissues of the body, over 90% of the body burden is deposited in the skeleton as insoluble lead phosphate. Following chronic exposure over many years, as occurs in some industrial workers, tissue stores such as bone become substantial. This can have a profound effect on the toxicokinetics of lead and associated long-term health risks. As a result, after cessation of exposure, blood concentrations may decline slowly with an elimination half-life of up to a year. This causes problems in occupational surveillance programmes where the benefits of reduced exposure of lead workers, as monitored by a decline in blood lead concentrations, may be underestimated by the continued contribution from bone and tissue stores (Mason and Williams 2005). Lead is poorly excreted from the body, the most important route being via the kidney. Normal urinary output of lead is less than 10 μg/day (50 nmol/day), but this can be increased greatly by chelation therapy. However, studies in rats suggest that chelating agents do not have access to bone lead stores; thus the skeleton may become a permanent internal reservoir of lead that is slowly released to soft tissues, causing toxicity over the lifetime of the individual.

Extensive studies have demonstrated the harmful effect of lead exposure on child development, behaviour and intelligence (Needleman

Table 17.6 Blood lead concentrations following occupational exposure as applied in the UK (Control of Lead at Work Regulations 1998)

Situation	*Concentration*[a]
Reference values in non-occupationally exposed adults (and children)	<10 μg/L (<0.5 μmol/L)
Action level in occupationally exposed females capable of bearing children	250 μg/L (1.2 μmol/L)
Suspension level in occupationally exposed females capable of bearing children	300 μg/L (1.5 μmol/L)
Action level in occupationally exposed males (400 μg/L in those under 18 years old)	500 μg/L (2.4 μmol/L)
Suspension levels in occupationally exposed males (500 μg/L in those under 18 years old)	600 μg/L (2.9 μmol/L)

[a]Reference values not given in regulations, but shown for comparison.

2006; Needleman and Gatsonis 1990; Shannon *et al.* 2005; Woolf *et al.* 2007). In adults and children a maximum blood lead concentration of 100 μg/L (about 0.5 μmol/L) is currently internationally recommended (Bellinger *et al.* 1992). However, recent evidence suggests that there may be intellectual impairment in children (from either pre- or postnatal exposure) with blood lead concentrations below 100 μg/L (Canfield *et al.* 2003; Shnaas *et al.* 2006). Somewhat higher levels may be acceptable in adults who are occupationally exposed to lead, but careful monitoring of exposure is essential. Occupational exposure limits apply in many countries; the current UK guidance is shown in Table 17.6. However, there is concern that current occupational limits are far too high (Schwartz and Hu 2007), particularly concerning occupational limits in female workers. There is evidence to show that pregnancy and lactation may cause mobilisation of lead from bone stores leading to an increased risk of lead toxicity to both the mother and her newly born child.

Lithium

Introduction

Lithium salts are used in the acute treatment of mania and in the prophylaxis of bipolar (manic–depressive) psychiatric disorders. These are usually prepared from lithium carbonate or citrate, and most are in the form of sustained-release preparations. The drug is well absorbed from the gut, with peak plasma lithium concentrations observed within 2 h for instant-release preparations and between 6 and 12 h for sustained-release formulations. Lithium is not bound to plasma proteins and is eliminated only via the kidneys. Plasma concentrations can accumulate to toxic levels if renal impairment develops. It is recommended that patients who receive therapy with lithium have regular monitoring to maintain plasma lithium concentrations in the therapeutic range. Nevertheless, overdosage with lithium, whether acute, acute on chronic or chronic, is relatively common (Bailey and McGuigan 2000). In acute overdosage the initial symptoms are largely of GI upset; signs and symptoms of central nervous system disturbance may then develop over the next 24 h as lithium is slowly distributed into the brain. Because of the delay in peak plasma lithium concentrations following ingestion of sustained-release preparations, toxicity may sometimes be unrecognised (Borras-Blasco *et al.* 2007). Most cases of chronic overdosage are due to renal impairment or interaction with other drugs and the main features are of central nervous system disturbance.

Signs and symptoms of toxicity include ataxia, tremor, dysarthria, slurred speech, drowsiness and coma. In assessing any case of suspected lithium poisoning it is important to obtain a full medical history, including dosage regime, use of other drugs and the results of any previous lithium measurements (Tyrer 1996).

Specimen collection

- Blood (5 mL) – a plain or K-EDTA tube. It is important to ensure that specimens are not taken into a lithium–heparin tube.

Analysis

Lithium can be quantified in biological fluids by various techniques including simple flame photometry, colorimetric assays, ion-selective electrodes, flame AAS and ETAAS. The specimens of choice are plasma or serum. Whole-blood measurements are possible using flame AES, although the presence of potassium in haemolysed specimens can cause falsely elevated values.

Interpretation

Recommended therapeutic concentrations of lithium in plasma or serum in the treatment of acute mania can be up to a maximum of 1.3 mmol/L; in the prophylaxis of bipolar disorders recommended values are generally 0.5–0.8 mmol/L. These may be associated with some side-effects such as gastrointestinal upset, polyuria, thirst and fatigue. Plasma lithium concentrations in cases of acute and chronic poisoning can often be very difficult to interpret clinically. Signs and symptoms of toxicity are generally associated with values above about 1.4 mmol/L, and values greater than 2 mmol/L require urgent medical attention. Lithium concentrations above 3 mmol/L, particularly in cases of chronic toxicity, can be life threatening and may require the use of active elimination therapy such as haemodialysis, which appears to be the therapy of choice (Eyer *et al.* 2006; Leblanc *et al.* 1996). Signs of toxicity following chronic or acute-on-chronic overdosage do not always correlate with the quantity of lithium ingested, with the serum lithium concentrations on admission to hospital, or with a fatal outcome (Waring *et al.* 2007).

Mercury

Introduction

Mercury has been used in the manufacture of thermometers and a range of other scientific and medical instruments for hundreds of years, but this use has now declined. Elemental mercury continues to be used widely across the world in a number of developing countries by subsistence gold miners using the mercury amalgamation process (Spiegel *et al.* 2005). Mercury and its compounds have also been used widely in the chemical industry and in the manufacture of drugs and pesticides. Some compounds, such as ethyl mercury derivatives, have been historically used as preservatives (thiomersal) in the manufacture of vaccines used in infants and young children. This has come under intense scrutiny, particularly regarding the aetiology of certain neuropsychiatric disorders such as autism. However, detailed follow-up studies in children do not support any causal link (Clements and McIntyre 2006; Hviid *et al.* 2003; Pichichero *et al.* 2002; Thompson *et al.* 2007). Dental amalgam fillings containing mercury are still used in many countries, although their use, particularly in children, does not appear to be associated with a risk of neurotoxicity (Bellinger *et al.* 2006; DeRouen *et al.* 2006; Needleman 2006).

The toxicity of mercury and its compounds is influenced greatly by the chemical form and valence state (Broussard *et al.* 2002; Clarkson *et al.* 2003; Nuttall 2004). The most toxic forms of inorganic mercury are its divalent (Hg^{2+}) water-soluble salts, particularly mercuric chloride, which was used as a disinfectant in earlier times. The fatal (oral) dose of mercuric chloride is less than 5 g in an adult, which led to its popularity as a homicidal and suicidal poison and gave it its popular name, corrosive sublimate. There is significant toxicity associated with both acute and chronic inhalation of (elemental) mercury vapour, which has a very high vapour pressure at normal room temperature (Broussard *et al.* 2002; Clarkson *et al.* 2003; Houeto *et al.* 1994; McNeil *et al.* 1984). Broken mercury thermometers can constitute a serious risk in children through inhalation of vapour, particularly in a home environment such as a bedroom (Velzeboer *et al.* 1997). Organic forms of mercury, such as methylmercury, are strongly neurotoxic and, being relatively lipid soluble, can accumulate in fatty tissues of the body such as the brain (Aschner and Syversen 2005; Bakir *et al.* 1973). Large-scale environmental disasters have occurred, such as that involving the Minimata Bay area in Japan where thousands of people died or became severely incapacitated. This

was caused by the factory discharge of industrial waste that contained mercury, which settled into the sediments of the bay and river and was methylated by microorganisms. The methylmercury became incorporated into the fish diet on which the residents of Minimata, a fishing village in Japan, largely existed, and this resulted in so-called Minimata disease (Ekino *et al.* 2007; Hachiya 2006). Mercury poisoning may also be seen after the use of traditional medicines and cosmetics (Ho *et al.* 2003; Kang-Yum and Oransky 1992; Soo *et al.* 2003; Weldon *et al.* 2000).

The signs and symptoms of acute and chronic mercury poisoning mainly involve the central nervous system, kidney or skin (Clarkson *et al.* 2003; Winship 1985). Characteristic symptoms in children include acrodynia ('pink disease'), which include signs such as pink hands and feet, which was historically associated with the use of mercurous chloride in teething remedies (Velzeboer *et al.* 1997; Warkany 1966). Mercury species may be retained in the body for a long time after the cessation of exposure, and blood elimination and urine excretion rates show long half-lives (Barregård *et al.* 1992; Nuttall 2004; Roels *et al.* 1987). Mercury may be excreted in the urine for 6–12 months after cessation of exposure, which makes urine measurements an attractive way to assess historical exposure and has advantages over use of other matrices such as hair or nails (Ritchie *et al.* 2004).

Specimen collection

Specimens are collected as follows:

- Blood – 10 mL, K-EDTA tube.
- Urine – 20 mL; a random 'spot' specimen in a sterile plastic universal container or aliquot of a 24-h collection (must be collected in a hard plastic container without preservative) is of greatest value in assessing chelation therapy). Preservation of mercury in stored specimens requires acidification and freezing.
- Hair – can be useful in environmental studies or unusual clinical cases.

Analysis

In the investigation of any suspected poisoning by or exposure to mercury, collection of both blood and urine specimens can be useful. In the case of acute symptomatic poisoning or recent exposure, blood specimen collection is particularly useful. In the case of 'historical poisoning' or the assessment of occupational exposure or that in asymptomatic patients, a 'spot' urine specimen is the initial sample of choice, although the stability of mercury in urine specimens is poor on prolonged storage.

Mercury is often determined in biological specimens (urine, blood and hair) using 'cold vapour' AAS, and a large number of reliable methods have been published (Ngim *et al.* 1988; Pineau *et al.* 1990). In recent years a number of commercial systems have been developed using flow cells that greatly increase sensitivity. The wider availability of ICP-MS has resulted in its use for mercury analysis of biological fluids, particularly blood, at very low levels of exposure (White 1999).

Interpretation

Reference values for mercury in non-exposed populations in blood are less than 4 μg/L (20 nmol/L) and less than 5 μg/L (25 nmol/L) in urine.

With chronic exposure there is generally a good association between exposure to mercury fumes and urine concentration, particularly where there is significant exposure. Blood and urine mercury concentrations can be more difficult to interpret at low levels of alleged exposure, where other sources of mercury from diet or mercury amalgams may contribute significantly. The current recommended BEI of the ACGHI (USA) for occupational exposure assessment is a pre-shift urine mercury (total) concentration of 35 μg/g creatinine or an end-of-shift, end-of-working-week blood mercury concentration of 15 μg/L (75 nmol/L).

In individuals with mercury amalgam fillings, urine mercury concentrations are rarely more than 8 μg/L (40 nmol/L). However, post-mortem studies have reported significantly higher concentrations of mercury in tissues such as brain in subjects with a greater number of amalgam fillings (Guzzi *et al.* 2006). Mercury from the diet (particularly fish) contributes to the concentration of mercury found in blood, but is usually well within the reference limits (see above). Populations who consume unusually large quantities of certain fish (e.g. swordfish) or of whale meat may accumulate high concentrations of (methyl) mercury (Kales and Goldman 2002). There is some evidence that such exposure presents a serious risk in pregnancy and early child development (Grandjean *et al.* 2003) or, in certain cases, loss of visual acuity or impairment of colour vision (Saldana *et al.* 2006). Hair mercury concentrations are generally <1 μg/g in individuals who do not eat fish, but elevated concentrations in hair can often be difficult to interpret and do not always correlate with blood mercury concentrations, or symptoms of toxicity (Nuttall 2006).

In cases of severe poisoning it is useful to monitor both blood and urine mercury concentrations, particularly when chelation therapy is given. Measurement of 24 h mercury excretion may be used as a guide to the efficiency of removal of chelated metal. Use of certain chelation challenge tests to assess the body burden of mercury in patients with ill-defined symptoms of alleged mercury toxicity may, however, be unreliable or associated with serious side-effects (Archbold *et al.* 2004).

Selenium

Introduction

Selenium is now firmly established as an essential trace element, although historically it was associated only with toxicity as a result of occupational or environmental exposure (Glover 1970; Yang *et al.* 1983). Selenium is found in nature mainly in the form of metal selenides in sulfide ores, sometimes in association with arsenic.

Most of the earliest reports of selenium toxicity are associated with poisoning in grazing livestock and the cause of 'alkali disease' and 'blind staggers' (Wilber 1980). The sources of selenium in such cases are particular plants that concentrate selenium when growing in selenium-rich soils. There are also well-documented early reports of chronic selenium toxicity (selenosis) in populations living in areas where there are excessive amounts of selenium in soil and water supplies, such as in parts of rural China.

There are many industrial uses of selenium, including the manufacture of solar and photoelectric cells, pigmented glass and ceramics. Selenium-compounds (e.g. selenium sulfide) are also used as anti-dandruff agents in shampoos and in gun-blueing compounds, which contain selenous acid. In the last decade there has been an increased interest and promotion of the value of selenium-containing nutritional supplements in the prevention of a wide range of disorders including degenerative illness, viral infections and various forms of cancer. Some supplements may contain relatively high concentrations of selenium, which may cause toxicity if ingested in excess (Clark *et al.* 1996).

Selenium is a metalloid placed in group VI of the periodic table. Common oxidation states of selenium are 2+ (selenide), 4+ (selenite) and 6+ (selenate). There are also a number of important organoselenium compounds in which selenium is able to substitute for sulfur (e.g. selenocysteine and selenomethionine). Recent years have seen a large increase in our understanding of the essential biological role of selenium, and important selenoproteins and glutathione peroxidases (GSHPx) are found in most tissues of the body (Thompson 1998). Selenium has been shown to have an important role in thyroid function, fertility (particularly sperm motility), mood regulation and immunity to infectious disease, and as a cellular 'antioxidant', acting in association with vitamins E and C (Rayman 2000; Reilly 1993). Deficiency of selenium is associated with a number of disorders, such as Keshan disease (China), and more recently with an increased risk of cancer (Bjelakovic *et al.* 2004). Selenium can also have a protective role in ameliorating human exposure to mercury (Hansen 1988).

In cases of chronic occupational or environmental exposure, selenium is associated with signs and symptoms such as skin irritation, garlic breath, painful and discoloured nails, brittle hair and alopecia. Toxicity may occur after ingestion or inhalation of different selenium compounds. However, elemental selenium is poorly bioavailable and organoselenium compounds, although very bioavailable, are relatively non-toxic. In comparison, soluble inorganic selenium compounds, particularly the selenites, selenious acid and selenious oxide and dioxide (following their *in vivo* conversion to selenious acid) are extremely toxic if ingested and are linked to severe intoxications or fatalities (Alderman and Bergin 1986; Brighthope 2007; Gasmi *et al.* 1997; Handsacker *et al.*

2005; Köppel *et al.* 1986; Lombeck *et al.* 1987; Matoba *et al.* 1986; Quadrani *et al.* 2000; Schellmann *et al.* 1986; Spiller and Pfiefer 2007).

Specimen collection

Specimens are collected as follows:

- Blood – 5 mL, K-EDTA tube
- Urine – aliquot of 24 h collection in severe cases of acute poisoning
- Stomach contents – useful in fatalities
- Scene residues – useful for identification purposes.

Analysis

Most earlier methods for measuring selenium in blood were based on fluorimetry. Techniques recently described include LC and GC, ETAAS by direct analysis or after hydride generation and ICP-MS, which can also measure selenium in tissues (Sheehan and Halls 1999). Reference materials suitable for internal accuracy control are commercially available, and a number of external quality-assessment schemes include the analysis of selenium in plasma and blood.

Interpretation

Reference ranges for selenium in whole blood and plasma vary from country to country because of differences in dietary sources of selenium. In the UK, adult plasma reference ranges are generally between 70 and 130 μg/L (0.9 and 1.7 μmol/L), with a median population value of approximately 90 μg/L (1.2 μmol/L).

