
Committee of Ministers of the Council of Europe

The Committee of Ministers of the Council of Europe (1998) has stressed that "health policy in custody should be integrated into, and compatible with, national health policy" (World Health Organization Regional Office for Europe, 2013). The Committee further explained that this initiative is not only in the interest of prisoners, but this integration also favors the health of the community at large. It is especially significant for policies related to infectious diseases that may have a chance to spread from prisons to the wider community. Similarly, majority of prisoners in prisons are usually for shorter period of time and eventually they will be released from prisons. They will return to society from which they belong, once their sentence is over. When they rejoin the community, it is important that, they joined back with the good health conditions (World Health Organization Regional Office for Europe, 2018).

World Health Organization Health in Prisons Programme

In order to support and improve the health care in prison and to establish a link between national and prison health system of member states, both at national and international system, World Health Organization has established health in Prisons Programme (HIPP) in 1995 (Bott, 2016). This program is meant to provide the technical assistance to member countries on issues related to mental health, illicit drug use and communicable diseases including hepatitis, tuberculosis and HIV/AIDS (World Health Organization Regional Office for Council of Europe, 2018). As part of HIPP, WHO/Europe established a network of national counterparts and international partner organizations to liaise between WHO/Europe and Member States. The network currently includes 44 national counterparts and meets once a year to discuss specific topics (World Health Organization Regional Office for Council of Europe, 2018).

All countries that are participating members of the WHO Health in Prisons Project (HiPP) are also members of the Council of Europe (Gatherer et al., 2005). It is recommended that in every prison there must be qualified medical practitioner and other medical personnel trained to provide healthcare delivery (World Health Organization Regional Office for Council of Europe, 2018). The European prison rules also made recommendations regarding patients who having mental health problems to be considered for special treatment (Enggist et al., 2014). All these reforms are designed to safeguard the community as a whole. If these inmates are not looked after properly in prisons, they will further increase the burden on the existing facilities, once they return to their communities after their release (Enggist et al., 2014).

The Organization of Prison Health Care

Across the globe, medical care to the prisoners is managed by various agencies by employing different approaches and mechanisms, usually it is the responsibility of Ministry of Health or their equivalents, Ministry of Interior and the Ministry of Justice (United Nations Office on Drug and Crime, 2008). However, to ensure that prisoners can receive better healthcare, it is very much based upon the close contact between public health and prison health administration. To do so, many countries around the world have started to strengthen such collaborations and links (Møller et al., 2007). Many prisons argue that prison health services should come under the public health services system rather being operated as a separate system run by the ministry of prisons. For instance, in Wales and England the responsibility and the prison budget both were transferred to National health Service in 2002 (Hayton and Boyington, 2006). Likewise, in Norway, the responsibility of health care was handed over to local health care authorities for the provision of prison health care services (Coyle, 2014). France introduced the legislation reforms in 1994, by putting prison health care under the Ministry of Health, supervised by General Health Directorate for public health issues (Dubois et al., 2017). The provision of health care in prisons in most of the European countries comes under the Ministry of Justice and further medical services are managed by the hospital administration, such as, in Italy the Ministry of Justice bears the costs of the health care in prisons (Council of Europe, 2014). While other member countries of WHO European Region including Finland, Kazakhstan, Republic of Moldova, Kosovo are planning to involve Health ministry (United Nations Office on Drug and Crime, 2008; 2013; Council of Europe, 2014).

Prisoners are admitted to hospital for treatment inside and also outside of the prisons, for example, in Cyprus, Norway, Sweden, Lithuania, and Turkey, the hospital treatment is only available outside the prison (Council of Europe, 2014). Besides, in many European countries, large prison systems have their own health and medical care staff, while others have appointed part time staff including dentists, psychiatrists, psychologists and gynecologists. However, in prisons, where physicians are part-time employed, a full time trained health care staff with trained nursing staff fulfils the requirements (Marshall et al., 2000). In France, the medical team is composed of general practitioners, dental surgeons, medical specialists, and pharmacists, along with a paramedical team of nurses, radiology technicians, and administrative personnel (Dubois et al., 2017). Contrary to this, in countries like Scotland, nurses are responsible for the delivery of primary health care to the prisoners, being the first point of contact between the prisoner and the health care system (Dubois et al., 2017; Møller et al., 2007). These responsibilities may include prisoner's preliminary health assessments upon arrival, issuance of medicines to patients, or application of prescribed treatments recommended by physician (Møller et al., 2007).

Pharmacy Services in Prisons

Pharmacy practice, for instance, in American prisons remains unique in terms of its distinct features, though it encompasses various aspects of hospital, community, and consultant pharmacy practice. It is also recommended in these guidelines, that such places should hire at least a pharmacist for the delivery of healthcare (American Society of Health System Pharmacists, 2013). Pharmacy services in prisons fall into the following these categories: (Norris, 2005).

1. An in-house service based on the supervision of a pharmacist inside prison.
2. A satellite service provided by a nearby prison to another prison-based patient with a type (a) service.
3. A service provided by outside contractors, such as independent companies, or by a community or hospital pharmacist.

The practicing pharmacist in such territories not only have to be familiar with the community standards of care, but they need to be aware of the rules and regulations implemented by federal or local jurisdictions. As in case of pharmacist practicing in American prisons, familiarity with the community level care as well as standards set by National Commission on Correctional Health Care and ASHP is a necessary requirement (American Correctional Association, 2002; American Correctional Association Commission on Accreditation for Corrections, 2003).

Role of Pharmacist

Since the emergence of pharmacy profession, pharmacist has been considered as the individual who has the knowledge about medicines and their optimum use (World Health Organization, 1997). The role further got the recognition when the subject

of pharmacy received the recognition worldwide (World Health Organization, 1997). Clinical pharmacy services offers the same activities, tailored to optimize the patients' health outcomes, ensure safety throughout the medicine management process and lower the risks associated with the use of medicines (Society of Hospital Pharmacists of Australia, 2014). Clinical pharmacy services also include therapeutic drug monitoring, adverse drug reaction management, medication reconciliation, medicines management plan, and participation in the interdisciplinary health care team (Society of Hospital Pharmacists of Australia, 2014). Hence many pharmacists work in the prison based pharmacy and are majorly concerned with the planning, coordination and delivery of pharmaceutical care to the patients in detention. They are usually assisted by pharmacy technician, employed by the prisons. The health care delivery in prison involves a mutual effort of the prison pharmacy staff and other health care members from multidisciplinary team including dentists, physiotherapists, psychiatrists, and radiologists (Norris, 2005).

It is suggested that the prisoners should get the same level of care and treatment what is available to the outside community. The next section of the chapter specifies the role of a prison pharmacist in the delivery of clinical services to prison-based patients:

As the Director of Pharmacy

In United States, a licensed pharmacist recognized by the National Association of Boards of Pharmacy should be appointed the pharmacy director of the facility. He or she should be hired, at least, on a consulting basis. Health care needs of the facility should be considered before staffing pharmacists for the facility (American Society of Health System Pharmacists, 2016). By the approval of relevant health authority and prison administration, the pharmacy director takes up the responsibility of the operations and policy implementation for pharmacy (Bott, 2016).

Provision of Drug Usage and Other Services

The review and monitoring of prescription by pharmacist focuses on the initiation and discontinuation of the treatment, adjustment of dose for the patient, monitoring of test result in relation to dose and side-effects (Allgeier, 2012). A pharmacist employed in prison is in a better position to provide a number of services and information, pertinent to drug and its interaction, nutrition, drug–food interactions, drug abuse and withdrawal treatment, medicines use in emergency, antidotes for poisoning, mental health, medical devices and supplies, and provision of health care for pregnant women (Bott, 2016).

Medication review by pharmacists is an effective tool to make prisoners understand their medicines and problems associated with the medicine use. It is especially useful for those patients who are on multiple medications, having chronic problems and most importantly for the prisoners going through detoxification treatment (Allgeier, 2012). Hence, pharmacist working in a prison is able to offer his expanding role as a service provider and can contribute through his expertise to be an active team player of the medical team (Bott, 2016).

Provision of Nonprescription Drug Selling and Storing

In some prisons, facility, such as a general store, typically called as commissary sells drug products to inmates without the prescription of the physician (Prison Fellowship, 2018). In some prisons nonprescription medicines are available for purchase by the inmates, pharmacist need to be stringent in checking that medicines are not being abused (Bott, 2016). The purchased quantity of the medicines should be minimized to prevent possible overdosing. Pharmacy director may take the lead in this regard and can inspect the premises to check that which type of nonprescription medication are being sold. He can also inspect the storage conditions to ensure that the quality and safety of the products remain intact. This task can be further improved by providing the leadership through regular meetings with the facility's medical, para medical, and mental health staff (Bott, 2016). Particular attention must be paid to psychotropic medications, medication used for the treatment of communicable diseases, or other medical conditions specific to inmates (American Society of Health System Pharmacists, 2010b).

Dispensing

The dispensing job of a pharmacist is quite different from what he does in community. Because in prison, there are many inmates who are undergoing the treatment for substance misuse. There are also some patients who are getting medication for psychological or depression problems, and the number of patients is higher than the community. There are some medicines, which are labeled as that can be kept by the patient or cannot be and hence labeled as in-possession or not-in-possession based on the type of drug and risk assessment of the prison-patient. So, a pharmacist has to be more careful while dispensing these medications. However, not in possession items are administered by nurses in specialized "medical hatches" to avoid the risk of drug misuse. As some medicines have a great value to the prisoners, and if they are selling those medications to other inmates, they will try to divert or conceal it from medical staff. Therefore, the role of pharmacist in dispensing in prisons is quite challenging. As its more strategic in prisons to provide health care services to the inmates. One example is tramadol which is not allowed to keep in possession by the inmates, but which is otherwise allowed in community to take four times a day. To overcome the challenge, some prison pharmacist has developed a way to dispense the drug as a modified slow release type, which cannot be abused by the prison-patients (Cox, 2018).

Medication Administration

It is not possible to have a huge number of healthcare professionals working in prisons, so sometimes the trained but nonhealth care staff are also involved in the process of drug administration, if nurses are unavailable (National Commission on Correctional Health Care, 2018). In such scenarios, the pharmacy director is considered liable to develop the medicine information forms and should ensure the particulars entry in the forms. The information includes particulars about type of administered drug, dose and its frequency, start and end date of drug administration, and history of allergies to the medicines. The pharmacy director is also responsible to design policies about the administration of the drug to the prisoners, or during court hearing, transfer to or release from the prison. For example, inmates upon their release from prison, may be issued with a discharge prescription having details of the medicines (Bott, 2016).

Substance Abuse and Rehabilitation Service

Various studies estimate that the percentage of individuals reporting problematic substance misuse is comparatively higher in prison than in the community. Different studies have indicated that the percentage of people in prison who have a drug problem, ranges from 40% to 80% particularly for women with drug problems. Substance abuse is a major societal problem bearing significant public health concern (Allgeier, 2012). Data from Centre for Disease Control and Prevention has found that substance abuse in prisons was linked with 7.6% of new HIV cases between years 2008 and 2011, involving transmission through the sharing of syringes for drug use and other equipment, hence proved to be the most common transmission route for Hepatitis C. As a result, substance abuse may be associated with the aggravation of mental illness, which ultimately led toward the use of such substances to deal with the physical or mental complication. Many studies have indicated that the individuals experiencing substance abuse problems are more in prisons than in the general population and they might range from 40% to 80% (Dolan et al., 2007), presenting a high ratio of females with substance abuse problem in incarceration. According to a study by The National Center on Addiction and Substance Abuse at Columbia University has estimated that only 11% of such individuals manage to receive substance abuse treatment in prisons (Centre on Addiction, 2010).

Hence, prison pharmacists are responsible to ensure safe and effective medication-use system. Pharmacist in such territories also need to tackle the legal and organizational responsibilities for medication distribution and control across the continuum of practice settings within prisons (Allgeier, 2012). Pharmacist's responsibilities for the treatment and rehabilitation of inmate patients with chemical dependency include provision of services to meet the medical needs of patients during detoxification; planning and development of detoxification protocols, withdrawal management; treatment options for patients, medication and addiction counseling by pharmacy; education of patients and their families and other clinical staff members (Haynes, 1988). To successfully fulfill this complex role, the pharmacist must have specialized skills to tackle addiction, including skills on nonpharmacological approaches. A pharmacist working in a chemical-dependency rehabilitation program has a unique opportunity to positively influence the physical and mental health of the prisoners (Haynes, 1988).

Special Need Services to the Patients

Pharmacist can assist patients with disabilities to follow their medication regimen by providing special clinical services. Such facilitative adjustments by the pharmacist to the inmate patients include use of large print labels and reminder charts, monitoring dosages, and compliance aids (Allgeier, 2012). Another pharmacist-led service is provided to the patient is the supervised self-administration of medication. This encourages the patients to administer the medicines by themselves. This is focused toward the administration of controlled substance for the treatment of substance abuse, but the administration of other medications is also considered (Allgeier, 2012).

Pharmacist in prisons can promote the healthy life style among inmate patients through verbal advice and provision of written material for the patients such as leaflets. Pharmacist may help to motivate the patients about their lifestyle and can provide behavior modification assistance, as, in case of smoking cessation (Allgeier, 2012). Various prison-based studies have showed that a pharmacist led clinic is useful, as prisoners received better information about their condition and the treatment plan (Mathis and O'Reilly, 2010; Tucker, 2004a, 2004b). A pharmacist led-clinic helped the patients to improve their understanding for the skin problem and to adhere with the treatment, which ultimately resulted in the improvement of their physical condition and quality of life (Tucker, 2004a, 2004b). Similarly, a pharmacist led warfarin management point of care service has resulted in the low incidence of adverse effects (Mathis and O'Reilly, 2010).

Education

Inmate patients have poor knowledge about health-related issues so there is a need to improve their health literacy level (Bott, 2016). The educational programs should encompass information on drug indications, administration, appropriate use for medications stocked for emergency use; monitoring for adverse events and allergic reactions; documentation; accountability; confidentiality; and the importance of adherence to medication regimens (Bott, 2016). This could also include provision of language- and age-based educational materials to the prisoners (American Society of Health System Pharmacists, 2010a). For instance, in Slovenia, a health education based program is provided to both staff and prisoners. These leaflets contain information for prisoners about personal

hygiene and maintenance of the cells, where they are living. Likewise, the staff is educated about control of infection. In addition to such programmed, prisoners are provided awareness about TB and HCV. While in Austria, the system is much developed since 1998, as the new inmates, upon their arrival to prisons are provided with Information & Care pack, that contains information about services and risk behaviors including drug and alcohol education, awareness about HIV and its prevention (United Nations Office on Drug and Crime, 2008).

In addition to this, the prisoners should have freedom to consult a pharmacist or request information about a particular drug, or to make choices regarding their own health care (Bott, 2016). Hence, qualified pharmacists must be authorized to provide such services to the inmate population provided, legal requirements are fulfilled, and necessary collaboration are agreed by the prison authorities (Bott, 2016).

Research

Research is a major trigger which can help in the improvement of quality of health services, because these findings will help the health services provider to have a better idea that whether health programs are appropriately executed. It also guides to find out the prevalence of disease and the associated risk behaviors in prison population. Research in prison health care facility not only aids to monitor the feedback on health interventions, but it also helps to modify the existing policies and procedures (Stevens, 2010).

All research that involves medications use in prisons, should be conducted in consultation with a prison pharmacist. The retrospective and prospective research is the need of the hour to advance the practice of prison-based pharmacy as it provides evidence-based clinical decisions. Research in prisons should be done with the potential to influence the patient care and it must include the informed consent and should be approved by relevant authorities (Bott, 2016).

Conclusion

Providing health care in prisons is a big challenge. However, it has major societal benefits and failure to provide health care to prison population may lead to adverse health outcomes. The services in prisons should be based on individual patient needs and should promote self-care. The role of pharmacist in the delivery of such services is both challenging and crucial. Hence, pharmacist led healthcare delivery can help the people in incarceration, to adopt a healthy and disease-free life style. The extended role of pharmacist in the delivery of clinical pharmacy services may help in the minimization of healthcare disparities among prison population.

Glossary

Incarceration The state of being confined in prison or in imprisonment.
Inmate A person who is forced by law to stay in a prison or hospital or in a correctional facility.
Turnover Turnover refers to the number or percentage of individuals who leave an organization and are replaced by new individuals.

Long-Term Care

Heather Smith*, Emily Turner†, *Older People/Interfaces of Care, Leeds Teaching Hospitals NHS Trust, Leeds, United Kingdom; †Leeds Teaching Hospitals NHS Trust, Leeds, United Kingdom

Learning Objectives

- Describe the pharmaceutical issues associated with long-term care.
- Describe interventions that pharmacists can make to support patients with long-term conditions.
- Summarize the evidence for pharmacist interventions on outcomes for patients with long-term conditions.

Introduction and Need

Modern medicine is reducing mortality but sometimes at the expense of morbidity (BMJ, 2014). Long-term conditions (LTCs) or chronic diseases are conditions for which there is currently no cure, and which are managed with drugs and other treatment, for example: diabetes, chronic obstructive pulmonary disease (COPD), arthritis, and hypertension (The Kings Fund, 2018). LTCs also include defined mental health conditions such as schizophrenia, ongoing conditions such as learning disabilities, symptom complexes such as frailty or chronic pain, sensory impairment such as sight or hearing loss, and alcohol and substance misuse (National Institute for Health and Care Excellence, 2016).

Multimorbidity is the presence of two or more LTCs (National Institute for Health and Care Excellence, 2016) and is now commonplace (BMJ, 2014). Multimorbidity has been shown to be associated with increased patient mortality, increased hospital admission and readmission, increased length of hospital stay, increased demand on health resources and complexity of care, increased dependency, and reduced patient quality of life (Harrison et al., 2016; Kingston et al., 2018).

Multimorbidity is not confined to older people, but the number of LTCs a person has increases with age and is also increased in less affluent areas. (BMJ, 2014; National Institute for Health and Care Excellence, 2016). In addition to multimorbidity, many of the oldest old also have sensory impairment and incontinence (Kingston et al., 2018).

Frailty is a distinctive health state related to the ageing process in which multiple body systems gradually lose their in-built reserves (British Geriatrics Society, 2014). Minor stressor events including acute illnesses such as urinary tract infections are associated with adverse health outcomes in patients with frailty such as dependency, institutionalization, and premature death

(Harrison et al., 2015). Around 10% of people aged over 65 years have frailty, rising to between a quarter and a half of those aged over 85 years (British Geriatrics Society, 2014).

As the number of LTCs conditions increases, often the number of medicines prescribed to treat these conditions or prevent complications from these LTCs also increases leading to polypharmacy. Polypharmacy is where an individual takes multiple medicines and is driven by an ageing population and the prevalence of multimorbidity (Duerden et al., 2013) but can also be caused by clinical guidelines, care pathways, and even processes for clinical remuneration (BMJ, 2014). Evidence for recommendations in national guidelines on single health conditions is regularly drawn from people without multimorbidity and polypharmacy (Duerden et al., 2013; National Institute for Health and Care Excellence, 2016) as often these people are excluded either directly or indirectly from clinical trials (Duerden et al., 2013; Hardy and Hilmer, 2011). Therefore, the evidence base for treating multiple LTCs with multiple medicines is poor, and pragmatic clinical trials need to be conducted that include patients with multimorbidity and polypharmacy (Duerden et al., 2013).

The Kings Fund has proposed the use of the terms appropriate and problematic polypharmacy. Appropriate polypharmacy has been defined as the prescribing for an individual for complex conditions or multiple conditions in circumstances where medicines use has been optimized and where the medicines are prescribed according to best practice. Appropriate polypharmacy can extend life and improve quality of life for people. Problematic polypharmacy has been defined as the prescribing of multiple medications inappropriately or where the intended benefit of the medication is not realized. Problematic polypharmacy increases the risk of adverse drug reactions (ADRs) (Duerden et al., 2013; McGrath et al., 2017), drug–drug, and drug–disease interactions (Duerden et al., 2013; McGrath et al., 2017), falls (BMJ, 2014; Marvin et al., 2016; Ziere et al., 2006); increases health-care costs (McGrath et al., 2017), hospital admissions (Describing deprescribing 2014), (Morandi et al., 2013), and mortality (National Institute for Health and Care Excellence, 2016; Thompson and Farrell, 2013); and reduces functional capacity (McGrath et al., 2017), adherence to medicines (Duerden et al., 2013; McGrath et al., 2017), and quality of life (Duerden et al., 2013). Evidence shows that many medicines are not taken as intended by the prescriber and are unused, underused, or wasted (Duerden et al., 2013). Patients with multimorbidity with a limited life expectancy or frailty may obtain limited benefit from medicines treating single conditions (National Institute for Health and Care Excellence, 2016), especially secondary prevention medicines.

Deprescribing is defined as the process of tapering, stopping, discontinuing, or withdrawing drugs, with the goal of managing polypharmacy and improving outcomes. Deprescribing reduces the number of medicines prescribed and medicine costs, but there is little evidence of impact on outcomes with the exception of falls so more research in this area is required, focusing on outcomes and the specifics of how to deprescribe safely and effectively (Hardy and Hilmer, 2011; Thompson and Farrell, 2013).

People living in long-term care facilities or care homes are at increased risk of multimorbity and polypharmacy. People often need residential care due to diseases related to ageing and/or frailty. Therefore, people in long-term care facilities tend to be older than those living in domiciliary settings, are more likely to have multiple long-term conditions, and, as a result, polypharmacy is common (Payne and Duerden, 2015). In the United Kingdom, care homes residents were taking an average of 8 medicines each (Barber et al., 2009). In a European study (Onder et al., 2012), half of all residents were taking 5–9 medicines and a further quarter were taking 10 or more. In Canada, 15% of long-term care residents were taking 9 or more medicines (Bronskill et al., 2012). Medication error rates in long-term care facilities result in preventable patient harm. Error rates of two adverse events per 100 resident months have been found in the United States (Payne and Duerden, 2015). In a UK study, 40% of care home residents were affected by a prescribing error and 10% experienced monitoring errors (Barber et al., 2009).

Therefore, pharmacists in various settings are well placed to ensure that people with multimorbidity are cared for appropriately. This should include reviewing how the person's health conditions and their treatments interact and how this affects quality of life; the person's individual needs, preferences for treatments, health priorities, lifestyle and goals; the benefits and risks of following recommendations from guidance on single health conditions; improving quality of life by reducing treatment burden, adverse events, and unplanned care and improving coordination of care across services (National Institute for Health and Care Excellence, 2016). This may include pharmacist involvement in consultations with people to review medicines and/or deprescribing and various tools are available to help pharmacists review long-term medicines.

Management

Care Models for Long-Term Conditions

Individual management of specific long-term conditions is beyond the scope of this chapter. Please see individual chapters for detailed management advice.

Models of care that aim to ensure that people treated for LTCs receive high-quality holistic care have been trialed and adopted into practice in different countries. These include the Chronic Care Model, the Innovative Care of Chronic Conditions, and the Kaiser Triangle Model.

The Chronic Care Model (CCM)

The Chronic Care Model was developed in the United States in 1998. It has 6 main principles: mobilizing community resources to meet the needs of people with LTCs; creating a culture, organization, and mechanisms that promote safe, high-quality care;

empowering and preparing people to manage their health; delivering effective, efficient care, and support for self-management; promoting care consistent with evidence and patient preferences; and organizing patient and population data to facilitate efficient and effective care (Singh and Ham, 2006).

The Innovative Care for Chronic Conditions Model

The World Health Organization developed the Innovative Care for Chronic Conditions model that focuses on improving care at three different levels: micro level (individual and family), meso level (health-care organization and community), and macro level (policy). This model suggests that positive outcomes for people with LTCs can only occur when people and their families, community providers, and health-care professionals are informed, motivated, and work together (Singh and Ham, 2006).

The Kaiser Triangle Model

The "Kaiser triangle," developed in the United States, is a proactive approach to managing care for people with LTCs. This is a hierarchical system where people are stratified according to need with intensive management targeted at those who are at highest risk. The Kaiser triangle includes supported self-care for the majority of people with LTCs (70%–80%) as a first step (Singh and Ham, 2006). Supported self-care aims to encourage individuals to cope and live well with their condition by equipping them, and their carers or supporter peers, with the necessary knowledge, skills, and confidence (NHS Greater Glasgow and Clyde, 2009). The next step is disease management of high-risk people (Singh and Ham, 2006), supporting people with information, monitoring, and proactive management. The aim is to slow down deterioration of their condition(s) and prevent complications including admission to secondary care (NHS Greater Glasgow and Clyde, 2009). The final step is case management of highly complex people (NHS Greater Glasgow and Clyde, 2009; Singh and Ham, 2006), which aims to identify and anticipate the care requirement and coordinate a multidisciplinary and/or multiagency care package to prevent emergency situations leading to admission to hospital (NHS Greater Glasgow and Clyde, 2009).

Assessment and Management of Frailty

Frailty is now recognized as a long-term condition in its own right. Frailty shares many similarities with other LTCs: it can't be cured, is progressive, reduces quality of life, can result in crises intermittently, and is costly to the person and the health-care system as a whole (Harrison et al., 2015). Various tools are available to identify frailty such as the Rockwood Clinical Frailty and Edmonton Frailty scales (British Geriatrics Society, 2014) and proactive identification of frailty can then be used to instigate person-centered, proactive care and treatment (Harrison et al., 2015). Older people with frailty should have comprehensive geriatric assessment (CGA), which is a comprehensive review of their medical, functional, psychological, and social needs and results in an individualized care and support plan outlining their treatment goals, management plan, and plans for urgent care. Reversible medical conditions should be considered and addressed if present, for example, acute infection. End of life plans may also need to be included for some people. The care and support plan should be shared between different health-care professionals and sectors caring for the frail person (British Geriatrics Society, 2014). Older people with frailty are at increased risk of inappropriate prescribing and harm from medicines (BMJ, 2016; Cullinan et al., 2015). Therefore, regular reassessment of medicines is required (BMJ, 2016), and evidence-based medication review should be part of their care (British Geriatrics Society, 2014). Health-care professionals also need to consider the risk of discontinuation reactions in any deprescribing activities as these may be more serious in frail people (BMJ, 2016).

Polypharmacy and Deprescribing

Appropriate polypharmacy that extends life and improves quality of life requires individualized, patient-centered care using medicines optimization (MO) (BMJ, 2014). MO is a process that allows patients to gain the most net benefit from taking medication where medicines are prescribed taking the patient's preferences and characteristics into account (Royal Pharmaceutical Society, 2013) and acknowledging that what is most valued by the person might be different to the health-care professional (BMJ, 2016). This patient-centered care also needs to be shared across the whole health-care system, but this can be difficult to achieve in practice, especially in countries with fragmented health systems, as organizational boundaries and professional silos cause challenges to the effective sharing of care. While it is unclear what the ideal process for delivering MO is, identifying medicines not likely to be benefiting the person and deprescribing should be included (BMJ, 2014). There is a lack of evidence regarding deprescribing and little to guide the person and the prescriber in how to reach a decision on what to stop, when, and how (Barnett and Garfinkel, 2018; BMJ, 2014; Johannon et al., 2016). Effective deprescribing is a complex process (BMJ, 2016) with a number of components. These include participation by patients and/or relatives, carers and supporting peers (Jansen et al., 2016; Reeve et al., 2014), prescriber/patient relationships and communication (Linsky et al., 2015; Straand and Sandvik, 2001; Turner et al., 2016), and shared decision-making (Jansen et al., 2016).

A Patient Attitudes Toward Deprescribing (PATD) questionnaire has been developed and tested in older out-patients and caregivers in Australia and inpatients in Italy (Barnett and Garfinkel, 2018; Galazzi et al., 2016). This showed that many older people were less aware of the reasons for taking their medicines and that many wanted to reduce the number of medicines taken. Key factors identified included perceived burden of medication taking, belief in appropriateness of medication use (benefits and harms),

concerns about stopping medicines, and level of involvement/knowledge of medicines. Another study identified four factors that are important to people in relation to stopping medicines: medication knowledge, concerns, importance, and interest in stopping medication (Barnett and Garfinkel, 2018). Poly-de-prescribing is the cessation of at least three medicines at the same time and one study in older people has shown that this is well tolerated and is associated with better patient outcomes compared to older people who take all the medicines recommended by clinical guidelines (Garfinkel, 2017).

End-of-life care is beyond the scope of this chapter, but clinicians need to apply "end-of-life" medication review where this is appropriate. This is applicable in patients with advanced LTCs and some patients with severe frailty as well as those with advanced terminal cancer (BMJ, 2014). Prescribers often do not receive training on deprescribing; therefore, focus is needed on educating prescribers and other health-care professionals about the benefits of deprescribing. Health-care professionals may be concerned about deprescribing amid perceptions of denying people medicines or cost-cutting and may be wary of stopping medicines started by specialists with more expertise in a particular field (BMJ, 2016). Absolute benefits of treatments can be assessed using the number-needed-to-treat (NNT) and absolute risks using the number-needed-to-harm (NNH). However, estimates of NNTs and NNHs are usually taken from, individual clinical trials (BMJ, 2016) and as mentioned earlier, those who are older, frail or with multiple comorbidities are not well represented (BMJ, 2016; Duerden et al., 2013), so NNTs may overestimate benefit and NNHs may underestimate harm in these groups. However, NNTs and NNHs may be helpful to explain to an individual the likely time for benefit or harm to occur. This is especially important for preventative medicines where benefits may not be seen for years (BMJ, 2016).

Clinical Medication Review

Clinical medication review has been defined as a structured, critical examination of a patient's medicines with the objective of reaching an agreement with the patient about treatment, optimizing the impact of medicines, minimizing the number of medication-related problems, and reducing waste. Medication review can be used to describe any activity that involves reviewing medicines in any care setting. Different levels of medication review have been described from unstructured, opportunistic reviews to a face-to-face review of medicines and conditions with the patient using the full patient record (Clyne et al., 2008).

As described earlier, medicines optimization using clinical medication review should be conducted in conjunction with the person themselves. A patient-centered approach to managing polypharmacy in practice has been proposed by Barnett et al. (2018). This is a structured approach but still allows flexibility for individualized care and is represented in **Fig. 1** (Barnett et al., 2018).

Other methods to structure the medication review process include the 7 steps. These include Step 1 where aims and objectives of drug therapy are identified; Step 2 where essential drug therapy is identified; Step 3 where unnecessary drug therapy is identified; Step

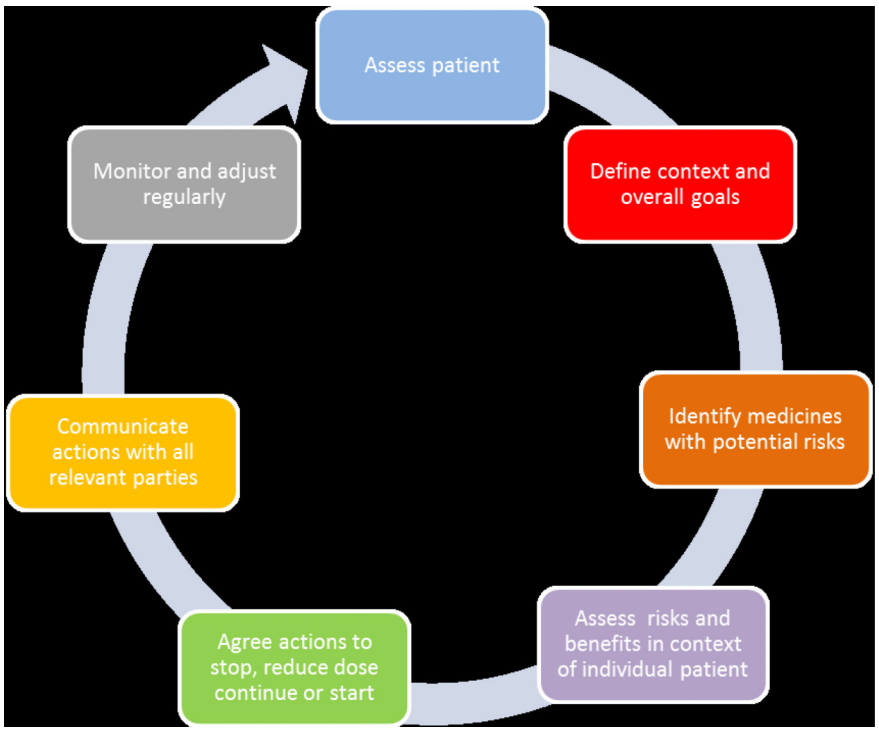

Figure 1 A patient centered approach to managing polypharmacy in practice.

Table 1 Web based tools and resources for review of polypharmacy and deprescribing

Tool	*Description*	*Web-site*
Medstopper	Developed by Canadian experts in evidence-based medicine and prescribing in the elderly and gives information on risks and benefits and how to withdraw treatment for different medicines. Frail elderly cab be selected which adjusts harm rating when using this tool	www.medstopper.com
Medichec	Developed by South London and Mawdsley NHS Foundation Trust to identify and assess the risk of medicines with anticholinergic effects (which increase the risk of cognitive impairment, dementia and early death in older people)	www.medichec.com
Anticholinergic Cognitive Burden Scale	Developed by the Indiana University Center for Ageing Research to identify and assess risk of anticholinergic medicines	www.agingbraincare.org/tools/abc-anticholinergic-cognitive-burden-scale
Canadian Deprescribing network algorithms	Algorithms to aid the deprescribing of certain classes of medicines such as proton-pump inhibitors, antihyperglycaemics and benzodiazepines	deprescribing.org
NHS Scotland resources	Resources for reviewing patients with polypharmacy including 7 steps approach, general guidance, NNT and NNH	www.polypharmacy.scot.nhs.uk

4 reviews effectiveness and whether therapeutic objectives are being achieved; Step 5 reviews safety including presence or risk of ADRs; Step 6 reviews cost-effectiveness of therapy; and Step 7 reviews adherence and patient centeredness (Anon, n.d.). Another option is the Australian 10 step discontinuation guide (Scott et al., 2013).

A number of tools have been developed to aid clinicians in reviewing potentially inappropriate medicines and can provide structure for clinicians conducting comprehensive reviews of complex medication regimens (Hanlon and Schmader, 2013). The NO TEARS tool was developed to help primary care physicians conduct medication review (Lewis, 2004), while the medication appropriateness index (Hanlon et al., 1992) can score individual medicines for appropriateness (Samsa et al., 1994). Several tools are specifically designed for reviewing potentially inappropriate medicines in older people. These include the Beers criteria (American Geriatrics Society, 2015), while the STOPP/START tool is an evidence-based screening tool of older people's prescription (STOPP) and screening tool to alert to right treatments (START) (O'Mahony et al., 2014). A further tool has been developed for reviewing potentially inappropriate medicines in frail older people, STOPPFrail (Lavan et al., 2017). IMPACT (Improving Medicines and Polypharmacy Appropriateness Clinical Tool) is a tool developed by PrescQIPP, which identifies potential clinical and cost benefits of deprescribing with recommendations for appropriately continuing or discontinuing medicines (PrescQIPP NHS Programme, 2016).

Some tools are also available online and are represented in **Table 1**.

While a comprehensive review of adherence is beyond the scope of this article, a key component of a clinical medication review or deprescribing consultation is to determine what medicines the person is actually taking, rather than what is prescribed and how they manage, or don't manage, their medicines. Consultation technique is important in terms of gaining the person's trust and elucidating information about medicine-taking behaviors but also the person's beliefs, values, and how they can incorporate medicine taking into their daily life.

Various consultation techniques can be used. A coaching approach has been advocated as being beneficial for improving adherence. This incorporates the four Es which are as follows:

Explore the person's knowledge, perceptions, and lifestyle goals
Educate by giving the patient the information they want, rather than what the health-care professional wants to tell them, cover the main points for patient safety, and check the person's understanding.
Empower the person by helping them decide whether they want to take the medicine or not and help them own any decision to take medicines, rather than being told what to do.
Enable the person to work out how they will incorporate medicines into their lives and how they will monitor their adherence and the medicine's effectiveness (Barnett et al., 2013).

Care Home Considerations

Care home or long-term care facility residents need special consideration. The number of care home residents living with severe frailty and multimorbidity including mental health problems has risen over recent years. Care home residents are supported by a multidisciplinary team of people who try to ensure that the resident lives well by maintaining health and quality of life, ages well by managing long-term conditions and that they can die well by ensuring a good quality end of life (National Institute for Health Research, 2017). The World Health Organization (WHO, 2003) recommends that regulatory standards should establish the minimum standards for long-term care facilities including aspects such as the level and qualifications of staff, minimum staffing levels, skill-mix, procedural standards, and infrastructure specifications. Some countries may also wish to regulate the rights of people to long-term care and enforce compliance with standards (WHO, 2003). Residents in care homes should be encouraged to

be involved in decisions about their care and treatment if they choose to, so that the health and life outcomes that the person actually wants are prioritized, using person-centered care (National Institute for Health Research, 2017; Payne and Duerden, 2015; Royal Pharmaceutical Society, 2016). Formal capacity assessments should be used to determine whether patients can make decisions for themselves. Residents with reduced mental capacity should be able to make decisions about the aspects of their care and lives for which they have capacity (National Institute for Health and Care Excellence, 2014). For example, a patient may be able to decide whether they need acetaminophen (paracetamol) or not for pain relief but may not be able to make a decision about long-term anticoagulation. This applies equally to patients with cognitive impairment living in domiciliary settings. Where residents have capacity, they should be asked about whether they want family or supporter peers to be involved in decisions about their care. Where residents lack capacity, the assessment and findings should be formally documented. How often capacity is assessed should depend on the cause, as in some circumstances, lack of capacity fluctuates or is temporary (National Institute for Health and Care Excellence, 2014). Laws around consent and capacity will differ between countries but health-care practitioners must ensure that they adhere to legal frameworks, best practice guidance, and put the best interests of the person without capacity first.

Partners, relatives, or supporter peers of care home residents often support the resident to communicate with the multidisciplinary team in order to voice their individual needs, which is especially important where residents may not be able to voice this themselves, for example, in severe dementia (National Institute for Health Research, 2017; Payne and Duerden, 2015). Care home staff can also provide valuable information to inform decision-making regarding medicines (Payne and Duerden, 2015), for example, on symptom control.

Some residents in care homes will not be able to manage some, or all of their medicines, due to physical or mental illness (Payne and Duerden, 2015). However, care home residents should be able to self-medicate if they are able and wish to do so (National Institute for Health and Care Excellence, 2014; Royal Pharmaceutical Society, 2016), take the medicines how and when they want to, and take nonprescription medicines if needed (Royal Pharmaceutical Society, 2016).

Care home residents may be at greater risk of ADRs due to a combination of multimorbidity, polypharmacy, and frailty. As discussed earlier, the number of medication errors in care homes is high. Patient factors contributing to medication errors include cognitive issues and lack of awareness of medicines, physical difficulties such as arthritis or dysphagia, or practical issues such as staff finding the person when a dose is due to be administered. Other factors relate to processes for prescribing and administration in care homes. These include availability of electronic decision support aids, access to clinical records, availability of medicines, care home policies, procedures and guidelines, accuracy of medicine administration records, staff interruptions, and staff training (Payne and Duerden, 2015). Monitored dosage systems (MDS) are often employed in care homes to speed up drug administration and reduce errors although the CHUMs study found no evidence that MDS reduced administration errors (Barber et al., 2009). Use of MDS also makes it difficult for staff to omit particular medicines (Payne and Duerden, 2015) that are not clinically appropriate on a given day, for example, diuretics in a patient who is dehydrated.

Approximately 80% of people in care homes have regular pain, which reduces quality of life, limits mobility, and can cause behavioral problems, especially in people with dementia (National Institute for Health Research, 2017). While, a review of the treatment of pain is beyond the scope of this chapter, it is important that any review of medicines for a resident of a care home explores pain symptoms and treatment.

While a review of falls and medicines that cause falls is beyond the scope of this chapter, pharmacists should be involving in assessing falls risk from medicines in care home residents (Royal Pharmaceutical Society, 2016). This is also applicable to people in domiciliary settings who are at high risk of falls and/or who are taking a number of medicines that could contribute to falls.

Studies have shown that antipsychotics are more commonly prescribed for those in care homes than those living in domiciliary settings. Pharmacists should play a key role in the multidisciplinary team to ensure oversight of antipsychotics in care homes and to keep prescribing of these agents to a minimum (Royal Pharmaceutical Society, 2016).

Many residents of care homes will end their lives there so pharmacists can give advice about, and access to, end-of-life, and anticipatory care medicines. Pharmacists can also be valuable assets to care home providers in reducing medicines waste, especially if they are given responsibility for the use of medicines in individual care homes. This can be achieved through regular medication review but also by training care homes staff and working in an integrated way with the multidisciplinary team (Royal Pharmaceutical Society, 2016).

Dysphagia

Dysphagia is a swallowing disorder, which is caused by neurological or physical impairment of oral, pharyngeal, or esophageal mechanisms (Barnett and Parmar, 2016). It is usually caused by another condition such as stroke, head injury, or progressive neurological diseases such as Parkinson's (Barnett and Parmar, 2016; PresQIPP NHS Programme, 2015). Dysphagia can also be drug induced. This can be due to ADRs, for example, anticholinergics affect smooth muscle function of the esophagus; some drugs cause xerostomia (dry mouth), which impairs food transport, for example, lisinopril, antihistamines and antidepressants, and antipsychotics can cause extrapyramidal side effects and tardive dyskinesia causing dysphagia. Medicines that reduce alertness can also cause dysphagia, for example, opioids (Balzer, 2000).

Up to two-thirds of stroke patients, two-thirds of people with dementia and a quarter of people with COPD will have dysphagia (Barnett and Parmar P, 2016). Dysphagia can cause dehydration and malnutrition and is associated with increased length of hospital

stay, increased need for long-term residential care, and an increase in health-care costs (Smithard et al., 1996). Dysphagia is also associated with aspiration pneumonia, which is caused by the inhalation of foreign matter such as food and fluids (Barnett and Parmar P, 2016). Patients with dysphagia should have food administered in a form that can be swallowed without aspiration following specialist assessment of swallowing such as provided by a speech and language therapist (SLT) (National Institute for Health and Care Excellence, 2008). Food and fluid intake should be monitored and if indicated, a referral made to a dietician (Scottish Intercollegiate Guidelines Network, 2010). Patients with dysphagia may be unable to take some solid oral formulations of medicines. Formulation should be based on recommendations from a SLT. Pharmacists need to understand appropriate fluid consistency and food texture to advise patients on the safest and most effective form of administration of medicines, to reduce the risk of aspiration pneumonia and choking. It should be noted that some patients with dysphagia can swallow solid dosage forms and that liquids are not necessarily better for these patients. Some thinner liquids can increase the risk of coughing and aspiration in some patients and a thicker liquid or medication mixed with more textured food might be preferable (Barnett and Parmar, 2016). Thickeners are used to thicken both liquids and food to various consistencies to aid swallowing in dysphagia. Thickeners help to slow down transit to allow the person with dysphagia more time to coordinate the swallowing process safely and should be recommended by SLTs. Different brands of thickeners are available, some are starch based and others contain gums. Increasing the viscosity by thickening foods and liquids could theoretically reduce the dissolution, disintegration, and bioavailability of medicines (PresQIPP NHS Programme, 2015). The electrical charge associated with some gum thickeners may also reduce drug dissolution so drug thickener interactions may be reduced by using starch-based products although these are often less stable and palatable (Barnett and Parmar, 2016; PresQIPP NHS Programme, 2015). However, further studies are needed to assess the true effect of thickeners on medicines (PresQIPP NHS Programme, 2015).

Where possible tablets and capsules should be administered whole with the appropriate fluid consistency or food texture. Smaller tablets (<4 mm) can sometimes be safely swallowed whole if mixed with a food of a suitable consistency, for example, a puree. If a patient can't swallow tablets or capsules, a liquid can be used but only if it is thickened to the right consistency. If no suitable liquid is available, pharmacists will need to investigate whether crushing tablets or opening capsules is appropriate for administration with appropriate food or fluids (Barnett and Parmar, 2016). Specialist resources are available to determine whether crushing tablets or opening capsules is feasible (Smith, 2015; White and Bradnam, 2015). The administration of crushed tablets and the contents of opened capsules exposes the patient to the unpleasant taste, potential unpalatability and reduced adherence, and potentially reduced efficacy of the medication, as well as having legal implications for professionals who administer medicines off-label (Barnett and Parmar, 2016). When licensed medicines are used, if a patient is harmed, liability rests with the manufacturer. When medicines are crushed or capsules opened, this renders them unlicensed and greater liability for any patient harm falls on the prescriber, dispenser, and person administering the unlicensed medicine. The prescriber should always be involved in any decision to supply or administer medicines outside of their product license (Wright and Tomlin, 2011; Wright et al., 2015). Some tablets should not be crushed including modified release preparations that will cause dose dumping; enteric-coated medicines that may not then deliver the medicine to an area of the gut from which it can be absorbed and hormonal, cytotoxic, and steroid medicines should not be crushed as they may be dispersed into the air and the person administering the medicine can be exposed to their harmful effects (Wright et al., 2015).

When reviewing or prescribing medicines for patients with dysphagia, the following issues should be assessed:

- Review whether the medicine is still needed (Barnett and Parmar, 2016; UK Medicines Information, 2016)
- Observe medication taking as technique may be at fault and education may rectify the problem (Wright and Tomlin, 2011)
- Check if the tablet/capsule can be swallowed whole with pureed food or yoghurt. If it can, check for drug–food interactions, for example, levothyroxine. Remember to also check SLT recommendations on diet and fluid consistency (Barnett and Parmar, 2016).
- Check if the tablet or capsule can be crushed or opened and administered with thickened fluid, pureed food, or yoghurt (Barnett and Parmar, 2016)
- Check if the tablet or capsule can be swallowed whole when mixed with appropriate consistency food or fluid? Check what size of tablet/capsule the person can comfortably swallow (Barnett and Parmar, 2016).
- Are other routes suitable, for example, transdermal, sublingual, buccal? (Wright et al., 2015)
- Are other licensed formulations available? (UK Medicines Information, 2016)
- If a feeding tube is used to administer medicines, check if there are any interactions with food (UK Medicines Information, 2016)
- Does the person administering the medicine, if it is not the patient themselves, know how to prepare, and administer the medicine?
- If the person with dysphagia is moving care settings, ensure that all the information on their swallow and administration of medicines is communicated (Barnett and Parmar, 2016).

Role of Pharmacist in Health-Care Team Current and Future Trends in Pharmacotherapy and Management

Primary/Community Care

There is good evidence that pharmacists working in community settings can reduce the risk of drug-related problems, improve appropriateness of prescribing, reduce polypharmacy, and reduce drug costs by conducting medication reviews. Patient satisfaction

also improved after community pharmacy medication reviews, but there is mixed evidence on whether this has any impact on hospital admission and no evidence on mortality or other clinical benefits. Medication review may also improve transition of care between providers (Centre for Policy on Ageing, 2014).

Medication reviews in primary care have been studied in a randomized controlled trial in Sweden. Patients 75 years or more who were taking at least 10 medicines and using at least 3 psychotropic's received a pharmacist-led medication review. This included patients in both care homes and domiciliary settings. Two months after the reviews, the number of intervention group patients with at least one potentially inappropriate medicine and the number of patients using ten or more medicines had decreased significantly. There was no significant change for patients in the control group. No changes were seen in the number of patients using three or more psychotropic medicines although dosages of these tended to decrease (Milos et al., 2013). Another Swedish study evaluated structured medication reviews for patients living in nursing homes or patients 65 years and over who were living at home with medication-related community help. This study focused on the clinical significance of recommendations made by clinical pharmacists and ranked these from 1 (adverse significance) to 6 (extremely significant). About 96% of recommendations made by pharmacists in this study were judged to have a significance of 3 of higher and more than half were judged to have a significance of 4 or more. The authors suggest that structured clinical medication review in this population increases prescribing quality and has the potential to contribute to better and safer drug therapy for elderly patients (Modig et al., 2015).

A further study was conducted at two general practice clinics in Australia. Participants were patients who had risk factors for medication-related problems (MRPs), for example, polypharmacy. Patients received a consultation with the pharmacist who reviewed the patient's medication regimen, adherence, and provided education. The median number of MRPs per patient identified by the practice pharmacist was 2. This fell to 0, 6 months after the review, and patients were highly satisfied with the pharmacist consultations. The number of patients who were adherent to their medicines also improved significantly. There was no significant effect on health service use (Tan et al., 2014).

An Australian randomized controlled effectiveness trial evaluated medication reviews in the community. The intervention involved GP education, home visits, pharmacist medication review, primary team conferences, GP implementation of action plans, and consultation with patients and follow-up surgery visits for monitoring. A total of 54.4% of clinical medication review recommendations were enacted, and 23.9% of these were implemented precisely as recommended. About 70.9% had a positive outcome with 15.7% having no effect and 3.7% a negative outcome. The most common problems identified were potential ADRs, suboptimal monitoring, and adherence issues. There were positive trends in clinical outcomes (reduction in adverse drug events and severity of illness) and a trend toward reduced health-care service costs. Subsequently, a domiciliary medication review program was implemented as a national Australian practice where GPs and pharmacists were reimbursed by the Australian government for such services (Sorensen et al., 2004).

In Switzerland, a controlled trial evaluated the Polymedication Check (PMC) in community pharmacies. A significant number of drug-related problems were identified. There was no significant increase in objective adherence perhaps due to the high baseline objective adherence of 87.5% in the study, but subjective adherence was improved by approximately 5% (Messerli et al., 2016).

Clinical pharmacist input into an internal medicine practice has also been evaluated and primary care physicians (PCRs) were studied in terms of their proactive input into medicines optimization as a result of the pharmacist recommendations. This showed that compared to patients who received no pharmacist input, patients of PCRs who received clinical pharmacist recommendations were more likely to have several medicines-related issues addressed including medication nonadherence, untreated indications, suboptimal medication choices, and cost-ineffective drug therapies. However, total medical (excluding Pharmacy) costs for the intervention and comparison groups were not significantly different (Altavela et al., 2008).

Structured pharmaceutical care delivered by community pharmacists, according to a protocol, for patients who were discharged on five or more medicines was studied in Amsterdam. This structured pharmaceutical care resulted in more changes in drug therapy. Home visits cleared redundant home drug supplies and patients were highly satisfied with the counseling at discharge from hospital by their community pharmacist (Hugtenburg et al., 2009).

Secondary Care

A retrospective study of pharmacist interventions was conducted on two older people's wards in Germany to evaluate the clinical significance of medication errors detected. The majority of interventions carried out at admission and discharge were due to an omission of medicines and clinically significant interactions requiring monitoring. About 68.1% interventions were considered significant, 7.2% were clinically serious, and 24.8% were of minor significance. The authors state that the study shows the importance of clinical pharmacist involvement in the optimization of pharmacotherapy in older adults (Cortejosos et al., 2016).

Patients from five internal medicine and two rheumatology departments in Norway were included in a perspective study where clinical pharmacists assessed drug-related problems (DRPs) by reviewing medical records and participating in multidisciplinary team discussions. A quality team assessed the clinical significance of the DRPs. A proportion of patients were randomly selected for interview with pharmacists. Significantly more DRPs were identified among the patients who were interviewed compared to those patients having only usual care examination. A high proportion of the DRPs identified in the interviews were of major clinical

significance. The authors concluded that clinical pharmacists seem to fill a gap ensuring that significant DRPs do not escape detection (Viktil et al., 2006).

A further study in a university hospital in Ireland calculated the cost–benefit of pharmacist interventions made over a 1 year period. The study evaluated the cost benefit of pharmacist interventions as 8.64:1 (Gallagher et al., 2014).

A study evaluated the impact of a specifically developed structured pharmacist review of medication (SPRM) intervention and computerized decision support systems (CDSS) intervention on the appropriateness of prescribing in older Irish hospital inpatients. The acceptance rate of recommendations was also examined. On admission, patients received a SPRM/CDSS intervention that screened DRPs. Any DRPs identified were then communicated to the medical team. Medical records were reviewed to identify the implementation of recommendations and appropriateness of prescribing. The authors concluded that DRPs are prevalent in older, Irish, hospitalized inpatients and the specially developed SPRM intervention supported by CDSS can improve the appropriateness and accuracy of medication regimens of older hospitalized inpatients (O'Sullivan et al., 2014).

A systematic review and metaanalysis of the appropriateness of prescribing in older patients concluded that multidisciplinary and patient care teams involving pharmacists may improve the appropriateness of prescribing in older, hospitalized patients. The overall calculated reduction in the MAI score per patient was 7.45 in the intervention group (pharmacist involvement) versus the control group (Walsh et al., 2016).

A further systematic review looked at 19 randomized controlled trials of pharmacist-led medication reviews in hospitals involving 4805 patients. Overall the rate of readmission and emergency department attendance did not differ between the intervention and control groups although drug-related readmissions had a lower relative risk in the group receiving a pharmacist-led clinical medication review (Renaudin et al., 2016).

Institutional Care

In three Norwegian nursing homes, pharmacists undertook medication review and joined the multidisciplinary team (MDT) meetings aiming to reduce DRPs. Each patient's drug regimen was systematically reviewed by a pharmacist according to the criteria of a Norwegian classification tool, and potential DRPs were identified and classified. On average, the pharmacists identified 5.1 DRPs per patient, 3.5 were acknowledged by physicians and nurses, of which 94% were followed up. Therefore, the MDT intervention was suitable to identify and resolve DRPs in nursing home settings. The authors recommend that systematic medication reviews and involvement in clinical teams should be implemented on a regular basis to achieve and maintain high-quality drug therapy (Halvorsen et al., 2010).

Six Portuguese nursing homes evaluated the need for pharmaceutical care in institutionalized, polymedicated elderly patients. Pharmacists identified DRPs and carried out a structured interview with each patient and consulted patient medical records to gather demographic data, information on health problems, and medications used. A total of 484 DRPs were found. The most common DRPs were nonallergic adverse drug events, drug treatments more costly than necessary, effect of drug treatment not optimal, and unnecessary drug treatment. The authors concluded that these results reinforce the need for implementation of pharmaceutical care services for institutionalized elderly patients to improve medicines efficacy and safety, better clinical outcomes, and cost reduction (Silva et al., 2015).

A study measured the impact of pharmacist-conducted clinical medication review with elderly residents in 65 UK care homes versus usual care. Recommendations were made to general practitioners for approval and implementation. Control patients received usual general practitioner care. The pharmacist reviewed 315 patients in 6 months. The mean number of drug changes per patient was 3.1 for the intervention and 2.4 for the control group. About 75.6% of pharmacist recommendations were accepted by the general practitioner; and 76.6% of accepted recommendations were implemented. There were respectively 0.8 and 1.3 falls per patient in the intervention versus the control group. Pharmacists made substantial changes to patients' medication regimens without change in drug costs. There was a reduction in the number of falls. There was no significant change in consultations, hospitalization, mortality, or mini-mental state examination scores (Zermansky et al., 2006).

A UK project implemented patient-centered, pharmacist clinical medication review in 20 care homes. A total of 422 reviews were completed, and 1346 pharmacist interventions were made. On average, 1.7 medicines were stopped per patient, and the authors calculated that for every £1 invested in the service, £2.28 was saved (The Health Foundation, 2014).

Cross-Sector/Transitions of Care

A study evaluated the effect of transition of care follow-up by a pharmacist. The pharmacist contacted patients over 65 years old by telephone after hospital discharge to perform medication reconciliation, review discharge instructions, and schedule a follow-up appointment. At this follow-up appointment, the pharmacist reviewed the patient's electronic medical record (EMR) and communicated recommendations to a physician. The current standard of care, which does not involve a pharmacist, at a similar local physician practice was used as a comparative group. The difference in 30-day readmission rates did not reach statistical significance, but there was a trending decrease in the percentage of patients readmitted in the intervention versus the control group. There was nearly a statistically significant decrease in readmission rates for those patients who interacted with the pharmacist face to face versus only over the telephone. The authors suggested that pharmacists have a potential role in decreasing 30-day readmissions (Tedesco et al., 2016).

A randomized controlled trial of a Medication Management Review (MMR) program was conducted in Jordon. This was a patient-focused, structured, and collaborative health-care service in a community setting to optimize patient understanding and quality use of medicines. Pharmacists based in an outpatient clinic identified treatment related problems (TRPs) during home visits. They assessed the type and frequency of TRPs and eventual effect of resolving TRPs identified by the pharmacist, and accepted by the physician, on the health status of participating patients. Therefore, home-based medication review for patients with chronic conditions can decrease TRPs and improve self-reported adherence (Basheti et al., 2016).

In the United Kingdom, a study was conducted on patients who were referred from the hospital to community pharmacists for follow-up. This included provision of the New Medicines Service (NMS) and postdischarge Medicines Use Reviews. The NMS is a service for patients started on new medicines for asthma, COPD, hypertension, Type 2 Diabetes Melllitus, or antiplatelets and anticoagulants where patients are followed up by their community pharmacist to support adherence. Patients who had a community pharmacy intervention postdischarge were found to have significantly reduced readmissions to hospital and a shorter length of stay if they were subsequently readmitted, compared to patients who were referred but who did not receive community pharmacy intervention (Nazar et al., 2016).

Person-centered pharmaceutical care bundles were evaluated in a UK hospital setting. The control group was a similar ward with usual clinical pharmacy care. The care bundles were designed for each medication type known to be correlated to admission and were used on socially isolated older people or those on high-risk medicines. Patients were given education and medicine support needs post discharge were assessed. Where patients were eligible for the New Medicine Service or medicines use review service from community pharmacy, they were referred on discharge. Where patients were not eligible, for example, housebound patients, the hospital team provided these services in the community. Length of stay did not differ between the intervention and control groups, but the 30-day readmission rate was reduced from 17% to 22% in the intervention versus the control group although the study was not powered to detect a reduction in readmissions (Blagburn et al., 2015).

In summary, clinical medication review by pharmacists in various settings seems to have positive benefits for people in terms of a reduction in MRPs, improved medication appropriateness, improved adherence, and reduced health-care system costs. Patient satisfaction with such services is high, but the evidence for an effect on other clinical outcomes such as mortality and readmissions isn't strong and further work is needed in this area. There is some evidence that face-to-face clinical medication review is more effective than remote reviews such as those performed over the telephone and some evidence that clinical medication review reduces falls.

While the lack of impact on some clinical outcomes is disappointing, there are multifactorial influences on outcomes such as mortality and readmissions, and therefore, often the link between positive changes to medicines and positive outcomes is difficult to prove. As discussed earlier, polypharmacy is associated with a number of harms. Therefore, this lack of impact on some outcomes shouldn't dissuade pharmacists from person-centered medicines optimization, which has other benefits and may well be shown to have a positive effect on a wider range of clinical outcomes in future trials.

Pharmacogenomic Testing

Pharmacogenomics (PGx) is the investigation of the effects of genetic differences (genome differences) on drug response. PGx aims to use genetic information to inform prescription decision-making and therefore make drug therapy safer and more effective (Rollinson et al., 2017) with better patient outcomes, for example, improvements in disease management, reduced ADRs, and improved quality of life (Elliott et al., 2017). PGx testing identifies genetic variants that influence drug response that can be used to select specific genotype-informed prescriptions. This is called precision, stratified, or personalized medicine. Some genetic variants can influence pharmacokinetics including drug-metabolizing enzymes such as the cytochrome P450 isoforms (CYPs). Genetic variants can also influence drug pharmacodynamic effects (Rollinson et al., 2017).

PGx tests are available that can test various CYPs, which could have clinical relevance in the selection and dosing of medicines metabolized by these CYPs. This has the potential to predict and reduce unnecessary ADRs and has been used in clinical trials in Psychiatry. A small study (Elliott et al., 2017) was conducted in home health management patients with polypharmacy who were over 50 years old in the United States. PGx testing of CYPs with guidance from a clinical decision support tool regarding reduced drug, gene, and interaction risk was used by pharmacists to make medication recommendations to doctors. Compared to usual care, the PGx-tested patients had reduced readmissions to hospital and emergency department visits at 60 days (Elliott et al., 2017).

PREPARE (**Pre**-emptive pharmacogenomic testing for **P**reventing **A**dverse Drug **Re**actions) is a clinical study initiated by the U-PGx (Ubiquitous Pharmacogenomics) consortium to implement and evaluate the impact of PGx testing on therapy outcomes in 7 European centers. The study started recruiting >8000 patients in 2017 and will analyze results in 2020. Patients will have the U-PGx test that tests for >40 clinically relevant PGx markers. For half the study patients, test results will be used to guide drug and dose selection for >40 drugs: the other half will have usual care and treatment (Ubiquitous Pharmacogenomics consortium, 2018).

In summary, PGx testing is in the early stages of development as a tool for people with long-term conditions to improve safer, more effective prescribing and may have a positive impact on patient outcomes such as readmission to hospital.

Glossary

Adherence is defined as the extent to which the patient's action matches the agreed recommendations from the prescriber
Aspiration pneumonia is an infection and inflammation of the lungs and bronchial tubes caused by the inhalation of foreign matter
Care Home is a long-term care facility and covers the provision of 24-h accommodation together with either nonnursing or nursing care
Care Home Staff includes registered nurses and social care practitioners working in a care home
Deprescribing is defined as the process of tapering, stopping, discontinuing, or withdrawing drugs, with the goal of managing polypharmacy and improving outcomes
Dysphagia is a swallowing disorder cause by neurological or physical impairment of the oral (mouth), pharyngeal (upper throat), and esophageal (lower throat) mechanisms
Frailty is a distinctive health state related to the ageing process in which multiple body systems gradually lose their in-built reserves
Long-term conditions are conditions for which there is currently no cure, and which are managed with drugs and other treatment, for example: diabetes, chronic obstructive pulmonary disease, arthritis, and hypertension. LTCs also include defined mental health conditions such as schizophrenia, ongoing conditions such as learning disabilities, symptom complexes such as frailty or chronic pain, sensory impairment such as sight or hearing loss, and alcohol and substance misuse
Medicines Optimization is a process that allows patients to gain the most net benefit from taking medication where medicines are prescribed taking the patient's preferences and characteristics into account
Medication Review is defined as a structured, critical examination of a patient's medicines with the objective of reaching an agreement with the patient about treatment, optimizing the impact of medicines, minimizing the number of medication-related problems, and reducing waste.
Mental capacity is defined as having sufficient understanding and memory to comprehend in a general way the situation in which one finds oneself and the nature, purpose, and consequence of any act or transaction into which one proposes to enter.
Monitored dosage systems are medication storage devices designed to simplify the administration of solid oral dose medication usually with a separate compartment for each dosage time of the day
Morbidity refers to having a disease or a symptom of disease or to the amount of disease within a population. Morbidity also refers to medical problems caused by a treatment.
Multimorbidity is the presence of two or more long-term conditions
Pharmacogenomics is the investigation of the effects of genetic differences (genome differences) on drug response.
Polypharmacy is where an individual takes multiple medicines
Appropriate polypharmacy has been defined as the prescribing for an individual for complex conditions or multiple conditions in circumstances where medicines use has been optimized and where the medicines are prescribed according to best practice.
Problematic polypharmacy has been defined as the prescribing of multiple medications inappropriately or where the intended benefit of the medication is not realized

Prescribing Insulin for People With Diabetes in Secondary Care: Recommendations and Future Direction

Amie Bain*, Sallianne Kavanagh†, Zaheer-Ud-Din Babar*, *School of Applied Sciences, University of Huddersfield, Huddersfield, United Kingdom; †Department of Pharmacy, Sheffield Teaching Hospitals NHS Foundation Trust, Sheffield, United Kingdom

Introduction

Diabetes is a chronic, incurable endocrine condition that is an important cause of mortality, morbidity, and associated healthcare costs worldwide (Global Burden of Metabolic Risk Factors for Chronic Diseases Collaboration, 2014). The global prevalence of diabetes is increasing; the latest International Diabetes Federation (IDF) estimates suggest that there were 425 million people with diabetes in 2017, which is set to rise to 629 million by 2045 (International Diabetes Federation, 2017). Although the majority of this increase involves people with type 2 diabetes, the number of people being diagnosed with type 1 diabetes is also increasing. Studies have shown that people with diabetes are more likely to be admitted to hospital, on a more frequent basis, and have longer lengths of stay than people without diabetes (Sajjad et al., 2018; De Berardis et al., 2012; Aro et al., 1994; Comino et al., 2015). Given the increase in incidence of diabetes globally, the increase in demand for secondary care services is likely to be sustained.

As the incidence of diabetes increases, so does the number of people with diabetes requiring insulin, with around 150-200 million people using insulin worldwide (Garg et al., 2018; Holden et al., 2014). Insulin is required by all people with type 1 diabetes, but also forms an important part of the management of people with other types of diabetes. It is understood that in type 2 diabetes, insulin secretory capacity decreases over time, therefore many people with this diagnosis may eventually require insulin (Home et al., 2014). Although insulin is vitally important, it is also associated with a significant risk of adverse effects such as hypoglycemia. Furthermore, insulin can be complex to prescribe and administer; as such, there is considerable scope for potentially serious medication errors to occur with its use.

The first section of this chapter includes a brief overview of medication errors involving insulin in hospital, focusing on prescribing errors. Approaches and interventions to help improve insulin safety is outlined and reviewed, and a variety of current recommendations for prescribing insulin in hospitals is summarized. Finally, a short series of case studies from a large teaching hospital in the United Kingdom is presented to illustrate how insulin prescribing safety may be investigated and improved by pharmacy teams at a local level.

Risks Associated With Insulin Use

Insulin is undoubtedly a life-saving medication of paramount importance, particularly to people with type 1 diabetes. It is, however, also classified as a high-alert medication by the Institute for Safe Medication Practices (ISMP) (Institute of Safe Medication Practitices, 2011). High-alert medications confer a heightened risk of causing significant harm when used inappropriately, and require particular safeguards to minimize the risk associated with their use. As insulin facilitates glucose movement from the bloodstream into cells, patients receiving excessive insulin may experience low blood glucose levels (hypoglycemia). Hypoglycemia can result in impairment of cognitive function, seizures, hemiparesis, and even coma. Inpatient mortality rates

and length of hospital stay for people using insulin, experiencing hypoglycemia, are also higher compared with those who do not use insulin (Turchin et al., 2009; Akirov et al., 2017).

Hyperglycemia can also occur when insulin is under-utilized, or when the dose prescribed and administered is not sufficient to control increased blood glucose levels. Hyperglycemia, if untreated, may result in diabetic ketoacidosis (DKA) or hyperosmolar hyperglycemic state (HHS) for people with type 1 and type 2 diabetes, respectively. These conditions can cause serious harm to patients, and may be fatal if not managed appropriately. People experiencing DKA or HHS face longer hospital stay, require more intensive nursing and monitoring, and potential progression to intensive care (Joint British Diabetes Societies Inpatient Care Group, 2012; Sinclair-Hammersley et al., 2010).

Unfortunately, these adverse effects of insulin therapy are not uncommon, and are often associated with suboptimal or erroneous insulin prescribing and administration in hospitals. In the United Kingdom, an estimated 9600 people required rescue treatment after falling into a coma following a severe hypoglycemic attack, in 2017. During the same year, 2200 people (1 in 25 people with type 1 diabetes) suffered from DKA due to under treatment with insulin (NaDIA HQIP, 2018). There are various types of medication errors involving insulin, and there are many possible causes for these errors. More importantly, all insulin errors have the potential to put patients at serious risk of harm, and should therefore be investigated and mitigated in order to improve patient safety (Cousins et al., 2011; Hellman, 2004).

The impetus to improve the safety of insulin prescribing and administration is currently of great significance to align with the World Health Organization third global patient safety challenge 'Medication without harm', which aims to reduce avoidable medication harm by 50% over 5 years and includes a focus on high risk situations, polypharmacy, and transitions of care, all of which are pertinent to insulin prescribing.

Medication Errors Involving Insulin

Insulin errors have been reported at all stages of the medication use process, including prescribing, transcribing, dispensing, storing, administration, and monitoring. Most errors with insulin have been found to occur at the point of prescribing and administration (Cousins et al., 2011; Cobaugh et al., 2013). Pharmacists are able to help improve insulin safety processes at all of these stages, but here we will focus on the types and causes of insulin prescribing errors in particular.

Insulin Prescribing Errors

The term 'prescribing error' may be defined as "a failure in the prescribing process that leads to, or has the potential to lead to, harm to the patient" (Aronson, 2009). In general, prescribing errors commonly involve incorrect doses, illegible details, or inappropriate interacting medications. There is some debate as to what exactly might be categorized as a prescribing error, however, with some taking the view that errors of omission, or prescribing contrary to local or national guidance would not constitute a prescribing error (Dean et al., 2000). This is further reflected in the variety of definitions of 'prescribing error' in the literature reporting on incidence, causes, or solutions to prescribing errors (Tully et al., 2009).

As a result, some have taken the approach to differentiate 'prescribing faults' from 'prescription errors', where the first encompasses the whole process of writing a prescription (e.g., including clinical decision-making and monitoring processes), and the second relates solely to the act of writing a prescription (Velo and Minuz, 2009). As both 'prescribing faults' and 'prescription errors' can lead to potentially serious consequences with respect to insulin, we will consider them together as essential to tackle in order to improve patient safety.

Types of Insulin Prescribing Errors

Prescribing errors involving insulin may involve the name, frequency, device, concentration, or number of units of insulin doses being omitted, incorrect or unclear, insulin being prescribed at the wrong time of day (e.g., pre-mixed biphasic insulin being prescribed at night), insulin prescriptions not being signed, or insulin being omitted from the prescription altogether (e.g., on admission to hospital as a result of incomplete clerking).

The abbreviation of the word 'units' to 'u' is a well-reported cause of insulin errors, with nursing staff mistaking the 'u' for an extra '0' at the end of the dose, therefore administering a 10-fold overdose (National Patient Safety Agency, 2010). More recently, there is potential for insulin errors to occur where more than one concentration of a particular insulin product exists. If the correct brand and strength is not stipulated, patients may inadvertently receive the wrong dose. The consequence of this depends upon the particular product being prescribed, examples include the introduction of glargine 300 units/mL, which has a different release profile to its 100 units/mL counterpart, compared with lispro and degludec in which the profile is the same. Despite the manufacturers attempt to mitigate errors through use of defined dose pens, patients have inadvertently received the wrong dose due to the inappropriate use of insulin syringes with the pen devices, and consequently received excess or subtherapeutic doses (NHS Improvement, 2016).

Similarly, failure to stipulate the type of insulin device can be a cause of significant confusion, delay, and potential error, with patients receiving the wrong delivery system and in some circumstances, being unable to receive their insulin dose when needed.

Prescribing errors with insulin can occur with both electronic and non-electronic systems in hospital, especially as the functionality of electronic prescribing systems can vary considerably. Clearly, there will be merits to the use of electronic prescriptions for

insulin; for example, prescription clarity may be improved and incorporating standard insulin order sets can encourage more appropriate insulin prescribing. The particular need for variable insulin dosing depending on blood glucose result may, however, pose difficulties to integrate effectively into some electronic prescribing systems. New types of error have also been found to be introduced with electronic prescribing. These include issues like misinterpreting the insulin strength as the dose to be administered and 'picking errors' (where prescribers choose the wrong insulin product from a dropdown list) and the inappropriate continuation of short-acting correctional dose insulin on discharge prescriptions. In particular, insulin device errors have been shown to persist following electronic prescribing system implementation (Goble et al., 2010). The potential causes of insulin prescribing errors like these discussed hereunder.

Causes of Prescribing Errors

The causes of prescribing errors are multifactorial, involving organizational processes, task and environmental conditions as well as individual unsafe acts such as knowledge-based mistakes, violations, slips, and lapses (Tully et al., 2009). In a systematic review of the causes and factors associated with prescribing errors in hospital inpatients, Tully et al. found that active errors were often made as a result of knowledge deficiencies regarding the drug or the patient for whom they are being prescribed. With respect to insulin, this is perhaps particularly pertinent, as studies have shown a particular lack of knowledge and confidence in healthcare professionals with respect to insulin use (Lee et al., 2013; Derr et al., 2007).

These results are somewhat unsurprising as insulin can be particularly complex to prescribe. Many different types of insulin are currently available, and can be described in a number of ways by both healthcare professionals and patients (e.g., long-acting, short-acting, rapid-acting, pre-mixed, human, animal, analogue, basal, bolus, nutritional, correctional, mealtime, cloudy, clear). Insulin also has generic and brand names, which can further complicate its communication and prescribing. Prescribing "insulin glargine", for example would be insufficient to describe exactly the insulin required, with many different preparations potentially available. As such, without sufficient education, experience, and training, prescribers may not have the confidence or competence to prescribe insulin accurately, completely, and safely.

Other causes of error involve rule-based mistakes, whereby prescribers are unsure what rules to apply when prescribing for patients in certain circumstances (Aronson, 2009). With respect to insulin, the inappropriate omission of insulin for people with type 1 diabetes who are nil by mouth, or have a one-off episode of hypoglycemia has been found to be a cause of error in practice. Prescribers may also find prescribing insulin in the perioperative period challenging, including converting patients from intravenous insulin back to subcutaneous insulin.

Violations of rules or guidelines are another cause of prescribing error. This is particularly well reported in studies originating from America and Canada, where hospital prescribers continue to prescribe discouraged retroactive subcutaneous sliding scale insulin monotherapy instead of basal bolus correctional regimens (Newsom et al., 2018; Helmle et al., 2017). Similar errors are recognized in the United Kingdom with the use of variable rate intravenous insulin infusions (commonly referred to as sliding scale infusions) and includes the inappropriate duration of infusion, use of required concomitant basal insulin and safe step down to usual therapy (Joint British Diabetes Societies for Inpatient Care, 2014).

Even with a sufficient knowledge base, and the application of correct rules and guidelines for prescribing insulin, prescribers may make 'slips' or 'lapses' as a result of being busy, tired, or distracted whilst prescribing. These particular causes of prescribing errors are quite common, and may also result in clinically significant errors due to the complexity and high-risk nature of insulin.

On account of the range of insulin prescribing error types and causes, various strategies to reduce errors have been proposed. A number of these strategies will now be outlined, followed by a summary of recommendations for good practice.

Interventions to Improve Insulin Prescribing

Interventions to improve prescribing practice, in general, have been the subject of much study, and are often targeted according to different error types (Aronson, 2009; Velo and Minuz, 2009). A variety of interventions to improve the quality of prescribing insulin for inpatients with diabetes has been recommended by consensus expert panels, including the use of dedicated insulin prescription forms, electronic prescribing systems, insulin order sets, education, and readily available insulin prescribing guidance and protocols (Cobaugh et al., 2013; American Diabetes Association, 2019; Cornish, 2014).

In a recent search of the literature, 35 studies were found to have reported interventions to improve insulin prescribing practice in hospital inpatients, measured as adherence to guidelines, completeness, accuracy, or reduction in insulin prescribing errors (Bain et al., 2018). Most studies (n = 24) reported adherence to the American Diabetes Association (ADA) recommendations to use basal bolus correctional insulin instead of subcutaneous sliding scale insulin. The other 11 studies reported interventions to improve insulin prescribing completeness, accuracy, or reduction in insulin prescribing errors.

Interventions described in the literature include introducing structured diabetes and insulin education sessions (Taylor et al., 2012; Al-Yassin et al., 2013; Horton et al., 2015; Vaidya et al., 2012), dedicated insulin prescribing charts (McIver et al., 2009), electronic insulin order sets (Newsom et al., 2018; Helmle et al., 2017; Yeung et al., 2018; Achtmeyer et al., 2002; Donsa et al., 2016; Guerra et al., 2010; Maynard et al., 2009; Schnipper et al., 2009; Schnipper et al., 2010; Valgardson et al., 2015 Jul; Wexler et al., 2010), incorporating prescribing guidance (Rushmer and Voigt, 2008; Hamilton et al., 2013; Donihi et al., 2006), the introduction of a diabetes specialist nurse prescriber service (Courtenay et al., 2007), implementation of a 'high dose insulin validation guideline' (Dooley et al., 2011), a medicines reconciliation sticker (Tully et al., 2018), and the use of algorithms or electronic software to

calculate required total daily and bolus insulin doses (Donsa et al., 2016). The non-randomized nature of the majority of studies, as well as the lack of consistency with respect to definitions of insulin prescribing errors, study methodology, number of interventions, implementation strategies, and outcome measures made it difficult to compare the results between studies. Despite this, a number of interesting results were found.

For example, the introduction of simple, small focused interventions led to an improvement in the completeness and accuracy of insulin prescribing, particularly when they involved 'hard stops' (such as pre-printing 'units' on dedicated insulin prescription charts to avoid misinterpretation of 'u') (McIver et al., 2009; Rushmer and Voigt, 2008; Hamilton et al., 2013). A small-scale quality improvement project undertaken by Tully et al. used a continuous improvement methodology to design and implement a sticker to prompt accurate and complete prescribing of insulin on admission, resulting in an increase in insulin medicines reconciliation from 64% to 91% (Tully et al., 2018).

In contrast, Newsom et al. describe a large-scale whole-organizational transition to the use of an electronic glucose management system integrated with the hospital's electronic health record. As a result, the prescribing of insulin became simpler and more standardized, and the use of subcutaneous sliding scale insulin monotherapy dramatically reduced from 95% to 4% (Newsom et al., 2018).

Interestingly, the applications of educational interventions alone to improve insulin prescribing were not associated with overwhelmingly significant improvements (Al-Yassin et al., 2013; Horton et al., 2015; Vaidya et al., 2012; Taylor et al., 2012). This may be on account of the non-randomized, uncontrolled before-and-after study design (mostly involving junior doctors), or perhaps more likely, the need for a multi-modal interventional approach involving the whole healthcare team. Indeed, improvement strategies involving system changes that engage multiple stakeholders at various levels were more likely to be effective and sustainable, which is consistent with the principles of total quality management (Pereira and Aspinwall, 1997).

In addition to interventions that have been reported in the literature, a number of international expert bodies have suggested ways in which insulin prescribing safety may be improved in the hospital setting. These will be summarized in the next section, which may provide a useful reference for practitioners and healthcare providers.

Insulin Prescribing Recommendations

The 2019 ADA guidelines for diabetes care in the hospital recommend that physiological, proactive insulin regimens (i.e., basal, bolus/nutritional, correctional insulin) should be used to treat non-critically ill people with diabetes (American Diabetes Association, 2019). The retroactive use of subcutaneous 'sliding scale' insulin is strongly discouraged as it leads to poorer glycemic control, increased length of stay and associated costs (American Diabetes Association, 2019; Umpierrez et al., 2007, 2011). ADA guidelines also state that insulin prescriptions should state the type of diabetes from the point of admission, and should be administered using validated written or computerized protocols that allow dose titration according to blood glucose results. Structured electronic insulin order sets that pre-populate the insulin prescription based on a template are also recommended because they are associated with improved glycemic control (American Diabetes Association, 2019).

The ISMP and the American Society of Health-System Pharmacists (ASHP) have developed practical recommendations for prescribing subcutaneous insulin in hospitals, which are included in **Table 1** (Cobaugh et al., 2013; Institute for Safe Medication Practices, 2017; American Society of Health- System Pharmacists, 2006). In the United Kingdom, the National Institute for Health and Care Excellence (NICE) published a document called 'safer insulin prescribing' in 2017 (National Institute for Health and Care Excellence, 2017). This was followed by a report from the charity 'Diabetes UK' in 2018 (Watts and Rayman, 2018). Both contain recommendations for insulin prescribing, which are outlined in **Table 2**.

Despite these comprehensive recommendations, insulin prescribing errors remain a significant and clinically important problem in hospitals (Cornish, 2014). It is appreciated that due to the variety of complex risk factors and causes of insulin prescribing errors, a rigorous and mutli-pronged approach will be needed by institutions in order to successfully and sustainably improve prescribing safety. The next section illustrates how pharmacists from a large teaching hospital in England approached the evaluation and improvement of insulin prescribing practice at a local level.

Case Study from a Teaching Hospital in the United Kingdom

Prevalence and Types of Insulin Errors Locally

Sheffield Teaching Hospitals NHS Foundation Trust (STHFT) is one of the largest and busiest NHS hospital trusts in England, operating across five hospitals and 40 community sites. Over 2.3 million patients a year are seen at STHFT, 15% of whom have a diagnosis of diabetes. Insulin, consistently, features as one of the top medicines responsible for safety incidents reported at the trust, despite the introduction of e-learning modules, specialist diabetes and link nurses, insulin prescription, administration, monitoring, and guideline charts and foundation doctor training. The safe use of insulin in hospitals is of concern for patients at STHFT, with local diabetes patient public involvement groups expressing interest in being involved with insulin prescribing safety initiatives.

During 2015, the UK National Diabetes Inpatient Audit (NaDIA) revealed that 28.1% of patients prescribed insulin had at least one medication error involving their insulin in 2015 at the main acute hospital in STHFT, compared with 18.5% in 2013.

Table 1 International recommendations for safe insulin prescribing from the ISMP and AHSP

Institute for Safe Medication Practices (2017)	*American Society of Health System Pharmacists (2006, 2013)*
The indication for insulin use is clearly documented in the health record and is readily accessible and visible to all clinicians during insulin order entry, verification, and administration.	Insulin prescriptions should include: • At least two patient identifiers • Indication for insulin and appropriate terminology for type of insulin used (e.g., basal, prandial) • Target blood glucose range • Both generic (e.g., glargine) and brand name (e.g., Lantus) • Dose(s) for each insulin type • Specific time of administration, either clock hour or as time prior to or with food or meals • Blood glucose monitoring regimen specified by time of day and/or as time prior to food or meals • Specific insulin dose regimen adjustment based on dietary intake and/or BG results. • Route of administration • Orders for management of Hypoglycemia • Description of the role of the patient in management of insulin therapy • Patient-specific issues and care needs
Organizations develop and utilize evidence-based insulin protocols and/or evidence-based insulin order sets with decision support capabilities, when appropriate. These should cover situations that involve, for example, transitions from intravenous to subcutaneous insulin, calculations and communication of basal, nutritional and correctional insulin doses, insulin prescribing with respect to nutritional intake, concentrated insulin, concomitant glucocorticoid use, pregnancy, hypoglycemia and post-discharge insulin management	Develop protocol-driven and evidence-based order sets for specific uses of insulin such as transition of administration route from intravenous to subcutaneous, administration via subcutaneous insulin pumps, post-discharge dosing, diabetic ketoacidosis, hyperosmolar states, hyperkalemia, and post-cardiac surgery care. Order sets should include orders for glucose monitoring and decision-support tools to guide insulin use, including the management of hypoglycemia.
Organizational policies are in place to guide the care of patients with a personal subcutaneous insulin pump.	Verbal and telephone orders for insulin should be minimized and used only when necessary in urgent medical situations.
The prescriber identifies the target glucose range in the patient's health record.	All patients receiving insulin should have their blood glucose monitored at appropriate times and evaluated at least daily.
Eliminate the use of sliding scale insulin doses based on blood glucose values as the only strategy for managing hyperglycemia.	Eliminate the routine prescription of correction/sliding scale insulin monotherapy.
Insulin orders are free of error-prone abbreviations and dose expressions.	The word "units" must be written in full. Leading zeroes should be used before all decimal points when insulin is ordered. No "trailing" zeroes should be used following decimal points. No "prohibited" abbreviations as determined by the organization should be used. Eliminate the use of "free text" insulin orders in electronic and paper medical records.
Strategies such as tall man lettering with bolded text for the unique letter characters are used to help distinguish look-alike insulin names (e.g., HumaLOG and HumuLIN)	When used, electronic prescribing systems include appropriate alerts to reduce risk of error in insulin prescribing and should prompt use of organization-specific protocols and orders for blood glucose monitoring.
Communicate all patient-specific information related to diabetes care in one designated place in the health record.	Approved insulin protocols should not require or should minimize the use of calculation.
An endocrinologist or practitioner trained in insulin management is consulted for patients with hospital-defined uncontrolled hyperglycemia or hypoglycemia.

In order to improve insulin safety at the trust, further investigation into the nature and prevalence of errors was required. A retrospective review of incidents reported to the trust on existing patient safety software (DATIX) was undertaken to identify and review insulin-related errors over the past 24 months. Results revealed that 160 medication errors were reported relating to insulin use in inpatients, which varied considerably with respect to severity and type. Prescription and administration errors were most commonly reported, as well as errors related to the use of IV insulin, and errors as a result of unclear discharge letters (which, at STHFT, incorporate prescriptions).Considering the limitations of data retrieved from the trust's incident reporting software (the reports are highly configurable, and there is a high-rate of under-reporting for prescribing errors), a prospective cross-sectional audit was undertaken to gain a snapshot of the problem. All inpatients prescribed insulin at the trust were identified during the NaDIA data collection. A single pharmacist then reviewed their medical notes to identify and document any insulin errors that had occurred during their admission. Insulin errors were then quantified and thematically analyzed to determine the nature and prevalence of insulin medication errors. Errors were categorized as either prescription errors, administration errors, errors involving

Table 2 Recommendations for safe insulin prescribing in the United Kingdom from NICE and Diabetes UK

National Institute of Health and Care Excellence (2017)	*Diabetes UK (2018)*
Ensure that people with diabetes who are receiving insulin therapy are given information about awareness and management of hypoglycemia.	All patients with a diagnosis of diabetes should be supported to self-manage their diabetes, wherever appropriate. Hospitals should have systems and training in place to supports this.
Be aware of 'sick-day' rules and ensure that people with diabetes who are receiving insulin therapy are given appropriate information about these.	Basic training on the safe use of insulin and the main diabetes harms and how they can be prevented should be mandatory for all healthcare professionals, caring for people with diabetes.
Several new insulin products have been launched recently, including high-strength, fixed combination and biosimilar insulins. Be aware of the differences between these products and ensure that people receive appropriate training on their correct use.	Effective electronic prescribing system for detecting, recording, and avoiding insulin errors should be used across hospitals.
Give adults who are using insulin therapy a patient information booklet and an "Insulin Passport" *(a booklet in which patients and healthcare providers can document contemporaneous information about the currently used insulin regimen).*	Hospitals should agree on local key indicators, such as insulin errors, to audit and to have methods in place that ensure data collection is robust and the data is subjected to rigorous analysis.

IV insulin or insulin monitoring errors. Relationships were found between errors and clinical areas, as well as administration status and diabetes team involvement.