The reference range for children is much lower than that of adults, particularly in babies and younger children (serum selenium approximately 35–115 μg/L). Reference values for whole-blood selenium are somewhat higher and are generally within the range 80–180 μg/L in adults. Values for plasma and blood selenium are greatly influenced by diet, particularly the intake of foods high in selenium content, such as Brazil nuts, or use of supplements containing selenium. Urine excretion of selenium may vary widely, depending on intake, but is usually within the range 20–200 μg/L. Measurement of urine selenium can be useful in monitoring occupational exposure to selenium compounds.

In cases of acute poisoning, very high concentrations of selenium may be detected in whole blood, plasma and urine. Blood selenium values below 1000 μg/L (12 μmol/L) indicate minimal toxicity, whereas values above 2000 μg/L (25 μmol/L) predict serious complications (Gasmi *et al.* 1997).

Thallium

Introduction

Thallium salts, particularly the sulfate, were introduced into medicine in the late nineteenth century for the treatment of several disorders, including the treatment of syphilis, but were soon discarded because of their toxicity. A somewhat later and lasting therapeutic application was as a depilatory agent in the treatment of ringworm of the scalp, particularly in children. This continued up until the 1940s, despite frequent problems associated with thallium toxicity, including many deaths. Thallium salts were also introduced as rodenticides in the 1920s and continue to be applied in some countries. Modern industrial uses of thallium salts include the manufacture of cosmetic jewellery, pigments, semiconductors, fireworks and optical lenses, and in producing special alloys for seawater batteries.

Most thallium compounds are colourless, tasteless and odourless. The water-soluble salts of thallium include the sulfate, acetate and carbonate, all of which are highly toxic (Aoyama *et al.* 1986; Moore *et al.* 1993; Saddique and Peterson 1983). The fatal oral dose in adults is thought to be 1–2 g. The clinical picture of thallium poisoning is highly complex, and poisoning can be very difficult to diagnose in its early stages and may be confused with colchicine poisoning, food poisoning or Guillain–Barré syndrome (Hoffman 2003; Matthews and Dubowitz 1977). Initial signs and symptoms of acute thallium poisoning may not be particularly severe but usually include abdominal pain, nausea, vomiting and diarrhoea, sometimes followed by constipation (Hoffman 2003; Villanueva *et al.* 1990; Wainwright *et al.* 1988). Neurological symptoms may develop over about 1–2 weeks and include both peripheral and central neurological changes (Cavanagh 1991; Cavanagh *et al.* 1974). The most characteristic feature is that of a rapidly progressive ascending peripheral neuropathy. Cardiovascular changes, such as an increase in blood pressure and tachycardia, may also develop after 1–2 weeks. The most characteristic signs associated with thallium toxicity are dermatological changes, which may take up to 4 weeks to develop fully, and include within the first week an initial dark brown or black pigmentation of the roots of the hair (only visible under a microscope) followed by a gradual loss of body hair (mainly scalp hair), which can result in total alopecia after about one month. Nail growth may also be impaired, with the development of white transverse lines, similar to those seen with arsenic poisoning. Thallium salts have a high oral bioavailability but the metal's pharmacokinetics are quite complex, with a high distribution volume and long terminal elimination half-life of between 1 and 4 weeks (Hoffman 2003). The mechanism of thallium toxicity is poorly understood. Because thallium has a similar ionic radius to that of potassium, it is thought that cell membranes are unable to differentiate between the two elements. As a consequence, thallium is able to accumulate in areas of the body with a high potassium content, such as the central and peripheral nervous systems. At high concentrations, thallium will also inhibit potassium-dependent enzyme systems, including those involved with energy production within the citrate cycle. Accidental poisoning with thallium is relatively uncommon in those countries that no longer permit the use of thallium as a rodenticide. However, thallium poisoning has been reported in some historical cases involving the adulteration of illicit drugs such as diamorphine and cocaine and, more recently, in suspected homicides, including political assassinations.

Specimen collection

Specimens are collected as follows:

- Blood – 5 mL, K-EDTA tube
- Urine – 20 mL, sterile plastic universal container (24 h collection only of value in monitoring oral antidotal therapy with Berlin [Prussian)] blue). Additional specimens that may be of forensic interest include hair and nails.

Analysis

Historically, the most commonly used approach to the analysis of thallium in blood or urine involves the use of ETAAS. More recently, ICP-MS has become the technique of choice, being easily applied to the analysis of thallium in a wider range of matrices including hair and nails (Hann *et al.* 2005; Yoshinaga *et al.* 1993).

Interpretation

Reference values for thallium in blood and urine are below 1 μg/L (5 nmol/L), and concentrations in excess of 100 μg/L (0.5 μmol/L) in blood and 200 μg/L (1 μmol/L) in urine are associated with toxicity. In particularly severe cases of thallium poisoning, extremely high levels of thallium in blood (>300 μg/L) and urine (>600 μg/L) may be recorded within the first few days after ingestion. Fatalities are associated with blood thallium concentrations in excess of 2500 μg/L (Hologgitas *et al.* 1980). A recent study has indicated that, in the case of short-term thallium intoxications, dematological findings appear to correlate with thallium concentrations. Measurement of thallium excretion in urine is useful in cases for which oral antidotal therapy with Berlin (Prussian) blue (potassium ferric hexacyanoferrate) is instituted (Heath *et al.* 1983; Hoffman 2003; Pedersen *et al.* 1978). This dye forms an insoluble complex with thallium in the gut, which leads to enhanced faecal excretion. Tissue concentrations of thallium have been reported in fatal cases of thallium poisoning, ranging up to 178 μg/g (wet weight) (Davis *et al.* 1981).

Anions

The systematic analysis of anions in body fluids presents a major analytical challenge. Historically, the main approach was the analysis of stomach contents and scene residues using classic colorimetric methods of analysis (Yeoman 1985). However, many anions are unstable and undergo rapid breakdown in the stomach and gut after absorption. The analysis of metabolites and various hydrolysis products in blood or urine using modern methods is also not well described. In some cases,

the investigation of poisoning caused by anions that are oxidising agents (e.g. chlorates) is best carried out by measurement of changes in blood chemistry, such as the formation of oxidised haemoglobin (methaemoglobin).

The development of analytical techniques such as ion chromatography to separate and measure anions in biological fluids has been slow. However, increased application of ICP-MS techniques has greatly enhanced the ability to detect the presence of elevated concentrations of particular elements (e.g. bromine, boron and iodine) in biological fluids and tissues that may indicate the ingestion of particular anions. Classic analytical chemical methods (colour tests) may sometimes still be applicable for cases in which stomach contents or scene residues are available (Yeoman 1985).

Borates

Introduction

Boric acid has been used as an antiseptic for external use for more than 100 years but has generally been superseded by modern agents. Sodium borate (borax) is still used in cleaning agents, contact lens solutions, wood preservatives, pesticides and fungicides. Boric acid has also been used as a preservative in urine specimens requiring bacteriological examination. Boron is widely distributed in the environment and is a normal constituent of the diet, including drinking water (Murray 1995). Boron is an essential element in plants, but its role as an essential trace element in animals is less well established. A number of clinical studies suggest that boron deficiency in humans might be significant in a wide range of disease states such as osteoporosis, arthritis and dementia. Boron-containing supplements have been promoted by the complementary health sector and there is the potential for excessive self-medication and toxicity.

Compounds of boron have relatively low toxicity and reports indicate that following a single acute ingestion symptoms are often very mild However, a number of cases of acute and chronic boron poisoning have been reported in children and adults (Hamilton and Wolf 2007; Linden *et al.* 1986; O'Sullivan and Taylor 1983; Wong *et al.* 1964). Signs and symptoms have generally included nausea and vomiting, diarrhoea and abdominal pain. In some cases patients may develop a generalised erythoderma sometimes described as a 'boiled lobster' appearance. Seizures, coma and renal dysfunction have been described in more severe cases.

Specimen collection

Specimens are collected as follows:

- Blood – 5 mL, K-EDTA tube
- Urine – 20 mL, sterile plastic universal container
- Stomach contents – useful in postmortem examination
- Collection of hair specimens may be useful in cases of chronic non-accidental administration.

Analysis

Transfer a portion of the sample to an evaporating basin, add 1 mL sulfuric acid and 3 mL of ethanol, and ignite. A green border around the flame indicates the presence of borate.

Quantitative methods Historically, borate has been measured in biological fluids and tissues by colorimetric procedures using carminic acid as a reagent. More recently, ETAAS has been used to investigate cases of suspected acute poisoning where the blood boron concentrations are high enough to compensate for the poor sensitivity of the methods. ICP-MS is far more sensitive and has been used successfully to measure the concentration of boron in blood and tissues in patients who receive treatment with boron-containing drugs such as boronphenylalanine (BPA) as part of boron neutron capture therapy of certain cancers (Morten and Delves 1999; Goulé *et al.* 2005).

Interpretation

Extremely high concentrations of boron have been detected in cases of acute poisoning with borates, particularly in children (Linden *et al.* 1986). Plasma boron concentrations ranging from 200 mg/L to 1600 mg/L have been reported in fatal cases. Survival has been reported in cases of adult poisoning despite admission boron concentrations in excess of 1000 mg/L. Reference values in healthy adults show blood boron concentrations between 14 and 44 μg/L, plasma concentrations between 19 and 79 μg/L, urine concentrations between 282 and 2072 μg/L and hair values between 0.26 and 1.87 μg/L (Goulé *et al.* 2005). There are no data on children or populations consuming food or water supplies with a high boron content that could greatly influence urine excretion of boron.

Bromide

Introduction

Bromide salts (e.g. ammonium, potassium and sodium bromides) were first introduced into medicine in the nineteenth century and were used extensively as anticonvulsants and sedatives. With the exception of organic bromides such as carbromal (a sedative), their use is now limited. However, potassium bromide may still be found in traditional medicines used in the treatment of epilepsy. Bromates have been used as preservatives and detonators. Methyl bromide is a colourless gas most commonly used as an insecticidal fumigant for grain stores and soil, but has also been used historically as a refrigerant and in fire extinguishers. Its use should eventually be phased out under the Montreal Protocol on Substances that Deplete the Ozone Layer, but is currently still in use in many parts of the world. Methyl bromide releases bromide ion as a metabolite and is associated with accidental poisoning, particularly within an occupational setting (Yamano and Nakadate 2006).

Following ingestion of bromide salts, absorption of bromide ion takes place rapidly from the stomach and proximal small intestine by passive diffusion. Bromide ions behave like chloride ions and are distributed mainly in extracellular fluid. The most important route of elimination is via the kidney. Their elimination half-life is relatively long, being of the order of 10 days after acute dosing, or several weeks following the cessation of chronic intake, particularly in cases of bromide intoxication.

Bromide poisoning may cause complex neurological symptoms (e.g. tremor, ataxia, autonomic disturbance, cognitive impairment) and clinical diagnosis can be difficult if the use of bromide salts is not suspected. Methyl bromide intoxication has been associated with a reversible symmetrical brain-stem and cerebellar MRI lesion, indicating that bromide exposure can produce an acute 'toxic energy deprivation syndrome' that is normally associated with nutritional and genetic disorders such as Wernicke's encephalopathy (Geyer *et al.* 2005). In contrast, bromate intoxication is associated with the development of irreversible hearing loss due to damage to the cochlea.

Specimen collection

Specimens are collected as follows:

- Blood – 5 mL, heparinised or EDTA tube
- Urine – 2- mL, sterile plastic universal container
- Stomach contents – useful in postmortem examination of fatalities
- Scene residues – useful for identification purposes.

Analysis

For the analysis of bromide ions in blood, plasma or urine, colorimetric procedures, ion-selective electrodes, GC or ICP-MS has been described (Corina *et al.* 1979; Quinones *et al.* 2006; Sunshine 1975). Routine clinical biochemistry methods for plasma chloride analysis can show spuriously elevated values when high levels of bromide ion are present (Wenk *et al.* 1976). One of the older colorimetric methods based on the reaction with gold chloride (Sunshine 1975) is still a useful technique for the rapid measurement of bromide ions in serum in cases of acute intoxication. The limit of detection of this method is 50 mg/L using 1 mL of specimen. A suitable calibration range is 100–2000 mg/L bromide ion. More recently, a number of ion-chromatographic methods have been developed to separate bromide and bromate in water disinfection by ozonisation (Schminke and Seubert 2000). The wider availability of ICP-MS makes analysis of bromide ion in biological fluids and tissues relatively easy, with a very low limit of detection.

Table 17.7 Plasma bromide concentrations in relation to 'therapeutic' use and intoxication

Situation	*Plasma bromide ion (mg/L)*	*Equivalent plasma bromide ion (mmol/L)*
'Normal' reference values	<5	0.05
Peak concentration after single oral dosage of 100 mg Br/kg	230	2.9
'Therapeutic' concentrations in adult epileptics	750–1000	9.3–12.5
Signs of intoxication	>1000	12.5
Signs and symptoms of severe intoxication	>3000	37.5

Interpretation

Although there is a complex relationship between bromide ion concentration and signs and symptoms of toxicity, measurement of bromide is helpful in the diagnosis and management of cases of intoxication. Table 17.7 shows reference values of bromide and typical concentrations after therapeutic use and for cases of bromide intoxication (Maes *et al.* 1985; Vaiseman *et al.* 1986). Elimination of bromide from the body may be extremely slow in cases of intoxication without the use of active elimination therapy (e.g. diuresis, haemodialysis or haemofiltration).

Chlorate

Introduction

Sodium chlorate ($NaClO_3$) is an effective, inexpensive, non-selective herbicide. Potassium chlorate is used in the manufacture of matches and some explosives. Both compounds are powerful oxidising agents. Early signs and symptoms of chlorate poisoning include nausea, vomiting and abdominal pain (Steffen and Seitz 1981; Vaiseman *et al.* 1986). Systemic absorption leads to substantial oxidation of haemoglobin to form methaemoglobin, which may cause cyanosis, dyspnoea, anuria and coma (Ellenhorn 1997). Intravascular haemolysis and severe metabolic acidosis may also occur (Ellenhorn 1997). Ingestion of potassium chlorate may cause hyperkalaemia.

Specimen collection

Specimens are collected as follows:

- Blood – 5 mL, lithium–heparin tube
- Urine – 20 mL, sterile plastic universal container
- Stomach contents – useful in investigation of fatalities
- Scene residues – useful for identification purposes.

Analysis

In clinical cases of chlorate poisoning the diagnosis rests on measurement of methaemoglobin, which is easily carried out as part of a routine biochemical analysis.

A method that involves ion chromatography for the direct analysis of chlorate in body fluids and tissues has been described by Eysseric *et al.* (1999). Ion chromatography can resolve chlorate from closely related anions such as nitrate, bromate and phosphate.

Interpretation

Serious and sometimes fatal poisoning can occur after the ingestion of 15 g or more of sodium or potassium chlorate. The case described by Eysseric *et al.* (1999) involved a 49-year-old man who was admitted to hospital with severe features associated with chlorate poisoning. He had acute haemolysis with a plasma haemoglobin of 3.9 g/L and 30% methaemoglobin formation. High concentrations of chlorate ion were found in the admission plasma (54 mg/L), gastric contents (1300 mg/L) and urine (4300 mg/L). The patient died 12 h after admission.

Cyanide

Introduction

Severe or fatal cyanide poisoning is relatively rare and mostly involves suicidal ingestion of cyanide salts. Hydrogen cyanide (HCN; prussic acid) is a highly toxic volatile liquid. Fumes of hydrogen cyanide are given off when cyanide salts are mixed with acids or produced in the stomach following oral ingestion. Although HCN has a characteristic almond-like odour, up to 50% of the population are unable to smell it. Surprisingly, it was not a characteristic feature *post mortem* of a large series of cyanide suicide deaths, although this could have been related to air-flow ventilation systems in postmortem rooms (Gill *et al.* 2004). Soluble salts of cyanide include potassium and sodium cyanide, which are used industrially in electroplating and metal processing and as laboratory reagents. Less soluble salts of cyanide include silver and gold cyanide, and mercuric cyanide, which also release HCN on contact with strong acids. As a general rule most cyanide suicide deaths are reported in those individuals, mostly male, who have occupational access to cyanide salts. HCN may also be formed as a combustion product in fires from nitrogen-containing materials such as wool and silk or synthetic polymers such as polyurethanes, polyamides and polyamides (Barillo *et al.* 1994; Baud *et al.* 1991; Chaturvedi *et al.* 2001). Less common sources of cyanide include the accidental or intentional ingestion of cyanogenic plants or their seeds.