As a result of data analysis, it was found that most prescribing errors involved the number of insulin units and device. We also found that surgical and admission wards had a greater volume of patients with diabetes and a greater number of insulin errors. Patients who self-administrated their insulin seemed to encounter fewer errors than with patients whose insulin was administered by nursing staff.

The introduction of electronic prescribing at the Trust, which included the prescribing of subcutaneous insulin, was anticipated to influence the number and types of errors, however a retrospective thematic analysis of the error reporting system did not support this. The error themes aligned with those of pre-electronic prescribing implementation. Cases where electronic prescribing could have impacted in the error were identified as combined use of the electronic and paper system. Unintended 'when required' (PRN) doses, and lack of cross referencing of other charts including monitoring and intravenous insulin prescriptions.

Undertaking these baseline audits allowed us to identify specific problem areas that could be targeted for further examination and improvement. These areas included the prescribing of insulin at the point of care transfer (hospital admission and discharge) and the promotion of patient self-administration of insulin.

Insulin Prescribing on Admission

Previous studies have shown that medication errors in hospitals are most common at the time of admission to hospital, pharmacists can help improve insulin prescribing on admission by undertaking medicines reconciliation (Dornan et al., 2010; Breuker et al., 2017a; Breuker et al., 2017b). Following results of the aforementioned local audits, we aim to establish the nature and prevalence of insulin prescribing errors, information discrepancies, and pharmacy interventions at the time of hospital admission at STHFT. We sought to assess the timeliness of medicines reconciliation for patients with insulin-treated diabetes, identify and characterize insulin prescribing errors and pharmacy interventions documented on admission, and investigate discrepancies between insulin information recorded by doctors on clerking documentation and pharmacy medicines reconciliation charts.

Pharmacists visited 3 medicines admissions and surgical wards on 4 non-consecutive weekdays each week for 3 weeks during January 2017 to identify recently admitted patients with insulin-treated diabetes. Medical records and prescription charts were reviewed to identify insulin prescription errors, information discrepancies, and details of any pharmacy interventions.

We found that insulin prescribing errors and information discrepancies were common at the time of hospital admission. From a sample of 25 patients, 86% experienced at least one insulin prescription error or information discrepancy at the time of admission to hospital. A total of 69 insulin prescription errors or information discrepancies were identified. The 50 insulin prescription errors included insulin device (n = 26), dose (n = 11), time (n = 4), and frequency (n = 3), with 47 (94%) being rectified by pharmacy intervention. Information discrepancies involved the complete omission of insulin from the clerking drug history (n = 13) or insufficient information documented during clerking to prescribe insulin (n = 6). Medicines reconciliation was completed by pharmacy staff within 24 h of admission for 100% of the patients on admissions wards and for 86% of the patients on the surgical wards.

By undertaking medicines reconciliation, which includes all the necessary details for complete and accurate insulin prescriptions on admission, ward-based pharmacists at STHFT demonstrated the value of their service in improving quality and safety through identifying and rectifying potentially harmful insulin errors and information discrepancies. The introduction of an insulin summary card that encompasses pertinent clinical details for the commonly used insulin products,

including type of insulin, dose timings and likely regimens, was utilized to support the clinical review aspect of the medicines reconciliation process.

Insulin Prescribing on Discharge

Medication errors at the point of discharge have previously been reported as 'common' (WHO Collaborating Centre for Patient Safety Solutions, 2007; Vira, 2006) and can include unintended omission of medication, continuation/re-prescribing of an intentionally stopped medication, or an error in medication dose, frequency or formulation (Callen et al., 2010; Herrero-Herrero et al., 2011; Riordan et al., 2016). Such errors have been found to persist post-discharge and may pose a greater risk to patient care than those identified on admission (Pippins et al., 2008). In response to local audit data that documented a number of patient safety incidents relating to insulin discharge prescriptions, we sought to investigate the nature and prevalence of insulin-related medication discrepancies documented in the hospital discharge summaries for patients with diabetes at STHFT. We also aimed to establish the timelines and completeness of relevant information regarding insulin therapy provided on discharge summaries.

We made use of the National Diabetes Inpatient Audit (NaDIA) to identify all inpatients at STHFT, who were prescribed insulin on one day in October 2016. We then undertook a retrospective analysis of their discharge summaries, auditing compliance to criteria for discharge prescriptions based on previous national guidance (Joint British Diabetes Societies for inpatient care, 2017; National Prescribing Centre, 2008).

A total of 42 patients were included, of which 33 (79%) had changes made to their insulin regimen during hospital admission. Eighteen (43%) patients were identified as having an error or discrepancy relating to insulin on their discharge summary. A total of 27 insulin errors or discrepancies were identified on discharge, most commonly involving non-communication of an insulin dose change ($n = 8$) and wrong insulin device ($n = 7$). Seventeen issues relating to completeness of insulin information were identified, including the particular time of insulin dose ($n = 10$) and unexplained insulin dose change ($n = 4$). Although not proof of causation, we found that 2 patients who had insulin-related errors identified on their discharge summaries, were readmitted to the hospital within 30 days of discharge, and this was due to poor diabetic control.

Following discussion of these results with the multidisciplinary inpatient diabetes team, pharmacists sought to improve insulin prescribing on discharge using a continuous quality improvement approach involving cycles of iterative change. Locally-tailored insulin discharge prescribing guidance was formed by consensus with the multi-disciplinary project team. A diabetes ward that had experienced a number of insulin discharge prescription errors in recent months (identified by further review of the trust's incident reporting system) piloted the planned improvement project. Electronic discharge prescriptions involving insulin from the ward during Monday to Friday of each week were examined retrospectively, and their adherence to the guidance was measured and analyzed. After baseline measurement, three cycles of iterative change, involving input and feedback from multiple healthcare professionals in the ward, were undertaken over a three-week period to introduce the guidelines and improve the quality of discharge prescriptions.

After the introduction of the guidelines in the form of a poster, and later a nursing checklist, the adherence to guidelines rose from an average of 50% to 99%. Qualitative data suggested that although it took pharmacists slightly longer to clinically verify discharge prescriptions, the interventions comprised a simple, clear, and helpful reminder to help improve discharge quality for the benefit of patient safety. In conclusion, pharmacists were able to demonstrate that small, low-cost, iterative changes made by a multi-disciplinary team could result in substantial improvement in the quality of insulin discharge prescriptions.

Self-Administration with Insulin

Following the publication of the Joint British Diabetes Societies recommendations for the self-management of diabetes during hospital admission (Joint British Diabetes Societies for Inpatient Care Group, 2012), STHFT amended its policy to allow people to continue to self-administer their insulin in the hospital setting. However, experience indicated that barriers, including patient access to insulin for self-administration, still existed. Discussions with the local Diabetes UK group revealed that the main points of concern for people with diabetes being admitted to hospital were not having access to their insulin and doses being given at the wrong time. The pharmacist, therefore led a series of projects, including audits, incident reviews, and service user interviews in order to facilitate self-administration of insulin in the hospital setting.

The trust's patient safety software was reviewed specifically for insulin self-administration or misappropriation incidents. Results identified cases where the patient self-administered the correct dose of insulin despite a wrong prescription, and 20 incidents that could have been prevented if the patient had been self-administering. A baseline trust-wide cross-sectional audit was then undertaken to assess insulin storage and self-administration status at home and in the hospital. Results showed that 58% (41/71) patients self-administered at home, 30 of which continued to do so in hospital (4 were deemed not suitable to do so whilst in hospital). Although policy stipulated that patients did not have access to their insulin, 23 patients who were self-administering had insulin access. Further risk assessments and options appraisals were undertaken, and the trust policy was amended to allow patients to maintain possession of their own insulin and continue self-care whilst in hospital.

After the policy change, a pharmacist-led service assessing and documenting the suitability of self-administration for people with type 1 diabetes admitted to hospital was successfully implemented to further support patients to self-administer.

Following these projects, pharmacists at STHFT are seeking to deeply explore the barriers and facilitators to the safe insulin prescribing for inpatients by the use of qualitative methodological approaches such as focus groups discussions and patient interviews. In line with the ethos of continuous improvement at the trust, further improvements and interventions will be designed and developed in order to help make insulin prescribing safer for patients in hospital.

Conclusion

Insulin prescribing is a process that is of critical importance, but is prone to risks. Pharmacists have the opportunity to help improve insulin prescribing safety in hospitals by the use of continual audit, implementation of decision-support tools such as dedicated insulin prescribing charts and algorithms, utilization and optimization of electronic prescribing software, and the development of locally-tailored, evidence based guidance. By integrating into the wider diabetes team, pharmacists have the potential to offer cost-effective interventions to improve insulin prescribing and patient safety. By prioritizing issues that are important to patients, pharmacists can make a positive contribution to the overall care and experience of patients, who use insulin in the hospital setting.

Pharmacotherapy and Deprescribing

Emily Reeve[*,†,‡], **Sarah N. Hilmer**[*,§], **Ian Scott**[¶,‖], [*]NHMRC Cognitive Decline Partnership Centre, Kolling Institute of Medical Research, Northern Clinical School, Faculty of Medicine and Health, University of Sydney, NSW, Australia; [†]Geriatric Medicine Research, Dalhousie University and Nova Scotia Health Authority, NS, Canada; [‡]College of Pharmacy, Dalhousie University, NS, Canada; [§]Departments of Clinical Pharmacology and Aged Care, Royal North Shore Hospital, NSW, Australia; [¶]Department of Internal Medicine and Clinical Epidemiology, Princess Alexandra Hospital, Woolloongabba, QLD, Australia; [‖]School of Clinical Medicine, The University of Queensland, Brisbane, QLD, Australia

Background

Effective and safe use of medicines is essential for achieving positive health outcomes and minimizing harms to individuals while also managing appropriate allocation of health-care resources. On the individual level, appropriate use of medicines involves the prescription of medications where the benefits outweigh the harms. Other considerations in determining appropriateness include whether there is a better alternative (e.g., safer or less expensive) and alignment with patients' goals of care, preferences, and values (Garfinkel et al., 2015; Scott et al., 2015; Spinewine et al., 2007). Older adults, who are frequently exposed to polypharmacy, are at a greater risk of harm from medication use due to the potential for drug–disease and drug–drug interactions, reduced physiological reserve, and changes in pharmacokinetics and pharmacodynamics (Reeve et al., 2015c; Scott et al., 2015). These concepts are covered in greater detail in Section "Geriatrics."

Potential benefits and harms of medications can both change in an individual over time, which means that a medication that was once appropriate can become inappropriate. For example, likely benefit may reduce if the medication is continued longer than the recommended duration, if onset of new diseases intervenes, or if there are changes in care goals, while harm may increase due to the aging process or prescription of a new interacting agent (Reeve et al., 2014a).

Polypharmacy (use of multiple medications) and inappropriate medication use are common, especially among older adults. Approximately half of adults aged greater than 65 years are taking five or more regular medications, with as many as one out of every five of these medications being potentially inappropriate (Hubbard et al., 2015; Opondo et al., 2012; Spinewine et al., 2007). Polypharmacy and inappropriate medication use have been associated with a number of negative health outcomes in older adults including adverse drug events (ADEs), reduced quality of life, hospitalization, falls, and mortality (Muhlack et al., 2017; Olsson et al., 2011; Passarelli et al., 2005; Steinman, 2016; Wallace et al., 2017). Therefore, quality use of medicines involves both initiating and continuing medications that are appropriate and will lead to a benefit and withdrawal of medications that are inappropriate.

What is Deprescribing?

The term "deprescribing" (or "deprescribing") first appeared in the English health literature in 2003 in an article published in an Australian hospital pharmacist journal (Woodward, 2003). The article outlined the principles considered essential for deprescribing:

1. Reviewing all current medications,
2. Identifying medications to be ceased, substituted, or reduced,
3. Planning a deprescribing regimen in partnership with the patient and
4. Frequently reviewing and supporting the patient

A systematic review conducted in 2014 investigated the definition of deprescribing provided in English language articles (Reeve et al., 2015b). Based on the results of the review and clinical considerations, the authors of the systematic review proposed the following definition for deprescribing:

> "Deprescribing is the process of withdrawal of an inappropriate medication, supervised by a health care professional with the goal of managing polypharmacy and improving outcomes."

A manuscript by Scott and colleagues, which is the most highly cited manuscript using the term deprescribing, contains the following definition:

> "The systematic process of identifying and discontinuing drugs in instances in which existing or potential harms outweigh existing or potential benefits within the context of an individual patient's care goals, current level of functioning, life expectancy, values, and preferences."(Scott et al., 2015)

While Thompson and Farrell provide the following definition (also highly cited):

> "Deprescribing is the process of tapering, stopping, discontinuing, or withdrawing drugs, with the goal of managing polypharmacy and improving outcomes."(Thompson and Farrell, 2013)

The components of these definitions and others are debated in the literature. First, there is not a consistent definition of "inappropriate medications," with some academics using the term only for high-risk medications. In the definitions above, it is used in the broad sense of any medication that is not appropriate in the individual at the time (i.e., where the potential harms outweigh the potential benefits in the individual or where use of the medication does not match care goals). Also, whether dose reduction can be categorized as deprescribing is contentious. The authors of the systematic review suggest dose reduction may be more appropriately considered as optimal prescribing rather than deprescribing, although mention that dose reduction may be an appropriate and beneficial outcome in many cases (Reeve et al., 2015b). Yet, it is included in other definitions of deprescribing.

It should be noted that this discussion is limited to the English language (as definition of a word is unique to the language in which it is used), although the concept crosses language boundaries. The term "deprescription" has been used in French literature as early as 2007 (Queneau et al., 2007). The concept of withdrawing medications that are no longer appropriate was around long before the term deprescribing became widespread. There are, however, several reasons why use of this term has increased and why it is beneficial for the end goal of improving care of older adults.

The first systematic review using the term deprescribing was conducted by Iyer and colleagues in 2008, who reviewed the outcomes of medication withdrawal trials in older adults (Iyer et al., 2008). However, they reported in their methods, "After a preliminary search using a number of different search strategies it was evident that there was no standard terminology for classifying clinical studies on cessation of drug therapy or medication withdrawal." As such they used a combination of different search strategies to inform their review. Alternative terms used in systematic reviews may cover broader concepts (such as rationalization or deescalation) or may be more simplistic (such as withdrawal, cessation, or discontinuation). This results in a large number of results to search through (time intensive) and may also mean that relevant articles are missed. This difficulty in identifying relevant research for synthesis and knowledge translation is one reason to advocate for use of the term deprescribing.

A consistent definition of deprescribing has both research and clinical applications. In research, determining the feasibility as well as the outcomes or success of deprescribing will depend on its definition and allow comparison of independently conducted studies. Where there is not yet international consensus (e.g., on dose reduction), it is important for pharmacists reading studies to be aware of what constituted deprescribing in that individual study. Clinically, the definition of deprescribing will have implications for guiding best practice and communications between health-care professionals (e.g., what does a recommendation of deprescribing from a pharmacist to a general practitioner mean?) As such, it is important that guidelines, training about deprescribing, and communication between health-care professionals are clear and descriptive in their messages. However, regarding the aim of improving patient care through optimization of medication use, the specific definition may be less important. In pursuit of optimizing therapy, deprescribing is part of good prescribing and the wider field of safe and appropriate medication use (Scott et al., 2015). However, there are a number of studies that support the need to discuss and conduct research with a focus on deprescribing. The high prevalence of inappropriate medication use shows that deprescribing is not occurring as often in practice as it should be (Opondo et al., 2012; Spinewine et al., 2007), the reasons for which are discussed below.

Overall, the core of definition is that deprescribing involves withdrawal of a medication to improve the risk:benefit ratio of medication use in an individual. It is a positive action done for the benefit of the patient and does not deny them potentially beneficial treatment. Generally, deprescribing is discussed as a patient-centered process that requires shared decision-making, informed consent, and monitoring throughout the process and after cessation. While there are inherent uncertainties of the benefits and risks of deprescribing in an individual, the same is true for initiating, or indeed continuing therapy.

Evidence of Outcomes of Deprescribing

The outcomes of deprescribing interventions can be assessed and categorized in various ways depending on the type of intervention and the outcome of interest.

- Indirect (or system level) deprescribing interventions are programmatic strategies aimed at populations of clinicians such as professional education programs, decision support tools, and prescribing policies.
- Generic direct interventions involve deprescribing on an individual patient level, but without the use of prespecified, structured, or explicit criteria, such as pharmacist-led medication reviews and comprehensive geriatric assessment.
- Structured direct (or patient level) interventions use explicit, systematic processes (such as using an algorithm or a structured deprescribing framework or guide) applied by individual clinicians to the medication regimens of individual patients. These can be medication class specific or directed to all medications.

Clearly, indirect and direct deprescribing can overlap and complement one another. Outcomes may be medication-centric, i.e., number of medications overall or of a specific class taken by either a broad population or specific patient groups; or patient-centric (including clinically relevant outcomes), i.e., drug-related burden, ADEs, hospitalizations, deaths, physical or mental impairment, costs, and inconvenience.

Effects of Indirect and Generic Direct Deprescribing Interventions

A number of systematic reviews have been conducted on indirect interventions and generic direct interventions. The studies have generally been of low to moderate quality, measuring medication- rather than patient-centric outcomes, of short duration, and have produced mixed results (Kaur et al., 2009). A review of 30 studies, 10 randomized, including pharmacist and physician-led reviews, multidisciplinary interventions, computer feedback, and educational interventions found significant reductions in number of medications in most controlled studies, although mixed results in randomized studies. Only 15 of the studies reported on clinical endpoints, of which only six reported benefits such as reduction in serious ADEs (Gnjidic et al., 2012). Similarly, more recent reviews (Cooper et al., 2015; Johansson et al., 2016) found interventions generally led to reduced use of potentially inappropriate medications (PIMs), although improvements in clinical end-points were not confirmed.

Reviews examining specific intervention types, patient populations, and settings have found similar results, generally concluding benefits to medication-centric outcomes (reduction of number of medications or PIMs) with scarce evidence on patient-centric outcomes. A review of 20 trials of pharmacist-led medication reviews, both inpatient and outpatient, saw the mean number of prescribed medications per patient reduced by 0.48, but with no effects on outcomes except for reduced hospitalizations in heart failure patients (Thomas et al., 2014). A review of 15 studies of academic detailing of family physicians saw a modest reduction in the number of inappropriate medications of certain classes (benzodiazepines and nonsteroidal anti-inflammatory drugs) (Chhina et al., 2013). In a recent systematic review of different interventions targeting frail older patients in various settings, 22 of 26 quantitative studies reported significant reductions of 3 to 20 percentage points in the proportions of medications deemed unnecessary (defined using various criteria) (Tjia et al., 2013). Another review of 8 randomized trials of various interventions involving nursing home patients showed more frequent identification and resolution of medication-related problems and improved medication appropriateness (Alldred et al., 2013). Individual studies do point toward clinically relevant outcomes. In two randomized trials conducted in aged care facilities that featured educational interventions aimed at either prescribers (García-Gollarte et al., 2014) or nursing staff (Pitkälä et al., 2014), the number of PIMs and days in hospital were significantly reduced, and declines in health-related quality of life were slower (García-Gollarte et al., 2014).

Effects of Structured Direct Deprescribing Targeting Specific Classes of Medications

The evidence base for structured, direct patient-level deprescribing is more rigorous as it often pertains to specific classes of medications. This allows recruitment of specific populations (such as those in whom the medication is inappropriate) and monitoring of clinical outcomes that are relevant to the medication of interest (such as known adverse drug reactions, for example, falls). A systematic review of 31 trials (15 randomized) that withdrew a single (targeted) class of medication in older people demonstrated that, with appropriate patient selection and education coupled with close monitoring during withdrawal, antihypertensive agents, psychotropic medications, and benzodiazepines could be discontinued without harm in 20%–100% of patients. However, psychotropics and to a lesser extent antihypertensives showed high posttrial rates of recommencement. Several of the studies indicated a benefit (such as a reduction in falls and improvement in daily function) from withdrawal of

psychotropics (Iyer et al., 2008). Another review of 9 randomized trials showed that antipsychotic agents used to control behavioral and psychological symptoms of dementia could be withdrawn in more than 80% of subjects. Their meta-analysis revealed no significant difference in symptoms between groups that continued versus discontinued (Declercq et al., 2013). In an observational study, cessation of inappropriate antihypertensives was associated with fewer cardiovascular events and deaths over a 5-year period (Ekbom et al., 1994). A randomized trial of statin withdrawal in patients with advanced illness, half of whom died within 12 months, demonstrated improved quality of life and no increased risk of cardiovascular events over the following 60 days (Kutner et al., 2015). In a randomized trial, direct patient education through distribution of an empowerment brochure by community pharmacists reduced benzodiazepine use by 77% among chronic users at 6 months with no withdrawal seizures (Tannenbaum et al., 2014).

Effects of Structured Direct Deprescribing Targeting All Medications

The evidence for direct deprescribing of all medications using explicit tools or structured processes is limited by relatively few high-quality randomized trials, small patient samples, short duration of follow-up, selection of specific subsets of patients, and the absence of comprehensive represcribing data and clinical outcomes. However, studies of these kinds suggest a benefit to patient-centric outcomes. In a controlled trial involving 190 patients in aged care facilities, the Good Palliative–Geriatric Practice algorithm resulted in, on average, 2.8 medications per patient discontinued, and a halving in both annual mortality and acute referrals to hospitals (Garfinkel et al., 2007). In a prospective cohort study, the same approach identified an average of 4.4 PIMs per patient ($n = 64$), of which 81% were successfully discontinued, with 88% of patients reporting global improvements in health (Garfinkel and Mangin, 2010). In another prospective cohort study of 50 older hospitalized patients receiving a median of 10 regular medications on admission, a formal deprescribing process led to cessation of just over 1 in 3 medications by discharge, representing 4 fewer medications per patient with less than 5% of ceased medications recommenced for relapsing symptoms over the following 2.5 months (McKean et al., 2015). A multidisciplinary hospital clinic for older patients achieved cessation of 22% of medications in 17 patients over 3 months without ill effect (Mudge et al., 2015). Of two randomized studies of older hospital patients that applied the Screening Tool of Older People's Prescriptions (STOPP), both reported significant reductions in PIMs at discharge but without any impacts on hospital admission, falls, or mortality (Dalleur et al., 2014; Gallagher et al., 2011). Recently, a randomized trial involving aged care residents saw a deprescribing intervention result in successful discontinuation of 207 (59%) of 348 targeted medications, and a mean reduction of two medications per patient at 12 months compared to none in controls, with no differences in mortality or hospitalizations (Potter et al., 2016). In a cohort of 240 patients receiving hemodialysis, a deprescribing tool led to 31 of 40 (78%) target medications being deprescribed, with only 5 recommenced 6 months later (McIntyre et al., 2017).

Other Potential Benefits of Deprescribing

Use of inappropriate medications is associated with significant financial costs to the individual and government funding bodies. Costs may occur not only through the purchase of such medications but also from the treatment of ADEs such as hospitalization. Therefore, deprescribing may result in the reduction of costs to the individual and release of funding to governments, which can be spent on more cost-effective services and/or treatments. There is some research to support this; however, the cost-effectiveness of the different deprescribing intervention types has not yet been fully explored (Gnjidic et al., 2012; Tannenbaum et al., 2017; Thompson et al., 2016). Deprescribing also has the potential to lead to improved adherence to the individual's remaining medications (Reeve et al., 2014).

Safety of Deprescribing

There is little evidence that judicious discontinuation of drugs with close monitoring is unsafe (Reeve et al., 2018b). Serious harm due to withdrawal syndromes is rare (Graves et al., 1997; Marcum et al., 2012; Paquin et al., 2014), with cardiovascular and central nervous system medications being most implicated in the absence of slow tapering of dose. For conditions such as hypertension, diabetes, or asthma, early detection of relapsing disease can be identified using surrogates, enabling rapid resolution by recommencing the drug. For diseases with no surrogates (e.g., gastroesophageal reflux), close monitoring for recurrent symptoms appears sufficient to prevent serious harm. For preventive medications with more distant end-points, determining the risk of relapse or complications is harder to assess and highly dependent on the disease and medication in question. For example, discontinuation of cholinesterase inhibitors in dementia does not worsen disease in some studies and populations, but does in others (Herrmann et al., 2016; O'Regan et al., 2015). While there is a concern that short-term discontinuation of these medications leads to irreversible worsening of the condition (Doody et al., 2001), not all studies support this (Pariente et al., 2012), and there are important limitations to the studies such as natural progression of the disease and lack of an active comparator group. In the case of deprescribing proton pump inhibitors, deprescribing reduces pill burden but may lead to more people experiencing an increase in dyspepsia and regurgitation versus those who continue (Boghossian et al., 2017). In frail, older patients with limited prognosis, many preventive drugs can be discontinued without risk (Lavan et al., 2017).

Summary

A recent systematic review of 132 studies (Page et al., 2016a), which aimed to summarize the evidence on the feasibility and outcomes of deprescribing, concluded that deprescribing is feasible and may lead to improved outcomes. Overall, there is sufficient evidence from this and other reviews that deprescribing of inappropriate medications appears to be safe and effective at reducing medication-centric outcomes, with some indication of benefit to patient-centric outcomes (depending on the intervention, population, and medication deprescribed).

Barriers to and Enablers of Deprescribing

Patients and Caregivers

Patient involvement in deprescribing is important for many reasons: they are the one in control of what they take, they have knowledge about their medications and past medical history as well as their treatment goals, it is in accordance with the ethical principle of autonomy, and patient-centered care leads to improved outcomes (Reeve et al., 2017). Quantitative studies have found that 71%–93% of individuals would be willing to stop one or more of their medications if their doctor said it was possible (Galazzi et al., 2016; Kalogianis et al., 2016; Ng et al., 2017; Qi et al., 2015; Reeve et al., 2013b; Sirois et al., 2017). It is important, however, to understand the potential patient barriers to and enablers of deprescribing in order to optimize deprescribing in practice.

Belief in the appropriateness of a medication that they are taking can act as a barrier if patients feel that it is appropriate. For example, they may feel that a medication is still needed for their condition or may recall the benefit it provided when it was started. Conversely, belief that the medication is inappropriate may enable deprescribing, such as if they are experiencing a side effect or do not think that it is needed anymore. Fear of a withdrawal reaction, return of their condition, and a nonspecific fear of how they would be without the medication have been described as barriers to deprescribing. The process of deprescribing (or lack thereof) and external influences can also both act as barriers to or enablers of deprescribing. For example, knowing that medication withdrawal is a trial and the medication can be restarted if necessary, and also being aware of the process and what to do if they get any symptoms may increase comfort with deprescribing. The primary external influence is that of their GP and can be toward or against deprescribing (Bokhof and Junius-Walker, 2016; Linsky et al., 2015; Luymes et al., 2016; Reeve et al., 2013a, 2016). Other external influences include family members, friends, media, and family history of disease (Luymes et al., 2016; Reeve et al., 2013a, 2016). The final enablers to deprescribing reported by patients relate to a dislike of medications including inconvenience and cost associated with medication use. These barriers and enablers do not work in isolation; individuals have reported belief in the benefits and/or necessity of their medications while also having a desire to reduce medication use and being concerned about adverse outcomes (Linsky et al., 2015; Moen et al., 2009). Patients appreciate discussing their doubts about their medications and also concerns that they may have about deprescribing with their GP (Luymes et al., 2016). In the setting of palliative care patients, being accepting of their disease trajectory led individuals to have reduced fears surrounding medication cessation (Todd et al., 2016).

Similar barriers to and enablers of deprescribing have been reported by caregivers of older adults. Additionally, acting as a surrogate decision maker may be difficult and complicated by feelings of guilt and responsibility if their care recipient's condition worsens (Post et al., 2001; Reeve et al., 2016).

Health-Care Professionals and the Health-Care System

Barriers

Deprescribing medications that patients may have been taking for many years is not always easy. Both doctors and patients often lack confidence about when and how to cease medications. In a recent systematic review of studies, mostly performed in primary care settings, which looked at barriers to deprescribing from the prescriber perspective, four themes emerged (Anderson et al., 2014).

First, prescribers may be unaware of what constitutes potentially inappropriate prescribing within their own practice until this is pointed out to them. Clinicians often overestimate the benefits and underestimate the harms of treatments (Hoffmann and Del Mar, 2017).

Second, after becoming aware, there is clinical inertia toward maintaining the status quo as deprescribing is viewed as a risky affair (Anderson et al., 2017; Reeve et al., 2014b). Doctors are fearful of provoking withdrawal syndromes or disease complications and damaging their reputation and relationships with patients or colleagues in the process. Commission or regret bias arising from ill-fated action may partly explain a clinician's hesitancy to proactively manage inappropriate polypharmacy (Bornstein and Emler, 2001), especially when patients appear to have not suffered any ill effects from PIMs to date. However, the reluctance of many patients to divulge noncompliance with medications because of side effects may perpetuate the false impression of prescribers that all is well. In older patients, there is a pervasive under-recognition of medication-related geriatric syndromes on the part of doctors and pharmacists (Klopotowska et al., 2013). For example, falls or incontinence may be viewed as signs of aging and not identified as side effects of medications.

Third, lack of self-efficacy—feeling ill-equipped, in terms of the necessary knowledge and skills to deprescribe appropriately—may pose a barrier, even if the need for deprescribing is accepted (Anderson et al., 2014). Lack of readily accessible and valid information about benefit–harm trade-offs of particular drugs in older, frail, multimorbid patients, and what may be reasonable alternative treatments (both drug and nondrug), is a major barrier (Fried et al., 2010). The uncertainty of benefit and harm mandates shared decision-making between clinician and patient and, where appropriate, between clinician and caregiver (Jansen et al., 2016). This process can be rendered more difficult for patients with cognitive impairment or limited health literacy. Confidence to deprescribe is further undermined by the lack of clear documentation regarding the indications for which drugs were originally prescribed by other doctors, outcomes of past trials of discontinuation, and current patient care goals.

Fourth, several external or logistical constraints may hamper deprescribing efforts such as patient unwillingness (real or perceived) to deprescribe certain medications, lack of prescriber time, poor remuneration (or lack of incentives), difficulty accessing services, and community and professional culture and attitudes toward more rather than less use of medications (Anderson et al., 2014).

Another complicating factor is that while doctors, pharmacists, nursing staff, and even patients and their families may be in broad agreement that deprescribing is worthwhile, they often differ in their perspectives on what takes priority in selecting medications for deprescribing in individual patients and how it should be done and by whom (Page et al., 2016b; Turner et al., 2016).

Enablers

While deprescribing presents challenges, several strategies can facilitate it at the level of individual clinical encounters.

First, patients should be empowered to ask their doctors and pharmacists when, and under what circumstances, might it be reasonable to stop a medication. Periodic review of the benefits versus harms of specific medications should be undertaken as a patients' health status and comorbidity burden evolve over time. Rechecking medications should be seen as akin to rechecking blood pressure or lipid levels. In turn, doctors and pharmacists should ask in a nonjudgmental fashion, at every encounter, whether patients are experiencing any side effects, administration and monitoring problems, or other barriers to adherence associated with any of their medications.

Second, deprescribing should be framed as an attempt to alleviate symptoms (of drug toxicity), improve quality of life (from drug-induced disability), and lessen the risk of morbid events (especially ADEs) in the future.

Third, compelling evidence that identifies circumstances in which medications can be safely withdrawn while reducing the risk of ADEs needs to be emphasized (Bennett et al., 2014). In language they can understand, patients should be informed of the benefit–harm trade-offs specific to them of continuing or discontinuing a particular medication, as far as these can be made explicit. Patients, like clinicians, often overestimate the benefits and underestimate the harms of treatments (Hoffmann and Del Mar, 2015). Providing such personalized information can substantially alter perceptions of risk and change attitudes toward discontinuation (Martin et al., 2013).

Fourth, onset of ADEs or onset of newly diagnosed diseases or deterioration in existing comorbidities, which all increase the risk of ADEs, serves as tipping points toward deprescribing which prescribers can make full use of (Anderson et al., 2017).

Fifth, a range of decision-making strategies to reconcile therapeutic uncertainty in multimorbid patients can be employed (Sinnott et al., 2015) and various tools, structured guides, guidelines, and algorithms are available (these are discussed further in the Section "Process of Deprescribing").

Sixth, pharmacists, nurses, and other health-care professionals can be creatively engaged to systematize the process of deprescribing and monitoring and follow-up, complementing the role of the doctor (Steinman et al., 2011). Interactive case conferences involving multidisciplinary teams can provide support, seek consensus, and share the risk and responsibility for deprescribing recommendations (Bregnhøj et al., 2009). Other organizational changes such as targeted funding for annual medications review, computer prompts (Anderson et al., 2016), improved information flows between prescribers, improved access to expert advice, regulatory changes, and increased availability of nonpharmaceutical therapies can further support deprescribing at scale (Wallis et al., 2017).

Finally, specialists can play a sentinel leadership role in advising and authorizing other health professionals to deprescribe in situations where current harms of medications they have prescribed some time ago are no longer outweighed by current benefits (Luymes et al., 2016; Scott and Le Couteur, 2015).

The Process of Deprescribing

Understanding of the enablers of and barriers to deprescribing as well as the principles of good clinical care have informed the process of how to undertake deprescribing in practice. Several models of the deprescribing process have been developed and several have been assessed in research studies (McKean et al., 2015; Reeve et al., 2014a, 2015a; Scott et al., 2015). All the processes contain similar steps, which are generally in concordance with the steps first proposed by Woodward in 2003 (Woodward, 2003). The key features of the processes are firstly obtaining a complete medication history with knowledge of their medical history. This includes what medications the person is taking (including dose and frequency), the indications for the medications, how long they have been taking them, and any evidence of benefit or of harm from the medication. The next step is to evaluate patient factors that may impact

on the decision to deprescribe a medication including the patient's goals of care and their prognosis/life-expectancy. Each drug on the patient's medication list should then be reviewed in view of these patient factors, and the other medications that the person is taking, and a decision reached in consultation with the patient, on whether it could be ceased. This will depend on the current risk: benefit ratio for the individual. Medications should be ceased one at a time if possible, aiming to start with those conferring greatest harm and least benefit as decided in consultation with the patient and family. Medications may be able to be ceased simultaneously where there is a very low risk of withdrawal reactions or return of conditions (e.g., vitamins that are not needed). The plan for withdrawal of each medication may be cessation or gradual tapering, depending on the pharmacology of the drug, how long the patient has been taking it, at what dose, and their current adverse effects. Monitoring for withdrawal symptoms and return of disease condition, support for the patient (which may include advice on nonpharmacological treatment or referral to other health-care professionals), and documentation of the outcome are the final steps. If withdrawal symptoms occur, then the tapering/withdrawal process can be slowed down, and if there is clear return of condition (after exclusion of other causes), then the medication can be restarted or continued at the lowest effective dose.

The process of identifying inappropriate medications that are suitable for deprescribing can be difficult in the older comorbid population. However, several tools, algorithms, and guidelines have been developed to assist health-care professionals with this step. Structured but implicit guides and algorithms (i.e., still requiring clinical experience and expertise) can be used to identify medications that are eligible candidates for deprescribing (Garfinkel et al., 2007; Scott et al., 2015, 2017). A number of explicit screening tools have been developed to help clinicians consider the risks and benefits of medications in older patients. Some tools, such as the updated Beers Criteria from the United States ("American Geriatrics Society 2015 updated beers criteria for potentially inappropriate medication use in older adults," 2015), identify PIMs for older adults overall and those with particular clinical characteristics, based on expert consensus review of the literature. Others, such as the STOPP/START Criteria version 2 from the United Kingdom (O'Mahony et al., 2015), use similar principles to generate lists of drugs that should and should not be used in specific circumstances, with a version for frail patients with limited life expectancy, which was published recently (Lavan et al., 2017). Pharmacological risk-assessment tools, which measure an individual's total exposure to specific drug classes, can inform the risk side of the risk:benefit ratio and identify patients and drug targets for possible deprescribing. These include many measures of anticholinergic burden (Kouladjian O'Donnell et al., 2017), the Drug Burden Index (which measures cumulative exposure to medications with anticholinergic and sedative effects) (Hilmer et al., 2007), central nervous system medication use (Wright et al., 2009), and consideration of cumulative serotonergic or hypotensive load. Algorithms on the number needed to treat vs number needed to harm for specific medications and indications as well as disease prediction tools (reviewed in a number of websites, see end of chapter) can help assess and discuss benefit and risk. Estimates of patient prognosis such as the "surprise question" and others (Moss et al., 2010; Yourman et al., 2012) can be useful to determine whether the patient is likely to have enough time to benefit from a preventative treatment. A number of practical guides have been developed on when and how to deprescribe medications, these are listed at the end of the chapter (useful websites). In particular, several drug class specific deprescribing guidelines have been developed over the past few years (Bjerre et al., 2018; Farrell et al., 2017a, 2017b; Reeve et al., 2018a). These have been developed according to robust clinical practice guideline standards (Farrell et al., 2016) and provide recommendations on when and how to deprescribe the medications including recommendations about tapering and monitoring.

As the evidence for deprescribing grows, efforts are being made to implement the deprescribing process, supported by some of the tools described above, into clinical practice (Hilmer and Gnjidic, 2018). Strategies are required to address barriers and enablers specific to different health-care settings (community, nursing home, hospital) and practitioners (primary and specialist, medical, pharmacy, and nursing), with an emphasis on communication between different settings and practitioners. Interventions have been tested that directly target consumers (e.g., EMPOWER, Tannenbaum et al., 2014) or are initiated by health-care professionals, often working as multidisciplinary teams (Wouters et al., 2017). Technology may be able to support the deprescribing process, through software packages that guide and support the process, which may be either stand-alone or integrated with electronic health records and medication management systems (Saddiq and Kauser, 2017). To be effective, the deprescribing process must be patient-centered (Reeve et al., 2014a), ensuring that decisions about medication management are consistent with patient goals and prognosis, are agreed to by the patient, and move with the patient between different health-care settings and providers. However, the most effective, efficient, cost-effective, and sustainable solution to implementing a robust deprescribing process into practice is yet to be determined.

Pharmacists' Involvement in Deprescribing

There is the potential for pharmacists to be involved throughout the deprescribing process as outlined above. However, there are specific components for which pharmacists are well placed to undertake. For example, taking a comprehensive medication history is a key part of pharmacist training. In fact, a pharmacist-acquired medication list on admission to hospital has been associated with reduced medication costs, length of stay, medication errors, ADEs, and mortality (Bond and Raehl, 2007; Nester and Hale, 2002). Additionally, pharmacists have pharmacokinetic and pharmacodynamic knowledge required for planning medication tapering and monitoring. They also have training in communication techniques (McConnell et al., 2008; Tannenbaum and Tsuyuki, 2013).

Pharmacist Attitudes Toward Deprescribing

The attitudes of pharmacists toward deprescribing, including their potential involvement, have been explored in several studies in Australia. Pharmacists have identified barriers to deprescribing in practice similar to those reported by medical doctors (Anderson et al., 2017; Kouladjian et al., 2016; Palagyi et al., 2016; Turner et al., 2016). The main barriers specific to pharmacists' involvement in deprescribing (as reported by pharmacists) are not being sure whose responsibility it is, or devolving of responsibility (Kouladjian et al., 2016), the need for GPs to play a key role in all deprescribing activities (Palagyi et al., 2016), not having a previously established relationship with the patient, a lack of avenues to provide follow-up/continuing care after deprescribing (Anderson et al., 2017; Palagyi et al., 2016), and being cautious where there is uncertainty of evidence (leading to inaction) (Anderson et al., 2017).

In a quantitative study conducted in Australia, hospital pharmacists responded to a survey about optimizing statin use in older adults (Wu et al., 2017). Over 90% felt that they had an important role in providing advice to doctors regarding initiation, continuation, and/or cessation of statins. Approximately two-thirds were confident in their ability to identify patients in whom statin therapy should be deprescribed, but only about half reported that they regularly made recommendations about deprescribing in older adults.

Consumer Attitudes Toward Pharmacists' Involvement in Deprescribing

In studies in Australia, Canada, and Singapore between 51% and 66% of older adults reported that they would be comfortable if a pharmacist was involved in deprescribing one of more of their regular medications including providing follow-up (Ng et al., 2017; Reeve et al., 2013b; Sirois et al., 2017). In a focus group study with older adults and caregivers of older adults regarding deprescribing, experiences, and attitudes toward pharmacists appeared to be limited to the retail community pharmacy setting (Reeve et al., 2016). Pharmacists were acknowledged as experts in medications (such as in identifying drug–drug interactions) and certain individuals recalled times where their pharmacist had been very helpful. However, there was a limited understanding of the scope of the pharmacists' work and their potential role in deprescribing.

Health-Care Professionals' Attitudes Toward Pharmacists' Involvement in Deprescribing

GPs have identified the potential benefits of involvement of pharmacists in deprescribing as part of a multidisciplinary team (Ailabouni et al., 2016; Palagyi et al., 2016; Schuling et al., 2012). However, GPs have expressed concerns that pharmacists may recommend deprescribing that is not appropriate, as they may not be familiar with the patient's complete medical history (Ailabouni et al., 2016; Palagyi et al., 2016). They have also cited a lack of resources to specifically support multidisciplinary meetings with pharmacists as a barrier (Ailabouni et al., 2016). Success of pharmacists' involvement in deprescribing will likely depend on the relationship between the GP and the pharmacist (Palagyi et al., 2016). This has been demonstrated in quantitative studies where pharmacist recommendations are more likely to be accepted and implemented by the GP where there was a preexisting working relationship (Sorensen et al., 2004; Spinewine et al., 2012). Pharmacists embedded within GP clinics are a promising model for enhancing deprescribing in primary care. This would not only lead to trust between professionals but also gives pharmacists access to complete medical records (Anderson et al., 2015; Freeman et al., 2012). Models such as this are currently being investigated to determine clinical benefits and cost-effectiveness (Freeman et al., 2016; Tan et al., 2014).

In the hospital setting, junior doctors have reported that it is not their responsibility to conduct medication reviews and deprescribe inappropriate medications. Instead, they looked to pharmacists (as well as consultants and the patient's regular GP) to conduct these activities (Jubraj et al., 2015). In a survey conducted among nurses working in residential aged care facilities, they recognized the benefit of involvement of a pharmacist in deprescribing. Similar to GPs, however, some questioned whether the pharmacist had sufficient knowledge of the patient to recommend changes (Ailabouni et al., 2017).

Future Directions of Pharmacists' Involvement in Deprescribing

Multidisciplinary interventions (such as those including a pharmacist) appear to be the most effective at achieving deprescribing (Cooper et al., 2015; Gnjidic et al., 2012). Pharmacist-led interventions in a variety of settings can lead to improvements in medication appropriateness and reduction of polypharmacy with some evidence to support improved clinical outcomes such as reduced hospitalization (Jokanovic et al., 2016; Viswanathan et al., 2015; Walsh et al., 2016).

Further investigation into how to best utilize the skills and experience of pharmacists in deprescribing activities is required. There is some evidence to suggest that interventions which do not include the patient's GP are less effective (Ostini et al., 2011; Reeve et al., 2014a), and as such pharmacist deprescribing should not be an isolated function. Lack of communication between health-care professionals and different levels of care is a concern for medication management internationally. Therefore, it is important to ensure that pharmacist deprescribing activities involve good communication and coordination with other health-care providers (Duncan et al., 2017). To address this concern, a communication template for conveying evidence-based deprescribing information from pharmacists to physicians is being investigated (Martin and Tannenbaum, 2018).

Limited time of GPs has been cited as a reason for pharmacists' involvement in deprescribing. Many health-care systems have mechanisms for community pharmacists to conduct medication reviews, which can result in deprescribing recommendations

(Chen, 2016; Duncan et al., 2017). However, these existing schemes may not overcome several of the barriers discussed, such as not being able to do follow-up visits. Further investigation into the differences in pharmacists' roles, scopes of practice, and remuneration schemes across different settings is required to determine how to best use the skills and experiences of this profession to optimize deprescribing practices (Anderson et al., 2015, 2017).

As an accessible and trustworthy member of health-care teams, it appears to be imperative to have pharmacists involved in deprescribing activities on an individual patient level as well as being involved in advocating, educating, and communicating about deprescribing to both other health-care providers as well as the community around them.

Conclusions

In the 15 years since the term "deprescribing" was first published, evidence on its safety, efficacy, and implementation has grown enormously. While deprescribing is a long-standing component of the practice of geriatric medicine, with the ageing of the population and increased use of medicines, it has expanded to primary care and other areas of specialist practice. This has resulted in opportunities for pharmacists to inform and support all stages of the deprescribing process, across primary care, nursing home, and hospital settings. The 2018 WHO 3rd Patient Safety Challenge: Medication Without Harm highlights the importance of addressing inappropriate polypharmacy for the ageing populations across the developed and developing world.

Management of Cardiovascular Disorders and the Pharmacist's Role: Hypertension

Hager A. Mohammed, Ahmed Awaisu, Sowndramalingam Sankaralingam, College of Pharmacy, Qatar University, Doha, Qatar

Learning Objectives

At the end of this chapter, the reader should be able to:

1. Describe the epidemiology, etiology, risk factors, and pathophysiology of hypertension.
2. Discuss the screening, diagnosis, and investigations involved in the management of hypertension.
3. Discuss the non-pharmacologic management of hypertension.
4. Discuss the general pharmacologic approach and compare different evidence-based guidelines for the management of hypertension.
5. Describe the current and emerging roles of the pharmacist in the management of hypertension.

Take-Home Messages and Summary

1. Hypertension is a persistent elevation of blood pressure. Guidelines differ in the level of blood pressure that should be considered as "hypertension" and the different goal targets for those diagnosed as hypertensive.
2. The American College of Cardiology and American Heart Association redefined hypertension in 2017 Guidelines for the Prevention, Detection, Evaluation and Management of High Blood Pressure in Adults, which resulted in an increase in the number of adults who have hypertension based on this definition.
3. Globally, the prevalence of hypertension is increasing. WHO global estimates in 2010 indicate the prevalence of hypertension to be around 1.39 billion people.

4. Hypertension can be classified as primary or essential hypertension and secondary hypertension. While the cause of essential hypertension is largely unknown, genetic factors and diet play a key role in its development.
5. Secondary hypertension occurs commonly due to endocrine causes, such as hyperaldosteronism and renovascular causes.
6. Several classes of drugs, such as non-steroidal anti-inflammatory drugs, steroids, anti-cancer drugs, and others can cause increase in blood pressure.
7. Increasing age, male gender, black race, and positive family history of hypertension are non-modifiable risk factors for the development of hypertension. Modifiable risk factors for hypertension include consumption of excess salt, alcohol, sedentary lifestyle, and lack of physical activity.
8. Routine laboratory investigations, such as complete blood count, serum electrolytes, and creatinine must be performed during screening and diagnosis. Other specialized tests, such as measurement of plasma aldosterone and urinary metanephrines may be necessary for the diagnosis of hyperaldosteronism or pheochromocytoma.
9. Pharmacists play an important role in the management of cardiovascular diseases (CVDs) as part of the healthcare team. They manage one or more of the risk factors for CVDs independently or as part of a multi-disciplinary team.
10. Pharmacists have a significant role in managing medications and monitoring blood pressure in patients with hypertension. Furthermore, the evidence has proven the benefit of pharmacist's interventions in improving outcomes among patients with hypertension.
11. Pharmacists can play a vital role in several aspects of patient management, such as assessment, screening, and counseling on risk factors for CVDs, medication review and education on adherence, and modification of drug therapy.

Introduction

Hypertension is a persistent elevation of blood pressure (BP). Meeting one or more of the following criteria is defined as having hypertension: (1) a systolic blood pressure (SBP) of 140 mmHg or greater; (2) a diastolic blood pressure (DBP) of 90 mmHg or greater; (3) taking antihypertensive medication or; (4) having been told at least twice by a physician or other health professional that one has hypertension (McConnell and Baker, 2013; Williams et al., 2018). According to the American Heart Association (AHA) 2017 guidelines, hypertension is classified as Stage 1 when the BP range is 130–139 mmHg systolic or 80–89 mmHg diastolic and as Stage 2 when the BP is ≥140 mmHg systolic or ≥90 mmHg diastolic (Whelton et al., 2017; Basile and Bloch, 2018).

Epidemiology

The World Health Organization (WHO) estimate of the global prevalence of high BP among adults above 25 years of age was about 40% in 2008 (WHO, 2017). Accordingly, almost 1 billion people had uncontrolled hypertension worldwide in 2008. According to other estimates in 2010, the global prevalence of hypertension was 1.39 billion affecting about 31% the adult population. This is a 5.2% increase in global prevalence between 2000 and 2010 (Basile and Bloch, 2018). According to estimates by the AHA, 41% of the US adult population could be diagnosed with the hypertension by 2030 (McConnell and Baker, 2013). The highest prevalence of hypertension of 46% is observed in Africa, while the lowest prevalence of 35% is found in the Americas (WHO, 2017). High BP is estimated to cause 7.5 million deaths worldwide that represents about 12.8% of total deaths.

Etiology of Hypertension

Hypertension can be classified as primary/essential hypertension or secondary hypertension. Essential hypertension is the most common form of hypertension that accounts for over 90% of all causes of hypertension. While the exact cause of hypertension is unknown, it could be attributed to several factors, such as over activation of sympathetic nervous system, excess salt intake and genetic factors (Leung et al., 2017). However, secondary hypertension most commonly occurs due to renovascular diseases or endocrine causes, such as hyperaldosteronism or Cushing's syndrome. In addition to renal and hormonal causes, several medications can increase BP. Oral contraceptive pills, non-steroidal anti-inflammatory drugs (NSAIDs), corticosteroids, decongestants, anticancer drugs, and weight loss medications can increase BP and long-term intake can cause hypertension (Basile and Bloch, 2018).

Risk Factors for Hypertension

Factors that increase the risk of developing essential (primary) hypertension can be classified as modifiable and non-modifiable risk factors (Leung et al., 2017). Age, gender, race, and family history are non-modifiable risk factors. The risk of systolic hypertension increases with advancing age. Men are at a higher risk of developing hypertension until about 45 years after which the risk in women increases due to menopause (Martins et al., 2001). Blacks have a higher risk of developing early onset and severe hypertension compared to the white population. In addition, genetic factors also contribute to the risk of developing hypertension. Therefore, individuals with a family history of hypertension are likely to develop hypertension.

Modifiable risk factors of hypertension include high-sodium diet, obesity, sedentary lifestyle, and excessive alcohol consumption. The INTERSALT study established the positive relationship between sodium intake and BP. While there has been a debate regarding the allowable limit of salt intake, it is agreed that salt intake in excess of 3 g/day could increase the risk of hypertension (INTERSALT, 1988). Obesity and physical inactivity also contribute to a rise in BP and that loosing body weight improves hypertension. Alcohol consumption of more than 14 and 9 standard drinks for men and women, respectively poses the risk of developing hypertension.

Pathophysiology of Hypertension

One of the key mechanisms of essential hypertension is over activation of the sympathetic nervous system (Bolivar 2013; Grassi, 2015). BP is the product of cardiac output (CO) and total peripheral resistance (TPR). Therefore, SNS-induced increase in CO or TPR changes increases the BP. One mechanism of increase in CO and TPR is the renin-angiotensin-aldosterone system. While angiontensin II causes an increase in TPR via vascoconstriction, aldosterone promotes sodium and water retention by the kidneys resulting in an increase in plasma volume and therefore an increase in CO. In addition, increase in sodium intake can also cause increase in intracellular calcium levels in vascular smooth muscle cells promoting vasoconstriction and increase in TPR. In secondary forms of hypertension, the cause of increase in plasma volume or TPR is known and is attributed to renal diseases or changes in hormonal levels such as aldosterone or cortisol.

Complications of Hypertension

Hypertension is the most important modifiable risk factor for a number of cardiovascular adverse events, such as stroke and ischemic heart diseases (Basile and Bloch, 2018). For every 20 mmHg higher SBP and 10 mmHg higher DBP, the risk of death from heart diseases or strokes doubles. Therefore, the complications of hypertension include ischemic and hemorrhagic stroke, myocardial infarction, left ventricular hypertrophy, heart failure, and chronic kidney disease.

Investigations, Screening, and Diagnosis of Hypertension

Accurate measurement of BP is essential for the diagnosis of hypertension and monitoring response to therapy (Leung et al., 2017). Four approaches can be used for the measurement of BP: (1) automated office BP (AOBP), (2) non-AOBP, (3) ambulatory BP monitoring (ABPM), and (4) home BP monitoring (HBPM). According to the Canadian Hypertension Education Program (CHEP) 2017 guidelines, using AOBP, mean SBP ≥135 mmHg or DBP ≥ 85 mmHg is considered high. However, using non-AOBP, mean SBP ≥140 mmHg or DBP ≥ 90 mmHg is considered high. HBPM is suggested for routine self-monitoring of BP or when there is discrepancy between other approaches using a validated device. A mean SBP ≥135 mmHg or DBP ≥ 85 mmHg is considered high. ABPM is considered as the gold standard for the diagnosis of hypertension. Having a mean awake SBP ≥135 mmHg or DBP ≥ 85 mmHg or the mean 24-h SBP ≥130 mmHg or DBP ≥ 80 mmHg is considered hypertension. Furthermore, laboratory tests should be performed in patients with hypertension at diagnosis and monitored at intervals, as medically necessary. Complete blood count, serum electrolytes including creatinine, urinalysis, blood glucose or HbA1C, serum lipid levels, thyroid stimulating hormone (TSH), and electrocardiogram (ECG) should be assessed in a patient screened for or diagnosed with hypertension (Basile and Bloch, 2018).

The common causes of secondary hypertension are endocrine conditions, such as hyperaldosteronism, pheochromocytoma (tumor of adrenal medulla), and renovascular hypertension (Leung et al., 2017). Screening for secondary causes of hypertension should be undertaken in early onset hypertension or hypertension that is resistant to treatment with three or more antihypertensive medications. Additionally, screening for hyperaldosteronism should be considered in patients with hypokalemia or hypertension resistant to treatment with three or more medications. Measurement of plasma potassium levels, aldosterone, renin levels, or renin activity is necessary for the diagnosis. Patients with sudden onset severe labile hypertension with BP≥180/110 mmHg and symptoms of sympathetic overactivation should be screened for pheochromocytoma. Measurement of 24-h urinary collection for catecholamines and metanephrine is necessary for diagnosis. Renovascular hypertension should be suspected in patients with sudden onset or worsening of hypertension, patients whose serum creatinine levels increase more than 30% after initiation of ACE inhibitors or resistant hypertension. Captopril-enhanced radioisotope renal scan and investigations for fibromuscular dysplasia should be performed for diagnosis.

Management of Hypertension

Non-pharmacologic Therapy

Various guidelines have recommended the following non-pharmacologic and lifestyle interventions for the management of hypertension in adults:

- Physical exercise: It is recommended by several guidelines for patients with hypertension to do physical exercise due to its multiple beneficial effects on overall health. Physical activity in patients with hypertension is associated with BP reduction. For non-hypertensive individuals, physical activity is recommended to reduce the risk of becoming hypertensive. Clinicians can prescribe the accumulation of 30–60 min of moderate intensity dynamic exercise (e.g., walking, jogging, cycling, or swimming) 4–7 days/week, in addition to the routine activities of daily living (Leung et al., 2017; Williams et al., 2018).
- Weight reduction: Body weight control is indicated to avoid obesity (BMI >30 kg/m^2 or waist circumference >102 cm in men and >88 cm in women), as is aiming at healthy BMI (about 20–25 kg/m^2) and waist circumference values (<94 cm in men and <80 cm in women) to reduce BP and CV risk (Leung et al., 2017; Williams et al., 2018). All overweight individuals with hypertension should be advised to lose weight (Williams et al., 2018).
- Alcohol consumption: The European Society of Cardiology (ESC) and the European Society of Hypertension (ESH) guidelines provide some details about alcohol consumption in patients with hypertension. The guidelines recommend that patients who drink alcohol should limit their alcohol consumption to 14-units/week for men and to 8-units/week for women (1 unit is equal to 125 mL of wine or 250 mL of beer). Alcohol-free days during the week are generally advised (Williams et al., 2018). Canadian Hypertension guidelines recommend all individuals to limit their alcohol consumption to two drinks or less per day, and that consumption should not exceed 14 standard drinks/week for men and 9 standard drinks/week for women (Leung et al., 2017).
- Diet: Dietary Approach to Stop Hypertension (DASH) diet is recommended by most guidelines (NICE, 2013; Leung et al., 2017; Whelton et al., 2017; Williams et al., 2018). DASH is a flexible and balanced eating plan that helps create a heart-healthy eating style for life. The DASH eating plan requires no special foods and instead provides daily and weekly nutritional goals. This plan is generally based on the following points: eating vegetables, fruits, and whole grains, fat-free or low-fat dairy products, fish, poultry, beans, nuts, and vegetable oils, limiting foods that are high in saturated fat, such as fatty meats, full-fat dairy products, and tropical oils, such as coconut, palm kernel, and palm oils, and limiting sugar-sweetened beverages and sweets. In addition to these, patients should be encouraged to increase the consumption of vegetables, fresh fruits, fish, nuts, and unsaturated fatty acids (olive oil); and to consume low amounts of red meat and full-fat dairy products (Leung et al., 2017; Whelton et al., 2017; Williams et al., 2018). A heart-healthy diet that facilitates achieving a desirable weight is recommended for adults with elevated BP or hypertension (Whelton et al., 2017).
- Sodium intake: There is a consensus across clinical practice guidelines to educate patients to reduce their sodium intake toward 2 g (5 g of salt or 87 mmol of sodium) per day (NICE, 2013; Leung et al., 2017; Whelton et al., 2017; Williams et al., 2018).
- Potassium intake: In patients not at risk of hyperkalemia, increasing dietary potassium intake may be recommended to reduce BP (Leung et al., 2017; Whelton et al., 2017; Williams et al., 2018). However, some guidelines recommend against the use of potassium supplement as a method of BP reduction to avoid putting the patient at the risk of hyperkalemia (NICE, 2013).
- Stress management: In patients with hypertension in whom stress may be contributing to high BP, stress management should be considered as an intervention (Leung et al., 2017). However, there is no evidence to confirm the beneficial effect of this approach in the management of hypertension (Whelton et al., 2017).

Pharmacologic Therapy

Initiation of Drug Therapy

Antihypertensive therapy should be prescribed for average DBP measurements of 100 mmHg or higher or average SBP measurements of 160 mmHg or higher in all patients even without macrovascular target organ damage or other cardiovascular risk factors (NICE, 2013). Antihypertensive therapy should be strongly considered for patients aged under 80 years with an average DBP reading of 90 mmHg or higher or for an average SBP reading of 140 mmHg or higher in the presence of any of the following factors: target organ damage; established CVD; renal disease; diabetes and; a 10-year cardiovascular risk equivalent to 20% or greater.

For patients with average DBP measurements of 90–99 mmHg or average SBP measurements of 120–139 mmHg, without any other complications, lifestyle interventions are recommended to determine, if this will normalize BP first (NICE, 2013; Leung et al., 2017; Whelton et al., 2017). This recommendation is slightly different from what JNC 8 guideline recommends. In JNC 8, it is recommended for general population aged ≥60 years, to initiate pharmacologic treatment to lower BP at SBP ≥150 mmHg or DBP ≥90 mmHg and treat to a goal SBP <150 mm Hg and goal DBP <90 mm Hg (James et al., 2014).

Blood Pressure Goals and Targets Among Individual Patients

The ultimate goal of antihypertensive therapy is a reduction in cardiovascular events risk. The higher the cardiovascular risk, the more likely it is that a patient will benefit from a more aggressive BP goal. However, it is important to keep in mind that the risk of adverse effects, cost, and patient inconvenience increases as more medications are added. Target BP is based on individual patient's characteristics and comorbid conditions. BP goals are slightly different across different guidelines. **Table 1** summarizes the goals and targets presented in the main guidelines used for the treatment of hypertension.

Uncomplicated Hypertension

Since the overall goal of treatment should be reduction in BP, in the context of underlying CVD risk, randomized control trials focused on identifying medication classes that can prevent CVDs. Numerous classes of antihypertensive agents are available to treat high BP. Five drug classes have been shown, in high-quality randomized controlled trials, to prevent CVDs: diuretics, ACE inhibitors,

Table 1 Blood pressure goals recommendations by different clinical practice guidelines.

Guideline	*Year*	*Population and BP targets*
ESC/EHS (Williams et al., 2018)	2018	• The first objective is to lower BP to <140/90 mmHg in all patients and, if well-tolerated, treated BP values should be targeted to 130/80 mmHg or lower in most patients. • In patients <65 years, SBP should be lowered to 120–129 mmHg in most patients. • SBP target of between 140–150 mmHg for older patients (65–80 years). • DBP target of <90 mmHg is always recommended, except in patients with diabetes, in whom values <85 mmHg are recommended.
JNC 8 (James et al., 2014)	2014	• Adults age < 60 years and those >18 with diabetes or chronic kidney disease: <140/90 mmHg • Adults age ≥60 years: <150/90 mmHg
American College of Cardiology/American Heart Association (ACC/AHA) (Whelton et al., 2017)	2017	• All adults: <130/80 mmHg
American Diabetes Association (ADA) (American Diabetes Association, 2017)	2017	• Adults with diabetes <140/90 mmHg Targets <130/80 mmHg, may be appropriate for individuals at high risk of CVD
Canadian Hypertension guidelines (Leung et al., 2017)	2017	• For patients with non-diabetic chronic kidney disease, target BP is < 140/90 mmHg. Patients with diabetes: <130/80 mmHg

ARBs, CCBs, and beta-blockers (Whelton et al., 2017; Williams et al., 2018). Agents that have been shown to reduce clinical events should be used preferentially. Therefore, the primary agents used in the treatment of hypertension include thiazide diuretics, ACE inhibitors, ARBs, and CCBs. (Whelton et al., 2017).

When the initial drug treatment of high BP is being considered, several different strategies may be contemplated. Many patients can be started on a single agent, but consideration should be given to starting with two drugs of different classes for those with stage 2 hypertension (James et al., 2014; Whelton et al., 2017; Leung et al., 2017). Two-drug approach can be provided as either two different pills or combination of two medications. Two antihypertensive drugs should be used if target BP levels are not achieved with standard-dose monotherapy. Add-on drugs should be chosen from first-line agents. Useful options include a thiazide/thiazide-like diuretic or CCB with either an ACE inhibitor, ARB or a beta-blocker. Caution should be exercised in combining a nondihydropyridine CCB and a beta-blocker. In addition, the combination of an ACE inhibitor and an ARB is not recommended (James et al., 2014; Leung et al., 2017).

Resistant Hypertension

Resistant hypertension is defined as resistance to treatment when the recommended treatment strategy fails to lower office SBP and DBP values to <140 mmHg and/or <90 mmHg, respectively, and the inadequate control of BP is confirmed by ABPM or HBPM in patients whose adherence to therapy has been confirmed (Whelton et al., 2017). Resistant hypertension is associated with older age (especially >75 years), male sex, African origin, high initial BP at diagnosis of hypertension, highest BP ever reached during the patient's lifetime, frequent outpatient visits, obesity, diabetes, atherosclerotic disease, hypertension-mediated organ damage (HMOD), chronic kidney disease (CKD), and a Framingham 10-year coronary risk score >20% (Whelton et al., 2017). Patients with resistant hypertension are at higher risk of HMOD, CKD, and premature cardiovascular events. The recommended treatment strategy for resistant hypertension should include appropriate lifestyle measures and treatment with optimal or best-tolerated doses of three or more drugs, including a diuretic, an ACE inhibitor or an ARB, and a CCB (Whelton et al., 2017; Carey et al., 2018).

Effective treatment for resistant hypertension should combine lifestyle changes (especially the reduction of sodium intake), discontinuation of possible causes of BP elevation, and the sequential addition of antihypertensive drugs to the initial triple therapy (Whelton et al., 2017). The optimal drug treatment of resistant hypertension has been poorly studied. The most effective strategy seems to be addition of diuretic treatment to decrease volume overload, together with the restriction of salt intake, particularly in patients with CKD (Whelton et al., 2017).

Furthermore, BP control may be improved by increasing the dose of the existing diuretic or by switching to a more potent thiazide-like diuretic (e.g., chlorthalidone or indapamide). A loop diuretic should replace thiazides/thiazide-like diuretics if the patient's eGFR is <30 mL/min. Although resistant hypertension may show a BP reduction if the existing diuretic dose is further increased, most patients would require the administration of additional drugs (Whelton et al., 2017; Williams et al., 2018). Also, there is growing evidence to suggest that the fourth-line treatment should involve the blockade of the biological effects of aldosterone through the use of spironolactone up to 50 mg/day (Whelton et al., 2017; Williams et al., 2018).

Hypertensive Urgency and Emergency

Hypertensive emergencies are defined as significant elevation in BP (>180/120 mm Hg) associated with evidence of new or worsening target organ damage. Examples of target organ damage include hypertensive encephalopathy, intracranial hemorrhage,

Table 2 Antihypertensive medications for the treatment of hypertensive emergencies (Williams et al., 2018)

Cardiovascular event	*First-line drug*	*Alternative drugs*
Acute aortic dissection	Esmolol and nitroprusside or nitroglycerine or nicardipine	Labetalol OR metoprolol
Acute cardiogenic pulmonary edema	Nitroprusside or nitroglycerine (with loop diuretic)	Urapidil (with loop diuretic)
Acute coronary event	Nitroglycerine, labetalol	Urapidil
Preeclampsia, Eclampsia, and HELLP syndrome	Labetalol or nicardipine and magnesium sulfate	Consider delivery
Hypertensive emergency	Labetalol Nicardipine	Nitroprusside Urapidil
Hypertensive encephalopathy	Labetalol, nicardipine	Nitroprusside

HELLP = Hemolysis, Elevated Liver enzymes, and Low Platelets

acute ischemic stroke, acute myocardial infarction, acute left ventricular failure with pulmonary edema, unstable angina, and eclampsia (Whelton et al., 2017; Leung et al., 2017). The one-year death rate associated with hypertensive emergencies is greater than 79%, and the median survival is 10.4 months, if the emergency condition is left untreated (Whelton et al., 2017; Williams et al., 2018). The rate and magnitude of an increase in BP may be at least as important as the absolute level of BP in determining the magnitude of organ injury. Therefore, detailed history and previous BP readings, if available, are important. In addition, patients with chronic hypertension can often tolerate higher BP levels than previously normotensive individuals (Williams et al., 2018).

The most common hypertensive emergency symptoms will depend on the organs affected, but this may include headache, visual disturbances, chest pain, dyspnea, dizziness, and other neurological deficits. In patients with hypertensive encephalopathy, the presence of somnolence, lethargy, tonic clonic seizures, and cortical blindness may precede a loss of consciousness; however, focal neurological lesions are rare and should raise the suspicion of concomitant stroke (Whelton et al., 2017). Hypertensive emergencies demand immediate reduction of BP, but this does not necessarily mean that BP should be brought to normal level. The aim of BP reduction is to prevent any further target organ damage (Whelton et al., 2017). In general, use of oral therapy is discouraged for hypertensive emergencies. (Williams et al., 2018). **Table 2** provides the major intravenous antihypertensive medications indicated for hypertension emergency.

For most hypertensive emergencies, the mean arterial pressure should be reduced gradually by approximately 10%–20% in the first hour and by a further 5%–15% over the next 23 h. This often results in a target BP of $< 180/ < 120$ mmHg for the first hour and $< 160/ < 110$ mmHg for the next 23 h (Elliott, 2006). The major exceptions to gradual BP lowering over the first day are:

- The acute phase of an ischemic stroke: The BP is usually *not* lowered unless it is ≥185/110 mmHg in patients who are candidates for reperfusion therapy or ≥220/120 mmHg in patients who are not candidates for reperfusion (thrombolytic) therapy (Jauch et al., 2013).
- Acute aortic dissection: The SBP should be *rapidly* lowered to a target of 100–120 mmHg (to be attained in 20 min) to reduce aortic shearing forces (Li et al., 2013).

In contrast, hypertensive urgencies are situations associated with severe BP elevation in otherwise stable patients without acute or impending change in target organ damage or dysfunction. Many of these patients have withdrawn from or are noncompliant with antihypertensive therapy and do not have clinical or laboratory evidence of acute target organ damage. There is no indication for referral to the emergency department, immediate reduction in BP in the emergency department, or hospitalization for such patients (Whelton et al., 2017). It is generally discouraged to lower the BP quickly as ischemic damage can occur in vascular beds due to sudden drop in the BP (Whelton et al., 2017).

Antihypertensive Medication Selection Based on Patients' Characteristics and Compelling Indications

Patients with hypertension may present, in many cases, with some other CVDs and other medical conditions. As antihypertensive medications can have health beneficial effect beyond lowering the BP, patient's other medical conditions should be taken into account when selecting antihypertensive therapy. In addition to the medical conditions, genetics and race can play an important role in the choice of treatment for hypertension. For instance, African American patients, as a group, have a smaller BP reduction than white patients in response to ACE inhibitors, ARBs, and most beta-blockers when given as monotherapy (Materson et al., 1993; Wright et al., 2005). However, these drugs are effective when given in combination with thiazide diuretics or calcium channel blockers. **Table 3** summarizes the recommendations by guidelines regarding the first line antihypertensive medication based on patients' characteristics and comorbid conditions.

Many drugs are available for the treatment of hypertension and in most patients; BP can now be controlled effectively and with minimal adverse effects (Katzung et al., 2012). These drugs have a variety of mechanisms of action, and this allows combinations that target variable sources of BP elevation. **Table 4** summarizes commonly used antihypertensive medications and their major characteristics.

Table 3 Antihypertensive medication classes and their indications based on patients characteristics and comorbidities (James et al., 2014; Williams et al., 2018)

A. Patients without major medical conditions	*First-line drug*	*Add a second drug (to reach target BP)*	*Add a third drug (to reach target BP)*
African descent	CCB or thiazide diuretic	ARB or ACEI	Combination of CCB plus ACEI or ARB plus thiazide diuretic
White and other non-African descent (age < 60 years)	ARB or ACEI	CCB or thiazide diuretic	Combination of CCB plus ACEI or ARB plus thiazide diuretic
White and other non-African descent (age ≥60 years)	CCB or thiazide diuretic; ARB or ACEI also effective	ARB or ACEI; CCB or thiazide diuretic if ARB or ACEI used first	Combination of CCB plus ACEI or ARB plus thiazide diuretic
B. Patients with medical conditions	*First-line drug*	*Add a second drug (to reach target BP)*	*Add a third drug (to reach target BP)*
Diabetes (African descent)	CCB or thiazide diuretic	ARB or ACEI	Alternative 1st drug (CCB or thiazide diuretic)
Diabetes (white and other non-African descent)	ARB or ACEI	CCB or thiazide diuretic	Alternative 2nd drug (CCB or thiazide diuretic)
Coronary artery disease	Beta-blocker plus ARB or ACEI	CCB or thiazide diuretic	Alternative 2nd drug (CCB or thiazide diuretic)
Symptomatic heart failure	Beta-blocker plus ARB or ACEI	Add diuretic and spironolactone regardless of BP	CCB can be added if needed for BP control
Stroke	ACEI or ARB	CCB or thiazide diuretic	Alternative 2nd drug (CCB or thiazide diuretic)
Chronic kidney disease	ARB or ACEI	CCB or thiazide diuretic	Alternative 2nd drug (CCB or thiazide diuretic)

Table 4 Antihypertensive medications and their major characteristics (Katzung et al., 2012; DiPiro et al., 2016)

Class	*Subclass*	*Drug*	*Usual dose range (mg/day)*	*Frequency*	*Comments*
ACEIs		Captopril	12.5–150	BID or TID	• Hyperkalemia and acute kidney failure may occur.
		Enalapril	5–40	OD or BID	• Dry cough
		Fosinopril	10–40	OD	• Teratogenic
		Lisinopril	10–40	OD	• Starting dose should be reduced to 50% in patients who are on a thiazide diuretic or the elderly due to risks of hypotension
		Perindopril	4–16	OD	
		Ramipril	2.5–10	OD or BID	
ARBs		Candesartan	8–32	OD or BID	• May cause hyperkalemia and acute kidney failure
		Irbesartan	150–300	OD	• Does not cause dry cough
		Losartan	50–100	OD or BID	• Teratogenic
		Telmisartan	20–80	OD	• Starting dose should be reduced to 50% in patients who are on a thiazide diuretic or the elderly due to risks of hypotension
		Valsartan	80–320	OD	
Calcium channel blockers	Dihydropyridine	Amlodipine	2.5–10	OD	• Avoid short-acting dihydropyridines such as immediate-release nifedipine and nicardipine
		Felodipine	5–20	OD	
		Nicardipine SR	60–120	BID	• Beneficial to use in Raynaud's syndrome
		Nifedipine	30–90	OD	
	Non-dihydropyridine	Diltiazem	180–360	BID	• Extended-release products are used as anti-hypertensives
		Verapamil	80–120	OD	
Diuretics	Thiazide	Chlorthalidone	12.5–25	OD	• Usually taken in morning to avoid nocturnal diuresis
		Hydrochlorothiazide	12.5–50	OD	• Thiazides are more effective anti-hypertensives than loop diuretics
		Indapamide	1.25–2.5	OD	
		Metolazone	2.5–10	OD	• May exacerbate hyperglycemia and hyperlipidemia
					• Use with caution in patients with gout
	Loop	Bumetanide	0.5–4	BID	• Evening or night dose to be avoided
		Furosemide	20–80	BID	• High dose may be needed for patients with renal failure or heart failure
		Torsemide	5–10	OD	• Preferred over thiazides in patient with renal dysfunction and resistant hypertension

(*Continued*)

Table 4 Antihypertensive medications and their major characteristics (Katzung et al., 2012; DiPiro et al., 2016) (*cont.*)

Class	*Subclass*	*Drug*	*Usual dose range (mg/day)*	*Frequency*	*Comments*
	Potassium sparing	Amiloride Triamterene	5–10 50–100	OD or BID OD or BID	• Weak diuretic • May cause hyperkalemia • Used in combination with a thiazide to minimize hypokalemia • Does not significantly lower BP • Reserved for patients experiencing diuretic-induced hypokalemia; • Avoid in patients with CKD
	Aldosterone antagonist	Eplerenone Spironolactone	50–100 25–50	OD or BID OD or BID	• Dose in the morning and late afternoon (when twice daily) to avoid nocturnal diuresis • May cause hyperkalemia. • Eplerenone is contraindicated in patients with an estimated CrCl $<$50 mL/min, elevated serum creatinine and type 2 diabetes with microalbuminuria. • Spironolactone used as add-on therapy in resistant hypertension • Avoid spironolactone in patients with CKD (estimated CrCl $<$30 mL/min.
β-Blocker	Cardioselective	Atenolol Betaxolol Bisoprolol Metoprolol tartrate Metoprolol succinate extended release	25–100 5–20 2.5–10 100–400 50–200	OD OD OD BID OD	• Abrupt discontinuation may cause rebound hypertension • Non-selective at high doses • Exacerbate asthma • May be used in patients with atrial tachyarrhythmia or preoperative hypertension
	Nonselective	Nadolol Propranolol Timolol	40–120 160–480 10–40	OD BID OD	• Abrupt discontinuation may cause rebound hypertension • Inhibit β_1- and β_2-receptors • Exacerbate asthma • Offers benefits in patients with essential tremor, migraine, thyrotoxicosis and portal hypertension
	Intrinsic sympathomimetic activity	Acebutolol Carteolol Pindolol	200–800 2.5–10 10–60	BID OD BID	• Abrupt discontinuation may cause rebound hypertension • Partially stimulate β-receptors • Contraindicated in patients post-myocardial infarction
	Mixed α- and β-blockers	Carvedilol Labetalol	12.5–50 200–800	BID BID	• Abrupt discontinuation may cause rebound hypertension • α-blockade properties cause vasodilation and orthostatic hypotension
	Cardioselective and vasodilatory	Nebivolol	5–20	OD	• Abrupt discontinuation may cause rebound hypertension • Does not result in more orthostatic hypotension

The Role of Pharmacist in the Management of Hypertension

Pharmacist cares for patients with cardiovascular diseases (CVDs) in general (Dunn et al., 2015; Swieczkowski et al., 2016), and hypertension in particular has been widely reported in the literature (Carter et al., 2009a,b; Morgado et al., 2011; Di Palo and Kish, 2018). The pharmacist has an important role in the care and management of patients with CVDs through the provision of pharmaceutical care (Dunn et al., 2015; Swieczkowski et al., 2016). The pharmacist is also considered as an integral member of the multidisciplinary CVD healthcare teams (Brush et al., 2015; Dunn et al., 2015). Pharmacists providing care to patients with CVDs can be generalists or specialists in the cardiology pharmacy practice area. Specifically, cardiology pharmacy practice area focuses on the pharmaceutical care of patients with CVDs. Clinical pharmacists specializing in cardiology function and practice are an integral members of collaborative healthcare teams in a variety of settings, including, to coronary care units, cardiovascular intensive care units, telemetry units, medical wards, medical intensive care units, and other specialty outpatient clinics.

The role of the pharmacist in CVD settings has been widely reported in the literature and by relevant professional healthcare organizations (Dunn et al. 2015; Brush et al., 2015). In a perspective paper, Dunn et al. provide pertinent information on the clinical pharmacist's role in the care of patients with CVD, their training, certification, and contribution in a variety of practice models (Dunn et al., 2015). The paper indicated that pharmacist has a substantial role in both inpatient and ambulatory care settings, largely through medication therapy management, optimization of drug therapy, patient education and counseling, and transition of care activities focusing on medication reconciliation and patient education.

Evidence of Benefit of Pharmacist Interventions in Hypertension Management

The 2017 guidelines for the Prevention, Detection, Evaluation and Management of High Blood Pressure in Adults issued by ACC and AHA has redefined hypertension, which places 46% of adult Americans as hypertensive (Whelton et al., 2018). Hypertension remains a modifiable risk factor of CVDs. Unfortunately, many patients do not achieve their therapeutic targets, owing to non-adherence to medications. Therefore, pharmacist has an opportunity to improve medication adherence and prevent clinical inertia in patients with uncontrolled high BP (Carter et al., 2009a,b; Di Palo and Kish, 2018). There are several approaches, services, and models of care provided by pharmacists to improve outcomes in patients with hypertension.

Evidence from clinical studies has clearly demonstrated the value of pharmacist intervention in significantly improving medication adherence and reducing BP (Di Palo and Kish, 2018). Since hypertension is a significant risk factor for CVD, stroke, and mortality, there is a considerable opportunity to improve outcomes by preventing the onset CVDs through optimal BP control. The risk of CVD morbidity, stroke, and mortality is particularly marked when there is insufficient control of BP.

Emerging Role of Pharmacist and Practice Models in Managing Hypertension

Recent hypertension clinical practice guidelines (Chobanian et al. 2003; Whelton et al., 2018) address the importance of improving adherence to antihypertensive medications, highlighting the role of healthcare professionals, including pharmacists. In this regard, pharmacists have been playing a key role in developing approaches and services to improve medication adherence and to prevent clinical inertia in hypertension management. The role of pharmacist in the management of hypertension is multifaceted and includes medication management, patient counseling and disease state education. Owing to their easy access to the public, pharmacists are highly placed to address the gap in the management of hypertension and should interact with patients to improve awareness of disease, identify CVD risk factors, and educate patients on anti-hypertensive medications adherence. Pharmacists can also work with other healthcare providers, especially physicians, to promote optimal treatment of hypertension. One key role is in the optimization of drug doses as an initial step, especially in patients receiving antihypertensive medications with documented benefits (e.g., ACEI in patients with concomitant CKD or post-MI). Pharmacists should also promote the use of combination therapy as a means to achieve target BP.

The focus of pharmacist's interventions in hypertension management have largely been on: (1) patient education and counseling on medications and disease state; (2) clinical recommendations to physicians about therapy management (identification and resolution of drug therapy problems); (3) direct medication therapy management with the patient (including monitoring and modification of therapy) (Tonna et al., 2007; Green et al., 2008; Carter et al., 2009a,b; Morgado et al., 2011; Carter et al., 2012; Santschi et al., 2015; Di Palo and Kish, 2018). Some of the activities which pharmacist can perform include the following:

- Assessment, screening, and counseling patients about cardiovascular risk and BP control.
- Recommendations to physicians about therapy management.
- Reviewing antihypertensive medications.
- Prescribing medications and modification of drug therapy.
- Educating patients on HBPM.
- Medication reconciliation in inpatient and outpatient settings.
- Ordering relevant laboratory tests.
- Referrals to physicians or general practitioners.
- Follow-up visits with the patients including BP monitoring.

Medication Therapy Management

Pharmacist-led medication therapy management service in patients with hypertension has demonstrated evidence of benefits in improving medication adherence, BP control, and cost-savings (Isetts et al., 2008; Di Palo and Kish, 2018). Medication therapy management is defined as a service or group of services that optimize therapeutic outcomes for individual patients (Bluml, 2005). In the USA, Canada, and other countries, clinical pharmacists in institutionalized and ambulatory care settings routinely provide medication therapy management to improve outcomes and minimize adverse drug events. Studies provide evidence that having pharmacist directly involved in drug therapy management improve therapy goals as well as improved economic outcomes (Isetts et al., 2008; Di Palo and Kish, 2018). A comprehensive medication management is provided through collaborative drug therapy management, which is an agreement between a physician and a pharmacist that allows the pharmacist to initiate, modify or discontinue drug therapy within a certain scope of practice (Di Palo and Kish, 2018). These collaborative practice agreements have demonstrated significant improvement in antihypertensive medication adherence, BP control, and utilization of evidence-based therapy.

Team-based Interventions

The management of hypertension using team-based approach involves the coordinated efforts of healthcare providers and inter-disciplinary clinicians including physicians, pharmacists, nurses, and others to deliver holistic and high quality care (Di Palo and Kish, 2018). Several studies have reported positive outcomes of pharmacist collaboration with other healthcare professionals. For

example, Carter et al. (2009a,b) in a cluster randomized controlled trial reported that a physician and pharmacist collaboration has resulted in better mean BP control compared to a control group. In addition, collaboration between pharmacist and nurse has also proven to be beneficial (Carter et al., 2012). Overall, team-based care involving pharmacist was associated with improved outcomes including medication adherence and BP control (Carter et al., 2009a,b; Morgado et al., 2011). A US Surgeon General's report documents the benefits of pharmacist delivered care in many settings and recommends optimizing the pharmacist's role in delivering patient centered care and disease prevention services in collaboration with physicians or as part of a healthcare team (Giberson et al., 2011).

Telehealth in Hypertension

The delivery of health services through various telecommunication pathways is increasing, especially with the advancement of mobile technology. With the advancement in information and communication technology, pharmacists are well positioned to provide telehealth and telemonitoring interventions that may potentially improve medication adherence and other clinical outcomes in patients with hypertension (Di Palo and Kish, 2018). Telehealth interventions may encompass short message service (SMS) reminders, telephone calls, digital pill counts, using mobile applications to track adherence, etc. The telemonitoring by pharmacists has also been demonstrated in hypertension. Green et al. (2008) had reported the effect of HBPM and web communication coordinated by a pharmacist on BP control. Overall, patients who received the home monitoring and web training plus pharmacist care have experienced greater reductions in BP compared with usual care (RR = 3.32; 95% CI, 1.86–5.94) (Green et al. 2008).

Conclusion

In conclusion, the care and interventions provided by pharmacists in patients with hypertension could make a substantial contribution to reducing clinical inertia and the CVD risks associated with the condition. Given their drug therapy expertise and patient counseling skills, pharmacists can play a significant role in the management of hypertension including monitoring BP, counseling and education, and managing patients' medications. Pharmacists with varying degrees of prescriptive authority can modify and optimize medication regimens to achieve better health outcomes. Furthermore, with their easy accessibility, pharmacists can also implement timely screening and prevention strategies among high-risk groups. Several models exist that allow pharmacists to provide patient-centered care to patients with high BP. However, practices differ from one country to another and caution should be exercised to practice within the context of the pharmacist's scope of practice and what is legally allowed in a particular country. Overall, pharmacist care and intervention in patients with hypertension could have meaningful results in terms of clinical and economic outcomes. The integration and recognition of pharmacists as key members of hypertension management can open the door of their involvement in other related chronic diseases.

Acute Coronary Syndrome

Hadar Zaman, V-Lin Cheong, Justine Tomlinson, Zaynab Nejadhamzeeigilani, University of Bradford, Bradford, United Kingdom

 http://dx.doi.org/10.1016/B978-0-12-812735-3.00501-X

Learning Objectives

- Develop an understanding into signs and symptoms of ACS and the process involved in making a diagnosis
- Understand the various clinical investigations used to make a diagnosis in ACS
- Understand the different treatment regimens in the acute and long term management in patients with STEMI and NSTE-ACS
- Appreciate the role and where pharmacists can be involved in managing patients with ACS
- Recognize the importance of life-style modification as a preventative strategy for future episodes of ACS

Take-Home Messages

- Cardiac troponin levels (I and T) are the most sensitive biomarkers used to determine myocardial infarction
- ECG is an important tool which will enable the correct diagnosis: NSTE-ACS or STEMI
- All patients with suspected ACS will have a risk assessment conducted to guide optimal clinical management
- Acute management of ACS involves administering parenteral opioids and glyceryl trinitrate to provide pain relief caused by ischemia
- In confirmed STEMI diagnosis reperfusion therapy is recommended within 12 hours of symptoms and 2 hours from diagnosis of STEMI
- After acute management of STEMI the long term management will involve the prescribing of DAPT, beta-blockers, statins, ACE inhibitors
- In patients with NSTE-ACS aspirin, antithrombin therapy and beta-blockers are used in the acute management stage
- Long term management of NSTE-ACS is very similar to STEMI management
- Lifestyle modification such as smoking cessation or choosing a cardio-protective diet can significantly reduce future cardiovascular events
- Pharmacogenomics will become even greater in the future for managing patients with ACS

Introduction

Acute coronary syndromes (ACS) form a subgroup of coronary heart disease (CHD) that usually present with abrupt onset of symptoms, mainly at rest, caused by obstruction to cardiovascular blood flow. Reduction of oxygenated blood to cardiac tissue results in myocardial ischemia which if prolonged can lead to death of cardiac muscle cells. This chapter will focus on the key

presentations of ACS: unstable angina (UA) and Myocardial Infarction (MI), both of which are medical emergencies. MI can be further classified as either Non-ST-elevated MI (NSTEMI) or ST-elevated MI (STEMI), both of which are a major cause of premature death worldwide. UA and NSTEMI can have identical clinical presentation and have more recently been grouped together by the term Non-ST Elevation-ACS (NSTE-ACS) (Amsterdam et al., 2014).

Etiology

ACS is triggered by the erosion and rupture of an atheromatous plaque within the coronary artery wall. This encourages thrombosis formation and obstruction to blood flow resulting in myocardial ischemia. It is worth noting that "ischemia" is defined as a reduction of myocardial oxygen for less than 20 minutes, which causes damage that is reversible (Hashmi and Al-Salam, 2015). Infarction is characterized as oxygen deficiency for longer than two hours, resulting in irreversible damage. If there is complete blockage of the coronary artery this will result in a STEMI. NSTE-ACS is caused by partial coronary arterial blockage. The main management strategy is to restore coronary blood flow with either thrombolysis or angioplasty (see later in chapter; pharmacotherapy).

Plaques are formed by the process of coronary atherosclerosis beginning in the patient's late teens or early twenties. Initially a fatty streak appears in the coronary artery wall, progressing over time to form atherosclerotic lesions in the coronary arteries (Worrall and Fletcher, 2007). This, coupled with endothelial dysfunction facilitates plaque formation (Santos-Gallego et al., 2014). The dysfunction causes the adhesion of monocytes to the area. Platelets are activated and aggregate which, through various pathological processes, causes macrophages to be internalized into the developing plaque (Santos-Gallego et al., 2014). Finally, circulating lipids penetrate the plaque and are laid down as cholesterol. As the plaque increases in size, cell death occurs at the center, resulting in a lipid rich core coated by an external fibrous plaque. If this plaque becomes less stable due to physical stress or erosion, it will rupture exposing the lipid core (Scott, 2004). This promotes activation of thrombus formation causing partial or complete blockage.

Epidemiology

More people die worldwide from cardiovascular disease each year than from any other cause (The World Health Organisation, 2017). While mortality from CHD has gradually declined within Western countries since the 1970s, it remains a major cause of premature death and disability (Sanchis-Gomar et al., 2016; Scott, 2004). CHD itself is the largest single cause of death in the United Kingdom with 73,680 deaths recorded in 2012 (Townsend et al., 2014). The 2016 Heart Disease and Stroke Statistics update of the American Heart Association estimated that approximately every 42 seconds, an American person will suffer from an MI (Sanchis-Gomar et al., 2016). It is also thought that more than 780,000 persons will experience an ACS event each year in the USA (Amsterdam et al., 2014). In Australia, there were approximately 68,200 ACS events in 2012 (Chew et al., 2016). There is still disparity in overall mortality rates however, with differences between ethnic groups and socio-economic background. For example, deaths from ACS events occur on average at younger ages in low- and middle-income countries and frequently affect the poorer communities within these settings (Vedanthan et al., 2014). Approximately 80% of the global burden of CHD occurs within low- and middle-income countries (Yusuf et al., 2004).

Intrinsic patient factors that increase the risk of ACS include age, gender, and family history. In an American observational study, of all patients presenting with NSTE-ACS between 2001 and 2003 (n = 64,775), the average age of presentation with an ACS diagnosis was 68 years and the male:female ratio was 3:2 (Amsterdam et al., 2014; Peterson et al., 2006).

There are many modifiable risk factors that can reduce a patient's chance of developing CHD and experiencing an ACS event (see **Fig. 1**). A review of evidence by O'Flaherty et al. in 2013 concluded that the contribution of lifestyle modification was approximately equal to that of drug and interventional cardiovascular treatments in reducing coronary mortality (Flaherty et al., 2013; Timmis, 2015).

ICD-10 Classification

The World Health Organisation classifies ACS within the ICD codes I20 to I25 (Ischaemic Heart Diseases) (The World Health Organisation, 2014). Unstable angina is given code I20.0 (an additional code for hypertension can be added if required). MI specified as acute or with a stated duration of 4 weeks or less from onset is given code I21 with various subcodes available for defining location.

Universal Definition

The Third International Definition (Thygesen et al., 2012; Timmis, 2015) defines acute MI as presentation of chest pain associated with:

Non modifiable risk factors:

- Age—Over 83% of people who die from CHD are aged 65 or older.
- Gender–Men have a greater risk of developing CHD than women. Throughout the UK, prevalence of MI in men is almost three times greater than that found in women (Townsend et al., 2014).
- Early menopause–A meta analysis of 18 studies demonstrated a modest effect of early menopause on the risk of developing CHD (Atsma et al., 2006).
- Family history–Risk is doubled in those with a first degree relative who develops pre mature (age <60 years) CHD. Additional first and, to a lesser extent, second degree relatives will further increase this risk.
- Race–Certain populations are at increased risk. Some of this is due do the differences in prevalence of type II diabetes mellitus. For example, in Black Caribbean and Indian males the prevalence rates are 9.5% and 9.2% respectively, compared with 3.8% in the general UK population (Scarborough et al., 2010).

Modifiable risk factors:

- Smoking status–Tobacco smoke was one of the first risk factors identified by the Framingham Heart study in 1960 to increase the chance of developing CHD. It is estimated that up to 20,000 UK deaths each year from cardiovascular disease can be attributed to smoking.
- High blood cholesterol–An increased level of low-density lipoprotein (LDL) raises the risk, while high-density lipoprotein (HDL) may be protective.
- High blood pressure–Risk of cardiovascular disease is directly related to higher levels of blood pressure. Unhealthy diet is estimated to be responsible for half of hypertension with physical inactivity and obesity accounting for 20% each (Townsend et al., 2014).
- Exercise–Physical inactivity is a risk factor for CHD.
- Obesity–People who have excess body fat are more likely to develop CHD even if they have no other risk factors. This is especially true of those with a high hip-to-waist ratio (central abdominal obesity).
- Diabetes mellitus–Diabetes doubles the risk of developing CHD and is even greater if blood glucose is not well controlled. People with diabetes are about three times more likely to experience an MI.

Figure 1 Risk factors for developing CHD. *Adapted from: Worrell and Fletcher 2007—will need permission to use.*

Increase or decrease in troponin levels with at least one value >99th centile of upper reference limit, plus at least one of the following:

- Symptoms of ischemia
- New ST segment or T wave changes or new left bundle branch block on electrocardiography
- Development of pathological Q waves on electrocardiography
- Imaging evidence of new loss of viable myocardium or new regional wall motion abnormality
- Identification of an intracoronary thrombus by angiography or at postmortem examination

Diagnosis

Signs and Symptoms

Diagnosis of ACS is time critical and inappropriate identification is associated with increased mortality (Timmis, 2015). Almost all people with suspected ACS require hospital admission or referral to confirm the diagnosis. Patients typically present with "gripping" or "crushing" chest pain that radiates to the arms, neck, or jaw and is often associated with sweating, pallor, and shortness of breath (Douglas et al., 2013; Scott, 2004; Worrall and Fletcher, 2007). ACS should be suspected in patients where this pain occurs at rest or with minimal exertion lasting for longer than 15 minutes and there is hemodynamic instability. Pain symptoms can last anywhere between 10 and 20 minutes (Amsterdam et al., 2014; Chew et al., 2016; National Institute for Health and Care Excellence, 2010a; Roffi et al., 2016). It is estimated that pain is absent in up to 30% of presentations (Douglas et al., 2013) and therefore the history of the presenting complaint should be considered along with a physical examination, serial 12-lead electrocardiography (ECG), troponin level and a holistic assessment of the patient's risk of ACS (Chew et al., 2016; National Institute for Health and Care Excellence, 2010a). Patients may also present with atypical symptoms of ACS such as epigastric pain, indigestion, stabbing or pleuritic pain, and increasing shortness of breath which require further investigation. Older patients, women, and those with diabetes mellitus, impaired renal function, or dementia are more likely to present with these atypical symptoms (Amsterdam et al., 2014).

Clinical Investigations

A resting 12-lead ECG is the first-line diagnostic tool in the assessment of patients with suspected ACS and should be obtained within 10 minutes of presentation (Roffi et al., 2016). ECG changes indicative of NSTE-ACS include pathological Q waves, left bundle branch block, or ST-segment and T-wave abnormalities (ST depression, transient ST-elevation, or new T-wave inversion) (National Institute for Health and Care Excellence, 2010b; Roffi et al., 2016; Thygesen et al., 2012). Persistent ST-elevation or anterior ST depression is indicative of a STEMI. While the ECG can be useful in identifying ischemia, it is not definitive and these changes may not be seen for some patients (Scott, 2004). The only definitive ECG change is the development of a Q wave, which generally persists over time (giving no real indication as to time of ACS event) (Scott, 2004). Please refer to **Fig. 2** to see ECG changes and potential diagnosis.

Troponins I and T are specific and sensitive regulatory muscle proteins which demonstrate cardiac necrosis and are the recommended biomarker for MI (Chew et al., 2016; National Institute for Health and Care Excellence, 2010a; Thygesen et al., 2012). Cardiac troponins are more sensitive and specific markers of cardiomyocyte injury than creatine kinase (CK), its MB isoenzyme (CK-MB) and myoglobin (Roffi et al., 2016). Troponin should be measured at the time of presentation and repeated at clearly defined intervals in patients with suspected ACS (Chew et al., 2016). Levels tend to rise within four hours of infarction, peak at 12 hours and remain elevated for several days (Scott, 2004).

Unstable angina causes only small increases in troponin levels due to the reduced severity of injury to myocytes which can only be detected with high sensitivity assays (Timmis, 2015). Other conditions that directly or indirectly damage heart muscle (such as arrhythmias, pericarditis, pulmonary emboli, and myocarditis) can also cause an increase in serum troponin (Shah et al., 2013) so careful interpretation of the troponin level alongside the other presenting features is needed.

Additional clinical investigations can include the following tests:

- Echocardiography which helps in detecting heart wall abnormalities or alternative pathologies associated with chest pain (Roffi et al., 2016).
- Cardiac magnetic resonance (CMR) imaging can be useful for the assessment of function and perfusion and for the detection of scar tissue. CMR can also be useful to exclude or detect ACS, to assess myocardial viability, and to detect myocarditis (Roffi et al., 2016).
- A chest X-ray is recommended in some guidance for the assessment of cardiac enlargement and identification of other non-coronary causes of chest pain where the diagnosis is yet to be established, though the utility of this investigation may be limited (Chew et al., 2016).

Differential Diagnosis

Chest pain is a hugely common presentation within the emergency department setting. It can be challenging to recognize ACS from symptoms of other conditions such as musculoskeletal pain and gastro-esophageal reflux disease. Studies performed in Australian

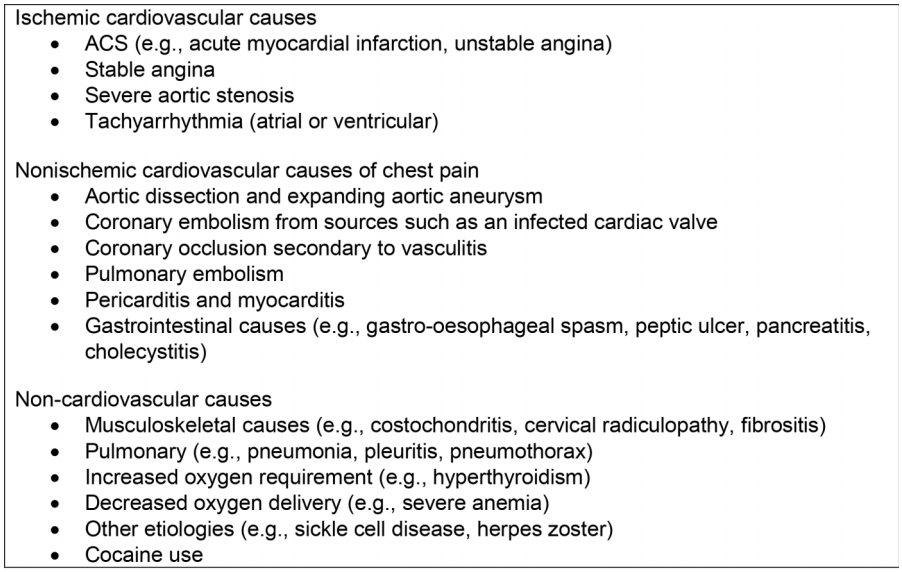

Figure 3 Differential diagnosis of causes of chest pain. *Taken from National Heart Foundation of Australia & Cardiac Society of Australia and New Zealand: Australian Clinical Guidelines for the Management of Acute Coronary Syndromes 2016 Permission needs to be sought.*

emergency departments demonstrated that the prevalence of different diagnostic groups in patients presenting with acute chest pain are: 2%–5% STEMI, 5%–10% NSTEMI, 5%–10% UA, 15%–20% other cardiac conditions, and 50%–70% noncardiac diseases, highlighting the importance of differential diagnosis (Chew et al., 2016). In fact, it is estimated that over 500,000 patients present with chest pain within Australia each year, but less than 20% of these patients will have a confirmed diagnosis of ACS (Chew et al., 2016; Kelly, 2012; Macdonald et al., 2011).

A systematic differential diagnosis must be made (Fig. 3) taking into consideration the patient's signs, symptoms, and investigations (Douglas et al., 2013). The European Society of Cardiology recommends that aortic dissection, pulmonary embolism, and tension pneumothorax should always be considered in the differential diagnosis of NSTE-ACS, because they are potentially life-threatening but also treatable (Roffi et al., 2016).

Prognosis

About 15% of people who have an acute MI in the US will die of it, half within the first hour of symptoms (Mozaffarian et al., 2016). Prognosis for patients with STEMI varies depending on time to presentation after onset of chest pain and time to treatment after presentation. Prognosis is improved by early reperfusion, adherence to appropriate medical therapy, and risk factor modification. Patients with elevated troponin levels have a worse prognosis than those with normal troponin levels (Setiadi et al., 2009). Adherence to evidence-based medicine has been shown to have better patient outcomes (Grech and Ramsdale, 2003). In-hospital death and reinfarction can affect 5%–10% of patients. Major bleeding as defined by the Bleeding Academic Research Consortium (BARC) or a raised Thrombolysis in Myocardial Infarction (TIMI) bleeding score is associated with worse 1-year mortality (Kikkert et al., 2014).

Patients who have experienced NSTE-ACS have a high risk of morbidity and death from a future event. The rate of sudden death in patients who have had an MI is 4–6 times the rate in the general population (Zaman and Kovoor, 2014). Life-threatening ventricular arrhythmias (sustained ventricular tachycardia or ventricular fibrillation) occurring after 48 hours from the index ACS indicates a poor prognosis, and are most frequently associated with left ventricular dysfunction (Moss et al., 2002). The benefit of implantable cardioverter-defibrillators, for both primary and secondary prevention, in patients with significant left ventricular dysfunction has been well demonstrated. Implantation for primary prevention should be considered at a minimum of 40 days following hospital discharge based on current recommendations (Hohnloser et al., 2004).

Modern therapy for NSTE-ACS, particularly statins and revascularization, has decreased morbidity and mortality by reducing the likelihood of cardiogenic shock, recurrent MI, and death. However, these benefits are offset by the mortality associated with trends of older age in patients who present with ACS (Jeger et al., 2008).

Risk Assessment

Various validated risk stratification tools have been developed to help guide optimal clinical management of those patients with confirmed ACS and are commonly used in practice (Backus et al., 2011; Fhadil et al., 2015). These scoring tools formally assess

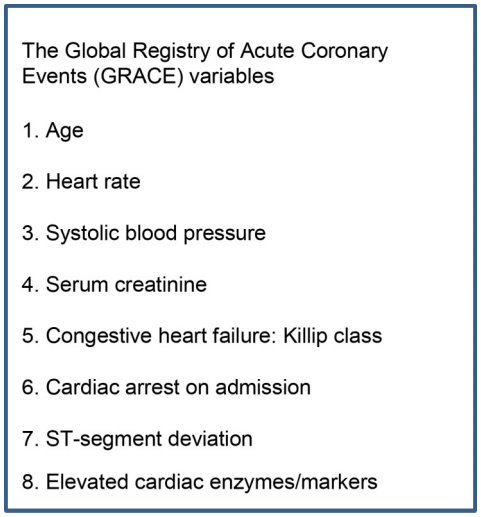

Figure 4 Variables used in the calculation of 6 month mortality specific for the GRACE tool. *Permission to use will be needed from: Fhadil, S., Wright, P., Antoniou, S., 2015. Non-ST elevation acute coronary syndrome: an update. Pharm. J. 295.*

Table 1 Risk stratification outcome scoring tool (Fhadil et al., 2015, permission needed)

Predicted 6-month mortality	*Risk of future adverse cardiovascular events*
1.5% or below	Lowest
>1.5%–3.0%	Low
>3.0%–6.0%	Intermediate
>6.0%–9.0%	High
Over 9.0%	Highest

individual risk of future adverse cardiovascular events and inform risk/benefit decisions regarding treatment using an established risk scoring system that predicts 6-month mortality (National Institute for Health and Care Excellence, 2010b). Examples that are validated in large populations and used internationally are the **T**hrombolysis **I**n **M**yocardial **I**nfarction (TIMI) risk score, the **G**lobal **R**egistry of **A**cute **C**oronary **E**vents (GRACE) score and the **P**latelet glycoprotein IIb/IIIa in **U**nstable angina: **R**eceptor **S**uppression **U**sing **I**ntegrilin (eptifibatide) **T**herapy (PURSUIT) score. The National Institute for Clinical Excellence (2010) in England and the European Society of Cardiology (2016) both advocate the use of the GRACE tool, however American (2014) and Australian (2016) guidelines are less prescriptive.

In a study comparing the various risk stratification tools, Yan et al. (2007) found that they all demonstrated good discrimination for in-hospital death. Compared with TIMI, both PURSUIT and GRACE were found to better at discriminating in-hospital and 1-year mortality in patients presenting with a wide range of ACS (Yan et al., 2007).

GRACE: An Example of Risk Stratification in Practice

GRACE uses eight clinical variables to risk stratify patients (see Fig. 4). To calculate the GRACE score, the patient is assigned a series of points for each of the clinical variables, which is most commonly converted to determine the six month mortality. Patients scoring ≤88 points are deemed to be at low risk (<3%) of death postdischarge to six months, 89–118 is considered to be at intermediate risk (3–6%), and >118 is regarded high risk (>6%) (see Table 1). This risk stratification can be used by health care professionals to make informed decisions about the patient's management.

Pharmacological Management of Acute Coronary Syndromes

The pharmacotherapy of ACS will be described in the section below in two parts: management of ST-elevated myocardial infarction (STEMI) and management of non-ST-elevated acute coronary syndrome (NSTE-ACS). These conditions are managed similarly, and therefore will be discussed concurrently in one part.

The general pathway for the management of ACS is outlined in Fig. 5 and will be referred to throughout the next sections.

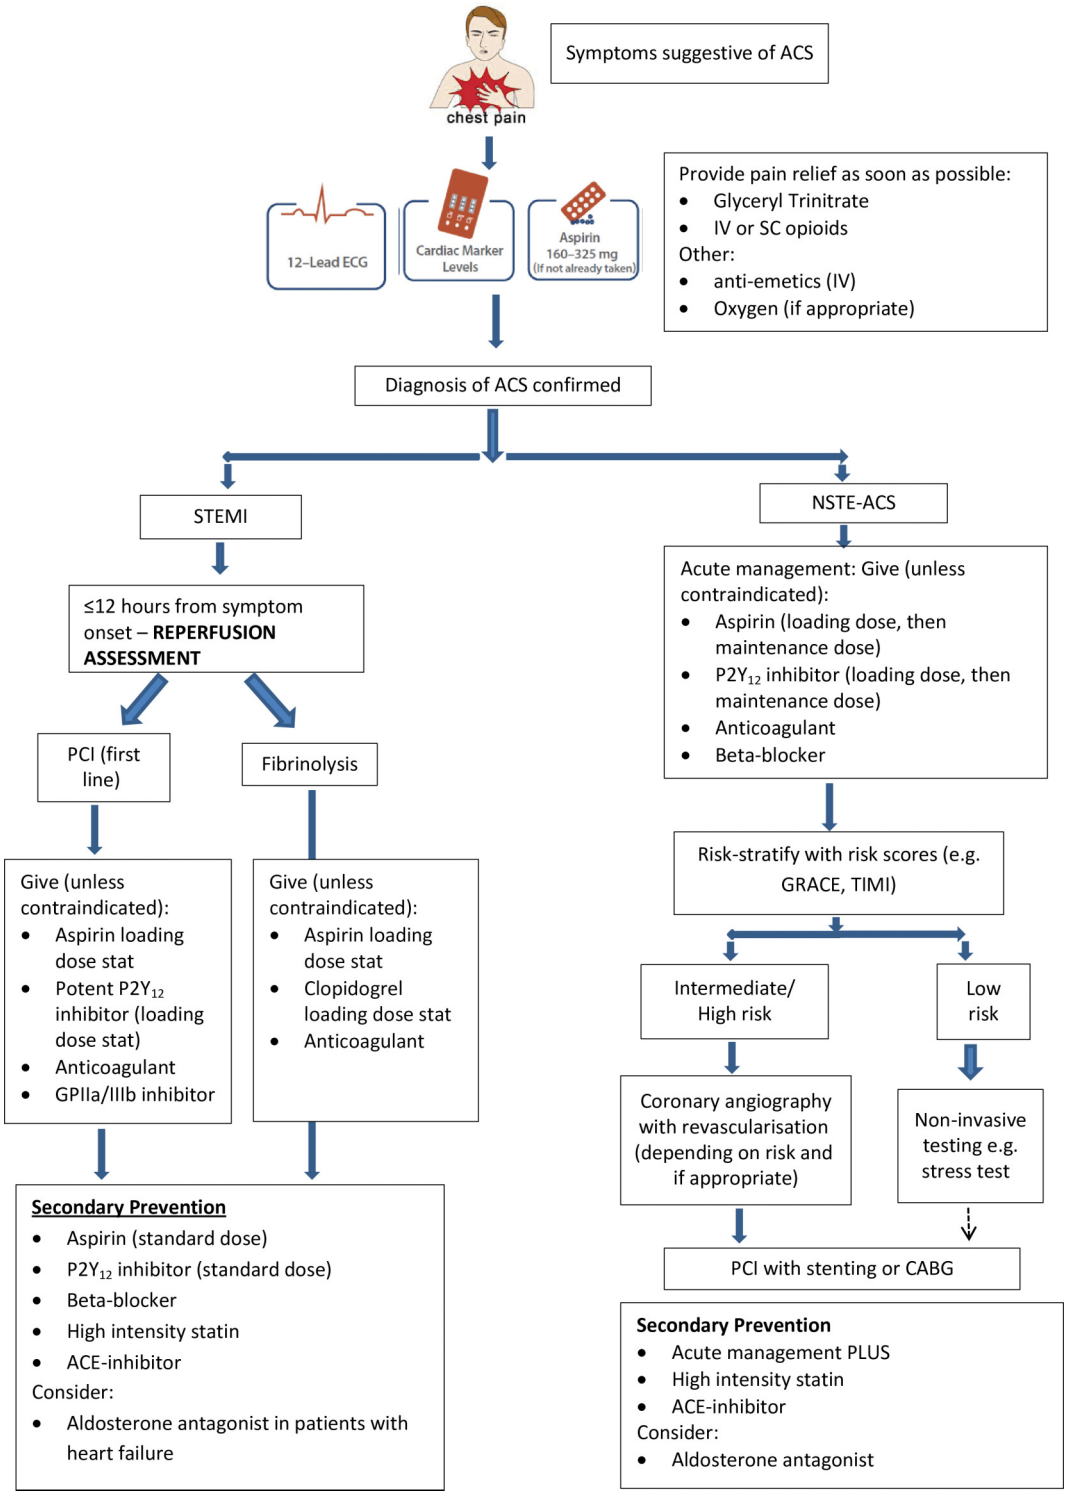

Figure 5 ACS pharmacotherapy management.

Pharmacotherapy Upon Presentation of Chest Pain Symptoms

All patients presenting with chest discomfort or other symptoms suggestive of ACS should be considered high priority medical cases. People who present with high-risk features such as ongoing chest pain, difficulty breathing, faintness, or palpitations should be admitted to hospital as soon as possible. Symptoms suggestive of ACS have been outlined in the "Signs and Symptoms" section earlier in the chapter.

The aim of initial treatment for all patients presenting with symptoms of ACS is provide pain relief caused by ischemia and to prevent further myocardial infarction (MI) and death. Aspirin is normally offered as soon as possible upon presentation of ACS, as a single loading dose (e.g., 300 mg at once in the UK). Immediate pain relief may be achieved with either glyceryl trinitrate (GTN), given sublingually or intravenously (IV); or parenteral opioids such as intravenous morphine (Chew et al., 2016; O'Gara et al., 2013).

GTN administered intravenously is more effective than sublingually with regard to symptom relief and regression of ST depression (Borzak et al., 1998). However, in certain cardiology units internationally, sublingual GTN is usually given first line, with IV GTN given if pain relief is not achieved after administration of sublingual GTN and IV morphine. Nitrates are contraindicated in patients who have recently taken phosphodiesterase type 5 inhibitors (either within 24 hours for sildenafil and vardenafil and 48 hours for tadalafil) due to the risk of severe hypotension (Schwartz et al., 2001).

Parenteral opioids such as diamorphine or morphine are commonly used to manage pain in ACS. An antiemetic (such as metoclopramide) can be given intravenously alongside parenteral opioid administration for the relief of opioid-induced nausea and vomiting. However, evidence suggests opioid use may slow the gastrointestinal absorption resulting in delayed onset of action of oral antiplatelet agents (e.g., clopidogrel, ticagrelor, and prasugrel) (Parodi et al., 2015).

Oxygen should be given to patients with evidence of hypoxemia ($SaO_2 < 90\%$), pulmonary edema or continuing MI.

Monitoring should be carried out during the initial phase of ACS for pain and symptom control, pulse, blood pressure, oxygen saturation, and heart rhythm. Clinical judgment should be used to determine how often monitoring should be done.

Confirmed ST-Elevated Myocardial Infarction Diagnosis

Many deaths occur very early after STEMI due to ventricular fibrillation (VF) (Larsen and Ravkilde, 2012). In patients following cardiac arrest and found to have ST-segment elevation on an ECG, an appropriate reperfusion strategy should be initiated as soon as possible.

Reperfusion

Reperfusion therapy, in this context, is a medical treatment to restore blood flow to blocked arteries after MI. There are two main types of reperfusion therapy: primary percutaneous coronary intervention (PCI) and fibrinolytic therapy.

Primary PCI is the preferred reperfusion therapy in patients with STEMI within 12 hours of symptom onset and within 120 minutes from the diagnosis of STEMI (Ibanez et al., 2017; O'Gara et al., 2013). PCI has been used over two decades and has evolved from balloon angioplasty to bare metal stent (BMS) implantation, drug eluting stents (DES), and more recently, biodegradable polymer stents (Serruys et al., 2009). The evolution of PCIs has been driven to help reduce the risk of stent thrombosis (ST). PCI has now become common practice where more than 300,000 patients undergo PCI procedures in the United States each year (Riley et al., 2011).

Fibrinolytic therapy or fibrinolysis is an alternative to primary PCI, particularly if PCI cannot be carried out within the timeframe as outlined above. Primary PCI is superior to fibrinolysis in reducing mortality, reinfarction, and stroke (Keeley et al., 2003). There is no current trial data which examine the extent to which the PCI-related time delay diminishes the advantages of PCI over fibrinolysis. The European (Ibanez et al., 2017) and UK guidelines (National Institute for Health and Care Excellence, 2013) recommend that the absolute time from STEMI diagnosis to PCI-mediated reperfusion should be up to 120 minutes. The American guideline (O'Gara et al., 2013) recommends 90–120 minutes depending on the capacity of the center in which the patient first presents. The Australian and New Zealand (ANZ) guideline (Chew et al., 2016) recommends within 90 minutes of first medical contact. The European guideline also recommends that for fibrinolysis, the bolus injection of fibrinolytics should be administered within 10 minutes from the STEMI diagnosis (Ibanez et al., 2017), while the American and ANZ guidelines (Chew et al., 2016; O'Gara et al., 2013) recommend administration within 30 minutes. The recommendation by Ibanez et al. (2017) for the European guidelines for fibrinolysis is based on the STREAM trial, where the median time from randomization to bolus administration was 9 minutes (Armstrong et al., 2013).

Fibrinolytic agents prevent 30 early deaths per 1000 patients treated within 6 hours after symptom onset (Fibrinolytic Therapy Trialists, 1994). The largest absolute benefit of fibrinolysis is when treatment is offered within two hours of symptom onset (Boersma et al., 1996). The later the patient presents (particularly after 3 hours), the more consideration should be given to transfer the patient for primary PCI because the efficacy and clinical benefit of fibrinolysis decreases as the time from symptom onset increases (Pinto et al., 2011). Fibrinolytic therapy is associated with a small but significant increase in strokes, largely due to cerebral

hemorrhage (Fibrinolytic Therapy Trialists, 1994). The use of fibrinolytic therapy is therefore contraindicated in patients with the following (Chew et al., 2016):

- uncontrolled systolic blood pressure (BP > 180/110 mmHg),
- previous stroke/transient ischemic attack (TIA)
- prior intracranial hemorrhage
- current anticoagulation use
- Recent trauma/surgery
- Gastrointestinal bleeding in the last 4 weeks

In this cohort of patients, the use of primary PCI may be preferred to fibrinolysis regardless of "time to reperfusion" (Chew et al., 2016).

Choice of Fibrinolytic

The fibrinolytics that are available on the market at the time of writing this chapter include: tenecteplase, reteplase, alteplase, and streptokinase. Tenecteplase, reteplase, and alteplase are fibrin-specific agents while streptokinase is nonfibrin-specific (O'Gara et al., 2013). Fibrin-specific agents are preferred to streptokinase (Chew et al., 2016; Ibanez et al., 2017). This is because fibrin-specific agents were found in a large scale trial to have a superior survival benefit over streptokinase (GUSTO Investigators, 1993).

Streptokinase and alteplase have short half-lives (18 minutes and 5 minutes respectively) and must be administered IV. Reteplase and tenecteplase (5.5 hours and 1–2 hours respectively) have longer half-lives and can be administered as bolus injections (Khatib and Wilson, 2018). Fibrinolysis therapy is usually coadministered with adjunct pharmacotherapies such as aspirin, clopidogrel, and anticoagulants. These are discussed later in this chapter under "Pharmacotherapy for Fibrinolysis."

Acute Management in ST-Elevated Myocardial Infarction

This section outlines the pharmacotherapy for different reperfusion pathways in the acute phase immediately after diagnosis of STEMI. This section will first outline the different pharmacotherapies and the evidence supporting their use. Individual drugs and corresponding doses used are outlined in **Table 2**. Dosages are based on those outlined in the guidelines from European, American, Australia and New Zealand, and UK, where appropriate.

Pharmacotherapy for Primary Percutaneous Coronary Intervention

Primary PCIs are performed as the initial approach to reperfusion for patients in the acute phase of STEMI, where its benefits are sensitive to the speed with which it is performed, as discussed earlier in this section. In contrast, some patients with STEMI may undergo a PCI during hospitalization that is not considered primary (Oberhauser et al., 2009). The pharmacotherapy discussed below is adjunct to primary PCI procedure in the acute phase of STEMI.

Patients undergoing primary PCI should receive dual antiplatelet therapy (DAPT) and a parenteral anticoagulant. DAPT is a combination of aspirin and a $P2Y_{12}$ inhibitor. The choice of $P2Y_{12}$ inhibitor and duration of DAPT has an effect on the net benefit of PCI.

Aspirin

Aspirin can be given orally, or IV before primary PCI to ensure complete inhibition of thromboxane A2 (Dai and Ge, 2012; Khatib and Wilson, 2018). The oral dose of plain aspirin (non-enteric-coated formulation) should be 150–300 mg. It is unclear what the optimal dose for IV aspirin is to achieve complete inhibition of platelet aggregation. A recent randomized study showed that a single dose of 250 or 500 mg acetylsalicylic acid administered IV was associated with faster and more complete inhibition of thromboxane-related platelet aggregation compared to aspirin 300 mg orally (Zeymer et al., 2017).

$P2Y_{12}$ Inhibitors

There is limited evidence with respect to the timing of $P2Y_{12}$ inhibitor initiation in patients with STEMI. However, early initiation of a $P2Y_{12}$ inhibitor while the patient is being transported to a primary PCI center is common practice in Europe. Otherwise, patients should be initiated on $P2Y_{12}$ inhibitor at the time of primary PCI. Most guidelines (European, UK, Australia, and New Zealand) state that the preferred $P2Y_{12}$ inhibitors are prasugrel (60 mg loading dose) or ticagrelor (180 mg loading dose). The American guideline (O'Gara et al., 2013) is less explicit in its preference.

Prasugrel and ticagrelor are superior to clopidogrel in onset of action, potency, and clinical outcomes such as reduction in the rate of death from vascular causes, MI, or stroke (Wallentin et al., 2009). Prasugrel or ticagrelor should not be used in patients with a previous hemorrhagic stroke, patients on regular oral anticoagulants, or in patients with moderate-to-severe liver disease. In the event that prasugrel and ticagrelor cannot be used, the ESC (Ibanez et al., 2017), ACC (O'Gara et al., 2013), and National Institute for

Table 2 Doses of antiplatelet and parenteral anticoagulant therapies in primary PCI

Antiplatelet therapies	
Aspirin	Loading dose: 150–300 mg orally or 75–250 mg intravenously[a] 162–325 mg orally[b] 300 mg orally[c,d] Maintenance dose: 75–100 mg/day[a] 75 mg/day[c] 100–150 mg/day[d] 81–325 mg/day[b]
Clopidogrel	Loading dose: 300–600 mg orally Maintenance dose: 75 mg daily
Prasugrel	Loading dose: 60 mg orally Maintenance dose: 10 mg daily Dose adjustment to 5 mg/day maintenance dose is recommended in patients with body weight ≤60 kg.
Ticagrelor	Loading dose: 180 mg orally Maintenance dose: 90 mg twice a day
Parenteral anticoagulants	
UFH	70–100 units/kg intravenous bolus when no GPIIb/IIIa inhibitor is planned 50–70 units/kg intravenous bolus with GPIIb/IIIa inhibitors
Enoxaparin	0.5 mg/kg intravenous bolus[a]
Bivalirudin	0.75 mg/kg i.v. bolus followed by intravenous infusion of 1.75 mg/kg/hour for up to 4 hours after the procedure
Glycoprotein IIb/ IIIa inhibitors	
Abciximab	Bolus of 0.25 mg/kg i.v. and 0.125 mcg/kg/min infusion (maximum 10 mcg/min) for 12 hours[a,b,c]
Eptifibatide	Double bolus of 180 mcg/kg i.v. (given at a 10-minute interval) followed by an infusion of 2 mcg/kg/min for up to 18 hours[a,b,c]
Tirofiban	25 mcg/kg over 3 minutes intravenously, followed by a maintenance infusion of 0.15 mcg/kg/min for up to 18 hours[a,b,c]

Doses are standard across ANZ, ESC, ACC, and the British National Formulary unless otherwise stated.
The abovementioned doses do not take into consideration drug interactions and renal impairment.
[a]ESC guideline.
[b]ACC guideline.

[d]ANZ guideline.

Health and Care Excellence (2015) guidelines recommend the use of higher clopidogrel loading dose (600 mg stat). Clopidogrel has not been evaluated against placebo in any large outcomes studies in primary PCI, but 600 mg/150 mg (loading dose/ maintenance dose) in the first week of STEMI was superior to the 300/75 mg regimen in the subset of patients undergoing PCI in the CURRENT-OASIS-7 trial (Mehta et al., 2010b).

The other $P2Y_{12}$ inhibitor, cangrelor, has limited use in current practice. A meta-analysis of three RCTs which compared cangrelor against clopidogrel in patients undergoing PCI. Steg et al. (2013) found that it was effective in reducing PCI complications. However, only about 18% of the patients in the trials presented with STEMI, and patients with ACS were not treated with potent $P2Y_{12}$ inhibitors (ticagrelor and prasugrel), limiting the applicability of results to current practice. Cangrelor is an IV preparation, which provides rapid onset of action (within a few minutes) and potent inhibition of $P2Y_{12}$ receptors. It has a half-life of 3–6 minutes, and has a fast offset of action. ESC and National Institute for Health and Care Excellence (2015) recommend that cangrelor may be an alternative option for some people undergoing PCI and for whom oral $P2Y_{12}$ inhibitors are not feasible or desirable. For example:

- Patients who are unable to absorb oral agents;
- Patients with an unclear coronary anatomy where early administration of long-acting $P2Y_{12}$ inhibitors may increase clinical risk such as aortic dissection, pericarditis, or esophageal tear; and
- Patients in an unconscious state undergoing emergency PCI in whom bleeding risk is deemed to be low (Ibanez et al., 2017; National Institute for Health and Care Excellence, 2015).

Anticoagulant

Anticoagulant options for primary PCI include unfractionated heparin (UFH), enoxaparin, and bivalirudin. The choice of anticoagulant in PCI differs between different international guidelines. In Australia and New Zealand, the first line of anticoagulant is either UFH or enoxaparin (Chew et al., 2016). In the USA and Europe, the ACC and the ESC recommend UFH (with or without GPIIb/IIIa inhibitors) and bivalirudin as first line treatments. NICE guidance in the UK has included all three agents in their recommendation (National Institute for Health and Care Excellence, 2013).

The dosing of UFH is weight adjusted and its anticoagulation effect monitored closely using either activated clotting time (ACT) or activated partial thromboplastic time (aPTT). There has been no placebo-controlled trial evaluating UFH in primary PCI, but there is a large body of experience with this agent (Ibanez et al., 2017). The recommended dosing of UFH depends on the concurrent use of fibrinolytics and GPIIb/IIIa inhibitors.

Enoxaparin is a low molecular weight heparin (LMWH) with a more predictable dose effect relationship than UFH and is associated less frequently with heparin-induced thrombocytopenia (HIT) (Junqueira et al., 2009). HIT is an adverse drug reaction of heparin, involving production of antibodies which activate platelets, leading to thromboembolic complications such as deep vein thrombosis, pulmonary embolism, MI, and stroke (Linkins, 2015). In a meta-analysis which included 23 trials, enoxaparin was superior to UFH in reducing death, MI complications and major bleeds in patients undergoing primary PCI (Silvain et al., 2012).

Bivalirudin acts by binding directly to thrombin and thereby inhibits the thrombin-induced conversion of fibrinogen to fibrin. It has a more predictable anticoagulant effect compared to UFH. A meta-analysis of five trials which compared bivalirudin with UFH, with or without GPIIb/IIIa inhibitors, showed that bivalirudin was noninferior to UFH in reducing mortality, superior in reducing risk of major bleeding and inferior in risk of acute stent thrombosis (Capodanno et al., 2016). The use of bivalirudin has been recommended by some guidelines for patients with high bleeding risk (Chew et al., 2016; Ibanez et al., 2017).

It is important to note here that the use of fondaparinux in the context of primary PCI was associated with potential risk of stent thrombosis in the OASIS 6 trial (Yusuf et al., 2006) and is not recommended to be used in primary PCI. The use of fondaparinux in other context is discussed elsewhere in this chapter.

Glycoprotein IIb/IIIa Inhibitors

Intravenous GPIIb/IIIa inhibitors block platelet aggregation by inhibiting fibrinogen binding to the GPIIb/IIIa receptor on two adjacent platelets (Patrono et al., 2011). The GPIIb/IIIa inhibitors currently available on the market are: eptifibatide, tirofiban, and abciximab. Studies of IV glycoprotein IIb/IIIa inhibition in combination with heparin among ACS patients were conducted in an era prior to the routine use of $P2Y_{12}$ inhibitors therefore limiting the applicability of the results of these studies (Chew et al., 2016; O'Gara et al., 2013). A meta-analysis of glycoprotein IIb/IIIa inhibition in ACS demonstrated a relative reduction in death or MI among patients undergoing PCI, but was associated with an increased risk of major bleeding (Bosch et al., 2010). A study by Stone et al. (2008) found that procedural use of abciximab plus UFH showed no benefit compared to bivalirudin. Therefore, both the European and American guidelines recommend the adjunctive use of GPIIb/IIIa agents at the time of PCI can be considered when there is evidence of large thrombus burden, no-reflow, or other thrombotic complications (Ibanez et al., 2017; O'Gara et al., 2013). The routine adjunctive use of GPIIb/IIIa inhibitors for patients receiving bivalirudin as the primary anticoagulant is not recommended (Stone et al., 2008).

Pharmacotherapy for Fibrinolysis

Antiplatelets

Aspirin (loading dose) and clopidogrel (loading dose) should be administered to patients with STEMI who receive fibrinolytic therapy. Clopidogrel added to aspirin reduces the risk of cardiovascular events and overall mortality in patients treated with fibrinolysis (Chen, 2005). Aspirin should be continued indefinitely and clopidogrel should be continued for at least 14 days and up to a year (Chen, 2005; Sabatine et al., 2005). The doses of aspirin and clopidogrel used for this indication are outlined in **Table 3**. The use of clopidogrel alongside aspirin and fibrinolytic therapy in the trials was for a duration of hospital stay (a mean of approximately 14 days) (Chen, 2005; Sabatine et al., 2005). The recommendation for the use of clopidogrel up to a year was extrapolated from experience with DAPT in patients with NSTE-ACS. Prasugrel and ticagrelor have not been studied as adjuncts to fibrinolysis.

Anticoagulant

Parenteral anticoagulation should preferably be given until the revascularization procedure (if performed). Otherwise, it should be given for at least 48 hours or for the duration of hospital stay, and up to 8 days (Ibanez et al., 2017; O'Gara et al., 2013). The doses of individual anticoagulants discussed below are outlined in **Table 3**. The ESC guideline recommends the use of enoxaparin over UFH owing to the net clinical benefit of enoxaparin (e.g., absence of death, nonfatal infarction, and intracranial hemorrhage) (Giraldez et al., 2007). The ACC guideline recommends the use of enoxaparin over UFH if anticoagulation is needed for more than 48 hours (O'Gara et al., 2013).

Fondaparinux was shown in the large OASIS-6 trial to be superior to placebo or UFH in preventing death and reinfarction especially in patients who received streptokinase as fibrinolytic agent (Yusuf et al., 2006). The ESC guideline recommends fondaparinux in patients treated with streptokinase (Ibanez et al., 2017). At the time of writing, fondaparinux was not yet approved for use in Australia (Chew et al., 2016).

Bivalirudin is not recommended as an adjunct to fibrinolysis. The use of bivalirudin with streptokinase was found to be associated with reduction in reinfarctions but had an increased risk of bleeding (White, 2001). The use of bivalirudin has not been studied with fibrin-specific agents so the evidence to support this combination use is limited.

Table 3 Doses of antiplatelet and anticoagulant therapies adjunct to fibrinolysis

Aspirin	Loading dose: 150–300 mg orally or 75–250 mg intravenously[a] 162–325 mg orally[b] 300 mg orally[c,d] Maintenance dose: 75–100 mg/day[a] 75 mg/day[c] 100–150 mg day[d] 81–325 mg/day[b]
Clopidogrel	Loading dose: 300 mg orally for patients ≤75 years of age[a,b] 75 mg orally for patients >75 years of age[a,b] Maintenance: 75 mg daily for at least 14 days and up to 1 year[a,b]
Enoxaparin	If age <75 years: 30 mg i.v. bolus, followed 15 min later by 1 mg/kg subcutaneously every 12 h (maximum 100 mg for the first two doses) If age ≥75 years: no bolus, 0.75 mg/kg subcutaneously every 12 h (maximum 75 mg for the first two doses) Duration: for the index hospitalization, up to 8 d or until revascularization
Unfractionated Heparin	IV bolus of 60 U/kg (maximum 4000 Units) followed by an infusion of 12 U/kg/h (maximum 1000 Units) initially, adjusted to maintain aPTT at 1.5–2.0 times control (approximately 50–70 s) for 48 hours or until revascularization[a,b]
Fondaparinux (only for use with streptokinase)	Initial dose 2.5 mg i.v., then 2.5 mg subcutaneously daily starting the following day, for the index hospitalization up to 8 days or until revascularization[a,b,c]

Doses are standard across ANZ, ESC, ACC, and the British National Formulary unless otherwise stated.
The abovementioned doses do not take into consideration drug interactions and renal impairment.

Secondary Prevention in ST-Elevated Myocardial Infarction

This section outlines the pharmacotherapy for the long-term maintenance treatment after the acute phase of STEMI. The section will first outline the different pharmacotherapies used and the evidence supporting their use. Individual drugs and corresponding doses used are outlined in Table 4. Dosages are based on those outlined in the guidelines from European, American, Australia and New Zealand, and UK, where appropriate.

The main goal of long-term maintenance pharmacotherapy is to prolong survival through risk factor modification and ultimately, prevent further acute coronary episodes also known as secondary prevention. Optimal medical therapy, lifestyle changes such as diet, exercise, and smoking cessation, is important in the prevention of recurrent ischemic events (Chow et al., 2010).

Aspirin

Aspirin is recommended indefinitely in all patients with STEMI (Mehta et al., 2010a). For long-term prevention, low dose aspirin (75–100 mg) is indicated. However, indefinite antiplatelet therapy with clopidogrel is recommended in patients who have had prior stroke (not related to atrial fibrillation) or if the patient has peripheral vascular disease, or cannot tolerate aspirin long-term.

$P2Y_{12}$ Inhibitors

In patients with confirmed STEMI at intermediate or high risk of recurrent ischemic events, the use of a $P2Y_{12}$ inhibitors at maintenance dose is recommended in addition to aspirin 75–100 mg daily (refer to Table 4 for doses). The ANZ and ESC guidelines recommend the use of ticagrelor or prasugrel over clopidogrel (Chew et al., 2016; Ibanez et al., 2017). This is due to the superiority of prasugrel (Wiviott et al., 2007) and ticagrelor (Wallentin et al., 2009) over clopidogrel in reducing mortality, recurrent MI, and stroke in patients with intermediate or very high risk ACS. However, in patients over 75 years of age or of low body weight (<60 kg) or previous cerebrovascular disease, prasugrel was associated with more harm than benefit when compared with clopidogrel.

Table 4 Maintenance treatment and doses post-STEMI

Aspirin	75–100 mg/day[a]
	75 mg/day[b]
	100–150 mg/day[c]
	81–325 mg/day[d]
Ticagrelor	90 mg BD for 12 months
	Duration could be shortened or lengthened depending on bleeding/thrombotic risk—see duration of DAPT section
Prasugrel	10 mg daily for 12 months
	Duration could be shortened or lengthened depending on bleeding/thrombotic risk—see duration of DAPT section
Clopidogrel	75 mg daily for 12 months
Beta-blockers:	
Metoprolol	Maintenance 200 mg daily in divided doses
Atenolol	Maintenance 100 mg daily
Carvedilol	Initially 3.125 mg twice daily, dose increased gradually at intervals of at least 2 weeks up to the highest tolerated dose. Maximum 25 mg twice daily in patients with severe heart failure or body-weight less than 85 kg; maximum 50 mg twice daily in patients over 85 kg
Nebivolol	Initially 1.25 mg once daily, dose increased at intervals of 1–2 weeks, to the maximum tolerated dose. Maximum 10 mg once daily
Bisoprolol	Initially 1.25 mg once daily, dose increased at weekly intervals, to the maximum tolerated dose. Doses at 5 mg or above will require longer titration interval of 4 weeks or more. Maximum 10 mg per day
Lipid-modifying therapy:	
Atorvastatin	80 mg daily
Other high intensity statins less preferable	An LDL-C goal of $<$1.8 mmol/L (70 mg/dL) or a reduction of at least 50% if the baseline LDL-C is between 1.8 and 3.5 mmol/L (70–135 mg/dL) is recommended
Ezetimibe	For patients unable to tolerate any dose of statin
	10 mg daily
ACE-inhibitors:	
Ramipril	Initially 2.5 mg twice daily for 3 days, then increased to 5 mg twice daily. (Lower starting dose may be required if patient is unable to tolerate 2.5 BD starting dose)
Perindopril (Arginine)	Initially 5 mg once daily for 2 weeks, then increased if tolerated to 10 mg once daily. (Lower dose may be required in elderly patients)
Perindopril (Erbumine)	Initially 4 mg once daily for 2 weeks, then increased if tolerated to 8 mg once daily. (Lower dose may be required in elderly patients)
ARB	
Valsartan	Initially 20 mg twice daily, increased if necessary up to 160 mg twice daily, doses to be increased over several weeks if tolerated
Eplerenone	Initially 25 mg daily, then increased to 50 mg daily, increased within 4 weeks of initial treatment
	Maximum dose of 25 mg daily with concurrent use of amiodarone or moderate inhibitors of CYP3A4

Individual drugs are largely derived from clinical trials conducted, and doses are standard across ANZ, ESC, ACC, and the British National Formulary unless otherwise stated. The abovementioned doses do not take into consideration drug interactions and renal impairment.

[d]ACC guideline.

Duration of Dual Antiplatelet Therapy

Dual Antiplatelet Therapy , combining aspirin and a $P2Y_{12}$ inhibitor, is recommended in patients with STEMI who are undergoing primary PCI (for up to 12 months) (Wallentin et al., 2009; Wiviott et al., 2007). Clopidogrel is recommended for 1 month in patients treated with fibrinolysis without subsequent PCI (Chen, 2005). However, extension of DAPT duration to 12 months should be considered in these patients (Ibanez et al., 2017). For patients undergoing fibrinolysis and subsequent PCI, DAPT is recommended for 12 months. Clopidogrel is the $P2Y_{12}$ inhibitor of choice as coadjuvant and after fibrinolysis. Potent $P2Y_{12}$ inhibitors have not been investigated in patients undergoing fibrinolysis, and safety (e.g., bleeding complications) is not well established. The evidence of $P2Y_{12}$ inhibitors in this cohort of patients is referred to under "Pharmacotherapy for Fibrinolysis" section.

In patients with high bleeding risk, studies have shown that shortening DAPT duration to 6 months, compared with 12 months or longer, reduces the risk of major bleeding complications, with no apparent trade-off in ischemic events (Costa et al., 2015).

On the contrary, two major studies have shown the benefit toward reduction of nonfatal ischemic events in patients receiving longer than 12 months of DAPT (Bonaca et al., 2015; Mauri et al., 2014). However, the DAPT study only included approximately 10% of STEMI patients and no information has so far been provided with respect to the benefit of prolonging clopidogrel or prasugrel from 12 to 30 months in this patient subset. Hence, no formal recommendations are possible for the use of clopidogrel or prasugrel beyond 1 year (Ibanez et al., 2017). Data available from the PEGASUS-TIMI 54 trial showed that extension of DAPT beyond 1 year (up to 3 years) in the form of aspirin plus ticagrelor 60 mg twice a day may be considered in patients who have tolerated DAPT without a bleeding complication and having one additional risk factor for ischemic events such as a previous stroke (Bonaca et al., 2015).

The use of DAPT may sometimes be indicated in addition to long-term oral anticoagulation, in patients with conditions such as atrial fibrillation (AF) (Kirchhof et al., 2017). The ESC guideline estimated that approximately 6%–8% of patients undergoing PCI have an indication for long-term oral anticoagulation (Roffi et al., 2016). This is referred to as "triple therapy," e.g., DAPT and oral anticoagulation. Triple therapy increases bleeding risk and therefore, the duration of triple therapy should be kept to the minimum required for maximum benefit/risks ratio. The recommended duration of triple therapy is highly dependent on the individual bleeding risk versus clotting risk factors of the patient. In the absence of safety and efficacy data, the use of prasugrel or ticagrelor as part of triple therapy should be avoided (Roffi et al., 2016). Coprescription with a proton pump inhibitor (PPI) is recommended for gastroprotection to help reduce the risk of gastrointestinal bleed.

Beta-Blockers

Beta-blockers should be started within the first 24 hours of the presentation of chest pain in patients who are hemodynamically stable (Ibanez et al., 2017). Beta-blockers reduce myocardial oxygen consumption by lowering heart rate, blood pressure, and myocardial contractility.

After early IV beta-blocker treatment such as metoprolol, patients should be continued on oral vasodilatory beta-blocker therapy long-term, unless contraindicated. Vasodilatory beta-blockers include carvedilol, bisoprolol, nebivolol, and metoprolol. These beta-blockers reduce peripheral vascular resistance while maintaining or improving cardiac output, stroke volume, and left ventricular function; and may limit infarct size (Dargie, 2001).

The benefit of long-term treatment with oral beta-blockers after STEMI is well established, although most of the supporting data come from trials performed in the pre-reperfusion era (Freemantle et al., 1999). However, the evidence supporting use of beta-blockers is stronger among patients with reduced Left Ventricular (LV) function following ACS. Therefore, in patients with MI without underlying heart failure, the ACC guideline recommends that beta-blocker use be limited to a three-year course (Smith et al., 2011). The National Institute for Health and Care Excellence (2013) recommends that beta-blocker use in this cohort of patients (without underlying heart failure) should be reviewed after 12 months with a view to stopping treatment, taking into account the extent of coronary disease or evidence of ischemia, concurrent conditions, and any adverse effects.

Lipid Modification Therapy

All the guidelines recommend that high-intensity statin (e.g. statin regimens that reduce low-density lipoprotein cholesterol (LDL-C) by approximately 50%) should be initiated as soon as the patient is stabilized and has no contraindications, and continued long term (Chew et al., 2016; Ibanez et al., 2017; National Institute for Health and Care Excellence, 2013; O'Gara et al., 2013). Treatment with statins in patients stabilized after an ACS, including STEMI, lowers the risk of CHD death, recurrent MI, stroke, and the need for coronary revascularization (Sacks et al., 1996). A metaanalysis of trials comparing more versus less intensive LDL-C lowering with statins indicated that more intensive statin therapy produced greater reductions in the risks of cardiovascular death, nonfatal MI, ischemic stroke, and coronary revascularization (Baigent et al., 2010).

Among currently available statins, only high-dose atorvastatin (80 mg daily) has been shown to reduce death and ischemic events among patients with ACS (Cannon et al., 2004; Schwartz et al., 2001). Treatment with statins is irrespective of cholesterol concentration at presentation.

In patients known to be intolerant of any dose of statin, treatment with ezetimibe should be considered. Ezetimibe is recommended for patients with intolerance of statin by the ESC (Ibanez et al., 2017) and the ANZ guidelines (Chew et al., 2016). This recommendation was largely based on the In the Improved Reduction of Outcomes: Vytorin Efficacy International Trial (IMPROVE-IT), where 18,144 patients with a recent ACS (29% with STEMI) were randomized to either ezetimibe plus simvastatin or simvastatin alone, which found that ezetimibe plus simvastatin produced statistically significant reduction in the composite outcome of cardiovascular death, MI, hospital admission for unstable angina, coronary revascularization, or stroke (Cannon et al., 2015).

Renin-Angiotensin System (RAS) Inhibitors

Oral angiotensin converting enzyme (ACE) inhibitors reduce fatal and nonfatal major cardiovascular events in patients with STEMI (Pfeffer et al., 1992). Their protective effects have been demonstrated independent of the use of other pharmacotherapies (e.g., fibrinolytics, aspirin, and beta-blockers). The magnitude of clinical benefit is greatest in high-risk patient subgroups (e.g. anterior MI, ejection fraction ≤40%, heart failure, prior MI, and tachycardia) (Dickstein et al., 2002). The role of routine long-term ACE inhibitor therapy in low-risk patients after STEMI is less clear (Braunwald et al., 2004). The benefit of early initiation of these agents in patients with MI is evident and thus recommended by the ACC, ESC, NICE, and ANZ guidelines for patients without existing contraindications. The guidelines recommend that all patients with evidence of heart failure, LV systolic dysfunction, or any other risk factors should be initiated on ACE inhibitors within 24 hours of STEMI. ACE inhibitors may be considered for patients with low-risk in the absence of contraindications.

In patients who cannot tolerate ACE inhibitors, angiotensin receptor blockers (ARBs) are indicated. Valsartan is the preferred ARB, owing to the VALIANT (Valsartan in Acute Myocardial Infarction) trial, where it was found to be noninferior to captopril (Pfeffer et al., 2003). Individual doses of ACE inhibitors and ARBs are outlined in **Table 4**.

Aldosterone Antagonist

Aldosterone antagonist is recommended in patients with Left Ventricular Ejection Fraction dysfunction (LVEF ≤40%) and heart failure after STEMI (Girerd et al., 2015). Eplerenone is the only aldosterone antagonist with evidence for use in this cohort of patients at the time of writing. The Eplerenone Post-Acute Myocardial Infarction Heart Failure Efficacy and Survival (EPHESUS) study established the benefit of eplerenone, added to optimal medical therapy in patients 3–14 days after STEMI with Ejection Fraction ≤40% and either symptomatic heart failure or diabetes mellitus (Pitt et al., 2003). A secondary analysis of the EPHESUS trial data suggested that initiation of eplerenone within 7 days of MI significantly reduced the rates of all-cause mortality, sudden cardiac death (SCD), and cardiovascular mortality/hospitalization, whereas initiation after 7 days had no significant effect on the above mentioned outcomes (Adamopoulos et al., 2009).

When using eplerenone, care should be taken in patients with reduced renal function and routine monitoring of serum potassium is warranted.

Confirmed Non-ST-Elevated Acute Coronary Syndrome Diagnosis

As soon as the diagnosis of UA or NSTEMI is made, and aspirin and antithrombin therapy has been offered, patients should be formally assessed to establish their risk of future adverse cardiovascular events and bleeding events using a risk scoring systems. The American College of Cardiology (ACC) does not recommend any one predictor model, while NICE and ANZ guidelines recommend the Global Registry of Acute Coronary Events (GRACE) scoring system. More information on risk scores are described earlier on in the chapter.

The risk of future adverse cardiovascular events would also determine if coronary angiography would be needed, and the urgency of the procedure. Patients deemed to be at high risk (refer to earlier section on risk stratification) require coronary angiography within 72–96 hours (with follow-on PCI if indicated). Coronary angiography is a procedure where a long, thin tube called a catheter is inserted into a blood vessel, usually through the groin or arm, which allows X-ray images (angiograms) to be taken. Coronary angiography is an important procedure to detect and determine the extent of any clots in the blood vessels, which helps to plan further interventions such as PCI (balloon and stent insertion to widen blocked arteries), or coronary artery bypass graft (CABG) (surgical procedure to divert blood around blocked arteries). Low risk patients require rapid angiography if they experience refractory or recurrent ischemic symptoms despite optimally treated with medicines, or if they are hemodynamically unstable, or if deemed clinically beneficial by consultant cardiologists and interventionists.

Pharmacotherapy in Non-ST-Elevated Acute Coronary Syndrome

This section outlines the pharmacotherapy for both the acute and maintenance phases of NSTE-ACS. Similar to the layout of the STEMI section, this section will first outline the different pharmacotherapies used and the evidence supporting their use. Individual drugs and corresponding doses are outlined in **Table 5**. Dosages are based on those outlined in the guidelines from European, American, Australia and New Zealand, and UK, where appropriate.

Acute Management in Non-ST-Elevated Acute Coronary Syndrome

This section outlines the pharmacotherapy in the acute phase of NSTE-ACS, immediately after diagnosis. Doses for individual drugs are outlined in **Table 5**.

Aspirin

Aspirin is normally offered as soon as possible upon presentation of UA or NSTEMI, as a single loading dose. For patients with aspirin hypersensitivity, clopidogrel should be given as an alternative (loading dose: 300–600 mg). Following this, a maintenance dose (75–100 mg) of aspirin should be continued indefinitely. The benefit of aspirin has been demonstrated in four RCTs in the pre-PCI era where aspirin has shown to be effective in patients with unstable angina by reducing the incidence of MI or death (Theroux et al., 1988).

$P2Y_{12}$ Inhibitors

As soon as the risk of adverse cardiovascular events has been assessed, patients should be offered a loading dose of 300 mg clopidogrel in addition to aspirin with a predicted 6-month mortality of more than 1.5% (GRACE criteria low risk or higher) and no contraindications (e.g., an excessive bleeding risk). Patients who may undergo PCI within 24 hours of hospital admission should also be treated with a 300 mg loading dose of clopidogrel.

Table 5 Doses of pharmacotherapy used in acute phase of NSTE-ACS

Aspirin	Loading dose: 150–300 mg orally or 75–250 mg intravenously[a] 162–325 mg orally[b] 300 mg orally[c,d]
Clopidogrel	Single loading dose: 300–600 mg Maintenance dose: 75 mg
Ticagrelor	Loading dose: 180 mg Maintenance dose: 90 mg BD
Prasugrel	Loading dose: 60 mg Maintenance dose: 10 mg daily
Anticoagulants	
Fondaparinux	2.5 mg s.c. once a day Not recommended if eGFR $<$20 mL/min/1.73 m^2
Unfractionated heparin (UFH)	60–70 units/kg i.v. (max 5000 units) and infusion (12–15 units/kg/h) (max 1000 units/h), target aPTT 1.5–2.5x control[a] 60 units/kg i.v. (max 4000 units) with initial infusion 12 units/kg/h (max 1000 units/h)[b]
Enoxaparin	1 mg/kg s.c. twice a day for the duration of hospitalization or until PCI is performed
Bivalirudin	Bolus 0.75 mg/kg i.v., infusion 1.75 mg/kg/h
Beta-blockers	
Carvedilol	Initially 3.125 mg twice daily, increased gradually at intervals of at least 2 weeks up to the highest tolerated dose
Bisoprolol	Initially 1.25 mg once daily, increased gradually at weekly interval up to 5 mg daily, then increased at 4-weekly intervals (if tolerated) to a maximum 10 mg per day

Individual drugs are largely derived from clinical trials conducted, and doses are standard across ANZ, ESC, ACC, and the British National Formulary unless otherwise stated. The abovementioned doses do not take into consideration drug interactions and renal impairment.
[a]ESC guideline.
[b]ACC guideline.
[c]British National Formulary.
[d]ANZ guideline.

Thereafter, a $P2Y_{12}$ inhibitor is recommended, in addition to aspirin, for 12 months unless there are contraindications such as excessive risk of bleeds. $P2Y_{12}$ inhibitors available at the time of writing include: clopidogrel, prasugrel, ticagrelor, and cangrelor. Their mode of action was described earlier in the chapter under "Pharmacotherapy for Primary PCI" section.

The choice of $P2Y_{12}$ inhibitor in patients with NSTE-ACS depends on the reperfusion strategy chosen. For example, prasugrel is only indicated for NSTE-ACS patients undergoing PCI, while ticagrelor and clopidogrel are indicated for all reperfusion strategies,e.g., PCI or angiography guided revascularization.

Ticagrelor is the preferred $P2Y_{12}$ inhibitor in all patients at moderate-to-high risk of ischemic events (e.g., elevated cardiac troponins) without contraindications (Amsterdam et al., 2014; Chew et al., 2016; Roffi et al., 2002). The loading dose of ticagrelor is 180 mg orally, followed by 90 mg twice a day. Ticagrelor is a $P2Y_{12}$ inhibitor with a fast and more consistent onset of action compared with clopidogrel in addition to more rapid recovery of platelet function (Gurbel et al., 2009). A major trial which compared clopidogrel with ticagrelor in patients with moderate to high risk NSTE-ACS was the PLATelet inhibition and patient Outcomes (PLATO) trial, which found that (Wallentin et al., 2009):

- Ticagrelor was more effective than clopidogrel at reducing primary end points including death from CV causes, MI or stroke, and all-cause mortality (Lindholm et al., 2014).
- Ticagrelor increased risk of major bleeds, but no statistically significant difference on fatal bleed compared to clopidogrel.
- Ticagrelor was superior at reducing stent thrombosis compared to clopidogrel (Lindholm et al., 2014).

In patients who are proceeding to PCI, prasugrel (60 mg loading dose, followed by 10 mg daily maintenance dose) is recommended (National Institute for Health and Care Excellence, 2013; Roffi et al., 2002). Prasugrel, a prodrug that blocks platelet $P2Y_{12}$ receptors, has a faster onset and a more potent antiplatelet effect than clopidogrel (Wiviott et al., 2007). The landmark trial was the Trial to Assess Improvement in Therapeutic Outcomes by Optimizing Platelet InhibitioN with Prasugrel Thrombolysis In Myocardial Infarction (TRITON-TIMI 38) which showed that prasugrel patients had less recurrent CV events and stent thrombosis, but more bleeding complications compared with clopidogrel (De Servi et al., 2014). Therefore, prasugrel should be considered in patients who present with stent thrombosis despite compliance with clopidogrel therapy (Wiviott et al., 2008).

Patients with NSTE-ACS should be treated with DAPT. Clopidogrel is also used in combination with aspirin at a maintenance dose of 75 mg daily in patients with NSTE-ACS although its place in therapy depends on individual guidelines. Clopidogrel is an inactive prodrug that requires oxidation by hepatic enzyme CYP450 to generate an active metabolite. Approximately 85% of the prodrug is hydrolyzed by esterase enzymes into an inactive form, leaving only 15% of clopidogrel available for transformation to the active metabolite, which inactivates platelet $P2Y_{12}$ receptors and thus inhibits platelet aggregation (Savi et al., 2001). For this reason,

pharmacodynamic and pharmacokinetic studies have shown substantial interindividual variability in the antiplatelet response to clopidogrel, resulting in an increased risk of ischemic and bleeding events in clopidogrel hypo- and hyper-responders, respectively (Matetzky et al., 2004; Simon et al., 2009) (please see "Pharmacogenomics" section for further details). DAPT comprising aspirin and clopidogrel has been shown to reduce recurrent ischemic events in the NSTE-ACS patients compared with aspirin alone (Yusuf et al., 2001).

Patients identified as having a higher risk of bleeding (e.g., those with previous bleeding complications, low platelet count, concurrent use of anticoagulation) should be assessed and considered for a shorter duration of dual antiplatelet therapy (e.g., less than 12 months) (National Institute for Health and Care Excellence, 2010b). DAPT duration may be shortened (e.g., 3–6 months) or extended (e.g., up to 30 months) if required based on individual patient ischemic and bleeding risk profiles (Navarese et al., 2015). A PPI is recommended to be taken in combination with DAPT in patients with higher risk of gastrointestinal bleeds. It is important to note the interaction between certain PPI which undergo CYP450 metabolism and hence reduce plasma levels of clopidogrel (Yasuda et al., 2009). For further information, see "Interactions" section.

Anticoagulant

Anticoagulation therapy should then be offered in the initial management of NSTE-ACS. Anticoagulants are used to inhibit thrombin generation, thereby reducing thrombin-related events.

There is evidence that anticoagulation is effective in reducing ischemic events in NSTE-ACS and that the combination with antiplatelets is more effective than either treatment alone (Eikelboom et al., 2000). Several anticoagulants, acting at different levels of the coagulation cascade, have been approved or are under investigation for this indication, which are discussed below.

During the acute phase of NSTE-ACS, parenteral anticoagulant should be administered, depending on the bleeding and ischemic risk profiles (clotting risk) of the patient. Parenteral anticoagulant options include: fondaparinux, bivalirudin, unfractionated heparin (UFH), or enoxaparin. These individual drugs and their mode of action are described in detail earlier in the chapter under "Pharmacotherapy for Primary PCI" section. The doses of anticoagulants used in the acute phase of NSTE-ACS differ from those used in acute phase of MI. The dosing regimen of all pharmacotherapy used in the acute management of NSTE-ACS can be found in **Table 3**.

Fondaparinux

Fondaparinux is the preferred parenteral anticoagulant by ESC due to its favorable safety and efficacy profile as found by the landmark trial OASIS-5 discussed below (Roffi et al., 2002). The recommended dose in NSTE-ACS is 2.5 mg a day. Fondaparinux has shown to be superior to enoxaparin in reducing in-hospital major bleeding and mortality and showed noninferiority to enoxaparin with respect to ischemic events in the Organisation to Assess Strategies in Acute Ischaemic Syndromes (OASIS-5) study (Yusuf et al., 2006).

Unfractionated Heparin

UFH remains a widely used anticoagulant in NSTE-ACS in the context of short delays to coronary angiography despite consistent evidence for greater bleeding risk compared with other strategies (Silvain et al., 2012). UFH is given in the PCI setting in combination with GPIIb/IIIa inhibitor. UFH should be stopped after PCI unless there is a clinically valid reason for it to be continued. One of the major adverse effects of UFH is HIT. HIT is covered earlier in the chapter under "Pharmacotherapy for Primary PCI Anticoagulant" section.

Low Molecular Weight Heparin

The most widely used anticoagulant in the acute phase of NSTE-ACS is enoxaparin (1 mg/kg administered subcutaneously twice daily, with appropriate dosage adjustment in patients with renal impairment). LMWH has the advantage over UFH for not requiring routine monitoring except for patients with renal impairment and with bodyweight of >100 kg.

A meta-analysis of all trials testing enoxaparin versus UFH in ACS showed a marginally significant reduction in the combined endpoint of death or MI at 30 days in favor of enoxaparin but no statistically significant differences in major bleeds at 7 days (Murphy et al., 2007).

Bivalirudin

Bivalirudin is recommended to be used as an alternative (to UFH plus GPIIb/IIIa inhibitors) in patients presenting in the acute phase of NSTE-ACS who have to undergo PCI (Roffi et al., 2002). In the ACUITY trial, which compared bivalirudin with UFH or LMWH, no significant differences were found between bivalirudin and UFH/LMWH for the composite ischemia endpoint at 30 days or for major bleeds (Stone et al., 2006). For this reason, the use of bivalirudin is now limited to being an alternative to UFH plus GPIIb/IIIa inhibitors during PCI (Roffi et al., 2016).

Beta-Blockers

Patients without contraindications should receive beta-blockers as soon as possible after diagnosis. The duration of treatment with beta-blockers in patients without heart failure is 1 year by National Institute for Health and Care Excellence (2013) and 3 years by ACC (Smith et al., 2011). In patients without left ventricular dysfunction and in whom beta-blockers are inappropriate, diltiazem hydrochloride or verapamil hydrochloride can be given.

The evidence for the beneficial effects of beta-blockers in NSTE-ACS are derived from a meta-analysis of 27 studies showing that beta-blocker treatment was associated with a significant 13% relative risk reduction (RRR) of mortality in the first week following MI (Yusuf et al., 1988). However, in more recent trials, beta-blockers have been associated with a significant reduction in recurrent MI and angina, but a significant increase in heart failure and cardiogenic shock (Kontos et al., 2011). Caution in using beta-blockers should be exercised when LV function is known to be low or there is evidence of hemodynamic compromise, conduction abnormalities, or inferior infarction (Amsterdam et al., 2014; Chew et al., 2016).

For patients with contraindications or severe side effects to beta-blockers, such as shortness of breath on initiation and those with severe peripheral vascular disease, a non-dihydropyridine calcium channel blocker (diltiazem or verapamil) can be given instead. Diltiazem is initiated at 60 mg three times daily and titrated to response, up to a usual maximum dose of 360 mg daily, which can be given in divided doses or as a long acting preparation. Similarly, verapamil can be started at 40–80 mg three times a day and increased according to response, up to a daily dose of 360–480 mg, depending on the preparation used. **Table 5** outlines the drugs and doses used in the acute management of NSTE-ACS.

Secondary Prevention in Non-ST-Elevated Acute Coronary Syndrome

This section outlines the pharmacotherapy for the long-term maintenance treatment after the acute phase of NSTE-ACS. The section will briefly outline the different pharmacotherapies used and the evidence supporting their use. The pharmacotherapy for secondary prevention in both STEMI and NSTE-ACS are similar, and most of the points discussed below can be cross-referenced to the earlier section of "Secondary Prevention in STEMI."

Lipid Modification Therapy

It is recommended to initiate high-intensity statin therapy as early as possible after admission in all NSTE-ACS patients (in the absence of contraindications) (Baigent et al., 2010). At the time of writing, the preferred statin in this case is atorvastatin 80 mg daily, unless patient preference, interacting drugs or high risk of adverse effects warrant a dose reduction. If the control of LDL-C is not sufficient after NSTE-ACS despite taking the maximum tolerated dose of statin, further cholesterol lowering with a nonstatin agent (, e.g., ezetimibe) may be considered (Cannon et al., 2015). There is only one trial, the IMPROVE-IT, at the time of writing, that was sufficiently powered for clinical outcomes to show a modest benefit with ezetimibe added to a statin (Cannon et al., 2015).

Antiplatelets

The duration of DAPT and choice of $P2Y_{12}$ inhibitor is discussed in the earlier section "Pharmacotherapy in NSTE-ACS."

Beta-Blockers

The evidence for the beta-blockers as maintenance secondary prevention therapy in patients after NSTE-ACS is unclear. In a large-scale observational propensity matched study in patients with known previous MI, beta-blocker use was not associated with a lower risk of CV events or mortality. The current recommendation from ESC and ACC guidelines is that beta-blockers should be used, in the absence of contraindications, in patients with reduced systolic LV function (LVEF $\leq$40%).

Angiotensin Converting Enzyme Inhibitors

ACE inhibitors are recommended in patients with systolic LV dysfunction or heart failure, hypertension or diabetes. Agents and doses with proven efficacy should be used such as captopril and enalapril. ACE inhibitors should be started while in hospital and continued long-term in all patients with NSTE-ACS or those with left ventricular systolic dysfunction to prevent cardiac remodeling (Amsterdam et al., 2014). Cardiac remodeling refers to changes in size, shape, structure, and function of the heart, often occurring after injury to the heart muscles (Pfeffer and Braunwald, 1990).

In patients who cannot tolerate ACE inhibitors, an ARB should be used: preferably candesartan or valsartan.

Aldosterone Antagonist

Aldosterone antagonist therapy with eplerenone is recommended in patients with LV dysfunction (LVEF $\leq$40%), heart failure, or diabetes after NSTE-ACS (Zannad et al., 2011).

Anticoagulant

Some anticoagulants such as the nonvitamin K antagonist oral anticoagulants (NOACs) have been trialed recently for their use in patients with recent ACS treated with clopidogrel and aspirin with no history of atrial fibrillation. The only NOAC currently approved for use in Europe is rivaroxaban 2.5 mg BD for this indication. This is following the ATLAS ACS-2 TIMI 51 trial, which compared rivaroxaban 2.5 mg and 5 mg twice daily with placebo in patients following ACS (Mega et al., 2012). At a mean follow-up of 13 months, both strengths of rivaroxaban resulted in a reduction in CV death, MI or stroke and stent thrombosis rate. Rates of CV death were significantly lower with rivaroxaban 2.5 mg compared with placebo but not with rivaroxaban 5 mg. Non-CABG major bleeds and intracranial hemorrhage were higher in rivaroxaban 5 mg cohort.

The use of rivaroxaban 2.5 mg twice daily, while not recommended in patients treated with ticagrelor or prasugrel, might be considered in combination with aspirin and clopidogrel if ticagrelor and prasugrel are not available for NSTE-ACS patients who have high ischemic and low bleeding risks. This combination should be continued for approximately 1 year.

This section outlines current recommendations for use of anticoagulants in combination with DAPT for patients with ACS alone, and does not cover treatment recommendations for patients needing oral anticoagulants long-term in combination with DAPT for other indications, e.g., atrial fibrillation, mechanical heart valves, or venous thromboembolism.

Interactions

Nitrates

Drugs with antimuscarinic effects may cause dry mouth, this can reduce the effectiveness of nitrate tablets. Caution should be exercised when administering nitrates and antihypertensives due to additive risk of hypotension. Phosphodiesterase type 5 inhibitors have a pharmacodynamic interaction with nitrates and they can exacerbate the vasodilatory action of nitrates (Schwartz and Kloner, 2010). Due to this interaction, which may cause severe life threatening hypotension their concurrent use, is contraindicated.

Fibrinolytics

Although combination of fibrinolytics with antiplatelets or antithrombins have known therapeutic benefits, caution must be taken due to the increased risk of bleeding. Nonsteroidal antiinflammatory drugs (NSAIDs) and other drugs which increase the risk of bleeding, should be avoided or used with caution (Joint Formulary Committee, 2017).

$P2Y_{12}$ Inhibitors

Clopidogrel is mainly metabolized by esterases and CYP2C19; therefore, concomitant use of drugs that inhibit the activity of CYP2C19, such as omeprazole, cimetidine, erythromycin, and carbamazepine results in reduced plasma concentrations of the active metabolite of clopidogrel and a reduction in platelet inhibition (Bates et al., 2011). Prasugrel is not known to have clinically significant interactions with inducers or inhibitors of cytochrome P450 enzymes. There is an increased risk of bleeding when prasugrel is given concurrently with other drugs that cause a similar effect (Joint Formulary Committee, 2017).

ACE Inhibitors and ARBs

Most interactions of ACE inhibitors and ARBs relate to additive risk of hypotension, hyperkalemia, or renal impairment when used concomitantly with other medications that share such actions. Furthermore, combination of ACE inhibitors and ARBs increases risk of hyperkalemia, hypotension, renal impairment, and angioedema. Close monitoring is required if ACE inhibitors or ARBs are used with mineralocorticoid receptor antagonists, potassium sparing diuretics, ciclosporin, and antihypertensives. ACE inhibitors and ARBs can increase plasma concentrations of lithium and digoxin, therefore close therapeutic dose monitoring is required in concurrent use (Joint Formulary Committee, 2017).

Beta-Blockers

Pharmacodynamic interactions can occur if beta-blockers are given with other drugs that share similar therapeutic effects, such as antihypertensives and drugs with negative inotropic effects, for example, digoxin, amiodarone, and rate-limiting calcium channel blockers (Joint Formulary Committee, 2017).

PCSK9 Inhibitors

This class of drugs are not thought to interact with other medications or cytochrome P450 enzymes.

Statins

Most statins are metabolized by cytochrome P450 enzymes. Therefore, the risk of side effects, particularly muscle-related, increases when they are concomitantly used with drugs that inhibit these enzymes. Examples to remember include azole antifungals, antiretrovirals, macrolides, calcium channel blockers, amiodarone, and grapefruit (Joint Formulary Committee, 2017). It may be necessary to avoid concurrent use.

Side Effects

Nitrates

Dizziness, postural hypotension, tachycardia, and throbbing headache are common side effects (Joint Formulary Committee, 2017). Due to risk of hemodynamic compromise in patients with ischemic heart disease, nitrates should be avoided in those with systolic blood pressure lower than 90 mmHg, or with marked brady- or tachycardia (Kushner et al., 2009). Prolonged intravenous infusion of nitrates has been associated with methemoglobinemia (Joint Formulary Committee, 2017).

Fibrinolytics

Hemorrhage is the most common side effect associated with this class of drugs, this can range from minor bleeding to major gastrointestinal bleed and hemorrhagic stroke. Therefore, fibrinolytics are contraindicated in active bleeding and in patients at high risk of bleeding (e.g., recent hemorrhage, trauma or surgery, coagulation defects, endocarditis). Another side effect is hypotension, this can usually be controlled by elevating the patients' leg, or by reducing the infusion rate or temporarily stopping it. Other side effects include allergic reactions, fever, nausea, and vomiting (Joint Formulary Committee, 2017).

$P2Y_{12}$ Inhibitors

Thienopyridines increase the risk of bleeding, however prasugrel has a greater bleeding risk than clopidogrel (Wiviott et al., 2007). Common side effects of clopidogrel include abdominal pain, bleeding disorders, diarrhea, and dyspepsia (Joint Formulary Committee, 2017).

ACE Inhibitors and ARBs

Adverse effects include dizziness, fatigue, headache, and nausea (Joint Formulary Committee, 2017). A profound first-dose hypotension can occur, especially in salt-depleted patients due to coadministration with diuretics (Wang et al., 2011). Therefore, for hypertension the first dose should preferably be given at bedtime. Some patients treated with ACE inhibitors may experience a persistent cough (Joint Formulary Committee, 2017). This can develop as early as one week after initiation or can be delayed by months; cessation of therapy will resolve symptoms (Wang et al., 2011). ACE inhibitors may rarely cause angioedema, with higher incidence reported in Afro-Caribbean patients. It can occur within hours to weeks of initiating treatment and can affect the GI tract, brain, tongue, and larynx. The ACE inhibitor must be stopped immediately and treatment with adrenaline may be required if there is potential airway obstruction and the ACE inhibitor should not be restarted (Joint Formulary Committee, 2017). ACE inhibitors should be discontinued if marked elevation of hepatic enzymes or jaundice occurs, due to reports of cholestatic jaundice, hepatitis, fulminant hepatic necrosis, and hepatic failure (Joint Formulary Committee, 2017). ARBs have a similar side effect profile to ACE inhibitors, however they are much less likely to cause cough or angioedema.

Beta-Blockers

Common side effects include fatigue, malaise, low mood, sexual dysfunction, and sedation. As a result of their therapeutic effect, beta-blockers can cause hypotension, bradycardia, and cardiac conduction disturbances. Beta-blockers may also mask signs of hyperthyroidism and hypoglycemia (Joint Formulary Committee, 2017).

Statins

Common side effects of statins include, GI disturbances, rash, insomnia, myalgia, and altered liver function tests (Joint Formulary Committee, 2017).

Pharmacogenomics in Acute Coronary Syndrome

In the last 10 years there has been considerable advancements in understanding genetic factors influencing response to a variety of drugs including those used for cardiovascular diseases. There is sufficiently strong evidence and genetic information available

relating to *CYP2C19* for clopidogrel, *VKORC1*, *CYP2C9;* and *CYP4F2* for warfarin; and *SLCO1B1* for statins to guide treatment and some clinicians are already using this genetic information to determine treatment appropriateness for their patients (Johnson and Cavallari, 2013).

There is strong evidence where genetic polymorphism on CYP2C19 has been associated with substantial reduction in the efficacy of clopidogrel, which is the mainstay pharmacological treatment for ACS resulting in diminished platelet inhibition and a significantly higher rate of major cardiovascular events (Lala et al., 2013). In response to the evidence regarding clopidogrel the US FDA announced a black box warning in March 2010 to alert clinicians to the reduced effectiveness of clopidogrel in subjects who are poor clopidogrel metabolizers. Despite the FDA warning and the risk that clopidogrel nonresponders face when on clopidogrel, it is still widely used (Antoniades et al., 2009). Moreover, interindividual, ethnic, and racial variability in drug metabolism of clopidogrel through genetic polymorphism of CYP2C19 enzymes in the Asian population has been attributed to adverse cardiovascular outcomes (Zhong et al., 2018).

Pharmacogenomics in CVD is not yet established clinical practice and some studies published on genetic polymorphisms have produced inconsistent results due to the complex systems underlying CVD. Large scale pharmacogenomic trials are needed to provide more convincing evidence to guide choosing drug treatment with the greatest potential of efficacy and smallest risk of adverse drug reactions (Johnson and Cavallari, 2013).

Nonpharmacological Management

Lifestyle Modification

Relevant lifestyle modification can reduce the risk of having further cardiovascular events. These include:

- Smoking cessation
- Adopting a cardio-protective diet (a diet similar to Mediterranean diet):
  - Total fat intake should be 30% or less of total energy intake, and saturated fat (which is mainly from animal sources) should be 7% or less.
  - Using olive oil or rapeseed oil for spreads, salad dressings, cooking, baking, and other food preparation rather than animal-based fats such as butter.
  - Eating at least 200 g of fruits and 200 g of vegetables per day.
  - Eating fish at least once a week, including a portion of oily fish.
  - Eating at least 4–5 portions per week of a mixture of unsalted nuts and seeds. (One portion is about a handful or about 30 g.)
  - Choosing wholegrain varieties of cereals, breads, and other starchy foods.
  - Keeping salt intake low (less than 6 g per day).
  - Minimizing intake of foods containing refined sugars, including fructose.
  - Dietary supplements including omega-3 capsules or supplemented foods are not recommended as there is no good evidence that they reduce CVD risk.
- Maintain an active lifestyle
  - In general, the minimum aim is 150 minutes per week of moderate-intensity aerobic activity (to the point of slight breathlessness).
  - Activity in bouts of 10 minutes or more is as effective as longer bouts so long as the total per week is as above. Moderate intensity activities include those that can be incorporated into everyday life such as brisk walking, using stairs, and cycling.
  - For people not active to this level, start at a level that is comfortable, and increase the duration and intensity of activity as fitness improves.
- Maintain a healthy weight (ideally Body Mass Index <25 kg/m^2)
- Limit alcohol consumption
  - In UK males and females should not consume no more than 14 units of alcohol per week.
  - Avoid binge drinking and intoxication.

Pharmacist Role in the Management of Acute Coronary Syndromes

Pharmacists are one of the most accessible health care professionals in the community and are experts in the safe and effective use of medicines. Pharmacists play an essential role in the care of ACS patients, starting from their admission to hospital, throughout their hospitalization, their transition to primary care settings and thereon (Coombes et al., 2002; Walker et al., 2009).

The expanding role of pharmacists has allowed pharmacists to become a valuable resource in assisting other members of the health care team with pharmacotherapeutic decision making, reducing medication errors, pharmacovigilance, and improving medication safety systems to optimize patient outcomes in addition to improving cost effectiveness.

Pharmacists also have a role to play in promoting secondary prevention strategies for patients with CHD. Patients with ACS choosing healthy lifestyles, managing risk factors and being on optimized drug treatment for ACS can reduce the risk of recurrent and fatal future episodes (Garcia et al., 2014).

The appropriate transition of patients from secondary to primary care can help reduce morbidity and mortality, therefore reducing readmission rates and associated health care costs. It is important that pharmacists ensure the correct continuation of prescribed medications when patients are transitioning between settings. This will help avoid discrepancies and confusion in the planned medication regimen. It is therefore paramount for pharmacists to recognize the importance of patients receiving and adhering to the prescribed drug therapy for successful ACS treatment outcomes and their quality of life.

Patient education is essential, while in hospital and on discharge, in addition to each patient interaction. Pharmacists are best placed in educating patients regarding the reasons for prescribing of specific medication and dosages and the importance of taking their medication as prescribed. Adherence to recommended therapies is vital to secondary prevention of events in ACS patients. It is also important to remember that this can be troublesome for some patients who are prescribed four or more medications on discharge. Such patients would benefit from regular monitoring and interactions with pharmacists and pharmacy teams to ensure adherence and compliance. Poor adherence may result in recurrent episodes of ACS, morbidity, and mortality in addition to rehospitalization and the need for further diagnostics tests, dosage adjustments, and changes to treatment plans (Sokol et al., 2005).