The signs and symptoms of cyanide toxicity appear rapidly after inhalation of HCN or ingestion of cyanide salts; the estimated fatal doses are approximately 100 mg HCN or 300 mg potassium cyanide (Ellenhorn 1997). Early neurological signs include headache, dizziness, anxiety and confusion. In severe cases there may be a rapid loss of consciousness, respiratory failure and convulsions that lead to cardiorespiratory arrest and death. The mechanism of cyanide toxicity is to block electron transport in the cytochrome a-a_3 complex; this leads to a dramatic fall in oxidative metabolism and cellular hypoxia, which most directly affects the brain and heart. Cyanide is metabolised rapidly in the liver by an enzyme (rhodanase) to thiocyanate (SCN), which is largely non-toxic. As a consequence, blood cyanide concentrations decline rapidly after exposure or ingestion, with an estimated elimination half-life of 1–2 h.

A number of antidotes are useful in the treatment of cyanide poisoning (e.g. cobalt EDTA and hydroxocobalamin). The measurement of blood cyanide concentrations is rarely useful in a medical emergency when dealing with the acute management of a patient. It can be useful in the retrospective evaluation of the severity of cyanide ingestion and in assessment of the efficacy of different antidotes. Measurement of blood cyanide is most useful in the investigation of suspected cyanide poisoning and in fire-related deaths, including aircraft accidents.

Specimen collection

Specimens are collected as follows:

- Blood – 10 mL, lithium–heparin or K-EDTA container
- Stomach contents – useful as part of postmortem examination, but great care is required because of the risk of secondary cyanide exposure
- Cyanide in blood is stable if kept at 4°C for up to 1 week, but is unstable if frozen or kept at room temperature. However, contradictory findings regarding cyanide stability in whole blood have often been reported (Lindsay *et al.* 2004).

Analysis

Numerous methods have been described for the analysis of cyanide in biological fluids. These involve colorimetric, fluorimetric or chromatographic techniques (Cruz-Landeira *et al.* 2000; Dunn and Siek 1990; Felscher and Wulfmeyer 1998; Gambaro *et al.* 2007; Lindsay *et al.* 2004; Lundquist *et al.* 1987; Odoul *et al.* 1994; Suzuki *et al.* 1982). Some of these methods can be laborious and are generally unsuited to the emergency diagnosis and management of patients (Lindsay *et al.* 2004). Many described methods are devoted to the forensic examination of postmortem blood and stomach contents. Some methods are based on the formation of the purple-coloured complex 2-nitrophenylhydroxylamine (Guilbart and Kramer 1966).

This complex is formed by the reaction of cyanide in alkaline solution with 4-nitrobenzaldehyde and 1,2-dinitrobenzene, and the reaction has been adapted for quantitative Conway diffusion methods (Dunn and Siek 1990; Flanagan *et al.* 1995). As this method has an unstable endpoint, great care is required in standardising the analytical procedure to ensure accurate results. However, a significant innovation described by Vesey *et al.* (1999b) has made major improvements. The new procedure is very much faster (<30 min) and has a stable endpoint that makes it suitable for the rapid analysis of blood cyanide in clinical cases.

A useful fluorimetric method has been described by Suzuki *et al.* (1982), which is based on the reaction of cyanide with pyridoxal 5-phosphate to produce highly fluorescent 4-pyridoxic acid 5-phosphate in acid solution. This method can be applied to both clinical and forensic cases, requires only 50 µL of blood and has a limit of detection of 0.1 mg/L. Analysis of plasma or urine thiocyanate may help to assess 'chronic' cyanide exposure, including the use of cyanogenic compounds (Haque and Bradbury 1999; Vesey *et al.* 1999a). This may be important in patients with renal impairment, in whom thiocyanate may accumulate to high levels and cause toxicity. The presence of thiocyanate and thiosulfate at concentrations of up to 50 mg/L does not interfere with the determination of cyanide (R Braithwaite, unpublished findings).

Interpretation

Very small quantities of cyanide are found in blood from normal metabolic processes and also from smoking. Reference values are somewhat variable. A recent review of published studies showed that reference values in non-smokers ranged between <0.01 and 0.08 mg/L, whereas in smokers values ranged between <0.01 and 0.18 mg/L (Lindsay *et al.* 2004).

Minor signs and symptoms of cyanide toxicity are associated with blood cyanide concentrations up to 1 mg/L. Severe symptoms are generally associated with higher concentrations, which may be as high as 20 mg/L on admission to hospital after suicidal ingestion or industrial exposure (Singh *et al.* 1989).

In postmortem cases after suicidal ingestion of cyanide salts, blood cyanide concentrations above 10 mg/L are generally observed. However, it is important to ensure that blood specimens are taken from reliable peripheral sites, such as the femoral vein. In cases of oral ingestion of cyanide salts, elevated (>50 mg/L) blood cyanide concentrations may sometimes be found in samples taken from the heart or other central sites; the cause is postmortem diffusion of unabsorbed cyanide from the stomach. In a study of 17 cases of suicide by cyanide reported from New York, postmortem blood cyanide concentrations ranged between <1 and 185 mg/L, with a mean value of 38 mg/L. However, the site of blood collection was not stated. The amount of cyanide detected in gastric contents ranged between 2 and 2218 mg, with an average of 232 mg (Gill *et al.* 2004). Fires can also generate considerable quantities of HCN (as well as carbon monoxide and a range of other toxic gases) and this may result in relatively high concentrations of cyanide in the blood of fire victims (Alarie 2002; Canfield *et al.* 2005; Lindsay *et al.* 2004; Yeoh and Braitberg 2004). In a study of fire victims who survived, blood cyanide concentrations ranged from 'not detected' to 3.9 mg/L, while fatal cases had levels of up to 7.4 mg/L (Lindsay *et al.* 2004). It seems clear that there is a synergistic effect between carbon monoxide and cyanide in causing toxicity and possible survival in accidents. This issue has been studied in some detail in the case of aviation accidents, where it has been shown useful to take into account the concentration of both carboxyhaemoglobin and cyanide in the blood (Canfield *et al.* 2005). An additional factor that may need to be taken into account in the interpretation of blood cyanide concentrations in fire victims is the amount of methaemoglobin present, which is able to sequester cyanide in the form of cyanomethaemoglobin (Moriya and Hashimoto 2003). There is evidence that administration of cyanide antidotes such as hydroxocobalamin at the fire scene, prior to hospitalisation, may save lives and that the benefits outweigh the risks (Boron *et al.* 2007; Fortin *et al.* 2006).

Where there is evidence of putrefaction, particularly in postmortem specimens, it is possible for bacterial or fungal contamination to either break down or generate cyanide in the body or in specimens. This can be reduced by collecting blood into anticoagulated tubes that contain sodium fluoride (Curry *et al.* 1967; Lokan *et al.* 1987).

Fluoride

Introduction

Fluoride is present in variable amounts in the soil and natural water supplies. It is also found in almost all plant and animal food products and is regarded as an essential trace element. Fluoride may also be added to domestic water supplies as a prophylaxis against dental caries, generally at a concentration of 1 mg/L where the 'natural' water content is low. Inorganic salts of fluoride have widespread use in industry, for example in smelting aluminium, and are also applied as insecticides and rodenticides. Fluoride is an effective enzyme inhibitor that has found extensive use in the preservation of biological specimens. The highly corrosive hydrofluoric acid (HF) is widely used industrially, for example in cleaning processes such as rust removal and in surface etching techniques. Different strengths of HF may be used industrially and the anhydrous form of the acid is particularly dangerous, following even minor exposure to skin (Huisman *et al.* 2001). Following ingestion, HF is rapidly absorbed from the stomach, causing extensive internal damage to tissues. Surface acid burns can also be particularly painful following deep penetration into tissues.

Acute and chronic poisoning caused by the ingestion of fluoride salts have been well documented (Augenstein *et al.* 1991; Gessner *et al.* 1994; Poklis and Mackell 1989; Sandy and Rose 1988). Fluoride compounds are available in tablet form to prevent dental decay in infants and children. They are also prescribed in the treatment of osteoporosis and other bone disorders. Signs and symptoms of acute fluoride poisoning by different routes of absorption include nausea, vomiting, diarrhoea and abdominal pain. In cases of oral ingestion of dilute concentrations of HF there may only be minimal damage to the oral mucosa but extensive damage to the lower GI tract. In severe cases there may be significant erosion of tissue and the development of hypocalcaemia, hypomagnesaemia and hyperkalaemia. This may also be associated with signs of cardiotoxicity including heart rhythm disturbances (Martinez *et al.* 2007). Chronic exposure to fluoride compounds has been associated with the development of osteofluorosis. Concern has also been expressed regarding the amount of fluoride in drinking water and possible association with hip fractures in the UK, but a large case–control study found no evidence of increased risk (Hillier *et al.* 2000).

Specimen collection

Specimens are collected as follows:

- Blood – 5 mL, plain or K-EDTA tube (avoid fluoride and/or oxalate anticoagulated containers)
- Urine – 10 mL, sterile plastic universal container
- Water – 10 mL, plastic universal container.

Analysis

Numerous colorimetric and spectrophotometric methods for the analysis of fluoride in biological fluids have been described (Cowell 1975). Some of these methods are very laborious to perform, particularly if fluoride has to be separated first by a diffusion process. A more convenient approach is to use an electrode specific to fluoride ions (Ekstrand 1977; Kissa 1987; Ohlson and Sheridan 1991; Speaker 1976). However, great care must be taken in the use and calibration of these electrodes (Kissa 1987; Martinez *et al.* 2007).

Interpretation

Reference ranges for serum, blood and urine vary widely, depending on dietary intake, access to fluoridated water and the use of fluoridated dental products. Reference ranges of 6–42 µg/L (serum) and 20–60 µg/L (blood) have been reported. For urine, a reference range of 0.2–3.2 mg/L has been reported, depending on dietary intake. Administration of multiple doses of 3–4.5 mg of fluoride yield steady-state plasma fluoride concentrations between 54 and 145 µg/L (Ekstrand *et al.* 1977). The therapeutic range for plasma fluoride concentrations in the treatment of osteoporosis is between 100 and 200 µg/L, with side-effects occurring at concentrations >300 µg/L. In fatalities, a wide range of antemortem and postmortem blood and urine fluoride concentrations have been reported. Fluoride concentrations in blood have ranged between 0.5 and 85 mg/L, whereas urine concentrations have ranged between 5 and 320 mg/L (Martinez *et al.* 2007) In a recent case of a suicidal

ingestion of rust remover by a 33-year-old psychiatric patient who died within 3 h of ingestion, the peripheral blood fluoride concentration was 19 mg/L, urine 670 mg/L, liver 40 mg/kg and kidney 60 mg/kg. The estimated dose of fluoride ingested was estimated to be 2.5–5 g (Martinez *et al.* 2007).

Nitrites and nitrates

Introduction

Sodium nitrate finds uses in artificial fertilisers, food preservatives and explosives (as do the potassium salts). Sodium nitrite is also used as a food preservative and in the manufacture of explosives, but has the additional property of causing vasodilatation, which has led to its application in treating angina pectoris. Organic nitrates (e.g. glyceryl trinitrate, isosorbide mononitrate and dinitrate) release nitrite ion when ingested and are also used as vasodilators. Intravenous injection of sodium nitrite to induce methaemoglobinaemia has been used to treat cyanide poisoning. Nitrite ion is rapidly converted into nitrate ion by the body. Symptoms of nitrate and/or nitrite poisoning include nausea, vomiting, diarrhoea, abdominal pain, confusion and coma. These strong oxidising agents can cause a life-threatening methaemoglobinaemia to which infants are particularly susceptible. Methaemoglobin measurement is the most useful test in the diagnosis and clinical management of poisoning cases. Treatment with oxygen and methylene blue to reduce methaemoglobin can be an effective therapy.

Specimen collection

Specimens are collected as follows:

- Blood – 10 mL K-EDTA tube
- Urine – 20 mL sterile plastic universal container.
- Stomach contents and scene residues may also be useful.

Analysis

A number of methods are used to quantify nitrate and nitrites in biological fluids, based on spectrophotometric or chromatographic techniques (El Menyawi *et al.* 1998; Giovannoni *et al.* 1997; Kage *et al.* 2002b; Moshage *et al.* 1995).

Interpretation

Plasma nitrite and nitrate concentrations in unexposed subjects are about 0.2 mg/L and 1.2 mg/L, respectively. Serum nitrite levels of 0.5 and 0.6 mg/L were measured in two men who became cyanotic after accidentally ingesting about 1 g of sodium nitrite, but survived after treatment (Sevier and Berbatis 1976). A child who absorbed sodium nitrite from a liniment solution applied to the skin developed a severe cyanosis and died some days later with a serum nitrite concentration of 1.0 mg/L and a blood methaemoglobin level of 76% (Saito *et al.* 1996). In a fatal suicide, nitrite concentrations were 0.5 mg/L (blood), 0.3 mg/kg (kidney), 8.7 mg/L (urine) and 3.9 mg/L (gastric contents) (De Beer *et al.* 1975).

Phosphine and phosphides

Introduction

Phosphine (hydrogen phosphide; PH_3) is a highly toxic colourless gas with a strong garlic or fishy smell; it is used in a number of industrial processes (e.g. the production of acetylene gas and manufacture of semiconductors). It is also generated by the action of moisture on phosphides. Aluminium phosphide is used extensively as a cheap and effective grain fumigant and rodenticide in developing countries. Aluminium phosphide poisoning has a high mortality and the 1990s have seen a dramatic increase in the number of poisoning cases and deaths caused by suicidal ingestion, particularly in India (Christophers *et al.* 2002). Poisoning cases involving inhalation of phosphine gas or ingestion of phosphides have also occurred in many European countries (Anger *et al.* 2000; Bayazit *et al.* 2000; Gregorakos *et al.* 2002; Memis *et al.* 2007; Popp *et al.* 2002).

Signs and symptoms of poisoning include headache, nausea, vomiting, cyanosis, coma, non-cardiogenic pulmonary oedema and heart rhythm disturbance, which may progress to hepatic and renal failure (Guale *et al.* 1994; Lakshmi 2002; Popp *et al.* 2002; Singh *et al.* 1996). Methaemoglobin formation has also been reported (Lakshmi 2002). Histological changes in liver and brain following postmortem examination of phosphine-related deaths have recently been reported (Saleki *et al.* 2007; Tripathi and Pandey 2007).

Specimen collection

Specimens are collected as follows:

- Blood – 10 mL, lithium–heparin or K-EDTA tube (use of special trace element tubes is recommended if the analysis of aluminium is to be carried out; glass containers should not be used)
- Urine – 20 mL, sterile plastic universal container
- Stomach contents – useful in postmortem cases
- Scene residues – may be useful for identification purposes.

Analysis

A quantitative test for phosphine in gastric contents can be carried out using a commercial detector tube (Guale *et al.* 1994). Phosphine can be measured in body fluids and postmortem tissues by headspace analysis and GC with either nitrogen–phosphorus detection or mass-selective detection (Anger *et al.* 2000; Chan *et al.* 1983; Chugh *et al.* 1996). Alternative approaches include the measurement of aluminium in blood using ETAAS or ICP-MS (Anger *et al.* 2000; Garry *et al.* 1993). Phosphorus can also be measured by ICP-MS (Anger *et al.* 2000).

Interpretation

A detailed case report by Anger *et al.* (2000) concerned the suicidal ingestion of aluminium phosphide by a 39-year-old man in whom phosphine was found in the brain (94 mg/g), liver (24 mg/g) and kidneys (41 mg/g), but was absent in the blood and urine. The blood contained a high concentration of phosphorus (76.3 mg/L) and 8.22 mg/g was found in the liver. The aluminium concentration in the blood was 1538 μg/L, compared with reference values of less than 15 μg/L. Raised aluminium concentrations were also found in the brain (36 μg/g) and liver (75 μg/g). Where there has been inhalation of phosphine gas, rather than oral ingestion of phosphides, it can sometimes be difficult to detect the presence of phosphine in blood, or in postmortem tissues, such as brain. This may be due to the rapid elimination of phosphine, particularly if patients are hospitalised prior to death.