An example of services provided by community pharmacists in the UK is the New Medicines Service (NMS). The service provides support for patients with long term conditions such as ACS who have been newly prescribed medications. This process increases patient engagement with their condition and medicines, while supporting them in making decisions about their treatment and self-management. This will aid in reducing hospital admissions due to adverse events from medicines in addition to a reduction in medicines wastage. The Medicines Use Review (MUR) and Prescription Intervention Service in the UK are examples of other services provided by community pharmacies which focus on improving adherence to treatment.

A study by Nunes et al. (2009b) estimated the level of nonadherence to medicines in patients with long-term conditions to be between 33% and 50%. Several studies show that there is a significant level of non-adherence to secondary prevention medicines by CHD patients. This was associated with a 10%–40% relative increase in risk of cardiac hospitalizations and a 50%–80% relative increase in mortality (Nunes et al., 2009a).

You are presented with two case studies on optimizing ACS management from a primary and secondary care perspective within the UK.

Medication Review in General Practice (Primary Care)

Clinical pharmacist in UK general practice often perform medication reviews for patients on long-term medicines. The aim of these reviews is to ensure patients are getting the best outcomes from their medicines by optimizing the prescribing, minimizing risks, and improving cost effectiveness. In this example a patient with a history of cardiac disease is reviewed.

Age 65 male; White-British; smoker; BMI 27

Previous Medical History

- STEMI 15 months ago
- Mild Left Ventricular Failure
- Hypertension
- Nonulcer dyspepsia
- Latest blood pressure 155/90 mmHg
- No recorded pulse rate
- Urea and electrolytes last done 12 months ago
- No recorded cholesterol since the STEMI
- Kidney function Class G3a 45–59 ml/min/1.73 m^2 (e.g., mild/moderate reduction)

Prescribed Medicines

- Bisoprolol 2.5 mg daily
- Ramipril 2.5 mg daily
- Aspirin 75 mg daily
- Ticagrelor 90 mg twice daily
- Atorvastatin 20 mg daily
- Lansoprazole 15 mg

Treatment Goals

1. To maximize secondary prevention of MI treatments/life style
2. To maximize LVF treatments

Specifically, to:

- Check if the patient is managing with his medicines; is adherent with medicines and if having any problems such as adverse effects
- Manage blood pressure to less than 140/90 mmHg or lower if possible
- Titrate ACE-I and beta-blocker to evidence-based dose or maximum tolerated dose
- Cholesterol aim for a 40% reduction in non-HDl cholesterol
- Stop smoking if possible

Interventions

The medication review firstly involves looking at the patient's clinical record to identify questions and to generate queries that might be answered from the record or might only be answered when the patient is seen.

In this example the following are identified from the record

1. The ticagrelor 90 mg twice can now stop as it is more than 12 months post-STEMI. Ticagrelor at this dose will provide no extra benefit but continued prescribing will increase the bleed risk. The dose should be reduced to 60 mg twice daily or it may be possible to stop all together depending on what advice the cardiologists have given.
2. Can the atorvastatin be increased to 80 mg? If it is increased, then liver function tests (especially ALT) and non-HDL cholesterol will need to be checked once on higher dose.
3. Can the ramipril dose be up-titrated? Is there any evidence in the record that this has been tried before but caused hypotension or worsening kidney function for example?
4. If the ramipril is up-titrated, then a check on Blood Pressure and U&Es will be needed after each dose increase to the evidence-based dose or maximum tolerated dose.
5. Once the ramipril has been managed can the beta-blocker dose be increased to an evidence-based dose or tolerated dose? Again is there evidence in the record that this has been tried before but caused problems such as bradycardia or other unacceptable side effects?
6. If the bisoprolol is up-titrated a check on blood pressure and pulse should be made after the dose increase

The patient is then invited in for a face-to-face review.

At this review any patient ideas, concerns, or expectations about the condition and the treatments should be explored before moving onto the pharmacist's agenda. The pharmacists will explain to the patient:

1. The treatment plan for the ACE-I and beta-blocker and check if the patient has had a failed dose titration before; the benefits of dose titration what adverse effects to expect.
2. Why you are recommending a change in ticagrelor dose and what side effects to expect, especially the bleed risk and what to do if a bleed occurs.
3. The benefits of smoking cessation advice and what support the practice can offer support.

The pharmacists should explore whether the patient has any adverse effects such as cough from ACE-I; muscle pains from atorvastatin; bleeds from antiplatelets. If any of these are present then appropriate action should be taken, e.g., change ACE-I to an ARB, recommend to GP a review of the antiplatelets.

Depending on the pharmacist's level of clinical examination expertise an assessment may also need to be made of whether loop diuretic are required for the LVF. If the pharmacists is less experienced and the patient is complaining of ankle swelling, symptoms of pulmonary edema than the pharmacist could refer onto a GP colleague or nurse practitioner within the surgery.

The lansoprazole should be left at 15 mg daily to provide gastro-protection against dual antiplatelet treatment.

Case Study of a Consultant Cardiologist Pharmacist Working in Secondary Care

CHD is the leading cause of death both in the UK and worldwide. Every year the Leeds Teaching Hospitals NHS Trust cardiology department treats over 2500 patients with myocardial infarction. Our audits showed that post-MI patients are waiting too long to be seen in outpatient cardiology for a review postdischarge. Many did not have all their cardiovascular risk factors and medicines optimized. We developed and delivered a new Consultant Pharmacist Led Post for Myocardial Infarction Medicines Optimization service to tackle these issues and improve patient experience and outcomes.

The multidisciplinary (MDT) medicines optimization outpatient clinics include both a Consultant Cardiology Pharmacist and a Consultant Cardiologist/interventionist. In the clinic, patients are triaged to see either a consultant pharmacist, a consultant cardiologist or both.

The consultation offered is based on the principles of medicines optimization as defined by NICE. Patients' needs and issues they wanted addressing are tackled and given priority. Patients receive full advice and provided with a clear plan which is shared with their GP and the cardiac rehabilitation team.

This new innovative service greatly improved medicines optimization post-MI, reduced patient's waiting time to be seen in outpatient cardiology postdischarge, and was associated with reduction in readmissions. The feedback from patients was tremendously positive. Patients expressed their extreme satisfaction with the service and indicated that their medicines needs were met and their concerns were alleviated.

The plans are to widen the service. Currently we are expanding the service by training advanced cardiovascular pharmacists to support these clinics.

Monitoring

Close monitoring of patients with ACS diagnosis and treatment is required which warrants a review by the cardiologist within 1–2 weeks of postdischarge. Lipid levels should be monitored at least every 6 months until a target LDL <1.8 mmol/L (<70 mg/dL) is reached. It may also be necessary to request cardiac ultrasounds to evaluate and monitor ventricular function (Amsterdam et al., 2014).

In addition to promoting healthy lifestyles patients should be encouraged to quit smoking when appropriate, increase physical activity and where available signpost patients to cardiac rehabilitation which has been proven to be extremely helpful in ACS patients.

Cardiac rehabilitation, a long-term multifaceted program including exercise, dietary and lifestyle interventions, patient education, and counseling is associated with improved clinical outcomes and should be promoted to all patients. Psychosocial risk factors such as anxiety and depression should be addressed in all ACS patients and pharmacists are best placed to screen and refer patients presenting with symptoms indicative of these conditions and this should be managed through pharmacological treatment where appropriate. Depression in particular has been associated with a poor prognosis (Lichtman et al., 2014).

Furthermore, ejection fraction should be assessed by echocardiography 3 months after the acute episode and then periodically thereafter, depending on LV function and symptoms. Patients with ejection fraction <35% at 3 months' follow-up should be referred to an electrophysiologist for consideration of an Implantable Cardioverter, as there is a high risk for arrhythmias in this population. Patients who develop diminished LV function and congestive heart failure should be followed up and managed appropriately (Sallam et al., 2015). Patients should also be encouraged to maintain their blood pressure <140/90 mmHg in the absence of known coronary artery disease conditions, diabetes, renal disease, or heart failure. Patients should also be encouraged to tightly control their blood glucose levels and should strive to keep their HbA1C <0.07 (<7% of total hemoglobin) especially in patients with diabetes (Roffi et al., 2016).

Acknowledgments

Our sincere appreciation to Dr. Rani Khatib (consultant cardiologist pharmacist) at Leeds Teaching Hospitals for providing the case study describing the role of a pharmacist in secondary care and his expert input reviewing the chapter. We also want to thank Dr. Duncan Petty (senior lecturer in pharmacy practice at University of Bradford and Primary Care Pharmacist) for providing the case study in relation to the role of a pharmacist working in primary care in managing patients with ACS.

Management of Coronary Artery Disease & Dyslipidemia and Pharmacist's Role

Ahmed Awaisu*, Yaw Owusu*, Sowndramalingam Sankaralingam*, Muna Al-Ismail†, Oraib Abdallah*, *Qatar University, Doha, Qatar; †Ibn Al Haytham Hospital, Amman, Jordan

Learning Objectives

Upon completion of reading the chapter, the reader will be able to:

1. Describe the epidemiology and the pathophysiology of coronary artery (heart) disease.
2. Assess cardiovascular risk in patients at risk of atherosclerotic cardiovascular diseases.
3. Discuss the current evidence and recent advances in the primary prevention of coronary artery (heart) disease.
4. Evaluate the current evidence and recent advances in the therapeutics of acute coronary syndromes and dyslipidemia.
5. Recommend secondary prevention (long-term management) of coronary artery (heart) disease.
6. Describe the role of pharmacist in the care of patients with coronary heart artery (heart) disease.

Take Home Messages

- Coronary artery disease (CAD), also called coronary heart disease (CHD) or ischemic heart disease (IHD), comprises of the following common clinical manifestations: (1) chronic stable angina and (2) acute coronary syndromes (ACS) of ST-segment elevation myocardial infarction, non-ST-segment elevation myocardial infarction, and unstable angina.
- CAD is as a result of an imbalance between myocardial oxygen demand and oxygen supply that is most often caused by coronary atherosclerosis.
- The clinical management of the wide spectrum of CAD is highly variable and is based on the manifestations a patient is experiencing.
- Early detection and modification of modifiable risk factors is a key strategy for delaying the progression of CAD and preventing CAD-related complications including mortality.
- Patients with angina-type chest pain (i.e., chest pressure that is typically provoked by activity and relieved with rest) should be assessed for CAD, whether or not the pain is associated with discomfort in the neck, shoulder, or arm.
- The goals of therapy for CAD depends on the clinical manifestation, but generally clinicians aim to control risk factors, alleviate acute symptoms of myocardial ischemia, prevent acute coronary syndromes, and prevent recurrent symptoms of myocardial ischemia or adverse cardiac events.
- The role of pharmacist in the management of CAD has become increasingly important as the primary focus of management shifts to optimizing drugs and targeting cardiovascular risk factor goals.
- Evidence has shown that HMG-CoA reductase inhibitors (statins), angiotensin-converting enzyme inhibitors (ACEIs), antiplatelets, and β-blockers provide vasculoprotective effects and reduce the risk of acute coronary events as well as mortality in patients with CAD.
- In all patients with a history of myocardial infarction without contraindications, antiplatelet therapy with aspirin should be considered, but dual antiplatelet therapy with P2Y12 inhibitors (e.g., clopidogrel, prasugrel, ticagrelor) may be considered in some patients.
- Other agents such as calcium channel blockers, nitrates, and anticoagulants are also used on as needed basis in the setting of CHD, depending on the specific diagnosis as well as patient's comorbidities.
- It is recommended that patients with a history of angina should have sublingual nitroglycerin tablets to relieve acute ischemic symptoms and should be educated on its use and when to call emergency medical service.
- Patients with CHD should be regularly monitored for drugs effectiveness, safety, and adherence.

Epidemiology and Pathophysiology of Coronary Artery (Heart) Disease

Definition of Coronary Artery Disease

Coronary artery disease (CAD), also termed coronary heart disease (CHD) or ischemic heart disease (IHD), is a global term referring to a wide spectrum of diseases comprising of stable angina, progressive angina, unstable angina (UA), non-ST-segment elevation

myocardial infarction (NSTEMI), and ST-segment elevation myocardial infarction (STEMI) (Agarwal et al., 2010). CHD occurs most commonly due to CAD, which is characterized by atherosclerotic narrowing of the coronary arteries. This results in myocardial ischemia and therefore is also known as IHD. These terms are used interchangeably among health-care professionals, although they may not sometimes refer to the same. CHD can present in a chronic form known as chronic stable angina also simply known as "stable angina" or in an acute form known as "acute coronary syndrome (ACS)." ACS comprises of STEMI, NSTEMI, and UA.

Epidemiology and Global Burden of Coronary Artery Disease

Cardiovascular diseases (CVD) are one of the leading causes of morbidity and mortality worldwide. The global incidence and prevalence of CVD is 54 million and 469 million, respectively (Disease et al., 2017). Importantly, the global incidence and prevalence of IHD is 20 million and 153 million, respectively. Globally, death due to CVD is estimated to be 17.6 million (Collaborators, 2017). This represents an increase of 14.5% between 2006 and 2016. IHD is responsible for 53.7% of all deaths due to CVD and accounts for 9.48 million deaths worldwide. This represents an increase of 19% between 2006 and 2016. Globally, IHD is the leading cause of total years of life lost (YLL). Total YLL due to IHD is less in high-income regions such as North America and Western Europe, whereas it is high in other regions such as Central Europe, Central Asia, and Eastern Europe.

Etiology and Pathogenesis of Coronary Artery Disease

CHD occurs when narrowing of the coronary arteries due to a process known as atherosclerosis reduces blood and oxygen supply to the heart. Therefore, oftentimes, the term IHD is used to refer to this group of conditions. This results in an imbalance between myocardial oxygen demand and supply. Consequently, during times of increased physical activity, oxygen supply to the heart is unable to meet the requirements of the functioning heart resulting in ischemia. In some forms of CHD, the atherosclerotic plaque ruptures resulting in further reduction in lumen of the coronary arteries due to thrombus formation and even occlusion leading to total lack of oxygen supply to the heart resulting in necrosis of the myocardium known as infarction (Antman and Loscalzo, 2018a, 2018b). Furthermore, inadequate perfusion of the myocardium results in decreased myocardial oxygen tension. This could affect the biochemical, electrical, and contractile functions of the heart. Since atherosclerosis tends to be focal, ischemic episodes affect certain regions of the myocardium, resulting in regional disturbances in contractile function. Initial periods of ischemia affect the endothelial function, reduce subendocardial perfusion, and alter cardiac energy metabolism. Prolonged periods of ischemia affect the relaxation and contractile functions of the heart (Antman and Loscalzo, 2018a, 2018b; Shaw et al., 2009).

Risk Factors of Coronary Artery Disease

The Framingham study was the first to identify several risk factors that could potentially increase the risk of CVD. Among these, the major risk factors are high blood pressure, high low-density lipoprotein (LDL) cholesterol, low high-density lipoprotein (HDL) cholesterol, smoking, and diabetes (Vasan et al., 2005). Age, gender, and psychosocial issues also constitute risk of developing heart diseases. Risk factors are classified depending on whether they are amenable to modification or not. The five leading modifiable risk factors are hypertension, high blood cholesterol levels, smoking, diabetes, and obesity. Others include lack of physical activity, diet, and stress. Conversely, nonmodifiable risk factors include age, gender, family history, and race. In about 90% of individuals experiencing CHD, at least one risk factor is present. Male gender tends to have a higher risk of CHD compared to female. The incidence of CHD in men is about threefold higher than women, and mortality is fivefold higher.

Chronic Stable Angina

Chronic stable angina occurs primarily as a result of inadequate myocardial perfusion resulting in imbalance between oxygen demand and supply. This inadequate perfusion is due to reduction in lumen of the epicardial coronary arteries, which most often occurs due to a process known as atherosclerosis.

Pathophysiology of Chronic Stable Angina

Atherosclerosis is a process that leads to accumulation of lipids in arterial wall of coronary arteries (Ross, 1986, 1999). Atherosclerotic plaque in arterial wall causes fixed partial obstruction of the coronary artery lumen resulting in reduced or inadequate oxygen supply to the myocardium under conditions of increased oxygen demand such as exercise (Antman and Loscalzo, 2018a, 2018b). One of the initial events that leads to atherosclerosis is endothelial dysfunction. Normally, the endothelium functions to maintain vascular tone and prevents platelet aggregation. Nitric oxide is one important factor that mediates normal functions of the endothelium. Endothelial dysfunction results in decreased nitric oxide generation resulting in endothelial activation and inflammation. Atherosclerosis begins with the formation of a fatty streak, which includes accumulation of lipids within the arterial wall. Endothelial activation recruits monocytes that transform into macrophages and uptake oxidized LDL. Oxidative stress within the fatty streak results in the development of atherosclerotic plaque. Smooth muscle cell migration and proliferation into the plaque result in the growth of plaque. This atherosclerotic plaque further reduces blood flow through the arterial lumen and is often observed in chronic stable angina. However, in ACS that is detailed below, inflammation leads to plaque rupture, adhesion and aggregation of platelets as well as activation of the coagulation cascade resulting in thrombus formation.

Clinical Presentation of Chronic Stable Angina

The condition is characterized by angina pectoris that presents as mild chest discomfort generally described as heaviness, pressure, or squeezing in character over the sternum (Antman and Loscalzo, 2018a, 2018b; Wright and Antoniou, 2012). Patients rarely experience frank pain. The discomfort may radiate to the shoulder, arms (ulnar surface), jaw, interscapular region (back), neck, and the epigastric region. This typically occurs in individuals during exertion (exercise) or emotion (anger or frustration). Importantly, patients with stable angina describe the discomfort as recurring after a certain fixed level of activity such as after walking for a certain distance or taking a certain number of flight of stairs, which is due to fixed coronary obstruction. This discomfort usually lasts for a few minutes and is relieved by rest or nitrates. However, stable angina may present with atypical symptoms in women and patients with diabetes in terms of location and may not be provoked by the factors mentioned above. The occurrence of such discomfort may be seasonal, being more common in the winter. In patients with diabetes and the elderly, other symptoms known as anginal equivalents such as dyspnea, nausea, fatigue accompanied by episodes of fainting may be observed.

Diagnosis of Chronic Stable Angina

Diagnosis of stable angina in patients with history of CAD can usually be made based on a known or typical history of angina, classic symptoms and whether additional cardiovascular risk factors are present (Antman and Loscalzo, 2018a, 2018b; Wright and Antoniou, 2012). However, investigations are necessary to confirm or rule out a diagnosis and to determine the extent of the disease. The initial choice of diagnosis is an exercise stress test with electrocardiogram (ECG), or imaging. In patients who are unable to perform exercise, pharmacological stress testing may be utilized. Exercise ECG changes such as ST depression of >0.2 mV suggest ischemia. In addition, investigations for evaluation of risk factors such as diabetes, renal disease, hyperlipidemia, and highly sensitive C-reactive protein (hsCRP) may be useful.

Acute Coronary Syndromes

ACS refers to a spectrum of clinical conditions ranging from UA to NSTEMI to STEMI due to acute myocardial ischemia (Kumar and Cannon, 2009). However, based on the need for evaluation of patients presenting with symptoms suggestive of ACS and the management strategy, ACS can be broadly classified as (1) acute myocardial infarction STEMI on ECG and (2) non-ST-segment elevation ACS (NSTE-ACS). The latter is further classified as those without myocardial necrosis known as UA or those with evidence of myocardial necrosis known as NSTEMI (Antman and Loscalzo, 2018a, 2018b; Giugliano et al., 2018).

Pathophysiology of Acute Coronary Syndromes

Once atherosclerotic plaque is formed, its progression and stability plays a role in the pathogenesis of ACS (Fuster et al., 1992; Kumar and Cannon, 2009; Libby, 2001). In some individuals, the characteristic of the atherosclerotic plaque may be described as being high risk or vulnerable plaque based on their tendency to rupture (Moreno et al., 1994). Even within the same individual, plaques at different locations may have different characteristics. Vulnerable plaques have a large lipid core surrounded by a thin fibrous cap, increased expression of matrix metalloproteinases that degrade collagen, outward remodeling of the atherosclerotic plaque all of which increase the risk of rupture of the plaque. These vulnerable plaques are abundant in macrophages and T lymphocytes and have very little smooth muscle cells. Macrophages promote inflammation, which determine the vulnerability of the plaques.

An important event that determines the occurrence of an acute coronary event is plaque disruption and subsequent thrombus formation. In most cases of fatal myocardial infarction, plaque rupture is the cause, while 25% of cases occur due to endothelial erosion (Moreno et al., 1994; van der Wal et al., 1994). In both cases, an overlying thrombus formation partially or totally occludes coronary lumen resulting in an acute coronary event. After plaque rupture or endothelial erosion, thrombus formation is initiated by the exposure of subendothelial matrix to circulating blood. Platelet adhesion to the arterial wall is mediated by the platelet Gp1b-IX receptor and von Willebrand factor (VWF) on endothelial cells. Upon subsequent platelet activation by agonists such as adenosine diphosphate (ADP), platelet aggregation is mediated by the platelet receptor GpIIb–IIIa and fibrinogen. Thrombin of the coagulation cascade activates factor XIII to XIIIa and also converts fibringen to soluble fibrin which is made into insoluble fibrin by factor XIIIa, resulting in a firm thrombus (clot) which traps platelets. These processes together result in formation and enlargement of the thrombus. STEMI is associated with rapid formation of thrombus that totally occludes the coronary artery lumen, while in UA/NSTEMI, thrombus formation is slow and partially occludes the artery.

Clinical Presentation of Acute Coronary Syndromes

UA and NSTEMI have certain similarities in terms of pathophysiologic mechanisms, clinical presentation, and management and will therefore be considered together. Chest pain is the most common presenting symptom in patients with both NSTEMI/UA and STEMI. It is described as severe heavy crushing chest pain, substernal in location that radiates to arms, lower jaw, neck, and occasionally to the abdomen, and lasts more than 10–20 min. The pain is very similar to that observed in angina, except that it is severe and lasts longer. This pain may occur at rest and is most common in the morning. Chest pain may also be accompanied by sweating (diaphoresis), nausea, vomiting, anxiety, and fear of impending doom. In addition, anginal equivalents such as breathlessness, loss of consciousness, or hypotension may suggest ACS (Antman and Loscalzo, 2018a, 2018b; Kumar and Cannon, 2009).

Diagnosis of Acute Coronary Syndromes

Diagnosis of NSTEMI/UA is based on ECG and cardiac biomarkers. A diagnosis of NSTEMI is made in such patients by the presence of cardiac biomarkers such as cardiac troponins and CK-MB, which are absent in UA (Kumar and Cannon, 2009). This may or may not be accompanied by ischemic ECG changes such as ST-segment depression, transient ST-segment elevation, or T-wave inversion. Similarly, both ECG and cardiac biomarkers are important in the diagnosis of STEMI. ECG criteria for the diagnosis of STEMI include: (1) New ST segment elevation at the J point in two contiguous leads of >0.1 mV in all leads except V2-V3. For leads V2-V3, ≥0.2 mV in men ≥40 years, ≥0.25 mV in men < 40 years, or ≥0.15 mV in women or (2) New left bundle branch block (LBBB) (Thygesen et al., 2012). Cardiac biomarkers are useful in establishing a diagnosis of STEMI. Cardiac-specific Troponin T and I are highly accurate and sensitive for the determination of myocardial injury (Alpert et al., 2000; Thygesen et al., 2007). However, these biomarkers may not be elevated up to 6 h after myocardial necrosis and therefore may need to be measured at presentation and after 3–6 h in patients with high suspicion for STEMI. Therefore, management decisions should be made largely based on clinical presentations and ECG findings.

Management of Acute Coronary Syndromes

Detailed information about the management of ACS is available in another chapter within the Encyclopedia. Therefore, our intention is to summarize the major evidence-based recommendations as provided in most recent clinical practice guidelines.

Acute Pharmacological Management—Onset of Stabilization

The initial management plan on presentation for patients with ACS is summarized in Table 1.

Table 1 Interventions on presentation and for onset of stabilization for any ACS (American College of Clinical Pharmacy (ACCP), 2016a; Amsterdam et al., 2014; Ibanez et al., 2018; O'Gara et al., 2013; Roffi et al., 2017)

Intervention	*Comments*
Oxygen	• Reduces the ischemic burden secondary to tissue hypoxia. • Supplemental oxygen should be considered if SaO_2 is less than 90%, respiratory distress, or other high-risk features of hypoxemia. • Oxygen is administrated at a rate of 2–4 L/min via nasal cannula. • It should be administered with caution in patients with chronic obstructive pulmonary disease (COPD) and carbon dioxide retention.
Nitrates	• Ameliorates signs and symptoms of MI by reducing left ventricular preload and increasing coronary blood flow. • Administer one sublingual nitroglycerin (NTG) tablet or one aerosol spray under tongue every 5 min up to three doses, then assess the need for IV NTG. • IV NTG is indicated if patient has persistent ischemia, HTN, or signs of heart failure (HF), provided there are no sign of hemodynamic compromise and no contraindication for its use. IV NTG can also be helpful in patients with pulmonary edema.
Aspirin	• Inhibits platelet aggregation. • Irrespective of the need for thrombolytic therapy, non-enteric-coated aspirin (162–325 mg) should be chewed and swallowed immediately, unless there is a compelling contraindication (e.g., history of anaphylactic reaction). • Patients with severe nausea and vomiting or known upper gastrointestinal disorders may use a rectal suppository dose of 600 mg.
Morphine	• Provides potent analgesic and anxiolytic effects and attenuates pain-induced sympathetic hyperactivity that increases myocardial oxygen demand and predisposes patients to tachyarrhythmias. It may also induce vasodilation. • IV morphine may be reasonable for continued ischemic chest pain despite maximally tolerated antiischemic medications. • Administer a dose of 2–4 mg IV over 1–2 min and repeat at 5–15 min intervals until ischemic pain is relieved or side effects occur (i.e., hypotension, respiratory depression, or vomiting) that preclude further administration.
β-Blocker	• Reduces myocardial oxygen consumption by reducing heart rate, contractility, and blood pressure and increases diastolic filling time of ventricles, thus produce favorable redistribution of coronary blood flow. • Oral β-blocker (without increased sympathomimetic activity) should be administered within the first 24 h of acute MI unless contraindicated. • May initiate IV β-blocker in patients with refractory hypertension or ongoing ischemia.
Statin	• In addition to LDL lowering, statin my lead to plaque stabilization, reversal of endothelial dysfunction, decreased thrombogenicity, and reduced inflammation. • High-intensity statin therapy (80 mg of atorvastatin or 20–40 mg of rosuvastatin daily) should be started as soon as possible after the diagnosis of ACS is established.

Revascularizations: Nonsurgical and Surgical

Nonsurgical Interventions

Details of interventional cardiology procedures are too broad to be discussed in this chapter and will be found elsewhere within the textbook. However, the following are some recommendations for preprocedural considerations and interventions in patients undergoing cardiac catheterization and percutaneous coronary intervention (PCI): (Ibanez, 2018; Levine et al., 2011, Levine, 2016; O'Gara et al., 2013).

1. Contrast-induced acute kidney injury (AKI)
    a. Patients should be assessed for the risk of contrast-induced AKI before PCI.
    b. Patients undergoing cardiac catheterization with contrast media should receive adequate preparatory hydration:

    Isotonic crystalloid (1.0–1.5 mL/kg/h) for 3–12 h before the procedure and continuing for 6–24 h after the procedure.
    N-acetyl-L-cysteine does not prevent contrast-induced AKI in patients undergoing angiographic procedures.

2. Patients with evidence of an anaphylactic reaction to contrast media should receive appropriate prophylaxis before repeat contrast administration.
3. Administration of a high-dose statin is reasonable before PCI to reduce the risk of periprocedural MI (Class IIaA for statin-naïve patients and IIaB for those on chronic statin therapy).
4. The glomerular filtration rate should be estimated and the dosage of renally cleared medications should be adjusted (e.g., eptifibatide, tirofiban, bivalirudin).
5. Bleeding risk—All patients should be evaluated for risk of bleeding before PCI and measures to minimize the risks of bleeding complications instituted.
6. Aspirin—Patients already on daily aspirin therapy should take 81–325 mg before PCI, while patients not on aspirin therapy should be given nonenteric aspirin 325 mg before PCI.

Common nonsurgical interventions (ACCP, 2016a, 2016b; Byrne et al., 2015; Helms et al., 2006; Ibanez et al., 2018; O'Gara et al., 2013; Roffi et al., 2016).

1. Plain old balloon angioplasty: Balloon inflation and at least temporary displacement of occlusion at site of lesion
    a. It is reasonable to perform balloon angioplasty without stenting in patients with high bleeding risk, inability to comply with 12 months of dual antiplatelet therapy (DAPT), or anticipated invasive or surgical procedures within the next 12 months, during which time DAPT may be interrupted.
    b. Risk of early abrupt vessel closure, coronary dissection, and relatively high rate of restenosis at the site of the treated lesion.
2. Stent placement
    a. It is important to take into consideration patient characteristics (e.g., medication adherence, risk of bleeding, financial status), types of stents, number of stents placed, and locations of stent placement.
    b. Bare metal stent (BMS)

    Requires aspirin for life and $P2Y_{12}$ antagonist (clopidogrel, ticagrelor, prasugrel) for at least 1 month (12 months preferred) to allow adequate time for endothelization of the stent(s)
    Preferred over drug-eluting stent in patients with high bleeding risk, inability to comply with 12 months of DAPT, or anticipated invasive or surgical procedures within the next 12 months, during which time DAPT may be interrupted
    Higher risk of in-stent restenosis over time as reendothelialization occurs

    c. Drug-eluting stent (DES)

    Reduce the rate of restenosis and, accordingly, target lesion revascularization compared to BMS
    Requires aspirin for life and $P2Y_{12}$ antagonist for at least 12 months. Longer duration may be considered, depending on the number and/or location(s) of the stent(s)
    Associated with lower rate of in-stent restenosis compared to BMS
    Higher risk of stent thrombosis; the rate of endothelialization over the stent is slowed by the drug coating on the stent, thus leaving metal exposed that can potentiate thrombus formation

Surgical Interventions

Again, details of PCI and coronary artery bypass grafting (CABG) procedures are too broad to be discussed in this section. According to the Society of Thoracic Surgeons/American College of Cardiology/American Heart Association (STS/ACC/AHA) CABG guidelines (2013), there are some recommendations for preprocedural considerations and interventions in patients undergoing urgent CABG

1. Aspirin (100–325 mg daily) should be administered to CABG patients preoperatively.
2. Clopidogrel and ticagrelor should be discontinued for at least 24 hours to reduce major bleeding complications.

3. Short-acting IV glycoprotein (GP) IIb/IIIa inhibitors (eptifibatide or tirofiban) should be discontinued for at least 2–4 h before surgery and abciximab for at least 12 h beforehand to limit blood loss and transfusions.
4. β-Blockers should be administered for at least 24 h before CABG to all patients without contraindications to reduce the incidence or clinical sequelae of postoperative atrial fibrillation (AF).
5. Preoperative administration of amiodarone to reduce the incidence of postoperative AF is reasonable for patients at high risk for postoperative AF who have contraindications to β-blockers.
6. Digoxin and nondihydropyridine calcium channel blockers can be useful to control the ventricular rate in the setting of AF, but are not indicated for prophylaxis.

Parenteral Antithrombotic Therapy in Acute Management of Acute Coronary Syndromes

Table 2 provides a summary of guidelines recommended parenteral antithrombotic agents used in acute management of ACS. The optimal use of these agents depends on the treatment strategy used and the diagnosis of STEMI compared with NSTEMI/UA.

The choice of an agent may depend on the diagnosis, management plan (i.e., invasive or ischemia-guided), timing/dose of preprocedural antiplatelet medication, clot burden during procedure, and estimated risk of the procedure.

Primary Prevention of Coronary Artery Disease

A group of risk factors contributes to CHD. These are not equally contributing to CHD, but they are affected by the presence of each other. Studies have demonstrated that primary prevention results in a decrease in the burden of CVD in patients who are at risk (Ebrahim, 2005; Puska, 2010). The focus of this section will be mainly on the modifiable and nonmodifiable risk factors of CHD, early identification of risk groups and their assessments, and the strategies that can be applied in primary care to modify the risk factors and prevent the development of new-onset CVD.

Risk Factors of CHD

Nonmodifiable Risk Factors

Advanced age, gender, family history of premature CHD are nonmodifiable risk factors for CHD that cannot be avoided or controlled (Lloyd-Jones, 2010). Guidelines indicated that, in both women and men, absolute risk of CHD increases with age due to atherosclerosis (Grundy et al., 1998). The development of CVD in women is 10 years later than in men (Epstein and Wei, 1992). However, the overall prevalence of CVD is more common in men than in women. In addition, the transition of menopause is associated with a worsening CHD risk profile (Maas and Appelman, 2010). Another strong indicator of CHD risk is family history of premature CHD, which is defined as having a definite MI or sudden cardiac death before age 55 years in first-degree male relatives, or before age 65 years in first-degree female relatives (Jellinger et al., 2017a, 2017b). Genetic factors are also considered as nonmodifiable risk factors for CHD (Steinberg and Cannon, 2016). Odonnell and Nabel (2011) have highlighted that many loci, which were identified by genome-wide association studies, contained genes that are crucial in the pathways that contribute to CVD development.

Modifiable Risk Factors

Dyslipidemia, diabetes mellitus, hypertension (HTN), and smoking are established atherosclerotic cardiovascular disease (ASCVD) risk factors that can be controlled if identified early.

Low-density lipoprotein cholesterol (LDL-C) has a great role in the process of CHD. It is reported that relative risk of CHD increases by 30% for every 30 mg/dL rise in LDL-C above 40 mg/dL and by reducing LDL-C by 1.0 mmol/L, the risk reduction in CVD mortality and nonfatal MI is estimated to be 20%–25% (Piepoli et al., 2016). The increase in high-density lipoprotein cholesterol (HDL-C) is associated with a reduction in CHD mortality. Thus, HDL-C is considered a negative cardiac risk factor, unlike high triglycerides levels, which increase CVD risk (Steinberg and Cannon, 2016). It is reported that type 2 diabetes mellitus (T2DM) is associated with a twofold increase in CHD mortality in men and threefold in women (Steinberg and Cannon, 2016). It should be noted also that this factor is always linked to obesity and physical inactivity, which are lifestyle risk factors for CHD. Furthermore, individuals who are diagnosed with HTN have ASCVD five years earlier than individuals with no HTN. The risk of death from stroke, heart disease, or other vascular disease is doubled with each systolic blood pressure rise of 20 mmHg and each diastolic blood pressure rise of 10 mmHg. Also, meta-analyses have demonstrated that prehypertension is associated with an increased risk for CVD and mortality (Benjamin et al., 2017). Finally, *to*bacco smokers are at an increased risk of developing CHD. This predictor is the most significant preventable contributing factor. Smoking in a short term leads to platelet aggregation and oxygen supply reduction. In the long-term, smoking causes an increase in triglycerides (TG), a decrease in HDL-C, endothelial damage, elevation of inflammatory markers, and rise in cortisol secretion (Wakabayashi and Groschner, 2013).

Other CHD Predictors

Guidelines discuss other risk factors that should be considered when evaluating an individual at risk of ASCVD. High level of high-sensitivity C-reactive protein (hs-CRP), which is a biomarker of vascular inflammation, has been associated with increased risk of

Table 2 Parenteral antithrombotic agents used in acute coronary syndromes (ACCP, 2016a; Bradley and Hass, 2017; Garcia et al., 2012; Helms et al., 2006; Zeind and Carvalho, 2018)

Medication	*Heparin (UFH)*	*Enoxaparin*	*Fondaparinux*	*Cangrelor*
	Indirect thrombin inhibition—mediates decreased propagation of clot			*$P2Y_{12}$ antagonist*
Mechanisms of action	*Inhibits factor IIa and Xa*	*Inhibits factor Xa> IIa*	*Inhibits factor Xa> IIa*	
Dosing	**Fibrinolysis[a], NSTEMI/UA, or ischemia-guided therapy[b]:** • 60 unit/kg bolus (max 4000 units) + 12 units/kg/hr infusion (initial max 1000 units/hr), titrated to therapeutic aPTT for 48 h or until revascularization **PCI with planned GPI:** • 50–70 units/kg IV bolus to achieve therapeutic ACT **PCI without planned GPI:** • 70–100 units/kg IV bolus to achieve therapeutic ACT	**Fibrinolysis:** • ≤75 yr: 30 mg IV bolus then 15 min later 1 mg/kg SC q12hr (max 100 mg for first two doses, give first dose with initial IV dose) • >75 yr:No bolus, 0.75 mg/kg SC q12hr (max 75 mg for first two doses) • Duration is for index hospitalization up to 8 days, or until revascularization **NSTEMI/UA/ischemia-guided therapy:** • 1 mg/kg SC q12hr for duration of hospitalization or until revascularization Primary **PCI:** • 0.5–0.75 mg/kg IV bolus if no anticoagulation previously 0.3 mg/kg IV if last SC dose was > 8 hr before PCI, or only one SC dose given	**Fibrinolysis:** • 2.5 mgIV × 1,then 2.5 mg SC daily starting the next day for index hospitalization up to 8 days or until revascularization **NSTEMI/UA /ischemia- guided therapy:** • 2.5 mg SC daily for duration of hospitalization or until revascularization **PCI:** • Not recommended without additional anticoagulant with anti-II activity	**PCI:** • 30 μg/kg IV bolus, 4 μg/kg/min infusion for at least 2 hr
Recovery of platelet function	N/A	N/A	N/A	Within 1 hr of discontinuation
Elimination	Hepatic and reticuloendothelial system	Renal	Renal	58% renal and 35% in feces inactive metabolite
Monitoring	aPTT, anti-Xa, and/or ACT (200–250 s during PCI with GPI or 250–300 s without GPI), Hgb, Hct, Plt, bleeding	Renal function, Hgb, Hct, Plt, anti-Xa (as indicated)	Renal function, Hgb, Hct, Plt, SrCr	Bleeding
Clinical pearls	• Cannot be used in patients with a history/suspicion of HIT	• Cannot be used in patients with history of HIT • If CrCl < 30 mL/ minute/1.73 m^2, 1 mg/kg SC daily	• Avoid if CrCl < 30 mL/minute/1.73 m^2 • Should not be used as a sole anticoagulant for PCI	• Must be loaded with oral $P2Y_{12}$ antagonist on transition off the infusion

Mechanisms of Action	Direct thrombin (II) inhibitor	GP IIb/IIIa inhibitor		
Dosing	• ACS: 0.15–2 mg/kg/hr infusion, titrated to aPTT goal • PCI: 0.75 mg/kgIV bolus + 1.75 mg/ kg/hr infusion	• PCI: 0.25 mg/kg IV/IC bolus, followed by 0.125 μg/ kg/min (max 10 μg/min) for 12 hr	• ACS: of uncertain benefit in patients adequately pretreated with a P2Y12 antagonist; single bolus used as in PCI • PCI: 180 μg/kg IV bolus (max 22.6 mg) × 2 (10 min apart) for PCI, followed by 2 μg/kg/min (max 15 mg/hr) infusion for 18–24 hr	• ACS: 0.4 μg/kg/minute for 30 min, then 0.1 μg/kg/ minute for 18–72 h • PCI: 25 μg/kg IV bolus followed by 0.15 μg/kg/min for 18–24 h
Recovery of platelet function	N/A	Within 24–48 h of discontinuation	Within 6–8 h of discontinuation	Within 4–8 h of discontinuation
Elimination	80% plasma proteolysis, 20% renal	Proteolytic cleavage	Renal	Renal
Monitoring	PTT and/or ACT as indicated (200–250 s during procedure), renal function, Hgb, Hct	Bleeding, Hgb, Hct, Plt, aPTT, PTT	Renal function, bleeding, PT/aPTT (maintain aPTT between 50 and 70 s unless PCI is to be performed), ACT with PCI (200–300 s during PCI)	Bleeding, Hgb, Hct, Plt,
Clinical pearls	• If CrCl $<$ 30 mL/ minute/1.73 m^2, reduce infusion to 1 mg/kg/h • If on hemodialysis, reduce infusion to 0.25 mg/kg/h • Can be used in patients with/without history of HIT	• Not recommended in ACS without PCI • Murine monoclonal antibody—may produce antigenicity	• If CrCl $<$50 mL/min Reduce infusion to 1 μg/kg/min • Contraindicated in ESRD	• If CrCl $<$ 60 mL/min/1.73 m^2, reduce infusion to 0.075 μg/kg/min

NSTEMI, non-ST-segment elevation acute coronary syndrome; UA, unstable angina; PCI, percutaneous coronary intervention; GPI, glycoprotein IIb/IIIa inhibitors; ACT, activated clotting times; S, second; Hgb, hemoglobin; Hct, hematocrit; Plt, platelet; HIT, heparin-induced thrombocytopenia; SrCr, serum creatinine; CrCl, creatinine clearance, PPT, prothrombin time; ACT, activated clotting times; S, second; Hgb, hemoglobin; Hct, hematocrit; Plt, platelet; HIT, heparin-induced thrombocytopenia; SrCr, serum creatinine; CrCl, creatinine clearance.

[a]Fibrinolytics preferred when PCI cannot be performed within 120 minutes of first medical contact (class I). Door-to-needle time less than 30 min. Those who receive fibrinolytic therapy should receive anticoagulation after fibrinolysis for at least 48 h with IV UFH or IV/ SC enoxaparin during hospitalization, up to 8 days (preferred, selected patients), or IV/SC fondaparinux during hospitalization, up to 8 days.

[b]Ischemia-guided therapy seeks to avoid the routine early use of invasive procedures unless patients experience refractory or recurrent ischemic symptoms or develop hemodynamic instability. Recommended for patients with a low-risk score (TIMI 0 or 1, GRACE less than 109).

CHD, and it is a strong predictor for first CV events (Steinberg and Cannon, 2016). The threshold for hs-CRP to be considered as risk discriminator is when it is more than or equal to 2.0 mg/L (Stone et al., 2014). Another risk factor is coronary artery calcium (CAC) score. Stone et al. (2013) concluded that measuring CAC was a useful approach for individuals at intermediate risk of CHD. Moreover, ankle-brachial index and albuminuria may help in screening patients at risk of ASCVD. However, they are weakly suggested as alternative risk stratifications.

Early Identification of At-risk Individuals and their Assessments

There are several risk calculators that are used to estimate ASCVD in adults including Framingham Risk Calculator, Reynolds Risk Score, ACC/AHA Pooled Cohort Equation Risk Calculator, Multi-Ethnic Study of Atherosclerosis (MESA) 10-year ASCVD Risk with Coronary Artery Calcification Calculator, and the United Kingdom Prospective Diabetes Study (UKPDS) Risk Engine. Each calculator focuses on a specific outcome. For example, the 10-year and lifetime ASCVD risk can be estimated when using ACC/AHA 2013 Pooled Cohort Calculator. In 2017, the American Association of Clinical Endocrinologists (AACE) published a table for key cardiovascular risk scoring tools, which summarizes the Framingham, MESA, Reynolds, and UKPDS ASCVD risk calculators (refer to AACE 2017 guidelines Page 7-8, for further information). These are useful tools that can be used in primary care for risk assessment and management.

Primary Prevention Strategies for CHD: What can be Done in Primary Care?

Health-care providers (HCPs) at primary care settings should assume their role in primary prevention of CHD and other CVD. They shall discuss with their patients the importance of managing existing risk factors after stratifying their risk. Screened individuals may be eligible for statin, aspirin, and other medical therapies and/or lifestyle modifications.

Statins

Statins have been proposed as the primary pharmacologic agents to achieve target LDL-C goals on the basis of morbidity and mortality outcome trials (AACE, 2017). A systematic review that included 19 RCTs showed that patients who received statins compared to those who did not, experienced fewer MI (RR 5 0.64, 95% CI: 0.57–0.71), ischemic stroke (RR 5 0.71, 95% CI: 0.62–0.82), and cardiovascular mortality (RR 5 0.69, 95% CI: 0.54–0.88). Regarding its safety with lifelong use, statins are remarkably safe when used for primary prevention. Despite the fact that statins do increase the risk of T2DM, a meta-analysis that focused on primary prevention trials did not find a statistically significant increase in the risk of diabetes (Kazi et al., 2017). AACE guidelines (2017) recommended that for very high-risk individual (based on risk estimators) with diabetes who also has at least one risk factor, should be treated with statins to target a reduced LDL-C treatment goal of <70 mg/dL and for extreme-risk individuals, statins is recommended to target an even lower LDL-C treatment goal of <55 mg/dL.

Aspirin

Aspirin use has been encouraged by the American Diabetes Association (2016) for all patients with diabetes who have Framingham score of 10% 10-year risk of CVD. The 2016 European Society of Cardiology (ESC) guidelines and the European Association for the Study of Diabetes (EASD) are against the use of aspirin for primary prevention in patients with diabetes who have no overt CVD (Piepoli et al., 2016; Ryden et al., 2013). Generally, aspirin benefit contributed to a 23% proportional reduction in nonfatal MI in primary prevention. HCPs need to weigh the ischemic and bleeding risk before starting patients on aspirin. When starting aspirin for primary CVD prevention, a low dose (75–100 mg) is recommended (Leggio et al., 2018).

Lifestyle Interventions

Physical inactivity is an important contributor to CHD. When regular physical activity is practiced, blood pressure will decrease and the likelihood of obesity will diminish. Guidelines recommend a steady activity of 30 min for 5 days or more per week. Such activities can include walking, swimming, cycling, and dancing. Also, patients with body mass index (BMI) more than 25 kg/m^2 should be advised to enroll in weight management program and follow a healthy diet so that a target of 5–10 kg weight loss over 3 months is achieved (Blenkinsopp et al., 2014).

Blood Pressure Control

In patients with overt or latent CHD, there are no clinical studies that concluded about the most appropriate target for blood pressure (Vlodaver et al., 2014). Guidelines recommend aggressive blood pressure-lowering approach for patients with HTN. A blood pressure target of <130/80 mmHg is recommended in individuals with diabetes mellitus, chronic kidney disease, CAD risk equivalents, peripheral arterial disease, or abdominal aortic aneurysm (Rosendorff et al., 2007).

Smoking Cessation

Smoking cessation reduces the risk of CVD. HCPs should determine the readiness of patients to quit smoking. Based on their willingness, education, counseling, social support referral, and initiation of the pharmacotherapy shall be determined. Nicotine replacement therapy, bupropion, and varenicline are examples of drugs that can be used (Vlodaver et al., 2014).

Long-term Management of Coronary Artery Disease

After the diagnosis of CAD and the treatment of the acute phase, the next level of treatments is directed toward prevention of future cardiovascular events and death (secondary prevention). The treatment strategy for secondary prevention of CAD targets the multiple modifiable risk factors using multiple approaches. These treatment approaches include medications (pharmacological) and lifestyle changes (nonpharmacological) (Smith et al., 2011). The pharmacological management involves the use of multiple medications from different pharmacological classes, which also target some of the risk factors associated with the CAD process such as HTN and dyslipidemia. The core classes of medications with proven benefit for secondary prevention of CAD include antiplatelet agents (e.g., aspirin and clopidogrel), statins (e.g., atorvastatin), β-blockers (e.g., carvedilol), and angiotensin-converting enzyme inhibitors (ACEIs) (e.g., lisinopril), or angiotensin receptor blockers (ARBs) (e.g., losartan). Other medications include aldosterone receptor blockers (e.g., spironolactone) and vaccinations (e.g., influenza vaccine) (Smith et al., 2011). Lifestyle changes improve the modifiable risk factors associated with CAD and it includes smoking cessation, engaging in physical activity, eating healthy diets, and maintaining healthy weight.

Pharmacologic Agents for Secondary Prevention of Coronary Artery Disease

Antiplatelet Agents

Low-dose aspirin (75–100 mg) is an antiplatelet agent that is recommended to be taken for long-term after CAD for secondary prevention of future CV events (Baigent et al., 2009). Evidence has not shown the benefit of high dose of aspirin (162–325 mg) over the low dose in preventing a future CAD. However, the low-dose aspirin is relatively safer as it is associated with lower incidence of gastrointestinal (GI) bleeding. For patients who are unable to tolerate low-dose aspirin, clopidogrel 75 mg/day is recommended as the long-term antiplatelet agent (Ibanez et al., 2017).

For patients who undergo PCI with stent placement, up to 12 months (6–12 months) of a second antiplatelet agent ($P2Y_{12}$ inhibitor such as clopidogrel, prasugrel, or ticagrelor) is recommended to be administered concomitantly with aspirin (Ibanez et al., 2017). The shorter duration (1–6 months) of DAPT of aspirin and $P2Y_{12}$ inhibitor in earlier guidelines was based on the type of stent (BMS vs. DES) implanted. The use of longer duration of $P2Y_{12}$ inhibitor beyond 12 months (i.e., 18–48 months) for outcomes such as secondary prevention of cardiac events, mortality reduction, and prevention of stent thrombosis have been studied, leading to the approval for the use of $P2Y_{12}$ inhibitor beyond 12 months for prevention of myocardial infarction and late stent thrombosis, but with a trade-off of significant GI bleeding (Bittl et al., 2016; Bonaca et al., 2015; Ibanez et al., 2017; Mauri et al., 2014).

In terms of the mortality benefits of the longer duration of DAPT, the "2016 ACC/AHA Guideline Focused Update on Duration of Dual Antiplatelet Therapy in Patients With Coronary Artery Disease" suggests that prolonged DAPT does not offer significant all-cause mortality benefit (Levine et al., 2016a, 2016b). For patients with history of CAD, this guideline has a Class I recommendation for the 6–12 months DAPT and a Class II recommendation for DAPT administered beyond 12 months (Levine et al., 2016a, 2016b). It also recommends lower daily doses of aspirin (75–100 mg/day) when DAPT is used (Levine et al., 2016a, 2016b).

The key to reducing the bleeding risk associated with the use of DAPT is to identify patients who are at increased risk of bleeding from DAPT. The factors associated with increased risk of bleeding include history of previous bleeding, oral anticoagulation, female gender, advanced age, CKD, diabetes mellitus, anemia, chronic steroid therapy, and nonsteroidal anti-inflammatory drug (NSAID) therapy (Levine et al., 2016a, 2016b). A risk score called DAPT score has been derived from a large DAPT study in patients who had received DAPT after stent implantation (Mauri et al., 2014). In this study by Mauri et al., 30 months of DAPT (longer duration DAPT) was compared to 12 months of DAPT (shorter duration) (Mauri et al., 2014). The DAPT score, which is based on ischemic and bleeding risk factors, can help in decision making regarding which patients would benefit from a longer duration of DAPT vs. short DAPT duration. A DAPT score ≥ 2 is associated with a favorable benefit/risk ratio for prolonged DAPT. However, DAPT score of <2 is associated with an unfavorable benefit/risk ratio (Yeh et al., 2016). The factors used to calculate the DAPT score and the respective points allocated to each factor are presented in **Table 3**.

Per the "2016 ACC/AHA Guideline Focused Update on Duration of Dual Antiplatelet Therapy in Patients With Coronary Artery Disease," the addition of a proton pump inhibitors (PPI) to DAPT should be avoided in patients with low risk of GI bleeding. However, in those with a history of GI bleeding, PPI should be added to DAPT. Also, patients at high risk of bleeding (e.g., concomitant use of anticoagulants, NSAIDs or oral steroids) will benefit from the use of PPIs (Levine et al., 2016a, 2016b).

Statins

Statins are initiated in all patients with established CAD who are 75 years or younger irrespective of their baseline LDL-C levels for secondary prevention (Stone et al., 2014). For those who can tolerate high-intensity statin therapy (e.g., atorvastatin 40–80 mg/day or rosuvastatin 20–40 mg/day) is the standard (Stone et al., 2014). If the high-intensity statin therapy cannot be tolerated, then the alternative option is the use of moderate-intensity statin (e.g., simvastatin 20–40 mg/day, pitavastatin 2–4 mg/day, pravastatin 40–80 mg/day, lovastatin 40 mg/day, atorvastatin 10–20 mg/day, or rosuvastatin 5–10 mg/day) (Stone et al., 2014). For patients with established CAD, there is evidence that the intensive statin therapy may be more effective in preventing CAD and death than the moderate-intensity statin therapy (Cannon et al., 2004; LaRosa et al., 2005; Pedersen et al., 2005).

Table 3 Factors used to calculate the score used to stratify patients to shorter vs. longer duration of DAPT

Variable	*Points*
Age ≥75 years	−2
Age 65 to <75 years	−1
Age <65 years	0
Current cigarette smoker	1
Diabetes mellitus	1
MI at presentation	1
Prior PCI or prior MI	1
Stent diameter <3 mm	1
Paclitaxel-eluting stent	1
CHF or LVEF <30%	2
Vein graft PCI	2

CHF, Congestive heart failure; *DAPT*, dual antiplatelet therapy; *LVEF*, left ventricular ejection fraction; *MI*, myocardial infarction; *PCI*, percutaneous coronary intervention.

Note: A total score of ≥2 is associated with a favorable benefit/risk ratio for prolonged DAPT; a total score of <2 is associated with an unfavorable benefit/risk ratio for prolonged DAPT.

Table adapted from Yeh et al. (2016)

β-Blockers

The use of β-blockers after CAD has two benefits. First, it is associated with prevention of future CAD (secondary prevention) and reduction of cardiovascular mortality (Freemantle et al., 1999; Hall and Lorenc, 2010). Second, it helps to manage BP, which is an established risk factor for CAD. The goal BP in patients with established CAD is less than 140/90 mmHg (James et al., 2014a, 2014b). β-Blockers are recommended for all patients with CAD unless contraindicated (Smith et al., 2011). In patients with CAD and normal LV function, β-blockers started after diagnosis is recommended to be continued for three years (Smith et al., 2011).

However, in CAD patients with LV dysfunction (i.e., ejection fraction (EF) ≤40%), specific β-blockers have been shown to reduce mortality. The β-blockers shown to reduce mortality in CAD patients with LV dysfunction are bisoprolol, carvedilol, and metoprolol succinate (Domanski et al., 2003; Packer et al., 1996; Poole-Wilson et al., 2003).

Angiotensin-converting Enzyme Inhibitors/Angiotensin Receptor Blockers

ACEIs are recommended to be given indefinitely to all CAD patients with LVEF ≤40% as it improves cardiovascular outcomes (Smith et al., 2011). They are also the recommended first-line therapy for CAD patients with HTN who require BP reduction (goal <140/90 mmHg), diabetes, or CKD (Smith et al., 2011). In CAD patients who are unable to tolerate ACEIs, ARBs are used. A meta-analysis of randomized trials published in 2017 showed that in CAD patients without HF, the benefit of ACEIs in reducing all-cause mortality, reducing cardiovascular mortality, and reducing MI was significant when compared to placebo, but not active controls (Bangalore et al., 2017). Based on Bangalore et al., it may be therefore beneficial to give ACEIs to only CAD patients with LV dysfunction if they do not have comorbid HTN, diabetes, or CKD, even though there is evidence that ACEI blockade with ramipril reduces death and cardiovascular events in patients with history of CAD who may not have these comorbidities (Yusuf et al., 2000).

Others

Aldosterone receptor antagonists

Per the "AHA/ACCF Secondary Prevention and Risk Reduction Therapy for Patients With Coronary and Other Atherosclerotic Vascular Disease: 2011 Update," aldosterone receptor blockers (e.g., spironolactone, eplerenone) are recommended for patients with established CAD who are on therapeutic doses of ACEIs and β-blockers, have LVEF ≤40%, and have either diabetes or HF (Smith et al., 2011). The use of aldosterone receptor blockers (eplerenone 50 mg/day) in those patients on optimal therapy after acute MI significantly reduces morbidity and mortality (Pitt et al., 2003; Zannad et al., 2011).

Vaccines

Annual influenza vaccine is recommended for all Individuals with established CAD irrespective of their age (Smith et al., 2011). Even in younger individuals less than 65 years old with high-risk medical conditions, it has been shown, that influenza vaccination significantly reduces hospitalization from acute respiratory diseases and CVD (CDC, 2017; Hak et al., 2005). Some randomized clinical studies have shown significant mortality benefit (all-cause mortality and cardiovascular mortality) at 12 months in individuals with CAD when they are vaccinated with the seasonal influenza vaccine (Ciszewski et al., 2008; Gurfinkel et al., 2004). However, there is a randomized trial in individuals with established CAD, which did not show significant mortality benefit even though the results showed significant reduction in cardiovascular events (Phrommintikul et al., 2011).

Nonpharmacologic Management for Secondary Prevention of Coronary Artery Disease

Smoking Cessation

Smoking cessation is probably the most important lifestyle modification when managing established CAD. There is a mortality benefit (up to 36% reduction in all-cause mortality) of stopping smoking, hence the need to enrol patients with CAD in smoking cessation programs to aid them to quit smoking (Critchley and Capewell, 2003). Also in patients with established CAD who continue to smoke, there is evidence of increased risk of recurrent coronary events (Rea et al., 2002). However, upon quitting smoking, this risk is reduced to the level of nonsmokers within 3 years (Rea et al., 2002). It is therefore recommended that at each clinic visit of a patient with CAD, smoking status is assessed using the "5 A's" approach to smoking intervention (Siu, 2015; Smith et al., 2011).

Physical Activity

Inadequate physical activity is a risk factor for CAD. But, there are multiple benefits of physical activity which include improving the other CAD risk factors such as LDL-C, HDL-C, weight, and BP. Physical activity include various activities such as walking, running, swimming, gardening, cleaning, and resistance exercises. Most organizations have guidelines that recommend 30 min of physical activity most days of the week. For patients with established CAD, physical activity should be recommended as tolerated after a thorough assessment due to potential limitation of physical activity as a result of CAD (Smith et al., 2011).

Healthy Diet

Healthy diet encompasses the consumption of diet from various food groups such as fruits, vegetables, legumes, whole grains and nuts, and fish and lean meat. In addition, the intake of foods such as red meat, non-vegetable oils/saturated fats, processed foods, sugary drinks, and high-calorie foods should be limited (Eckel et al., 2014). Different diet plans such as the Dietary Approaches to Stopping Hypertension (DASH) diet include foods from the various healthy food groups.

Weight Management

An added advantage of the lifestyle changes (i.e., diet and physical activity) is weight management. Being overweight with a BMI of 25.0–29.9 kg/m^2 or obese (BMI ≥30 kg/m^2) are risk factors for CVD. The 2011 AHA/ACCF guideline on secondary prevention and risk reduction therapy for patients with coronary and other atherosclerotic vascular disease recommends a healthy weight of BMI 18.5–24.9 kg/m^2. The initial goal of weight loss for patients with high BMI is to lose 5%–10% of body weight over 3–6 months (Smith et al., 2011). The loss of 5%–10% of body weight provides cardiovascular protection.

Blood Pressure Management

The nonpharmacologic management of BP in established CAD include the use of low sodium diet (2400 mg/day or less), DASH diet, adequate physical activity, limiting alcohol consumption (2 drinks per day for adult males and 1 drink per day for adult females), and regular BP monitoring (Piepoli et al., 2016). The goal BP in patients with CAD is 140/90 mmHg (James et al., 2014a, 2014b).

Cholesterol Management

High levels of LDL-C and TG, as well as low levels of HDL-C, are risk factors for CAD collectively referred to as dyslipidemia (Jellinger et al., 2017a, 2017b). After a CAD diagnosis, dyslipidemia is managed with both medications and lifestyle changes. Lifestyle changes with diet and exercise reduce LDL-C and TG and increase HDL-C.

Dyslipidemia Management—New Updates

In 2013, a new guideline on the treatment of dyslipidemia by the ACC/AHA was published (Stone et al., 2013). That report changed the old standard of treating lipid disorders. The focus of treatment was not on the specific level of cholesterol as usual. It was mainly based on ASCVD risks. Thus, treating individuals at specific LDL-C level was no longer recommended. The guidelines have listed four statin benefit groups as follows: individuals with clinical ASCVD, individuals with primary elevations of LDL-C >190 mg/dL, individuals 40–75 years of age with diabetes and LDL-C 70 to 189 mg/dL without clinical ASCVD, and individuals without clinical ASCVD or diabetes who are 40–75 years of age and have LDL-C 70 to 189 mg/dL and an estimated 10-year ASCVD risk of more than or equal to 7.5%. These individuals can be identified using the risk estimators discussed in "Primary Prevention of Coronary Heart Diseases" section of the chapter. Later on, American Association of Clinical Endocrinologists (AACE) 2017 Guidelines were published and the treatment goals for dyslipidemia were suggested to be personalized according to risk levels. **Table 4** indicates the risk category and the treatment goals for each group (Jellinger et al., 2017a, 2017b).

Patients with familial hypercholesterolemia should receive treatment for reducing LDL-C levels by 50% from baseline. For other lipid parameters, total cholesterol is recommended to be less than 200 mg/dL, HDL-C should be greater than 40 mg/dL. A non–HDL-C goal to be 30 mg/dL higher than the individual's specific LDL-C goal is recommended and for 25 mg/dL higher for those at extreme risk and needs to be less than 150 mg/dL. In order to achieve these targets, it is recommended to have a comprehensive strategy that includes modifying risk factors, treating metabolic abnormalities, and use of pharmacotherapy. Statins are recommended as the primary pharmacologic agent among all lipid-lowering agents. Fibrates are recommended for

Table 4 AACE 2017 Guidelines' ASCVD risk categories and LDL-C treatment goals

		Treatment goals		
Risk category	*Risk factors/10-year risk*	*LDL-C (mg/dL)*	*Non-HDL-C (mg/dL)*	*Apo B (mg/dL)*
Extreme risk	• Progressive ASCVD including unstable angina in individuals after achieving an LDL-C <70 mg/dL • Established clinical cardiovascular disease in individuals with DM, stage 3 or 4 CKD, or HeFH • History of premature ASCVD (<55 male, <65 female)	<55	<80	<70
Very high risk	• Established or recent hospitalization for ACS, coronary, carotid, or peripheral vascular disease, 10-year risk >20% • DM or stage 3 or 4 CKD with 1 or more risk factor(s) • HeFH	<70	<100	<80
High risk	• ≥2 risk factors and 10-year risk 10%–20% • DM or stage 3 or 4 CKD with no other risk factors	<100	<130	<90
Moderate risk	≤2 risk factors and 10-year risk <10%	<100	<130	<90
Low risk	0 risk factors	<130	<160	NR

ASCVD, atherosclerotic cardiovascular disease; CKD, chronic kidney disease; HeFH, heterozygous familial hypercholesterolemia; ACS, acute coronary syndrome.

severe hypertriglyceridemia. The use of combination therapy can be considered when monotherapy does not achieve specific therapeutic goal.

Pharmacological Management of Dyslipidemia

Statins

Statins work by inhibiting cholesterol synthesis by reducing the conversion of HMG-CoA to mevalonate and increasing the number of hepatic LDL receptors to enhance the uptake and catabolism of LDL. They are considered the most potent LDL-lowering agents. However, they have a less pronounced effect on TG and HDL-C (Urteaga, 2013). Common side effects of statins are myalgia, myositis, and GI upset. Myopathy/rhabdomyolysis occurs in rare cases. Hepatotoxicity occurs in less than 0.3%, thus liver function test prior to therapy is indicated (Martin and Talbert, 2013). A drug–drug interaction may occur potentially between some statins and CYP450 3A4 inhibitors, protease inhibitors, cyclosporine, and warfarin (Jellinger et al., 2017a, 2017b).

Fibrates

Fibric acid derivatives (fibrates), which include gemfibrozil, fenofibrate, and fenofibric acid, act by the activation of peroxisome proliferator-activated receptor (PPAR-α) that increase lipoprotein lipase activity and reduces secretion of very low-density lipoprotein (VLDL) from the liver (Urteaga, 2013). Primarily, fibrates decrease TG by 20%–35% and increase HDL-C by 6%–18%. However, fenofibrate may reduce TC and LDL-C by 20%–25% (Jellinger et al., 2017a, 2017b). Common adverse effects of fibrates include abdominal pain, indigestion, and acute appendicitis. Rarely, they may cause a potential reduction in renal function, hepatotoxicity, myopathy, rhabdomyolysis, and cholelithiasis (Martin and Talbert, 2013).

Bile Acid Sequestrates

Cholestyramine, colestipol, colesevelam are bile acid sequestrants that act by binding to bile acids resulting in resin–bile acid complex excretion in feces. This results in a compensatory conversion of hepatic cholesterol to bile, thus depleting hepatic stores and resulting in upregulation of LDL receptors (Urteaga, 2013). They, primarily, reduce LDL-C by 15%–25%. Side effects of this class include constipation, abdominal pain, flatulence, and nausea. Rarely, they cause steatorrhea. Serious but rare side effects such as fecal impaction, intestinal obstruction, fat-soluble vitamin deficiency (vitamins A, D, and K), and osteoporosis on long-term use may occur (Martin and Talbert, 2013).

Niacin

Niacin or nicotinic acid acts by decreasing hepatic synthesis of LDL-C and VLDL-C. Niacin reduces LDL-C by 10%–25%, reduces TG by 20%–30%, and increases HDL-C 10%–35%. Side effects of niacin include skin flushing, pruritus, abdominal discomfort, hepatotoxicity nausea, peptic ulcer, atrial fibrillation, and uric acid elevation (Jellinger et al., 2017a, 2017b).

Omega-3 Fatty Acid

Omega-3-acid ethyl esters and icosapent ethyl reduce TG by 27%–45%, TC by 7%–10%, VLDL-C by 20%–42%, apo B by 4%, and non-HDL-C by 8%–14% in individuals with severe hypertriglyceridemia. Icosapent ethyl reduces LDL-C by 5%, and omega-3-acid ethyl esters increase LDL-C by 45% (Jellinger et al., 2017a, 2017b). Omega-3 fatty acids work by reducing VLDL production.

They cause a reduction in all-cause and CV mortality post-MI. Dyspepsia, fishy taste, and burping are common side effects of Omega-3 fatty acid (Urteaga, 2013). Omega-3 fish oil may prolong bleeding time thus monitoring for coagulation status is advised.

Cholesterol Absorption Inhibitors

Ezetimibe inhibits intestinal absorption of exogenous cholesterol and biliary free cholesterol leading to LDL receptor upregulation. It reduces LDL-C by 10%–18%. When combined with statins, an additional reduction of LDL by 25% is achieved (Jellinger et al., 2017a, 2017b). However, there is no definitive evidence that it reduces coronary events in clinical trials (Kopin and Lowenstein, 2010). Diarrhea, arthralgia, and upper respiratory infection symptoms are common side effects of ezetimibe. Rare but serious adverse effects include myalgia, anaphylaxis, angioedema, pancreatitis, hepatitis, and cholelithiasis (Martin and Talbert, 2013).

New Therapies for Dyslipidemia

PCSK9 inhibitors (subcutaneous alirocumab and evolocumab, which is given every 2 weeks), cholesterol ester transfer protein inhibitors (torcetrapib, dalcetrapib), the antisense inhibitor of apoB synthesis (Mipomersen), and microsomal transfer protein inhibitors (Lomitapide) are new emerging therapies for treating dyslipidemia. As they are newly approved, ongoing trials to explore their definite outcomes are needed for better understanding of their roles in the management of dyslipidemia.

Nonpharmacological Management of Dyslipidemia

Lipid-lowering medications should be used adjunct with lifestyle modifications including healthy diet, regular exercises/physical activity (at least 30 min for 5 days per week), smoking cessation, and weight loss as needed. Details of these were previously discussed in the Long-Term Management of Coronary Artery Disease section.

The Role of Pharmacist in the Care and Management of Patients with Coronary Artery Disease

Pharmacist has an important role in the care and management of patients with CVDs in general and CAD in particular (Dunn et al., 2015; Swieczkowski et al., 2016; White, 2006). In general, the cardiology pharmacy practice area, which is considered a speciality in some countries such as North America, focuses on the delivery of pharmaceutical care (PC) for patients with CVDs (Dunn et al., 2015; White, 2006). Even in countries where the delivery of PC in cardiology setting is available but not considered as a specialization, the role of pharmacists is highly recognized and becoming increasingly important. This section highlights the role of pharmacist as an integral member of multidisciplinary CVD and CAD health-care teams and summarizes the evidence supporting the benefits of pharmacists' services in this setting.

Typically, pharmacists specialize in cardiology practice as part of interprofessional health-care teams in a variety of settings, including, but not limited to, coronary care units, cardiovascular intensive care units, medical wards, telemetry units, cardiac rehabilitation units, and other outpatient (ambulatory) clinics (White, 2006). Cardiology specialty ambulatory clinics focus on HTN, dyslipidemia, CHD, HF, anticoagulation, arrhythmias, and others. Some of the activities of cardiology pharmacists reported in the literature include disease state and medication therapy management; patient education and counseling on cardiovascular medications, adverse effects, and self-care skills; therapeutic drug monitoring; modification of medications based upon evidence-based guidelines and potential for adverse effects; medication reconciliation; dosage adjustments based on renal function, hepatic function, and potential drug interactions; pharmacokinetic monitoring; education and training of pharmacy students, medical students, and residents; and involvement in clinical, health services, basic, and translational research. A perspective paper by the American College of cardiology (ACC) (Dunn et al., 2015) has outlined that the clinical pharmacist may operate on a patient-specific, facility-specific, or global level to achieve optimal medication outcomes. Patient-specific services include, but are not limited to, patient education, drug interaction screening, drug therapy monitoring, drug and disease management, pharmacogenetics, drug information, pharmacokinetic–pharmacodynamic dosing, and collaborative practice agreements. On the other hand, facility-specific services include protocol, guideline, and policy development and review, research, core measure and quality improvement initiatives, formulary management and financial stewardship, and medication safety. Finally, global services include governmental and societal committees and agencies, societal guideline and policy development, legal consultations, and public health initiatives (Dunn et al., 2015).

Pharmacist role in various CVD settings has been highlighted in the literature and by professional health-care organizations such as the American College of Clinical Pharmacy (ACCP) and the ACC (Brush et al., 2015; Dunn et al., 2015; White, 2006; Wiggins, 2013). Collaborative (team-based) cardiovascular care, including the involvement of clinical pharmacists, can result in the delivery of high-quality care (Dunn et al., 2015). In 2015, the ACC issued a health policy statement on team-based care and the role of advanced practice providers in cardiovascular care (Brush et al., 2015). Furthermore, a perspectives paper from the Cardiovascular Team and Prevention Councils of the ACC provides pertinent information on the pharmacist's role, training, credentialing, and potential contribution in a variety of practice models (Dunn et al., 2015). The paper succinctly summarized several systematic reviews, highlighting the benefit of clinical pharmacy services in CVD settings. The report highlighted that clinical pharmacist has substantial roles in inpatient and ambulatory settings, mainly through optimization of drug therapy,

avoidance of adverse drug events, and transitional care activities focusing on medication reconciliation and patient education. However, barriers to implementation of such services identified include policy, legislation, and compensation barriers. Professional organizations and health-care institutions should support efforts to overcome these barriers, allowing pharmacists to deliver high-quality patient care to the full extent of their education and training.

It is worthwhile to note that pharmacists providing care to patients with CVDs can be generalists or specialists in the cardiology pharmacy practice area. The specialists possess unique knowledge, skills, and experience in the care of cardiovascular patients. As a prerequisite, pharmacists specializing in cardiology typically complete formal postgraduate residency training in cardiology practice settings (Dunn et al., 2015; Wiggins et al., 2013). They should have sound knowledge of the epidemiology and pathophysiology of CVDs; interpretation of laboratory and diagnostic procedures used in cardiology; pharmacotherapy of CVDs; advanced cardiac life support; application of pharmacokinetics, pharmacodynamics, and pharmacogenetics in cardiovascular care; evaluation of biomedical literature in cardiovascular pharmacotherapy; as well as systems and procedures designed to ensure medication safety. Pharmacist who do not have the opportunity to specialize in cardiology pharmacy practice can still provide care to patients with CVDs, but they must be competent in the knowledge areas listed above. Countries should develop formal and structured training programs to train competent pharmacists in the area of cardiology.

Evidence supports the role of the pharmacist as part of a multidisciplinary team caring for CVD patients (Peterson et al., 2008; White, 2006). Pharmacist care in cardiovascular ICU has been associated with economic benefits (White and Chow, 1998).The literature has reported the effect of pharmacist care on the management of major CVD risk factors and on secondary prevention of CAD with varying results. Here we summarized available systematic reviews and meta-analyses, which highlight the benefit of pharmacist care in CVD and CAD setting. A systematic review by Santschi et al. (2011) among adult outpatients with CVD risk factors documented significant reductions in blood pressure, cholesterol, and tobacco smoking. Equally, a systematic review by Altowaijri et al. (2013), involving 59 studies (45 RCTs), reported the clinical and economic effectiveness of pharmacist intervention in secondary prevention of CVDs. However, another systematic review in patients with CAD by Cai et al. (2013) concluded that pharmacist has a beneficial role in the care of patients with CAD, but the evidence supporting positive impacts on mortality and morbidity remains uncertain.

Furthermore, the impact of multidisciplinary health care on the outcomes of patients with ACS is well-established in the literature. There is evidence of benefits of interventions provided by pharmacists and other health-care providers in improving outcomes such as medication adherence, rehospitalization, and mortality, among patients post-ACS. Pharmaceutical care activities, including discharge counseling and education, medication reconciliation, and post-discharge follow-up and monitoring, have been shown to decrease adverse cardiovascular outcomes postdischarge (Ho et al., 2014; Peterson et al., 2012; Xavier et al., 2016). Varying models of care have been used in this setting. Particularly, pharmacists have been involved in the care of patients with ACS after hospital discharge either as part of multidisciplinary teams or as sole providers. In addition to traditional dispensing of medications, other activities performed by pharmacist in ACS setting include discharge patient education and counseling on medications, medication reconciliation, promoting self-care, and other PC interventions (Dunn et al., 2015; Wiggins et al., 2013). Nevertheless, there is paucity of evidence on the role of pharmacist care in this setting. Kang et al. (2016) conducted a systematic review with quantitative and qualitative meta-analysis to determine the impact of a pharmacist-involved care for patients with ACS and HF. Although all-cause hospitalization and performance measures such as prescription rates demonstrated improvement in the PC group, the strength of evidence for most of the outcomes was insufficient. This review concluded that the evidence of benefit of pharmacist care on patient-related outcomes was not conclusive. Similarly, a recent systematic review by El Hajj et al. (2018) has evaluated the impact of pharmacist care on readmission, mortality, emergency visits, and medication adherence among patients with ACS at or post-discharge. The authors concluded that there was a lack of adequate evidence regarding the effect of pharmacist care on emergency visits, hospitalization, readmission, and mortality in ACS patients. However, the reviewers pointed that the reviewed studies had several limitations that might have hindered the effectiveness of pharmacist care. Further research is warranted to determine the contribution of pharmacist care on tangible endpoints of CAD.

Furthermore, pharmacists have an important role in interdisciplinary cardiac rehabilitation teams. Although, a previous review by White and Anderson (2005) has reported that there is insufficient evidence about the effectiveness of the involvement of pharmacists in cardiac rehabilitation, but recent studies have found that pharmacists can play a vital role as part of an interdisciplinary cardiac rehabilitation team to ensure proper adherence to cardiac medications and patient safety through patient education and interventions (Packard et al., 2012). Pharmacists in cardiac rehabilitation provide medicines information and education to patients, and optimize drug therapy. Some studies have also reported economic benefits and improvement in quality of life as a result of the involvement of a pharmacist in cardiac rehabilitation (Anchah et al., 2017; Kammer, 2004).

Pharmacists providing care and/or specializing in cardiology pharmacy practice area have demonstrated tremendous benefits and value in improving health-care outcomes. Because of their expertise in pharmacotherapy, pharmacists have unique opportunity to function as part of interdisciplinary health-care teams to ensure medication safety and to improve health outcomes in patients with CVDs. Therefore, we recommend the inclusion of pharmacists as part of the interdisciplinary team caring for patients with CAD to improve quality of care and overall health outcomes. Professional health organizations, accreditation agencies, and academic institution should jointly design formal training programs to produce competent pharmacists in the area of cardiology pharmacy practice. We also recommend that more robust clinical studies should be designed to determine the effect of pharmacist care on the outcomes of patients with CAD in general.

Management of Cardiovascular Disorders and the Pharmacist's Role: Heart Failure

Alexandra (Sasha) Bennett, NSW Therapeutic Advisory Group, Sydney, NSW, Australia

Objectives

- To optimize pharmacist's skills and knowledge in the implementation of evidence-based pharmacotherapy in HF sufferers and strategies to overcome common barriers to optimal HF management.
- To improve pharmacist's knowledge and contribution in the nonpharmacological management of HF.
- To expand knowledge of pharmacists' roles and settings in which they may practice to improve HF patient's goals of therapy.

Take Home Messages

1. Despite identification of the means to significantly improve HF outcomes, the burden of HF is increasing with sufferers experiencing poor quality of life, frequent hospitalizations, and reduced survival.
2. HF with reduced ejection fraction has a good evidence base that guides pharmacological management and improves sufferers' outcomes.
3. There is good evidence that a structured multidisciplinary team approach improves a HF sufferer's outcomes.
4. HF patients commonly have comorbidities and experience polypharmacy, both of which require frequent review by multidisciplinary teams across the continuum of care.
5. Pharmacists have an important role to play in ensuring safe and effective dosing of HF medications, monitoring medication adherence, and reducing inappropriate polypharmacy.
6. As readily accessible health-care professionals, community pharmacists can assist HF sufferers' understanding and adherence to medicines and self-care management strategies.

Introduction to the Condition

Heart failure (HF) occurs when the heart is unable to pump sufficient blood to meet the body's requirements (or can only do so at an elevated intracardiac filling pressure). It is a complex clinical syndrome resulting from structural or functional cardiac disorders that impair the ability of the ventricle(s) to fill with and/or eject blood. HF is a multifactorial disease involving a number of organs and activation of a number of neurohormonal systems. No one drug can counteract all the adverse pathophysiological pathways.

Epidemiology

The prevalence of HF is approximately 1%–2% of the adult population in developed countries and is increasing (Ponikowski et al., 2016). Up to 2 in 1000 adults are diagnosed with HF each year. Its incidence increases with increasing age and at least 10% of over 70 years old have HF.

The burden of HF is increasing with sufferers experiencing poor quality of life, frequent hospitalizations, and reduced survival. Annual mortality rates vary between approximately 7% for stable HF patients to 17% for hospitalized HF patients (Fonarow et al., 2011).

HF is a common cause of hospitalization and death in older adults. Approximately 1% of all hospital admissions are due to HF, and it is the most common condition for which patients aged 65 or over are admitted to hospital. In addition, approximately 50% of HF patients will be readmitted to hospital within 6 months of their last admission. Up to two-thirds of hospitalizations are reported to be preventable. Most deaths in HF patients are cardiovascular either due to sudden death from arrhythmia or worsening HF. However the cause of hospitalizations is often for noncardiovascular reasons, and optimal management of comorbid conditions is an essential strategy to improve outcomes in HF patients.

Although heart transplant could be considered a cure, it provides no solution due to the scarcity of donor hearts and mechanical hearts, their expense, and the complexity of management accompanying such interventions.

Etiology

There are a number of conditions due to diseased myocardium, abnormal loading conditions, or arrhythmias that can lead to HF (Atherton et al., 2018; Ezekowitz et al., 2017; Ponikowski et al., 2016). The most common are ischemic heart disease, hypertension, and diabetes. Less common causes are nonischemic idiopathic dilated cardiomyopathy, valvular disease such as aortic stenosis, viral cardiomyopathy, and alcoholic cardiomyopathy. Illicit drugs such as cocaine and metamphetamine (Ecstasy'), anticancer therapies such as anthracyclines, antineoplastic antibodies (e.g., trastuzumab, pertuzumab), tyrosine kinase inhibitors (e.g., sunitinib, sorafenib), clozapine, and thiazolinediones may cause cardiomyopathies resulting in HF (Ezekowitz et al., 2017; Maxwell and Jenkins, 2011; Reed et al., 2014).

Types of HF: HF sufferers are generally classified into two groups: those with left ventricular systolic dysfunction, identified with a finding of an ejection fraction of less than 50% and those with preserved systolic function (i.e., having an ejection fraction of greater than 50%.) The former is commonly referred to as HF with reduced ejection fraction (HF-rEF) and the latter as HF with preserved ejection fraction (HF-pEF), also previously called diastolic HF.

Reports of the proportion of HF-pEF sufferers within the HF population vary between 30% and 70%. The characteristics of the HF-rEF and HF-pEF populations differ: compared to HF-rEF sufferers, HF-pEF sufferers tend to be older, more often women, and have a history of hypertension and atrial fibrillation (Ponikowski et al., 2016). Nevertheless, there is overlap between the populations, and it would be a mistake to jump to conclusions based on the age, gender, and clinical history of the HF patient.

Once diagnosed with HF, the prognosis is grim, with a survival rate less than many cancers, frequent episodes of hospitalization and poor quality of life accompanied by high costs of care (Stewart et al., 2001). Strategies that reduce the high HF hospitalization rates and support the increasing ambulatory care may have a profound effect on reducing economic and humanistic burdens.

Pathophysiology of HF With Reduced Ejection Fraction

The current concept of the pathophysiology of HF involves an unrelenting vicious cycle of neurohormonal activation and ventricular remodeling that leads to amplification of reduced cardiac output, further myocardial damage, arrhythmia potential, vasoconstriction, water and salt retention, and possibly other vascular structural and skeletal muscle changes.

The seminal event of HF is a loss of ventricular functionality resulting in reduced cardiac output. This seminal event may have a sudden onset such as after a myocardial infarct or a slow and subtle onset such as occurs after long-standing hypertension. At some point in time, the patient becomes symptomatic, and morbidity and mortality dramatically increase. Accompanying this transition into symptomatic HF is a marked increase in neurohormonal activity involving systems such as the sympathetic nervous system (SNS) and the renin–angiotensin–aldosterone system (RAAS) and other neurohormones such as natriuretic peptides and cytokines as well as a series of maladaptive changes within the myocardium, labeled "ventricular remodeling" (Mann, 2004). The neurohormonal activation and overexpression that result in a direct toxic effect on the cardiovascular system describe the "neurohormonal" model of HF (Katz, 2000; Mann, 2004; Packer, 1992). It provides an explanation as to why no one drug is sufficient to inhibit or control the multiple pathways that lead to and progress HF (Bleske, 2000; Mann, 2004).

Pathophysiology of HF With Preserved Ejection Fraction

The pathophysiology of HF-pEF is poorly understood. The symptoms of diastolic dysfunction relate to alterations in ventricular stiffness. Rather than a single distinct pathophysiological entity, it likely reflects a wide range of heterogeneous cardiovascular problems (Desai, 2007). The applicability of the "neurohormonal" model in HF-pEF is unclear. To date, none of the major clinical trials have identified therapies that improve survival, although beneficial effects on hospitalization have been reported (Ezekowitz et al., 2017; Ponikowski et al., 2016).

Clinical Presentation

HF is a clinical syndrome characterized by shortness of breath, fluid retention, and fatigue. Unfortunately, HF symptoms can be nonspecific, and diagnosis may be delayed. **Table 1** displays typical HF symptoms and signs.

Diagnosis

HF is the final consequence of the multitude of diseases that can affect the heart including ischemic heart disease, hypertension, and toxic or viral cardiomyopathies. The workup to diagnose HF includes identification of (1) the underlying cause of HF, (2) the precipitating cause for acute decompensation, (3) the predominant pathophysiology, (4) the presence of any reversible or treatable causes, (5) comorbidities, and (6) the goal(s) of treatment.

A number of national guidelines provide diagnostic algorithms (Atherton et al., 2018; Ezekowitz et al., 2017; Ponikowski et al., 2016; Yancy et al., 2013).

Echocardiography is the most useful tool for initial diagnosis and to guide subsequent management. It is able to provide information of the mechanism and severity of the underlying cardiac dysfunction. Echocardiography is often underutilized, and improving access to and use of echocardiography are important remediable measures that are required to improve HF patient outcomes (Krum et al., 2001).

HF presentations to hospitals may be as new-onset HF following an acute event such as myocardial infarct, occur more gradually following slow worsening of symptoms (over weeks to months) such as in dilated cardiomyopathy or may be an episode of decompensation in the chronic stable HF patient (Ponikowski et al., 2016). Occasionally, a patient may have HF due to a condition that could resolve completely such as acute viral myocarditis or tachycardiomyopathy. However, the vast majority of patients will

Table 1 Typical symptoms and signs of heart failure

Symptoms	*Signs*
Ankle swelling	Cognitive impairment/delirium[a]
Bloated feeling	Elevated jugular venous pressure
Breathlessness (usually with exertion)	Hepatomegaly
Confusion[a]	Nocturia
Cool extremities	Oliguria
Fatigue, increased time to recover postexercise	Peripheral edema (ankle, sacrum)
Nocturnal cough	Pulmonary crepitations
Orthopnea	Tachycardia
Paroxysmal nocturnal dyspnea	Third heart sound (gallop rhythm)
Palpitations	Weight gain (>2 kg/week)
Reduced exercise tolerance	Weight loss in advanced HF

[a]More common in elderly.

Developed with the special contribution of the Heart Failure Association (HFA) of the ESC. Eur. J. Heart Fail., 18, 891–975; Atherton et al., 2018)

experience a patient journey characterized by slow deterioration and chronic limitation with episodic exacerbations requiring emergency hospitalizations over 5–10 years and ending with a death that appears sudden and unexpected (Levenson et al., 2000; Lynn et al., 1997). Such patient journeys differ to those suffering incurable cancer or frailty and dementia. Prognosis determination is notoriously challenging in the HF patient.

There are a variety of International Classification Disease (ICD) codes for HF. ICD-10 coding and reporting should document the type (diastolic, systolic, or mixed) and acuity of heart failure. If these details are not specified, the code 150.9 Heart Failure is documented. Additional coding should indicate HF etiology.

Detection and Management of Precipitating Factors

The underlying precipitants should be considered during the workup of a HF patient and during any subsequent episodes of decompensation. There is often more than one precipitant. If the precipitants are not identified and managed, episodes of decompensation due to these precipitants are likely to reoccur. **Table 2** shows significant precipitating factors that may lead to HF decompensation and hospitalization.

Pharmacists in both hospital and community settings have an important role in identifying and managing medication-related precipitants. This includes recognizing medications that should be avoided; ensuring HF patients are up to date with influenza and pneumococcal immunization; and, monitoring adherence to evidence-based management and self-care strategies.

Common Comorbidities

The comorbidity burden is high in HF patients. Reasons include the fact that HF is the end condition of all heart disease, that HF predominantly affects the elderly, and that many of the risk factors, for example, smoking and obesity that have contributed to HF development may also cause other conditions such as chronic airways limitation and obstructive sleep apnoea. HF should not be considered an isolated condition. Conditions such as renal impairment, hepatic impairment, anemia, and cachexia should also be considered as they are common and negatively affect prognosis. Risk of hospitalization and potentially preventable hospitalizations are known to increase with the number of conditions such as CAL, renal failure, diabetes, and depression. HF itself and some HF therapies may lead to the development of other comorbidities such as arrhythmias, gout, thyroid disorders, and renal impairment. Some first-line therapies for HF may compromise the treatment of other comorbidities and vice versa. Comorbidities in the presence of HF have important ramifications for diagnosis of HF, polypharmacy, and self-care strategies. Consultation with generalist health-care professionals such as geriatricians and pharmacists may be useful during decision-making processes to ensure that proper consideration of comorbidities and their therapies is given. Awareness of a comorbidity's impact on HF management or vice versa has meant that HF-specific guidelines are now more likely to discuss the ways in which HF may change the usual management of common comorbidities (Ezekowitz et al., 2017; Ponikowski et al., 2016).

Table 2 Precipitating factors for worsening HF

Precipitating factor category	*Details*
Medical conditions	
	Arrhythmia including atrial fibrillation
	Infection
	Ischemia/infarction
	Anemia
	Pulmonary thromboembolism
	Chronic airways limitation
	Thyroid dysfunction
	Renal dysfunction
	Uncontrolled hypertension
Nonadherence	
	Medications
	Salt and fluid restriction
Concomitant medicines	
	Nonsteroidal anti-inflammatories including COX-2 inhibitors
	Corticosteroids
	Beta-blockers
	Nondihydropyridine calcium antagonists
	Class 1 antiarrhythmics
	Moxonidine
	Thiazolidinediones
	High-salt medications
Inadequate EBM prescription	
	Nonprescription of EBM
	Inappropriate reduction in dosing of EBM or diuretics
Other	
	Delay in seeking help
	Poor social support
	Poor continuity of care

EBM, Evidence-based medicine; includes ACE inhibitors and HF-specific beta-blockers in HF-rEF.

Developed with the special contribution of the Heart Failure Association (HFA) of the ESC. Eur. J. Heart Fail., 18, 891–975; Ezekowitz, J.A., O'Meara, E., McDonald, M.A., Abrams, H., Chan, M., Ducharme, A., Giannetti, N., Grzeslo, A., Hamilton, P.G., Heckman, G.A., Howlett, J.G., Koshman, S.L., Lepage, S., Mckelvie, R.S., Moe, G.W., Rajda, M., Swiggum, E., Virani, S.A., Zieroth, S., Al-Hesayen, A., Cohen-Solal, A., D'Astous, M., DE, S., Estrella-Holder, E., Fremes, S., Green, L., Haddad, H., Harkness, K., Hernandez, A.F., Kouz, S., Leblanc, M. H., Masoudi, F.A., Ross, H.J., Roussin, A., Sussex, B., 2017. 2017 Comprehensive Update of the Canadian Cardiovascular Society Guidelines for the Management of Heart Failure. Can. J. Cardiol., 33, 1342–1433;, Maxwell, C.B., Jenkins, A.T., 2011. Drug-induced heart failure. Am. J. Health-Syst. Pharm., 68, 1791–1804.; Reed, B.N., Rodgers, J.E., Sueta, C.A., 2014. Polypharmacy in heart failure: drugs to use and avoid. Heart Fail. Clin., 10, 577; Rich, M. W., Vinson, J.M., Sperry, J.C., Shah, A.S., Spinner, L.R., Chung, M.K., Davila-Roman, V., 1993. Prevention of readmission in elderly patients with congestive heart failure: results of a prospective, randomized pilot study. J. Gen. Intern. Med., 8, 585–590;, Tsuyuki, R.T., Mckelvie, R.S., Arnold, J.M., Avezum A, JR., Barretto, A.C., Carvalho, A.C., Isaac, D.L., Kitching, A. D., Piegas, L.S., Teo, K.K., Yusuf, S., 2001. Acute precipitants of congestive heart failure exacerbations. Arch. Intern. Med., 161, 2337–2342.

Polypharmacy increases the risk of adverse effects, drug interactions, medication errors, and costs. Both polypharmacy and number of chronic diseases have been implicated in falls risk (Hilmer et al., 2007). Pharmacists can identify inappropriate polypharmacy and also provide advice regarding regimen simplification such as use of once daily dosing medications or formulations.

Goals of Treatment

The major goals of HF therapy are to prolong survival, to reduce the need for hospitalization, and to improve patient quality of life including reduction of activity-limiting symptoms and adverse drug effects from medications. The priority these goals are given may vary between patients and may vary over time.

Pharmacological Management of the Condition

Pharmacotherapy is the mainstay of HF management supported by nonpharmacological management for the large majority of HF patients. There are gaps in the judicious, appropriate, safe, and effective use of medicines in HF and hence pharmacists can make an

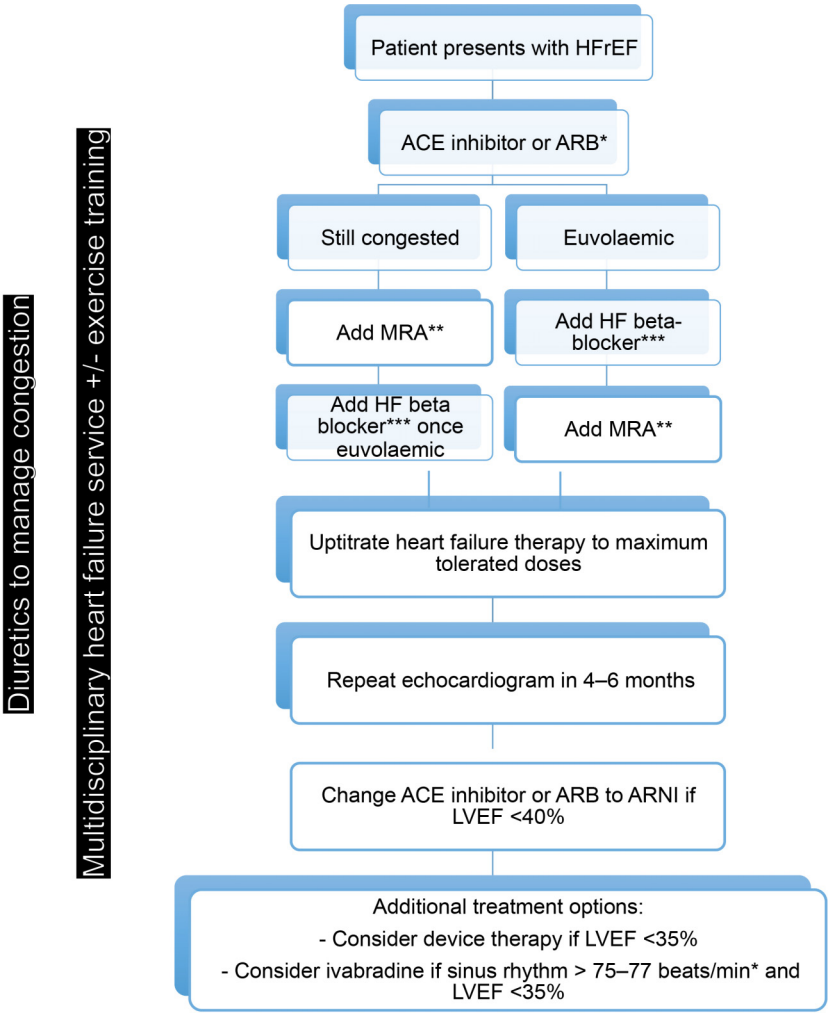

Figure 1 HFrEF management algorithm. *HF*, heart failure; *ACEI*, ACE inhibitor; *ARB*, angiotensin receptor blocker; *ARNI*, angiotensin receptor blocker-neprilsyin inhibitor; *LVEF*, left ventricular ejection fraction. *ARB only if ACEI contraindicated or not tolerated. **MRA contraindicated if serum potassium concentration is >5 mmol/L or creatinine clearance is <30 mL/min. *** HF beta-blockers= carvedilol, bisoprolol, metoprolol-modified release, or nebivilol.

important contribution to the management of HF in hospital and community settings. An understanding of the pathophysiology of HF provides an understanding of the mechanisms by which current HF pharmacological management is thought to exert its effect. The therapeutic management of acute decompensated HF (ADHF) will not be discussed, and readers are referred to the latest international HF guidelines for this information.

Pharmacotherapy in HF-rEF

Most of the drugs shown to improve outcomes in HF-rEF patients (improved survival and reduced hospitalizations) modulate neurohormonal systems. Major therapeutic targets are the RAAS and the SNS and more recently the natriuretic peptide system. Inhibitors of these systems, the angiotensin-converting enzyme (ACE) inhibitors, mineralocorticoid receptor antagonists (MRAs), and angiotensin receptor-neprilysin inhibitor (ARNI) and beta-blockers are recommended at various phases of the HF-rEF patient journey unless contraindicated or not tolerated (Atherton et al., 2018; Ezekowitz et al., 2017; Ponikowski et al., 2016; Yancy et al., 2013) (see **Fig. 1**, **Table 3**).

Other Drugs for HF-rEF

Other medications commonly used in HF-rEF patients include amiodarone, warfarin, and antiplatelet medications and relate to the causes or complications of HF. Apart from digoxin, amiodarone is the only antiarrhythmic, which does not have a negative

Table 3 Medicines used in chronic HF with reduced ejection fraction (HF-rEF)

Drug class/medicine and examples	*Dosing strategy*	*Benefits*	*Target HF-rEF population*	*Comments*
Renin-angiotensin-aldosterone system (RAAS) inhibitors				
ACE inhibitors (ACE-Is): perindopril, enalapril, lisinopril	Start low and uptitrate to target dose, if tolerated as reduced HF hospitalization with higher dose (Packer et al., 1999)	Improves survival; reduces HF hospitalizations; improved ejection fraction; improved symptoms, and exercise tolerance (McMurray, 2011)	Indicated for mild, moderate, or severe HF-rEF and asymptomatic LVSD to delay onset of HF.	Dizziness and renal impairment more common at higher doses but do not usually require discontinuation. Also indicated in patients with systolic dysfunction after myocardial infarct. May commence BBs prior to reaching target doses of ACE-I (or ARB). Gaps in current practice include uptitration to target doses and to a lesser extent, prescription of ACE-Is. (Maggioni et al., 2013; Newton et al., 2016)
Angiotensin receptor blockers (ARBs): candesartan, valsartan	Start low and uptitrate to target dose, if tolerated as reduced HF hospitalization with higher dose (Konstam et al., 2009)	Decreases cardiovascular mortality and HF hospitalizations (Cohn et al., 2001; Granger et al., 2005)	Indicated for mild, moderate, or severe HF-rEF in those who cannot tolerate ACE-Is (Pitt et al., 1999) due to cough or angioedema (NB. cautious use in angioedema patients).	Combination of ACE-I and ARB is generally discouraged due to increased risk of adverse effects such as hypotension, hyperkalemia and renal dysfunction. (McMurray, 2006)
Mineralocorticoid receptor antagonists (MRAs): spironolactone, eplerenone	Commence low dose (25 mg daily) and increase to 500 mg after 4–8 weeks.	Improves survival, reduces HF hospitalization (Pitt et al., 1999) (Solomon et al., 2016; Zannad et al., 2011)	Indicated for moderate to severe HF-rEF and consider in mild HF-rEF	May be commenced prior to BB if the patient remains congested despite ACE-I/ARB and diuretic therapy. (Atherton et al., 2018) Requires vigilant electrolyte and renal function monitoring, especially if also taking ACE-I/ARB and/or renal impairment present (Juurlink et al., 2004) Switch to eplerenone if gynecomastia occurs with spironolactone.
ARNI: sacubitril/valsartan	Start low-moderate dose and uptitrate every 2–4 weeks to target dose, if tolerated.	Improves survival, reduces hospitalization (McMurray et al., 2014)	Replaces ACE-I/ARB if persistent HF-rEF with LVEF $<$ 40% despite optimized use of ACE-I/ARB and BB +/− MRA for 3–6 months.	New drug class—sacubitril, a prodrug for a neprilysin inhibitor, promotes the activity of natriuretic peptides and bradykinin leading to vasodilation and sodium and fluid elimination. PARADIGM study demonstrated improved outcomes with sacubitril/valsartan compared to enalapril (McMurray et al., 2014) Must cease ACE-I/ARB at least 36 h prior to ARNI initiation (as increased risk of angioedema). Adverse effects include angioedema, hypotension, hyperkalemia, and renal impairment.
Beta-blockers				
Beta-blockers: carvedilol, bisoprolol, modified release metoprolol, nebivolol	Start low and uptitrate to target dose, if tolerated. Initiate and uptitrate when the patient is clinically stable (not during decompensation).	Improves survival, reduces hospitalizations, improved quality of life (Flather et al., 2005; MERIT-HF Study Group, 1999, CIBIS-II Investigators and Committees, 1999; Packer et al., 1996)	Indicated for mild, moderate, or severe HF-rEF and asymptomatic LVSD to delay onset of HF.	Only listed BB examples are indicated for HF-rEF—other BBs have not shown benefit. Pivotal nebivolol trial recruited HF patients aged $>$70 years—most of whom had reduced LVEF. Ongoing debate whether one HF-specific BB is better than another. (Kaye and Krum, 2007; Poole-Wilson et al., 2003) Usually commenced after ACE-I/ARB but may be commenced before if patient is euvolemic. (Willenheimer and Silke, 2005) Well tolerated if uptitrated slowly. Too rapid uptitration may precipitate acute symptomatic deterioration (due to withdrawal of cardiac adrenergic tone). Adjustment of diuretic dose BB during dose uptitration may be considered, for example, decrease diuretic if symptomatic hypotension and increase diuretic if increasing congestion. Patients (and carers) require counseling regarding uptitration and monitoring of condition and adverse effects during dose adjustments.

Diuretics				
Diuretics: furosemide, hydrochlorothiazide	Use lowest possible dose to achieve euvolemia	Limited mortality or morbidity benefit shown (Faris et al., 2012)	Indicated for symptomatic relief of peripheral edema or pulmonary edema.	Do not use as monotherapy for HF. Loop diuretics most commonly used. Regularly review doses: lower dose or cease once euvolemia achieved. Monitor blood pressure and symptomatic hypotension, renal function and electrolytes (particularly for hypokalemia) closely especially if on loop diuretic. Patients may be educated to use flexible diuretic regimen (requires daily weight monitoring).
Other medicines				
Ivabradine	Start low dose and uptitrate every 2–4 weeks to target dose, if tolerated.	Improved cardiovascular survival and reduced HF hospitalization. (Swedberg et al., 2010)	In symptomatic HF-rEF or those with a LVEF $<$ 35% who are in sinus rhythm and have heart rate $\geq$ 70 bpm, despite optimized use of ACE-I/ARB and BB (unless latter contraindicated) +/− MRA.	Ensure patient is on maximally tolerated BB dose (unless contraindicated). Aim for sinus rhythm 50–60 bpm. Greater benefit seen in those with faster sinus rates. Requires patient to be in sinus rhythm to exert pharmacological effect and unlike BBs does not lower BP or contractility. May cause bradycardia and visual changes. Cease if patient develops persistent/permanent AF.
Combination of hydralazine and isosorbide dintrate	Start low doses and uptitrate over 2–4 weeks to target doses, if tolerated.	Improved survival. (Cohn et al., 1991)	Only indicated in those where ACE-I/ARB contraindicated/not tolerated.	Isosorbide mononitrate usually substituted for the dinitrate formulation to reduce pill burden and improve adherence. May be useful in African-Americans, whose response to ACE-Is is variable. Most common adverse effect is symptomatic hypotension.
Digoxin	Start low dose ($<$0.125 mg daily) aiming for target plasma range	Improved symptoms and reduced hospitalizations but no improvement in survival. (The Digitalis Investigation Group, 1997) Recent analyses have shown increased mortality. (Vamos et al., 2018)	Second-line drug Indicated only in HF-rEF patients in sinus rhythm who remain symptomatic despite optimized use of ACE-I/ARB, BB, MRA and diuretic.	Target plasma range: 0.5–0.9 μg/L (0.6–1 nanomol/L) as higher concentrations associated with increased mortality and hospitalization. (Rathore et al., 2003) May also be useful in HF and atrial fibrillation, particularly if there is a rapid ventricular rate and no other therapeutic options are available.
Omega-3 polyunsaturated fatty acids	$>$850 mg combined DHA and EPA (in 1 g fish oil)/day	Small benefit on death and CV hospitalization. (Tavazzi et al., 2009)	Only as adjunct to optimized ACE-I/ARB & BB +/− MRA.	Wide variety of proprietary fish oil supplements, which may not have required DHA/EPA content. Pivotal study used ratio of approximately 1:1.2 DHA and EPA to fish oil.

AF, Atrial fibrillation; *BP*, blood pressure; *bpm*, beats per minute; *CV*, cardiovascular; *DHA*, docosahexaenoic acid; *EPA*, eicosapentaenoic acid; *LVEF*, left ventricular ejection fraction; *LVSD*, left ventricular systolic dysfunction.

inotropic effect on the heart. In the past, it was commonly used in HF with AF and for severe, symptomatic, and sustained ventricular tachycardia. Its benefit does not seem evident with the more widespread uptake of BBs in HF-rEF (Torp-Pedersen et al., 2007b). Amiodarone has multiple effects on the thyroid system and may play a role in the thyroid dysfunction frequently seen in HF patients. Its use is problematic with a long half-life, numerous adverse effects, and interactions with medications such as digoxin and warfarin.

Given that HF is a prothrombotic condition, randomized control trials have compared the efficacy and adverse effects of warfarin versus aspirin or aspirin and clopidogrel in HF-rEF patients in sinus rhythm (Homma et al., 2012; Massie et al., 2009). In general, there has been no difference demonstrated in primary outcomes of death, nonfatal myocardial infarct, or nonfatal stroke. Two meta-analyses also identified that although there were reductions in stroke in the warfarin arm, this was offset by increased major bleeding events (but not intracranial hemorrhage) (Hopper et al., 2013; Kumar and Goyal, 2013). They concluded that there may be benefit in warfarin use to prevent stroke but noted there was no difference in mortality. Routine anticoagulant use in HF-rEF patients in sinus rhythm is now discouraged unless intracardiac thrombus is identified (Ezekowitz et al., 2017). Studies using the non-Vitamin K oral anticoagulants (NOACs) in HF-rEF patients in sinus rhythm are currently being undertaken (Ponikowski et al., 2016).

Aspirin is usually prescribed in HF with ischemic etiology unless they are already taking as an anticoagulant. Given the effects of nonsteroidal anti-inflammatories on renal hemodynamics, controversy surrounds the use of aspirin in patients taking ACEIs (or ARBs), particularly if they are also taking diuretics, have severe symptoms or frequently hospitalized (Cleland et al., 1995; Hall, 2001). Furthermore, aspirin use is associated with a substantial risk of gastrointestinal bleeding, particularly with increasing age.

Statins have not demonstrated any survival benefit in HF-rEF patients (Kjekshus et al., 2007). Their role is restricted to HF patients who require it because of underlying coronary artery disease and/or hyperlipidemia (Ponikowski et al., 2016).

Device Therapy

Device therapy includes pacemakers, biventricular pacing [also called cardiac-resynchronization therapy (CRT)], and implantable cardioverter defibrillators (ICDs) (Ezekowitz et al., 2017; Ponikowski et al., 2016). ICDs have shown a 20%–30% reduction in mortality over a 1–5-year period in patients with LVEF $< 35\%$. CRT reduces symptoms and hospitalizations and mortality in symptomatic patients with dilated cardiomyopathy, low ejection fractions, prolonged QRS intervals, and in sinus rhythm (Bristow et al., 2004). ICD therapy may also be combined with CRT to improve symptoms as well as mortality. Device therapy is expensive but may be applicable to a wide range of HF patients. The means by which to allocate such therapies is an on-going debate. Generally, evidence-based pharmacotherapy would be optimized prior to considering device therapy.

HF With Preserved Ejection Fraction (HF-pEF)

There has been a paucity of trials to evaluate therapies in HF-PSF. Furthermore, results of the few trials that have been undertaken have been disappointing and not provided therapeutic guidance in this large group of HF patients. The goals of therapy are generally to alleviate symptoms and improve well-being given that HF-pEF sufferers are generally older with poor quality of life. Diuretics are indicated to improve the congestion. Thiazide diuretics may be sufficient diuretic therapy. Neither BB nor MRA therapies have demonstrated symptom benefit, and ACEI/ARB therapy has produced inconsistent results on symptom improvement (Ponikowski et al., 2016).

The Candesartan in HF-Assessment of Mortality and Morbidity-Preserved (CHARM-Preserved) trial investigated the prognostic value of candesartan added to standard background HF therapy in 3000 HF-pEF patients (Yusuf et al., 2003). The result was a nonsignificant 11% reduction in the combined endpoint of CV death or HF hospitalization. The investigators attributed the statistical shortfall to a short duration of follow-up (3.5 years). The CHARM-Preserved study did find a significant but modest morbidity benefit (reduced HF hospitalizations). This benefit was not apparent until 6 months after candesartan commencement. Another trial investigating the use of irbesartan in HF-pEF patients (LVEF $> 45\%$, mean LVEF 60%) did not show cardiovascular mortality or morbidity benefit, and there was an increase in adverse events including serious hyperkalemia (Massie et al., 2008). A trial evaluating perindopril therapy in elderly HF-pEF patients reported no significant improvements in all-cause mortality or HF-related hospitalizations (Cleland et al., 2006).

Other therapies assessed in HF-pEF patients include digoxin in the Digitalis Investigators Group (DIG) study and nebivolol, a beta-1 selective BB, in the Study of Effects of Nebivolol Intervention on Outcomes and Rehospitalisation in Seniors with HF (SENIORS) study (Ahmed et al., 2006b; Flather et al., 2005). An ancillary study of the DIG trial (EF $> 45\%$) did not find digoxin had any significant effect on mortality or HF, cardiovascular-related or all-cause hospitalization in HF-pEF patients in normal sinus rhythm (Ahmed et al., 2006a).

Although there is a lack of evidence-based recommendations for the use of BBs in HF-pEF, these patients may gain benefit from the use of BBs if they also have ischemic heart disease or hypertension. Patient may also gain benefit from a reduction in heart rate that allows an increase in diastolic filling time, reduction in sympathetic nervous system activation, relief of ischemia that improves diastolic relaxation, and prevention or attenuation of left ventricular hypertrophy (Yancy et al., 2006). The

SENIORS study, which included a small proportion of HF-pEF patients, found that the significant reduction in the combined endpoint of all-cause mortality and cardiovascular hospitalization in patients allocated to nebiviolol was not influenced by ejection fraction (Flather et al., 2005). However, this trial did not demonstrate a significant effect on all-cause mortality.

The value of spironolactone in HF-pEF was assessed in the Treatment of Preserved Cardiac Function HF with an Aldosterone Antagonist (TOPCAT) trial (Pitt et al., 2014). Patients with symptomatic HF and a LVEF > 45% received either spironolactone (15–45 mg daily) or placebo. Of the components of the primary outcome (cardiovascular death, aborted cardiac arrest, or HF hospitalization), only HF hospitalization had a significantly lower incidence in the spironolactone group than in the placebo group, 12.0% vs. 14.2%, $P = 0.04$). Treatment with spironolactone was associated with increased serum creatinine levels and a doubling of the rate of hyperkalemia but reduced hypokalemia. With frequent monitoring, there were no significant differences in the incidence of serious adverse events.

In summary, there is evidence that nebiviolol, digoxin, spironolactone, and candesartan may reduce HF hospitalizations, but not mortality in HF-pEF patients in sinus rhythm. Thus, despite recent attempts to provide evidence-based recommendations for the management of HF-pEF, there remains a lack of knowledge of the pathophysiology of HF-pEF, a paucity of evidence-based guidance for clinicians, and therapy remains empirical. Despite the high prevalence of HF-pEF, overall quality of HF care lags behind that of HF-rEF and emphasizes the optimal management of comorbidities, symptoms, blood pressure, and heart rate.

Specific Considerations Regarding Pharmacotherapy of Comorbidities in HF Sufferers

Atrial Fibrillation

Atrial fibrillation is common in HF, and patients will require anticoagulation unless contraindicated. The non-Vitamin K oral anticoagulants (NOACs) are contraindicated in moderate to severe renal impairment and given renal impairment is common in HF, renal function will require frequent monitoring if they are used in mild renal impairment and during HF exacerbation. Specialist input regarding the appropriate strategy, rhythm, or rate control is recommended.

Chronic Obstructive Pulmonary Disease

Chronic obstructive pulmonary disease (COPD) is common in HF and complicates the diagnosis of HF and worsening HF. Although beta-blockers are relatively contraindicated in asthma, they may be used in COPD. The more beta-2 specific BBs such as bisoprolol are preferred. Although oral corticosteroids are problematic in HF due to sodium and water retention, inhaled corticosteroids can be used in HF patients.

Depression

Depression is common in HF and is associated with worse outcomes. It also impacts adherence medication and nonpharmacological recommendations. Selective serotonin reuptake inhibitors are thought to be safe in HF. However, it is recommended that tricyclic antidepressants are avoided as they may be arrhythmogenic, lower blood pressure, and worsen HF. Nonpharmacological therapies, such as cognitive behavioral therapy should also be considered.

Diabetes

Diabetes is a common comorbidity in HF patients and is associated with poorer functional status and worse prognosis. The presence of diabetes in a HF patient also has therapy ramifications. Thiazides may not be appropriate depending on diabetic control and while beta-blockers do not have adverse effects on HF outcomes, some beta-blockers may be better in HF than others (Torp-Pedersen et al., 2007a). Contrary to previous recommendations, metformin is now the treatment of choice in patients with HF and diabetes but is contraindicated in HF patients with severe renal or liver impairment because of the risk of lactic acidosis.

Insulin is a necessary therapy for type 1 diabetes and is often required in type 2 diabetes. However, insulin is a potent sodium-retaining hormone and when combined with a reduction in glycosuria can exacerbate fluid retention and lead to worsening HF. Therapies that promote insulin secretion such as sulphonylureas can increase the risk of HF exacerbations and should be used with caution. Thiazolidinediones such as rosiglitazone, also cause sodium and water retention and increase the risk of worsening HF and hospitalization. They should be avoided in HF patients.

Dipeptidyleptidase-4 (DPP-4) inhibitors (gliptins) and GLP-1 analogues also stimulate insulin release. In a recent trial, the DPP-4 inhibitor, saxagliptin, showed an increased risk of HF hospitalizations (Scirica et al., 2013). Other DPP-4 inhibitors (sitagliptin, alogliptin, linagliptin) have not shown this effect but if used, patients should be monitored closely (Green et al., 2015; Rosenstock et al., 2015; Zannad et al., 2015). The sodium-glucose co-transporter 2 inhibitors reduce glucose reabsorption in the kidney and may be used in HF patients if renal function is not significantly impaired. A recent study involving empagliflozin reduced HF hospitalizations and mortality, but not other cardiovascular outcomes in patients with diabetes and high cardiovascular risk, some of whom had HF (Zinman et al., 2015). It is unknown whether this is a class effect.

Gout, Arthritis, and Management of Pain

Gout is common in HF due to the condition itself and diuretic therapy. Allopurinol may be used in HF patients although the dose may need reduction in renal impairment. Colchicine is the preferred agent for treatment of acute gout attacks, but caution is required if renal impairment is severe or the patient suffers diarrhea. Systemic corticosteroids are best avoided although corticosteroid injection to a single joint is permissible. Nonsteroidal anti-inflammatories including COX-2 inhibitors are contraindicated due to their significant adverse effects on fluid status, the cardiovascular system, and renal function. This also means these agents should not be used systemically as analgesics or arthritic therapies in HF patients. Patients should be counseled on how they should best manage pain such as headache or osteoarthritis. Paracetamol is the preferred analgesic in HF patients.

Hypertension

Optimized control of blood pressure is important in HF patients as hypertension is associated with increased adverse events (including death and stroke) in those with new onset HF (Lip, 2015). The negative inotropic calcium channel blockers (CCBs), verapamil and diltiazem, which are often used in IHD and hypertension and have been shown to reduce left ventricular hypertrophy are contraindicated in HF-rEF. Amlodipine has shown no mortality and morbidity benefit in HF-rEF but may be used in HF-rEF if ACEI/ARB, BB, MRA, and diuretic therapy have not adequately lowered blood pressure. Hydralazine is also a consideration. However, uncontrolled hypertension is not normally an issue in HF-rEF if the recommended HF therapies are used. In contrast, optimization of blood pressure control is an important therapeutic strategy in HF-pEF.

Iron Deficiency and Anemia

Iron deficiency (ID) with or without anemia is a common comorbidity in chronic HF. Its etiology is multifactorial and not fully understood (Drozd et al., 2016; McDonagh and Macdougall, 2015). ID may contribute to HF symptoms such as breathlessness and fatigue and may be a precipitant for decompensated HF. ID is associated with poor quality of life and poor prognosis. Patients should be screened for ID, and reversible causes for iron deficiency is corrected.

Supplementation using the intravenous iron formulations, iron sucrose and ferric carboxymaltose, enable more rapid repletion of iron stores and has demonstrated improvement in prognosis, symptoms, quality of life, and exercise tolerance in HF-rEF. They should be considered in patients with symptomatic HF and iron deficiency. The ferric carboxymaltose formulation has the advantage of quicker administration time and reduced fluid load but is significantly more costly.

Currently, the evidence does not demonstrate improved outcomes using oral iron supplementation in iron-deficient patients with HF-rEF. Repletion of iron stores using oral iron supplementation is compromised for a variety of reasons including poor gastrointestinal absorption, adverse effects such as nausea and constipation, and poor adherence. Erythropoietin-stimulating agents are generally not recommended for HF-associated anemia but may be considered when due to renal dysfunction (together with iron supplementation).

Renal Impairment

Renal function is frequently impaired in HF patients and often worsens during exacerbation. The presence of renal impairment worsens outcomes in HF patients. Renal impairment shares the many of the same risk factors as HF. Pharmacists should be aware of medicines such as digoxin and the NOACs that may accumulate and cause toxicity in HF exacerbations. HF patients will require greater doses of diuretics as renal impairment progresses.

Inhibitors of the RAAS are generally well-tolerated in renal impairment. There is often a slight worsening in renal function, especially during ACEI/ARB/MRA initiation and uptitration. No action is necessary as long as the change in serum creatinine is small (<30% change in eGFR), stabilizes within 2 weeks, and the patient is asymptomatic. However, greater changes will necessitate urgent review for potential renal artery stenosis, hyper- and hypovolemia, potentially nephrotoxic medications, and hyperkalemia. Those with preexisting moderate to severe renal impairment when first diagnosed with HF are more susceptible to acute kidney injury if affected by dehydrating illnesses, overdiuresis, and nephrotoxic medications. Patients should be counseled regarding the importance of renal function and electrolyte monitoring and the required testing frequency in general and especially during changes in relevant medications and their doses or during acute illnesses.

Complementary and Alternative Medicines in HF

Although the use of CAM in HF patients is not common, patients who do use them often use a significant number (Bennett et al., 2004). CAMs are often recommended by family members. Their use is often not reported to their treating physicians. As applies to many conditions in which CAM may be promoted, there is a lack of randomized controlled trials of CAM in HF and when they do occur, participant sample sizes are small. Of the CAMs that have been evaluated, coenzyme Q 10, a naturally occurring antioxidant, may have a modest beneficial effect on ejection fraction, decrease symptoms, and HF hospitalizations (Fotino et al., 2013; Weant

and Smith, 2005). No positive effect on survival has been demonstrated. It is an expensive therapy. Its adverse effects are generally gastrointestinal in nature, and it may increase bleeding time. There is potential for interactions with antihypertensives, alkylating agents, and warfarin. International guidelines do not advocate its use.

Other CAMs that are sometimes recommended by CAM proponents include magnesium, hawthorn, selenium, and Vitamins C and E. There is no evidence that they provide benefit and some may compromise the use of evidence-based medicines. For example, magnesium and hawthorn have vasodilatory effects and may reduce blood pressure. Their use may compromise the prescription or uptitration of medicines that also vasodilate but are known to improve outcomes in HF patients such as ACEI/ARBs and beta-blockers. A thorough evaluation of safety, likely effectiveness, convenience, and cost which included discussion with specialist and general physicians and pharmacists should be undertaken prior to considering use on a trial basis, which would include the use of objective measures to determine effectiveness.

Nonpharmacological Management of HF

Nonpharmacological therapies include recommendations regarding fluid management, nutrition, alcohol intake, self-management and education, exercise programs, smoking cessation, psychosocial support, and immunization. Failure to adhere to nonpharmacological therapies may result in increased mortality and morbidity.

Restricting dietary sodium consumption is controversial. An ongoing randomized clinical trial is anticipated to provide guidance on this vexed question (Ezekowitz et al., 2017). It is now generally advised that salt intake should be restricted to less than 3 g/day. Patients and their carers should be taught how to read food labels and select lower sodium content foods.

The restriction of fluid intake is also controversial. High-quality evidence is lacking. It is generally advised to restrict fluid intake to 2–3 L/day; the specific amount will be influenced by the clinical situation, the severity of symptoms, the season, the size of the patient, and their activity. Tighter restrictions may be considered in hyponatremic patients with hypervolemia.

Daily weight monitoring is advised to recognize worsening HF or less commonly, dehydration. An increase of 2 kg (equivalent to 2 L of fluid) in 2–3 days portends HF decompensation. Patients and carers should seek medical attention early as treatment is much easier in the early stages of decompensation and may avoid hospitalization and intravenous therapy. Some patients (or carers) will be able to identify the likely cause of the deterioration (e.g., nonadherence to diet or diuretics, use of contraindicated medicines, infection) and use a flexible diuretic regimen to manage the fluid retention. Electrolyte and renal function monitoring will be required for any prolonged increased diuretic dose. Addressing the precipitant(s) of HF exacerbations will be required.

Alcohol consumption should be limited for all HF patients (maximum of 10–20 g/day) and counted in the fluid allowance. Those whose cardiomyopathy is thought to be due to alcohol toxicity should practice total abstinence.

Infections add an additional load on the heart. Prevention using influenza and pneumococcal vaccinations is an important strategy to reduce the risk of worsening HF.

Obese patients especially those with HF-pEF should be provided with assistance to lose weight.

Last but not least, physical activity (unless decompensated) is advised. Enrolment in an exercise training program, if available and eligible, is encouraged.

Barriers to Effective Heart Failure Management

Several studies have shown that heart failure exacerbations may be attributable to nonmedical factors. Table 4 outlines such factors identified in studies that hinder successful treatment of heart failure management. A number of these may benefit from the input of pharmacists with their expert knowledge in medication adherence and review.

Strategies to Overcome Barriers to Optimal HF Management

A number of strategies have been devised to overcome these barriers and maximize clinical outcomes. Recent strategies to improve outcomes include guidelines developed by cardiology organizations generally directed at other HCPs including the primary care physician; specialist HF clinics; disease state management programs involving a multidisciplinary management team; individualized care; patient education and counseling that ideally also involves family or carers and includes promotion of self-care management; flexible but intensive follow-up particularly postdischarge that may include home visits and telephone follow-up, which may proactively detect and address issues that may hinder optimal outcomes; and patient-initiated access to appropriate advice and support which is available through a variety of channels, for example, telephone, written, and or the Internet. The influence of comorbid conditions, age, symptomatic limitation, the patient's own goals, and the ability to adhere to a complex regimen needs to be taken into account. In some patients, the management plan may focus on improvement in survival and slowing disease progression; while in others, it may be more appropriate to limit symptoms and improve quality of life. A brief discussion of some of these strategies is as follows.

Table 4 Barriers to effective HF management

Drug Related	
	Patient adherence to medication
	Adverse drug reactions from HF medications
	Inappropriate use of medication
	Polypharmacy
	Inadequate medical treatment
Multiple co-morbidities	
	Coronary heart disease
	Hypertension
	Diabetes
	Renal insufficiency
	Respiratory disease
	Arthritis
Non-pharmacological non-adherence	
	Diet including salt, fluid, alcohol, exercise, and other self-care measures
	Failure to recognize early warning signs of decompensation
	Psychosocial problems, depression, social isolation
Financial constraints	
	Inability to work
	Retired from work
Physical limitations	
	Symptomatic limitation
	Reduced visual and auditory acuity, neuromuscular deficits: stroke, arthritis, Parkinsonism
Cognitive impairment	
	Poor understanding of disease and self-care measures
	Low reading age
	Non-English speaking background
	Poor coping skills

Multidisciplinary care for people with chronic heart failure: Principles and recommendations for best practice. 2010

HF Management Guidelines

In the last two decades, there has been a concerted effort to develop and disseminate HF management guidelines. Guidelines provide a strategy to improve use of new and existing therapeutic modalities of proven benefit. In order to be implemented, guidelines need to deal not only with therapies that are efficacious but also consider the practical aspects necessary in the day-to-day care of the patient. All major cardiac societies or organizations now publish regularly updated guidelines including the National Heart Foundation of Australia and Cardiac Society of Australia and New Zealand, the Heart Failure Society of America, the American College of Cardiology and American Heart Association, the Canadian Cardiovascular Society, and the European Society of Cardiology (Atherton et al., 2018; Ezekowitz et al., 2017; Krum et al., 2011; Ponikowski et al., 2016; Yancy et al., 2013, 2016, 2017). These and similar organizations also offer eLearning modules and information for health-care professionals:

Disease State Management Programs

The management of HF has evolved from that of crisis management to the use of proactive, preventative multidisciplinary disease state management programs that recognize the complexity of medical, psychosocial, behavioral, and financial issues that are faced by many patients and their carers. They attempt to provide a relatively formalized mechanism to overcome many of the barriers to

effective care. Team members may include physicians, general practitioners, nurses, pharmacists, social workers, dietitians, occupational therapists, and physiotherapists and may be hospital, outpatient, or community based.

A landmark study published in 1995 trialled the effect of a nurse-directed multidisciplinary team on rates of readmission within 90 days of hospital discharge, quality of life, and costs of care (Rich et al., 1995). The intervention consisted of comprehensive education of the patient and family, a prescribed diet, medication review, social service consultation, and early discharge planning, as well as intensive follow-up. The number of readmissions for heart failure was reduced by 56.2% in the treatment group ($P = 0.04$). Quality of life scores improved more from baseline in the intervention group ($P = 0.001$), and costs of care were reduced due to the reduction in hospital admissions.

A number of systematic reviews of randomized trials of disease management programs (DMPs) in heart failure have since been published (Gohler et al., 2006; Gonseth et al., 2004; Holland et al., 2005; McAlister et al., 2001, 2004; Phillips et al., 2004; Whellan et al., 2005). Overall, the DMPs showed a consistent and favorable effect on rehospitalization, particularly HF rehospitalization, although the effect on mortality and quality of life was more controversial. (Gonseth et al., 2004; Gwadry-Sridhar et al., 2004; McAlister et al., 2004; Phillips et al., 2004) The interventions vary between the DMPs and evidence is required to identify the components with the greatest impact on adverse outcome. Elements that appear to be efficacious in DMP have been the use of multidisciplinary teams, an emphasis on patient education and self-management and enhanced access to specialist clinics or home visits. The use of home-based intervention strategies had the advantage of not only reinforcing education and compliance but also of detecting clinical deterioration and identifying hitherto unknown problems likely to contribute to poorer long-term outcomes (McAlister et al., 2004). Telephone-based systems designed to enhance follow-up by primary care givers appear to be less effective (McAlister et al., 2004). Team-based disease management care delivery versus single person care delivery and in-person communication versus telephonic delivery was also found to be more effective (reduced HF hospitalizations and length of hospital stay) in a review of HF management programs (Sochalski et al., 2009). The findings of these and other studies have led to the development of a taxonomy for disease management programs. A core component of such programs is medication management (Krumholz et al., 2006).

A recent Cochrane review compared the effects of different HF management interventions (case management, clinic-based models, and multidisciplinary models), which were not solely educational, versus usual care, in terms of death (from any cause or HF), rehospitalizations, quality of life, and cost-related outcomes (Takeda et al., 2019). The analysis included 47 randomized controlled trials (RCTs) involving 10,869 participants. The authors concluded that case management and multidisciplinary interventions probably have an effect on all-cause mortality and rehospitalizations. Clinic-based interventions were of less certain benefit. Unfortunately, the review was hampered by the poor quality of evidence resulting in uncertainty of the various interventions' benefits. The methodology of further RCTs requires optimization to improve the quality of evidence and provide certainty to the benefits (or lack of benefits) of various interventions in HF patients so that scarce health-care dollars are directed appropriately.

Evidence for Pharmacists as Part of the Multidisciplinary Team

While the role a multidisciplinary team in the treatment of HF patients has been established, there is less evidence to characterize the role of specific team members (Gohler et al., 2006; McAlister et al., 2004). In 2008, Koshman et al. published a systematic review of randomized trials that evaluated the effect of pharmacist care on HF patients outcomes (Koshman et al., 2008). Twelve RCTs involving 2060 patients were identified. Pharmacist care was associated with a significant reduction in all-cause and HF hospitalization [OR 0.71 (0.54–0.94) and 0.69 (0.51–0.94), respectively. There was a nonsignificant reduction in mortality [0.84 (0.61–1.15)]. Greater reduction in HF hospitalizations was achieved when the pharmacist was part of a multidisciplinary team rather than when pharmacist care was pharmacist initiated and managed. Details of the activities pharmacists undertook were difficult to identify in the literature, and the investigators contacted primary authors to clarify the activities pharmacists performed. Nevertheless, there were notable differences in the pharmacists' activities and further investigations regarding key elements of pharmacist's activities are warranted. The authors concluded that a pharmacist should be part of the multidisciplinary team caring for HF patients whether it be outpatient or community based.

Current and Future Role of Pharmacists as Part of the Health-Care Team Managing Patients with HF

HF is a chronic condition usually accompanied by numerous comorbidities and treated with multiple medications. The time and effort and possibly costs that a patient (and their carers) may need to spend to ensure optimal self-care of their HF is substantial. The pharmacist has a major role to play in ensuring patients' outcomes are optimized and their goals of therapy are achieved.

The activities pharmacists can play are numerous and include:

1. ensuring prescription of evidence-based medicines,
2. optimizing dosing of medications, including ensuring appropriate uptitration,
3. monitoring for adverse drug effects and HF symptoms and signs,
4. checking for and managing any drug interactions,
5. counseling patients and their carers, as appropriate, about the medicines including potential adverse effects, what to do about forgotten doses,

6. assisting appropriate patients (and carers) with understanding and management of flexible diuretic regimen,
7. providing proactive counseling about management of incidental health issues, for example, pain management, gastrointestinal conditions, and gout,
8. optimizing management of comorbidities,
9. providing supporting written material to verbal counseling,
10. monitoring medication adherence and identifying and managing-related issues,
11. ensuring medicines that should be avoided by the HF patient are avoided,
12. simplifying medication regimens where possible,
13. assisting, providing, and updating medication lists,
14. undertaking medication reconciliation particularly between transitions of care,
15. assisting with dose administration aids where appropriate,
16. to ensuring that patients understand the monitoring requirements for the medications,
17. identifying when a comprehensive medication review may be appropriate,
18. undertaking a comprehensive medication review,
19. ensuring a patients immunization status is up to date,
20. supporting a patient's (and carer's) knowledge of and adherence to nonpharmacological management,
21. undertaking clinical audits of HF therapies in various care settings,
22. support end-of-life care,
23. supporting other health-care professionals and HF team members in their roles,
24. referring to other health-care professionals, and
25. reinforcing other health-care professional's messages and counseling.

These activities can be undertaken in a variety of settings including hospitals and community pharmacies. Newer settings for pharmacists include hospital outpatient clinics, posthospital discharge programs that include home visits, home visits as part of comprehensive medication review programs, and primary care practices (Bennett and Brien, 2002; Hargraves et al., 2008; Kalisch et al., 2010; Lowrie et al., 2011, 2014; Ponniah et al., 2007; Roughead et al., 2009). A retrospective cohort study using data from 2004 to 2006 Australian veteran affairs claims database of veterans aged 65 years or over receiving HF-specific beta-blockers demonstrated the value of comprehensive home medication review (Roughead et al., 2009). The study analyzed subsequent HF hospitalizations of those who received a home medicines review (HMR) and those who did not. At the time of the study, the process of home medication review involved referral from a general practitioner (GP) to an accredited pharmacist via the community pharmacy, a home visit by an accredited pharmacist to identify any medication-related problems, and a pharmacist report to the GP who then consults with the patient regarding the findings and recommendations in the report. The GP is responsible for developing med management plan in collaboration with the patient and following up the patient. When conducting a HMR, the pharmacist is expected to spend between 30 and 60 min with the patient in their home and 2 h writing and sending the report to the GP. Two hundred and seventy-three Australian war veterans and war widows receiving HF-specific BBs received the HMRs, and they were compared with 5444 veterans receiving HF-specific BBs who had not. The age of the two groups was similar, with a mean of almost 82 years, and the HMR group had a median of eight comorbidities compared to the non-HMR group of seven comorbidities. After adjustment, there was a 45% reduction in the rate of HF hospitalization at any time.

The effect of pharmacist intervention on HF-rEF patients under the care of 174 Scottish general practices was investigated by Lowrie et al. (2011). The intervention was delivered by 27 nonspecialist pharmacists who practiced within general practice. These pharmacists received 1-day in-house training from HF pharmacists and a GP with an interest in HF as well as reading material. Patients in the intervention group were offered a 30-min interview with the pharmacist. The intervention's main focus was the optimization of evidence-based medicines. If the patient and the doctor agreed, the medications could be initiated, discontinued, and modified over 3–4 weekly or fortnightly appointments by the pharmacist. Baseline use and dosing of EBM were already fairly high (86% ACE/ARB & 62% BB) (dosing at target levels was 55%) and similar between the two groups. Patients were recruited over 2.5 year and followed-up for a further 2 years. The study showed no difference in the primary outcome of death or HF hospitalization or its component outcomes. However, there were significant differences in the use of EBM with increases in prescription and dosing to target in the pharmacist intervention group. Changes in medications that should be avoided in HF were also noted but were not significant.

Another study conducted in Scotland explored the perspectives of patients receiving and pharmacists delivering an enhanced pay for performance community pharmacy HF service (Lowrie et al., 2014). Pharmacists reported that they were confident in delivering the structured service and valued the repeated contacts with HF patients enabling the opportunity to improve self-care and medicines adherence. Challenging areas were discussion of non-HF comorbidities and persuading patients to modify behavior. HF patients reported that they were comfortable discussing HF symptoms with their pharmacist and that the service assisted them with their self-care and HF medication management strategies and believed that community pharmacists should provide such a service.

Support for nurse practitioner (NP)-led clinics that involve clinical pharmacists (CPs) is growing given the success of community disease state management programs involving CPs given the vulnerable postdischarge phase that HF sufferers often experience (Gheorghiade et al., 2013; Hickey et al., 2016). A recent pilot study demonstrated improved adherence to guideline recommendations, which suggested improved HF readmission rates in those attending the NP-CP clinic (Rheault et al., 2018).

The widespread implementation of extended roles for pharmacists is in its infancy. Evidence to date supports these roles. Health-care policy surrounding and funding for these roles needs to be explored as the focus of pharmacists' roles change from medicines supply to cognitive services. Further research is also required to determine if some pharmacist interventions are of more value than others and how to stratify patients to pharmacist intervention and type of pharmacist intervention.

Specific Pharmacist Activities

Medication Uptitration

Clinical guidelines recommend the use of target doses of evidence-based medicines in HF-rEF. Initially, these medicines are commenced at low doses and product information commonly recommends uptitration of doses every 2–4 weeks. However, in most real-world studies, only 10%–20% of patients achieve target doses in the 3–6 months postinitiation. Furthermore, failure to tolerate an uptitrated dose does not mean this cannot be subsequently reattempted. Many structured postdischarge HF programs provide support to patients and community health-care practitioners during the uptitration phase as these have been shown to increase rates of target dosing in HF-rEF patients. Pharmacists within those programs may take a direct or indirect role in uptitrating doses. Moreover, concomitant medicines that may compromise the ability to uptitrate require identification and a review of their benefit to harm ratio in each patient. For example, previously used antihypertensives such as dihydropyridine calcium antagonists are generally best ceased prior to uptitration of EBM dose uptitration. Close review of diuretic doses is also necessary. Regular, more frequent monitoring of blood pressure, heart rate, volume status, renal function, and electrolyte concentrations are required during uptitration. Supporting information and tool kits for medicine uptitration can be found at http://www.heartonline.org.au/articles/medications/titrating-medications-in-heart-failure and https://www.escardio.org/static_file/Escardio/Guidelines/ehw128_Addenda.pdf

Medications to be Avoided in HF

There are a number of prescriptions, over-the-counter, and complementary medicines that are contraindicated or should be used cautiously in HF (see **Table 5**). Pharmacists should ensure that patients and carers understand that they should obtain advice before commencing over-the-counter and complementary medicines or medicines initiated by other health-care practitioners and periodically check with patients for any medicine changes.

Table 5 Common medicines to be avoided or used cautiously in HF patients

Medicines	*Comments*
Adrenergic agents including pseudoephedrine, amphetamines	Adverse cardiovascular effects including increased blood pressure, tachycardia, proarrhythmic effects. Avoid use. Proactively counsel appropriate management of colds and flus
Antiarrhythmics (Classes I and III)	Negative inotropic and proarrhthymic effects. Avoid all antiarrhythmics except amiodarone and digoxin
Carbamazepine	Negative inotropic and chronotropic effects and anticholinergic effects. Avoid if possible
Caffeine, high dose	Increase systemic vascular resistance, blood pressure. Includes CAM such as guarana, high-energy drinks, and products to keep people awake plus coffee $>$ 4 cups/day. Counseling may be required
Corticosteroids, systemic	Sodium and fluid retention. Consider likely benefits vs potential harm. If beneficial, use for minimal period at lowest effective dose. Monitor for HF symptoms and signs
Itraconazole	Negative inotropic effect. Avoid
Drugs that cause QTc prolongation	Numerous different drug classes. Ensure likely benefit $>$ potential harm. If beneficial, use minimum doses. Also check for drug interactions and drug–disease interactions
High sodium content medicines	Increase fluid retention and contribute to HF exacerbation. Examples include urinary alkalinisers, effervescent medicines, some antacid medicines
Medications requiring accompanying fluid	Examples include bulk-forming agents for constipation. Accompanying fluid needs to be counted in the recommended fluid allowance. Consider alternative
Moxonidine	Avoid. RCT showed increased mortality in HF patients
NSAIDs and COX-2 inhibitors	Increase salt and fluid retention, worsen HF, blunt diuretic effect; worsen renal function, increase blood pressure, increase risk of myocardial infarct. Use of low-dose aspirin controversial (ensure likely benefit $>$ potential harm)
Thiazolidinediones	Sodium and fluid retention. Increase risk of worsening HF and HF hospitalizations. Use other hyoglycemic agents. (See Diabetes section.)
TNF-alfa antagonists	Adalimumab, certolizumab, etanercept, golimumab, infliximab. Weigh likely benefits versus potential risks. Closely monitor. Avoid in NYHA III-IV HF and LVEF $<$ 50%. Use cautiously in mild disease
Tricyclic antidepressants	Negative inotropic effects; increased automaticity; proarrhythmic; slowing of intracardiac conduction. Consider SSRI as alternative for depression and other medicines for neuropathic pain
Verapamil and diltiazem	Negative inotropic effect and neurohormonal activation. Contraindicated in HF-rEF. May have role in HF-pEF

Source: Adapted from Maxwell and Jenkins, Drug-induced Heart Failure (Maxwell and Jenkins, 2011) and Reed et al. Polypharmacy in Heart Failure: Drugs to Use and Avoid (Reed et al., 2014)

Identifying Adverse Effects of Medicines

Some adverse effects are to be expected and can be avoided with appropriate vigilance and action. It is important to ensure that new medicines are not introduced to treat an adverse effect (the prescribing cascade). Patients should be routinely monitored for common adverse effects and encouraged to report them to their usual health-care practitioners. A modification can frequently be made that will not necessitate the cessation of EBM.

Identifying and Managing Drug Interactions

Given the high number of medicines most HF patients will be taken, pharmacists should be alert for potential drug interaction. Combinations of certain medications should also be avoided. For example, an ARB should not be added as therapy to patients already taking an ACEI and MRA due to the increased risk of renal dysfunction and hyperkalemia. The combination of a diuretic, ACEI/ARB, and NSAID/COX-2 inhibitor (known as the "Triple Whammy") is also highly problematic.

Commonly used medicines in HF patients that are frequently involved in drug interactions include amiodarone, digoxin, some proton pump inhibitors, phosphodiesterase inhibitors, and H2 antagonists (Reed et al., 2014).

Pharmacists should ensure HF patients and carers understand that they should obtain advice from their usual health-care practitioners before commencing, ceasing, or changing the doses of any medicines.

Ensuring Optimal Medication Adherence

The HF patient commonly takes at least nine medications, six of which are cardiovascular (Bennett et al., 2004; Masoudi et al., 2005). Multiple dosing throughout the day is usually required. This complexity increases the risks of confusion, drug interactions, adverse effects, and monitoring requirements that impact quality of life. There may also be significant cost burden. Medication nonadherence is associated with an increased risk of all-cause mortality and cardiovascular hospitalizations (Fitzgerald et al., 2011). Medication nonadherence may be as high as 50% in HF patients (Zhang et al., 2013). Although 80% is the common threshold for differentiating between satisfactory and suboptimal medication adherence, investigators identified significantly better patient outcomes when the adherence was greater than or equal to 88% (Wu, 2009). A possible explanation for this high threshold is the need for comprehensive neurohormonal blockade. Nonadherence to dietary recommendations is also common. The reasons for medication nonadherence are complex and vary in different conditions and for different medications. For example, in HF, nonadherence with diuretics is common, particularly elderly women (Riegel and Dickson, 2016).

Nonadherence may be intentional or unintended. Both types may occur in the one patient.

It is important to not only investigate why patients are nonadherent to medicines but also identify factors that promote their adherence.

Concordance with the therapeutic plan can be achieved through shared decision making. Shared decision making is when decisions are made by health professionals and patients together, using the available evidence and considering and respecting the patient's characteristics and values. It is also called "patient-centered care."

Health professional requirements for successful shared decision making
Establish a context in which the patient's beliefs and views about medicines options are valued
Identify patient preferences, so that appropriate therapeutic options can be discussed;
Educate patients about their treatment options, such as potential harms versus likely benefits, in a way that they can understand
Help patients make a treatment decision and make sure that decisions are made based on the correct information and motives (i.e., the facts not misconceptions)

Ideally, a therapeutic alliance (a relationship between the various health professionals and the patient) can be established that leads to the development of an agreed patient-centered treatment plan with an ongoing support to adhere to the plan.

Pharmacists have a critical role in identifying medication nonadherence. Pharmacists should be vigilant in adherence monitoring and take the time to ask the patient or carer about it. **Box 1** displays some indicators that a patient may be nonadherent to medicines.

Apart from questioning the patient or their carer, pharmacists have the advantage of being able to objectively measure adherence. Consider:

- Repeat refills/community pharmacy electronic alert systems
- Pill counts—could perform this on home visits
- Labels on bottles—when was the medicine last dispensed? Is the patient picking up repeat medicines as scheduled? Is there more than one community pharmacy, prescriber involved?
- Consider markers of effect: e.g., blood pressure, heart rate, INR, symptoms (weight increase, breathlessness, angina, palpitations)

Patient-related factors to consider when medication non-adherence in an HF patient is identified, as shown in **Table 6**. When nonadherence is detected, consider how best this may be addressed acknowledging that there may be more than one problem and one solution. Patient/carer education regarding the medicine's benefits and associated information is usually required but is rarely sufficient alone or adequate when only provided once. Both verbal and written information should be provided. Patient-focused interventions appear to be more effective than provider-focused interventions (Ruppar et al., 2015) (**Box 2**).

Box 1 Indicators of potential medication nonadherence

Condition-related
- Asymptomatic disease/mild symptoms
- Cure appears worse than the condition
- Needs medicines that have negative publicity

Treatment-related
- Frequent brand changing
- High cost
- Multiple medications and complex regimen required
- Complaints of adverse effects form medicines

Have poor response or less than anticipated
Missed appointments, missed getting repeats
Forgetful/confused
Depression
Cognitive impairment, mental disorder
Poor health literacy and/or numeracy
Non-native speaking background
Chaotic lifestyle
Lack social support
Lack of or incorrect knowledge about condition/treatment
Belief system, e.g., want "natural" medicines; dislike taking "medicines"

Table 6 Patient-related factors to consider when nonadherence in HF patients is identified.

Patient-related factors	*Examples*
Actual or perceived adverse effects	Need to frequently urinate because of diuretics (especially if away from home); using an ACE inhibitor can cause a persistent cough; some beta-blockers can cause fatigue, dizziness, and shortness of breath during exercise; anticoagulants can cause bruising and excessive bleeding; gynecomastia from spironolactone
Rejection of the diagnosis	Patients may be in denial, especially in the early stages of HF
Limited understanding of the importance of some medicines or their dosing	HF patients may be resistant to uptitration because they believe it indicates severe disease
Loss of faith in medicines	A patient is prescribed spironolactone because the use of diuretics, ACE inhibitors and beta-blockers, hasn't improved their heart failure adequately. If the patient believes that spironolactone is also not going to work, they may not take spironolactone and may stop taking other medicines as well.
Poor sight	Patients with poor sight can't read the medicine's label or the consumer medicines information
Poor memory	Patients with poor memory can't remember the information they read or what was given to them. Poor cognition is common in HF patients.
Lack of self-efficacy	Patients may lack the confidence to make recommended behavioral changes, including taking medicines as prescribed. Adopting and maintaining self-care strategies is complex and time consuming, which may be particularly challenging in socially isolated frail HF patients.
Language or literacy barriers	Patient's medicines information may not be available in their native language, or the level of information may be too high for patients with low literacy levels. Check professional societies and consumer organizations as many provide patient information about various aspects of HF management in a variety of languages.

Box 2 Potential patient-focused interventions to improve adherence

Simplifying regimens—ideally choose once daily formulations, ideally choose medicines that can be taken with meals
Minimising costs—for example, can some medicines be combined into one, or a higher strength formulation cut in half?
Strategies to minimize adverse effects, for example, provide advice on when and how to take a diuretic so that it is effective but does not interfere with quality of life.
Consider alarms, dosette boxes, blister packs.
Event diaries, self-monitoring diaries
Posthospital discharge follow-up
Telephone/videophone follow-up

A meta-analysis of medication adherence interventions in HF patients reported that improvement in medication adherence was more likely when one behavior at a time is targeted rather than attempting to improve adherence at the same time as changing other health behaviors (Ruppar et al., 2015). The National Heart Foundation of Australia provide an e-Learning module for health-care professionals on medication adherence: http://myheartmylife-elearning.com.au/moodle/enrol/index.php?id=5.

Patient Education of Self-Care Strategies by Pharmacists

Pharmacists have an important role in educating patients about potential medication-related strategies including the use of a flexible diuretic regimen, if the HF team/specialist believes the HF patient is appropriate and supporting the uptake and maintenance of nonpharmacological self-care strategies and monitoring medication adherence and providing solutions, if nonadherence occurs.

Disease Monitoring

Pharmacists can assist patients understand and monitor their symptoms. Nonadherence to medications and nonpharmacological recommendations and use of contraindicated medications are frequent reasons for clinical deterioration. HF patents should be provided with an action plan that details their actions if symptoms of deterioration occur. Patients should be advised not to delay seeking help as it is much easier to manage the early stages of deterioration. An example of a HF action plan can be found at https://www.heartfoundation.org.au/images/uploads/publications/CON-035.v5_LWWCHF-2015-web_v2.pdf

Flexible Diuretic Regimen

The aim of a flexible diuretic regimen is to prevent HF exacerbations and hospital admissions. Daily weight monitoring is an essential component when assessing fluid status and is useful in guiding diuretic dosing. Patients should be aware of their "dry" weight and the action required if their weight increases or decreases by 2 kg within a few days. The dose of diuretic that will be required to address the exacerbation will depend on whether a diuretic is currently being used of not: if on a diuretic, the dose is usually doubled, if not 20 mg of furosemide/kg gained is a common recommendation. Patients should be counseled to watch for dizziness. Vomiting and/or diarrhea is the usual reason for a sharp decrease in weight. In these cases, the diuretic should be temporarily stopped to avoid dehydration and renal function deterioration. A diary is a useful tool for patients to monitor their weight and symptoms and adjust diuretic dosing. An example can be found at http://www.heartonline.org.au/media/DRL/Weight_and_symptom_diary.pdf. A tool to assist patients monitor their fluid intake is useful for patients:

https://www.heartfoundation.org.au/images/uploads/main/AusPAnet/My_fluid_plan.PD

Practical Guidance

Given evidence that there issues related to the real-world implementation of evidence-based therapy in HF and the acknowledged complexity of the HF patient, professional societies and hospital/community HF programs have developed practical guidance to assist uptake of evidence-based recommendations. The European Society of Cardiology has useful online practice guidance for prescription of and problem solving with ACEI/ARBs, BBs, MRAs, diuretics, and ivabradine. https://www.escardio.org/static_file/Escardio/Guidelines/ehw128_Addenda.pdf. The Canadian and Australian guidelines also provide practical tips. The American College of Cardiology have also published practical guidance that addresses key gaps in optimal care of HF-rEF patients. In Australia, the Heart Online website provides information and problem-solving plans and information to assist health-care professionals apply guideline-recommended HF management. http://www.heartonline.org.au/

Patient Resources

Professional societies and related organization provide a number of useful resources for patients and can also be used by health-care professionals when counseling patients.

- European Society of Cardiology: Heart Failure Matters-Website for patients that highlights lifestyle adjustments that enable HF sufferers and their carers to improve their quality of life.
  - https://www.escardio.org/Sub-specialty-communities/Heart-Failure-Association-of-the-ESC-(HFA)/Advocacy/heart-failure-matters-website-for-patients
- Heart Failure Society of America—provides a number of self-contained patient learning modules and information about other relevant organizations
  - http://www.hfsa.org/patient/patient-tools/educational-modules/
  - http://www.hfsa.org/patient/patient-resources/
- The National Heart Foundation of Australia
  - https://www.heartfoundation.org.au/images/uploads/publications/Living_well_with_heart_failure_2017.pdf

End-of-Life Care

HF is a progressive condition. Prediction of the specifics of the individual patient journey is challenging. Increasingly frequent recurrent hospitalizations, declining functional status, deteriorating renal function, increasing diuretic dosage, and the appearance of malignant arrhythmia indicate the HF patient is entering the terminal phase although this may last over a year. Discussion of the likely patient journey and documentation of the patient's advance-care directives should occur early and involve family members and the health-care team members. The involvement of a palliative care team may also be considered. Although EBM such as ACEIs and BBs should be continued if possible because they can help alleviate HF symptoms, hypotension, renal impairment, electrolyte derangements can necessitate their withdrawal. Diuretics for congestive symptoms and opioids for breathlessness, pain, and anxiety are useful. Cessation of medications that will not have any immediate effect on symptoms or quality of life should be considered. These include osteoporosis medicines and statins.

Management of Cerebrovascular Disease and the Pharmacist's Role: Stroke

Siew Mei Yee, SEGi University, Selangor, Malaysia

Learning Objectives:

- To understand the epidemiology of stroke.
- To identify the pathophysiology and etiology of stroke.
- To explain the treatment used for acute ischemic stroke and its secondary prevention.
- To identify the nonpharmacological approaches in preventing ischemic stroke attack.

Take Home Messages

- Stroke is the second leading cause of death, and approximately 42.4 million people suffered from stroke globally in 2015.
- Stroke that is caused by reduced blood flow to the brain can either be hemorrhagic or ischemic in nature.
- Atherosclerosis due to plaque formation in blood vessels is the main factor that leads to reduced blood flow to the brain.
- Early reperfusion with thrombolytic agents such as alteplase may reduce the sequela and disabilities associated with stroke attack.
- Therapy with antiplatelet, antihypertensive, and anticholesterol agents is the cornerstone in the prevention recurrence of stroke.
- Blood pressure lowering and cholesterol-lowering therapy regardless of blood pressure and baseline cholesterol level had been proven to reduce recurrence of stroke episodes.

Introduction

According to the Global Burden of Disease Study 2015 (GBD 2015), prevalence of stroke was reported at 42.4 million in 2015 (Vos et al., 2016). Although the global age-adjusted mortality rate for stroke decreased, the absolute number of people who have stroke increased between 1990 and 2015 (Benjamin et al., 2018). In 2016, stroke is the second leading cause of death globally and has remained the leading cause of death in the past 15 years (WHO, 2018).

Stroke is a cerebrovascular disease affecting the central nervous system, resulting either from insufficient blood flow to the brain or hemorrhage into the parenchyma or subarachnoid space of the central nervous system. Stroke patients may develop focal or global cerebral function disturbances lasting more than 24 h or death. Stroke survivors may experience various complications such as loss of vision, loss of speech, paralysis, and confusion (Koda-Kimble et al., 2013). High blood pressure and atrial fibrillation are the two important risk factors for stroke (Hörnsten et al., 2016).

Stroke can be either classified as ischemic or hemorrhagic. According to the American Heart Association report 2015, 87% of all strokes are ischemic, while 13% is hemorrhagic (Mozaffarian et al., 2015). Although hemorrhagic stroke is less common, it is more fatal than ischemic stroke with up to 46.5% of fatality rates compared to 9%–23% for ischemic stroke (Godoy et al., 2015).

Transient ischemic attack (TIA) is due to inadequate cerebral or ocular blood flow. The inadequate blood supply may be caused by low blood flow, thrombosis, or embolism, which leads to loss of cerebral or ocular function with symptoms lasting less than 24 h (George Rudd et al., 2017). The symptoms appear rapidly, and the clinical presentations depend on the portion of the cerebrovascular branch affected. The symptoms include slurred speech, aphasia, weakness or paralysis of a limb, or blindness (Koda-Kimble et al., 2013). Approximately 20% of TIA patients experienced at least one symptom (Godoy et al., 2015).

Ischemic stroke is caused by occlusion of cerebral artery, leading to decreased cerebral blood flow. The occlusion of blood vessels is caused either by local thrombus formation or by embolic phenomena. Atherosclerosis is a causative factor in most cases of ischemic stroke (DiPiro et al., 2017). Emboli can arise from intracranial or extracranial origin. Cardiogenic embolism is prone to happen in patients suffering from atrial fibrillation, valvular heart disease, or other heart conditions that lead to clot formation (Mozaffarian et al., 2015).

Hemorrhagic strokes include subarachnoid hemorrhage (SAH) and intracerebral hemorrhage (ICH) (DiPiro et al., 2017). SAH involves leakage of blood into the brain and the space surrounding the brain or subarachnoid space. Cerebral artery aneurysm, arteriovenous malformation, hypertensive hemorrhage, and trauma are among the major causes of SAH (Koda-Kimble et al., 2013). ICH occurs when a blood vessel ruptures within brain parenchyma, resulting in the formation of hematoma. Uncontrolled high blood pressure and antithrombotic or thrombolytic therapy are among the risk factors for ICH (DiPiro et al., 2017). The leakage may be typified by sudden onset of severe headache and vomiting (George Rudd et al., 2017).

Severe neurological deficits happen as stroke progresses and thus, timely initiation of appropriate therapy for stroke patients is important (Saver, 2006). Involvement of pharmacists in stroke care team reduces the door-to-needle time (Kevin Brandon et al., 2018; Rech et al., 2017). Besides, pharmacists also play an essential role in providing counseling and education to stroke patients in order to ensure poststroke treatment adherence (Rhoney, 2011), minimize the impact of stroke-related complications (Rhoney, 2011; Sreenivasan, 2012), and improve patients' health-related quality of life (Hohmann et al., 2009).

Epidemiology

According to the GBD 2015, the incidence of both ischemic and hemorrhagic stroke increased by 15.8% and 14%, respectively, from 2005 to 2015 globally (Vos et al., 2016). In the United States, on average, someone suffers from stroke every 40 s (Mozaffarian et al., 2015). In 2015, every 3 min 45 s, one patient died of stroke, which accounted for approximately 1 of every 20 deaths in the United States. It is projected that by 2030, nearly 4% of the United States' population will have a stroke attack (Ovbiagele et al., 2013).

Stroke events are more likely in those patients with lower income and lower educational level (Ovbiagele et al., 2013). Around 70% of stroke cases and more than 85% of stroke-related deaths and disability-adjusted life years are found in low- and middle-income countries, and the incidence has been on the increasing trend over the past 40 years (Feigin et al., 2009; Owolabi et al., 2015; Strong et al., 2007). On the other hand, the incidence of stroke decreased by 42% in high-income countries (Owolabi et al., 2015; Strong et al., 2007). High-income countries such as Austria and Switzerland have reported a relatively low stroke mortality rate, although a large proportion of their population is elderly (aged more than 65 years old) (Thrift et al., 2017). According to Owolabi et al. (2015), stroke occurs 15 years earlier in people living in low- and middle-income countries and causes more deaths compared to people living in high-income countries. Furthermore, up to 84% of patients in low- and middle- income countries die within 3 years of stroke diagnosis, making the mortality rate five times higher than in patients with stroke living in high-income countries (Owolabi et al., 2015). Besides, 34% of stroke patients in low- and middle-income countries are diagnosed with hemorrhagic stroke, which is almost four times higher when compared with the hemorrhagic stroke incidence reported in high-income countries (Owolabi et al., 2015).

The risk of having stroke varies with race or ethnicity, age, and gender. Generally, the incidence of having first stroke attack was higher in black individuals than with white individuals (Howard et al., 2016). Male generally has lower lifetime risk of stroke than female (Centers for Disease Control and Prevention, 2012). Furthermore, the lifetime risk of stroke among those 55–77 years of age is 1–5 for women and approximately 1–6 for men (Seshadri et al., 2006). In the United States, there have been approximately 55,000 more females suffering from stroke attack when compared to male patients (Persky et al., 2010). Age-specific stroke incidence rate is almost similar in older age group; however, the incidence rate is lower in female than in male in younger and mid-age populations (Benjamin et al., 2018).

In the United States, the estimated prevalence of TIA is around 0.5 million annually and affects 1.1 per 1000 of the population (Panuganti and Dulebohn, 2018). There are important racial, ethnic, gender, and age differences in incidence rates for TIA. The incidence increases with age. Male, African American and Mexican Americans showed higher incidence rate when compared to the female, non-Hispanic white populations (Kissela et al., 2004; Kleindorfer et al., 2005; Morgenstern et al., 2004). There is an

established correlation between the occurrence of TIA and increased risk of subsequent stroke. Around 12% of all stroke events reported is associated with TIA (Hankey, 1996). Stroke attack is reported to be the highest within the first 30 days after TIA event and the TIA risk of stroke within 90 days is reported at 3.7%–17% (Amarenco et al., 2008; Giles and Rothwell, 2007; Johnston et al., 2000; Wu et al., 2007).

In the United States, the total medical cost of stroke (both direct and indirect medical cost) incurred in 2012 to 2013 was $33.9 billion with the estimated direct medical cost being $17.9 (Agency for Healthcare Research and Quality, 2014). It is projected that by the year 2030, the total direct medical stroke-related costs will be $184.1 billion (Ovbiagele et al., 2013). Recurrent stroke patients had 38% higher cost per patient a year after discharge from hospital as compared to new stroke patients (Engel-Nitz et al., 2010). From 2001 to 2005, the average cost involved in stroke rehabilitation was $11,145 (Godwin et al., 2011). Besides, health-care costs associated with stroke survivors with complications such as spasticity are fourfold higher than those without spasticity (Lundström et al., 2010).

Poststroke depression and stroke-related disability are those factors affecting stroke survivors' health-related quality of life (HRQoL). Nearly 30% of stroke survivors suffered from poststroke depression (Abubakar and Isezuo, 2012; Hackett and Anderson, 2005). Poststroke depression has been found to be associated with higher chances of suicidal ideation (Fuller-Thomson et al., 2012). Depression also slows down the rehabilitation process and negatively affects patients' HRQoL (Gray et al., 2007; Williams et al., 1999). However, poststroke depression is a treatable condition, and early diagnosis may prevent the progression to chronic depressive disorder. The degree of stroke-related disability measured by Modified Rankin Scale (MRS) also has negative impact on patients' quality of life (QoL). Patients who remained disabled 3 months after stroke had poor QoL (Godoy et al., 2015; Hackett & Anderson, 2005), although another study has reported poor QoL even in patients without disability after stroke (Lai et al., 2002).

Pathophysiology

Stroke may arise due to local damage to a vessel wall from atherosclerosis. Development of atherosclerosis begins with endothelial injury and inflammation, leading to plaque or clot formation which affects the cerebral blood flow of the brain. The clot may form near the infarcted area in the brain or it might have migrated to the brain from a distant source. Clot arising from a distant source is considered as embolus. However, if the clot is formed near the infarcted area, it is considered a thrombus (Frizzell, 2005).

Thrombotic infarction is mainly due to atherosclerosis. The release of adenosine diphosphate (ADP), thrombin, epinephrine, and a variety of other substances due to tissue injury or turbulent blood flow may stimulate platelet migration. Adhesion of platelet to the damaged blood vessel wall is enhanced by the exposure of collagen and other subendothelial surfaces of the blood vessel wall. Phospholipase is activated as a result of platelet adhesion and aggregation, which leads to the formation of thromboxane A_2 (TXA_2). TXA_2 induces platelet release and aggregation, which results the formation of clot in blood vessel (Sangkuhl et al., 2011).

The pathophysiology of ischemic stroke due to embolic event is similar to ischemic stroke due to thrombotic event. Embolus composes of platelet, clot, or plaque debris that can be either originated from the heart or major blood vessels. Portions of these clots may break away and travel through the blood to the brain, which occlude the intracranial arteries leading to partial or totally occlusion of blood flow. Atherosclerotic plaque is commonly found in the carotid artery that accounts for up to 20% of ischemic stroke, while cardiac embolus accounts for up to 30% (Arboix and Alió, 2010). Cardiac events such as myocardial infarction, atrial fibrillation and flutter, rheumatic and prosthetic valves, and infective endocarditis are among the major risk factors for embolus formation (Arboix and Alió, 2010; Koda-Kimble et al., 2013). Other risk factors of ischemic stroke are listed in **Table 1**.

Inflammatory process is responsible for the development of ischemic stroke. Within hours of infarction, substances such as adhesion molecules, C-reactive protein, proinflammatory cytokines, such as tumor necrosis factors-alpha, interleukin-I, interleukin-6, free oxygen radicals, and chemokines increase and lead to inflammation. Inflammation enhances the development of thrombotic lesions and causes occlusion of blood vessels (Jin et al., 2010).

Normal cerebral blood flow in a healthy adult is 30–70 mL/100 g/min. The reduction of cerebral blood flows to less than 20 mL/100 g/min causes an electrical silence and irreversible neuronal injury including neuron cells death might happen if the cerebral blood flow continues to reduce to less than 10 mL/100 g/min (Hakim, 1998; Jones et al., 1981). There are three mechanisms that lead to cell death during brain ischemic events, namely, excitotoxicity and ionic imbalance, oxidative and nitrosative stresses, and apoptotic-like cell death (Carbonell and Rama, 2007). Excitotoxicity and ionic imbalance and oxidative and nitrosative stresses cause cell death in the central core. Apoptotic like cell death normally happens in the penumbral region of the brain.

Intracerebral hemorrhage (ICH) refers to bleeding in the brain parenchyma and surrounding meningeal spaces. ICH is a manifestation of underlying small vessel disease. Hypertension and cerebral amyloid angiopathy (CAA) are the important risk factors for ICH. The risk of hypertension-related ICH increases with increasing blood pressure (Matsukawa et al., 2012), whereas CAA-related ICH tends to occur in elderly (Ariesen et al., 2003). Other risk factors include cerebral artery aneurysm, arteriovenous malformation, and trauma (Koda-Kimble et al., 2013). Hypertensive vasculopathy due to longstanding hypertension changes the walls of the small and medium penetrating vessels. CAA leads to deposition and accumulation of amyloid-beta peptide in the walls of small vessel (Vinters, 1987). These subsequently result in the changes in the vessel wall characterized by the loss of smooth muscle cells, wall thickening, luminal narrowing, microaneurysm formation, and microhemorrhages (Viswanathan and Greenberg, 2011). Vessel rupture leads the leakage of blood into the brain and its surrounding structures. Neurologic dysfunction in ICH is due to the direct irritant effects of blood that is in contact with the brain tissues (Gund et al., 2013).

Table 1 Risk factors for ischemic stroke

Modifiable risk factors:
- Cardiovascular disease
- Hypertension
- Atrial fibrillation
- Asymptomatic carotid stenosis
- Dyslipidemia
- Diabetes mellitus
- Sickle cell disease
- Postmenopausal hormone replacement therapy
- Obesity
- Cigarette smoking
- Physical inactivity

Potentially modifiable:
- Metabolic syndrome
- Alcohol abuse
- Hyperhomocysteinemia
- Drug abuse
- Hypercoagulability
- Oral contraceptive use
- Inflammatory process
- Acute infection

Non-modifiable risk factors:
- Age
- Race
- Sex
- Low birth weight
- Family history of stroke

Clinical Presentations and Diagnosis of Ischemic Stroke

Clinical signs and symptoms of stroke or TIA are determined by the location of the brain area that is affected. For example, if the left side of the brain that controls the motor function is affected, then the muscle strength or movement on the right side of the body will be disturbed. The clinical signs and symptoms of stroke or TIA include paresis or paralysis of the limbs, slurred speech, blurred vision, facial drop, dizziness, and difficulty in swallowing (DiPiro et al., 2017; Koda-Kimble et al., 2013).

Resumption of adequate blood perfusion to the affected blood vessels is the immediate primary treatment goal of stroke. According to the American Heart Association/American Stroke Association 2018 guideline (Powers et al., 2018), formal stroke scores based on NIH Stroke Scale (NIHSS) is recommended to be performed. The formal stroke scores quantify the degree of neurological defects that may aid in the decision of type of treatment and identify those patients who are at higher risk of intracerebral hemorrhage and other complications (Adams et al., 1999; Fonarow et al., 2012; Frankel et al., 2000; Wahlgren et al., 2008). Brain imaging evaluation using noncontrast computerized tomography (NCCT) is recommended over diffusion-weighted magnetic resonance imaging (DW-MRI) for all patients admitted to hospital suspected of acute stroke to exclude the use of antithrombotic agents in intracerebral hemorrhage (Powers et al., 2018). Blood glucose assessment should be performed prior to the initiation of IV alteplase in all patients, while other tests such as baseline ECG assessment, international normalized ratio (INR), activated partial thromboplastin time, and platelet count may be needed in certain circumstances; however, the treatment with IV alteplase should not be delayed while pending for these investigations (Powers et al., 2018).

Management of Ischemic Stroke

The immediate approach to the management of a stroke patient is to ensure that the patient is supported from a respiratory and cardiac standpoint and to determine whether the patient is having ischemic or hemorrhagic stroke. The goals of treatment of ischemic stroke are to (1) re-establish adequate blood perfusion in the occluded vessel, (2) reduce the ongoing neurological injury, (3) decrease mortality and long-term disability, (4) prevent complications to immobility and neurologic dysfunction, and (5) prevent stroke recurrence (DiPiro et al., 2017; Koda-Kimble et al., 2013). The treatment algorithm for ischemic stroke is summarized in Fig. 1.

Acute Treatment of Ischemic Stroke

Thrombolytic Agent

Blood clot that causes blockage to the brain artery is one of the main causes of ischemic stroke. Timely initiation of thrombolytic agent, which dissolves blood clot, ensures blood perfusion to the blocked area before a major damage to the brain occurs (Wardlaw et al., 2014). Time is brain and early blood reperfusion leads to better recovery from ischemic stroke. However, the use of thrombolytic agent may cause hemorrhage in the brain, which could be fatal in severe cases. The use of thrombolytic agent is contraindicated in hemorrhagic stroke. Thus, it is important to exclude patients with hemorrhagic stroke from initiating thrombolytic therapy.

Alteplase (i.e. tPA) is one of the thrombolytic agents used in ischemic stroke patients. The benefit of the treatment is time dependent. For better outcome, thrombolytic agent should be administered to suitable ischemic stroke patients as fast as possible after the onset of symptoms (Ettehad et al., 2016; Wardlaw et al., 2014). The efficacy of alteplase is proven if administered within 3–4.5 h after ischemic stroke onset (The ATLANTIS, ECASS, 2004; Wahlgren et al., 2007; Wardlaw et al., 2014, 2012).

Thrombolytic treatment is strongly recommended for patients with ischemic stroke caused by large vessel occlusion and those who are candidates for endovascular thrombectomy (Goyal et al., 2016). For ischemic stroke patients who meet specific eligible

Table 2 Contraindication of thrombolytic treatment

- Active systemic bleeding
- Systemic coagulopathy with
  - Platelet count $< 100{,}000\ mm^3$
  - INR > 1.7
  - Elevated ATPP with unfractioned heparin use within 48 h
  - Abnormal antifactor Xa activity with low molecular weight heparin use within 24 h
  - Abnormal coagulation profile with direct oral anticoagulant use within 24 h
- Infective endocarditis
- Acute intracranial hemorrhage

Adapted from Sandercock. Peter AG, Counsell. Carl, Mei-Chiun. Tseng and Cecconi. Emanuela, 2014, Oral antiplatelet therapy for acute ischemic stroke. Cochrane Database of Systematic Reviews, 3, Art No.: CD000029. Copyright 2014 by the Cochrane Collaboration

criteria, alteplase 0.9 mg/kg (maximum 90 mg) administered intravenously over 1 h with initial 10% of the dose given as bolus injection over 1 min should be initiated (Goyal et al., 2016; Wardlaw et al., 2014).

Tenecteplase, a more fibrin-specific agent with longer duration of action, is another thrombolytic agent used in ischemic stroke management. Both alteplase and tenecteplase are associated with intracerebral hemorrhage risk (1%). According to a clinical trial involving 1100 patients, tenecteplase failed to demonstrate superiority over alteplase in patients with minor neurological impairment (NIHSS score 4) and no major intracranial occlusion (Logallo et al., 2017). Contrary, based on the study conducted by Campbell et al. (2018), tenecteplase performed better than alteplase before thrombectomy for ischemic stroke patients with better 90-day functional outcome and better MRS score. Although the safety profile of tenecteplase appears to be similar to alteplase, whether it is as effective as or more effective than alteplase still remains unclear due to the lacking of sufficient clinical evidence (Haley et al., 2010; Huang et al., 2015; Logallo et al., 2017; Parsons et al., 2012).

If a patient is not a candidate for thrombolytic therapy, antiplatelet therapy should be initiated after hemorrhagic stroke is excluded (Sandercock et al., 2014). Bleeding risk or potential bleeding risk is one of the contraindications to thrombolysis. Other contraindications of thrombolytic treatments are listed in **Table 2**.

There are few clinical conditions that do not exclude the use of thrombolytic agents; however, these make the initiation of thrombolytic agents to be carefully considered due to risk and benefit. Those clinical conditions include (Sandercock et al., 2014):

- Uncontrolled high blood pressure with systolic and diastolic blood pressure more than 185 mmHg and 110 mmHg, respectively
- History of intracranial hemorrhage
- Major head trauma or spinal or cranial surgery within 3 months
- Major surgery or trauma within 14 days
- Gastrointestinal or genitourinary tract bleeding within 21 days
- Ischemic stroke within 3 months
- Central nervous system neoplasm

Treatment with thrombolytic agent should only be initiated if the BP $< 185/110$ mmHg and should have the BP monitored in the first 24 h after the treatment (Powers et al., 2018). Regardless of diabetic status, antihyperglycemic therapy should be started when blood glucose level is greater than 10 mmol/L (Middleton et al., 2011).

There are insufficient data to support the safe use of intravascular thrombolytic agents and direct oral anticoagulants within 48 h of stroke onset. However, this is not an absolute contraindication to stop using thrombolytic agents. There are several ways to initiate thrombolytic treatment in patients who use direct oral anticoagulant within 48 h, and these include reversal of anticoagulant with specific antidote, appropriate coagulation testing, and immediate thrombectomy (Hankey et al., 2014).

Antiplatelet Therapy

Antiplatelet therapy with aspirin as the most commonly known agent, is part of the antithrombotic therapy in stroke management. Antiplatelet agents inhibit platelet adhesion and aggregation in intracerebral artery. They decrease the neurological complications, risk of morbidities and mortalities, as well as risk of early recurrent stroke (Sandercock et al., 2008, 2014). Although increased risk of intracerebral hemorrhage may offset its benefit, recent clinical trials reported a relatively low risk of major bleeding with the use of aspirin in embolic stroke compared to an anticoagulant (Hart et al., 2018; Sandercock et al., 2014). Thus, aspirin is highly recommended in ischemic stroke patients who are not candidates for reperfusion therapy after brain imaging excludes hemorrhage (Powers et al., 2018).

Administration of aspirin is highly recommended in acute ischemic stroke patient within 24–48 h after symptoms onset. Aspirin given at the dose between 150 mg and 300 mg has been proven to be safe and effective (Castillo et al., 1998; Sandercock et al., 2014; Sandercock and Group, 1997). Rectal or nasogastric administration is further recommended in a patient who is unable to swallow (Powers et al., 2018). Combination use of aspirin and alteplase within 24 h significantly increases the risk of intracranial hemorrhage with no apparent benefit (Zinkstok et al., 2012). Although the evidence is not strong, acute antiplatelet therapy is recommended to be deferred at least for 24 h after administration of alteplase (Powers et al., 2018).