Sulfide

Introduction

Many organic and inorganic sulfide compounds are used in industry, but the most common cause of sulfide poisoning is by inhalation of hydrogen sulfide (sewer) gas, particularly in industrial or waste disposal sites, fisheries, tanneries, dye works and sewer networks (Christia-Lotter *et al.* 2007; Guidotti 1994; Jappinen and Tenhunen 1990; Kage *et al.* 2002a; Knight and Presnell 2005). The gas has a very characteristic foul odour of rotten eggs and has a very low odour threshold (0.03 ppm). However, very high sulfide concentrations (>100 ppm) may cause paralysis of the olfactory nerves and failure to detect the characteristic smell that would normally be a clear hazard warning (Guidotti 1994). At even higher sulfide concentrations (>700 ppm) there may be a rapid loss of consciousness, apnoea and respiratory failure leading to a rapid death (Knight and Presnell 2005).

Hydrogen sulfide is unstable and is metabolised rapidly in the body, such that it may be difficult to detect in biological samples from cases of suspected poisoning. It is metabolised into thiosulfate, which presents a useful approach to the investigation of acute or chronic sulfide poisoning.

Specimen collection

Specimens are collected as follows:

- Blood – 10 mL of anticoagulant blood (K-EDTA)
- Urine – 20 mL, sterile plastic universal container
- Stomach contents – useful in postmortem examination of fatalities
- Scene residues – useful for identification purposes.

Analysis

Early methods used microdiffusion followed by colorimetric measurement. Ion-selective electrodes have also been used (Jappinen and Tenhunen 1990). More recently, GC methods have been described using derivative formation and mass spectrometric detection (Kage *et al.* 2002a, 2004). A number of methods for measuring the main metabolite thiosulfate in blood and urine have been reported, including GC, LC and GC-MS (Kage *et al.* 1991, 1997, 2004; Kangas and Savolainen 1987).

Interpretation

Reference values for sulfide concentrations in biological fluids are very low (<10 μg/L). In a series of cases of hydrogen sulfide poisoning from a sulfate pulp mill reported by Jappinen and Tenhunen (1990), sulfide concentrations ranged from 30 μg/L to 130 μg/L in blood samples taken 0.5–2 h after exposure. Similar concentrations have been reported by Kage *et al.* (2002a) in fatal and non-fatal poisonings. In cases of suspected acute or chronic exposure to hydrogen sulfide, blood specimens must be collected as soon as possible because of its rapid metabolism. Measurement of blood or urine thiosulfate concentration may be the most viable investigation in some cases (Durand and Weinstein 2007; Kage *et al.* 1991, 1997).

Postmortem case reports after industrial accidents have shown blood sulfide concentrations of 0.9–3.8 mg/L (Goodwin *et al.* 1989). In a recent report of four acute adult fatalities that occurred in a Japanese dye works, postmortem blood sulfide concentrations ranged between 0.3 and 9.4 mg/L and thiosulfate concentrations ranged between 0.1 and 0.2 mmol/L (Kage *et al.* 2004).

CHAPTER

18 Drugs in Saliva

V Spiehler

Introduction

Definitions

Saliva is the secretion product of the salivary glands of the head and mouth. The fluids found in the oral cavity are a mixture of predominantly saliva, with lesser amounts of gingival crevicular fluid, cellular debris and blood. For this reason the New York Academy of Sciences meeting on saliva testing in 1993 agreed to use the term 'saliva' for glandular secretions that are collected directly from the salivary glands (most often the parotid glands), and the term 'oral fluid' for fluid collected by placing absorbents in the oral cavity or by expectoration (Malamud 1993).

Advantages of saliva drug testing

The advantages of saliva drug testing are twofold. First, saliva drug concentrations can be related to plasma free drug concentrations and pharmacological effects of drugs. Second, collection of saliva or oral fluid is non-invasive and simple, and can be done on-site under observation.

Saliva drug concentrations are related to blood or plasma concentrations of the unbound, unionised parent drug or its lipophilic metabolites (Haeckel, Hanecke 1996). Since it is the free lipophilic drug and drug metabolites that cross cell membranes, such as the blood–brain barrier, and cause physiological effects, free drug in plasma, and its reflection in saliva, can be correlated with drug effects. The presence and concentration of drugs in saliva therefore provide much of the same information as determination of drug presence and drug concentrations in blood or plasma. Saliva drug concentrations can be used to determine pharmacokinetic parameters. Additionally, saliva or oral fluid collection is much easier than venepuncture.

The collection of saliva or oral fluid is simple and non-invasive. It can be carried out by the specimen donor him- or herself by having the donor place a cotton swab or absorptive material attached to a stick into his or her mouth for a few minutes. The oral fluid absorbed on the material can then be processed for testing. Saliva can be collected at the site of the incident in accident or crime investigation. If necessary, saliva flow can be stimulated with citrate hard candy or citrate salts or by chewing on gum or rubber to ensure adequate sample volume. Because saliva collection is non-invasive and can be carried out by the donors themselves in most situations, it is more acceptable to most people than providing urine, blood or hair (Fendrich *et al.* 2002), and can be achieved while the donor is under observation by the collector. An exception may be when the donor is unconscious or sedated such that he or she is unable to follow instructions. Finally, it is difficult to adulterate or substitute oral fluid specimens in an attempt to avoid detection of drug use as any adulterating substances held in the mouth will dissipate, be swallowed or be spat out during the 10-minute observation period before collection of the specimen (Jehanli *et al.* 2001).

A simple non-invasive collection finds many applications in toxicology. For example, investigation of the involvement of drugs in impaired driving is facilitated by a roadside test for drugs or alcohol in saliva. The feasibility of detecting drugs in saliva samples obtained from impaired drivers was first investigated by Peel *et al.* (1984). They found that the presence of drugs in saliva correlated well with officers' judgements of driving while intoxicated. This was confirmed by better correlation of drugs in oral fluid or serum with driving and impairment symptoms observed by police officers and medical officers than of drugs in urine (Toennes *et al.* 2005). Saliva testing has also been compared with urinalysis in a population of arrested persons (Yacoubian *et al.* 2001) and in drugged drivers (Steinmeyer *et al.* 2001). The greatest advantage of saliva in roadside testing is the possibility of having the sample collected by the donor under observation shortly after the time of the incident.

Disadvantages of saliva drug testing

Like any biofluid from human, oral fluid may transmit infectious agents and should be handled with the appropriate universal precautions for human biological fluids. Saliva contains mucopolysaccharides and mucoproteins, which make it less fluid and less easily poured or pipetted than urine. Some drugs, medical conditions or anxiety can inhibit saliva secretion and cause a dry mouth; accordingly, saliva may not be available from all individuals at all times. Finally, because saliva drug concentrations depend on plasma drug concentrations, drugs that have a short plasma half-life and are rapidly cleared from the body will be detectable in saliva only for a short time. This is a potential disadvantage against detection of drugs in hair, sweat or urine. Saliva and blood will have the shortest detection windows. Drugs or their long-lived metabolites will be detectable in urine and sweat for several days to a week after use. Drugs will be detectable in hair for months or even years after use depending on the length of the hair. In general, drugs enter saliva from the blood and will be detectable in plasma and saliva from the time that the drug enters the general circulation until approximately four half-lives after administration. It is important to bear in mind that some drugs may be detected in oral fluid as a consequence of external contamination (see later) and that the measured drug concentration may not accurately reflect that in the blood.

Anatomy and physiology of saliva

The saliva glands

The human salivary glands produce between 0.5 and 1.5 L of saliva daily. During resting conditions, most mixed saliva is supplied by the submandibular glands (70%), with a lesser amount (25%) from the parotid glands and the remainder (5%) from the sublingual and other minor glands. During stimulation saliva output from the parotid gland increases to about half of the total. Saliva is composed of 99% water, 0.3% protein (largely amylase) and 0.3% mucins. The parotid gland produces mostly serous fluid. The submandibular and sublingual glands excrete both serous fluid and mucins. The salivary glands, like the liver, kidney and brain, are well supplied with arterial blood.

Salivary glands comprise two regions: the acinar region, which contains the cells that are capable of secretion, and the ductal region, lined with water-impermeable cells that carry the secretions to the outlets in the mouth (Turner 1993). Similarly, saliva formation occurs in two

stages. Water and exocrine proteins are secreted by the secretory cells in the acinar region. The fluid that collects in the acinar lumen is isotonic with plasma. As the fluid travels down the saliva ducts, sodium and chloride are reabsorbed while potassium and bicarbonate are secreted. Therefore, when saliva moves rapidly through the ducts, less time is available for sodium reabsorption and the pH of the saliva is higher (Dawes, Jenkins 1964). When the fluid reaches the mouth it is hypotonic to plasma.

Salivary glands are activated by the autonomic nerves. Generally, sympathetic stimulation via noradrenaline causes low levels of fluid and high concentrations of protein, while parasympathetic stimulation via acetylcholine induces large amounts of fluid secretion.

Movement of drugs into saliva

Excretion and diffusion

Some drugs such as digoxin, steroids and hormones are actively excreted into saliva by the acinar cells. Most drugs enter saliva by simple diffusion across the phospholipid bilayer of the acinar cells or though the cell membranes of the ductal cells in the tubules. Diffusion across cell membranes requires that the molecules are lipid soluble, non-ionised and unbound. For this reason the concentrations of drugs in saliva represent the free, non-ionised fraction in the blood plasma.

Henderson–Hasselbach equation

At equilibrium, drug and lipophilic metabolite concentrations in saliva are a function of a drug's pK_a, plasma and saliva pH, and the fraction of drug bound to saliva and plasma protein as shown by the following form of the Henderson–Hasselbach equation for saliva (S/P is the saliva : plasma ratio):

$$S/P = \frac{1+10^{(pK_d - pH_S)}}{1+10^{(pK_d - pH_p)}} + \frac{f_p}{f_s} \text{ for basic drugs}$$

$$S/P = \frac{1+10^{(pH_s - pK_a)}}{1+10^{(pH_p - pK_a)}} + \frac{f_p}{f_s} \text{ for acidic drugs}$$

where S is the drug concentration in saliva and P is the drug concentration in plasma; pK_d is the log of the ionisation constant for basic drugs; pK_a is the log of the ionisation constant for acidic drugs; pH_s is the pH of saliva and pH_p is the pH of the plasma; f_p is the fraction of drug protein bound in plasma and f_s is the fraction protein bound in saliva.

The pH value that governs this equilibrium is the pH of the saliva in the acinar lumen and in the duct at the moment of secretion. When the fluid enters the mouth, carbon dioxide is lost and the pH increases. Dawes and Jenkins (1964) demonstrated that saliva pH is inversely proportional to flow rate and the reabsorption of sodium in the salivary tubules. At faster flow rates, less sodium is reabsorbed in the tubules on the way from the salivary glands to the saliva outlets in the mouth, and the pH rises. For this reason, unstimulated saliva has a low pH and stimulated saliva has a higher pH. The pH of unstimulated saliva is fairly constant. The normal pH of saliva at low flow rates is between pH 6.0 and pH 7.0. The pH of stimulated saliva can reach as high as pH 8.0.

Since human saliva normally has a lower pH than human plasma, the saliva : plasma ratios for acid drugs are generally less than unity and the saliva : plasma ratios for basic drugs are greater than unity, providing an amplification of basic drug levels in saliva. For drugs that have a pK_a between 5.5 and 8.5, the saliva/plasma ratio can vary between stimulated and unstimulated saliva. This is true of many drugs of abuse. For this reason it is more conservative to use a cut-off value for drugs of abuse in saliva rather than to determine the absolute concentration. The most common example given is that of cocaine, which has a pK_a of 8.6 (Haeckel 1993; Schramm *et al.* 1992). As the saliva pH varies from 5.0 to 7.8, the saliva : plasma ratio for cocaine varies from 273 to 0.44. The theoretical range of saliva : plasma ratios over a saliva pH range of 6.4–7.6 have been calculated for cocaine, amfetamine, metamfetamine, 6-monoacetylmorphine (6-MAM), morphine, codeine, methadone and diazepam, and compared with published saliva : plasma ratios (Spiehler *et al.* 2000).

The protein binding of drugs is mainly to albumin or α-acid glycoprotein in plasma. Saliva mucoproteins have very little binding capacity for drugs. Oral fluids may contain albumin from the gingival crevicular fluid.

Oral deposition: smoked drugs and sublingual or buccal routes of administration

The deposition into mouth tissues of drugs taken by smoking, snorting or oral routes of administration is an additional source of drugs in oral fluid. For example, Jenkins *et al.* (1995) showed that the saliva : plasma ratio for smoked diamorphine was 100–400 times that of diamorphine administered intravenously. After smoking of diamorphine, it was detected in oral fluid up to 24 h compared with up to 30 min after intravenously administration.

O'Neal *et al.* (2000) reported codeine saliva : plasma ratios of 75–2580 in the first 15–30 min after and of 13–344 for several hours after oral administration of liquid codeine phosphate, despite efforts at decontamination by having people brush their teeth and vigorously rinse their mouth prior to saliva collection.

Similarly, Jenkins *et al.* (1995) reported that when cocaine was smoked the saliva : plasma ratio was 5–300 times that found after cocaine administered intravenously. The pyrolysis product of cocaine, anhydroecgonine methyl ester (AEME), was detected in oral fluid collected after smoking cocaine but not in plasma. Similarly, the cannabinoids found in oral fluid are almost totally due to oral deposition of cannabinoids from smoked marijuana rather from secretions or diffusion into saliva (Ohlsson *et al.* 1986).

The formation of oral mucosa depots of drug that are rapidly absorbed into the blood circulation is used for drug administration. Sublingual or buccal absorption of drugs such as nitroglycerin, buprenorphine or fentanyl has the advantage of very rapid delivery that bypasses the liver and gastrointestinal first-pass metabolism. Drugs administered by this route also produce large concentrations of the parent drug in oral fluid with a short detection window as the drugs are rapidly absorbed.

Individual drugs in saliva

Opiates: diamorphine, 6-MAM, morphine, codeine and related drugs

The major metabolite found in saliva following diamorphine use is 6-MAM, which has a saliva : plasma ratio of 6 (Cone 1993; Cooper *et al.* 2005; Jenkins *et al.* 1994, 1995; Moore L *et al.* 2001; Presley *et al.* 2003). Diamorphine parent drug was found in oral fluid for up to 24 h after smoking and up to 60 min after injection of diamorphine with a saliva : plasma ratio after intravenous administration of 2.13, range 0.12–7.2 (Jenkins *et al.* 1995). If diamorphine is snorted (Cone 1993) or smoked (Jenkins *et al.* 1995) then very high concentrations of diamorphine in the milligram per litre range may be detected in oral fluid for several hours after use owing to deposition of parent drug in the oral cavity. In addition to diamorphine and 6-MAM, morphine may be found in saliva after diamorphine use. An average saliva : plasma ratio of 0.67 (range 0.1–1.82) for morphine in oral fluid after intravenous administration of diamorphine was reported by Jenkins *et al.* (1995). Euphoria after diamorphine use occurs rapidly and diminishes within the first hour, paralleling the time course of diamorphine in saliva and blood. Miosis caused by diamorphine peaks approximately 15 min after administration by smoking or intravenous injection and persists for up to 4 h. Miosis parallels the time course of saliva and blood concentrations of 6-MAM and morphine (Jenkins *et al.* 1994).

Morphine appears in saliva after administration of morphine sulfate with a saliva : plasma ratio of 0.2 (Cone 1993). Leute *et al.* (1972) detected

morphine in saliva at concentrations exceeding 200 μg/L using a free-radical immunoassay. Gorodetzky and Kullberg (1974) reported the detection of morphine in saliva by radioimmunoassay (RIA) for 6 h after dosing in patients receiving 30 mg morphine sulfate subcutaneously. Cone (1990) reported that morphine concentrations in saliva ranged from 0.6 μg/L to 10.9 μg/L after intramuscular administration of 10 mg morphine sulfate and 37.8 μg/L in a single individual who received 20 mg morphine sulfate by the same route. Saliva concentrations peaked at 0.5 h after dosing and were no longer detectable after 24 h. Miosis was noted within 15 min of dosing and declined to baseline after 24 h. Morphine is also found in oral fluid after diamorphine use (Cone 1993; Jenkins *et al.* 1994, 1995; Moore L *et al.* 2001).

Hydromorphine is found in saliva with a saliva : plasma ratio in the elimination phase ranging from 0.25 μg/L to 2.32 μg/L for eight subjects with both inter-individual and intra-individual variation (Ritschel *et al.* 1987). Hydromorphone was detected in saliva for up to 10 h by RIA after administration of 2–5 mg intravenous hydromorphone. The terminal elimination half-life for saliva (2.12 h) was not significantly different from that for plasma (2.36 h). Hydromorphone confirmation in oral fluid by gas chromatography–mass spectrometry (GC-MS) using a methoximine derivative has been reported (Jones *et al.* 2002).