Clopidogrel inhibits platelet aggregation induced by ADP. Based on CAPRIE trial (Clopidogrel vs Aspirin in Patient at Risk of Ischaemic Event) (CAPRIE Steering Committee, 1996), relative risk of ischemic event reduction of 7.3% was observed in patients receiving clopidogrel 75 mg/day as compared to those patients receiving aspirin 325 mg/day. Clopidogrel is associated with higher incidence of rash and diarrhea than aspirin. Reduction in neutrophils counts and thrombocytopenia purpura are reported in patients receiving clopidogrel (Azarm et al., 2011; Rubano et al., 2015). Clopidogrel is considered as an alternative to aspirin in secondary prevention of stroke (Koda-Kimble et al., 2013).

Dual antiplatelet regimen with aspirin and clopidogrel has shown to reduce recurrent stroke and its associated morbidities and mortalities with no increased risk of bleeding compared with aspirin monotherapy, as reported in CHANCE trial (Clopidogrel in high-risk patients with acute nondisabling cerebrovascular events) (Wang et al., 2015). However, this trial mainly focused on Asian Chinese population, making the benefit of the dual antiplatelet therapy uncertain to the non-Asian population. This gap nonetheless has recently been filled by Claiborne Johnstan et al (S. Claiborne Johnston et al., 2018) where they conducted a randomized trial on international population with ischemic stroke or high risk of TIA. The result showed that those patients receiving dual antiplatelet therapy had lower risk of major ischemic events although they experienced higher risk of major bleeding than those receiving aspirin monotherapy in the 90-day trial period (S. Claiborne Johnston et al., 2018).

Ticlopidine is an antiplatelet agent, which is chemically related to clopidogrel. It works by inhibiting ADP-induced platelet aggregation. According to two large clinical trials, TASS (Ticlopidine Aspirin Stroke Study Group) (Hass et al., 1989) and CATS (Canadian American Ticlopidine Study) (Gent et al., 1988), which recruited a total of 4141 patients, ticlopidine significantly reduced risk of stroke by 21%–33.5%. However, hematological and gastrointestinal adverse effects limit its use. The risk of adverse effects is greater with ticlopidine than aspirin (Hass et al., 1989). Fatal thrombotic thrombocytopenia purpura (TTP) has been associated with ticlopidine. Among the 60 cases of ticlopidine-induced TTP reported to the U.S. Food and Drug Administration (FDA) in 1998, approximately one-third of the patients had died from TTP (Bennett et al., 1998). Other potentially fatal types of hematologic adverse effects such as agranulocytosis, aplastic anemia, neutropenia, pancytopenia have been reported (Paradiso-Hardy et al., 2000). Due to the severe adverse effects, a complete blood count should be performed prior to the initiation of ticlopidine therapy and every 2 weeks for the first 3 months of the therapy (Koda-Kimble et al., 2013).

Ticagrelor, a platelet aggregation inhibitor, is found to be inferior to aspirin. The primary outcomes measured in SOCRATES trial (Acute Stroke or Transient Ischaemic Attack Treated With Aspirin or Ticagrelor and Patient Outcomes) (S. Claiborne Johnston et al., 2016) including the time to the composite end point of stroke, myocardial infarction, and death up to 90 days suggest that ticagrelor is not as effective as aspirin. However, based on its safety profile, which is similar to aspirin, ticagrelor might be considered a reasonable alternative in patients who have contraindications to aspirin (S. Claiborne Johnston et al., 2016; Powers et al., 2018).

Glycoprotein IIb/IIIa Receptor Antagonists

The efficacy of glycoprotein IIb/IIIa receptor antagonists such as abciximab, tirofiban, and eptifibatide in the management of acute ischemic stroke are not well established (Adeoye et al., 2015a, 2015b; Pancioli et al., 2008; Siebler et al., 2011). Administration of glycoprotein IIb/IIIa receptor antagonists in the treatment of acute ischemic stroke is harmful with associated increased risk of intracerebral hemorrhage (Ciccone et al., 2014). The increased risk of intracerebral hemorrhage with the use of abciximab in acute ischemic stroke patients in AbESTT trial (A Study of Effectiveness and Safety of Abciximab in Patient With Acute Ischaemic Stroke) led to early termination of the trial (Harold P. Adams et al., 2008).

Anticoagulants

Common anticoagulants such as heparin and warfarin are part of the antithrombotic therapies for patient with cardioembolic acute ischemic stroke (Powers et al., 2018). They reduce the propagation of a thrombus in an intracerebral artery and reduce early recurrent thromboembolic stroke. Oral anticoagulation is the treatment of choice for the prevention of stroke in patients with atrial fibrillation. Atrial fibrillation is an independent risk factor for stroke, and it increases the risk by about fivefold (Wolf et al., 1991). In the European Atrial Fibrillation Trial (EAFT), patients with nonvalvular atrial fibrillation and prior stroke were randomized to warfarin, aspirin, or placebo (European Atrial Fibrillation Trial, 1995). A reduction of risk of cardiovascular events including stroke and death was reported in up to 53% of patients treated with an anticoagulant (European Atrial Fibrillation Trial, 1995). However, risk of major bleeding is a limiting factor to its use (Sandercock et al., 2008, 2014). Nevertheless, SPAF III trial (Stroke Prevention in Atrial Fibrillation) suggested that targeting INR of 2.5 in patients with nonvalvular atrial fibrillation in preventing stroke was associated with lowest risk of bleeding (Kernan et al., 2014; Meschia et al., 2014). Due to its high risk of major bleeding, anticoagulant is recommended only in TIA/stroke patient associated with cardioembolism (Sandercock et al., 2008).

The use of heparin, either the unfractionated heparin (UFH) or low molecular weight heparin (LMWH) for deep vein thrombosis prophylaxis in immobilized patients with acute ischemic stroke, is not well established. Prophylactic use of UFH or LMWH is associated with significant reduction of pulmonary embolism and deep vein thrombosis, but it also associated with significant increases in intracranial hemorrhage and extracranial hemorrhage. Due to the risk of hemorrhage, intermittent pneumatic compression (IPC) should be considered as deep vein thrombosis prophylaxis in immobilized stroke patients (Dennis et al., 2016). The usefulness of novel oral anticoagulants (NoACs) such as dabigatran, direct thrombin inhibitor such as argatroban (Barreto et al., 2012, 2017; Kate et al., 2015), and factor Xa inhibitor, such as rivaroxaban, apixaban, and edoxaban (Gioia et al., 2016) in the treatment of acute ischemic stroke either as a single or an adjunct therapy to alteplase are not well established.

Acute Blood Pressure-lowering Agents

High blood pressure is one of the risk factors for ischemic stroke and hemorrhagic stroke (Geeganage et al., 2012) and up to 70% of those stroke patients admitted to hospital have a history of high blood pressure (National Stroke Foundation, 2015). Patients with acute ischemic stroke can present with several acute comorbidities such as acute heart failure, aortic dissection, preeclampsia/eclampsia, which demand emergency blood pressure reduction to prevent serious complications. However, drastic blood pressure lowering in the acute phase care to systolic blood pressure (SBP) < 140 mmHg increases the risk of renal adverse effects (Qureshi et al., 2016) and does not benefit the patient on death or functional outcome (Geeganage et al., 2012). For acute ischemic stroke patients with blood pressure greater than 220/120 mmHg, blood pressure should be gradually reduced to 20% over the first 24 h (Powers et al., 2018) and subsequently to the target level of SBP of 140 mmHg (Barreto et al., 2012).

BP is an important monitoring criterion to decide the optimal timing for the initiation of thrombolytic therapy. For candidates who meet the criteria for treatment with IV alteplase, their SBP and diastolic blood pressure (DBP) should be less than 185 mmHg and less than 110 mmHg, respectively, before the treatment is given. The BP should be maintained at <180/105 mmHg for the first 24 h after the treatment (Powers et al., 2018). Studies suggest that there is greater risk of hemorrhage in patients with high BP (Butcher et al., 2010; Endo et al., 2013; Mazya et al., 2012; Perini et al., 2010; Waltimo et al., 2016; Wu et al., 2016). According to the American Heart Association/American Stroke Association 2018 management of acute ischemic stroke guideline (Powers et al., 2018), thrombolytic agent should not be initiated if BP is more than 185/110 mmHg. For patients meeting the criteria of IV alteplase treatment with BP > 180/110 mmHg, the following antihypertensive treatment regimen is recommended (Powers et al., 2018):

1. IV Labetalol 10–20 mg over 1–2 min may repeat 1 time OR
2. IV Nicardipine 5 mg/h, titrate up 2.5 mg/h every 5–15 min, with maximum dose of 15 mg/h OR
3. IV Clevidipine 1–2 mg/h, titrate by doubling the dose every 2–5 min until desired BP with maximum dose of 21 mg/h OR
4. Other agents such as hydralazine and enalapril may be considered.

Patient's BP should be monitored closely for the first 24 h from the start of IV alteplase to maintain at ≤180/105 mmHg. BP should be checked every 15 min for 2 h from the initiation of IV alteplase treatment followed by every 30 min for 6 h and then every hour for 16 h. If the SBP is more than 180–230 mmHg or the DBP is more than 105–120 mmHg, the following therapy may be considered (Powers et al., 2018):

1. IV Labetalol 10 mg followed by IV continuous infusion 2–8 mg/min OR
2. IV Nicardipine 5 mg/h, titrate up by 2.5 mg/h every 5–15 min to desired blood pressure, with maximum dose of 15 mg/h OR
3. IV Clevidipine 1–2 mg/h, titrate by doubling the dose every 2–5 min to desired blood pressure, with maximum dose of 21 mg/h

IV sodium nitropruside may be considered if DBP > 140 mmHg or patient's BP is not controlled with the abovementioned therapy.

General Supportive Care

Antipyretic treatment should be given to lower body temperature in stroke patients with hyperthermia as the risk of death is greater for patient with body temperature above 39̊C (Saxena et al., 2015). However, there is lacking of evidence of benefit of inducing hypothermia in ischemic patient. Some studies have proven that inducing hypothermia is associated with higher risk of pneumonia and other types of infections (Geurts et al., 2017; Hemmen et al., 2010; Lyden et al., 2016; Piironen et al., 2014).

Patient's blood glucose should be monitored and treated accordingly to the range of 140–180 mg/dL as poor blood glucose control leads to worse outcomes during the first 24 h after acute ischemic stroke. Since hypoglycemia and hyperglycemia may mimic the ischemic stroke presentations, determining blood glucose level is needed prior the initiation of thrombolytic agent (Powers et al., 2018).

Dysphagia screening is recommended before allowing oral administration of food and medications preferably within 4 h after an acute stroke attack (Bray et al., 2017). Behavioral approaches such as swallowing exercise and dietary modification are recommended for stroke survivors who have swallowing difficulties (Geeganage et al., 2012).

Secondary Prevention of Ischemic Stroke

Poststroke patients exhibit an accumulated risk of up to 43% of having recurrent stroke in 10 years of time (Hardie et al., 2004). Early stroke symptoms identification by the patients or family members are crucial in seeking for timely medical assistance or treatment. FAST test has been a well-accepted stroke screening test for health-care professionals and general public (Harbison et al., 2003), although some stroke patients may have a negative FAST test (Powers et al., 2018). Secondary prevention with pharmacological agents and through nonpharmacological approach is able to manage or minimize the risk factors of recurrent stroke. In this context, medication adherence is one of the important aspects.

Pharmacological Approach

Antihypertensive therapy

High BP is a modifiable risk factor for stroke and should be included in the secondary stroke prevention treatment regimen as a discharge medication (Thrift et al., 2017). Poststroke survivors with BP more than 140/90 mmHg should be considered as the

Table 3 Drugs for preventing transient ischemic attack (TIA) and ischemic stroke

Drugs	*Action*	*Dose*
Aspirin	Antiplatelet	50–300 mg/day
Clopidogrel	Antiplatelet	75 mg/day
Ticlopidine	Antiplatelet	50 mg/day
Dipyridamole	Antiplatelet (in combination with aspirin)	200 mg sustained-released twice daily
Warfarin	Anticoagulant	Titrate to INR 2-3

Adapted from Koda-Kimble, Anne Marry, Young JY, 2013, Applied therapeutics: the clinical use of drugs. Philadelphia, Wolters Klumer Health/Lippincott Wiliams & Wilkins, p. 1428. Copyright 2013 by Wolters Klumer Health/Lippincott Wiliams & Wilkins

candidate for long term BP-lowering therapy with the target SBP between 120 mmHg to 140 mmHg (Costas Thomopoulos, 2016; Ettehad et al., 2016). Among the antihypertensive agents, beta blocker should be considered as first-line agent for patient with ischemic heart disease. Angiotensin-converting enzyme inhibitor or angiotensin II receptor antagonist should be considered as the drug of choice for patient with diabetes mellitus (Shrout et al., 2017). Calcium channel blockers and thiazide diuretics are also acceptable as antihypertensive therapy for poststroke patients (Lakhan and Sapko, 2009; Mukete et al., 2015).

Antiplatelet and anticoagulant therapy

Antiplatelet therapy has been the cornerstone in preventing recurrent stroke. It reduces the risk of stroke due to the formation of blood clots. There are several therapeutic options that could be used to prevent blood clot, including low dose of aspirin, clopidogrel, and combination of low dose aspirin and modified release dipyridamole. Long-term antiplatelet therapy is highly recommended to all stroke survivors (Rothwell et al., 2016; Sandercock et al., 2014). Aspirin is generally given at 300 mg as a STAT dose followed by 100–150 mg daily. A loading dose of 300 mg followed by 75 mg daily of clopidogrel would be considered as well if dual antiplatelet regimen is to be used. Both aspirin and clopidogrel proved to reduce recurrent ischemic stroke events (Rothwell et al., 2016; Sandercock et al., 2014).

Anticoagulant is an agent of choice for stroke survivors after cardioembolic stroke event secondary to atrial fibrillation. Warfarin has been widely used as an anticoagulant, especially for those who suffered from valvular atrial fibrillation or renal impairment (Tawfik et al., 2016). The introduction of novel direct oral anticoagulants (NoACs), such as dabigatran, apixaban, and rivaroxaban, which do not require routine monitoring of INR, is preferred over warfarin in nonvalvular atrial fibrillation patients with prior stroke attack (Ruff et al., 2014). The doses of antiplatelet agents and anticoagulants used in preventing TIA and ischemic stroke are summarized in **Table 3**.

Cholesterol lowering agents

Regardless of patients' baseline cholesterol level, a cholesterol-lowering agent should be prescribed for secondary prevention of stroke or cardiovascular events. Statins, especially high intensity therapy with atorvastatin 80 mg or rosuvastatin 40 mg, should be considered along with lifestyle changes and dietary modifications (Amarenco et al., 2008; Manktelow and Potter, 2009). It should be considered as first-line therapy in women and men ≤ 75 years old who have atherosclerotic cardiovascular disease (Powers et al., 2018).

Nonpharmacological Approach

Lifestyle modification is a crucial management to prevent recurrent stroke. Behavioral changing strategies focusing on daily lifestyle activities should be conveyed to public especially poststroke patients. However, according to the National Stroke Audit of Acute Services, only about half of those stroke survivors were counseled about the lifestyle modification approach to minimize the risk of recurrent stroke (National Stroke Foundation, 2015). Thus, all poststroke patients should be assessed and counseled on the risk factors for recurrent stroke and approaches to modify the risk factors (Powers et al., 2018).

Smoking cessation

Smoking has been identified as one of the major risk factors of stroke (Aldoori and Rahman, 1998). Stroke survivors who smoke are highly advised to stop smoking. Health-care professional should support and assist those tobacco dependent stroke survivors to stop smoking through smoking cessation programs.

Diet

Patient should be advised to consume at least five servings of fruit and vegetables daily because diet high in fruit and vegetable reduces the risk of stroke (Dauchet et al., 2005; He et al., 2006). BP reduction in patient with cardiovascular diseases through sodium restriction has proved to be effective in preventing stroke attack (He et al., n.d.). Excessive alcohol intake increases the risk of stroke, but light alcohol consumption with one to two standard drinks is protective against stroke (Reynolds et al., 2003; Ronksley et al., n.d.). Limiting the intake of alcohol, restricting the consumption of food, which is high in saturated fat and high sugar content, and maintaining healthy body weight may help to prevent stroke (Government National Health and Medical Research Council Department of Health and Aging, 2013).

Physical activity

Overweight and obesity are modifiable risk factors of ischemic stroke (Strazzullo et al., 2010). Healthy diet pattern and exercise are both effective ways to maintain body weight. To prevent stroke and other cardiovascular diseases, patients are advised to be physically active (Warburton et al., 2006). Adults in the age range of 18–64 years old should do at least 150 min moderate intensity or 75 min of vigorous intensity exercise weekly. For those aged 65 years old and above, 30 min daily of moderate intensity exercise is recommended (Government Department of Health Ageing, 2005).

Medication adherence

Medication adherence issue is generally high in elderly patients with the prevalence up to 43% (McKenzie et al., 2015). Nonadherence to prescribed medication is a major barrier to effective secondary prevention of stroke. Lacking of information, burden of the treatment, concerns about medication side effects, beliefs toward medication, difficulties in taking medication, and inability to self-care are some of the factors contributing to nonadherence (Kronish et al., n.d.).

Monitoring and Complications Associated With Stroke

Monitoring of Alteplase Administration

The recommended treatment regimen of alteplase is 0.9 mg/kg infused over 60 min with 10% of the total dose given as a bolus injection over 1 min. During and after the administration of IV alteplase, measurement of BP and neurological assessment should be performed every 15 min for 2 h, followed by every 30 min for 6 h then every hour until 24 h after the treatment initiation. If the patient develops severe headache, acute hypertension, nausea and vomiting, or showed worsening neurological examination stop the IV infusion. BP monitoring should be more frequent if patient's SBP is >180 mmHg or DBP is >105 mmHg. Starting antihypertensive treatment should be considered to maintain desired BP. A follow-up CT or MRI scan at 24 h after the infusion is performed before starting antiplatelet or anticoagulant therapy (Powers et al., 2018). If symptomatic intracranial bleeding (sICH) develops within 24 h after alteplase therapy, infuse 10U cryoprecipitate over 10–30 min and administer additional dose to achieve a fibrinogen level of ≥150 mg/dL (Powers et al., 2018; Yaghi et al., 2017). Platelet transfusion is considered only in patients with thrombocytopenia with platelet count <100 000/μL (Yaghi et al., 2017).

Glycemic Control

Blood glucose level in poststroke patients fluctuates in the first 72 h in diabetic and nondiabetic patients (Allport et al., 2006). Glucose intolerance is commonly noted in poststroke patients (Allport et al., 2006; Vancheri et al., 2005). Although there have been huge variation from 8% to 83% incidence rate, the development of hyperglycemia after stroke attack is not uncommon (Vermeer et al., 2006) and is linked to higher recurrent stroke (Vermeer et al., 2006). Regardless of the patient's diabetic status, all stroke patients should be initiated with appropriate antihyperglycemic therapy if the blood glucose level is greater than 10 mmol/L followed by close blood glycemia monitoring at the first 72 h after hospital admission (Middleton et al., 2011). Monitoring blood glucose level and treating the blood glycemic level to the target are associated with better outcomes at 90 days (Middleton et al., 2011). However, tight range of glycemic control at 4–7.5 mmol/L is not recommended as it does not improve mortality or functional outcomes but increases the risk of hypoglycemia in patient treated with intravenous insulin (Bellolio et al., 2014; Ntaios et al., 2014).

Body Temperature

Poorer outcome is associated with patients who develop pyrexia (Greer et al., 2008) with body temperature greater than 37.5°C and up to 50% of poststroke patient develop pyrexia (Castillo et al., 1998). Thus, monitoring patients' body temperature every 6 hourly for 72 h is recommended (Middleton et al., 2011).

Complications

There are various complications that may arise due to stroke. Besides weakness of the limbs and losing strength of the affected muscle, seizure may occur in up to 20% of poststroke patients. In addition, pneumonia, pulmonary edema, arrhythmias, and deep vein thrombosis may be seen in stroke patients (Koda-Kimble et al., 2013). Stroke-associated psychological disorders such as depression may affect up to 30% of the patients (Abubakar and Isezuo, 2012; Hackett and Anderson, 2005).

Role of Pharmacist in Health-Care Team: Stroke Management

Acute ischemic stroke is a severe neurological event that needs timely treatment. Patients who survive from stroke may experience complications and the risk of recurrence stroke is higher than patients who did not experience stroke. Stroke patients may interact with different health-care providers, including physicians, nurses, pharmacists, and physiotherapists, throughout their course of disease management and rehabilitation process.

Pharmacist is a member of the multidisciplinary health-care team in providing pharmaceutical care to stroke patients. Timely administration of thrombolytic agents within 3 h after the onset of ischemic stroke with a door-to-needle time of 60 min is associated with better clinical outcomes (Powers et al., 2018). Involvement of pharmacist in the emergency department in reducing the door-to-needle time is promising. A study was conducted to evaluate the door-to-needle time in stroke patients with the presence of pharmacist and without the presence of pharmacist. In the presence of pharmacist, the door-to-needle time was reduced from 73 min to 43 min, and the goal of door-to-needle time of ≤ 60 min was achieved in 71% of patients (Rech et al., 2017).

Administration of thrombolytic agents involves careful dose calculation based on patient's body weight and proper drug reconstitution process to prevent unwanted side effects such as hemorrhage owing to overdose. Brandon et al conducted a study to evaluate the involvement of pharmacists in calculating the dose of thrombolytic agent to be administered to stroke patients and the expanded role of pharmacists in mixing thrombolytic agent at bedside together with nurses in the hospital emergency department. The study reported reduction of decision-to-needle thrombolytic administration time in the presence of pharmacists. Besides, up to 78% of the cases achieve zero minute decision-to-needle time with the involvement of pharmacists in managing stroke patients (Kevin Brandon et al., 2018).

Medication treatment in stroke patients is complicated and may cause wide range of drug-related problems (DRPs), which eventually result in morbidity, mortality, prolonged hospital stay, and incur additional treatment cost. Identifying the DRPs is one of the primary roles of in-patient pharmacist or clinical pharmacist to prevent unwanted side effects and promote optimal therapeutic outcomes. According to a study conducted by Hohmann et al. (2012), DRPs happened in almost 70% of stroke patients admitted to hospital with at least two medications given in the ward and at discharged. Those DRPs identified by pharmacist in ischemic stroke patients are associated with the issue of under treatment, and most of the missing drugs were stroke-related secondary prevention therapies (Hohmann et al., 2012). Besides, Lindblad et al. (McAlister et al., 2014) reported an average of 2.8 pharmaceutical interventions made per patient encountered in stroke prevention clinic and up to 64% of the interventions made by the pharmacists were accepted by the physician. These findings support the role of pharmacist in the stroke management team within hospital setting.

Antithrombotic agents together with antihypertensive agents and lipid-lowering agents have been the mainstay in preventing recurrent stroke in poststroke survivors. Uncontrolled high blood pressure and consistently high level of low density lipoprotein are among the modifiable risk factors leading to stroke. Better achievements of SBP and low-density lipoprotein to the targeted level have been reported in stroke patients who receive monthly follow-up by pharmacist (Chiu et al., 2008; McAlister et al., 2014; Nguyen et al., 2011). On top of that, studies showed pharmacists' interventions resulted in a significant increase in the prescribing of antihypertensive and antithrombotic agents to ischemic stroke patients (Khalil et al., 2015). These findings accentuate the significant role of pharmacist in enhancing the adherence of stroke treatment guidelines by medical doctors in order to prevent recurrence of stroke in stroke survivors (Khalil et al., 2015).

Although warfarin is not commonly used in the majority of ischemic stroke patients, there is beneficial effect of warfarin in preventing recurrent stroke in patients suffering from atrial fibrillation (Shah et al., 2014). The role of pharmacist in deciding the rational use of warfarin and providing counseling service on the proper use of warfarin to patients reduces the bleeding risk associated with warfarin use. A study reported the pharmacist-led anticoagulant review clinic reduces the inappropriate use of anticoagulant and the risk of atrial fibrillation-related stroke incidents (Dowling et al., 2016). In terms of cost-effectiveness in running this pharmacist-led anticoagulant review clinic compares to the cost incurred in atrial fibrillation-related stroke associated health-care cost, pharmacist-led anticoagulant review clinic is considered cost-effective if it is able to prevent only two incidents of stroke per year (Dowling et al., 2016).

Appropriate medication counseling increases drug adherence. Adherence to prescribed treatment regimen reduces recurrence of stroke and minimizes unwanted side effects of drugs. Stroke patients are always discharged with multiple medications including antithrombotic agents, antihypertensive agents, and lipid-lowering agents. Most of the time, the discharged medications are different from the medications used before their hospital admission. Complex and large amounts of discharged medications make patients confused with the treatment. The issue is further worsened when patients consult multiple health-care professionals for different health conditions. The lacking of proper and effective communication between health-care professionals may eventually lead to polypharmacy and over-prescribing. Effective communication between the hospital and primary care physician is important for the continuity care of stroke patients after discharge from hospital. Providing detailed information on medication changes by pharmacist to primary care physician showed significant improvement with regard to the adherence of post stroke-treatment regimen (Hohmann et al., 2013).

Proper and adequate stroke education and prevention strategies provided to the public especially the post stroke patients are needed. Pharmacists play a role in identifying patients at risk of first strokes attack or recurrent TIA or recurrent stroke. Proper education to high-risk patients on the signs and symptoms of TIA or stroke and the need for urgent evaluation and treatment are keys to early stroke detection and timely management. Identifying and overcoming barriers to timely diagnosis and treatment are associated with better clinical outcomes. Besides, ensuring appropriate primary and secondary stroke prevention strategies would minimize the impact of stroke-related complications. Study showed an increased in stroke patients' overall satisfaction with the present of pharmacist in providing stroke-related education in multidisciplinary health-care team (Rhoney, 2011; Sreenivasan, 2012). Involvement of pharmacist in the education of stroke patient on risk factors and stroke prevention further reduced the hospital readmission rate (Bruner, 2012; Hooker and Evans, 2018).

Care for post stroke patients does not end after hospital discharge and thus the role of pharmacists in stroke management is not just limiting at hospital setting. Community pharmacists play an equally important role as hospital pharmacists in promoting

optimal pharmaceutical care in post stroke patients. Easy access to community pharmacy setting provides a platform for the public and the post stroke patients as well as their care givers to seek medications and medical advices. Participation of community pharmacists in providing medication reviews and education for post stroke patients who were discharged home showed positive impact on patient health-related quality of life (Hohmann et al., 2009). A study to measure stroke medication adherence was conducted through examining the number of days that the patients were late for prescription refills. With the intervention of community pharmacist, there was significant reduced in the average number of days patients were late for stroke medication prescription pickup (Fincham and Wallace, 2000).

Using mobile medical applications in managing patients' clinical conditions has been widely accepted in recent years. Atrial fibrillation increases risk of stroke. Early identification of undetectable atrial fibrillation in the community and subsequently initiating appropriate antithrombotic treatment could reduce stroke burden. A study was conducted to investigate the feasibility of community screening for unknown atrial fibrillation through an iPhone electrocardiogram (iECG) in pharmacies and to determine the cost-effectiveness of this approach. The study found that screening with iPhone electrocardiogram (iECG) was both feasible and cost-effective. The high and largely preventable risk of stroke of those with newly identified atrial fibrillation reported in this study highlights the potential benefits of atrial fibrillation screening in community pharmacy setting (Lowres et al., 2014). Available evidence proves the significant role of pharmacist in both the hospital setting and community pharmacy setting.

Management of Cardiovascular Disorders and the Pharmacist's Role: Venous Thromboembolism

Seif El Hadidi, University College Cork (UCC), Cork, Ireland; Future University in Egypt (FUE), Cairo, Egypt

Learning Objectives

- Identify modifiable and nonmodifiable risk factors of venous thromboembolism (VTE).
- Describe the appropriate pharmacological management of VTE.
- Identify the applicability of the different nonpharmacological strategies in VTE management.
- Design a personalized guideline-driven anticoagulant therapeutic and monitoring plan for patients with VTE.
- Describe the roles of pharmacist in VTE management.

Take Home Messages

1. Dabigatran is as effective as warfarin at reducing VTE recurrence and is associated with less bleeding risk in acute settings.
2. Rivaroxaban is noninferior to warfarin in preventing VTE recurrence and is associated with similar bleeding rates in acute pulmonary embolism (PE).
3. Apixaban is noninferior to low-molecular-weight heparins (LMWHs) and vitamin K antagonist-based therapy for VTE recurrence and VTE mortality, but showed greater reduction in bleeding rates.

4. In patients with VTE who have completed 6–12 months of anticoagulation, rivaroxaban 10 mg/day reduces the risk of recurrent VTE without significantly increasing the risk of bleeding compared to aspirin.
5. Pharmacists are well-positioned to educate and guide providers and patients on the benefits and risks of various anticoagulants. Patients also need to be counselled on adherence, drug interactions, and what to do when doses are missed.

Introduction

Thrombosis refers to abnormal, life-threatening blood clots that form in the artery or vein. Thrombosis can affect any venous or arterial circulation. Venous thromboembolism (VTE) is a fairly common condition in which blood clots form most often in the deep veins of the leg (known as deep vein thrombosis, DVT) and can travel through blood circulation and lodge in the lungs (known as pulmonary embolism, PE) (Di Nisio et al., 2016). VTE is a pathological condition that is associated with significant morbidity and mortality. The spectrum of disease ranges from a clinically unsuspected silent disease to a massive embolism causing long-term sequelae. It is a leading cause of hospital-associated premature death and disability worldwide (Jha et al., 2013). VTE burden consumes an estimated cost of more than USD 1.5 billion per year in the United States (US) and more than €3 billion per year in Europe (Dobesh, 2009). It claims more lives than acquired immune deficiency syndrome (AIDS), breast and prostate cancer, and motor vehicle crashes combined in the United States and Europe (Cohen et al., 2007). However, it is considered a preventable cause of morbidity and mortality (Jha et al., 2013). Around 60% of VTE cases occur during or after hospitalization (Jha et al., 2013). Patients are at high risk for VTE events after surgery due to the associated inflammatory state, endothelial vascular injury, or venous stasis. Other predisposing factors have been identified, each conferring differing degrees of VTE risk (**Table 1**).

Anticoagulants are the mainstay of VTE management and are given in three phases: acute, maintenance, and extended treatment phases. Pharmacists, particularly clinical pharmacists, are well-positioned to play a significant role in VTE risk assessment, management, and provision of guideline-driven patient care (Bauer et al., 2008; Davis et al., 2013; Gharaibeh et al., 2017).

Epidemiology

VTE is a significant vascular disease. The precise number of people affected by DVT/PE is unknown due to lack of data, although as many as 900,000 symptomatic and asymptomatic cases of VTE (1 to 2 per 1000) occur annually in the United States (Beckman et al., 2010). Worldwide, the annual incidence rates range from 0.75 to 2.69 per 1000 individuals (ISTH Steering Committee for World Thrombosis Day, 2014). The incidence increases to between 2 and 7 per 1000 among individuals aged ≥70 years. Although the incidence is lower in individuals of Chinese and Korean ethnicity, their disease burden is not low because of ageing population (ISTH Steering Committee for World Thrombosis Day, 2014). Furthermore, one-third of VTE patients will have a recurrence within 10 years (Heit, 2015).

Independent predictors of recurrent VTE include old age, high body mass index (BMI), male gender, active neoplastic condition, and leg paresis-related conditions (Heit, 2015). Furthermore, pathologists believe that up to 63% of DVT cases are missed clinically (Beckman et al., 2010). The survival rates after VTE are not promising. The survival of PE incidence in the absence of DVT history is significantly lower than the one of PE incidence after DVT by 20%. The risk of early death is 18-fold higher in patients having PE than in those with DVT alone (Heit, 2015). Without adequate treatment, VTE can cause serious complications such as venous ulcers, chronic thromboembolic pulmonary hypertension (CTEPH), and postthrombotic syndrome (PTS) (Winter et al., 2017). PTS occurs in up to 20%–50% of adults with DVT. It includes long-term pain, swelling, skin problems, and in severe cases, ulcers on the calf (Winter et al., 2017). CTEPH occurs frequently after pulmonary embolic events, but is less common after DVT (Martinez et al., 2018). Also, VTE represents a significant risk of substantial mortality, with reported mortality rates of up to 40% in a period of 10-year postdiagnosis (Winter et al., 2017). Among elders with DVT, 21% will die within a year, as will 39% of those with PE (ISTH Steering Committee for World Thrombosis Day, 2014; Winter et al., 2017). Twenty-five percent of PE patients progresses to sudden death (Beckman et al., 2010).

Etiology and Risk Factors

Many transient and persistent risk factors have been identified in the past two decades. However, a third to half of VTE cases do not have an identified provoking risk factor. This segment of VTE cases is classified as unprovoked VTE (*i.e., VTE of unknown cause*). The risk factors are additive or multiplicative. The higher the number of risk factors, the higher the likelihood of thrombosis (Di Nisio et al., 2016; Piazza et al., 2009). These risk factors are of different strength [e.g., strong factors are of high odds (>10), e.g., hip or knee replacement surgeries, others are of moderate odds (~2–9) such as chemotherapy or heart failure disease, and others are of weak odds (<2) like obesity or hypertension] (Anderson Frederick and Spencer Frederick, 2003). Collectively, these factors actively increase the risk of VTE by inducing simultaneous stasis, hypercoagulability state, and endothelial damage that encourage clot formation. **Table 1** lists the risk factors for VTE (Di Nisio et al., 2016; Piazza et al., 2009). Many conditions increase the risk of thromboembolic events such as history of hypercoagulability disorders (e.g., protein C or S deficiency, presence of antiphospholipid antibodies, antithrombin deficiency, or activated protein C resistance), arterial or venous thrombosis within the previous month,

Table 1 List of risk factors for venous thromboembolism

Risk factor	*Strength*	*Modifiability*
1. *Injury to a vein:*		
a. Fractures	Strong	–
b. Severe muscle injury	Strong	–
c. Major surgery (particularly involving the abdomen, pelvis, hip, or legs)	Strong	–
d. Varicose veins	Moderate	Modifiable
2. *Slow blood flow:*		
a. Confinement to bed	Weak	–
b. Limited movement (e.g., a cast on a leg to help heal an injured bone)	Weak	Modifiable
c. Sitting for a long time, especially with crossed legs	Weak	Modifiable
d. Paralysis/spinal cord injury	Strong	–
e. Acute heart failure or atrial fibrillation hospitalization	Strong	–
3. *Increased estrogen:*		
a. Oral contraceptive pills	Moderate	Modifiable
b. Hormone replacement therapy (HRT)	Moderate	Modifiable
c. Pregnancy, for up to 6 weeks after giving birth	Weak	Modifiable
4. *Certain chronic medical illnesses:*		
a. Heart disease	Strong	Modifiable
b. Lung disease	Strong	Modifiable
c. Cancer and its treatment	Moderate	Modifiable
d. Inflammatory bowel disease (Crohn's disease or ulcerative colitis)	Moderate	–
e. Autoimmune disease	Moderate	–
5. *Other concomitant risk factors:*		
a. Previous DVT or PE	Strong	–
b. Family history of DVT or PE	Moderate	–
c. Age (risk increases as age increases)	Weak	–
d. Obesity	Weak	Modifiable
e. A catheter located in a central vein	Moderate	Modifiable
f. Inherited clotting disorders, e.g., thrombophilia	Moderate	–
g. Air embolism	Weak	Modifiable

DVT, deep venous thrombosis; *PE*, pulmonary embolism.

Venous thromboembolic events in hospitalised medical patients. Thromb Haemost., 102, 505–510; Di Nisio, M., Van Es, N., Buller, H.R., 2016. Deep vein thrombosis and pulmonary embolism. Lancet, 388, 3060–3073

thromboembolism associated with malignancy, mechanical mitral valve in conjunction with atrial fibrillation, previous stroke, poor ventricular function, or coexisting mechanical aortic valve.

Hospitalized medical and surgical patients are significantly at increased risk of VTE. There are several scores to estimate the burden of the risk factors. These scores aim to risk stratify patients who have a potential risk for VTE occurrence, not to diagnose VTE disease. For example, Padua score (**Table 2**) is an explicit tool to stratify the risk in medically hospitalized patients (Barbar et al., 2010). On the other hand, Caprini score (**Table 3**) stratifies VTE risk in surgical patients (Caprini et al., 1991). These at-risk patients should be identified as soon as possible after admission to the hospital in order to provide appropriate thromboprophylaxis. Thromboprophylaxis is the most important patient safety strategy in patients admitted to the hospital. If VTE risk outweighs the bleeding risk, an appropriate pharmacological VTE prophylaxis should be considered (**Table 4**) (Piazza et al., 2009).

Diagnosis

Deep Venous Thrombosis Diagnosis:

1) *Wells' score*: The score assesses the clinical pretest probability (risk) of DVT. In those with suspected DVT, a clinical assessment of probability can be useful to determine which tests to perform. The Wells' score should only be applied to those patients who have been deemed at risk for DVT. If there is no concern for DVT, then there is no need for risk stratification. Wells' scores can be

Table 2 Risk factors for venous thromboembolism in hospitalized medical patients

Risk factor	*Points*	*Patient score*
Active cancer	3	
Previous VTE involving deep veins	3	
Reduced mobility	3	
Thrombophilia	3	
Trauma or surgery within 30 days	2	
Age ≥ 70 years	1	
Heart and/or respiratory failure	1	
Acute myocardial infarction or ischemic stroke	1	
Acute infection or rheumatologic disorder	1	
Obesity (BMI ≥ 30 kg/m^2)	1	
Hormone replacement therapy	1	
Total Patient's Padua score =	**20**	
• Padua Score < 4 points →		
◦ *Pharmacologic (anticoagulant) prophylaxis is **not** indicated.*		
◦ *Consider using mechanical (nonpharmacological) prophylaxis.*		
• Padua Score ≥ 4 points →		
◦ *Pharmacologic prophylaxis is indicated.*		
◦ *If high risk of bleeding, use mechanical prophylaxis.*		

BMI, Body mass index; *VTE*, venous thromboembolism.

Splitting, crushing, or chewing	May split tablet in half May crush tablet and mix with water or applesauce immediately before use	No; will increase exposure to medication	May crush tablet and mix with water or applesauce immediately before use Do not administer via feeding tubes placed distal to the stomach due to decreased absorption	May be crushed and suspended in 60 mL D_5W and immediately delivered through nasogastric tube	No recommendations provided
Drug interactions					
Shifting from VKA to a NOAC agent		1) Stop VKA 2) Initiate dabigatran once INR $\leq$2.0	1) Stop VKA 2) Initiate rivaroxaban once INR $\leq$2.5	1) Stop VKA 2) Initiate apixaban once INR $\leq$2.0	1) Stop VKA 2) Initiate edoxaban once INR $\leq$2.5
Shifting from NOAC to VKA		CrCl $\geq$ 50 mL/min: **Start warfarin 3 days before discontinuing dabigatran** CrCl 31–50 mL/min: **Start warfarin 2 days before discontinuing dabigatran** CrCl 15–30 mL/min: **Start warfarin 1 day before discontinuing dabigatran** CrCl $<$ 15 mL/min: **No dosing recommendations are available**	• Discontinue the NOAC agent. • Begin both a parenteral anticoagulant and warfarin at the time the next dose of the NOAC would have been taken. • Discontinue the parenteral anticoagulant when the INR reaches an acceptable range.		[b]*Footnote*
Food interactions	Yes	No	No	No	No

(*Continued*)

Table 4 Pharmacological profile of warfarin and new oral anticoagulants (*cont.*)

	Warfarin	*Dabigatran*	*Rivaroxaban*	*Apixaban*	*Edoxaban*
Drug–drug interactions	For patients taking CYP2C9, CYP3A4, CYP1A2 inhibitors and inducers: consider avoiding concomitant use or adjusting warfarin dose with close INR monitoring For initiation or changes with medications that have high protein binding: consider increased INR monitoring	p-GP inhibitors: CrCl <50 mL/min: avoid concomitant use – p-GP inducers (e.g., rifampin): avoid concomitant use	Dual p-GP inhibitors and strong CYP3A4 inhibitors (e.g., ketoconazole, itraconazole, ritonavir, indinavir, conivaptan): avoid concomitant use – Dual p-GP inducers and strong CYP3A4 inducers (e.g., carbamazepine, phenytoin, rifampin, St.John's wort): avoid concomitant use	Dual p-GP inhibitors and strong CYP3A4 inhibitors (e.g., ketoconazole, itraconazole, ritonavir, clarithromycin): - for patients receiving doses of 5 or 10 mg BID, reduce dose by 50%; for patients taking 2.5 mg BID, avoid coadministration – Dual p-GP inducers and strong CYP3A4 inducers (e.g., carbamazepine, phenytoin, rifampin, St. John's wort): avoid concomitant use	p-GP inhibitors (e.g., verapamil, quinidine, or short term-concomitant administration of azithromycin, clarithromycin, erythromycin, oral itraconazole, or oral ketoconazole): reduce dose to 30 mg daily – p-GP inducers: avoid concomitant use with rifampin
Discontinuation prior to elective or invasive surgery procedures	At least 5 days	24–48 h 3–5 days if CrCl <50	at least 24 h Black box Warning of epidural/ spinal hematomas	24–48 h	at least 24 h

BID, Twice daily; *CAD*, coronary artery disease; *CrCl*, creatinine clearance; *CYP*, cytochrome; *D_5W*, 5% dextrose; *FDA*, US Food and Drug Administration; *GI*, gastrointestinal; *INR*, international normalized ratio; *kg*, kilogram body weight; *LMWH*, low-molecular-weight heparin; *NOAC*, new oral anticoagulant; *OD*, once daily; *ODA*, once daily administration; *p-GP*, p-glycoprotein; *PCC*, prothrombin complex concentrates; *$t_{½}$*, half-life; *T_{max}*, time to maximum effect; *UFH*, unfractionated heparin; *VKA*, vitamin K antagonist; *VTE*, venous thromboembolism.

[a]Rivaroxaban missed dose: If a dose is missed during the 15 mg twice daily treatment phase (days 1–21), the patient should take the missed dose immediately and take the next dose on time (if the next dose is due two 15 mg tablets can be taken together). The patient should then continue with 15 mg twice daily. If a dose is missed during the once-daily treatment phase (day 22 and onward), the patient should take the missed dose immediately, and continue on the following day with the once daily intake as recommended. The dose should not be doubled within the same day to make up for a missed dose.

[b]Conversion of edoxaban to warfarin: (1) Oral option: For patients taking 60 mg of edoxaban, reduce the dose to 30 mg and begin warfarin concomitantly. For patients receiving 30 mg of edoxaban, reduce the dose to 15 mg and begin warfarin concomitantly. The INR must be measured at least weekly and just before the daily dose of edoxaban to minimize the influence of edoxaban on INR measurements. Once a stable INR ≥ 2.0 is achieved, edoxaban should be discontinued and warfarin continued. (2) Parenteral option: Discontinue edoxaban and administer a parenteral anticoagulant and warfarin at the time of the next scheduled edoxaban dose. Once a stable INR ≥ 2.0 is achieved, the parenteral anticoagulant should be discontinued and warfarin continued

Perioperative management of antithrombotic therapy: Antithrombotic Therapy and Prevention of Thrombosis, 9th ed: American College of Chest Physicians Evidence-Based Clinical Practice Guidelines. Chest, 141, e326S–e350S (Douketis et al., 2012); Steuber, T., 2017. The role of direct oral anticoagulants in the management of venous thromboembolism. Am J Manag Care, 23, S383–S390 (Steuber, 2017) and summary of product characteristics (SPC) of each medication listed in the table.

categorized as high if >2, moderate if 1 or 2, and low if <1, with likelihoods of 53%, 17%, and 5%, respectively. Confirmation of diagnosis may require a further diagnostic study, particularly in patients with a high Wells' score (Wells et al., 1997).

2) *Physical examination*: The physical examination of the patient's signs and symptoms significantly improves the diagnostic accuracy of noninvasive tests and should be routinely performed. DVT is mainly asymptomatic, but if symptoms do occur, they can include: pain, swelling, and tenderness in one legs (usually the calf), a heavy ache in the affected area, warm skin in the area of the clot, or red skin, particularly at the back of the leg below the knee (Bates et al., 2012).
3) *D-Dimer test*: D-Dimer is a byproduct of fibrin degradation. This is a diagnostic (not screening) test. The normal range is lower than or equal to 500 ng/mL Fibrinogen Equivalent Units (FEU). D-Dimer is almost always elevated during acute VTE. It is of note that other conditions may increase the D-Dimer results such as disseminated intravascular coagulation (DIC), recent surgery, trauma, pregnancy, cancer, and age older than 65 years. A positive result requires further diagnostic verification. D-Dimer values ≤500 ng/mL FEU in conjunction with clinical pretest probability (<2) exclude VTE diagnosis (Bates et al., 2012).
4) *Doppler ultrasonography*: This is the most common diagnostic imaging method (test of choice) for DVT and preferred to venography. However, it is not the gold standard diagnostic method. The advantage of color flow Doppler ultrasonography is the ability to determine motion and the direction of blood flow. An absence of blood flow confirms the diagnosis of DVT. It indicates the presence of thrombus within a vein. However, it cannot reliably detect small blood clots in distal veins. This noninvasive test does not carry the adverse effects of venography (hypotension, cardiac arrhythmias, vessel wall irritation, and nephrotoxicity caused by the contrast medium). A positive Doppler ultrasound finding in combination with a moderate to high clinical pretest probability or a positive D-Dimer result can be used to confirm the diagnosis. Negative test result does not exclude DVT, particularly in calf veins. Doppler ultrasound successfully identifies 95% of DVT cases that occur in the large veins above the knee. The ability to diagnose a new DVT can be difficult in patients with a past history of DVT (Bates et al., 2012).
5) *Contrast venography*: Venography is the gold standard diagnostic method for DVT. It is used when the ultrasound does not provide a clear definitive diagnosis. It is an invasive test where a contrast medium is injected into a vein, and then an X-ray of the leg is taken. The medium makes the vein visible on the X-ray. The X-ray will show whether blood flow is slow in the vein. Thrombus is depicted as an intraluminal filling defect. This test is expensive and can cause anaphylaxis and nephrotoxicity. Thus, the use of iodinated contrast is not advised in patients with a history of contrast allergy or in patients with impaired renal function. Other than medications, the patient should be advised to not to eat or drink anything for several hours before the procedure (Bates et al., 2012).

Pulmonary Embolism Diagnosis:

1) *Wells' score*: A clinical pretest probability stratifies patients according to the likelihood of PE occurrence (Wells et al., 2001). Confirmation of diagnosis requires a further diagnostic study.
2) *Physical examination*: Physical examination of PE manifestations significantly improves the diagnostic accuracy of noninvasive tests. The patient may have acute onset of the following symptoms: chest pain, which may get worse upon deep breathing or coughing; coughing, coughing up blood, dizziness or even fainting, tachypnoea and tachycardia, irregular rhythm, and shortness of breath (Beckman et al., 2010).
3) *Laboratory tests*: Serum concentrations of D-Dimer are almost always elevated. A plasma D-Dimer level of <500 ng/mL FEU and a Wells' score lower than 4 essentially exclude PE. The patient may have an elevated erythrocyte sedimentation rate (ESR) and high white blood cell (WBC) count. The arterial blood gases (ABG) on room air demonstrate hypoxemia (partial arterial oxygen tension, PaO_2 <80 mmHg) and an elevated alveolar-arterial oxygen gradient. Acid–base status may demonstrate respiratory alkalosis (Bates et al., 2012; Konstantinides et al., 2014).
4) *Helical computed tomography (HCT)*: HCT is the most commonly used method to diagnose PE because it is minimally invasive and allows concurrent visualization of the parenchyma, pleura, and mediastinum of lungs. It is the preferred option for PE diagnosis unless contraindications exist. Contrast medium is typically used, which can make the test unsuitable for patients with impaired renal function. Positive scan results have good specificity and generally confirm the diagnosis of PE. Negative scan results may require further diagnostic studies if PE seems likely because of clinical pretest probability scoring and/or D-Dimer results. Both the sensitivity and specificity of the scan are improved with central clots compared with those that are more peripheral (Bates et al., 2012; Konstantinides et al., 2014).
5) *Ventilation/perfusion (V/Q) scanning*: V/Q scanning is the most common screening technique for PE diagnosis; it measures the distribution of blood flow and airflow in the lungs. The ventilation part of the test looks at the ability of air to reach all parts of the lungs, while the perfusion part evaluates how well blood circulates within the lungs. When there is a large mismatch between blood flow and airflow in one area of the lung, the probability is high that the patient has a PE. The test scans with positive findings have good sensitivity and help to confirm the diagnosis. Specificity can be impaired by chronic obstructive pulmonary disease (COPD), asthma, and heart failure. A scan with negative findings also has good specificity and generally rules out the diagnosis. V/Q scanning is often preferred in patients with renal insufficiency or with allergies to contrast media. It is preferred rather than pulmonary HCT to minimize radiation exposure unless patients have preexisting lung disease. For that latter group, an HCT scan is preferred (Bates et al., 2012; Konstantinides et al., 2014).
6) *Pulmonary angiography*: This is the gold standard diagnostic method for PE. It is a minimally invasive procedure, but requires the administration of intravenous contrast medium into the pulmonary artery. This test is expensive and can cause anaphylaxis and nephrotoxicity (Bates et al., 2012; Konstantinides et al., 2014).

7) *Pulmonary embolism severity index (PESI) or simplified PESI score*: PESI score determines PE severity to stratify mortality risk after the confirmation of PE diagnosis (Aujesky et al., 2005; Jimenez et al., 2010).

Venous Thromboembolism Management and Therapeutic Regimens

Goals of Therapy

There are four general goals of therapy for VTE: (1) improving patient's quality of life and exercise capabilities; (2) preventing DVT complications into PE or PTS; (3) preventing VTE recurrence; and (4) reducing further PE causing morbidity occurrence as pulmonary hypertension (Coleman and MacCallum, 2010).

Treatment Modalities

The mainstay of VTE management is the pharmacologic anticoagulation therapy since the introduction of unfractionated heparin (UFH) in 1930 (Ita, 2015). Many other anticoagulants such as vitamin K antagonist (VKA), low molecular weight heparins (LMWHs), and thrombolytic agents have been subsequently developed. These agents have been added to the treatment algorithms of VTE. All these medications aim to either dissolve or stop clotting (Ita, 2015). Immediate initiation of therapeutic anticoagulation is crucial for patients with suspected DVT or PE. Heparin-induced anticoagulation reduces the mortality rate from 30% to less than 10%. VTE treatment modalities include many other nonpharmacological strategies such as compression stocking and vena-vaca filters.

The therapeutic regimen of a parenteral anticoagulant (UFH, LMWH, or fondaparinux) plus a VKA (warfarin) has been the most frequently prescribed regimen for VTE management before the introduction of the new oral anticoagulants (NOACs), (Akl et al., 2014). Recently, NOACs such as dabigatran, rivaroxaban, apixaban, or edoxaban are recommended over VKA (e.g., warfarin) therapy in several clinical settings. In long-term anticoagulant therapy settings, VKA therapy is recommended over LMWH or UFH for VTE in the absence of concomitant cancer disease. However, LMWH is still suggested over VKA or NOACs for VTE and concomitant cancer (Thein et al., 2016). The updated CHEST guidelines in 2016 recommended against an inferior vena cava filter (IVCF) for VTE treated with anticoagulants (Kearon et al., 2016). Also, routine use of compression stockings is not recommended for the prevention of PTS. Close monitoring is recommended over pharmacological anticoagulation for patients having a low risk of recurrent VTE (Kearon et al., 2016).

Treatment at home is an available option for patients with uncomplicated DVTs and low-risk PEs. Patient medical awareness and adequate home circumstances are required for home VTE treatment, which includes well-maintained living conditions, strong support from family or friends, telephone access, and ability to return to the hospital quickly if deterioration occurs (Kearon et al., 2016). However, patients with acute massive PE causing hemodynamic instability should be treated initially in the hospital with a thrombolytic agent (Sharifi et al., 2013). Tissue plasminogen activators (t-PA) are the first-choice thrombolytic agents (Meyer et al., 2014). For instance, alteplase is administered as 100 mg intravenous infusion over 2 h. Then, heparin could be introduced after the infusion ends (Kearon et al., 2016; Konstantinides et al., 2016).

Pharmacological Treatment Practicalities

Treatment Approach

The pharmacologic treatment of VTE includes three sequential phases: the acute phase (first 5–10 up to 21 days since the diagnosis has been made), a maintenance phase (first 3–6 months after the acute phase), and an extended phase (following the initial 3–6 months) (Mazzolai et al., 2017). The duration of therapy depends on the clinical situation of each patient. Long-term anticoagulation is necessary to prevent the high frequency of recurrent venous thrombosis or thromboembolic events. There are several drug regimens for this threefold treatment timescale.

Therapeutic Regimens

Apixaban and rivaroxaban are the only NOACs that are approved for use in the acute phase of VTE treatment as monotherapy without being preceded by a parenteral anticoagulant (Agnelli et al., 2013; Buller et al., 2012; Robertson et al., 2015). Apixaban should be prescribed as a 10-mg bid for the first 7 days, then tapered to a 5- or 2.5-mg bid beyond 6 months upon the patient's risk and clinical factors. Rivaroxaban regimen is a 15-mg bid for the first 21 days, then, 10 up to 20-mg beyond 6 months according to patient risk and clinical factors.

Other regimens must include an immediate-acting parenteral anticoagulant (e.g., LMWH) for the first 5–10 days as initial treatment followed by maintenance treatment with an oral anticoagulant agent. This oral agent can be one of the following agents: (i) a VKA, e.g., warfarin; (ii) dabigatran 150-mg bid; or (iii) edoxaban 60-mg OD (if creatinine clearance $>$ 50 mL/min. and in absence of any concomitant proton pump inhibitors). **Table 4** presents the different characteristics of the various oral anticoagulants.

Initial treatment with a parenteral anticoagulant (UFH, LMWH, or fondaparinux) should continue for at least 5 days to allow the shift to the oral route (Guyatt et al., 2012; Robertson et al., 2015). However, only bridging with the VKA should be initiated on the third day of parenteral treatment start. When intravenous UFH infusion is used, achieving a therapeutic aPTT (1.5–2.5 times baseline) in the first 24 h has been linked to decreased VTE recurrence rates (Smythe et al., 2016). Dosing of heparin is very crucial and its adjustment deemed one of the pharmacist's responsibilities before administration. The therapeutic regimen of (LMWH + VKA) is affordable to the low budget health-care settings (Middeldorp et al., 2014). **Table 5** discusses the prescribing tips of the various parenteral anticoagulants.

Black Box Warning

Epidural or spinal hematomas, which may result in long-term paralysis, may occur in patients who are anticoagulated with LMWHs or heparinoids and are receiving neuraxial anesthesia or undergoing spinal puncture.

Management: Stop all heparins 8–12 h prior to spinal puncture + close monitoring of this type of patients for any neurological impairment.

The warfarin dose should be adjusted based on the patient's INR. An initial dose of 5–10 mg is preferred for otherwise healthy patients (Garcia et al., 2016). Lower doses may be needed in some populations that are sensitive to warfarin (e.g., malnourished, drug interactions, elderly). Higher initial treatment doses (e.g., 10 mg) have been associated with obtaining a more rapid therapeutic INR in DVT outpatients. The therapeutic target INR range is 2–3. Higher INR levels have been associated with higher bleeding events without a greater benefit of VTE risk reduction. Lower INR levels (1.5–2) are not as effective with no clear benefit on bleeding outcomes. Warfarin maintenance dose can be adjusted by determining the weekly dose and reducing the weekly maintenance dose by 10%–25% based on the degree of INR elevation. Maintenance dosing of warfarin is preferred to be tailored to the patient's genotype for better achievement of optimum therapeutic doses (Bazan et al., 2012). Personalization of warfarin dosing through genetic testing reduces the risk of combined adverse events in patients undergoing orthopedic surgery (Do et al., 2012). On the other hand, warfarin resistance is a problematic condition in which individuals have a high tolerance for the drug. The health-care team should assess the type and reasons for this resistance. Warfarin resistance does not appear to cause any health problems other than those associated with warfarin drug treatment (Azzam et al., 2016; Osinbowale et al., 2009).

Selection of the Oral Anticoagulants

There are many clinical and patient-related factors that influence the selection of the most suitable anticoagulant agent and regimen (**Table 4**). These factors include the patient's adherence, socioeconomic level, renal function, history of gastrointestinal (GI) bleeding, concomitant medications, and age (Kearon et al., 2016; Konstantinides et al., 2016). For instance, dabigatran and rivaroxaban are not preferred for VTE management in patients with a history of GI bleeding of unclear etiology. Also, the dosing regimen is another important factor to consider. Rivaroxaban has the advantage of once-daily administration. Furthermore, VKAs are preferred over NOACs in several different settings. NOACs are not used in patients with prosthetic heart valves because of a greater risk of valve thrombosis (Vandvik et al., 2012). In patients with renal insufficiency, warfarin may be the preferred oral agent. For patients with creatinine clearance (CrCl) <30 mL/min, there is insufficient evidence compared with warfarin, and the NOACs must be dose adjusted. Furthermore, NOACs are not recommended in patients with CrCl <15 mL/min (Steuber, 2017).

It is important to recognize some general contraindications to the anticoagulation therapies: (1) active major bleeding, (2) hemophilia or other hemorrhagic tendencies, (3) severe liver disease with elevated baseline prothrombin time, (4) severe thrombocytopenia (platelet count < 20,000/mm^3), (5) malignant hypertension, and (6) inability to meticulously supervise and monitor treatment.

Management of Recurrent Thromboembolic Events

In the absence of contraindications, aspirin 80–100 mg once daily is recommended to prevent recurrent VTE in patients with an unprovoked proximal DVT or PE following anticoagulation cessation (Becattini et al., 2012; Brighton et al., 2012). Furthermore, among patients undergoing total knee arthroplasty, low-dose aspirin as monotherapy was found to provide protection against postoperative VTE that is not inferior to that of other anticoagulants (Hood et al., 2018). Although some prescribers expressed some concerns about aspirin safety in certain vulnerable populations such as congestive heart failure and ischemic cardiomyopathies, robust evidence showed the benefit of aspirin continuation in such populations (Bermingham et al., 2014; Cleland et al., 2004; Homma et al., 2012; Massie et al., 2009).

Patients with recurrent VTE while on treatment with a non-LMWH anticoagulant should first be assessed. This segment of patients should be switched to LMWH therapy. Those who suffer from recurrent VTE in spite of administration of LMWH therapy should receive an increased dose of LMWH (Kearon et al., 2016). In cancer patients at risk of recurrent VTE, LMHW is strongly recommended over VKA (Akl et al., 2014). Recently, once-daily rivaroxaban was found to lower recurrence of VTE according to SELECT-D trial (Young et al., 2018).

Table 5 Prescribing tips of parenteral anticoagulants used for the management of acute venous thromboembolism

Unfractionated heparin (UFH)	*Low-molecular-weight heparins (LMWHs)*	*Factor Xa inhibitor: Fondaparinux*
IV administration: √ treatment of choice for those with end-stage renal failure. √ preferred route because of improved dosing precision. *Laboratory workout:* 1) baseline aPTT, PT, CBC with platelet count. 2) CBC with platelet count every day. 3) STAT aPTT 6 h post-IV bolus. 4) aPTT every day starting from the 3rd day of heparin administration. 5) Order aPTT 6 h after any dose change adjusting heparin infusion by the sliding scale until aPTT is within the therapeutic range (46–70 s). 6) When 2 consecutive aPTT are within therapeutic range, order aPTT and readjust heparin drip as needed every 24 h. Initial bolus and the initial rate of the continuous infusion can be either weight adjusted (80 units/kg IV bolus, followed by 18 units/kg/h infusion) or a fixed dose (bolus 5000 units, followed by 1000 units/h). Adjust subsequent doses to attain a goal aPTT based on the institution-specific therapeutic range. *Subcutaneous administration:* - 17,500 units (250 units/kg) given every 12 h (an initial 5000-unit IV bolus dose is recommended to attain rapid anticoagulation). - Adjust subsequent doses to attain a goal aPTT based on the institution-specific therapeutic range. *Heparin sodium preparation:* * Usual diluent: dextrose 5% (D_5W) or 0.9% normal saline solution (NSS) * Standard dilution: 250,000 units/ 250 or 500 mL titration * Loading Dose: IV push or add to 50 mL D_5W * Expiry date: 1 day * Administration: When heparin is added to an infusion solution for continuous IV administration, the container should be inverted at least six times to ensure adequate mixing and prevent pooling of the heparin in the solution. *Calcium heparin preparation:* Same preparation as the sodium salt, but not to be diluted with Ringer's solution as this may precipitate calcium.	√ Gold standard antithrombotic agent. √ Allows for outpatient treatment of uncomplicated DVT. √ Start 12 or more hours preoperatively or 12 h or more postoperatively √ preferred in cancer, liver disease, coagulopathies, pregnancy, or pregnancy risk. *Dalteparin:* 200 units/kg subcutaneously once daily or 100 units/kg subcutaneously twice daily. Not FDA approved for treatment of VTE in patients without cancer. Dosage form: single-dose syringes *Enoxaparin:* √ The only LMWH licensed for both VTE prophylaxis and treatment. 1.5 mg/kg subcutaneously once daily or 1 mg/kg subcutaneously twice daily; if CrCl < 30 mL/min: 1 mg/kg subcutaneously once daily Dosage form: prefilled syringes *Tinzaparin:* 175 units/kg subcutaneously once daily. √ Safer in pregnancy than other LMWHs. Dosage form: prefilled syringes	√ Licensed for VTE prophylaxis in surgical patients and the treatment of acute DVT For body weight < 50 kg (110 lb), use 5 mg subcutaneously once daily For body weight 50–100 kg (110–220 lb), use 7.5 mg subcutaneously once daily For body weight > 100 kg (220 lb), use 10 mg subcutaneously once daily
Contraindications Hypersensitivity to UFH History of HIT	*Contraindications* Hypersensitivity to LMWH, unfractionated heparin, pork products, methyl-paraben, or propyl-paraben History of HIT or suspected HIT	*Contraindications* Hypersensitivity to fondaparinux Severe renal insufficiency (CrCl < 30 mL/min) Body weight < 50 kg (110 lb) Bacterial endocarditis Thrombocytopenia with a positive in vitro test for antiplatelet antibodies in the presence of fondaparinux
Antidote options (reversal)		
Protamine sulfate is the full reversal agent of UFH and "partial" reversal agent for LMWHs. Protamine neutralizes around 60% of the antifactor Xa activity if LMWH was given in the previous 8 h, then 1 mg of protamine should be administered for every 100 units (or 1 mg) of the LMWH. If the LMWH dose is given in the previous 12 h, a 0.5-mg dose of protamine should be given for every 100 antifactor Xa units. Use of protamine sulfate is not recommended if the LMWH was administered more than 12 h earlier due to LMWH metabolism. Protamine administration induces risk of hypersensitivity reactions and anaphylaxis.		No specific antidote

aPTT, Activated partial thromboplastin time; *CBC*, complete blood count; *CrCl*, creatinine clearance; *FDA*, US Food and Drug Administration; *HIT*, heparin-induced thrombocytopenia; *IV*, intravenous; *kg*, kilogram body weight; *lb*, pound; *LMWH*, low-molecular-weight heparin; *PT*, prothrombin time; *UFH*, unfractionated heparin; *VTE*, venous thromboembolism. √, refer to an advantage.

Chest, 141, e326S–e350S) and summary of product characteristics (SPC) of each medication listed in the table.

Gaps in Evidence

To date, there are still some gaps in evidence. First, little is known about the optimal length of treatment of patients having unprovoked VTE (Robertson et al., 2017). Herein, the physicians in collaboration with the clinical pharmacists are in a position to decide upon extended treatment based on benefit (i.e., prevention of VTE recurrence) and risk (i.e., bleeding) associated with treatment. Particularly, in the elderly population, there are several clinically important unmet needs such as the definition of the real risk of VTE recurrence after a first event. While it is possible that initial treatment is associated with a lower risk of recurrence, the bulk of information to date is drawn from observational studies that were published long time ago. Up-to-date studies are warranted to better address this issue. Furthermore, more information is needed on the use of low-dose NOACs for extended treatment in elderly patients. The data appear promising, but more research is warranted to evaluate their use over longer periods of time and to assess bleeding risks. Additional treatment options also need to be evaluated in order to effectively reduce the risk of bleeding while protecting against VTE recurrence (Palareti and Poli, 2018).

Second, there are no large-scale trials addressing the direct comparison between LMWH and NOAC agents in terms of efficacy and safety in patients with cancer and concomitant VTE (Carrier et al., 2018). Current trials are highly selective and controlled studies. Patients at high risk of bleeding or worsening renal functions are excluded for safety reasons. In addition, none of the studies was specific to cancer patients. Thus, their results should be interpreted with caution (Aronis Konstantinos and Hylek Elaine, 2018; Raskob et al., 2017). Also, there is a lack of data about NOACs use in patients at high risk of acute renal injury such as advanced heart failure patients (Steinberg et al., 2016). To date, the full safety profile of the NOAC agents is not very clear (Salazar et al., 2010; Steinberg et al., 2017).

Third, there is considerable uncertainty of warfarin initial daily dose (Garcia et al., 2016). Early achievement of the therapeutic INR (2–3) is highly recommended to minimize the duration of parenteral anticoagulant administration (Garcia et al., 2016). Although a 5-mg loading-dose tends to prevent excessive anticoagulation, a 10-mg loading-dose may achieve a therapeutic INR more quickly (Quiroz et al., 2006). Also, there is a lack of evidence to recommend genotype-guided initiation. Thus, adequately powered trials to detect effects on adverse events are warranted (Heneghan et al., 2010).

Moreover, the impact of patient adherence with the prescribed NOAC has not been rigorously assessed (Steinberg et al., 2018). The frequency of patients' nonadherence in VTE is considerable. A recent report showed that 50% of patients who were prescribed an anticoagulant were not adherent to their therapy. Also, the achievement of the recommended target dose of oral anticoagulants represents a challenge to routine clinical practice fear of medication's adverse drug reactions or medication initiation burden (Aronis Konstantinos and Hylek Elaine, 2018; Byrne and Weaver, 2013). This prescribing problem is clearly revealed in the landmark clinical trial ORBIT-II (Outcomes Registry For Better Informed Treatment Of Atrial Fibrillation II). Hence, 12.5% of patients have been prescribed a lower dose than the recommended (Steinberg et al., 2016, 2018).

Thrombolytic Therapy

If PE causes severe instability due to high pressure on the heart (massive PE) and leads to low blood pressure or shock-related symptoms (acute manifestations), recombinant tissue plasminogen activators (t-PA) are highly recommended for management. Streptokinase, tenecteplase, alteplase, and urokinase are thrombolytic agents that the Food and Drug Administration (FDA) has approved for use in PE (Guyatt et al., 2012). This therapeutic thrombolysis prevents hemodynamic decompensation, but increases the risks of major hemorrhage and stroke (Meyer et al., 2014; Sharifi et al., 2013). The outcome of this therapy is optimal when the patient arrives at the hospital within 3 h of the emboli occurrence.

Absolute and Relative Contraindications to Thrombolytic Agents (Konstantinides et al., 2014)

1. Absolute contraindications
    a. GI bleeding within the past 6 months
    b. Active or recent internal bleeding
    c. History of hemorrhagic stroke
    d. Intracranial or intraspinal disease
    e. Recent cranial surgery or head trauma
    f. Pregnancy
2. Relative contraindications
    a. Major surgery or trauma within the past 2 weeks
    b. Biopsy within 10 days
    c. Other invasive procedures
    d. Procedures in a location inaccessible to external compression
    e. Uncontrolled coagulation defects such as thrombocytopenia
    f. Nonhemorrhagic stroke

Nonpharmacological Strategies

Physical Activity and Ambulation

Regular physical activity and weight loss are essential prophylactic measures against VTE events. Frequent intensive exercise does not provide further prevention of VTE risk than a regular moderate one (Armstrong et al., 2015). It is important to encourage early ambulation as tolerated by the patient during the acute treatment phase. Patients on any anticoagulants should avoid aggressive activities that could cause trauma (Liu et al., 2015).

Vena Cava Filters

These are a type of vascular filters (net) that are implanted by interventional radiologists or vascular surgeons into a major vein (inferior vena cava) to prevent the blood clot from travelling to lungs causing life-threatening PE while maintaining vena cava patency. IVCFs are often used as an alternative to anticoagulation (Haut et al., 2014; Konstantinides et al., 2016; Weinberg et al., 2013).

Intermittent Pneumatic Compression

Intermittent pneumatic compression (IPC) is an adjunct approach for prophylaxis and treatment of VTE (Feldman et al., 2012; Liu et al., 2017). IPC devices are used to help prevent blood clots in the deep veins of the legs. The devices use cuffs around the legs that fill with air and squeeze patient's legs. The graduated sequential compression devices produce sequential compression from distal to proximal veins. This increases blood flow through the veins of the legs and helps prevent blood clots (Zhao et al., 2014).

Medical Elastic Stockings

This type of compression stockings can improve venous flow and reduce vessel wall damage caused by passive venous dilatation or during surgery. Routine use of compression stockings is not recommended for the prevention of PTS (Kearon et al., 2016). They are recommended as an adjunct in moderate and high-risk cases. They should be applied preoperatively and continued throughout hospitalization. However, it is crucial to avoid improper fitting stockings. The ankle pressure should be 30–40 mmHg to help prevent PTS, if possible. There are several types of stocking where the physicians and pharmacists should select the most comfortable stockings size for their patient on an individual basis (Mazzolai et al., 2017; Zhao et al., 2014).

Diet

High intake of folate and omega-3 fatty acids has been associated with lower levels of homocysteine, which may lower the risk of VTE. Omega-3 fatty acids have positive effects on vascular function, which may also lower VTE risk (Steffen et al., 2007). In general, there are no special dietary requirements or restrictions for VTE. Diet should be as tolerated per patient. An exception, however, applies to patients prescribed oral warfarin therapy, who must avoid vitamin supplements that contain vitamin K and must limit foods that are rich in vitamin K (e.g., broccoli, cabbage, red and green lettuce, onion, peppers, spinach, oils, mayonnaise, black and green leaf teas). These nutrients can lessen warfarin's effectiveness (Mahtani et al., 2014). For the patients who are prescribed oral warfarin therapy, the diet should remain steady, with no drastic changes in content in order to facilitate accurate and regular monitoring of the INR (Nutescu et al., 2006).

The Role of Pharmacist in the Management of Venous Thromboembolism

Pharmacist in Venous Thromboembolism Management

There is a considerable lack of appropriate VTE prophylaxis and treatment in clinical practice (Byrne and Weaver, 2013; Cohen et al., 2008; Trujillo-Santos et al., 2017). Failure to prevent an avoidable VTE event is associated with a substantial clinical and economic burden due to not only the initial event but also to VTE recurrence and its long-term sequelae (Bungard et al., 2009). From a clinical perspective, the management of VTE with or without concomitant diseases is complex and multifaceted. The prescriber faces various prescribing challenges due to the complex drug regimens, monitoring procedures, as well as the broad range of drug interactions and patient's adherence issues (Aronis Konstantinos and Hylek Elaine, 2018; Konstantinides et al., 2014; Schmerge et al., 2018).

Pharmacists herein have a threefold technical role to improve health system's compliance with the guideline-driven VTE quality measures. The first role is the provision of patient-specific services including the appropriate selection, dosing and monitoring of anticoagulant agents, screening of drug–drug and drug–food interactions, review of drug utilization, and provision of drug and clinical information to prescribers. The second role is the provision of facility-specific services such as design and review of management algorithms, policy development, medication safety, and implementation of VTE quality measures. Third, clinical pharmacists can have a global contribution to the national and international organizations, medico-legal consultations, and public health initiatives (Dunn et al., 2015).

Anticoagulant Drug Therapy Problems

The pharmacist is uniquely positioned to manage drug-therapy problems in order to optimize the quality of VTE care (Schmerge et al., 2018; Vande Griend et al., 2018). Anticoagulants are highly associated with preventable adverse drug reactions (Gray et al., 2007; Steinberg et al., 2016). Among studies that reported pharmacist-led interventions in VTE management, the cumulative results are significantly promising in favor of pharmacy service (Schmerge et al., 2018).

Pharmacists are competent to select the appropriate doses and duration of treatment and able to reconcile the VTE risk assessment with the clinical practice guidelines (Schnipper et al., 2006). At the Colchester Hospital University – NHS Foundation Trust, VTE risk assessments increased from zero in 2007 up to 70% in 2009 by the incorporation of clinical pharmacists in the VTE health-care team (Eradiri, 2011). Pharmacists are well-positioned to communicate VTE priorities to clinical colleagues and can screen those patients who have not been risk-assessed, those who have been risk-assessed and not prescribed, and those not administered the prescribed prophylaxis. The pharmacists showed positive outcomes when involved in root cause analysis, and identification of VTE cause in patients developing the condition while in the hospital or soon after discharge. A recent meta-analysis including 17 studies showed the lower likelihood of bleeding and recurrence of VTE events in the pharmacist-led arm of patients (Hou et al., 2017).

Pharmacists are experts in selecting the most appropriate regimen of thromboprophylaxis for patients identified to be at risk of VTE (Dunn et al., 2015). They can offer several strategies to optimize VTE prevention via passive dissemination, audit and feedback, documentation aids, computer-based decision aids, continuous education, quality assurance activities, or advertising (Dunn et al., 2015; Tooher et al., 2005). For instance, the inclusion of pharmacist in critical care settings had optimized the number of critically ill patients receiving VTE prophylaxis according to the recommendations of the guidelines upon discharge and at one-year postdischarge (Vervacke et al., 2014). The pharmacists are concerned to investigate the potential reasons for inappropriate thromboprophylaxis such as inappropriate dose, insufficient or incomplete duration of guideline-directed prophylaxis, application of mechanical prophylaxis only, or absence of prophylaxis (Amin Alpesh et al., 2009). Also, the pharmacist should track patients who are not receiving the indicated thromboprophylaxis due to bleeding risk factors. This segment of patients needs a continual reassessment of their risk level, whereas thromboprophylaxis should be initiated when appropriate and feasible.

Elsewhere, the pharmacist significantly showed a higher rate of NOAC uptitration at baseline and over a 6-month period of follow-up by 15% (Ashjian et al., 2017). Once VTE therapy is initiated, pharmacists have a critical role in monitoring and uptitration of the prescribed therapies (Davis et al., 2013). The inclusion of a clinical pharmacist in the VTE health-care team results in a reduction of medication errors, adverse drug events, and improved outcomes (Schnipper et al., 2006). The review of the patient's daily chart by pharmacist identifies omitted doses, interactions, adverse events, and biochemical and hematological changes. Chilipko and Norwood showed the advantage of the pharmacist-managed inpatient anticoagulation service over physician-managed service in terms of lower incidence of supra-therapeutic INRs and longer time of target INR achievement (Chilipko and Norwood, 2014).

Patient Education and Adherence

A large number of cancer patients are not aware of the increased risk of thromboembolism (53% in one study) (Sousou and Khorana, 2010). Patients who are well aware of the risk are more likely to use the prescribed prophylaxis and accept its negative sides, such as daily injections or frequent monitoring (Sousou and Khorana, 2010). Pharmacists are unequivocally well-positioned to advise patients on the indications, contraindications, and side effects of their medications. This role is particularly useful when dealing with high-risk medications, such as LMWH, narrow therapeutic index medications, such as warfarin, or medications of short half-lives, such as NOACs.

Medication nonadherence and missed doses expose patients to a considerable risk of VTE (Aronis Konstantinos and Hylek Elaine, 2018). The pharmacist is able to enhance patient's adherence via several strategies: (1) provision of pill organizers, blister packs, calendars, and dose counters; (2) verbal reinforcement and detailed written information of medications; (3) periodical telephone call assessment of refill dates and compliance; (4) encouraging family support; (5) informing the patient about the possible most common side effects and self-monitoring indices; and (6) encouraging patient's participation in regular physical activity programs and in Anticoagulation Management Service. The beneficial outcomes of this role were clearly illustrated in the anticoagulation management service of Michigan University Hospitals. The continuous pharmcist-led education has increased the patient's adherence level by 12% over a 6-month follow-up (Ashjian et al., 2017).

Prescribers Education

The NOAC agents have the advantage of predictable and safe pharmacokinetics. However, appropriate prescription of these agents requires a comprehensive assessment of patient-specific factors such as age, renal function, weight, history of GI or intracranial bleeding, patient's adherence, and literacy levels (Di Palo et al., 2018; Steinberg et al., 2016). Hence, it is important to consider that underdosing of anticoagulant agents is significantly associated with an increased risk of adverse events (Chopard et al., 2018). A 2017 report involving more than 1500 patients who were being treated for VTE with a NOAC highlighted the lack of clinicians familiarity with the recommended dosing (Trujillo-Santos et al., 2017). Herein, the pharmacists are in a position to

provide continuous educational service to clinicians to optimize prescribing outcomes (Schmerge et al., 2018; Di Palo et al., 2018). Vyas et al. reported the positive impact of pharmacist-led education to improve prescribers' behaviors by 16% in 2 months (Vyas et al., 2013).

Transition of Care

Pharmacists represent an important part of the health-care team responsible for the design of VTE management and monitoring guidelines because of their clinical and pharmacological knowledge as well as their oversight of patient care as patients are transferred from one service to another during the hospital stay or at discharge (Davis et al., 2013). The pharmacists have to ensure the full compliance of the prescribed anticoagulation therapy with the guideline-driven quality measures (Schnipper et al., 2006). When parenteral or oral anticoagulants are withheld before procedures, the pharmacists should ensure that they are resumed when patients are transferred to recovery units or another service. This transition of care should cover the following points: follow-up INR scheduled if warfarin is prescribed, prescriber's awareness of discharge and transition plans, and patient education. Herein, the pharmacist should provide a comprehensive education to the patient about VTE, its management, and monitoring (Davis et al., 2013).

Outpatient Settings

Many patients will continue with therapy after hospital discharge. This is an important opportunity to introduce and reinforce complex information at discharge point and at regular occasions in the outpatient settings (Sousou and Khorana, 2010; Vyas et al., 2013). This also needs to be communicated to general practitioners (GPs) via accurate discharge letters to ensure that treatment continues and that patients are appriopriately monitored. Home treatment of VTE is now feasible in several settings. Similar to the inpatient settings, the community pharmacists have the same opportunities for counselling the ambulatory patients about risks, preventive measures for and management of VTE at home, or upon their transfer to long-term care facilities (Sousou and Khorana, 2010). Pharmacists in each of these outpatient settings (long-term care settings and community pharmacy) should first assess patient's VTE risk and should intervene and make appropriate recommendations when necessary. Also, they have to reconcile the patient's medications and manage any possible adverse drug reactions. The community pharmacists have an essential role to select the affordable drug product and provide the medication-related information to the patients or their caregivers to ensure their adherence.

Economic Justification

A large economic report showed the cost-saving benefit of a pharmacist-led anticoagulation clinic where the pharmacist's services saved $505,349 in terms of events and related expenditures of hospitalization and emergency department (ED) visits versus the nurse-led services (Gray et al., 2007). The benefit of events reduction that represented an odds ratio (OR) of 7.68 (95%CI = 1.1–55.9) was in favor of the pharmacist-led arm (Bauer et al., 2008). Similar benefits were rationalized in Gary and colleagues analysis (Gray et al., 2007).

Conclusion

Overall, there is sufficient evidence of benefit of clinical pharmacy services for better clinical outcomes in terms of reduction of VTE occurrence, recurrence, bleeding complications, and mortality, while reducing excess hospitalization and health-care costs (Dager and Gulseth, 2007; Dunn et al., 2015; Gray et al., 2007). Pharmacists are well-positioned to enhance many facets of VTE prevention and management (Dunn et al., 2015; Strand et al., 1990). They are able to develop or expand the anticoagulation management services (Dager and Gulseth, 2007).

Management of Respiratory Disorders and the Pharmacist's Role: Asthma

Amy Hai Yan Chan*, Kim Watkins†, Carl R. Schneider‡, *UCL School of Pharmacy, London, United Kingdom; †Curtin University, Perth, WA, Australia; ‡The University of Sydney, Sydney, NSW, Australia

Learning Objectives

By the end of the chapter, the reader will be able to:

- Discuss the etiology, epidemiology, and clinical presentation of asthma.
- Provide clinical recommendations for the management of asthma using evidence-based principles. Recommendations include, self, pharmacist, and interdisciplinary delivery of both pharmacotherapeutic and nonpharmacotherapeutic care.
- Describe current and future roles of the pharmacist in the provision of care to individual patients with asthma as well as to the wider population with asthma.

Take Home Messages

- Asthma is a chronic condition with a high global prevalence, affecting over 330 million individuals worldwide.
- Asthma may occur in the presence of other diseases of the respiratory system such as allergic rhinitis and chronic obstructive pulmonary disease.
- Inhaled corticosteroids remain the mainstay of treatment however the therapeutic gains resulting from these are limited by poor adherence to treatment.
- There is a shift in focus from underuse of controller therapy to overuse of reliever treatment—optimal pharmaceutical management should focus on both types of treatments.
- There are many opportunities for pharmacists to be involved in optimizing the care of individuals with asthma—from optimizing treatment to improving adherence, particularly around addressing concerns around treatment and need for ongoing regular therapy.

Introduction to Condition

Asthma is a well-known common chronic condition of the airways. Historically, mention of breathlessness or troubled and noisy breathing was found in the earliest known ancient Chinese and Egyptian medical writings, however it is to the Greek we must look for the first mention of asthma by Hippocrates (460–377 BCE) in reference to breathlessness, with the Change to Aretaeus first accurate characterization of asthma as a disease was by Aretaeus the Cappadocian (circa 81–138 CE) (Cohen, 1992; Diamant et al., 2007).

We are now in an era in which the characterization of asthma has evolved from this idea of asthma as a single disease to a respiratory condition that is heterogeneous in nature. Currently, there is still a lack of a definitive definition of asthma, however there is consensus in definitions on asthma being characterized as a heterogeneous condition that has acute periods of variable expiratory airway limitation. These exacerbations may result in symptoms of shortness of breath of variable frequency, duration, and severity as well as associated symptoms such as chest tightness, wheeze, and cough (Global Initiative for Asthma, 2018; National Asthma Council Australia, 2017; World Health Organization, 2018).

Epidemiology, Burden and Pharmacoeconomics

It is estimated that asthma affects up to 334 million people worldwide (Global Asthma Network, 2014). Prevalence is increasing with a prediction of over 400 million affected in 2025 as a result of increasing urbanization (Akdis and Agache, 2013). The burden of disease is shifting to low-income countries with the majority of people with asthma located in developing nations, with such nations reporting higher mortality rates due to asthma (Global Asthma Network, 2014). The burden of disease as measured by disability adjusted life years is greatest in the elderly peaking in the 75–79 year age group with a secondary peak in adolescence in the 10–14 year age group (Global Asthma Network, 2014). Economically, asthma that is poorly controlled results in higher economic costs to both patients as well as to the wider society. Limited data from low-income countries does not allow an accurate picture of the global economic costs of asthma to be estimated. In the US, asthma costs in 2013 were estimated at US$81.9 billion as a result of lost productivity, health care utilization, and mortality (Nurmagambetov et al., 2018).

Etiology

The etiology of asthma has been revised in recent years, yet the specific cause of asthma remains unknown. Traditionally, it was thought that asthma was due to atopy or hypersensitivity to an allergen or "trigger." The inflammatory response was mediated by an increased production of T-helper 2 (T_H^2) cells because of hypersensitivity to a specific allergen. When exposed to the allergen, a primarily cytokine mediated inflammatory cascade ensues, resulting in rapid mast cell degranulation in the presence of IgE,

followed by infiltration of eosinophils and other inflammatory mediators into the airways (de Groot et al., 2015; Wenzel, 2012). However, this process does not explain all asthma disease. An emergent approach to classification of asthma is that of asthma phenotypes (Wenzel, 2012). Asthma phenotypes recognize the heterogeneity of asthma in individuals by grouping according to age of presentation, etiology, and pathophysiology. Broadly, phenotypes can be clustered according to the type and level of inflammation. The most common phenotype is that of "allergic asthma." This phenotype is considered to have the classical T_H^2 cell inflammatory response described above. Other asthma phenotypes may not exhibit a T_H^2 cell inflammatory cascade, e.g., obesity-related and smoking-related phenotypes (Wenzel, 2012). Similarly adult-onset eosinophilic asthma demonstrates independent eosinophilic inflammation and pulmonary infiltration without allergen-dependent activation of T_H^2 lymphocytes (de Groot et al., 2015). A recent metaanalysis suggests that while early-onset asthma is more likely to be due to atopy, late-onset asthma is more related to environmental risk factors suggesting that preventative strategies may be employed in these phenotypes (Tan et al., 2015).

Clinical Presentation

Asthma is not readily distinguishable from other diseases in which airflow obstruction may occur. People typically access health care services with symptoms suggestive of an acute asthma exacerbation or a "flare-up" prior to formal diagnosis of asthma. Such symptoms typically include but are not limited to wheeze, breathlessness, chest tightness, and cough (British Thoracic Society and Scottish Intercollegiate Guidelines Network, 2016).

Differential diagnosis include conditions such as airway obstruction due to a foreign body, alpha1-antitrypsin deficiency, bronchiectasis, congenital heart disease, congestive heart failure, chronic obstructive pulmonary disease (COPD), cystic fibrosis, pulmonary embolism, and vocal cord dysfunction (Global Initiative for Asthma, 2018). Untreated asthma is often characterized by chronic inflammation related to various cells and cellular elements, airway hyperresponsiveness, and intermittent airway narrowing due to bronchoconstriction, congestion or edema of bronchial mucosa, or a combination of these. However, asthma is now thought to have significant overlap with features of other respiratory diseases such as COPD and allergic rhinitis (National Asthma Council Australia, 2017). Recently, the concept of "united airway disease" has emerged as a term to integrate coexistent asthma and rhinitis as an airway-hypersensitivity syndrome due to the shared underlying pathophysiological nature of both diseases (Passalacqua et al., 2000).