Pholcodine is found in saliva in the range 1.5–350 μg/L after oral doses of 20 and 60 mg (Chen *et al.* 1988). The saliva : plasma ratio was 3.6 calculated from the mean areas under the concentration–time curves for plasma and saliva. The elimination half-life for pholcodine from saliva was 51.2 ± 11.9 h. Pholcodine was detectable in saliva for 20 h after the last dose on day 11 of chronic dosing.

After codeine administration, codeine is found in saliva with a saliva : plasma ratio of 3.3 (Cone 1993). O'Neal *et al.* (1999) reported a mean saliva : plasma ratio of 3.7 ± 0.28 when measured 2–12 h after oral administration of 30 mg codeine and concluded that saliva codeine concentrations could be used to estimate plasma concentrations through use of saliva : plasma ratios. Chen *et al.* (1991) determined saliva and plasma concentration–time profiles for codeine following single and chronic oral doses of 30 mg codeine. The codeine saliva : plasma ratio was 3.0 from the area under the concentration–time curves. Chen *et al.* (1991) concluded that pharmacokinetic parameters for codeine for individuals and their individual status as a poor or extensive metaboliser can be determined from saliva measurements if a 1 h clearance time is allowed after oral dosing. Codeine 6-glucuronide was not found in saliva (Chen *et al.* 1991).

O'Neal *et al.* (2000) reported that saliva codeine concentrations collected by expectoration or draining of unstimulated of oral fluid were 1.3–2.0 times higher than codeine concentrations in oral fluid collected by swabbing with absorptive devices (OraSure, Salivette and Finger Collector containing AccuSorb foam). As expected from the Henderson–Hasselbach equation above, codeine concentrations in unstimulated saliva collected by expectoration were 3.6 times higher than concentrations in specimens collected by expectoration after acidic stimulation by citric acid. In unstimulated saliva collected by expectoration into test tubes, O'Neal *et al.* (2000) found codeine in 15 of 22 specimens at 24 h after oral administration of 30 mg liquid codeine phosphate but in only 20–40% of specimens collected with the absorptive swabs. Jehanli *et al.* (2001) reported that three of five volunteers' oral fluid specimens were positive for codeine with the Cozart RapiScan Saliva collection and testing system at 24 h after oral administration of 16 mg codeine. These were confirmed by GC-MS using a cut-off of 5 μg/L (Fig. 18.1). The clinical sensitivity and specificity for codeine were 91% and 98% respectively (Fig. 18.2).

Other prescription opiates and opioids reported in oral fluid include hydrocodone, oxycodone (Jones *et al.* 2002), dihydrocodeine (Skopp *et al.* 2001) and dextromethorphan (Lutz *et al.* 2004; Rodrigues *et al.* 2008).

The sensitivity and specificity of a qualitative analytical test are functions of the decision threshold cut-off employed in the test. If the saliva : plasma ratio values are multiplied by the lower limit plasma levels for therapeutic or recreational effects from Uges (1996), the resulting suggested cut-offs for opiates in saliva are: 6-MAM 30 μg/L, morphine 40 μg/L, codeine 66 μg/L, methadone 50 μg/L, cocaine 60 μg/L, amfetamine 56 μg/L, metamfetamine 40 μg/L and diazepam 3.6 μg/L (Spiehler *et al.* 2000). The proposed US workplace cut-off for opiates in saliva is 40 μg/L morphine equivalents by immunoassay and the confirmation cut-offs are 40 μg/L morphine, 40 μg/L codeine or 4 μg/L 6-MAM (SAMHSA 2001).

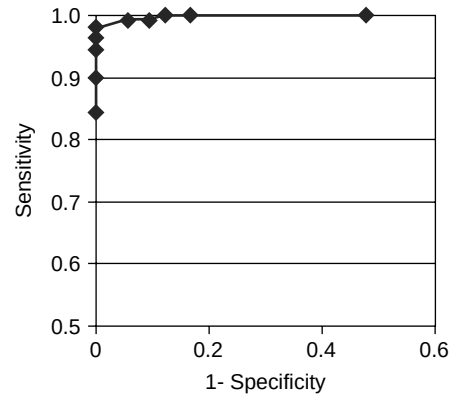

Figure 18.1 Receiver operating curve for saliva opiates using the Cozart Microtiterplate Opiates test for putative cut-offs of 1 to 100 ng/mL morphine equivalents in diluted oral fluid.

A laboratory-based oral fluid opiate test (Intercept, OraSure Technologies, Bethlehem, PA, USA) used a cut-off of 10 μg/L in dilute oral fluid (threefold dilution) and found a correlation of 93.6% with urine specimen results in a population of diamorphine abusers (Niedbala *et al.* 2001b). Ingestion of 5.2–40 g of poppy seeds produced saliva opiate positive results at 15 min but not at 1 h. However no 6-MAM was found in saliva after poppy seed ingestion.

Speckl *et al.* (1999) evaluated a collection device (ClinRep) consisting of a treated cotton roll which was then centrifuged and the oral fluid collected and filtered before extraction, derivatisation and analysis by GC-MS. They reported that the concordance of the analytical results for opiates of the saliva samples with urine was 93% for a decision limit of 100 μg/L and 98% for a decision limit of 300 μg/L.

An on-site lateral-flow immunoassay for opiates in oral fluid employing up-converting phosphor antibody labels (UPLink System, OraSure Technologies, Inc.) was reported to have a sensitivity (true positive rate) for opiates vs GC-MS(-MS) of 62% using a decision cut-off of 40 μg/L morphine equivalents and a specificity (true negative rate) of 84% (Niedbala *et al.* 2002). The assay had a cross-reactivity of 87% with 6-MAM, greater than 73.7% with diamorphine, 60% with codeine, hydrocodone and hydromorphine, and 30–40% cross-reactivity with oxycodone, oxymorphone and normorphine.

The cut-off of the Cozart RapiScan Oral Fluid Drug Testing System (Cozart BioScience Ltd, Abingdon, UK), was established by receiver operating curve (ROC) analysis, as 10 μg/L morphine equivalents in diluted oral fluid or 30 μg/L morphine equivalents in neat saliva (Moore L *et al.* 2001). The Cozart RapiScan antibody is equally cross-reactive with morphine, 6-MAM, diamorphine, dihydrocodeine and codeine. Saliva opiate-positive results with the Cozart RapiScan were confirmed by GC-MS in 18 of 22 specimens collected from volunteers at a substance abuse treatment clinic and negative results in 49 of 49 specimens (Moore *et al.* 2001).

		Opiates by Cozart RapiScan	
		+	–
Codeine dose given	yes	40	4
	no	1	42

Sensitivity	40/44	90.9 %	3.0%
Specificity	42/43	97.7 %	1.6%

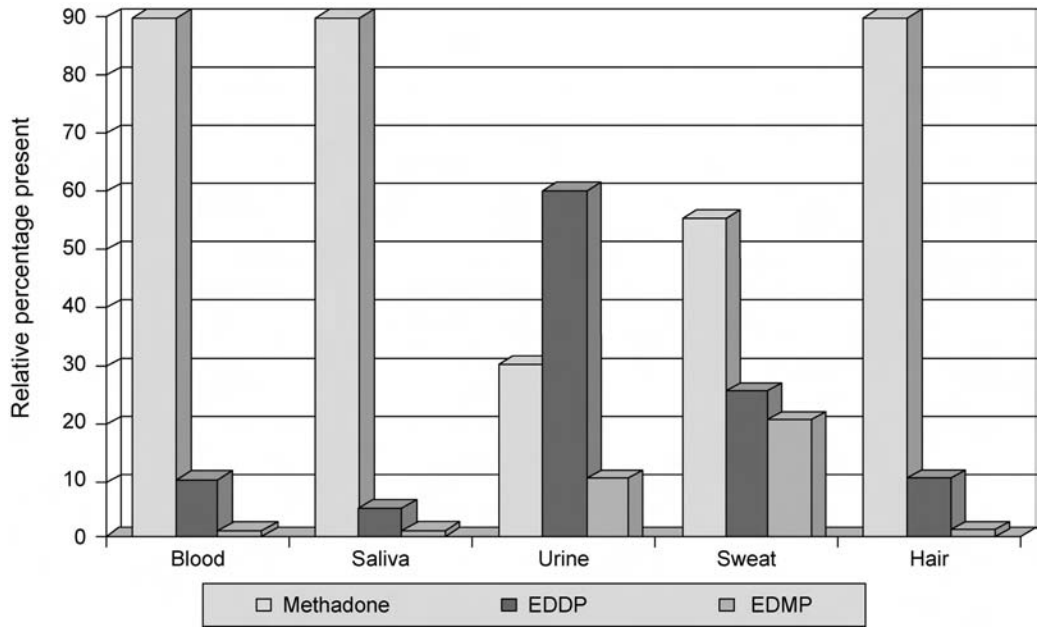

Figure 18.3 Metabolic profile of methadone in blood, saliva, urine, sweat and hair.

Methadone

Lynn *et al.* (1975) reported that methadone was found in saliva after parenteral administration of methadone. Kang and Abbott (1982) reported a GC-MS method for methadone and 3-ethylidene-1,5-dimethyl-3,3-diphenylpyrrolidine (EDDP) in saliva. The relative metabolic profile for methadone in blood, saliva, urine, sweat and hair is shown in Fig. 18.3.

Wolff *et al.* (1991) found that saliva methadone concentrations could be used to estimate plasma methadone concentrations to monitor consumption of methadone. Patient volunteers from an addiction treatment unit were asked to expel stimulated mixed saliva into plastic tubes before consumption of the daily dose of methadone linctus. Saliva and plasma methadone and EDDP were determined by high performance liquid chromatography (HPLC). A correlation coefficient of 0.8 was found by linear regression. Wolff *et al.* (1991) reported a saliva : plasma ratio of 1.30. This was greater than the ratio of 0.51 found by Kang and Abbott (1982), but less than the value of 4 reported by El Guebaly *et al.* (1981).

Since methadone has a pK_a of 8.3, the saliva : plasma ratio is a function of saliva pH. Bermejo *et al.* (2000) reported that the methadone saliva : plasma ratio as a function of saliva pH ranged from 0.6 to 7.2 with an average of 3.7 ($n = 10$) over a measured saliva pH range of 5.0–7.0. In the same specimens, the saliva : plasma ratio of EDDP ranged from 0.2 to 1.8 with an average of 0.89 and was not a function of saliva pH. Malcolm and Oliver (1997) reported that the saliva : whole blood ratio ranged from 0.45 to 3.4. Saliva was collected using the Omni-SAL collection device and analysed by microplate enzyme immunoassay and GC-MS.

Moore L *et al.* (2001) reported that saliva methadone positive results with the Cozart RapiScan Saliva Test were confirmed by GC-MS in 37 of 37 specimens collected from volunteers at a substance misuse treatment clinic and negative results in 34 of 34 specimens. The Cozart RapiScan oral fluid drug testing system cut-off is 10 μg/L methadone equivalents in diluted oral fluid or 30 μg/L methadone equivalents in neat saliva. The correlation to microtitre plate enzyme immunoassay for methadone for different saliva methadone cut-offs is shown in Fig. 18.4.

Cocaine

Cocaine parent drug is the major analyte found in saliva after cocaine use. In unstimulated saliva, cocaine is ion-trapped in saliva and the saliva : plasma ratio may be 5 or greater (Schramm *et al.* 1992, 1993a). In stimulated saliva, the saliva : plasma ratio ranges from 0.5 to 3.0 (Cone, Weddington 1989; Cone *et al.* 1988, 1997; Jenkins *et al.* 1995). Cocaine appears in saliva immediately after administration of the drug by intravenous injection. Benzoylecgonine and ecgonine methyl ester appear in saliva within 15 min of cocaine administration and are found in saliva at concentrations similar to those found in blood. Schramm *et al.* (1993a) reported a saliva : plasma ratio of approximately 2.5 for benzoylecgonine. Jenkins *et al.* (1995) reported saliva : plasma ratios for benzoylecgonine ranging from 0.02 to 0.66. Norcocaine and *p*-hydroxycocaine may be found in saliva after cocaine administration. Jufer *et al.* 2000 reported a saliva : plasma ratio of 8.7 (range 3.8–13.2) for cocaine, 3.7 (range 2.3–5.1) for ecgonine methyl ester, 0.4 (range 0.3–0.5) for benzoylecgonine, 10.3 (5.6–13.6) for norcocaine and 6.1 (range 2.4–10.8) for *p*-hydroxycocaine. Cocaethylene is found in saliva when ethanol is ingested concurrently with cocaine. In a rat model, Barbieri *et al.* (1994) reported a saliva : plasma ratio of 1.3 for cocaethylene after cocaethylene administration. Jenkins *et al.* (1995) reported that a pyrolysis product of cocaine, anhydroecgonine methyl ester (AEME), was detected in oral fluid collected after smoking cocaine but not in plasma.

Inaba and Kalow (1975) reported that radiolabelled cocaine given orally was detectable for up to 5 h in saliva. Thompson *et al.* (1987) reported that cocaine was found in saliva immediately after intravenous

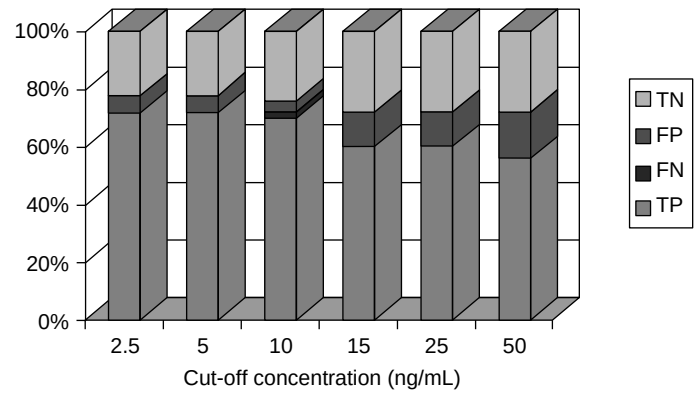

Figure 18.4 True negatives, false positives, false negatives and true positives for the Cozart RapiScan Saliva Methadone Test for different cut-offs versus a microplate enzyme immunoassay.

doses of cocaine and that saliva and plasma cocaine concentrations paralleled each other. Saliva cocaine concentrations correlated with the physiological and behavioural effects of the drug. Cocaine saliva : plasma ratios ranged from 0.36 to 9.74. Cone and Weddington (1989) reported detection of cocaine equivalents by immunoassay for 5–10 days after abstinence in heavy cocaine addicts and GC-MS confirmation for 1–2 days. In a more recent study of cocaine and metabolite elimination patterns, Moolchan *et al.* (2000) measured cocaine, benzoylecgonine and ecgonine methyl ester in saliva of admitted cocaine abusers for 12 h. In the later specimens, metabolites predominated, as is consistent with their longer half-lives in the body. Saliva terminal half-lives were 7.9 h for cocaine, 9.2 h for benzoylecgonine and 10 h for ecgonine methyl ester. Cone and Menchen (1988) reported the correlation of saliva and plasma cocaine concentrations after intravenous cocaine administration with an average half-life of cocaine of 34.7 min in saliva and 34.9 min in plasma. Jenkins *et al.* (1995) reported a detection time for cocaine in saliva of up to 8 h after intravenous injection and 12 h after smoking of cocaine. Cone *et al.* (1997) reported mean detection times of cocaine in saliva of 3.92 h after intravenous administration, 5.67 h after insufflation and 3.17 h after smoking of cocaine, which correlated with pupil diameter, heart rate and feeling of drug changes, but not with drug-induced euphoria and feeling high, which were of much shorter duration. Jufer *et al.* (2000) reported a prolonged terminal elimination half-life for cocaine metabolites from saliva after chronic (16-day) administration of cocaine due to accumulation of lipophilic drug.

Kato *et al.* (1993) compared cocaine in unstimulated with that in stimulated saliva. Unstimulated saliva collected by expectoration contained, on average, 5.2 (range 3.0–9.5) times as much cocaine as saliva collected under stimulated conditions (citric acid sour candy). The mean ratios of unstimulated to stimulated area under the concentration–time curve for benzoylegconine and ecgonine methyl ester were 6.0 (range 3.3–9.0) and 5.5 (range 2.5–8.8), respectively.

Jenkins *et al.* (1995) followed cocaine and metabolites in saliva after smoked and intravenous administration. It was shown that, after smoking, cocaine and pyrolysis products of cocaine persisted in saliva for up to 6 h. Cone *et al.* (1997) compared cocaine appearance in saliva after intravenous, intranasal and smoked administration, and found that both intranasal and smoked routes of administration produced elevated saliva : plasma ratios of cocaine due to contamination of oral fluids, which cleared within 2 h after administration.

Niedbala *et al.* (2001a) established an optimum screening cut-off of 10 μg/L benzoylecgonine equivalents by immunoassay by ROC analysis of clinical trial saliva results using GC-MS with a cut-off of 10 μg/L benzoylecgonine as the reference standard. The Cozart RapiScan Oral Fluid Drug Testing System uses a cut-off of 10 μg/L benzoylecgonine or 25 μg/L cocaine in diluted oral fluid, which is equivalent to 30 and 75 μg/L, respectively, in saliva (Cooper *et al.* 2004). The Cozart RapiScan antibody has a 40% cross-reactivity with cocaine. The proposed US workplace screening cut-off is 20 μg/L benzoylecgonine equivalents by immunoassay. The proposed US workplace confirmation cut-off is 8 μg/L benzoylecgonine or cocaine (SAMHSA 2001). Jufer *et al.* (2000) reported detection times in saliva of 15 h, 45 h and 35 h, for cocaine, benzoylecgonine and ecgonine methyl ester, respectively, at a 10 μg/L cut-off, and detection times of 85, 93 and 93 h respectively at a 1 μg/L cut-off threshold.

Amfetamines: amfetamine, metamfetamine, MDMA, MDA and MDEA

Amfetamine, metamfetamine, 3,4-methylenedioxymethamfetamine (MDMA), 3,4-methlyenedioxyamfetamine (MDA) and other amfetamine class drugs can be found in saliva. Parent drug rather than amfetamine metabolites is found in saliva. The saliva : plasma ratio for amfetamine is 2.76 and for metamfetamine is 3.98. After administration of 10 mg amfetamine, plasma levels ranged from 1 μg/L to 20 μg/L and saliva concentrations ranged from 10 to 60 μg/L (Wan *et al.* 1978). When amfetamine was administered to subjects as a racemic mixture, both *d*- and *l*-isomers were found in saliva (Wan *et al.* 1978). Saliva has been found to be positive for metamfetamine as long as 50 h after dosing (Suzuki *et al.* 1989). Cook *et al.* (1993) and Huestis and Cone (2007) compared metamfetamine concentrations in saliva and plasma of volunteers administered drugs by smoking and intravenous routes. Because of the high concentrations of amfetamines in oral fluid, amfetamines are easily detected in reduced volumes of oral fluid using rapid extraction and automated assays (Moore *et al.* 2007a).

The excretion profile of MDMA and its metabolites in saliva and in plasma after ingestion of a single 100 mg dose has been reported (Navarro *et al.* 2001). In eight healthy volunteers, salivary concentrations peaked at 1.5 h after ingestion and the peak values ranged from 1728.9 μg/L to 6510.6 μg/L. These peak values corresponded to an average ± standard deviation saliva : plasma ratio of 18.1 ± 7.9. The time profile of the saliva : plasma ratio was also reported, with the peak occurring at 1.5 h followed by decline to a plateau between 7.3 and 6.4 at 10 and 24 h after dosing. MDA was found in saliva at concentrations approximately 4–5% of MDMA concentrations (relative area under the curve [AUC]) with highest concentrations between 1.5 and 4 h after dosing. 4-Hydroxy-3-methoxymethamfetamine (HMMA) was detected in trace amounts in saliva. Pichini *et al.* (2002) reported that MDMA could be reliably detected in oral fluid using a Drugwipe only if oral fluid was pipetted directly onto the collector.

Samyn and van Haeren (2000) also found MDMA saliva : plasma ratios exceeding theoretical values. Samyn *et al.* (2002) quantified MDMA, MDA and MDEA concentrations in 50 μL of oral fluid by LC-MS(-MS). They reported detection of MDMA in oral fluid of volunteers dosed with 75 mg of MDMA for 5 h duration, which paralleled impairment in psychomotor skills important for car driving (Laloup *et al.* 2005).

After administration of 100 mg *N*-methyl-1-(3,4-methylenedioxypheny)-2-butanamine (MBDB) to a single patient, saliva concentrations ranged from 14 μg/L to 1082 μg/L (Kintz, Samyn 1999). Peak saliva concentrations were observed at 2 h and both MBDB and the desmethylated metabolite, BDB, were detected in saliva for 17 h.

Based on the therapeutic range of 20–150 μg/L for amfetamine (Uges 1996), saliva positives at a cut-off value of 56 μg/L amfetamine or greater would indicate pharmacologically significant levels of amfetamine drugs in blood. The proposed US workplace screening cut-off in saliva is 50 μg/L amfetamines by immunoassay and the confirmation cut-off is 50 μg/L metamfetamine, MDMA, MDA or amfetamine (SAMHSA 2001). The Cozart RapiScan Oral Fluid Drug Testing System has a cut-off of 10 μg/L amfetamine in diluted oral fluid or 30 μg/L amfetamine or MDA in saliva. This would correspond to a plasma concentration of approximately 10 μg/L amfetamine or MDA in plasma. The metamfetamine/MDMA cartridge has a cut-off of 50 μg/L MDMA or metamfetamine or 150 μg/L metamfetamine or MDMA in neat saliva. The Securitec Drugwipe on-site saliva sampling and test strip has a cut-off of 80 μg/L *d, l*-amfetamine sulfate. The Cozart DDS testing system detects as much as 45 μg/L amfetamine and metamfetamine in neat oral fluid.

Analysis of 81 matching saliva and urine clinical specimens (57 from self-reported metamfetamine users and 24 from non-users), using a cut-off of 30 μg/L saliva for screening with a microtitre plate enzyme immunoassay (EIA) and a confirmation cut-off of 10 μg/L by GC-MS, found 97.5% correlation for positive results and a 92.7% correlation for negative results between oral fluid and urine. Metamfetamine concentrations ranged from 10 μg/L to over 10 000 μg/L (Simer *et al.* 1998).

Barbiturates and antiepileptic drugs

Wilson (1993) reviewed the attempts to use saliva for therapeutic drug monitoring of anticonvulsant drugs, including barbiturates. These drugs generally have a neutral or acidic pK_a and many are highly protein bound in blood. Their saliva : plasma ratios are usually less than unity. For example, carbamazepine saliva levels correlate well with dose and blood concentrations. The saliva : plasma ratio for carbamazepine is 0.13–0.33 and intra-individual variation is about 5% (Miles *et al.* 1991).

However, phenytoin has been reported to have saliva : plasma ratios varying from 0.01 to 0.25, average 0.09, for blood total and from 1.06 to 2.22 for blood-free phenytoin. Miles *et al.* (1991) reported an inter-individual variation of 5–10%. Phenytoin saliva concentrations do not

correlate with blood concentrations or therapeutic effect. They do show compliance or non-compliance and elevated levels are related to toxicity. Kamali and Thomas (1994), using atropine-induced reductions in saliva flow rate, demonstrated that the saliva : plasma ratio and saliva phenytoin concentrations were dependent on saliva flow rate but that this did not account for all of the intra-individual variance in the saliva : plasma ratio for phenytoin.

Phenobarbital saliva : plasma ratios of 0.31–0.63 have been reported (Mucklow *et al.* 1978; Nishihara *et al.* 1979; Wilson 1993). Dilli and Pillai (1980) reported a half-life for pentobarbital in saliva of 17–19 h and for amobarbital 22–26 h. Sharp *et al.* (1983) reported saliva secobarbital concentrations of 210 ± 40 μg/L at 3 h after oral administration of 50 mg secobarbital. The saliva : plasma ratio was 0.30 ± 0.04. Van der Graaff *et al.* (1986) reported pharmacokinetics of hexobarbital in plasma and saliva. Wilson (1993) listed the following therapeutic ranges for saliva: carbamazepine 1.4–3.5 mg/L, phenobarbital 5.0–15 mg/L and diphenylhydantoin 1.0–2.0 mg/L.

Benzodiazepines

Benzodiazepines have an unfavourable saliva : plasma ratio (0.01–0.08) owing to acid pK_a values and a high percentage protein binding in plasma (95–99%), so that sensitive methods must be used for detection of benzodiazepines in saliva (Tjaden *et al.* 1980). Immunoassays have been reported that detect various subgroupings or clusters of the very large class of benzodiazepine drugs (Kintz *et al.* 2005; Smink *et al.* 2006). One or more immunoassays may be needed to screen for the most common benzodiazepines in a certain region. A number of LC-MS and LC-MS(-MS) methods have been reported for benzodiazepines in oral fluid (Moore *et al.* 2007b; Ngwa *et al.* 2007; Quintela *et al.* 2005; Smink *et al.* 2006) and, because of the wide spectrum of benzodiazepines detected, LC-MS(-MS) has been suggested as a screening tool as well as a confirmation method for benzodiazepines (Allen *et al.* 2005).

Lucek and Dixon (1980) reported a mean saliva : plasma ratio for chlordiazepoxide of 0.027 ± 0.011. Saliva concentrations were found to be equal to the concentrations of unbound drug in plasma. The drug half-lives determined from plasma and saliva concentration–time curves after intravenous administration of 35 and 50 mg and chronic dosing of 10 mg three times a day for 4 days were 17.2 and 17.8 h for the 35 mg dose, 12.2 and 11.6 h for the 50 mg dose, and 21.9 and 19.9 h after cessation of chronic dosing.

Diazepam (pK_a 3.3) and its metabolites are found in saliva at concentrations of 2–5 μg/L with a saliva : plasma ratio of 0.02 (Giles *et al.* 1977). Di Gregorio *et al.* (1978) reported a ratio of 0.035 ± 0.0047 for parotid saliva : plasma and a mixed saliva : plasma ratio of 0.029 ± 0.0048 after a single 10 mg oral dose. There were no significant differences between diazepam concentrations or time course in parotid saliva and mixed saliva. Giles *et al.* (1980) reported saliva desmethyldiazepam levels in patients receiving chronic diazepam therapy. Hallstrom and Lader (1980) reported a saliva : plasma ratio of 0.016 ± 0.003 for diazepam and 0.029 ± 0.01 for nordiazepam in chronic diazepam users. de Gier *et al.* (1980) reported saliva : plasma ratio of 0.017 ± 0.003 for diazepam, but failed to accurately predict plasma free diazepam levels from saliva diazepam concentrations. The Cozart Rapiscan oral fluid cut-off is 10 μg/L temazepam or 20 μg/L diazepam in diluted oral fluid or 30 and 60 μg/L, respectively, in saliva. The Cozart DDS testing system has a cut-off of 20 and 50 μg/L for temazepam and diazepam in neat oral fluid, respectively.

Concheiro *et al.* (2005) reported windows of detection of tetrazepam in urine, oral fluid and hair after drug-facilitated sexual assault. Laloup *et al.* (2007) compared tetrazepam and diazepam in oral fluid, urine and hair after oral dosing with Myolastan (tetrazepam) and Valium (diazepam).

Methods for detection of midazolam and its hydroxymetabolites have been reported for plasma and oral fluid. Midazolam is a useful probeol drug for CYP3A phenotyping (Link *et al.* 2007). Oral fluid is a more convenient specimen for multiple samplings in pharmacokinetic studies or in phenotype screening.

Kangas *et al.* (1979) and Hart *et al.* (1987) reported that saliva concentrations of nitrazepam were considerably lower than the protein unbound fraction in serum and that monitoring of saliva nitrazepam was of no clinical value. However, Hart *et al.* (1988) reported that, while diazepam, nordiazepam and clonazepam are stable in saliva, nitrazepam is unstable in saliva and is rapidly converted to 7-aminonitrazepam on standing in saliva at room temperature.

Samyn *et al.* (2002) reported detection of flunitrazepam and 7-aminoflunitrazepam in oral fluid using chemical ionisation GC-MS for up to 6 h after giving four volunteers an oral dose of 1 mg Rohypnol (flunitrazepam). Maximum concentrations, reached 2–4 h after dosing, were less then 1 μg/L for flunitrazepam in oral fluid and 1–3 μg/L for 7-aminoflunitrazepam. A cut-off concentration of 0.25 μg/L of 7-aminoflunitrazepam was proposed as corresponding to the duration of substantial impairment in motor abilities (6 h). Flunitrazepam and its metabolites were not stable in oral fluid specimens even after treatment with sodium fluoride and refrigeration.

Kintz *et al.* (2004) reported the windows of detection of lorazepam in urine, oral fluid and hair.

Studies of the effect of benzodiazepines on psychomotor performance and driving performance have compared saliva and plasma concentrations (de Gier *et al.* 1981; Jansen *et al.* 1988; Linnoila *et al.* 1983). Results indicated good correlation between saliva and plasma concentrations, but poor correlation with psychomotor impairment.

Cannabis

Δ^9-Tetrahydrocannabinol (THC), 11-nor-Δ^9-tetrahydrocannabinol-9-carboxylic acid (THCA) and conjugated 11-nor-Δ^9-tetrahydrocannabinol-9-carboxylic acid (THCA-glucuronide) have been reported in oral fluid (Day *et al.* 2006; Moore *et al.* 2006a, 2007c), as well as the pyrolytic precursor Δ^9-tetrahydrocannabinolic acid-A, cannabinol and cannabidiol (Moore *et al.* 2007d). Because of the lipophilicity of THC, early methods of collection of oral fluid sometimes suffered false negatives owing to problems of recovery from and stability of cannabis components on collector absorbents (Dickson *et al.* 2007; Kauert 2000; Langel *et al.* 2007). Since more than half of the THCA content of oral fluid may be present as the glucuronide conjugate, false negatives can occur if the specimen is not hydrolysed before analysis or analysed by a method such as LC-MS that is able to detect glucuronide conjugates. Moore *et al.* recommended base hydrolysis (average 63.4% increase in THCA detected) or β-glucuronidase enzymatic hydrolysis (48.2% increase) (Moore *et al.* 2007c).

Idowu and Caddy (1982) calculated a theoretical saliva : plasma ratio of 0.099–0.129 for THC and of 0.060–0.099 for 11-OH-THC. However, the measured saliva : plasma ratio for THC after smoking marijuana is 10 and is a function of the time since smoking (Cone 1993). Cannabinoids in saliva are often due to residual material left in the mouth during ingestion or smoking of cannabis or cannabis products (Niedbala *et al.* 2001c). For this reason, concentrations are highest immediately after smoking and decline rapidly over the first 2–4 h. In contrast, cannabinoids may not appear in urine or sweat for several hours after smoking (Fig. 18.5). Niedbala *et al.* (2001c) reported an average lag time to urine appearing positive for cannabinoids of 4 h (GC-MS) to 6 h (EIA). The advantage of measuring cannabinoids in saliva is that it is an indication of recent use of cannabis. By detecting THCA and THCA-glucuronide in oral fluid, passive contamination by environmental cannabis smoke can be ruled out (Moore *et al.* 2007c).

Just *et al.* (1974) detected THC by two-dimensional thin-layer chromatography and mass spectrometry in saliva extracts for 2 h after smoking a single tobacco cigarette that contained 2.8 mg of THC. Gross *et al.* (1985) reported that saliva THC levels by RIA were greater than 400 μg/L at 0.5 h after smoking, rapidly dropped to less than 10 μg/L, and were undetectable 5 h after smoking. Maseda *et al.* (1986) detected THC in saliva using capillary GC with electron capture detection (ECD) (limit of detection 1 μg/L) for 4 h after smoking cannabis containing approximately 10 mg THC. Concentrations in saliva ranged from 250 μg/L 1 h after smoking to 34 μg/L at 4 h. Maseda *et al.* (1986) reported that saliva Δ^9-THC concentrations at 1 h were lowered by drinking 200 mL of beer immediately after the cannabis smoking. Thompson and Cone (1987) reported THC in saliva using

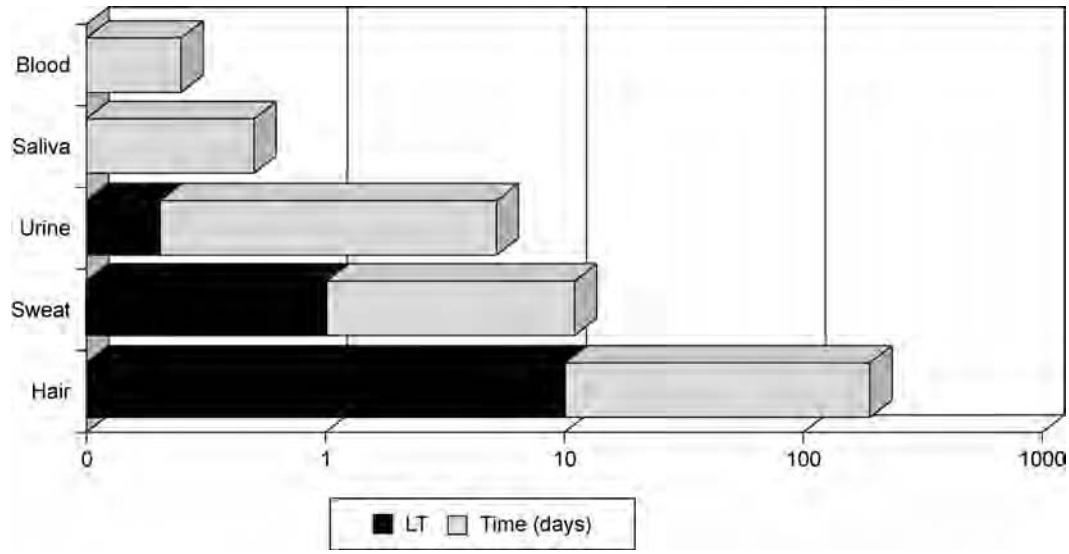

Figure 18.5 The lag time and window of detection for cannabinoids in blood, saliva, urine, sweat and hair after smoked marijuana. LT, lag time; time days, window of detection.