Diagnosis

The diagnosis of asthma fundamentally relies on clinical judgment as unfortunately there is no reliable diagnostic test or criteria by which all asthma can be diagnosed. This is compounded by the nonspecific nature of respiratory symptoms which may be caused by other respiratory conditions, instead of, or even in addition to asthma. Another issue in the diagnosis of asthma is the situation of delayed presentation due to some patients delaying presentation with their respiratory symptoms.

Due to the importance of clinical judgment in the diagnosis of asthma, when asthma is suspected, it is essential to obtain a detailed history from the patient and/or their caregiver. The second diagnostic activity involves a careful physical examination including auscultation of the chest. It is important to establish the presence or absence of other conditions that may affect the diagnosis and treatment of the symptoms such as allergic rhinitis and/or COPD.

Diagnosis is made according to two criteria (Global Initiative for Asthma, 2018):

- History of variable respiratory symptoms and
- Confirmed variable expiratory airflow limitation

The second criterion requires the confirmation of airflow limitation preferably by spirometry, as well as confirmation of excessive variability in lung function by lung function testing, e.g., positive bronchodilator reversibility test, exercise challenge test, bronchial challenge test, excessive variability in peak expiratory flow (PEF) over a two-week period or significant improvement in lung function after four weeks of anti-inflammatory therapy. However, if there is a high probability of asthma, a trial of treatment should be given if clinical urgency is present.

Other tests that may provide additional information such as assisting in identification of triggers or asthma phenotype include allergen testing and measurement of the fractional concentration of exhaled nitric oxide (FENO). Allergen testing can be performed by skin prick testing or by measuring the level of specific IgE in serum. Either method may aid in identification of the allergic asthma phenotype, however are not specific tests for asthma. Likewise, FENO is a test that is sensitive for asthma phenotypes that result in increased eosinophil expression in sputum and blood. It is also useful for predicting response to inhaled corticosteroid therapy (Global Initiative for Asthma, 2018).

The diagnosis of asthma in very young children (i.e., those under 5 years of age) is often difficult due to the difficulty in performing lung function testing. In this population, the presence of prognostic markers including symptoms (most commonly disturbed sleep or limitation of activities associated with coughing or wheezing), atopy or a clear provoking stimulus, together with patient history may be all the information a practitioner has to make a diagnosis in the very young.

Traditionally asthma was categorized according to severity of symptoms (see "Introduction" section), however the current approach is to initially assess asthma control (Global Initiative for Asthma, 2018). The following questions may be asked to assess control over the last 4 weeks in patients over 6 years of age:

- Daytime asthma symptoms more than twice/week?
- Any night waking due to asthma?
- Reliever needed for symptoms (except prior to exercise) more than twice/week?
- Any activity limitation due to asthma?

Asthma control is rated as "well controlled," "partly controlled," or "uncontrolled" according to having no symptoms, 1–2 symptoms, or 3–4 symptoms respectively (Global Initiative for Asthma, 2018) (see "Role of the Pharmacist" section).

Asthma disease severity is currently assessed after a patient is stable and has been on regular controller treatment for several months. Severity is rated as "mild," "moderate," or "severe" based on the level of pharmacotherapy required (Global Initiative for Asthma, 2018).

For categorization purposes, asthma is listed under ICD-10 Chapter 10: Diseases of the respiratory system in several categories including J45: Asthma. Asthma is subcoded as intermittent or persistent, with mild, moderate, or severe as descriptors. In addition, a fifth digit is used to describe asthma as uncomplicated, with exacerbation or with *status asthmaticus* (World Health Organization, 2016). Asthma can also be coded in two other categories for specific types of asthma; J46: *Status asthmaticus* and J82: Pulmonary eosinophilia, not elsewhere classified, in which eosinophilic asthma is categorized. It should be noted however that current clinical coding systems including ICD-10 and SNOMED do not align with current clinical terminology with ICD-10 presenting confusion for how acute severe asthma (*status asthmaticus*) should be coded (Lougheed et al., 2017; McKenzie and Wood, 2005).

Place of Pharmacotherapy in Context of Treatment Options

Asthma pharmacotherapy can be broadly classified into two categories—controller treatment which should be taken regularly except in the mildest of asthma cases, and acute short-term reliever treatment for the immediate relief of asthma exacerbations (Global Initiative for Asthma, 2018).

Controller treatment is used in asthma in a stepped approach depending on the symptoms experienced by the patient and the response to the prescribed therapy (see **Fig. 1**) (Global Initiative for Asthma, 2018).

This stepped approach is used as treatment aims to achieve early control—hence treatment should be started at the level most appropriate to the individual's initial clinical presentation—and then for the treatment to be adjusted to the individual's ongoing control. The choice of treatment for maintenance depends on patient factors such as age, ability to use the inhaled device (e.g., inhaler technique) or prescribed formulation, patient preference and goals, severity of asthma, clinician experience (as some therapies are recommended for use only under specialist supervision), and any comorbidities. At any stage of treatment, it is recommended that adherence, inhaler technique, and individual trigger factors be reviewed before any change in therapy (see also "Role of the Pharmacist" section) (British Thoracic Society and Scottish Intercollegiate Guidelines Network, 2016; Global Initiative for Asthma, 2018; National Institute for Health and Care Excellence, 2017).

Controller Treatment

Inhaled Corticosteroids

The mainstay of asthma treatment for both adults and children (with the exception of nonatopic children under five—who often do not have chronic atopic asthma) are the inhaled corticosteroids (ICS) (Adams et al., 2001, 2005; Calpin et al., 1997). Professor Peter Barnes first reported on the use of ICS as first-line treatment for people with persistent asthma (World Health Organization, 2016), highlighting that the use of ICS is associated with improved asthma symptoms, lung function, and reduced risk of exacerbations, hospitalization, and asthma mortality (Barnes, 1998). The mechanism of action of ICS is through the anti-inflammatory effects of the corticosteroid; this suppresses the multiple inflammatory cascades which are activated in the airways of a person with asthma. This inflammation leads to increased mucus production and airway constriction, which contributes to asthma symptoms. Reduction in underlying inflammation through sustained use of ICS can result in symptom improvement and reduced asthma-related morbidity and mortality (Barnes and Adcock, 2003; Barnes and Ulrik, 2015). ICS thus form the basis of most of the controller treatment regimens, with other controllers considered as add-on treatments if response to ICS alone is inadequate (Global Initiative for Asthma, 2018).

Guidelines may vary in terms of when ICS should be started (British Thoracic Society and Scottish Intercollegiate Guidelines Network, 2016; Global Initiative for Asthma, 2018; National Institute for Health and Care Excellence, 2017) but generally ICS should be considered in individuals who use inhaled short-acting beta2-agonists (SABAs) three times a week or more; have symptoms three times a week or more; or wake at least one night a week with asthma, or have any symptoms plus any risk factors for exacerbations (British Thoracic Society and Scottish Intercollegiate Guidelines Network, 2016; Global Initiative for Asthma, 2018). For example, in adults and children 5–12 years, ICS should be considered if they have had an asthma exacerbation

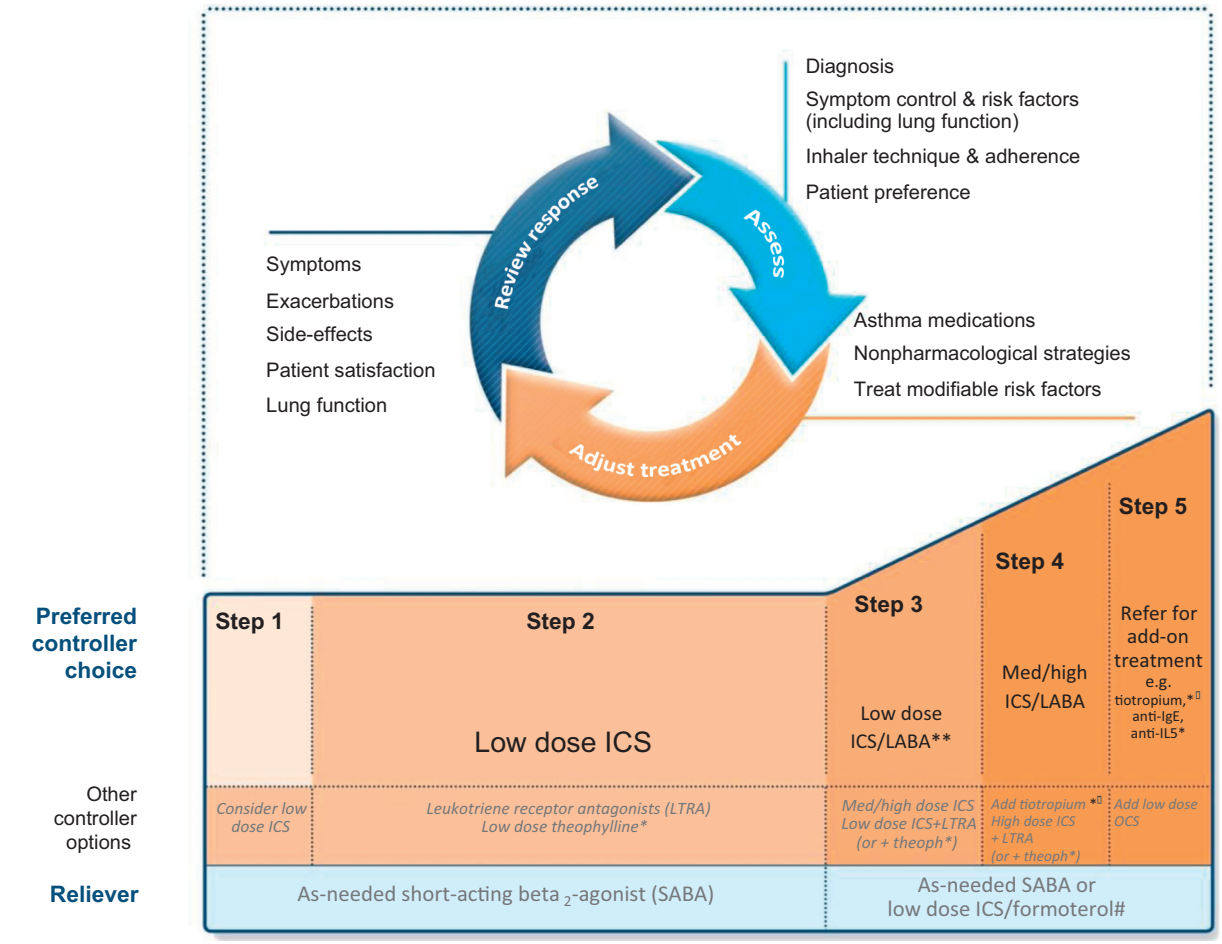

Figure 1 Stepwise approach to control asthma symptoms and minimize future risk. *Source: Reproduced with permission from the Global Initiative for Asthma (Global Initiative for Asthma, 2018).*

or "flare-up" requiring oral corticosteroids in the last two years (British Thoracic Society and Scottish Intercollegiate Guidelines Network, 2016; National Institute for Health and Care Excellence, 2017; O'Byrne et al., 2001; Pauwels et al., 2003; Sorkness et al., 2007; Szefler et al., 2007). ICS should be started at a dose appropriate to the individual's asthma symptoms, and titrated to the lowest effective dose at which asthma control is maintained (British Thoracic Society and Scottish Intercollegiate Guidelines Network, 2016; Global Initiative for Asthma, 2018). Reductions in dose should be slow, with close monitoring for any worsening in asthma control; the individual and/or family/caregiver should be advised about the potential risks and benefits of reducing maintenance treatment. A suggested rate of reduction is 25%–50% reduction in dose, every 3 months (Global Initiative for Asthma, 2018; Hawkins et al., 2003; National Institute for Health and Care Excellence, 2017). In adults who are current or ex-smokers, the dose of ICS required may be higher as the effect of ICS is reduced by current or previous smoking (Tomlinson et al., 2005).

As the adverse effects of ICS are dose-related, there is a need to consider the overall steroid exposure of the individual (i.e., whether the individual is on any other steroid therapies) so that systemic risk can be adequately assessed. This is particularly important in children, as exposure to medium-high doses of ICS can lead to systemic effects such as adrenal suppression, and growth retardation (Sharek and Bergman, 2000). Adrenal suppression can place children at risk of clinical adrenal insufficiency during intercurrent illness or surgery, and therefore this should be considered in any child presenting with shock or reduced consciousness (British Thoracic Society and Scottish Intercollegiate Guidelines Network, 2016; Global Initiative for Asthma, 2018).

In individuals who are not adequately controlled on ICS alone, add-on treatments maybe trialed, following an assessment of adherence, inhaler technique, and review of triggers/risk factors, and comorbidities which may be contributing to symptoms (National Institute for Health and Care Excellence, 2017; Global Initiative for Asthma, 2018). Response to the add-on treatment should be monitored closely, and where there is no response, the add-on treatment should be discontinued (British Thoracic Society and Scottish Intercollegiate Guidelines Network, 2016). The approach to treatment varies depending on the age of the patient (**Figs. 2 and 3**).

Inhaled Long-Acting Beta Agonists

The addition of inhaled long-acting beta agonists (LABAs) to ICS monotherapy have been shown to improve lung function, and reduce symptoms and asthma exacerbations (De Blic et al., 2009; Ducharme et al., 2011; Kips and Pauwels, 2001; Morice et al., 2008). This evidence is stronger in adults—the use of LABA should be considered one of the first-choice add-on therapy in adults (British Thoracic Society and Scottish Intercollegiate Guidelines Network, 2016). A systematic review comparing LABA as add-on treatment to ICS, compared to leukotriene receptor antagonists (LTRAs) as add-on to ICS in adults, found that adding LABA to ICS was more effective in terms of reducing asthma exacerbations, reducing SABA use, and improving symptoms and quality of life (Chauhan and Ducharme, 2014; Ducharme et al., 2011). In children over 5 years old, add-on therapies can be either LABAs or LTRA, as the evidence supports both with little evidence to demonstrate the benefit of one over the other (Chauhan and Ducharme, 2014; Ducharme et al., 2011). It is worth noting here that the guidance on when LABAs should be added to ICS differs between the current BTS/SIGN and GINA guidelines and the NICE asthma guidelines (White et al., 2018). BTS/SIGN and GINA both recommend a trial of add-on LABA if asthma is uncontrolled on low-dose ICS monotherapy (British Thoracic Society and Scottish Intercollegiate Guidelines Network, 2016), while NICE recommend trialing LTRAs first, then adding LABA (with or without LTRA, depending on patient response). A key reason for this difference is due to cost—LABAs are more expensive than LTRAs, thus NICE adopts a more cost-effective approach while BTS/SIGN favor LABA as the more effective treatment (White et al., 2018).

LABAs are add-on therapies which should only be used in combination with ICS, either in separate or combination inhalers. LABAs work by keeping the airways open and relaxing the muscles of the airways, but does not treat any underlying inflammation (Johnson, 1995). As such, LABAs should always be used with ICS and never alone as a series of studies and reports showed an increased risk of death and severe asthma exacerbations from use of LABA monotherapy (Drazen and O'Byrne, 2009; Kramer, 2009; Martinez, 2005), potentially through a masking effect of deteriorating asthma (Chowdhury and Dal Pan, 2010). Most current formulations of LABA are combined with ICS in a single inhaler to support adherence, and to ensure that LABAs are not administered without ICS (British Thoracic Society and Scottish Intercollegiate Guidelines Network, 2016).

In certain adult individuals who remain poorly controlled with ICS and LABA, or medium-dose ICS monotherapy, a regime using the combination ICS/LABA as both controller and reliever therapy has been shown to be effective. This regimen—called maintenance and reliever therapy (MART)—has been shown in two systematic reviews to reduce the risk of asthma exacerbations in individuals not controlled on ICS monotherapy and who have a history of exacerbations (Cates and Karner, 2013; Kew et al., 2013), compared to ICS/LABA as controller and SABA as reliever (Kew et al., 2013), or ICS monotherapy or ICS with/without LABA (Cates and Karner, 2013). The formulations which are licensed for MART vary between countries—local regulations should be checked prior to prescription.

If control remains inadequate to LABA add-on treatment, despite improvement with LABA, then one of two strategies can be used (British Thoracic Society and Scottish Intercollegiate Guidelines Network, 2016; Global Initiative for Asthma, 2018; National Institute for Health and Care Excellence, 2017). The LABA can be continued and the ICS dose increased; or the LABA and ICS continued, but additional treatment added. Below describe the three add-on treatments that can be considered (LTRAs, long-acting muscarinic antagonists (LAMAs), or theophyllines). If the LABA trial was ineffective, then the LABA should be stopped, and either the dose of ICS increased; or a trial of LTRA or LABA started (as add-on to ICS).

Leukotriene Receptor Antagonists

LTRA work by blocking the effects of cysteinyl leukotrienes in the airways—these leukotrienes are released during asthma flare-ups and cause bronchoconstriction (Jones et al., 1995). LTRAs are licensed for use in both adults and children 5 years and over. In children under five years who are unable to take ICS, LTRAs may be used as an alternative preventer. In those over 5 years of age, LTRAs are usually considered as add-on therapies to ICS or ICS plus LABA, though evidence for use of LTRA is primarily from studies where LTRA were added to ICS monotherapy (British Thoracic Society and Scottish Intercollegiate Guidelines Network, 2016). Addition of LTRA to ICS may lead to improvements in asthma symptoms and lung function in those over 5 years, the evidence is most robust for adolescents and adults (≥12 years) as evidence in children is limited (Joos et al., 2008).

Long-Acting Muscarinic Antagonists

LAMA can be considered as add-on treatment in adults—the evidence primarily relates to tiotropium bromide as add-on treatment to ICS/LABA therapy (rather than ICS alone) (Kew et al., 2015). The use of tiotropium as add-on to ICS/LABA was found to reduce asthma exacerbations, improve lung function, and asthma control compared to ICS/LABA alone (Kew and Dahri, 2016).

Theophyllines

Theophyllines have been used historically for asthma management, however are no longer commonly used to the need for therapeutic drug monitoring, and the increased risk of side effects (Weinberger and Hendeles, 1996). These are primarily used as last-line failing trials of LTRAs or LAMAs as add-on therapy (National Institute for Health and Care Excellence, 2017), and recommended only in adults (Global Initiative for Asthma, 2018).

Slow-Release Beta2-Agonist

These oral formulations of beta2-agonists can be considered as add-on treatment in adults who remain uncontrolled after trials of other add-on therapies. Although these can improve lung function and symptoms, the risk of side effects is higher, so use is generally reserved in latter stages of treatment. Caution is advised in individuals already on LABA treatment (British Thoracic Society and Scottish Intercollegiate Guidelines Network, 2016).

Other Controller Therapies

Antihistamines and ketotifen have been investigated as controller asthma therapies, however little evidence remains to support their use (British Thoracic Society and Scottish Intercollegiate Guidelines Network, 2016). In some patients, low-dose maintenance oral corticosteroids may be required but the risks of potential long-term side effects need to be balanced against any benefit (Global Initiative for Asthma, 2018).

Biologics

In individuals with a high steroid burden who continue to have frequent asthma exacerbations, symptoms, and impaired lung function, in whom allergy has been identified as an important cause of the asthma, injectable maintenance treatment with monoclonal antibodies may be considered. Omalizumab is a humanized anti-IgE monoclonal antibody which binds to free circulating IgE, thus reducing free IgE levels (Bousquet et al., 2005). This is given as a subcutaneous injection every 2–4 weeks, dosed according to IgE level and weight (Lanier et al., 2009). Omalizumab has been shown in three systematic reviews to reduce asthma exacerbations in individuals with moderate-severe allergic asthma, compared to placebo, in addition to oral steroids or ICS (Norman et al., 2013; Normansell et al., 2014; Rodrigo et al., 2011). This has been shown to reduce overall steroid burden for the individual.

Anti-interleukin-5 monoclonal antibody injections have been investigated in adults and adolescents (12 years or older) with severe eosinophilic asthma (Powell et al., 2015). Options include intravenous reslizumab (18 years or older) or subcutaneous mepolizumab or benralizumab (12 years or older) and can be considered as add-on failing response to previous therapies (Global Initiative for Asthma, 2018).

Acute Reliever Treatment

Short-Acting Beta-Agonists

These SABAs work on beta2-receptors in the airways to relax the smooth muscle, leading to immediate but short-lived bronchodilation effects (Barnes, 1995). These are useful as intermittent therapy for acute symptom relief in individuals with infrequent, short-lived wheezing episodes. SABA is the preferred treatment in individuals with intermittent symptoms as SABA works quicker with fewer adverse effects than other bronchodilator alternatives. There have been ongoing concerns however around overuse or overreliance on SABA therapy, which have been related to poor asthma control, asthma exacerbations, and increased mortality (Patel et al., 2013; Pavord et al., 2017; Suissa et al., 1994). Individuals identified as frequent users of SABA (e.g., prescriptions of more than one short-acting bronchodilator therapy per month or reported use of SABA more than twice a week) should have their asthma reviewed urgently (British Thoracic Society and Scottish Intercollegiate Guidelines Network, 2016; Global Initiative for Asthma, 2018). Future advances in therapy are focusing on a move away from SABA monotherapy except in the mildest of cases (Pavord et al., 2017) (see What's coming up in pharmacological management); though current BTS/SIGN asthma guidelines recommend using ICS even in very mild cases (British Thoracic Society and Scottish Intercollegiate Guidelines Network, 2016), an approach that is more in line with recommendations from the UK National Review of Asthma Deaths (NRAD) (Levy, 2014).

Other Bronchodilators

Falling within this class are the inhaled short-acting muscarinic antagonists (SAMA—e.g., ipratropium bromide), and per oral formulations of beta2-agonists (e.g., tablets or syrup) (see previous sections for details). These are considered not as effective as SABA, and should be viewed as alternatives only if SABA is not indicated or tolerated for use (British Thoracic Society and Scottish Intercollegiate Guidelines Network, 2016).

Other Treatments

Vaccinations should be considered in all individuals with asthma, particularly as influenza contributes to acute asthma exacerbations (Global Initiative for Asthma, 2018). A recent systematic review of influenza vaccine efficacy in individuals with asthma found that the live vaccine reduced febrile illness by 72%, and the vaccine prevented 59%–78% of asthma exacerbations leading to emergency visits and/or hospitalizations (Vasileiou et al., 2017).

Nonpharmacological Treatment

Beyond treatment with pharmacotherapy, there are a several nonpharmacological management options which should be considered for all people with asthma. These fall in the categories of supported self-management, trigger minimization and optimization of delivery route (e.g., consideration of inhaler technique or device).

Supported Self-Management

Self-management refers to the tasks that the individual needs to do to live with their long-term condition. In asthma, this primarily relates to the management of symptoms, such as knowing when asthma flares up and how to manage this, and when to seek additional help. Understanding and assessing asthma control is the first step to proactive asthma management; what is crucial is the response to deteriorating asthma control. Patients with poor asthma control need to adjust treatment to improve lung function and restore symptom control.

There is a significant role for education to support self-management. Written asthma action plans have been proven to be highly beneficial to improving asthma health outcomes including reductions in exacerbations and decreases hospitalizations, emergency department, and emergency medical practitioner visits (Gibson and Powell, 2004). Education incorporating the use of written personalized asthma action plans, with regular health professional review, improves outcomes in individuals with asthma, regardless of ethnicity, age, asthma severity, and health care context (Gibson et al., 2003; National Institute for Health and Care Excellence, 2017; Powell and Gibson, 2002). These asthma action plans should include advice about how to recognize when asthma control is deteriorating (e.g., what symptoms and/or signs to look for), and what actions to take and when (e.g., seeking help or starting/changing treatment (Gibson and Powell, 2004). Patients can actively participate in the step-up and step-down adjustments to their treatment (Global Initiative for Asthma, 2018). Of greatest benefit are individualized plans that have two to four action points and used both inhaled corticosteroids (ICS) and oral corticosteroids (OCS) (Gibson and Powell, 2004).

This self-management support can be delivered by health professionals or via technology-based platforms depending on the individual's needs and health care setting (Bussey-Smith and Rossen, 2007; de Jongh et al., 2012). The most effective self-management support is ongoing, personalized to the individual (e.g., consideration of the individual's age and language), and continually reviewed to ensure it meets the changing needs of the person with asthma (British Thoracic Society and Scottish Intercollegiate Guidelines Network, 2016).

Self-management support should also encompass issues relating to treatment and monitoring adherence. Adherence to regular monitoring, such as use of peak flow monitoring, is poor with rates as low as 6% reported (Redline et al., 1996). Similarly, adherence to regular controller treatment averages around 33%–50%; this tends to worsen with time (Krishnan et al., 2012). This poor adherence may be unintentional (i.e., when the individual does not adhere to factors not directly within their control such as difficulties with medication-taking or financial barriers to treatment access (Clifford et al., 2008; Horne et al., 2005), or intentional (i.e., the individual chooses not to adhere due to their beliefs about treatment or perceptions of asthma (Clifford et al., 2008). To optimize adherence, the individual's adherence should be regularly assessed (e.g., by asking specific questions about treatment use in a nonjudgmental fashion, exploring their attitudes/beliefs around medication, and/or reviewing their prescription record (Horne et al., 2005); and adherence support tailored to address the individual's unique medication-taking barriers provided (Covvey et al., 2014).

Trigger Minimization

Part of successful asthma management is understanding the warning signs of an asthma flare-up but also recognizing what can trigger an exacerbation. Triggers are substances or events that lead to an acute worsening of asthma symptoms. Patients with asthma may have multiple triggers. Common triggers in asthma include allergens (both indoor and outdoor), environmental pollutants or irritants (Lin et al., 2003), infections, weather, exercise, foods, smells, emotions and stress and even laughing. Occupational asthma can be particularly difficult for patients to manage, due to the wider implications of avoidance.

Each individual will have different triggers—these should be identified and lifestyle changes made to minimize exposure to these, where possible (Global Initiative for Asthma, 2018; National Institute for Health and Care Excellence, 2017). Regardless of the individual's unique triggers, current recommendations supports smoking cessation as part of the nonpharmacological management of asthma, as direct or passive exposure to cigarette smoke can affect lung function, asthma quality of life, and asthma symptoms (Ehrlich et al., 2001; Mannino et al., 2002). Electronic cigarettes have been marketed as safer alternatives to cigarette smoking for individuals who have difficulty quitting smoking. Data on safety are conflicting and e-cigarettes cannot be considered harmless (Pisinger and Døssing, 2014); in individuals with asthma there is even more limited data on safety, however one small retrospective study suggests that use of e-cigarettes to substitute traditional smoking can lead to reduce cigarette consumption and therefore lead to improvements in asthma outcomes (Polosa et al., 2014). E-cigarettes may therefore be a potential option to consider as part of a harm minimization strategy in those who are regular cigarette users; however abstinence from both traditional and electronic cigarettes should be supported where possible.

Optimization of Treatment Delivery

Inhaler technique is an important aspect of asthma management to ensure optimal medication delivery. Inhaler training should be incorporated as part of routine asthma consultations and technique reviewed on a regular basis. In terms of inhaler device choice, this should primarily be based on the individual's preference and their ability to use the device correctly in everyday situations (e.g., many individuals may not wish to carry around a spacer to use with a metered-dose inhaler, in which case a dry powder inhaler may be more appropriate) (British Thoracic Society and Scottish Intercollegiate Guidelines Network, 2016) (see "Role of the Pharmacist" section for additional details).

Other Nonpharmacological Treatments

There have been several other nonpharmacological treatments studied in the research setting, such as the use of fish oils and probiotics (Helin et al., 2002; Stephensen, 2004). However, current guidelines report that there is generally insufficient evidence to recommend other nonpharmacological treatments in the routine management of asthma (British Thoracic Society and Scottish Intercollegiate Guidelines Network, 2016). The evidence around weight-loss interventions is still in its early stages, but may be considered for overweight or obese adults and children with asthma as this may improve asthma control (British Thoracic Society and Scottish Intercollegiate Guidelines Network, 2016). Similarly, certain breathing exercises may be useful in people with asthma as an add-on, but not in place of, pharmacological treatment of asthma (O'Connor et al., 2012).

Family therapy may have a place as an adjunct to pharmacological treatment—in a recent Cochrane review, family therapy was found to be useful particularly in difficult childhood asthma, however the small study samples limits the widespread recommendation of this therapy (Yorke and Shuldham, 2005).

Management of Acute Asthma

The management of acute asthma depends on the setting to which the individual presents (e.g., primary care versus hospital), age of the individual, and the individual's severity of acute asthma exacerbation. Acute asthma can present as moderate, severe, or life-threatening. Any individual presenting with features of acute severe or life-threatening asthma requires early hospital referral.

Treatment of Acute Asthma in Adults

Acute asthma is generally managed in the hospital setting. Local guidelines may govern the management of acute asthma so there may be variations in the treatment(s) used, however the mainstay of treatment generally includes: oxygen, SABA, corticosteroids, and SAMA.

Many individuals are hypoxemic, and emergency oxygen should be given as soon as possible (Rebuck and Read, 1971). High-dose SABAs (e.g., salbutamol or terbutaline) should be given via metered-dose inhalers through large volume spacers to quickly relieve bronchospasm, unless asthma is life-threatening in which nebulized or intravenous administration may be required (Cates et al., 2006; Travers et al., 2001).

All individuals should be given corticosteroids as these have been proven to reduce mortality, relapses and re-admission, and requirements for SABA treatment. These should be given early for better outcomes (Rowe et al., 2007). Corticosteroids can be given as tablets or parenterally, and during the course, ICS should be continued as usual. The corticosteroid courses used for acute asthma exacerbations can generally be stopped abruptly without tapering, as the courses tend to be time-limited and less than 3 weeks' duration, and the individual will continue to be on ICS treatment (Hatton et al., 1995).

Nebulized SAMA should be considered in individuals with acute severe or life-threatening asthma, or if the individual has had a poor initial response to the SABA treatment. The addition of SAMA has been shown to lead to greater bronchodilation than SABA alone, and faster recovery with shorter admission time (Rodrigo et al., 1999).

Treatment of Acute Asthma in Children

Like adults, children can present with different levels of severity of asthma exacerbations, ranging from moderate to acute severe or life-threatening. Treatment decisions will depend on the severity of the airways obstruction based on presentation and clinical signs. The mainstay of acute treatment should include oxygen, inhaled SABA, corticosteroids, and SAMA.

Inhaled SABAs are considered first-line treatment for acute asthma in children aged 2 years or older (Schuh et al., 1999). As with adults, these should be given via a pressured metered-dose inhaler with spacer; the nebulized route is associated with a higher risk of side effects such as tachycardia and hypoxia (Cates et al., 2006). Any LABA in children should be discontinued if SABA treatment is needed more frequently than every 4 hours. Oral corticosteroids should be given early on as use can reduce risk of relapse, with benefits seen within 3–4 hours (Rowe et al., 2001). As in adults, there is no need to taper the corticosteroid course, unless treatment duration exceeds 14 days (Hatton et al., 1995). Any usual controller ICS treatment should be continued during an asthma exacerbation.

Nebulized SAMA may be used in addition to SABA treatment in children with severe or life-threatening asthma, if there is a poor response to SABA treatment alone (Plotnick and Ducharme, 2000); this should be started early in the course of treatment for maximal benefit.

Monitoring of Treatment

During acute treatment, close monitoring of the following should be undertaken: PEF, oxygen saturation, blood gases, heart rate, serum potassium, and blood glucose (British Thoracic Society and Scottish Intercollegiate Guidelines Network, 2016).

For individuals on prolonged or recurrent courses of oral steroids (e.g., recurrent frequent asthma flare-ups), the overall steroid load should be monitored. Monitoring should include blood pressure, urine or serum blood sugar, cholesterol, bone mineral density (in adults and children >5 years), growth (height/weight in children), cataracts, or glaucoma (adults).

What's Coming Up in Pharmacological Management

Immunotherapy

There have been recent studies investigating the use of subcutaneous and sublingual allergen immunotherapy (SCIT and SLIT). These involving administration of increasing doses of extracts of various allergens (e.g., house dust mite, grass pollen, cat/dog allergen, moulds). These may have benefits in reducing symptoms and bronchial hyperreactivity (Abramson et al., 2010), however few studies have compared immunotherapy with ICS versus immunotherapy as add-on treatment to ICS, so it remains unknown where this may fit in the asthma treatment pathway. Furthermore, reported side effects are frequent with SCIT with a high possibility of a local adverse reaction or systemic reaction such anaphylaxis, asthma, urticaria, rhinitis, or a combination of these. While SLIT is associated with fewer adverse reactions, the benefits in terms of asthma control remain small (Calamita et al., 2006).

Changes in Management of Acute Symptoms (Reliever Treatment)

The recent 2017 Lancet Commission has suggested a move away from use of SABA monotherapy as reliever treatment, and instead to use a combination ICS/SABA inhaler in all but the mildest of asthma cases (Pavord et al., 2017). This represents a significant shift in the treatment of asthma and is a step to reducing the increasing overreliance and overuse of SABA currently seen. How this will be implemented in practice in the coming years remains to be seen.

The Role of the Pharmacist in Asthma Management

Pharmacists are highly accessible health care professionals and are recognized as medicines experts. Within a hospital or other secondary/tertiary care setting, pharmacists play an essential role in the multidisciplinary team to optimize asthma management. In primary care, community pharmacists are highly accessible (Bush et al., 2009; International Pharmaceutical Federation, 2009), and as such are ideally placed to play a significant role in asthma management (Bollmeier and Prosser, 2014; Garcia-Cardenas et al., 2016; Saini et al., 2011a). The accessibility of pharmacists in supporting patients is particularly beneficial due to the intermittent nature of the condition and the high degree of patient self-management required. Quality use of medicines (QUM) is an essential element to controlling symptoms and reducing risk of exacerbations in asthma and pharmacists are critical members of the health care team to ensure access to appropriate pharmacotherapy, misuse and suboptimal use of medications abounds (Murphy et al., 2012; Price et al., 2014; Rabe et al., 2000, 2004).

Evidence for the Role of the Pharmacist in Asthma Management

Research has demonstrated the capacity and potential of pharmacists to improve clinical, humanistic, and economic outcomes for asthma patients (Benavides et al., 2009; Bollmeier and Prosser, 2014; Garcia-Cardenas et al., 2016). Pharmacist-led interventions to improve asthma management have focused on areas such as patient education, drug therapy monitoring, and supporting patient self-management. The benefit of these pharmacist-led interventions have been demonstrated by improvements in measures of asthma severity, asthma symptoms, lung function, quality of life, ED visits, hospitalizations, and direct and indirect cost savings (Benavides et al., 2009). More recent research has investigated the benefit of comprehensive interventions in the form of community pharmacy-based asthma programs (Bollmeier and Prosser, 2014). There has been increasing acknowledgement that pharmacists have an important role to play in chronic disease-state management (DSM) programs, which use a collaborative approach and put the patient at the center of their own care (Saini et al., 2011a). Positive outcomes from DSM asthma programs have included improvements in patient asthma knowledge scores, inhaler device technique, quality of life, asthma control, symptom scores, and lung function (Bollmeier and Prosser, 2014). What is clear, from the research at this point in time, is the immense potential that pharmacists have to influence outcomes (Garcia-Cardenas et al., 2016).

Currently, pharmacists already play an important role in the provision of medications to treat asthma, but there is little evidence about routine clinical practice in the community pharmacy setting (Benavides et al., 2009). While there are examples of excellence and expanded clinical roles in asthma in pharmacy, generally the indications are that current practice is variable, suboptimal and there is a lack of translation of research findings (Kritikos et al., 2010; Royal Pharmaceutical Society, 2013; Schneider et al., 2009, 2011). Research has highlighted deficiencies in pharmacy practice in the areas of patient assessment, medication counseling, demonstration of inhaler technique as well as a lack of pharmacist engagement with patients (Basheti et al., 2009; Schneider et al., 2009; Takemura et al., 2012). Efforts have also been made to examine the underlying reasons for suboptimal asthma management and patient care by pharmacists. Identified barriers to optimal care of asthma patients in the pharmacy setting include lack of knowledge, lack of time, lack of confidence, patient-related factors, and environmental issues (Basheti et al., 2009; Bollmeier and Prosser, 2014; Kritikos et al., 2010; Watkins et al., 2016b). Another issue identified in the literature on pharmacist involvement in asthma management is the lack of participation in collaborative care. Research in asthma management has shown that pharmacists do not routinely communicate with other members of the primary health care team (Cairns and Everleigh, 2000; Emmerton et al., 2012). The advantages to patients of collaborative care are well established (Gums et al., 2014), but have been difficult to foster in the primary health care setting. Jargon, such as "silos," relate not only to medical practitioners but also to pharmacists and patients may also play a role in undermining health professional collaborative care (Cheong et al., 2013). It could be argued that optimal asthma management will only be achieved when collaborative care issues have been addressed.

Encouragingly, research has shown that patients have a high degree of satisfaction with expanded asthma services provided by community pharmacists (beyond the current offering which primarily revolves around medication supply) (Armour et al., 2007; Bereznicki et al., 2008a,b; Kritikos et al., 2007; Naik-Panvelkar et al., 2010; Saini et al., 2004; Smith et al., 2007). This demonstrates patient receptivity and the potential to develop this role in a more consistent and sustainable way, if some of the barriers to practice change can be addressed.

Expanded services that have been identified as opportunities for greater participation by pharmacists in asthma management (George et al., 2010; Mehuys et al., 2008; Saini et al., 2011a) include: patient screening to facilitate early intervention (Armour et al., 2011; Bereznicki et al., 2008b; Fathima et al., 2013; Saini et al., 2011a; van Boven et al., 2013); patient education (Saini et al., 2011b); inhaler technique education and review (Basheti et al., 2005, 2007; Takemura et al., 2012); self-management education and support (Barbanel et al., 2003; Dolovich et al., 2007; Kheir et al., 2001; Smith et al., 2007); improving quality use of medication and adherence (Bereznicki et al., 2008b; Elliott et al., 2008; Herborg et al., 2001); comprehensive disease state management (Armour et al., 2007; Mangiapane et al., 2005); health promotion and servicing rural and remote populations where access to services is limited (Kritikos et al., 2005; Shah et al., 2005). Also relevant are contributions to smoking cessation and management of comorbid conditions (Brown et al., 2012).

To unlock the potential of pharmacists, more effort needs to go into the translation of research through implementation science. It is recognized that medication management and patient health outcomes in asthma are suboptimal. It remains to be seen whether the potential of pharmacists can be realized to affect change in outcomes.

Medication Management by Pharmacists in Asthma

Pharmacists are medication experts (Kehrer et al., 2013), are part of the medication supply chain and participate in health referral pathways. These attributes and functions determine they are integral in asthma management. Medications are the mainstay of treatment and can effectively control the symptomatic manifestations of this chronic, incurable disease, in the majority of patients (Bateman et al., 2004; Global Initiative for Asthma, 2018). Inappropriate use of medication has been found to be a key issue in many of the instances of suboptimal asthma management (Al-Jahdali et al., 2013; Garcia-Cardenas et al., 2016; Reddel et al., 2015). There are several areas where pharmacists can intervene or support patients to ensure QUM in asthma management.

Medication Supply

Chronic conditions such as asthma require that patients have continual and reliable access to high quality medications. However, in many countries and certain socio-economic demographics accessibility to medications continues to be a problem. Access to high quality asthma medications is a multifactorial problem that requires initiatives and funding at a global and national level to be addressed (The Global Asthma Network, 2014). Pharmacists form part of a global workforce that facilitates patient access to medications and health care advice (International Pharmaceutical Federation, 2017). Maintaining a strong global network of pharmacists to equitably and adequately service the ongoing medication needs of patients with asthma is crucial to reducing the individual and societal burden of the disease.

Medication Education

Patient education is crucial due to the combination of medications generally used to manage the condition. Patients can be overwhelmed with information at the time of diagnosis and require repeated educational opportunities to assimilate the required knowledge to be proactive in the management of their health.

Many patients remain unaware of the role and benefits of ICS as controller therapy (Menckeberg et al., 2012) and have detrimental beliefs about their potential for side effects (for example, concerns over effects on growth in children). Overreliance on reliever medications (SABAs) is also well documented and puts patients at risk of severe exacerbations and even death (Levy, 2014; Partridge et al., 2006; Reddel et al., 2015; Sawyer and Fardy, 2003). Similarly use of LABA without ICS is contraindicated and associated with increased mortality and requires intervention (Armour et al., 2011; Levy, 2014; Reddel et al., 2015; Watkins et al., 2016a). Patients need to be provided with the knowledge of how to use medication in an emergency first aid situation, which can be life-saving. Patients also need to be aware of ways to minimize side effects of medications such as rinsing their mouth and use of spacer devices.

The knowledge and belief of patients are intrinsically linked to their health behaviors and pharmacists are in an ideal position to engage with individuals to support appropriate medication self-management. This is particularly relevant to situations where patients may not necessarily be seeking health professional assistance or advice, or in areas where access to health services may be limited. Inappropriate medication management identified by pharmacists requires intervention. It also requires communication and collaboration with other health professionals and the patient.

Medication Dose Monitoring

The characteristic disease variability in asthma requires frequent adjustments to pharmacotherapy using a control-based asthma management cycle that involves assessment, treatment, and review on a continual basis. Medication is stepped up or down depending on the symptom control and assessments of future exacerbation risk (**Fig. 1**) (Global Initiative for Asthma, 2018). Pharmacists can play a role in ensuring that patients maintain good asthma control using the minimal effective doses of medications, thus reducing the potential for unwanted side effects and limiting unnecessary overuse of medication (Watkins et al., 2016a).

Medication Adherence

Pharmacists have the capability to monitor medication adherence, not only due to their regular contact with patients, but also through their access to medication records and data mining (Bereznicki et al., 2008a; van Boven et al., 2013). Poor adherence to prescribed medication regimens is a complex problem and a major cause of poor clinical outcomes in asthma (Bender, 2002; Saini et al., 2011b).

Having uncovered any adherence issues, the challenge is for the pharmacist to resolve what predicates patient behaviors. Lack of medication adherence can be intentional or unintentional. To provide appropriate patient-centered care, and resolve adherence issues that may undermine patient health, the pharmacist needs to appreciate the patient perspective and gain insight into a patient's medication beliefs (Gadkari and McHorney, 2012). The strategies that pharmacists can use to promote patient medication adherence are as many and varied as the reasons for patient nonadherence. Strategies may include suggesting simplified medication regimens. For instance, reducing the types of devices a patient uses, utilizing combined medication formulations or formulations that allow for lower dosing frequencies. Education can be used to address any misconceptions patients may have about the disease and the medications used to treat it. Even so called "unintentional nonadherence" has been shown to relate to patient's perceptions around the necessity and importance of the medication (Gadkari and McHorney, 2012). Patients may also be struggling psychologically with the diagnosis, motivation, and self-efficacy to manage the condition. Pharmacists can directly address such issues or refer patients for appropriate care from other health professionals. Some patient adherence issues may relate to financial considerations. Pharmacists are well placed to suggest cost effective therapeutic solutions (such as generic preparations) or inform patients of medication subsidy systems they can access. Finally, some patients can benefit from pharmacists suggesting or offering organizational strategies which encourage routines that assist medication adherence. Newer digital technologies such as medication reminder texts, electronic adherence monitoring, smart phone applications and online medication ordering, and delivery have the potential to improve medication adherence (Chan et al., 2013; Tran et al., 2014).

Inhaler Technique Assessment and Education

In terms of QUM, one of the major roles for pharmacists is to assess and educate patients with respiratory diseases (such as asthma) on correct inhaler device use. The majority of medications used to treat asthma are inhaled medications and incorrect use is detrimental to patient health and results in increased health care costs (Inhaler Error Steering Committee et al., 2013; Levy et al., 2016). It is important that patients are provided a suitable device and educated to use the device correctly maximizes the therapeutic benefits obtained from pharmacotherapy. There are startling statistics demonstrating the urgent need to address the issue of poor inhaler technique. Research indicates that up to 90% of patients use their inhalers incorrectly (Levy et al., 2016). Given their role in medication supply, pharmacists may be the last health professional to have access to a patient before they commence using a medication. Ensuring inhaler technique is correct is therefore a key responsibility of the pharmacist and an area where they can play a significant role in improving patient outcomes. However, it is incumbent on pharmacists to have the ability to demonstrate correct inhaler use. Across all health professional disciplines involved in inhaler training there is evidence that between 15% and 69% do not have the skills or training to correctly demonstrate inhaler devices (Levy et al., 2016). Furthermore, these skills can decline over time. An effective way for pharmacists to maintain skills is to be routinely involved in counseling patients on inhaler technique (Basheti et al., 2009).

An important aspect of assisting with inhaler technique is ensuring patients' therapy is maximized through the selection of an appropriate device. Pharmacists are required to understand the various strengths and limitations associated with different devices. For instance, a dry powder device may be a poor choice for a patient with an exacerbation of asthma and low inspiratory flow rate. A metered dose inhaler may be inappropriate for a patient with arthritis and dexterity issues or cognitive impairment. The appropriateness of devices may change over time and pharmacists are appropriately placed to make interventions when necessary. Pharmacists can also encourage patients to use spacer devices to improve lung drug deposition and efficacy. Advice on how to appropriately care for devices such as spacers is another role for pharmacists.

Disease Management by Pharmacists in Asthma

Patients require a holistic understanding of asthma to self-manage the condition appropriately. Pharmacists can play a significant role in, not only educating patients, but by facilitating "patient activation." Education can provide patients with "technical know-how." However, assisting patients to actively and effectively self-manage their condition requires imparting the motivation, courage, skills, ability to problem solve, make decisions, and troubleshoot the condition (Saini et al., 2011b). There is evidence to suggest that patients display asthma acceptance and the limitations asthma puts on their lives rather than managing the condition fully (National Asthma Council Australia et al., 2010). Pharmacists can play a role in solving the problem.

Assessing Asthma Control

The goals of treating asthma include managing symptoms and improving quality of life. Essential to achieving these goals is maintaining good asthma control. Pharmacists have the ability to assess patient asthma control at every encounter which allows for early referral of patients whose condition may be deteriorating. Overuse of SABA is a significant indicator of poor control that pharmacists can identify when patients present with medication requests. The importance of this was highlighted by the National Review of Asthma Deaths (NRAD) in the UK undertaken in 2014. There was evidence of overprescribing of relievers in the preceding year in approximately 40% of the deaths reviewed. In 4% of cases this overuse was extreme and involved prescription of more than 50 reliever inhalers in a 12-month period (Levy, 2014).

Along with considering reliever use, there are a variety of easy to administer tools that pharmacists can use to assist in the assessment of patient asthma control, such as the asthma control test (ACT) (Thomas et al., 2009). Pharmacists can also educate patients on the importance and how to monitor their own asthma control. Symptom recognition is an important way that patients can learn to respond to their asthma.

Supporting Proactive Self-Management and Use of Written Asthma Action Plans

Written asthma action plans are generally written by medical practitioners and the role of the pharmacist is to encourage regular medical review, ownership and appropriate use of a written asthma action plan. However, it is feasible in the future that pharmacists could expand their role and be involved in the development of asthma action plans in collaboration or consultation with medical practitioners (Watkins et al., 2016a).

Assessing Trigger Factors

Pharmacists can play an active role in increasing patient awareness of asthma triggers and, where possible and appropriate, provide advice on how to reduce exposure and mitigate risk. Respiratory infections are a common trigger for asthma and difficult for patients to avoid. However, pharmacists can recommend and/or administer influenza and pneumonia vaccinations and encourage hygiene to reduce viral or bacterial transmission. Advice to patients to avoid cigarette smoke and passive smoking can confer health benefits beyond those related to asthma management.

Assessing Lung Function

Lung function testing is not diagnostic in asthma and does not correlate well with asthma symptoms in either adults or children. However, spirometry (which is the gold standard in lung function testing) can be both a useful diagnostic tool and mechanism for evaluating future exacerbation risk in asthma (see "Diagnosis" section for further detail). Patients with a low forced expiratory volume in 1 second (FEV_1) are more at risk of exacerbations. The recommendation in asthma guidelines is that lung function should be assessed at diagnosis of asthma, once treatment has been initiated, and 3–6 months after the initiation of a controller medication to ascertain a measure of patient "best lung function." Periodic testing at intervals of every one or two years is recommended thereafter (Global Initiative for Asthma, 2018). Historically lung spirometry has been performed in hospitals by specialist technicians. However, technological advances have seen the development of more cost effective and portable equipment and it is now offered in medical practices and usually undertaken by nurses or medical assistants. This also makes it a service that is well suited to community pharmacy practice. There is evidence that pharmacists with specialized training are capable of offering quality spirometry testing and this is likely to be an area of expanded practice is the near future (Cawley and Warning, 2015).

Another form of lung function testing that patients can undertake as part of asthma self-management is PEF monitoring. PEF can be especially beneficial for patients who have trouble gauging asthma control based on symptoms, experience intermittent asthma or need to monitor response to changed treatment. Pharmacists have a role to play in assisting patients to effectively use PEF in conjunction with symptom monitoring and written asthma management plans as part of proactive self-management.

Managing Complex Patients

The medication and disease management skills of pharmacists are at their most valuable when assisting patients with complex health needs. These complexities may relate to certain patient populations (e.g., asthma phenotypes, pregnancy, exercise-induced asthma), multiple chronic conditions, multiple care providers, polypharmacy, frequent exacerbations of asthma, and limitations to daily functioning. There is increasing recognition that asthma is a heterogeneous disease and that different phenotypes exist (see "Etiology and Clinical Presentation" sections) (Global Initiative for Asthma, 2018). Some phenotypes may be resistant to standard therapies making management challenging and the input of pharmacists invaluable, especially in collaborative patient management.

Asthma is often considered to be a disease of childhood, however there is a high prevalence of older adults (aged over 65 years) that have asthma (Yawn and Han, 2017). Many of these patients have comorbid conditions that can directly impact on asthma symptom management and therapeutic choices due to drug-disease or drug-drug interactions. Lung function declines with age and patients may confuse asthma symptoms with aging or other comorbidities. Pharmacists can play a role in the management of conditions such as rhinosinusitis, obesity, psychiatric disorders, and gastro-esophageal reflux disease, all of which can worsen asthma symptoms. Drugs including aspirin (and other nonsteroidal anti-inflammatory drugs), beta-adrenoceptor antagonists (beta blockers), and angiotensin converting enzyme (ACE) inhibitors can be problematic or contraindicated in some patients with asthma. It has even been demonstrated that nonselective beta-antagonist eye drops can impact on lung function (Morales et al., 2016). Elderly patients with asthma may be more susceptible from adverse drug reactions from asthma treatments, especially the cardio-toxic effects of beta-2-agonists and systemic effects from corticosteroids (Global Initiative for Asthma, 2018).

Management of patients who have mixed respiratory diseases can be particularly difficult. It is possible for patients to present with chronic respiratory symptoms and features characteristic of both asthma and COPD. This is particularly true in smokers and the elderly. Patients with mixed etiology disease tend to have more exacerbations, a reduced quality of life and represent a greater burden on health care resources (Global Initiative for Asthma, 2018). Given the detrimental effect smoking has on lung function another crucial role for pharmacists in asthma management is supporting smoking cessation, both through psychological support and provision of nicotine replacement therapy.

Asthma control in pregnancy can often change for the better or worse and throughout pregnancy. Exacerbations can have consequences for the baby (preterm delivery, low birth weight, increased perinatal mortality) and mother (preeclampsia) and need to be avoided through vigilant supported management (Global Initiative for Asthma, 2018).

It is important to encourage exercise in patients with asthma, but many will develop asthma symptom during physical activity. Exercise-induced asthma can be successfully managed with appropriate pharmacotherapy. Pharmacists can play a role in supporting patients to participate in exercise.

Pharmacists can play a significant role in the management of complex patients through extended consultations, pharmaceutical care and disease management programs. In many countries pharmacists are now routinely involved in higher level clinical services such as medication use reviews and DSM programs which support this form of practice (International Pharmaceutical Federation, 2017) (**Fig. 4**).

Health Promotion Activities by Pharmacists

Pharmacists are uniquely placed to play a significant role in health promotion. This is because they have regular contact with a large proportion of the population on a regular basis. They see sick and healthy people and encounter people not necessarily actively seeking health care advice. Pharmacists are highly trusted health care professionals and this also enhances their ability to reinforce health messages (Anderson, 2000).

While promoting health is part of the accepted role of pharmacists in their daily interactions with patients they also participate in more structured health promotional events. Pharmacists may participate as agents for governments and not for profit health agencies or even self-direct health promotion activities. For instance, the first Tuesday in May has been designated as World Asthma Day. It is an annual event to raise awareness about asthma globally and was established by the Global Initiative for Asthma (GINA) in 1998. Pharmacists will often use such events to focus their health promotional activities. However, one of the barriers to expanding the health promotion role of pharmacists is the limited opportunities for remuneration.

Remuneration and Funding for Service Delivery

The potential scope of practice for pharmacists in asthma management is significant and could have a profound impact on patient health outcomes and the societal burden associated with asthma. The role of the pharmacist and pharmacies are essential to the

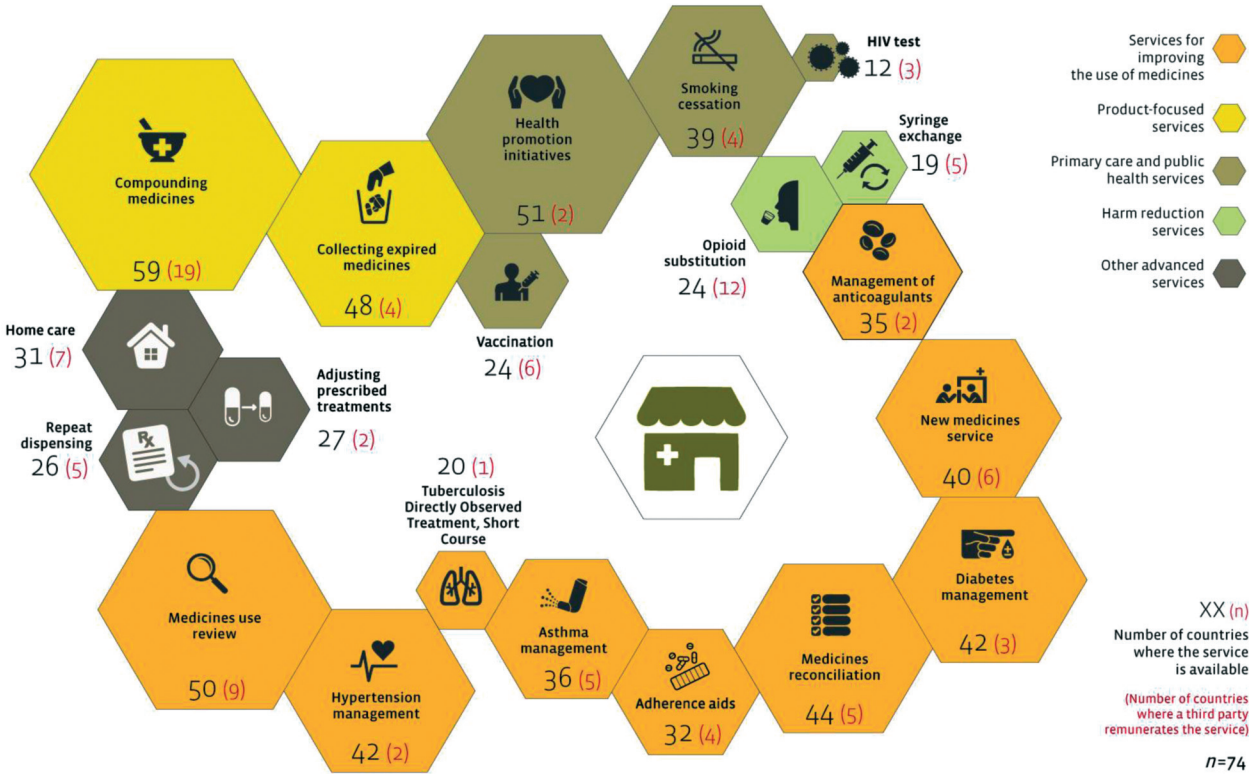

Figure 4 Services community pharmacies are providing and being remunerated for beyond dispensing. *Source: Reproduced with permission from the International Pharmacy Federation.*

health system framework of every country. However, a report by the International Pharmacy Federation from 2015 identified that there is worldwide concern over the long-term financial viability of the community pharmacy sector. The report also noted that despite the shift to a more service-focused clinical practice model, remuneration has remained predominately product-focused. Income still largely depends on dispensing-related activities with funding from third party payers. The issue is that these income sources are decreasing. There is an urgent need to identify other revenue sources to maintain high quality, comprehensive pharmacy services in a sustainable way (International Pharmaceutical Federation, 2015).

At this point in time there is limited financial recognition for many of the clinical services provided by pharmacists for asthma management. This results in ad hoc, inconsistent service provision and impedes the involvement of pharmacists in expanded clinical practices where they could potentially improve patient health and health service utilization. Fig. 4 gives a global picture of service provision and remuneration for clinical services by pharmacists. For instance, pharmacists in 36 countries undertake asthma management services, but remuneration for that service only occurs in five countries (International Pharmaceutical Federation, 2017). The picture is similar across the breadth of clinical services outlined in Fig. 4.

Without a more effective remuneration model it is unlikely that pharmacists will realize their potential in playing a role in improving asthma, and indeed any health outcomes. There are few financial incentives for pharmacists to develop and use higher level clinical skills. It is a testimony to the commitment and dedication of pharmacists that they have pursued clinical service provision and play the important role that they already do in patient health with so few financial incentives.

Management of Respiratory Disorders and the Pharmacist's Role: COPD

Johnson George[*,†], **Jenifer Liang**[*], [*]Centre for Medicine Use and Safety, Monash University (Parkville Campus), Parkville, VIC, Australia; [†]Monash University, Melbourne, VIC, Australia

Foreword

This chapter draws information from the international Global Initiative of Obstructive Lung Disease (GOLD) guidelines—a widely distributed report updated on a yearly basis to incorporate new evidence for COPD prevention, diagnosis, and management (Global Initiative for Obstructive Lung Disease, 2018). In addition, many regional guidelines on COPD management have been developed by various thoracic societies and professional organizations, which inform practice in that region or a particular country.

Learning Outcomes

On completion of this chapter you should be able to:

- Define COPD and outline its pathophysiology, including risk factors, and the changes in airways and other systems;
- Characterize the symptoms of COPD (undiagnosed and/or poorly controlled) and recognize when to make referrals to doctors for diagnosis, and further assessment/management;
- Compare and contrast the pathophysiology, diagnosis, and management of COPD and asthma;
- Understand asthma-COPD overlap (ACO) and when to make referrals to specialist physicians;
- Understand the pharmacological and non-pharmacological management of both stable COPD and COPD exacerbations, including preventive measures to slow the progression of the disease, management of symptoms, and reversal of the underlying pathophysiology; and
- Apply the knowledge in optimizing the management of patients at risk and/or with COPD through education, feedback, follow-up, and promotion of self-management.

Case Study 1

Mr. Trafalgar is a 40-year-old construction worker who visits Meadow Inn Pharmacy occasionally to buy an over-the-counter (OTC) cough suppressant. Mr. Trafalgar came to the pharmacy this morning complaining of occasional shortness of breath (SOB) and an annoying cough, which occurs most commonly on cold mornings and when he walks around the construction site. In addition to the cough medicine, Mr. Trafalgar wanted something for his breathlessness. The pharmacy assistant suggested that Mr. Trafalgar talks to the pharmacist on duty. Mr. Trafalgar told the pharmacist that he becomes breathless after climbing even a single flight of stairs. He is unable to lift anything heavy either, due to lack of breath. He had two chest infections during last winter, both of which required a course of antibiotics.

Mr. Trafalgar has smoked heavily for 25 years (on average 25 cigarettes per day), but has cut down to 10 per day in the last six months. He experiences frequent bouts of cough which he often treats using OTC cough-and-cold preparations. He believes he has "smoker's cough," which is further aggravated by dust inhalation at the construction site, but has never considered quitting smoking even though he knows that smoking may cause cancer. Based on the history, the pharmacist wants to check whether Mr. Trafalgar has already developed COPD.

Chronic Obstructive Pulmonary Disease

The Global Initiative for Chronic Obstructive Lung Disease (GOLD) defines chronic obstructive pulmonary disease (COPD) as "*a common, preventable and treatable disease that is characterized by persistent respiratory symptoms and airflow limitation that is due to airway and/or alveolar abnormalities usually caused by significant exposure to noxious particles or gases*" (Global Initiative for Obstructive Lung Disease, 2018). COPD is a heterogeneous condition, with multiple clinical features and comorbidities, which are known to increase its morbidity and mortality. COPD is sometimes referred to as chronic obstructive airways disease (COAD) or chronic obstructive

lung disease (COLD). Some definitions of COPD in the past have incorrectly used the terms "*emphysema*" and "*chronic bronchitis*"; however, the GOLD reports (first report in 2001) have not used those terms in defining COPD. Emphysema, characterized by alveolar dilatation and destruction, is a pathological diagnosis and describes only one of the several structural abnormalities present in patients with COPD (Global Initiative for Obstructive Lung Disease, 2018). Chronic bronchitis refers to the presence of daily cough and sputum production for at least 3 months each year in two or more consecutive years, but is present in only a minority of subjects with an existing diagnosis of COPD when this definition is used (Global Initiative for Obstructive Lung Disease, 2018; Kim et al., 2015).

Burden of COPD

COPD causes approximately three million deaths annually (5.6% of all deaths) globally and is the fourth leading cause of global mortality, behind ischemic heart disease, stroke, and lower respiratory infections (Lozano et al., 2012). In 2015, deaths from COPD (3.2 million globally) were eight times more common than deaths from asthma. Globally, COPD affected 104.7 million males and 69.7 million females in 2015 and was ranked eighth (2.6% of global disability adjusted life years [DALYs]) among the 315 global burden of disease causes (GBD Chronic Respiratory Disease Collaborators, 2017). COPD also imposes significant social and economic burden on health systems and society. In 2010, the cost of COPD in the United States of America was approximately $50 billion, which included $20 billion in indirect costs and $30 billion in direct health care expenditures (Guarascio et al., 2013). Burden data and prevalence rates of COPD vary across countries due to differences in survey methods, diagnostic criteria, and analytical approaches used. Prevalence of COPD is known to be higher in smokers and ex-smokers compared to nonsmokers, in those ≥40 years of age compared to those <40 years, and in men compared to women (GBD Chronic Respiratory Disease Collaborators, 2017). Deaths due to COPD are projected to increase to 4.5 million per year (6.5% of all deaths) by 2030 (World Health Organization, 2012).

Causes of COPD

Globally, chronic exposure to tobacco smoke is the most important, preventable risk factor in the development of COPD (Fletcher and Peto, 1977). In high-income countries, smoking and second-hand smoke are the most important risk factors for COPD, whereas environmental risks and occupational risks contribute to significant amount of the burden in lower-income countries. In susceptible people, smoking causes irreversible obstructive changes in the respiratory system, earlier disability and death (Fletcher and Peto, 1977). Smoking increases the rate of decline of lung function and causes airflow obstruction. The Framingham Offspring cohort study of those who had two or more valid spirometry measurements during follow-up (n = 4391; baseline age ranged from 13 to 71 years, with a median follow-up time of 23 years), found that 33.0% of continuous-smoker males and 24.2% of continuous-smoker females developed airflow obstruction during follow-up, compared to 7.4% of men and 5.6% of women, who were never-smokers (Kohansal et al., 2009). Among continuous smokers, lung function (forced expiratory volume in 1 second—FEV_1; measured using spirometry) declined both in males (from 8 to 63 mL/year) and females (from 14 to 49 mL/year) (Kohansal et al., 2009).

Other common etiologies of COPD include exposure to biomass fuel, air pollutants, or occupational dusts and fumes; chronic asthma; impaired lung growth; and genetic predisposition (Omland et al., 2014; Stoller and Aboussouan, 2005). An international cohort study of more than 4000 young adults without asthma who participated in the European Community Respiratory Health Survey found that smoking accounted for 29%–39% of the new cases of COPD (incidence rate of 2.88 cases/1000/year during follow-up) (de Marco et al., 2011). Airway hyperresponsiveness was the second strongest risk factor (15%–17% of new cases); other determinants were respiratory infections in childhood and a family history of asthma (de Marco et al., 2011).

In many middle-low income countries, biomass and coal are used as the main sources of energy for cooking, heating, and other household needs (Assad et al., 2015). Wood, animal dung, crop residues, and coal, typically burned in open fires or poorly ventilated dwellings can lead to very high levels of indoor air pollution (Assad et al., 2015; Orozco-Levi et al., 2006). Outdoor air pollution can also have a significant impact on lung health. The inverse relationship between risk of developing COPD and socio-economic status may be a confounding effect of exposures to indoor and outdoor air pollutants, poor nutrition, infections, or other factors related to low socioeconomic status (Gershon et al., 2011).

Airway hyperresponsiveness is a major risk factor for COPD and an indicator of risk of excess decline in lung function in those with COPD (de Marco et al., 2011). In a cohort of more than 3000 adult subjects from Arizona (USA), those with physician-diagnosed asthma were found to have a 12-fold higher risk of acquiring COPD compared to those without asthma, after adjusting for smoking (Silva et al., 2004). Despite distinct differences present in the pathology of airflow limitation, inflammatory cells and mediators involved in asthma and COPD, distinguishing the two can be challenging in adults with a history of exposure to smoking, and a personal and/or family history of atopy. A subset of patients with airways disease may have features of both asthma and COPD (Leung and Sin, 2017).

Alpha-1 antitrypsin deficiency is a genetic disorder (SERPINA1 gene mutation is frequently implicated) that affects about one in 2000–5000 individuals (Stoller and Aboussouan, 2005). Alpha-1 antitrypsin is mainly produced in the liver and has a protective effect in the lungs by preventing proteolytic damage from neutrophil elastase (Stoller and Aboussouan, 2005). Serum levels less than 11 micromol/L (i.e., the serum protective threshold) increase the risk for emphysema in individuals (Stoller and Aboussouan, 2005).

Pathology of COPD

Lung inflammation occurs after inhalation of irritants such as smoke from combustible tobacco and biomass fuels. The chronic inflammatory response in patients with COPD causes pathological changes including parenchymal tissue destruction (from emphysema), and modifications to normal repair and defense mechanisms (from small airway fibrosis) (Hogg and Timens, 2009). Changes in the airways, lung parenchyma, and pulmonary vasculature lead to gas trapping and progressive airflow limitation.

Pathogenesis

The normal inflammatory response to inhalation of noxious particles appears to be modified in patients with COPD. It is not well understood what the mechanisms are for this amplified inflammation. Genetic factors may be involved in those with no history of smoking (e.g., those with alpha-1 antitrypsin deficiency). Oxidative stress, protease imbalance in the lungs, increased inflammatory cells and inflammatory mediators, autoantigens and changes in lung microbiome may play roles in the lung inflammation and the pathological changes characteristic of COPD (Global Initiative for Obstructive Lung Disease, 2018).

Pathophysiology

Decreased FEV_1 results from the chronic inflammation and narrowing of peripheral airways. Parenchymal tissue destruction (from emphysema) also contributes to airflow limitation and leads to reduced gas transfer. There may also be a loss of small airways, which may play a part in airflow limitation.

Characteristics of COPD include the following:

- Airflow limitation and gas trapping
  - Reduction in FEV_1 and FEV_1/FVC ratio dependent on extent of inflammation, fibrosis, and luminal exudates
  - Peripheral airway limitation progressively traps gas during expiration, ultimately leading to hyperinflation
  - Static hyperinflation reduces inspiratory capacity and is commonly associated with dynamic hyperinflation during episodes of exercise
- Gas exchange abnormalities
  - Abnormalities in gas exchange processes result in hypoxemia and hypercapnia
  - Gas transfer for oxygen and carbon dioxide worsens as disease progresses
  - Reduced ventilation may be due to reduced ventilator drive or increased dead space ventilation
  - Carbon dioxide retention can result when combined with reduced ventilation, due to increased effort to breathe because of severe limitation and hyperinflation coupled with ventilator muscle impairment
  - Abnormalities in alveolar ventilation and reduced pulmonary vascular bed worsen ventilation perfusion ratio (VA/Q)
- Mucous hypersecretion
  - Results in chronic productive cough
  - Chronic productive cough is characteristic of chronic bronchitis but is not always associated with airflow limitation; however, not all patients with COPD have symptomatic mucus hypersecretion
  - Chronic exposure to irritants causes increased goblet cell numbers and enlarged submucosal glands
- Pulmonary hypertension
  - Develops late in disease, mainly due to hypoxic vasoconstriction of small pulmonary arteries, eventually resulting in structural changes in these arteries
  - Significant abnormalities in pulmonary microvascular blood flow are already seen in mild COPD and smokers susceptible to emphysema
  - An inflammatory response, similar to that in the airways, and endothelial cell dysfunction seen in vessels
  - Loss of pulmonary capillary bed in emphysema increases pressure in pulmonary circulation
  - Progressive pulmonary hypertension can lead to right ventricular hypertrophy and eventually right-sided cardiac failure
- Exacerbations
  - Are acute episodes of worsening symptoms
  - Triggered by respiratory infections due to bacteria or viruses (these may coexist), environmental pollutants, or unknown factors
  - Increased dyspnea due to increased hyperinflation and gas trapping with reduced expiratory flow; worsening of VA/Q abnormalities resulting in hypoxemia; increased airways inflammation
  - Conditions such as pneumonia, thromboembolism, and acute cardiac failure mimic or aggravate COPD exacerbations

Table 1 Key indicators for considering a diagnosis of COPD (Global Initiative for Obstructive Lung Disease, 2018)

Consider COPD and perform spirometry to confirm COPD diagnosis, if any of these indicators (especially multiple indicators) are present in an individual over 40 years.	
Dyspnea that is	Progressive over time
	Characteristically worse with exercise
	Persistent
Chronic cough	May be intermittent and may be unproductive
	Recurrent wheeze
Chronic sputum production	Any pattern of chronic sputum production
Recurrent lower respiratory tract infections	
History of risk factors	Genetics factors, congenital/developmental abnormalities
	Tobacco smoke
	Smoke from home cooking and heating fuels
	Occupational dusts, vapors, fumes, gases, and other chemicals
Family history of COPD and/or childhood factors	e.g., low birth weight, childhood respiratory infections

- Systemic features
  - Most patients with COPD have multiple comorbidities
  - Airflow limitation and hyperinflation affect cardiac function and gas exchange
  - Systemic circulation of inflammatory mediators may initiate or worsen conditions such as skeletal muscle wasting, cachexia, ischemic heart disease, heart failure, osteoporosis, normocytic anemia, diabetes, and metabolic syndrome.

For more detailed explanation of pathological changes in COPD please refer to GOLD Report, Chapter 1: Definition and Overview, https://goldcopd.org/.

Diagnosis of COPD

Investigations for COPD should be considered in patients presenting with dyspnea, chronic cough (productive or unproductive), sputum production, and/or history of exposure to risk factors (**Table 1**). It is important to note that not all patients with airflow limitation present with symptoms. Likewise, not all patients with symptoms display airflow limitations. Patients usually seek health advice because of chronic respiratory symptoms or an acute respiratory episode.

Symptoms

Symptoms in COPD can vary from day-to-day. Dyspnea is a key symptom, and is usually the major cause of disability and anxiety associated with COPD. Dyspnea may be described differently by individuals. Some patients experience wheezing and chest tightness which can also vary between days. Chronic cough is usually the first and most disregarded symptom. Coughing may start as intermittent and progress, to being present every day and throughout the day. Chronic sputum production is hard to assess as not all patients expectorate it. Fatigue, weight loss, and anorexia are common in more severe cases of COPD.

Spirometry and Other Investigations

A detailed medical history (risk factor exposures, past medical history, family history, comorbidities, etc.), physical examination, and spirometry testing are necessary in new and already diagnosed patients. Spirometry is the "gold standard" for diagnosing airflow obstruction present in COPD.

Forced expiratory volume in 1 second (FEV_1) and forced vital capacity (FVC) are important measures. COPD is confirmed by the presence of persistent airflow limitation (post-bronchodilator FEV_1/FVC ratio < 0.7).

Patients with COPD often have reductions in both FEV_1 and FVC (**Fig. 1**). Increase in FEV_1 greater than 400 mL following bronchodilator, may be suggestive of asthma, or coexisting asthma and COPD. However, degree of reversibility after administration of a short-acting bronchodilator or corticosteroids (i.e., volume of FEV_1 change or % change in FEV_1) is no longer recommended as it does not inform therapeutic decisions or differentiate an asthma diagnosis (Albert et al., 2012). If the post-bronchodilator FEV_1/FVC ratio is between 0.6 and 0.8, the result should be confirmed by repeat spirometry on a separate occasion (Schermer et al., 2016).

Two different criteria are used in practice for interpreting spirometry. The fixed cut-off ($FEV_1/FVC < 0.7$) method is relatively simple and is independent of reference values (i.e., comparisons with population values based on age, height, gender, and race). The lower limit of normal (LLN) method uses reference values for FEV_1/FVC based on the normal distribution of the healthy population; the bottom 5% is classified as abnormal. The fixed cut-off method may result in overdiagnosis of COPD in the elderly, and underdiagnosis in adults <45 years, especially in mild COPD.

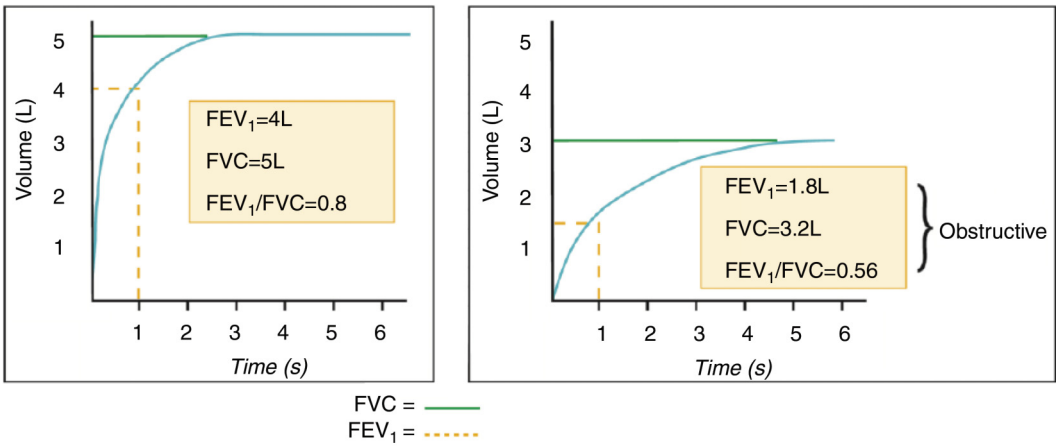

Figure 1 Normal vs. obstructive spirometry traces (Global Initiative for Obstructive Lung Disease, 2018).

Do you:	**Yes**	**No**
Have a new, persistent, or changed **cough**?		
Cough up **mucus, phlegm, or blood**?		
Get **breathless** more easily than others your age?		
Experience **chest tightness or wheeze**?		
Have frequent **chest infections**?		
Experience **chest pain, fatigue, or sudden weight loss**?		
If you answered yes to any of the above questions, your lung health could be at risk... particularly if you:		
Smoke or have ever smoked?		
Work or worked in a job that **exposed** you **to dust, gas, or fumes**?		

Figure 2 Lung Health Checklist (Lung Foundation Australia, 2018).

Correct performance of spirometry and careful interpretation of results are key to avoiding misdiagnosis. Regular calibration of the spirometer and periodical retraining in the technique and interpretation are essential for maintaining performance standards (Miller et al., 2005). Trained pharmacists can perform spirometry with acceptable repeatability based upon standards set by the American Thoracic Society/European Respiratory Society (ATS/ERS) guidelines (Miller et al., 2005).

Case-Finding

Screening spirometry in the general population is not currently recommended (Siu et al., 2016). However active case finding (i.e., spirometry testing in patients with symptoms and/or risk factors) is advocated. Community pharmacists are in an ideal position to be involved in case finding of COPD utilizing a combination of risk assessment/symptom questionnaires (e.g., Lung Health Checklist [from Lung Foundation Australia—Fig. 2], modified Medical Research Council [mMRC] questionnaire, COPD Assessment Test [CAT]) and microspirometry (Fathima et al., 2017).

It should be noted that these questionnaires identify symptoms of lung disease and not just specifically COPD. These questionnaires may also identify other respiratory conditions such as asthma, pulmonary hypertension, lung cancer, etc.; hence it is important to refer those with symptoms to a doctor/specialist for further investigation. Further investigations, including chest X-ray, hematology and biochemistry, complex lung function tests, exercise stress testing, and electrocardiography and echocardiography, may be necessary to confirm or exclude other conditions with a similar presentation to COPD (e.g., bronchiectasis, lung cancer, heart failure, and anemia).

The PiKo-6 and COPD-6 devices have been used to screen for airway obstruction (Fig. 3). These devices are good for targeted case finding to identify individuals for further investigative spirometry. Different FEV_1/FEV_6 cut-off values have been trialed in the clinical

(A) (B)

Figure 3 (A) COPD-6. (B) Piko-6.

setting. A FEV_1/FEV_6 <0.75 has been associated with an 86%–90% probability that a patient has abnormal lung function (Frith et al., 2011). It is advisable to then order spirometry to confirm the diagnosis.

Case Study 1

Let us revisit our patient, Mr. Trafalgar. The pharmacist used the Lung Health Checklist to gauge symptoms Mr. Trafalgar has been experiencing. The pharmacist also asked Mr. Trafalgar to blow into a microspirometer.

Based on the reading (FEV_1/FEV_6 = 0.69) and responses to the questionnaire (coughing, breathlessness), the pharmacist recommended that Mr. Trafalgar makes an appointment with the general practitioner (GP) to review his symptoms and lung health. The following week, the GP assessed Mr. Trafalgar's lung function by having him blow into a spirometer. His spirometry readings were:

FEV_1—pre-bronchodilator: 1.95 L (58%); post-bronchodilator: 1.98 L (59%)
FEV_1/FVC—pre-bronchodilator: 0.61; post-bronchodilator: 0.62

The GP told Mr. Trafalgar that his lungs were damaged from smoking and he had moderate COPD. The GP started Mr. Trafalgar on a once daily inhaler for his COPD, and a "when-required" inhaler for his acute SOB. The GP also asked Mr. Trafalgar to contact Quitline and the community pharmacist for some advice on quitting smoking.

Assessment of Severity

Assessment involves determining the degree of airflow limitation, impact of disease on health status, risk of future events (exacerbations, hospital admission, or death), to guide therapy. Disease severity should be regularly assessed after diagnosis to determine any necessary changes to medication regimens.

Assessment of the following areas is recommended:

- Presence and severity of airflow limitation after spirometry
- Nature and magnitude of symptoms
- Exacerbation history and future risk
- Comorbidities

Severity of Airflow Limitation

Airflow limitation can be classified into categories depending on severity (Table 2). There is weak correlation between FEV_1, symptoms and patient health status; so it is important that assessment of symptoms is undertaken in all patients.

Symptom Assessment

The mMRC (Celli et al., 2004, Mahler and Wells, 1988) dyspnea grade questionnaire is commonly used for measuring breathlessness as it predicts mortality risk and correlates well with other health status measures. It is a scale consisting of five statements describing levels of dyspnea based on the extent to which various physical activities precipitate breathlessness. Each statement corresponds to a grade; grade 0 indicates no dyspnea and grade 4 indicates severe dyspnea to the point of almost incapacity.

Other disease-specific questionnaires such as the Chronic Respiratory Questionnaire (CRQ), St George's Respiratory Questionnaire (SGRQ), COPD Assessment Test (CAT), and COPD Control Questionnaire (CCQ) are used for comprehensive symptom assessment in practice, but more in research. Details of these questionnaires are beyond the scope of this chapter.

Table 2 Classification of airflow limitation severity in COPD (based on post-bronchodilator spirometry) (Global Initiative for Obstructive Lung Disease, 2018)

In those with $FEV_1/FVC < 0.7$		
GOLD 1	Mild	$FEV_1 \geq 80\%$ predicted
GOLD 2	Moderate	$50\% \leq FEV_1 < 80\%$ predicted
GOLD 3	Severe	$30\% \leq FEV_1 < 50\%$ predicted
GOLD 4	Very severe	$FEV_1 < 30\%$ predicted

Table 3 Differences in asthma and COPD (Global Initiative for Obstructive Lung Disease, 2018)

Asthma	*COPD*
Onset early in life (often childhood)	Onset in mid-life
Symptoms vary from day-to-day	Symptoms slowly progressive
Symptoms worse at night/early morning	Long smoking history
Allergy, rhinitis, and/or eczema also present	
Family history of asthma	

Exacerbation Risk

A history of exacerbations is the best predictor of having frequent exacerbations (two or more exacerbations per year) (Hurst et al., 2010). More severe airflow limitation and higher blood eosinophil counts may also be associated with higher exacerbation rates.

Comorbidities

Patients with COPD usually present with multiple comorbidities. Having COPD may increase the risk for developing other diseases. Comorbidities such as cardiovascular disease, skeletal muscle dysfunction, metabolic syndrome, osteoporosis, depression, anxiety, and lung cancers need to be considered (may still be undiagnosed) and should be managed appropriately. Suboptimal management of comorbidities may affect mortality and hospitalizations (Global Initiative for Obstructive Lung Disease, 2018).

Combined Assessment—ABCD Assessment Tool

The GOLD recommends the use of the ABCD assessment tool (Vogelmeier et al., 2017, Global Initiative for Obstructive Lung Disease, 2018) which takes into account spirometry-based classifications, exacerbation history, patient reported symptom severity, and risk of exacerbations (CAT and mMRC) to understand the impact of COPD on an individual patient. This tool acknowledges that severity of COPD may differ between two patients despite having the same FEV_1 % predicted value.

Other Investigations

The World Health Organization recommends alpha-1 antitrypsin deficiency screening to all patients with a diagnosis of COPD (World Health Organisation, 1997). Chest X-ray, lung volumes and diffusing capacity, oximetry and arterial blood gas measurement, exercise/physical activity testing, and investigations to exclude differential diagnoses (e.g., bronchiectasis, pulmonary fibrosis, tuberculosis) may be considered during work-up of a patient.

Asthma-COPD Overlap

Both asthma and COPD are associated with chronic inflammation of the airways, which may manifest similar symptoms. However, the pathology of airflow limitation and inflammatory cells and mediators involved are different in the two conditions (**Table 3**).

There is a subset of adults with features of both asthma and COPD, which has been controversially termed asthma-COPD overlap (ACO). ACO is not a single, well-defined entity, but includes a range of airway disease phenotypes with different causal mechanisms (see https://assets.nationalasthma.org.au/resources/Asthma-COPD-overlap-info-paper-HP.pdf). It can develop in any smoker, ex-smoker, or nonsmoker, and tends to be worse in the elderly. Patients with ACO have more symptoms, more flare-ups/exacerbations of greater severity, worse quality of life, worse lung function despite lower tobacco exposure, more rapid decline in lung function, a greater need for health care use, and higher mortality rates (Reddel, 2015).

ACO should be considered in adults when they have:

- a history of asthma or have asthma-like symptoms, and
- spirometry before and after bronchodilator shows expiratory airflow limitation that is not completely reversible.

Diagnosis of ACO is based on the probability of asthma or COPD, and the presence of the clinical features of either condition. In-depth evaluation, encompassing complete medical history, physical examination, pulmonary function tests, and imaging is usually

required to diagnose correctly and properly classify patients. Blood eosinophil counts provide an estimate of airway eosinophilia (present in ACO) and testing can be performed easily in routine practice.

Management of ACO should be different in this patient group compared to patients with either condition alone. Previous research has not extensively investigated the ACO patient group specifically, so clear guidelines on the management of these patients are limited. Referral to specialist physician is usually required for definitive diagnosis and ongoing management.

Long-term inhaled corticosteroid (ICS) treatment (at the lowest effective dose) is recommended to reduce the risk of serious flare-ups, even if asthma symptoms appear to be mild or infrequent. For more details on ACO please refer to the "*Further Reading*" section.

Case Study 2

Ms. Nancy Cloti is a 51 year-old female who presents to GP with a complaint of dyspnea while doing heavy housework (e.g., vacuuming) and when climbing stairs. Twelve months ago, she was much better, but the symptoms have become progressively worse in the last 6 months. Nancy admits smoking half a packet of cigarettes per day. She had wheeziness as a child and used to get eczematous patches on her face and around her elbow. She used to use a puffer (salbutamol) when her wheeze was really bad; however, the symptoms improved when she started high school and then she stopped using the puffer. During spring, she gets hay fever for which she uses a corticosteroid nasal spray.

Her FEV_1 is 66% of predicted, FVC is 82% of predicted, and FEV_1/FVC is 0.64. When post-bronchodilator measurements were taken, the FEV_1 is 74% of predicted, FVC is 87% of predicted, and the FEV_1/FVC is 0.69.

What Assessments are Needed for Confirming ACO in Ms. Cloti?

Spirometry should be conducted to establish irreversible airflow limitation in Ms. Cloti. It is also important to evaluate Ms. Cloti for eosinophilia, as this can influence treatment choice and outcomes. Based on demographics, social/medical history and spirometry (≥35 years of age, a smoking history, potential history of asthma, post-bronchodilator FEV_1/FVC <70%; a marked response to a bronchodilator and differential eosinophil count [≥3% of total leukocytes or ≥300 cells/μL eosinophil concentration]), the GP's diagnosis is ACO. The GP refers Ms. Cloti to see a respiratory physician.

What are the Management/Treatment Options for Ms. Cloti?

Preventative measures, including lifestyle modifications should be discussed with and recommended to Ms. Cloti, along with management of symptoms using a short acting beta2-agonist inhaler. A regular ICS is prescribed for Ms. Cloti.

Ms. Cloti should be provided a written action plan (self-management plan). An asthma action plan or a COPD action plan template should be chosen, depending on her dominant clinical features.

Challenges in COPD Management and the Pharmacist's Role

Under-recognition and underdiagnosis of COPD often delay the initiation of appropriate management in many patients with COPD. Furthermore, COPD is a disease characterized by multiple comorbidities (e.g., cardiovascular diseases, osteoporosis, anxiety, depression), which also require ongoing management and monitoring of therapy. Optimal COPD management relies on choosing the right combination of pharmacological and non-pharmacological measures according to a confirmed diagnosis and severity, as well as ongoing monitoring and modifications in treatment, as required. Team efforts of various health professionals (including pharmacists), carers and patients are essential for optimal COPD management.