HPLC with electrochemical detection (limit of detection 1 μg/L). Saliva was collected by sour candy stimulation and stored at −20°C. Concentrations reached greater than 500 μg/L THC immediately after smoking one or two cannabis cigarettes and fell to 10 μg/L at 7 h. Saliva concentrations were greater than serum concentrations throughout. Cone (1993) found saliva levels of greater than 100 μg/L for the first 1 h after smoking a 3% THC cigarette, which rapidly dropped to less than 1 μg/L within several hours.

Niedbala *et al.* (2001c) found saliva concentrations of 0.3–216 μg/L THC from 1 to 72 h after smoking a cannabis cigarette, and saliva concentrations of 6–684 μg/L at 15 min to 1 h after smoking. Following oral ingestion of cannabis concentrations were from 0.12 μg/L to 21.3 μg/L for 1–48 h. There were no detectable cannabinoids in saliva after passive exposure to cannabis smoke. There were no significant differences in cannabinoid concentration or detection for oral fluid collected simultaneously from the right and left sides of the mouth. Using GC-MS(-MS) with a 0.5 μg/L THC cut-off concentration, Niedbala *et al.* (2001c) detected THC in oral fluid of 10 participants who smoked 20–25 mg THC for an average of 34 h.

Menkes *et al.* (1991) found that saliva levels of THC correlated with rapid heart rate and psychological feelings of a 'high'. Saliva THC concentrations were measured after smoking a cigarette containing 11 mg THC. Subjective intoxication was measured using a visual analogue scale and heart rate, and correlated significantly with the log of the saliva THC concentration.

Using ROC analysis, Laloup *et al.* (2006) found that the optimal cut-off value for THC in oral fluid in order to predict a positive plasma result for THC was 1.2 μg/L THC. They reported that a cut-off value of 5.2 μg/L THC in oral fluid by LC-MS(-MS) corresponded to the serum legal cut-off for driving in Belgium of 2 μg/L. Kintz *et al.* (2000) recommended a screening cut-off concentration of 2 μg/L THC in oral fluid when oral fluid is used to detect the presence of drugs in impaired drivers. Niedbala *et al.* (2001c) used a screening cut-off of 1 μg/L in diluted oral fluid (0.4 mL specimen and 0.8 mL preservative solution) collected by swabbing with citrate stimulation and a confirmation cut-off of 0.5 μg/L by GC-MS(-MS) for a laboratory-based saliva testing system. However, the Epitope absorbant that they used has been shown to retain THC. The proposed US workplace cut-off for opiates in saliva is 4 μg/L THC or THC equivalents by immunoassay and the confirmation cut-off is 2 μg/L THC (SAMHSA 2001). The Cozart RapiScan Oral Fluid Drug Testing System cut-off is 10 μg/L THCA in diluted oral fluid or 30 μg/L THCA in saliva. The Cozart DDS oral fluid drug testing system detects at least 30 μg/L THC.

Hall *et al.* (1998) applied solid-phase microextraction (SPME) to the determination of cannabidiol, Δ^8-THC, Δ^9-THC and cannabinol in human saliva by quadrupole ion-trap GC-MS. SPME allowed analysis of small saliva samples and eliminated the use of organic solvents. Samyn and van Haeren (2000) reported on-site testing of drivers with the DrugWipe (Securitec, Munich, Germany) and confirmation by GC-MS after solid-phase extraction and derivatisation. Cannabinoids were confirmed in 10 of 15 subjects; THC concentrations ranged from 1.4 μg/L to 42 μg/L saliva.

LC-MS and LC-MS(-MS) methods have been published for confirmation of THC, THCA and other cannabinoid metabolites in oral fluid (Laloup *et al.* 2006; Teixeira *et al.* 2004).

Phencyclidine and ketamine

Phencyclidine (PCP) has low protein binding in plasma (less than 10%) and a pK_a of 9.43. From the Henderson–Hasselbach equation, the saliva : plasma ratio would be expected to be greater than unity. After giving oral (1 mg) and intravenous (0.1 or 1 mg) doses of radiolabelled PCP to healthy male volunteers, Cook *et al.* (1982a) reported that the parent drug was found in saliva at concentrations higher than would be expected from the pH differential between plasma and saliva and the binding of drug in plasma and saliva. The saliva : plasma ratio ranged from 1.5 to 3.0. Saliva was collected by expectoration into glass vials. Saliva pH averaged 6.7 ± 0.17.

PCP is primarily abused by smoking tobacco or cannabis cigarettes that have been dipped into PCP-containing solvents. Inhaled PCP would be trapped in the tissues of the mouth. Cook *et al.* (1982b) also reported that both PCP and phencyclohexene (PC) were present in plasma after volunteers smoked 100 μg of radiolabelled PCP. The persistence of PCP or PC in saliva after smoking of PCP was not reported.

McCarron *et al.* (1984) analysed paired serum and saliva samples from 100 patients suspected of PCP intoxication. Both serum and saliva tests were positive for PCP by RIA in 70 of the cases. Both were negative in 7 cases. In 21 cases with no clinical evidence of PCP intoxication, both serum and saliva RIA were negative in 17 cases, and positive in 3 cases. Saliva PCP concentrations ranged from 2 μg/L to 600 μg/L.

The proposed US workplace cut-off for PCP in saliva is 10 μg/L PCP equivalents by immunoassay and the confirmation cut-off is 10 μg/L PCP (SAMHSA 2001).

Ketamine is a structurally related dissociative anaesthetic. Methods for detection and the pharmacokinetics of ketamine in oral fluid have been reported (Cheng *et al.* 2007).

Collection of saliva

The greatest advantage of saliva is the possibility of having the sample collected by the donor while under observation. In addition, in on-site

testing such as close to the patient or roadside testing, the specimen can be collected shortly after the time of the incident. Saliva collection is non-invasive and can be done by donors themselves in most situations. An exception may be when the donor is unconscious or so sedated as to be unable to follow instructions. Oral fluid has been collected from donors by spitting, draining, absorption and suction. A number of devices are available for saliva and oral fluid collection.

Collection devices

Peel *et al.* (1984) asked 'driving while intoxicated' suspects to spit into a test tube with or without sour candy stimulus. A similar approach was taken by Cone (1993) at the Addiction Research Center in their many controlled-administration drug studies. The Greiner Bio-One Saliva Collection System requires the donor to rinse his or her mouth with Saliva Extraction Solution (pH 4.2) and spit the resulting mixed liquid into a collection beaker. This is then emptied into a graduated saliva transfer tube for measurement of the volume. The Bio-One Saliva Extraction Solution contains a food dye that serves as an internal standard for photometric determination of the saliva concentration. In a study with 102 donors, the recovered fluid volume ranged between 4.4 and 9.8 mL with a saliva content of 39–89% (median 66%) (Schmidt *et al.* 2007).

The Salivette collector (Sarstedt, Germany) employs a dental cotton roll, which is chewed by the donor for 30–45 s with or without citric acid stimulation. After the oral fluid is collected, it is placed in a container that fits into a centrifuge tube. During centrifugation the saliva passes from the cotton roll into the lower part of the tube. Cellular particles are retained at the bottom of the tube. The cotton roll reliably absorbs 1–1.5 mL of oral fluid. The disadvantage of the cotton roll is that it may adsorb analyte(s) or give off compounds that may interfere in hormone and drug assays.

The Finger collector (Avitar, Canton, MA, USA) uses a proprietary dental absorbent (AccuSorb foam) that absorbs saliva when placed in the mouth for a few minutes. Saliva is expressed from the absorbent using finger pressure. Volume recovery ranges from 83% (1.86 mL collected and 1.48 mL recovered, Salivette) or 78% (0.82 mL collected and 0.64 mL recovered, Intercept) to 18% (1.69 mL collected 0.3 mL recovered, Hooded Collector) (Crouch 2005).

The Drugwipe (Securitec, Munich, Germany) saliva test attempts to wipe the tongue with a wiping pin and then transfer the oral fluid collected by washing it onto a test strip (Frontline urine test strip, Boehringer Mannheim GmbH, Germany) developed for testing surfaces for traces of drugs. Pichini *et al.* (2002) reported that the Drugwipe wiping pin holds at most 2 μL of fluid. They also reported that placing 2 μL saliva on the collection pin produced the best accuracy, but that wiping the tongue with the pin produced inadequate sample for reliable results.

The Intercept saliva sampling device comprises an absorbent paper pad impregnated with buffered salts on a plastic rod. The pad is placed in the mouth for 2–5 min. After collection, the paper is placed in a tube with preservative liquid and shipped to the laboratory for analysis. The Intercept pad is estimated to absorb approximately 0.4 mL of oral fluid, which is diluted 1 : 3 with 0.8 mL preservative fluid. Several studies have shown that some drugs such as THC are poorly eluted from the absorbent paper pad (Kauert 2000; Langel *et al.* 2007). Crouch (2005) reported losses of greater than 40% at room temperature from the Intercept pad.

Collection indicators

Modern oral fluid collection devices generally use an absorbent material on a plastic rod with a colour indicator to signal when a certain volume has been collected. It is essential to know the volume collected if the sample is to be diluted with buffer and reagents for point-of-collection testing or with preservatives for shipment to a laboratory for testing.

For example, the Cozart DDS Oral Swab (Cozart BioScience, Abingdon, UK) consists of a cotton bud on a plastic stem. The mouth of the oral fluid donor is swabbed with the cotton bud until the sample presence indicator turns blue. This usually occurs within less than a minute (mean time 34 s for drug-free subjects and 44 s for drug users) and indicates collection of 0.34 ± 0.06 mL average volume (Speedy *et al.* 2007). Drug recovery was greater than 90% for THC, amfetamine, cocaine, methadone, metamfetamine, morphine and temazepam (Speedy *et al.* 2007).

Other collectors (RapiScan, Cozart Bioscience, Abingdon, UK; Omnisal, SDS, StateSure Diagnostics Systems, Framingham, MA, USA; Quantisal, Immunoalysis, Pomona, CA, USA) use a detachable absorbent cotton pad on a plastic handle containing a sample volume adequacy indicator. After the indicator has turned from white to blue, indicating that 1 mL of saliva has been collected on the pad, the pad can be detached and kept in a test tube containing preservative buffer until analysis. Drug recovery and stability have been reported for the SDS type collector (Dickson *et al.* 2007; Langel *et al.* 2007; Moore *et al.* 2006b) and depends on the drug and the buffer/preservative solution used.

Schramm and colleagues (Schramm, Smith 1991; Schramm *et al.* 1993b) developed a small plastic sack (SalivaSac, BioQuant) composed of semipermeable membranes which contains high-molecular-weight sugars. When it is placed in the mouth, osmotic pressure drives an ultrafiltrate of saliva into the interior of the sack. The drawback with this system is that the sack requires from 10 to 20 min (depending on the sack size) for collection of sufficient fluid for testing.

Foley *et al.* (2000) developed an aspirator (LifePoint, Rancho Cucamonga, CA, USA) that would draw saliva directly from the mouth of the test subject through a tube with a disposable individual sterile mouthpiece. For on-site testing the saliva passed directly into the analyser, eliminating the need to elute saliva from the collector pad with buffer and transfer it into an immunoassay cartridge.

For collection of saliva (generally parotid saliva), small intraoral cups (Schaeffer cup, Curby cup) that can be placed over the Stensen's duct of the parotid gland are available. The collection cup is placed in the buccal vestibule with the opening over the duct orifice. Gentle pressure on the cheek over the cup causes air to be expressed from the cup and creates a slight negative pressure that keeps the cup in place until it has collected sufficient saliva.

The collection device or method has been shown to influence the pH of the saliva by stimulating saliva flow and hence the drug content of oral fluid according to the Henderson–Hasselbach equation (Kintz, Samyn 2002; O'Neal *et al.* 2000) Collection devices can also affect recovery of drugs from oral fluid due to retention of oral fluid in the absorbent, and adsorption of drug on device components and drug recovery from device buffers (O'Neal *et al.* 2000). After controlled administration of codeine, oral fluid codeine concentrations were higher in specimens obtained by spitting than those obtained using absorptive devices (O'Neal *et al.* 2000).

Dealing with adulterants

One of the advantages of saliva testing is that the sample is collected under direct observation. Before collection of saliva or oral fluid, the collector should observe the donor for a 10–15 min period in which the donor should not smoke, consume food or drink. Experience with saliva and breath alcohol testing is that contaminants, such as ascorbic acid from foods or drink, will clear from the oral cavity either by swallowing of saliva or by dissipation into the general circulation within 10–15 min. Also, a simple experiment shows that a person cannot hold saliva, especially saliva containing liquid or solids, in the mouth for more than 3 min without swallowing or dribbling (Jehanli *et al.* 2001). Rinsing of the mouth is not required for collection of saliva nor does it reduce the levels of drugs found in oral fluid. Wong *et al.* (2005) studied the effects of adulterants and foodstuffs on oral fluid THC and opiates and found no false positives or negatives.

Sample treatment

Cone *et al.* (1997) stored collected saliva samples at -20°C. The OraSure System (OraSure Technologies, Bethlehem, PA, USA) provides for shipping the oral fluid collected with the Intercept pad to a central laboratory

for analysis following the addition of a preservative fluid. The process requires no special refrigeration and no sample treatment is required for immunoassay screening of the saliva or its dilutions. If the analyte of interest is unstable in aqueous solutions (e.g. cocaine) or subject to changes by oral fluid bacteria or enzymes (e.g. nitrazepam, flunitrazepam) then further preservation efforts may be required. Freezing of the collected oral fluid reduces interference from mucins in pipetting and liquid–liquid extractions for chromatographic confirmation testing. Solid-phase extraction or solid-phase microextraction reduces the need for freezing the sample (e.g. dos Santos Lucas *et al.* 2000; Hall *et al.* 1998). Moore *et al.* (2006b) described losses of 10% and 20% for THC when the Quantisal oral fluid collections device was stored in the refrigerator or at room temperature, respectively.

Analysis of saliva for drugs

Screening tests

Immunoassays for detection of drugs in saliva must target or have significant cross-reactivity with the parent drug and lipophilic metabolites. For example, cocaine parent drug and ecgonine methyl ester, heroin and 6-MAM, and THC predominate in saliva owing to their lipophilicity. When drugs are leached into saliva from buccal depots, which is the case for smoked drugs such as cannabis, smoked cocaine or diamorphine, parent drug and pyrolysis products will predominate in saliva. Immunoassays have been developed that are appropriate for saliva screening. In addition, clinical trials and analysis of the sensitivity, specificity and predictive value of different putative cut-off values for saliva screening assays as illustrated in Figs. 18.1, 18.2 and 18.4 have been published for specific immunoassays for saliva drug screening.

On-site testing

A number of on-site test systems have been developed for drugs in oral fluid. These tests are immunochromatographic screening tests (see also Chapter 31). They generally employ lateral diffusion of the oral fluid sample mixed with labelled antibodies in buffer across a linear array of immobilised drugs. When drugs are present in the oral fluid, they bind to the anti-drug antibodies, and the antibodies then pass by and do not bind to the corresponding test line containing the immobilised drug conjugate. Visualisation of the antibody label (using colloidal gold, phosphor or other indicator) reveals a lack of response from the array location corresponding to the drug(s) present.

The first on-site saliva test was the Cozart Rapiscan Oral Fluid Drug, Testing System (Cozart BioScience Ltd, Abingdon, UK) in 1998, which uses lateral transfer immunoassay with colloidal gold-labelled anti-drug antibodies. The procedure is typical of those used for on-site oral fluid testing. The saliva specimen is collected using a collection pad and placed in a test tube containing 2 mL running buffer. When placed in the mouth, the collection pad absorbs 1 mL of saliva. This is indicated by the development of a blue colour in the indicator section of the handle (Fig. 18.6). The pad is then placed in the tube, where it is diluted with 2 mL of buffer fluid. The cellulose pad is separated from the plastic handle along a perforated edge. After removing the cap and plastic collector handle, the cotton pad is compressed using a dispensing filter which is used to dispense six drops of the saliva–buffer mixture onto the cassette by directing the tip of the dispensing filter tube into the cassette well and gently squeezing the tube.

For each test, a fresh disposable cassette and collection kit are used. The cassette or cartridge is inserted into the hand-held instrument for incubation, reading and reporting. The saliva/run fluid rehydrates the gold-labelled anti-drug antibodies contained within the cartridge. This mixture travels by capillary action across an array of immobilised drug sites (3–5 min for single-panel and two-panel tests; 12 min for a five-panel test). The absence of colour development at an immobilised drug position indicates presence of the drug. The quality control position contains anti-mouse IgG to ascertain that complete lateral transfer of specimen has been achieved.

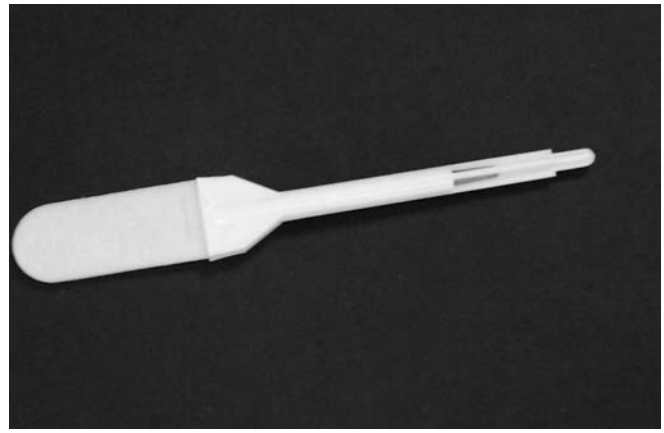

Figure 18.6 The Cozart RapiScan collection device.

The cassette result (binding of gold-labelled antibody to immobilised drug in the absence of drug in sample) is monitored by the portable, battery-powered reader and reported on the display screen. In addition, if one or more positive results are obtained, then a light on the face of the reader will appear red in colour. If all results are negative the light will appear green. The results can be printed out on an optional battery-powered printer to provide a permanent record of results. Results are sent to the printer via the multifunctional port, which also serves for charging the instrument's batteries and to up-load new versions of the instrument software, new drug combinations, etc. via an internet interface module.

If the saliva screening test is positive, the remainder of the sample (2.8 mL fluid) and the whole of a second sample of saliva collected at the same time as the first or at the time of the positive reading (10–15 min later) may be capped, tamper-proof tape placed across the cap and the samples sent to the designated laboratory for confirmation.

Alternatively, a urine or blood sample may be collected and sent with the remainder of the positive saliva to the laboratory, depending on the preference of the contracting laboratory.

Recently developed point-of-collection tests have shortened the time of the immunochromatographic test by using multiple test strips with only two drug tests per strip (Cozart DDS, Abingdon, UK; Drager Drug Test 5000, Drager Safety AG, Lubeck, Germany). For example, the Cozart Drug Detection System (DDS) shown in Fig. 18.7, displays results for up to six different drugs in under 5 min and two drugs in under 90 s. Other on-site immunochromatographic oral fluid drug tests that use colloidal gold antibody labels are ORALScreen System (Avitar, Canton, MA, USA) (Barrett *et al.* 2001) and Drugwipe and Drugread (Securitec GmbH, Ottobrun bei Munchen, Germany) employing the Frontline urine dipstick (Boehringer-Manheim GmbH, Manheim, Germany).

Figure 18.7 The Cozart DDS Saliva Test reader and cassette.

An on-site immunochromatographic assay has been developed by Orasure Technologies that uses an up-converting phosphor based on lanthanide particles that absorb infrared light and emit visible light (up-conversion) as the antibody label (Up-Link Rapid Detection system, OraSure Technologies, Inc., Bethlehem, PA, USA). Biological matrices do not up-convert, eliminating test background from autofluorescence. As in the immunochromatographic procedure described above, oral fluid specimens are collected in a device that indicates sample adequacy and retains oral fluid sample for confirmation testing if required. Specimens are mixed with buffer and introduced to a test cassette. Antibodies labelled with up-converting phosphor microparticles contained on a lateral flow membrane in the cassette are mobilised when liquid sample flows across the pad. The presence of increasing amounts of drug in the sample decreases the amount of antibody-bound label bound to the corresponding test line containing the immobilised drug conjugate. A 10 min incubation is required. The test simultaneously detects amfetamine, metamfetamine, PCP and opiates in oral fluid with 40% or better displacement at 10 µg/L drug (Niedbala *et al.* 2001b). A reader utilising an excitation infrared laser (980 nm) and photomultiplier tube with a filter to determine visible light visualises the location of the bound phosphor-labelled antibody, which indicates whether drugs are present in the oral fluid. Up-converting phosphors that emit visible light at 475, 505, 550 and 720 nm are available. Different phosphors can be used as labels for different anti-drug antibodies. This allows close spacing of the drug conjugate lines on the immunochromatography strip.

Confirmation testing

When immunoassays are used as screening tests for drugs in saliva, chromatographic tests should be used for confirmation (Spiehler *et al.* 1988). Like screening tests, confirmation tests for drugs in saliva must be able to detect the parent drug or lipophilic metabolites. They must also be able to detect the levels of drugs that appear in saliva. GC-MS methods for confirmation of prescription opiates (Jones *et al.* 2002), opiates and methadone (Moore L *et al.* 2001), diamorphine (Jenkins *et al.* 1995), cocaine (Wang *et al.* 1994) and cannabinoids (Kintz *et al.* 2000) have been reported. A tandem immunoaffinity chromatography/HPLC procedure for cannabinoids was published by Kircher and Parlar 1996. GC-MS(-MS) methods have been published for confirmation and quantification of cannabinoids in saliva (Hall *et al.* 1998; Niedbala *et al.* 2001c). Many LC-MS and LC-MS(-MS) methods are published for confirmation of drugs in oral fluid.

Interpretation of saliva drug results

The foremost question in the application of saliva testing to forensic casework is 'What is the relationship of saliva positive results to blood drug concentrations?'. Drug concentrations in saliva reflect the free, unbound parent drug and lipophilic metabolites circulating in the blood. Since these are the forms of the drug that cross the blood–brain barrier and affect performance and behaviour, saliva is a good specimen for detecting patient compliance with medication, drug involvement in driving behaviour, fitness for duty or impairment of performance for many drugs. However, efforts to use saliva concentrations to predict blood free-drug concentrations, cerebrospinal fluid (CSF) concentrations or degree of performance impairment have not reached the accuracy of blood measurements. Without knowledge of the instantaneous saliva pH, saliva drug concentrations may not be extrapolated to blood drug concentrations. When appropriate cut-off concentrations are employed, saliva drug presence may be associated with recent drug use and in some cases with being under the influence of the drug.

Saliva concentrations can be exceptionally high when the route of administration is via inhalation, such as occurs with cannabis, cocaine, metamfetamine and diamorphine, sublingual or buccal adsorption or snorting of the drug. In cases involving these routes of administration, 2–4 h must elapse before the contamination of saliva by the remains of ingested drug is cleared from the mouth and saliva concentrations reflect plasma levels. Cannabis is an example. For the first hour or so, THC found in saliva is most likely coming from cannabinoids deposited in the oral mucosa as a result of smoking the drug. However, saliva concentrations of THC follow the same time course as the appearance and decline of physiological indices of cannabis's pharmacological effects. The rate of clearance of THC from the oral tissues appears to match the binding and clearance of THC from the central nervous system site of action of cannabinoids.

Conclusion

For many drugs the saliva drug concentrations are related to the blood concentration of the unbound, unionised parent drug or its lipophilic metabolites. For these drugs, saliva concentrations are a function of circulating drug blood levels. For many patient populations the ease of obtaining oral fluid and avoiding venepuncture outweighs the inaccuracy of estimation of drug levels from saliva. This includes clinical uses in infants and children, elderly people, and HIV-positive patients. Saliva is useful in pharmacokinetic studies since multiple specimens can be obtained over time with minimal discomfort to the subject. In forensic practice, saliva drug collection and testing, unlike venepuncture, can be carried out in non-clinical settings, provides information about the presence of drugs, indicates recent ingestion and may be correlated to psychomotor impairment for some drugs such as cannabis. Finally, in large-scale testing such as the US workplace drug-testing programmes, collection and testing of oral fluid provide specimens that can be collected under direct observation and that are not easily diluted or adulterated. For this reason, saliva drug testing has been proposed for US federal workplace testing as a specimen for random testing, for testing triggered by reasonable suspicion or cause and for post-accident testing. Both laboratory-based and on-site saliva drug testing are anticipated in the workplace.

Saliva alcohol

Ethanol is a low-molecular-weight compound that passes through cell membranes and does not ionise or bind to plasma proteins. Ethanol distributes to all body fluids in proportion to their water content. The measured saliva : plasma ratio for alcohol, 1.10, is slightly higher than the calculated value, perhaps because of the high blood flow to the salivary glands; saliva ethanol is in equilibrium with arterial blood rather than venous blood collected for analysis. Saliva equilibrates rapidly with blood ethanol.

Pharmacology

The passage of ethanol into saliva and the close correlation between saliva and blood alcohol concentrations was reported in the 1930s (Friedemann *et al.* 1938). Jones (1979b) reported an ethanol saliva : plasma ratio of 1.077 with a range of 0.84–1.36 in 48 men between 1 and 3 h after ingestion of 0.72 g/kg ethanol in a fasting condition. Variation was determined by analysis to be equally due to inter- and intra-individual components. Individual variation in saliva : plasma ratios showed no systematic variation through absorption, distribution and elimination phases of ethanol metabolism. Jones (1993) confirmed this value with a measured saliva : plasma ratio of 1.094 (range 0.88–1.36) in 21 male volunteers. McColl *et al.* (1979) found a highly significant linear correlation between blood ethanol concentrations and those in mixed saliva obtained before and after rinsing and drying the mouth and parotid saliva. McColl pointed out that this applies only if the saliva ethanol is determined in saliva obtained more than 20 min after ingestion of ethanol.

Haeckel and Bucklitsch (1987) reported that ethanol concentrations reached higher peak concentrations in saliva than in peripheral blood. It was noted that saliva ethanol concentrations, like breath ethanol concentrations, more closely correlate with capillary blood than with venous blood. Haeckel and Peiffer (1992) reported a saliva : plasma ratio of 0.85 (if related to the aqueous compartment of blood) in saliva and breath samples taken from motorists detained by the police.

Newman and Abramson (1942) correlated saliva alcohol concentrations with ethanol's effects on performance. Jones (1993) compared

saliva, breath and blood concentration–time profiles with subjective feelings of intoxication, body sway, hand tremor, positional nystagmus and roving ocular movement after ingestion of 0.68 g/kg ethanol by fasting men. Saliva concentrations were higher than blood and breath concentrations. All three correlated equally well with measures of alcohol effects. Maximum impairment was reached at the same time as peak saliva, blood and breath concentrations. The mean elimination rate of ethanol from saliva of 13 ± 2.5 mg/100 mL per h was not significantly different from that of blood, 12 ± 1.1 mg/100 mL per h and paralleled the recovery of baseline function in the physiological tests.

Analysis

Ethanol can be analysed in saliva by the same headspace chromatographic (Jones 1978) or enzymatic methods (Jones 1979a) as used for blood. Dipstick or reagent strip tests for alcohol have been reported (Pate *et al.* 1993; Tu *et al.* 1992) but were found to be too unreliable for use in determining blood alcohol content (Lutz *et al.* 1993; Pate *et al.* 1993; Wong 2002). Current enzymatic tests have proven more reliable as quantitative tests (Bendtsen *et al.* 1999; Christopher, Zeccardi 1992; Jones 1995; Smolle *et al.* 1999) and several commercial tests for on-site or point-of-collection testing of saliva alcohol are available.

An example of a point-of-collection quantitative test is the QED Saliva Alcohol Test (OraSure, Bethlehem, PA, USA) (Fig. 18.8). The saliva or oral fluid is collected by the donor with a cotton swab which is applied to the test pad.

As the saliva moves along the reagent bar by capillary action, any ethanol present is oxidised by alcohol dehydrogenase to acetaldehyde with the simultaneous reduction of nicotinamide adenine dinucleotide (NAD). This results in a cascade of electron donor–acceptor reactions catalysed by diaphorase and involving FeCN and a tetrazolium salt, which proceed to production of a purple-coloured endpoint. The length of the resulting purple-coloured bar on the QED device is directly proportional to the concentration of ethanol in the specimen. The alcohol concentration can be read directly from the height of the coloured reaction bar from a printed scale in mg/dL or mg% ethanol just as in reading a thermometer (Fig. 18.8). To get an accurate reading the capillary must draw saliva all the way to the top of the device. This is signalled by development of a purple colour within 5 min at the QA spot at the top of the 'thermometer' (Fig. 18.8).

Since the saliva moves along the reagent bar, and reacts directly with the indicator chemicals, any oxidant in the saliva can cause a false-positive result. The most common oxidant found in saliva is ascorbic acid, which is commonly added to fruit juices, sodas and soft drinks as a preservative. Ascorbic acid is absorbed in the gums and is still found in the mouth in amounts sufficient to give a false positive with the QED Saliva Alcohol Test for up to 10 min after drinking some soft drinks and sodas.

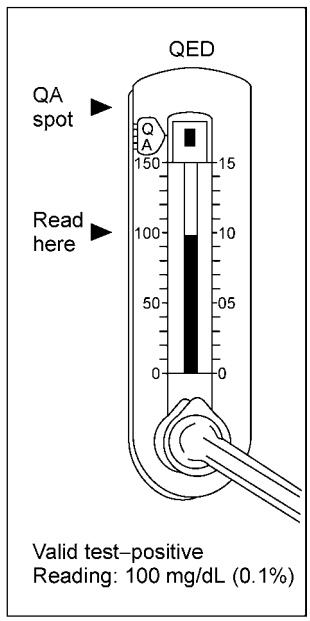

Figure 18.8 The QED Saliva Alcohol Test.

The QED Saliva Alcohol Test comes in two ranges: 0–150, which can be read from 10 mg/100 mL to 150 mg/100 mL, and 0–350, which can be read from 20 mg/100 mL to 350 mg/100 mL. The first, lower, range is for Department of Transport and driving-under-the-influence applications, the second is for hospital and overdose applications.

An example of a headspace enzymatic assay is the On-Site Alcohol Assay for qualitative detection of alcohol in urine and saliva (Roche Diagnostics, Nutley, NJ, USA; Ansys Technologies Inc., Lake Forest, CA, USA). The On-Site Saliva Alcohol test is similar to the QED Saliva Alcohol Test in that saliva is collected by the donor from his or her own mouth with a cotton swab and then the swab is applied to the specimen well. Since alcohols are volatile, alcohol vapours will diffuse from the sample pad to the reaction pad where they react with alcohol dehydrogenase and diaphorase. The hydrogen released is transferred to a tetrazolium salt to produce a highly coloured formazan dye. The presence of alcohol is indicated by the appearance of a purple plus sign (+) in the result pad. The On-Site Saliva Alcohol test does not have a control spot, so an external control must be run in each testing session on an additional test unit. Since the test detects alcohol vapours from the saliva, the saliva sample does not come into contact with the reagents. Therefore, there is no possibility of false positives from oxidising agents such as ascorbic acid in the saliva. However, the result is only qualitative. The cut-off is 0.02 g%, so a purple plus sign (+) indicates only the presence of alcohol at greater than 0.02 g%.

Interpretation

Saliva ethanol concentrations are an accurate reflection of blood alcohol concentrations. Saliva alcohol can be used to estimate blood alcohol concentrations, to estimate pharmacokinetics of ethanol in an individual, as evidence of impairment and to determine fitness for duty in the workplace.