In the management of COPD, combination therapy has been demonstrated to be clinically beneficial and cost effective. No existing COPD medications have been shown to modify the long-term decline in lung function; medications and modifications to lifestyle can only slow the decline of disease. Reduction of therapy is not normally possible once symptom control has been achieved—it is often necessary to progressively introduce additional pharmacological and non-pharmacological treatments to cope with the deteriorating lung function in many patients. Moreover, patients often need to tailor their drug regimen depending on disease severity, respiratory tract infections and seasonal changes. Patients with COPD are likely to be on complex medication regimens comprising regular and "when required" inhaled respiratory medications and other medications, all of which are major barriers to treatment adherence. Depression, a common comorbidity in patients with COPD, is a known risk factor for nonadherence.

Pharmacists have a major role to play in all areas of COPD prevention, diagnosis, treatment, and monitoring (van der Molen et al., 2017). Some key actions and interventions pharmacists can consider at each stage of the disease include (but are not limited to) the following:

- Prevention—smoking status of patients (both with and without COPD diagnosis) should be screened, assessed, and appropriate smoking cessation therapy should be initiated or referrals made to appropriate health professionals or organizations;

- Case finding/Diagnosis—patients who have any characteristic COPD symptoms could be identified and referred to GPs for spirometry. Case-finding and spirometry programs have previously been implemented in pharmacy settings and evaluated with positive results (Castillo et al., 2009; Cawley and Warning, 2015; Fathima et al., 2017);
- Treatment—assessment of pharmacological treatment appropriateness, medication adherence, and inhaler technique should be performed on a regular basis; influenza (Arabyat et al., 2018) and pneumococcal vaccination; patient education (on the disease and proper inhaler technique); make recommendations for non-pharmacological therapies; and
- Monitoring—assessment of treatment effectiveness and proposing recommendations for subsequent changes in inhaler therapy according to disease stage and severity. When stepping up of pharmacotherapy is necessary, consider combination therapies in single inhalers and minimize the types of inhalers used. Ensure that patients have an up-to-date self-management plan with clear instructions on changes to be made in therapy when symptoms get worse.

Support Patients to Quit Smoking

Smoking cessation is the most important and cost-effective intervention to slow decline in lung function. When a smoker stops smoking, the lost lung function cannot be recovered, but the average rates of further decline will revert to that of a nonsmoker (Fletcher and Peto, 1977).

Smoking cessation advice from multiple health professionals motivates smokers to have quit attempts, which in turn increase long-term abstinence rates. Hospital admission provides an ideal opportunity to initiate smoking cessation as the smoker is in a setting where there are smoking restrictions, absence of usual environmental cues, and most likely in a state of perceived vulnerability and hence more receptive to advice and cessation interventions. However, motivation and post-discharge support are critical for achieving long-term abstinence. A comprehensive approach to supporting smoking cessation involves behavioral support and pharmacological treatment of nicotine dependence. The 5-As framework (Clinical Practice Guideline Treating Tobacco Use and Dependence 2008 Update Panel, Liaisons, and Staff, 2008) is recommended to aid in providing support to smokers:

- **Ask** and identify smokers at every health care visit;
- **Assess** nicotine dependence and the motivation to quit;
- **Advise** about the risks of smoking and benefits of quitting;
- **Assist** cessation; and
- **Arrange** follow-up contact with smoker

First line treatments for nicotine dependence include nicotine replacement therapy (NRT), varenicline, and bupropion. The most effective forms of pharmacotherapy are either combination NRT (e.g., a patch combined with a rapid-acting form of NRT such as mouth spray) or varenicline. Longer courses of treatment (>12 weeks) may reduce relapse.

Advice on quitting should be clear and unambiguous, and provided in a supportive and nonconfrontational manner. Even a brief assessment, as little as three minutes, along with advice to quit has been shown to measurably effect quit rates. Relapse following a quit attempt is very common among smokers, and should not be considered as failure of the health professional or patient. Health professional follow up, either face-to-face or via telephone, has been shown to increase the likelihood of long-term smoking abstinence.

Mr. Trafalgar (Case study 1) should be actively supported by the pharmacist to quit smoking, given that he still smokes 10 cigarettes per day. The pharmacist can recommend OTC NRT (e.g., patch) along with behavioral support. Elements of motivational interviewing can be employed when counseling Mr. Trafalgar on smoking cessation. If Mr. Trafalgar is interested, he should be referred to the GP for initiation of a prescription medication (e.g., NRT patch, varenicline, or bupropion). Referral could also be made to support groups for smokers interested in quitting (e.g., Quitline). Whatever recommendation that is made, the GP should follow-up with Mr. Trafalgar to evaluate his progress.

Non-Pharmacological Therapy

Advice on non-pharmacological strategies should be considered along with pharmacological therapies.

Pulmonary Rehabilitation

There is strong evidence for the benefits of pulmonary rehabilitation that involves supervised (usually by a physiotherapist) exercise training alone or in conjunction with patient education or other non-pharmacological interventions (e.g., behavior change, nutritional intervention, and psychosocial support) (Spruit et al., 2013). Programs can be delivered in hospital outpatient departments or in the community setting.

Benefits are evident not only in those with stable COPD but also following an acute exacerbation of COPD. However, research shows that only a small proportion of patients who would benefit from pulmonary rehabilitation actually access these programs. Pharmacists can facilitate in making patients become aware of pulmonary rehabilitation programs and assist in the referral process.

In the absence of specialist exercise professional (e.g., physiotherapist or exercise physiologist) consultation, individuals with COPD should be encouraged to be physically active as inactivity is associated with increased mortality and exacerbations. Some support groups provide opportunities for patients with COPD to perform group exercise activities, after completion of a rehabilitation program.

Mr. Trafalgar (Case study 1) will benefit from pulmonary rehabilitation. He may be referred to a hospital-based program for at least six weeks and then continue exercising at home. Joining a support group, where Trafalgar is likely to meet other people with the same condition and take part in group exercise programs, will ensure that he continues to have regular physical activity, in turn achieving better quality of life.

Pharmacological Therapy

Pharmacological therapies aim to reduce symptoms, prevent exacerbations, and improve health status, by targeting the pathophysiology of COPD (Global Initiative for Obstructive Lung Disease, 2018). Medications can only slow disease progression and manage symptoms; they do not modify long-term decline in lung function. The choice of agent within each therapeutic class depends on availability, cost, clinical response, and side-effect profile.

Inhalation route is primarily used for delivery of medications directly to the lungs. It is common for patients to have issues with inhaler technique, with studies reporting operating errors in 50%–100% of patients. Poor technique may lead to worse outcomes and symptom control in patients with COPD. Moreover, inhaler device polypharmacy is an increasing problem, and with the introduction of many new combinations of medications and inhaler devices onto the market, there are greater chances for errors in their use. The array of agents available as monotherapy and combination therapy, may cause confusion in both patients and prescribers, resulting in duplication of therapy and increased adverse effects.

Key considerations when choosing an inhaler device include cost, access, inspiratory flow rate required for the device, patient dexterity and preference. With any inhaler prescription, education and training in the proper use of devices is imperative. Available inhalation devices are numerous and include: nebulizers, metered-dose inhalers (MDIs) with or without spacers, soft-mist inhalers, and breath-actuated devices (e.g., breath-actuated MDIs and single/multidose dry powder inhalers [DPIs]). Inhaler technique should be regularly assessed while on long-term therapy, and considered when presented with signs of treatment failure. Pharmacists play crucial roles in ensuring optimal inhaler technique education on initial and subsequent supply to patients. Resources, including demonstration videos and checklists for assessment of inhaler technique are available from asthma/lung foundations and thoracic societies.

Note: The GOLD guidelines provide detailed explanations of each drug class and recommendations for initiation and subsequent drug therapy (and have been used for the preparation of this chapter) (**Table 4**), however specific guidelines/formularies are available for COPD management in many countries.

Bronchodilators

Bronchodilators are used to increase FEV_1. They act by altering airway smooth muscle tone, widening the airways to improve symptoms and exercise capacity. Short-acting bronchodilators (i.e., beta 2-agonists or muscarinic antagonists) are used on a "when required" basis for short term symptom relief. Cardiac rhythm disturbances and tremor may occur with high doses in susceptible patients. Long-acting bronchodilators are usually given on a regular basis to prevent or reduce symptoms. Combining bronchodilators of different classes may improve efficacy, without the associated side effects from increasing the dose of a single bronchodilator too high.

Beta-2 Agonists

Beta2-agonists relax airway smooth muscle by stimulating beta2-adrenergic receptors, which increases cyclic AMP and antagonizes mechanisms of bronchoconstriction. There are short-acting beta2-agonists (SABA) and long-acting beta2-agonists (LABA). SABAs improve FEV_1 and symptoms; doses usually last 4–6 hours. LABAs can last for 12 hours or more and do not preclude additional benefit from "when required" SABA dosing. Twice daily LABAs (formoterol and salmeterol) and once daily LABAs (indacaterol, olodaterol, and vilanterol) can improve dyspnea, health status, and reduce exacerbation rate. Some patients may experience cough following indacaterol inhalation.

Muscarinic Antagonists

Muscarinic receptor antagonists relax smooth muscle by blocking M3 muscarinic receptors expressed in airways smooth muscle that cause bronchoconstriction. There are short-acting muscarinic antagonists (SAMAs) and long-acting muscarinic antagonists (LAMAs). SAMAs include ipratropium and oxitropium. LAMAs can be administered once daily (tiotropium and umeclidinium), or twice daily (aclidinium and glycopyrronium). LAMA treatments have been shown to improve symptoms, health status, effectiveness of pulmonary rehabilitation, reduce exacerbations and related hospitalizations.

Inhaled antimuscarinic drugs have poor systemic absorption—wide dose ranges have been safely used across various clinical settings, with the main side effect being dry mouth. Some patients using ipratropium report a bitter, metallic taste. Nebulizer treatments may cause acute glaucoma due to contact with the eyes; hence eye protection is recommended.

Table 4 Commonly used medications in COPD

Generic	*Brand*	*Form*	*Usual dosage*
Bronchodilators			
Long-Acting Beta$_2$-Agonists (LABAs)			
Arformoterol	Brovana	soln	Adults: Inhale 15 μg twice daily (AM & PM) by nebulization (max: 30 μg/day). Use standard jet nebulizer with air compressor (see literature). Children: Not recommended.
Formoterol	Perforomist	soln	Adults: One 20 μg vial twice daily (AM & PM) by oral inhalation via nebulizer (max: 40 μg/day). Children: Not recommended.
Indacaterol	Arcapta Neohaler	caps	Adults: 1 inh of one 75 μg caps once daily, using Neohaler device. Do not swallow caps. Children: Not recommended.
Olodaterol	Striverdi Respimat	MDI	Adults: 2 inh daily; max 2 inh/day. Children: Not established.
Salmeterol	Serevent Diskus	DPI	Adults: 1 inh (50 μg) twice daily (AM & PM) every 12 hrs. Children: Not recommended.
Short-Acting Anticholinergics			
Ipratropium bromide		soln	Adults: 500 μg by oral nebulization 3–4 times daily every 6–8 hrs. Children: Not recommended.
	Atrovent HFA	MDI	Adults: 2 inh 4 times daily (max: 12 actuations/day (408 mcg/day). Children: Not recommended.
Long-Acting Anticholinergics			
Aclidinium bromide	Tudorza Pressair	DPI	Adults: 1 inh (400 μg) twice daily. Children: Not established.
Glycopyrrolate	Seebri Neohaler	caps	Adults: 1 oral inhalation of one 15.6 μg caps twice daily (AM & PM). Do not swallow caps. Children: Not established.
Tiotropium bromide	Spiriva HandiHaler	caps	Adults: 2 oral inhalations of one 18 μg caps once daily, using HandiHaler device. Do not swallow caps. Children: Not recommended.
Umeclidinium	Incruse Ellipta	DPI	Adults: 1 inhalation every 24 hrs. Children: Not established.
Anticholinergic + Beta$_2$-Agonist			
Ipratropium bromide + albuterol		soln	≥18 yrs: 1 vial (3 mL) 4–6 times daily via nebulizer. <18 yrs: Not recommended.
	Combivent Respimat	MDI	Adults: 1 inh 4 times daily (max: 6 inh/day). Children: Not recommended.
Anticholinergic + Long-Acting Beta$_2$-Agonist (LABA)			
Glycopyrrolate + formoterol	Bevespi Aerosphere	MDI	Adults: 2 inh twice daily (in the AM + PM) (max: 2 inh twice daily). Children: Not established.
Glycopyrrolate + indacaterol	Utibron Neohaler	caps	Adults: 1 oral inhalation of one 27.5 μg/15.6 μg caps twice daily (AM & PM), using Neohaler device. Do not swallow caps. Children: Not established.
Tiotropium + olodaterol	Stiolto Respimat	MDI	Adults: 2 inh once daily (max: 2 inh/day). Children: Not established.
Umeclidinium + vilanterol	Anoro Ellipta	DPI	Adults: 1 inh once daily. Children: Not established.
Corticosteroids			
Corticosteroid + Long-Acting Beta$_2$-Agonist (LABA)			
Budesonide + formoterol	Symbicort 160/4.5	MDI	Adults: 2 inh of 160/4.5 μg twice daily. Children: Not indicated.
Fluticasone + salmeterol	Advair 250/50 Diskus	DPI	Adults: 1 inh of 250/50 μg twice daily. Children: Not recommended.
Fluticasone + vilanterol	Breo Ellipta	DPI	Adults: 1 inh of 100/25 μg once daily (max). Children: ≤17 yrs: Not established.
Corticosteroid + Anticholinergic + Long-Acting Beta$_2$-Agonist (LABA)			
Fluticasone + umeclidinium + vilanterol	Trelegy Ellipta	DPI	Adults: 1 inh once daily (max). Children: Not established.
Other			
PDE4-Inhibitor			
Roflumilast	Daliresp	tabs	Adults: One 500 μg tab once daily. Children: Not recommended.

Global Strategy for the Diagnosis, Management, and Prevention of Chronic Obstructive Pulmonary Disease; Lung Foundation Australia, 2018. Lung Health Checklist.)

Methylxanthines

The exact mechanism and duration of action of xanthine derivatives is not well established. They may act as nonselective phosphodiesterase inhibitors but other non-bronchodilator actions have also been reported. Theophylline is the most commonly used methylxanthine, but not as first line. Theophylline has a narrow therapeutic index, and is beneficial only at near-toxic doses—this poses a great risk as clearance of the drug declines with age, and many physiological variables and drugs/diet/social habits affect theophylline metabolism (significant interactions with many common medications, smoking and caffeine consumption). Extensive monitoring is required to avoid toxicity when methylxanthines are prescribed.

Antiinflammatory Agents

Inhaled Corticosteroids

Combination of ICS and LABA is more effective at improving lung function, health status, and reducing exacerbations in moderate-very severe COPD than monotherapy. ICS use is associated with pneumonia, oral candidiasis (oral thrush), voice hoarseness, and bruising of the skin. Smoking, age ≥55 years, history of exacerbation or pneumonia, body mass index $<25 kg/m^2$, low mMRC dyspnea grade, and/or severe airflow limitation, are risk factors in developing pneumonia while on ICS therapy.

Oral Glucocorticoids

Long-term oral glucocorticoid therapy is associated with many side effects without evidence of benefits in stable COPD. Side effects such as steroid myopathy contribute to muscle weakness, reduced functionality, and respiratory failure are important considerations before initiating long-term oral glucocorticoid therapy. However, in acute COPD exacerbation, oral glucocorticoid therapy has been shown to reduce treatment failure and rate of relapse, and improve lung function and breathlessness. Prednisolone is commonly used in the management of COPD exacerbations.

Phosphodiesterase-4 (PDE-4) Inhibitors

PDE-4 inhibitors primarily reduce inflammation by inhibiting the breakdown of intracellular cyclic AMP. Roflumilast is a once daily oral PDE-4 inhibitor which may improve lung function and reduce exacerbations when used alone or with LABA/ICS combinations, in severe to very severe COPD. Common side effects include diarrhea, nausea, reduced appetite, weight loss, abdominal pain, sleep disturbance, and headache. Adverse effects usually occur early in treatment, but are reversible, and diminish over time with continued treatment. Roflumilast should be used with caution in underweight patients and those with depression.

Antibiotics

COPD exacerbations with signs and symptoms of infection benefit from antibiotics. First-line agents include oral amoxicillin or doxycycline for five days. In patients requiring admission to hospital or when pneumonia is suspected, a chest X-ray should be performed and pneumonia treatment should be initiated according to local treatment guidelines. Long-term azithromycin (250 mg/day or 500 mg three times per week) or erythromycin (500 mg two times per day) therapy over one year may reduce exacerbations. Bacterial resistance and hearing impairments have been reported with azithromycin treatment.

Mucolytics and Antioxidant Agents

Mucolytics such as N-acetylcysteine (NAC), ambroxol, sobrerol, and carbocysteine may reduce sputum viscosity, and have antioxidant, antiinflammatory, or antibacterial activity. Regular use of NAC and carbocysteine may reduce the risk of exacerbations in certain patient groups. A high dose (≥1200 mg/day) of NAC should be considered as an effective therapy for reducing exacerbations (Cazzola et al., 2015). In patients with chronic bronchitis but without airflow limitation, a dose of 600 mg/day leads to reduced exacerbations (Cazzola et al., 2015).

Other Antiinflammatory Agents

Some observational studies suggest that statins (e.g., simvastatin) may have positive effects on some outcomes in patients with COPD who receive them for cardiovascular and metabolic indications. Immunoregulators, nedocromil, and leukotriene modifiers, anti-TNF-alpha antibody (infliximab), and vitamin D supplementation have been trialed, however their place in COPD therapy is unclear.

Combination Inhaler Therapy

Combination Bronchodilator Therapy

Combinations of SABA and SAMA are superior compared to either medication alone at improving FEV_1 and symptoms. LAMA/LABA combinations increase FEV_1, improve symptoms, and reduce exacerbations compared to monotherapy or ICS/LABA combinations.

Triple Therapy

The use of an ICS/LABA inhaler together with a LAMA inhaler remains an option for patients with moderate to severe COPD who require additional treatment. Triple therapy (ICS/LAMA/LABA) improves lung function, symptoms and health status, and reduces

exacerbations compared to ICS/LABA or LAMA monotherapy. For the initiation of triple therapy (LABA/LAMA/ICS) the patient must have a post-bronchodilator FEV_1 <50% predicted prior to therapy, a history of frequent exacerbations (two or more) with significant symptoms despite regular bronchodilator therapy with a LAMA/LABA or an ICS/LABA or the patient must have been stabilized on a combination of a LAMA, LABA, and an ICS for COPD.

Pharmacological Treatment Algorithm

The ABCD grading systems allows the clinician to determine initiation of therapies and subsequent escalation/de-escalation regimens (more details are available in the GOLD strategy document—https://goldcopd.org/).

Briefly, the recommendations for pharmacological regimes of patients in each group are as follows:

Group A

- should be initiated on a short or long-acting bronchodilator based on response on breathlessness
- should be continued if breathlessness is controlled

Group B

- should be initiated on a LABA or LAMA (dependent on patient's self-reported symptom relief)—if symptoms persist, combine LABA and LAMA
  - if addition of additional bronchodilator does not relieve symptoms, can revert to single bronchodilator again
- if patient has severe breathlessness, initial therapy using dual bronchodilators can be considered
- investigate comorbidities that may be contributing to symptoms

Group C

- should be initiated on a long acting bronchodilator—LAMA is recommended over LABA
- if persistent exacerbations occur, step-up to LABA/LAMA combination or LABA/ICS combination
  - consider risk of pneumonia with ICS introduction, step up to LABA/LAMA combination is preferred for this reason

Group D

- Preferred initial therapy is LABA/LAMA
  - LABA/ICS combination is associated with higher risk of pneumonia, however ICS may be beneficial in ACO patients
- **If further exacerbations develop while on LABA/LAMA:**
  - Escalate to triple therapy (LABA/LAMA/ICS) or
  - Switch to LABA/ICS
- **If further exacerbations develop while on triple therapy, consider the following:**
  - Add roflumilast (if FEV_1 < 50% predicted, has chronic bronchitis and experienced at least one hospitalization in previous year)
  - Add macrolide—best evidence for azithromycin
  - Stop ICS

Vaccination

Influenza vaccination is recommended for all patients with COPD as it reduces exacerbations, serious illness, and death in patients with COPD. Adverse effects are mild, localized, and transient. Community pharmacists are trained and can offer vaccination in many countries.

Pneumococcal vaccinations, PCV13 and PPSV23, are recommended for all patients >65 years. The PPSV23 is also recommended for younger COPD patients with significant comorbid conditions including chronic heart or lung disease. Pneumococcal immunization has additive beneficial effect on COPD exacerbations, when added to annual influenza immunization.

It is important to commence Mr. Trafalgar (Case study 1) on one or more long-acting bronchodilators (depending on symptoms and response). He should also be recommended influenza and pneumococcal vaccination.

COPD Self-Management and Action Plans

Self-management interventions in COPD are defined as *"structured but personalised and often multi-component, with goals of motivation, engaging and supporting the patients to positively adapt their health behaviour(s) and develop skills to better manage their disease"* (Effing

et al., 2016). Education and supportive interventions are provided by health care professionals with the aim of increasing patients' skills and confidence in managing their own health problems. Programs are not limited to emotional support, problem solving, and decision-making, but also include development of therapeutic partnerships, goal setting, and action planning. A multidisciplinary team is usually in-charge of the delivery of such programs; the doctor, specialist physician, respiratory and primary care nurses, physiotherapists, psychologists, nutritionists, occupational therapists, social workers, and pharmacists are professionals commonly involved in the care of patients with COPD.

COPD action plans are recommended as part of self-management. They provide agreed instructions (between the clinician and patient) on action required when experiencing symptoms of an exacerbation. COPD exacerbation action plans that are prescribed and delivered within a single short educational program, with ongoing support surrounding use of the action plan, reduce in-hospital health care use and increase the initiation of corticosteroids and antibiotics for exacerbation episodes. Templates for COPD actions plans are available; an example from the Lung Foundation Australia is available here: https://lungfoundation.com.au/health-professionals/clinical-resources/copd/copd-action-plan/.

Self-management interventions, which include written negotiated actions plans between the patient and health care professional for worsening symptoms, may reduce risk of respiratory-related and all-cause hospitalizations, and may improve health status.

COPD Exacerbations—Prevention and Management

COPD exacerbations are episodes of acute worsening of symptoms that result in additional therapy. It is usually associated with increased airway inflammation, increased mucous production, and significant gas trapping, which ultimately results in increased dyspnea, cough, and sputum. A history of exacerbations is the best predictor of future exacerbations.

Triggers for exacerbations include:

- Viral (most common is human rhinovirus) or bacterial respiratory infection
- Exposure to fine particulate matter
- Left ventricular failure
- Psychosocial stressors, and
- Environmental factors (e.g., air pollution, ambient temperature)

COPD exacerbations can be classified based on severity:

- Mild (treated with short acting bronchodilators only)
- Moderate (treated with short acting bronchodilators and/or oral corticosteroids), or
- Severe (require hospitalization/emergency departments visits, may be associated with acute respiratory failure)

Exacerbation episodes usually last 7–10 days. Exacerbations contribute to disease progression, especially if recovery from these episodes is slow. Early recognition and management of exacerbations improve recovery and quality of life, reduce hospitalization and may prevent progressive functional deterioration. Educating patients on signs and symptoms of a COPD exacerbation is important. A COPD action plan may help patients and carers to recognize and respond to early signs of exacerbations and prevent unnecessary hospitalization.

The main aims of COPD exacerbation treatment are to reduce the negative impact of the current exacerbation episode and to prevent subsequent events. Exacerbations can be managed in the outpatient setting or in hospitals, depending on severity. Majority of exacerbations are managed in the outpatient setting with pharmacological therapies. Indicators for hospitalizing patients with exacerbation include insufficient home support, other serious comorbidities (especially cardiac related issues), onset of new physical signs (e.g., cyanosis, peripheral edema, acute respiratory failure), severe symptoms (e.g., increased respiratory rates, decreased oxygen saturation, confusion, drowsiness, sudden worsening of resting dyspnea), and initial treatment failure.

Upon presentation to hospital, patients are assessed to determine if the exacerbation is life threatening and if noninvasive ventilation is required to help breathing. Hospitalized patients can be classified, depending on clinical signs, into: (1) no respiratory failure; (2) acute respiratory failure—nonlife threatening; and (3) acute respiratory failure—life threatening.

Supplemental oxygen is administered and noninvasive ventilation is considered if necessary. Initiation of bronchodilator therapy, oral corticosteroids, and antibiotic therapy (if there are signs of bacterial infection such as purulent sputum or fever) is considered. Fluid balance monitoring, venous thromboembolism prophylaxis, and treatment of comorbidities are important.

Pharmacological Treatment of Exacerbation

Bronchodilators

SABAs, with or without short-acting anticholinergics, are recommended as initial bronchodilators in treating an acute exacerbation. Nebulizers are commonly used to deliver agents, despite no significant difference compared to MDI with or without spacer, when treating inpatients. Inhaled long-acting bronchodilators, regardless of ICS therapy, should be used during exacerbation episodes.

Glucocorticoids

Short courses (no longer than five to seven days) of systemic corticosteroids can improve lung function (FEV_1), shorten recovery time and length of hospitalization. Prednisolone 40 mg daily for five days is usually recommended. If oral route cannot be used, intravenous methylprednisolone 0.5 mg/kg/6 hrs may be given.

Antibiotics

Antibiotics may be used in patients who show signs of bacterial infection (e.g., sputum purulence), although the evidence behind the use of antiinfectives in exacerbations is still unclear. Short courses (no longer than five to seven days) of antibiotics may shorten recovery time, reduce early relapse, treatment failure, and hospitalization duration. The antibiotic to be prescribed depends on local guidelines/formulary restrictions, but initial empirical treatment usually involves an aminopenicillin with clavulanic acid, macrolide, or tetracycline.

Other Adjunct Therapy

Use of diuretics (for fluid balance), anticoagulant treatment (for other comorbidities), nutritional considerations, smoking cessation support, and deep vein thrombosis prophylaxis should be considered in all hospitalized patients.

Respiratory Support

Oxygen is imperative in patients to improve hypoxemia; the target oxygen saturation is 88%–92%. Administration of oxygen is via nasal cannula at a rate of 0.5–2 L/min (Yang et al., 2017). Arterial blood gases should be monitored. Noninvasive (nasal or facial mask) or invasive (orotracheal tube or tracheostomy) ventilation are instigated to manage acute respiratory failure.

Hospital Discharge and Follow-up

Although, evidence behind formalized care programs posthospital discharge is insufficient, it is good practice to focus on areas such as education, optimization of medication, inhaler technique corrections, optimizing comorbidity management, smoking cessation, early rehabilitation, telemonitoring, and continued patient contact to improve outcomes. Follow-up with patients after discharge is important to review progress. Pharmacists can play a major role in ensuring liaison with primary care professionals with regard to pharmacological treatments and smooth transition from acute care to chronic community-based care.

Advanced Stages of COPD

Long-term continuous oxygen therapy (ideally at least 18 hours a day) may be appropriate for patients who meet criterion for blood gas levels (Yang et al., 2017). Extensive assessment of suitability for oxygen is performed before initiating therapy. Surgical interventions such as bullectomy and lung transplantation are options in advanced stages.

Patients with advanced COPD experience many distressing symptoms including breathlessness, fatigue, depression, anxiety, and insomnia. Palliative care is aimed at improving the quality of life of patients and their families when facing life-threatening illness, by preventing and relieving suffering through controlling symptoms and addressing physical, psychosocial, and spiritual issues. Early access to and discussions about palliative care is recommended for patients with COPD and persisting symptoms.

Nomenclature

ACO asthma COPD overlap
DALY disability adjusted life years
FEV_1 forced expiratory volume in 1 second; the volume of air exhaled during the first second of the forced expiratory maneuver
FEV_6 forced expiratory volume in 6 seconds; the volume of air exhaled during the first six second of the forced expiratory maneuver
FVC forced vital capacity; the volume of air forcibly exhaled from the point of maximal inspiration
FEV_1/FEV_6 forced expiratory volume in 1 second/forced expiratory volume in 6 seconds
FEV_1/FVC forced expiratory volume in 1 second/forced vital capacity
GOLD Global Initiative for Chronic Obstructive Lung Disease
GP general practitioner
ICS inhaled corticosteroid
LABA long acting beta2 agonist
LAMA long acting muscarinic antagonist
OTC over-the-counter
SABA short acting beta2 agonist
SAMA short acting muscarinic antagonist
SOB shortness of breath

Glossary

Dyspnea Breathlessness; shortness of breath; patients typically describe dyspnea as a sense of increased effort to breathe, chest heaviness, air hunger, or gasping.
Exacerbation of COPD An event in the natural course of the disease characterized by a change in the patient's baseline dyspnea, cough, and/or sputum and beyond normal day-to-day variations, that is acute in onset and may warrant a change in regular medication in a patient with underlying COPD.
Forced expiratory volume in 1 second This is the volume of air expelled in the first second of maximal forced expiration from a position of full inspiration.
Forced vital capacity This is the volume of air expelled by a forced maximal expiration from a position of full inspiration. It is usually 3–6 liters, varying with age, gender, and height. In normal subjects the fraction of the FVC which can be expelled in 1 second is >80% of the predicted value.
Rehabilitation A branch of medicine that aims to enhance and restore functional ability.
Spirometry A common test used to assess how well someone's lungs work by measuring how much air they can inhale, how much they can exhale, and how quickly they can exhale. It can measure how effectively air can be moved in and out of the lungs.

Management of Respiratory Disorders and the Pharmacist's Role: Cough, Colds, and Sore Throats and Allergies (Including Eyes)

Jack Charles Collins, Rebekah Jane Moles, The University of Sydney School of Pharmacy, The University of Sydney, Camperdown, NSW, Australia

Background

Complaints relating to the upper airways are arguably one of the most common reasons for presentation to community pharmacies and other primary care providers, and contribute to a substantial loss of productivity and absence from work and school (Deckx et al., 2016; Sclar et al., 1996). The common cold, influenza, and allergies affect a large proportion of the population every year. Infections of the upper respiratory tract (URTI) show a seasonal trend, with cases peaking in the winter months. Allergies may be either seasonal or perennial depending on allergen sensitivity. It is necessary to elicit a sufficient history from patients to reach a differential diagnosis and manage symptoms appropriately (May and Dolen, 2017).

The respiratory tract serves the vital functions of bringing oxygen into the body for distribution throughout the body via the vascular system and expelling toxic carbon dioxide. The respiratory tract is divided into two sections: the upper and lower respiratory

tract. The upper airways, also referred to as the upper respiratory tract, consist of the nose, the nasal passages, the paranasal sinuses, the pharynx (throat), and the larynx (voice box). The lower airways consist of the trachea, bronchi, and lungs. The purpose of the upper airways is to take in, filter, and humidify the air, as well as expel carbon dioxide during respiration.

Common Cold, Influenza, Sore Throats, and Cough

The Common Cold

The common cold is the most common infection of the upper respiratory tract. The common cold is caused by over 200 virus strains, which are predominantly rhinoviruses, but also human coronaviruses and adenoviruses (Heikkinen and Järvinen, 2003; Mäkelä et al., 1998). A successful vaccine for the common cold has not yet been developed (Heikkinen and Järvinen, 2003). The common cold primarily affects the nose, pharynx, and sinuses, presenting symptoms often include a blocked or runny nose, fever, headaches, coughing, a sore throat, and sneezing. The common cold is transmitted through air droplets from infected individuals, which are then breathed in or, more commonly, enter the body through the eyes or mouth via the hands after coming into contact with a contaminated surface (Arroll and Kenealy, 2018). Unlike influenza, there is no antiviral therapy available to eradicate the causative virus (Jefferson and Tyrrell, 2001). The common cold is usually mild and self-limiting in nature with an average duration of 7–10 days (Arroll and Kenealy, 2018). The virus penetrates the tissues of the airways, resulting in local inflammation which presents as nasal discharge, sneezing, sore throat, and cough. Children experience between 5 and 7 colds each year, and adults have 2–4 infections each year. Infections may be more severe in the young or elderly or those who are immunocompromised (Arroll and Kenealy, 2018).

Influenza

Unlike the common cold, influenza, colloquially referred to as "the flu," is a more serious infection that tends to present with an abrupt onset of symptoms and may include systemic symptoms that are not restricted to the upper airways such as lethargy, diarrhea, nausea, and muscular aches. There are a number of strains of the influenza virus, and those known to infect humans are broadly divided into Type A, Type B, and Type C influenza. The influenza virus is transmitted similarly to the common cold, via air droplets from infected individuals (Radojicic, 2018). Individuals will often say that they are experiencing influenza when they are presenting with the common cold, it is important for pharmacists to differentiate between the two and educate patients on the difference. Although seasonal influenza infection may prove fatal to the young or elderly or those who are immunocompromised, epidemic strains such as the recent "swine flu" A/H1N1 strain also have the potential to kill otherwise fit and healthy individuals (Donaldson et al., 2009). Unlike the common cold, influenza can be treated with antiviral therapy such as the neuraminidase inhibitors oseltamivir and zanamivir, which stop the virus from replicating (Jefferson et al., 2006b). Seasonal attenuated live influenza vaccines are produced annually and are recommended as routine vaccinations for certain populations such as those who are immunocompromised and pregnant women (Radojicic, 2018). Pharmacists may be able to administer these vaccines in certain jurisdictions. It is worthy to note that these vaccines are produced using chicken eggs, and people with a known allergy to eggs should not receive the vaccine (Radojicic, 2018).

Pharmacological Management

Pharmacological management of upper respiratory tract infections in the community pharmacy consists primarily of symptomatic relief for the presenting symptoms. Choice of product should be based on patient preference, presenting symptoms, and clinical considerations such as contraindications and potential drug–drug interactions.

Cough

In patients presenting with an upper respiratory tract infection, coughs can be classified as productive (chesty) or nonproductive (dry). Nonproductive coughs may be the result of increased throat irritation due to sensitization from the virus, whereas productive cough results from increased mucosal secretions (Fuller and Jackson, 1990). Opioid derivatives are commonly sold as cough suppressants (antitussives) to suppress the cough reflux from the medulla in the brain stem to provide relief from frequent coughing. Common drugs include dextromethorphan, pholcodine, dihydrocodeine, and codeine. These may be sold as syrups, medicated lozenges, or as tablets or capsules. There is limited quality evidence for the benefit of these agents (Smith et al., 2014); however, consumer demand for these products may be high. Caution should be taken with preparations that may cause drowsiness such as codeine and dihydrocodeine. Dextromethorphan has been implicated in serotonin toxicity and should not be given to patients taking other drugs known to contribute to serotonin toxicity. Patients presenting with a nonproductive cough who are known to have asthma should not be supplied cough suppressants as these may contribute to respiratory depression or mask signs and symptoms of asthma flareups. Narcotic cough suppressants may be subject to misuse and abuse and this must be considered when supplying. In order to combat misuse and abuse, some formulations contain laxatives such as sorbitol to discourage consumption of supratherapeutic doses.

Productive coughs present as a cough where mucus is expectorated when coughing. Drugs licensed for the management of productive coughs fall into two categories: expectorants (protussives) and mucolytics. Like antitussives, these drugs come as syrups, medicated lozenges, and tablets or capsules. Expectorants, such as guaifenesin, stimulate the secretion of mucus in the airways and

reduce adhesion to improve the efficacy of coughing in clearing mucus. Mucolytics, for example, bromhexine, act to thin the mucus to facilitate easier clearance. Mucolytics and expectorants are sometimes sold in combination products to provide a synergistic effect in aiding cough management. Similar to antitussives, quality evidence for the clinical efficacy of expectorants and mucolytics is limited (Rubin, 2007; Smith et al., 2014).

In 2008, the United States Food and Drug Administration advised that cold and flu products should be avoided in children under 2 years of age due to the risk of serious adverse effects. Following this announcement, manufacturers in the United States changed the packaging of cold and flu products to state they should not be used in children under 4 years of age (Fashner et al., 2012; U. S. Food and Drug Administration, 2018). In response to this withdrawal from market, products containing complementary medicines such as ivy leaf (Hedera helix) have entered the market as a treatment option in children. Although individual studies suggest some efficacy of these preparations, quality data from randomized controlled trials are lacking (Holzinger and Chenot, 2011).

A nonmedicated alternative for cough syrups is demulcents such as simple syrup or honey. These ingredients are included in many cough syrups and are thought to be responsible for some of the reported symptom relief from the use of these syrups. It has been proposed that these may increase salivation and the secretion of pulmonary mucus (Eccles, 2002; Fuller and Jackson, 1990). These are safe to use in children and other populations where medicated syrups or lozenges are contraindicated.

Sore Throat

Sore throats manifest during an infection with the common cold or influenza due to an increase in inflammation in the throat. Sore throats may be either viral or bacterial in nature, with the vast majority (up to 90%) of cases caused by a virus. Sore throats attributed to a bacterial infection are most often caused by *Streptococcus pyogenes*, resulting in the term "strep throat." Pustules on the throat and tonsils do not necessarily indicate a bacterial infection, and the causative organism of a sore throat can only be determined through culturing a throat swab and considering associated symptoms. Sore throat lozenges, gargles, and sprays may contain a combination of antiinflammatory agents (such as flurbiprofen and benzydamine hydrochloride), antiseptic agents (such as dichlorobenzyl alcohol), and local anesthetics (such as lidocaine). Povidone-iodine throat gargles are also used with the notion that the use of these gargles reduces viral load in the throat (Satomura et al., 2005) as povidone–iodine has been shown to exert antibacterial, antifungal, and antiviral activity. In addition to throat-specific products, patients experiencing a sore throat may also benefit from simple analgesia such as acetaminophen (paracetamol) or ibuprofen. Regular dosing of simple analgesia has been shown to improve sore throat symptoms for patients (Schachtel et al., 1988).

Pain and Fever

Pain and fever are common symptoms during an infection with the common cold or influenza as the body's immune system responds to the invading virus. Simple analgesics such as acetaminophen (paracetamol) or ibuprofen also exert antipyretic effects and can be used to manage both pain and fever. Nonsteroidal antiinflammatory drugs (NSAIDs) have been shown to be effective in improving pain symptoms associated with the common cold (Kim et al., 2015). Aspirin should not be used in children as there is an increased risk of Reye's syndrome, and caution may be required with the use of the ibuprofen and other NSAIDs in patients with asthma, hypertension, electrolyte disturbances, and renal impairment. Fever in children is of particular concern to parents and may be managed overaggressively (Crocetti et al., 2001), the pharmacist has a role to educate parents on fever and reduce "fever phobia." Routine monitoring of body temperature is not necessary in uncomplicated cases of upper respiratory tract infections.

Nasal Congestion

As mucous production increases in the nose and sinus cavities, patients may experience a blocked nose, which results in difficulty breathing through the nose and discomfort. Patients may also describe thick, purulent discharge from the nose. Sympathomimetics are most commonly used for blocked noses and may be systemic (oral) or topical (as a nasal spray or drops). Sympathomimetics used in these preparations include pseudoephedrine, phenylephrine, and oxymetazoline. Although the quality of the evidence available is poor, decongestants may improve the subjective measures of symptoms. There is insufficient evidence to suggest whether systemic or topical agents provide superior relief (Deckx et al., 2016). Topical preparations of sympathomimetics should not be used for more than three-to-five consecutive days due to the risk of "rebound congestion" (rhinitis medicamentosa), this does not seem to occur with oral decongestants. Topical decongestants are preferred in pregnancy and in people with poorly controlled hypertension due to the low level of systemic exposure. Sympathomimetics (including topical) should be avoided in patients using monoamine oxidase inhibitors (e.g., moclobemide, phenelzine) due to the risk of hypertensive crisis. Systemic sympathomimetics can be used in children over 12 years of age, whereas most topical agents are appropriate from 6 years and above. In some jurisdictions, the sale of pseudoephedrine may be controlled or prohibited due to its use as a precursor for methamphetamine, leaving phenylephrine as the only remaining systemic option. The efficacy of oral phenylephrine compared to both placebo and oral pseudoephedrine has been questioned (Eccles, 2006). In addition to medicated nasal sprays, saline douches, drops, and sprays may also be used to clear mucus from a blocked nose. These saline preparations present a viable option in patients who cannot use sympathomimetics, and limited evidence suggests that saline irrigation may help relieve symptoms associated with an URTI, although this may not be clinically significant (King et al., 2015).

Rhinorrhea

Rhinorrhea may occur in an upper respiratory tract infection, or as a result of allergic rhinitis (allergies). In the case of rhinorrhea as a result of an upper respiratory tract infection, symptomatic management can be achieved with muscarinic antagonists, such as

atropine, in a nasal spray formulation (AlBalawi et al., 2013). Antihistamine (H_1 antagonist) monotherapy (both sedating and less sedating) appears to have a limited effect on rhinorrhea of an infectious origin or any symptoms of the common cold (Sutter et al., 2003). There is currently insufficient quality evidence for or against the use of intranasal corticosteroids to relieve the symptoms associated with a common cold (Hayward et al., 2015). For the management of allergic rhinorrhea, see the Section "Allergic Rhinitis."

Diarrhea and Vomiting

Gastrointestinal syptoms, such as diarrhea and vomiting, may present in some patients infected with influenza, in particular, pediatric patients (Dilantika et al., 2010). The mainstay of therapy for patients experiencing diarrhea and/or vomiting is ensuring adequate hydration. This can be achieved through the use of oral rehydration solutions, available in a number of brands and formulations worldwide. Oral rehydration solutions replace essential electrolytes lost from diarrhea and vomiting, glucose aids sodium absorption, and citrate counters acidosis that results from dehydration. The revised WHO reduced-osmalarity formula contains 75 mmol/L glucose and sodium, 20 mmol/L potassium, 65 mmol/L chloride, and 10 mmol/L citrate. Preparations may be sold as powders or effervescent tablets, which require reconstitution in clean water or ready-to-drink formulations. Patients should be discouraged from reconstituting oral rehydration solutions using, or rehydrating with, caffeinated drinks, soft drinks (soda), milk, or fruit juice. Opioid antidiarrheal agents such as loperamide and diphenoxylate (often supplied in combination with atropine to reduce abuse potential) are available in some jurisdictions and may be considered in adult patients in combination with rehydration therapy as a short-term management of symptoms for social convenience.

Antiviral Medicines

In some jurisdictions, antiviral medicines may be available from a pharmacist under certain circumstances without the prescription of a physician. There are two main classes of antiviral medicines that are available to manage infection with influenza: neuraminidase inhibitors and M2 ion channel inhibitors. Pharmacists should follow local guidelines on the supply of these medicines with regard to time since onset of symptoms and seasonal supply restrictions. Reviews of evidence state poor quality trials are a barrier to evaluating the role of these agents as prophylaxis and treatment in both seasonal and pandemic influenza (Jefferson et al., 2006b); however, one review stated that the use of M2 ion channel inhibitors in influenza infection should be discouraged (Jefferson et al., 2006a). Patient demand for antibiotics in upper respiratory tract infections may be high and this may be further driven by patient beliefs that antibiotics help them get better faster and prevent mores serious illness when they are experiencing a common cold (Gualano et al., 2014). Current evidence suggests that antibiotics have no benefit in the management of the common cold and place users at risk of adverse effects (Kenealy and Arroll, 2013). As such, patients should be reminded that antibiotics do not play a role in the management of the common cold or influenza as the causative organism is viral and not bacterial in nature.

Combination Products

Products containing various combinations of active ingredients are available on the market. Combinations may include ingredients to manage more than one symptom, such as analgesia and a decongestant. Combination products may be more convenient for patients, but may also contain subtherapeutic doses, irrational combinations (such as an antitussive and an expectorant), or may increase the risk of duplication of therapy. Evidence suggests that combination products are effective, convenient for patients, and not inherently more dangerous than single ingredient preparations (Eccles et al., 2014). Pharmacists should ensure patients are aware of the ingredients in combination products and that only ingredients to manage symptoms that are present are used.

Complementary Medicines

Complementary medicines may be often sought by consumers in upper respiratory tract infections to either reduce symptom severity or decrease the duration of symptoms. Preparations may commonly include ingredients such as vitamin C (ascorbic acid), zinc, garlic, propolis, Echinacea, ivy leaf (Hedera helix), and Andrographis paniculata (Fashner et al., 2012). Evidence supporting the use of these preparations is of mixed quality and individual patient circumstances, the potential for adverse effects and drug interactions, and patient expectations must be considered when complementary medicines are used for the common cold. Precaution must be taken in certain patient groups with some common complementary preparations, for example, the use of Echinacea in patients with asthma and Andrographis in pregnant women.

A Cochrane Review on the use of regular vitamin C in prevention and treatment of the common cold suggests that there is a mixed evidence regarding its efficacy for prevention but may have a role in those who undertake extreme exercise or are placed under cold stress. Some efficacy was demonstrated in reducing the duration of cold symptoms; however, current evidence is not sufficient to recommend routine supplementation (Hemilä and Chalker, 2013). Given the limited risk of adverse effects from using vitamin C and its low cost, some patients may wish to trial vitamin C supplementation. Similarly to vitamin C, there is some evidence to suggest that zinc, in particular zinc lozenges, may be beneficial in reducing the duration of cold symptoms if taken close to onset of symptoms (within 24 h), although the use of zinc in prophylaxis has not been established (Singh and Das, 2013).

Echinacea is another complementary medicine commonly marketed in tablets and lozenges with claims of benefits in preventing and treating the common cold. The most recent Cochrane Review to examine the effects of Echinacea was unable to establish a

recommendation based on the included trials, although it did acknowledge some preparations may have a benefit (although the clinical significance is questionable) (Karsch-Völk et al., 2014).

Nonpharmacological Management

Patients presenting with the common cold are often told to rest and drink plenty of fluids. Increasing fluid intake is recommended with the notion that dehydration may occur in episodes of upper respiratory tract infections and may also assist with reducing the viscosity of mucus. A review article was unable to establish the benefit of this advice in a primary care setting due to the majority of studies being observational in nature and in an in-patient setting (Guppy et al., 2011).

In addition to rest and increasing fluid intake, steam inhalation is also commonly recommended to patients with upper respiratory tract infections. It is believed that inhaling heated and humidified air helps to relieve congestion associated with the common cold, and it is also hypothesized by some that the increased temperature may limit the ability for rhinoviruses to replicate. Current evidence does not demonstrate significant benefits or harms from using steam inhalation, with the exception of some nasal irritation, lightheadedness, and worsening of congestive symptoms (Singh et al., 2017).

Topical preparations containing camphor, menthol, and eucalyptus oil (vapor rubs) are used by adults and children alike to alleviate common cold symptoms and are commonly applied to the chest area or above the upper lip. A recent randomized trial compared the effects of vapor rub, white petroleum jelly, and no treatment on parents' perceptions of their child's symptoms found that vapor rub was superior to petroleum jelly and no treatment, although irritation was reported in those using the vapor rub (Paul et al., 2010).

When to Refer

Pharmacists in the community setting should be able to reach a diagnosis of a common cold with relative ease. In the event a clear diagnosis cannot be reached, or a more serious infection is suspected, for example, influenza or involvement of the lower airways, then patients should be referred to a medical practitioner for further assessment.

Referral is also warranted in the event of prolonged or recurrent symptoms (especially cough), infections resulting in exacerbation of chronic respiratory conditions (asthma or chronic obstructive pulmonary disease), suspected dehydration, high-grade fever, neck stiffness, young infants, and the elderly. A cough that persists for greater than 3 weeks, or is concomitant with breathing difficulties, wheezing, pain on inspiration, or blood in the sputum or a persistent nocturnal cough (particularly in children) also requires referral.

Allergies

Allergic Rhinitis

Allergies affecting the nose (allergic rhinitis) are common among the population, and it is estimated that approximately 23% of the European population and up to 40% of the world's population experiences allergic rhinitis (Bauchau and Durham, 2004; May and Dolen, 2017). Allergic rhinitis is characterized by inflammation of the nasal passages, congestion, itching, sneezing, and rhinorrhea. These symptoms are a result of the inflammatory chemical mediators released (histamine, leukotrienes, and prostaglandins) due to the activation of immunoglobulin type E (IgE) on the surface of mast cells in the nasal passages in response to the presence of triggering allergens. This immune response tends to result in sneezing and bilateral watery rhinorrhea at first, which may progress to nasal congestion. In addition to nasal symptoms, ocular symptoms may also be present. After the initial activation of the immune response, extra inflammatory cells, such as eosinophils and T-lymphocytes, are attracted to the site resulting in chronic inflammation. The presence of these cells also results in "priming" of the immune response, resulting in increased sensitivity to the offending allergen as well as other allergens (Greiner, 2018).

Formal diagnosis is not common, and patients often (correctly) self-diagnose and self-manage their symptoms (May and Dolen, 2017). Allergic rhinitis can be classified several ways, including whether it is seasonal or perennial (intermittent or persistent), and mild or moderate–severe. As the name suggests, seasonal allergic rhinitis (hay fever) is triggered by seasonal allergens such as high pollen counts during spring. The presence of allergens implicated in seasonal rhinitis and the duration of the presence of allergens, can differ depending on both the time of year and geographical location. Unlike seasonal allergic rhinitis, those who experience perennial allergic rhinitis may experience symptoms at any time when exposed to allergens such as animal dander, dust mites, or mold spores. Although individuals experiencing allergic rhinitis symptoms have a high degree of presenteeism at work and school, productivity may be reduced when symptoms are present, quality of life is impacted, and the economic burden of allergic rhinitis is estimated to be billions of dollars each year in the United States alone (Crystal-Peters et al., 2000).

Individuals may present to the pharmacy with symptoms they attribute to the common cold, when they may in fact be experiencing allergies. To reach a differential diagnosis, the pharmacist should consider associated symptoms, timeline of symptoms, recent social history, and personal and familial medical history. Unlike an upper respiratory tract infection, fever, headache, cough, thick nasal discharge, and cough are not common with allergic rhinitis. Symptoms are bilateral in nature (i.e., both nostrils are affected), cases where symptoms are unilateral require referral for further investigation. If the symptoms suggest allergic rhinitis, it may be worthwhile taking a recent social history to identify if any possible triggers can be identified, for example, the patient may

have been exposed to a friend's cat or a moldy room. A personal and familial medical history may assist in confirmation of differential diagnosis as a personal of familial history of atopy such as allergic rhinitis, asthma, and/or atopic dermatitis (the "atopic triad") is often present. Up to 85% of patients with asthma may have comorbid allergic rhinitis. Poorly controlled allergic rhinitis in those who are comorbid with asthma results in poorer asthma control and increased asthma medication use.

Pharmacological Management

Management of symptoms is not specific to the offending allergen, and so identification of causative allergens is not necessary to commence therapy. Treatment should aim to reduce the severity of symptoms and their subsequent impact on quality of life, and in some cases reduce the likelihood of future flare ups or complications. There are a number of preparations for the management of allergic rhinitis symptoms available both over-the-counter and on prescription. Classes of medicines used in these preparations include H_1 antihistamines (oral and intranasal), intranasal corticosteroids (INCS), mast cell stabilizers, anticholinergic agents, decongestants (oral and intranasal), and intranasal leukotriene receptor antagonists. Choice of treatment should be based on frequency and severity of the symptoms and patient preference (including the cost of treatment). There are regional variations in guidelines for the management of allergic rhinitis and these must be considered when making therapeutic recommendations.

Intranasal Corticosteroids (INCS)

Intranasal corticosteroids are considered first-line therapy for patients with moderate to severe allergic rhinitis as they are the most effective in controlling symptoms resulting from the inflammatory response (May and Dolen, 2017). INCS exert their effects by decreasing the release of cytokines and other chemicals implicated in the inflammatory mechanism of allergic rhinitis from cells in the nasal mucosa by exerting immunosuppressive effects via glucocorticoid receptors. Many agents are available on the market including budesonide, fluticasone, and mometasone. Each has been shown to be effective in the management of allergic rhinitis, and so patient preference in terms of device, dosing frequency, and cost must be considered in order to choose between them. When supplying INCS, patients should be counseled on the correct use of the device to ensure therapy is successful. Patients should also be informed that some benefit should be seen within 24 h; however, it can take 7 days or more before the full benefit of treatment is seen. Some patients may wish to use an oral or topical antihistamine during initiation of INCS therapy due to their faster onset of effects, although Allergic Rhinitis and its Impact on Asthma (ARIA) guidelines state there is limited evidence supporting the need for routine recommendation of an oral antihistamine in conjunction with INCS (Brożek et al., 2017). For convenience of those who use both INCS and an intranasal antihistamine, combination products are available. Much like the use of inhaled corticosteroids in asthma, adverse effects typically associated with systemic corticosteroids (e.g., adrenal suppression) are unlikely with the use of INCS, with adverse effects restricted to local irritation in the nose and throat.

Antihistamines (H_1)

H_1 antihistamines act by blocking the actions of the histamine-1 receptor, thereby reducing the inflammatory effects of the receptors. These antihistamines can be categorized as either sedating ("first generation") or less-sedating ("second generation"). Sedating antihistamines include promethazine and dexchlorpheniramine. Examples of oral less-sedating antihistamines are cetirizine (most likely to cause sedation), fexofenadine, and loratadine. Oral antihistamines may be preferred by some patients due to ease of use and cost and may be particularly useful in patients with both nasal and ocular symptoms due to their systemic effects. The systemic use of antihistamines, in particular sedating antihistamines, may result in undesirable adverse effects such as sedation, dry mouth, and constipation. There is no evidence to suggest that either sedating or less-sedating antihistamines are more efficacious.

In addition to oral preparations, intranasal antihistamines, such as azelastine, are also available (with or without an INCS). Intranasal antihistamines have been shown to be at least as effective as oral antihistamines and work faster, and may be preferred by some patients. Combination therapy of intranasal antihistamines and INCS may have some benefit over INCS alone; however, ARIA guidelines place emphasis on INCS as the preferred choice for therapy over antihistamines alone (Brożek et al., 2017).

Leukotriene Receptor Antagonists

Leukotriene receptor antagonists, such as monteleukast, block the effects of leukotrienes at leukotriene receptors, thus reducing nasal inflammation and subsequent nasal congestion. Leukotriene receptor antagonists are only available with a physician's prescription in many jurisdictions. These agents may be more expensive than antihistamines and there is limited evidence to suggest using them over antihistamines; however, some evidence suggests they may be useful in patients with comorbid asthma (Brożek et al., 2017).

Decongestants

Much like in the management of cold symptoms, decongestants (either topical or oral) may be used in allergic rhinitis to alleviate congestive symptoms. As these medicines have no effect on the inflammatory response and simply constrict blood vessels to reduce mucus production, they may not be useful in monotherapy for the management of allergic rhinitis. In some markets, oral decongestants may be sold in combination with antihistamines. Topical agents (e.g., oxymetazoline and phenylephrine) should not be used for extended periods due to the risk of rhinitis medicamentosa ("rebound congestion"). Adverse effects of systemic agents, such as pseudoephedrine, include tachycardia, insomnia, and reduced appetite. The sale of pseudoephedrine is restricted in some markets due to its use as a precursor to methamphetamine.

Anticholinergics

Much like decongestants, the anticholinergic ipratropium may be used in allergic rhinitis as it is in the common cold to alleviate rhinorrhea by reducing mucus secretion in the nasal passages. Again, this has no effect on the underlying inflammatory processes implicated in allergic rhinitis and may be of little use in monotherapy.

Mast Cell Stabilizers

Mast cell stabilizers, such as sodium cromoglycate, are available as intranasal preparations and reduce the secretion of inflammatory mediators such as histamine from mast cells in the nasal mucosa, thus reducing inflammation. Intranasal preparations are generally well-tolerated with adverse effects restricted to local irritation. Sodium cromoglycate is less efficacious than INCS and so may not be a preferred option.

Nonpharmacological Management

Where possible, people who experience allergic rhinitis should attempt to avoid allergens that are known to trigger their allergies (although causative allergens may not always be known). In the case of pollen, windows should be kept shut, outdoor time restricted (particularly if pollen counts are high), and clothes and bedding should be dried in a clothes dryer rather than on an outdoor washing line. Air filters either inside the home, or on air conditioning units may also prove useful. In the instance of allergic rhinitis from mold spores or dust mites, regular cleaning may help reduce exposure to these allergens. In some cases, physicians may decide that the patient is a candidate for skin prick allergy testing in an effort to determine any allergens that may be responsible for allergic rhinitis.

Saline irrigation (nasal douching, wash) is another practice that is sometimes recommended for patients with allergic rhinitis. This is achieved through using either isotonic (0.9% sodium chloride), hypotonic, or hypertonic saline preparations, which are administered into the nose and sinus cavities through either a spray or a squeeze bottle or similar device. The proposed mechanism of action for this procedure is the mechanical "flushing out" of mucus, allergens, and inflammatory mediators. A recent Cochrane Review found that there is limited quality evidence investigating the use of saline irrigation in allergic rhinitis, but that it may have a role in its management (Head et al., 2018). Given the favorable adverse effect profile (uncommonly local irritation, a feeling of ear fullness, and nose bleeds), and the low cost of treatment, saline irrigation may be considered in the management of allergic rhinitis.

Allergic Conjunctivitis

Allergic conjunctivitis (allergies affecting the conjunctiva of the eyes) is characterized by red, itchy eyes with a watery discharge. It is estimated that approximately 25% of the American population experiences allergic conjunctivitis in their lifetime. As with allergic rhinitis, allergic conjunctivitis is the result of an IgE-mediated allergy in response to the presence of allergens in the eye. Allergic conjunctivitis may be classified as seasonal (occurring at particular times during the year according to pollen counts, for example) or perennial (occurring at any time of the year in response to allergens such as dust mites, mold, and animal dander). Allergic conjunctivitis is highly comorbid with allergic rhinitis, and a personal or familial history of atopy (atopic dermatitis, asthma, and/or allergic rhinitis) should be confirmed during history-taking.

Table 1 outlines the distinguishing characteristics of the three primary classifications of conjunctivitis. Individuals with red eye symptoms may come to the community pharmacy seeking advice and treatment with what they may misdiagnose as infectious (bacterial) conjunctivitis. The pharmacist should be able to reach a differential diagnosis with relative ease with adequate history-taking. The presence of itch is a key differentiating factor for the diagnosis of allergic conjunctivitis, along with a personal or familial history of atopy. Watery discharge may be present both in viral conjunctivitis and dry eye syndrome, the presence of itch and consideration of associated symptoms will help in distinguishing allergic conjunctivitis from these conditions. The management of bacterial and viral conjunctivitis and dry eye syndrome is covered elsewhere in this book.

Table 1 Characteristics of different types of conjunctivitis

Characteristic	*Bacterial conjunctivitis*	*Viral conjunctivitis*	*Allergic conjunctivitis*
Discharge	Thick, purulent, yellow	Watery	Watery
Sensation	Gritty	Gritty	Itchy
Affected eyes	One at first, commonly spreads to other after initial infection of first eye	One at first, commonly spreads to other after initial infection of first eye	Both eyes
Associated symptoms	Nil	Recent signs and symptoms of an upper respiratory tract infection	May be associated with a personal or family history of allergic rhinitis or atopy (eczema, asthma)
Pathology	Infection with bacterial organism (commonly *Staphylococcus aureus*, *Streptococcus pneumoniae*)	Infection with a virus such as adenovirus (most common) or herpes simplex	Exposure to allergens such as animal dander, dust mites, pollen
Contagious	Highly	Highly (if adenovirus infection)	No

Management

The goals of management for conjunctivitis are to reduce the severity of symptoms and, in some cases, reduce the chance of reoccurrence. If eye drops are recommended as part of therapy, patients should be reminded of correct eyedrop administration technique, the importance of hygiene when using eye drops, and the appropriate discard date after opening dropper bottles (if not supplied as single dose units). Single-dose units (preservative-free preparations) may preferred in those with known sensitivity to commonly used preservatives such as benzalkonium chloride. Users of contact lenses should be advised to remove their lenses for administration of eye drops and replace them no earlier than 15 min after administration.

Antihistamines (H_1)

Both oral and topical antihistamines may be considered for use in patients presenting with allergic conjunctivitis. Oral antihistamines may be preferred in patients who are also experiencing nasal symptoms so both nasal and ocular symptoms can be managed. Oral antihistamines, in particular sedating antihistamines such as promethazine, may contribute to drying of the eyes, and hence less-sedating antihistamines should be recommended over these agents. Topical antihistamines include levocabastine, ketotifen, and pheniramine and are administered as eye drops. This local delivery results in a faster onset of action than oral agents. Adverse effects of topical antihistamines are limited to local irritation of the eye and bad taste. A recent review found that topical antihistamines are beneficial for controlling signs and symptoms in allergic conjunctivitis in short-term use, but was unable to make a recommendation between the available agents (Castillo et al., 2015).

Mast Cell Stabilizers

Mast cells stabilizers, including nedocromil sodium and sodium cromoglicate, are sold in eye drop preparations for the management of allergic conjunctivitis. Adverse effects are mild and limited to the eye and nose. A recent review found that mast cell stabilizers may be useful in controlling signs and symptoms of ocular allergy, but could not make a recommendation between the available agents (Castillo et al., 2015).

Ocular Decongestants

Ocular decongestants, for example, naphazoline, are available in single-ingredient eye drops and in combined preparations with topical antihistamines. Their role in allergic conjunctivitis is limited to superficial reduction in redness of the eye as they have no effect on the underlying pathology of the allergic response. As with topical agents used in nasal congestion, extended use of ocular decongestants may result in conjunctivitis medicamentosa (rebound hyperemia), as such patients should be advised to avoid using these preparations for extended periods of time. Due to the risk of systemic absorption with poor administration technique, caution should be taken when recommending ocular decongestants in patient groups who would be excluded from taking oral decongestants (e.g., uncontrolled hypertension, concomitant use of phenelzine) as well as those at risk of angle-closure glaucoma.

Lubricating Drops and Saline

Lubricating eye drops (artificial tears) or normal saline (0.9% sodium chloride) may be useful in conjunction with other therapies to relieve discomfort in the eye and dilute both allergens and inflammatory mediators released during the allergic response. Lubricating eye drops contain lubricants such as carmellose and may be used as often as required. If insufficient lubrication is achieved with an eye drop, a gel or ointment applied before sleep may be considered.

Nonpharmacological Management

Prevention of allergic conjunctivitis is achieved through allergen avoidance. Where the causative allergen(s) are known patients should take necessary measures to avoid or minimize exposure to these. Practical measures may include limiting time outdoors during high pollen counts, keeping windows and doors shut, using air filters in air conditioning units, and undertaking strict cleaning routines to reduce animal dander and dust mites. If a specific allergen cannot be identified a physician may refer patients for further investigation such as a skin prick test.

When to Refer

Community pharmacists should be able to reach a differential diagnosis when it comes to allergies and conditions that present similarly. In the event, a clear differential diagnosis cannot be reached, and patients should be referred to either a medical practitioner or optometrist for further assessment. In nasal allergies obstruction or rhinorrhea from just one nostril may indicate the presence of a foreign object in the nose and this should be particularly considered in pediatric patients. Rhinitis symptoms persisting despite over-the-counter treatment should be assessed for the possibility of prescription therapy by a medical practitioner, as should rhinitis that is associated with pain or suspected to be the result of medication use (either prolonged use of topical decongestants or other drugs known to cause rhinitis medicamentosa). Due to the association between poorly managed allergic rhinitis and worsening asthma, patients who are comorbid should have their asthma control assessed by the pharmacist (e.g., frequency of "reliever" use) and referred if worsening of asthma symptoms occurs.

In the case of ocular allergies, in addition to nonspecific referral points such as over-the-counter treatment failure, specific referral points include if there is a change in vision, a foreign body present, eye pain, or photophobia then the patient should be referred.

Some eye conditions (including allergic conditions) may result in scaling or other changes to the eye lids and surrounding tissue, these conditions are beyond the scope of community pharmacy practice and should also be reviewed by a medical practitioner.

The Role of the Pharmacist

Similar to many other common minor ailments, the community pharmacy (among other primary health-care providers) is often the first port of call for people experiencing allergies and signs and symptoms of upper respiratory tract infections. Pharmacists have a unique opportunity, due to their accessibility and expertise in medicines, to make a differential diagnosis, educate patients on the management of these common conditions, and provide appropriate therapy and advice.

Consumer expectations of over-the-counter products for management of the common cold and associated symptoms may be high, and pharmacists can educate patients on the expected effects of any over-the-counter medicines (including complementary and alternatives medicines) and comment on the limited evidence supporting their use. Patients should be reminded that there is no cure for the common cold or influenza and that antibiotics do not play a role in the management of infections of viral origin, this is of particular importance in jurisdictions where antibiotics are available over-the-counter without a physician's prescription and consumer demand may be high. As always, pharmacists should promote safe, judicious, and appropriate use of medicines. Consumers may have misconceptions about the common cold and influenza, including the need to seek medical attention for a common cold, in this case the pharmacist can dispel myths surrounding these common infections and act as a "triage" for those who truly need referral for medical assessment based on their presenting symptoms, thereby reducing burden on the health system for ailments that can be easily managed in the scope of the community pharmacy. Where local laws permit, pharmacists should also offer (and administer) vaccination against seasonal influenza or other infectious diseases to patients who are eligible.

Literature has demonstrated that people living with allergic rhinitis do not frequently speak to health-care professionals about their condition, and instead make a (correct) self-diagnosis and self-select over-the-counter treatments, which are readily available. Several reasons have been proposed for this, including the self-perception that allergic rhinitis is relatively less severe than asthma (given that the two are frequently comorbid). Given that consumers may not be discussing their allergic rhinitis with a physician, pharmacists can take the opportunity to engage with consumers requesting medicines such as antihistamines or intranasal corticosteroids to elicit a history and make a differential diagnosis. Pharmacists can assist these patients in optimizing therapy, explain the correct use of devices, and educate patients about allergic rhinitis, for example, emphasizing the benefit on comorbid asthma if allergic rhinitis is managed appropriately. Finally, pharmacists can identify patients who require referral to another health-care provider (medical practitioner, optometrist).

Management of Respiratory Disorders and the Pharmacist's Role: Cystic Fibrosis

Muhammad Rehan Sarwar*, Sadia Iftikhar†, Anum Saqib*, *The Islamia University of Bahawalpur, Punjab, Pakistan; †Akhtar Saeed College of Pharmaceutical Sciences, Lahore, Pakistan

Learning Objectives

After completion of the chapter, the reader will be able to:

- Describe the epidemiology, etiology, and pathophysiology of cystic fibrosis (CF) and its multiple organ system involvement.
- Describe the genetic modifications and the genotypic classification of CF transmembrane regulator gene defect.
- Explain the clinical presentations and diagnosis of CF and its associated complications.
- Recommend appropriate pharmacologic therapies for the management of CF and its multi-organ system complications.
- Identify appropriate nonpharmacologic therapies for the management of CF and its complications.
- Design monitoring plans for acute and chronic CF pharmacotherapy.
- Recognize the pharmacist's traditional and emerging roles of in the management of CF.

Take-Home Messages

- Cystic fibrosis (CF) is a genetic disorder that occurs as a result of a defect in the cystic fibrosis transmembrane conductance regulator protein—a chloride channel responsible for regulating fluid and electrolyte transport within secretory epithelial cells in the entire body.
- The primary manifestation of CF encompasses pancreatic insufficiency and pulmonary dysfunction associated with chronic airway obstruction, infection, and inflammation whereas, the secondary manifestation includes malnutrition.
- CF is diagnosed through screening of newborn, appearance of typical signs and symptoms of the disease, or through documented abnormalities in ion transport or presence of two CF genetic mutations.
- Malabsorption, vitamin deficiencies, and poor nutritional status associated with CF are managed by using pancreatic enzymes and fat-soluble vitamins.
- The mainstay of therapy for managing CF includes inhaled dornase alfa and hypertonic saline along with mechanical airway clearance techniques for combating obstruction of airway.
- Inhaled antibiotics are administered to manage airway infections, and oral azithromycin is used to treat inflammation of the airways.
- Patients with CF may periodically experience acute pulmonary exacerbations along with increased pulmonary symptoms, acute loss of lung function, and weight loss, thus requiring the intensification of airway clearance and administration of systemic antibiotics and nutritional supplements.
- Key monitoring parameters in CF include observing trends in pulmonary function tests for determining response to therapies and identification of possible acute pulmonary exacerbations.
- Special consideration must be given to the disease-associated complications such as CF-related diabetes mellitus, osteoporosis, and depression.
- Pharmacists can play an important role in the management of patients with CF due to their expertise in pharmacotherapy, pharmacokinetics, pharmacodynamics, and drug interactions.
- Pharmacist's care of patients with CF can improve medication nonadherence, decrease incidence of readmission, and improve quality of life.

Introduction

Cystic fibrosis (CF) is a genetic disorder, which occurs due to a defect in the CF transmembrane conductance regulator protein—a chloride channel responsible for regulating fluid and electrolyte transport within secretory epithelial cells in the entire body. This affects many organ systems including respiratory system (lungs and sinus), liver, sweat glands, pancreas, intestine, and reproductive system (Cutting, 2015). The 10th revision of the International Statistical Classification of Diseases and Related Health Problems (ICD-10) classified CF as category E84. On the basis of manifestations, this genetic defect is categorized as CF with pulmonary manifestation (E84.0), CF with intestinal manifestation (E84.1), CF with other manifestations (E84.8), unspecified CF (E84.9), CF with meconium ileus (E84.11), and CF with other intestinal manifestations (E84.19) (World Health Organization, 2016).

CF transmembrane regulator (CFTR) gene shows expression in multiple organs like pancreas, lungs, bile system, and sweat glands. The mutation causes defect in the gene, leading to this hereditary autosomal disease. Another name for CF is mucoviscidosis because rise in sodium and chloride level causes exocrine glands to produce excessively thick mucus, and cause obstruction in pancreas, intestine, bile duct, and bronchi. It is also accompanied by lower body temperature and difficulty in breathing and digestion (World Health Organization, 2018). The symptoms of CF vary from person to person. In most of the patients, symptoms appear in early childhood (e.g., poor growth rate despite good appetite, meconium ileus, foul bulky stools, malabsorption, recurrence of pneumonia, chronic bronchitis with cough, emphysema, bronchiectasis, salt depletion in hot weather, and clubbing of the fingers). However, some patients suffer from mild form of the disease and remain asymptomatic until adulthood. Although it is an incurable disease, the advancements in medical and pharmaceutical sciences have increased the average life expectancy of CF patients up to an average of 37 years of age (Health, 2018).

Epidemiology

CF is a genetic disorder affecting more than 70,000 people globally (CF Foundation, 2017). This life-shortening disease is predominantly found in Caucasians, because most of them (1 in 29 individuals) are carriers of the CF gene (O'Sullivan and Freedman, 2009). According to the World Health Organization (WHO), CF is prevalent in Europe (1 in 2000–3000 live births), North America (1 in 3500 live births), the United Kingdom (1 in 10,000 individuals), Latin America (1 in 3900–8900 neonates), Middle East (1 in 2560–15,876 people), Japan (1 in 100,000–350,000 live births), and India (1 in 40,000–100,000 live births), irrespective of the particular race and ethnicity (Cuppens et al., 2004; Farrell et al., 2008; World Health Organization, 2004). The apparently low incidence rate of CF in Asia, Latin America, and Africa may be due to the fact that CF remains underdiagnosed (World Health Organization, 2002). The progression and diagnosis of CF are markedly influenced by the age and gender of the patients because factors such as social, cultural, behavioral, and physiological dissimilarities have an impact on it (Demko et al., 1995). Among children, females are less commonly diagnosed with CF as compared to male patients (MacKenzie et al., 2014) while among adult patients, CF is more prevalent in women with shorter life expectancies than men (Nick et al., 2010). Biological mechanisms like female sex hormones have been identified as the root cause of this disparity. It is believed that estrogen increases the viscosity of mucus by modulating the ion channels on respiratory epithelium and reducing the air surface liquid on bronchial epithelial cells (Harness-Brumley et al., 2014). The advancement in treatment has decreased the morbidity among children and it is now predominantly found in adult population. The number of adults with CF is predicted to increase by 70% by 2025 (Burgel et al., 2015). The median life expectancy can be improved with better provision of care (e.g., mucociliary clearance) in multidisciplinary CF centers and the use of efficacious drugs in the treatment and control of infections (Burgel et al., 2015).

Etiology

Genetic Basis of Cystic Fibrosis

CF is the result of mutation of a gene on chromosome number 7 (Knowlton et al., 1985). This gene encodes the CFTR protein. The extent and severity of CF-associated illness depend on the insertion, deletion, and duplication of the CFTR gene. To date, approximately 2000 mutations of CFTR gene have been reported. On the basis of genotype, these mutations are grouped into six major classes (**Table 1**). These defects are not mutually exclusive, because a given mutation can demonstrate abnormalities across more than one mutation class (Hudock and Clancy, 2017).

CF shows an autosomal recessive pattern of inheritance. It means that patients suffering from CF have two copies of mutant CFTR gene, while carriers have only one copy. If both the parents are carriers, then there will be 25% chances that either next generation will be CF sufferer or disease free, while 50% chances that child will be careers but not sufferers. But when one parent is a carrier and other is a sufferer, then the chances of next generation to become sufferers and carriers will be 50% (C. F. Foundation, 2017).

Table 1 Classification of mutations of cystic fibrosis transmembrane regulator gene

Class	*Defect*	*Mechanism*	*Outcome*	*Example of gene mutation*
I	Biosynthetic defects	Frameshift mutations and large deletions lead to PTC	Absence of CFTR expression	G542X, W1282X
II	Defect in trafficking and protein folding	Missense mutations and in-frame deletions cause folding defect of CFTR	CFTR is not transported to the surface or only transported in residual amount	N1303K, F508del
III	Gated defect	CFTR channel does not open in response to agonist due to disrupting regulation	Absence or decreased opening of CFTR ion gated channel	G551S, G551D
IV	Conductance defect	Some mutations cause changes in structure of protein	The abnormal shape of CFTR pore of the channel restricts the movement of chloride ions	R347P, R117H
V	Splice abnormalities	Some mutations result in alternative splicing that disrupts mRNA processing and lesser number of normal CFTR protein synthesized	Less number of normal CFTR protein at the surface	A455E
VI	Defect in channel	Different types of mutations lead to increased turnover of CFTR protein at cell surface	Functional CFTR protein is unstable at cell surface and is quickly removed and degraded by cell machinery	F508del, 120del23

CFTR, CF transmembrane regulator; *PTC*, premature termination codons.
(Cystic Fibrosis Foundation, 2017c; Fanen et al., 2014; Marson et al., 2016; Tsui, 1995)

Consequences of Cystic Fibrosis Transmembrane Regulator Gene Mutation

Normally, the CFTR protein is responsible for the ion conduction and is regulated by cyclic adenosine monophosphate (cAMP). Primarily, it controls the movement of chloride ions in the luminal side of epithelium. It also hinders the activity of amiloride-sensitive epithelial sodium channel (ENaC) and causes reduction in reabsorption of sodium ions in the lung. The inability of CFTR protein to function normally in CF results in altered ionic concentration and volume of airway surface liquid in the lungs of individuals with CF (McKone and Aitken, 2004). Since CFTR gene is located in various organs like lungs, sinus, pancreas, intestine, liver, and sweat glands, ionic conduction in these organs is disturbed due to defective gene.

Clinical Presentations

Since CF involves abnormal functioning of multi-organ systems, several phenotypic features of pulmonary and gastrointestinal diseases are consistent with its diagnosis (Rosenstein and Cutting, 1998).

Pancreatic Involvement

CF affects both the exocrine and endocrine functions of the pancreas. Normally, the pancreatic enzymes are secreted into bicarbonate-rich fluid from the pancreatic duct. The dysfunctioning of CFTR inhibits the secretion of digestive enzymes and bicarbonate into the duodenum, leading to ductal obstruction. As time progresses, these enzymes (lipase, protease, and amylase) accumulate and start digesting the pancreatic tissue (Li and Somerset, 2014). The term "cystic fibrosis" refers to the fibrotic scar tissue, which replaces the destroyed pancreas. The absence of these enzymes leads to poor digestion of fats, proteins, and carbohydrates. Consequently, almost 90% of patients experience pancreatic insufficiency (PI), which in turn is characterized by steatorrhea (fatty stools), decreased absorption of the fat-soluble vitamins (A, D, E, and K), malnutrition, and deterioration of the normal function of pancreas (Hackert et al., 2014; Peretti et al., 2005). In early life, the concentration of amylase and lipase rises secondary to pancreatic autodigestion. This may lead to either painful or asymptomatic chronic pancreatitis. Subsequently, the destruction of the pancreas leads to glucose intolerance in about 17% of children and 75% of adults (Koda-Kimble, 2012; Sterescu et al., 2010). Almost 40%–50% of adult sufferers of CF also develop diabetes mellitus (Kayani et al., 2018). This complication is associated with increased morbidity and mortality. Decreased insulin sensitivity is linked with pulmonary exacerbations. Initial aggressive insulin therapy may result in improved clinical outcomes (Moran et al., 2010).

Pulmonary Involvement

The following are common pulmonary presentations in patients with CF:

- Persistent colonization/infection with typical CF pathogens, including *Staphylococcus aureus*, nontypeable *Haemophilus influenzae*, mucoid and nonmucoid *Pseudomonas aeruginosa*, *Stenotrophomonas maltophilia*, and *Burkholderia cepacia*.
- Chronic cough and sputum production.
- Persistent chest radiograph abnormalities (e.g., bronchiectasis, atelectasis, infiltrates, hyperinflation).
- Airway obstruction, manifested by wheezing and air trapping.
- Nasal polyps; radiographic or CT abnormalities of the paranasal sinuses.
- Digital clubbing.

Gastrointestinal Involvement

The following are common gastrointestinal abnormalities in patients with CF:

- Intestinal—Meconium ileus, distal intestinal obstruction syndrome, rectal prolapse.
- Pancreatic—PI, recurrent acute pancreatitis, chronic pancreatitis, pancreatic abnormalities on imaging.
- Hepatic—Prolonged neonatal jaundice, chronic hepatic disease manifested by clinical or histological evidence of focal biliary cirrhosis or multilobular cirrhosis.

Nutritional Abnormalities

Failure to thrive (protein-calorie malnutrition), hypoproteinemia, edema, and complications secondary to fat-soluble vitamin deficiencies are typical nutritional abnormalities found in CF.

Other Abnormalities

Other abnormalities commonly encountered in CF include:

- Salt loss syndromes: acute salt depletion, chronic metabolic alkalosis.
- Genital abnormalities in males, resulting in obstructive azoospermia.

Diagnosis

In individuals presenting with clinical signs and symptoms of CF or a positive family history, the following diagnostic tests are recommended:

Sweat Test

1. A patient is said to have CF if the sweat chloride value is ≥60 mmol/L. If the mutation analysis finds that there is a mutation in two CF genes, then the sweat chloride test is recommended for confirmation. Such patients are more likely to develop this disorder irrespective of their age.
2. If a patient aged ≥6 month is presented with a sweat chloride value ≤39 mmol/L, then he/she cannot be categorized as CF. Such patient should be referred to a CF care center for follow up if he/she is identified with mutation in two CF genes (Farrell et al., 2008; Stern, 1997).
3. If the sweat chloride value ranges between 30 and 59 mmol/L in patients aged <6 months and 40–59 mmol/L among patients aged >6 months, then the extensive CFTR mutation analysis (e.g., gene sequencing, expanded panel of CFTR mutations and evaluation of deletions) is recommended for confirmation (LeGrys et al., 2007).

    a. If the individual is found to have mutation in two CF genes, then he/she must be treated as a CF patient.
    b. If the individual is found to have no or mutation in one CF gene, then he/she can be either categorized as a CF patient or high-risk patient on the basis of family history and the clinical presentation of CFTR dysfunctioning (i.e., bronchiectasis, obstructive azoospermia and acute, chronic or recurrent pancreatitis). Patients aged 6 months to 2 years must undergo repeated sweat chloride test. If the sweat chloride values are found to be intermediate on repeat testing, then the patient must be referred to a CF center and confirmation should be made on the basis of ancillary testing, which may include signs and symptoms, expanded gene testing, respiratory tract culture testing for the identification of causative microorganism (e.g., *P. aeruginosa*), and exocrine pancreatic function tests (Elborn and Bradley, 2006).

Ancillary Test

On the basis of signs and symptoms, patients may be prescribed several ancillary tests, including pancreatic imaging, high-resolution computed tomography (HRCT) for chest, bronchoalveolar lavage, assessment of reproductive system, respiratory function tests (not routinely recommended for infants), nasal potential difference (NPD) test, assessment for presence of immune deficiency, and ciliary dyskinesia.

An individual is said to be suffering from CF, if it is confirmed by clinical presentation, laboratory biomarkers, and microbial culture test. If an individual does not show any signs and/or symptoms related to CF, but has sweat chloride values in intermediate ranges, then he/she must be regularly monitored for the appearance of CF-related signs and symptoms.

Management of Cystic Fibrosis

CF is an incurable disease, but there are several therapeutic agents available to reduce or prevent its complications, control its symptoms, and improve the quality-adjusted life years (QALY) of patients with CF (Klimova et al., 2017). The treatment of the CF encompasses the use of medications and techniques for mobilizing pulmonary secretions, antibiotics for treating infections, and anti-inflammatory agents for reducing the inflammation of airways (National Health Services, 2018). Early diagnosis, close monitoring, multidisciplinary collaborative care approach, and referral to a regional CF center are highly recommended strategies for improving chances of survival (Mayo Clinic Staff, 2016). In 2007, the Pulmonary Therapies Committee, founded by the Cystic Fibrosis Foundation (CFF) of America, had established guidelines on the basis of safety and efficacy of therapeutic agents (Flume et al., 2007). With the approval of novel medicines for treating CF patients, these guidelines were revised by the committee in 2013 (Mogayzel et al., 2013). Various therapeutic options have been summarized in **Table 2**.

Cystic Fibrosis-Associated Pulmonary Exacerbations

Pharmacological Management

Cystic fibrosis transmembrane regulator modulators

Novel therapeutic agents that target the aforementioned classes of mutation are developed (Sawczak et al., 2015). CFTR modulators are classified into three groups of drugs: potentiator, corrector, and read-through agents. If the CFTR channel is correctly located, then the potentiator enhances its activity. The defect in trafficking and protein folding is corrected by the correctors, while read-through agents produce full-length protein by allowing the ribosome to ignore the premature codon (Edmondson and Davies, 2016).

Table 2 Treatment options for patients with cystic fibrosis

Pharmacological therapies	
CFTR modulators	*Potentiator*: Ivacaftor
	Corrector: Lumacaftor, Tezacaftor
	Combination therapy: Ivacaftor/Lumacaftor; Ivacaftor/Tezacaftor
	Read-through agents: Ataluren
Antibiotics	Flucloxacillin; Amoxicillin and clavulanic acid; Tobramycin; Azithromycin; Clarithromycin; Rifampicin; Fusidic acid; Tetracyclines
Bronchodilators	β_2-Receptor agonists
Mucolytic and mucoactive agents	*N*-acetylcysteine; Dornase alpha
Anti-inflammatory agents	*NSAIDS*: Ibuprofen
	Corticosteroids: Leukotriene β_4-receptor antagonist
Nutritional therapies	Pancreatic enzymes replacement therapy; Multivitamin supplements
Anti-hyperglycemic agents	Insulin
Anti-osteoporosis agents	Bisphosphonates
Non-pharmacological therapies	
Oxygen therapy	
Chest physiotherapy	
Lung transplantation	
Gene therapy	
Preventive measures to control infections	
Vaccination	Influenza vaccine; prevnar vaccine
Monoclonal antibody	Palivizumab

CFTR, CF transmembrane regulator.
(Cystic Fibrosis Foundation, 2017a; Döring et al., 2012; Flume et al., 2007; Stenekes et al., 2009)

Potentiator The role of potentiator is to restore CFTR activity and function in CF patients. These agents cause the CFTR channel to remain open and functional for prolonged period of time. In this way, the defects related to gating and conductance can be improved (**Fig. 1**) (Sloane and Rowe, 2010; Van Goor et al., 2014).

Ivacaftor Ivacaftor 150 mg (VX-770) is a potentiator of CFTR chloride channel that improves the lung function of patients with CF by 10%, and reduces the pulmonary exacerbation by 55% and sweat chloride concentration within indeterminate range (Davies et al., 2013). The most common adverse drug reactions (ADRs) associated with its use include nausea, headache, upper respiratory tract infections, abdominal pain, nasal congestion, nasopharyngitis, oropharyngeal pain, dizziness, diarrhea, and rash whereas, serious ADRs may include elevation in liver transaminases. There is little evidence suggesting ocular toxicity, so regular eye examination is recommended for patients. As Ivacaftor is administered orally, patient's adherence affects treatment outcomes. It has been found in phase II clinical trials that withdrawal of Ivacaftor caused diminished therapeutic outcomes (Accurso et al., 2010).

Corrector These are the small molecules that increase gating, conduction, and improve the cell-surface expression by making F508del to leave the endoplasmic reticulum (ER). They work either as "pharmacological chaperones" (i.e., to improve folding of CFTR protein by direct binding) or as "proteases regulators" (Mijnders et al., 2017). This class mainly includes Lumacaftor (VX-809), and Tezacaftor (VX-661) (**Fig. 1**).

Lumacaftor Lumacaftor (VX-809) improves CF symptoms by acting as protease regulators (i.e., show an improvement in CFTR folding by adapting protein homeostasis—proteostasis), aiding the conformational stability of F508del-mutated CFTR proteins and thus causing an increased processing and trafficking of mature protein to the cell surface. In phase IIa of clinical trial, Lumacaftor showed a dose response change in sweat chloride (Clancy et al., 2012).

Tezacaftor Tezacaftor (VX-661) is a novel drug that improves processing and trafficking of CFTR to the cell membrane among CF patients with F508del mutation. Cough, nausea, increased sputum, and fatigue are the most commonly reported ADRs with Tezacaftor monotherapy. Unlike Lumacaftor, it neither induces CYP3A enzyme nor shows any drug interaction with Ivacaftor during metabolism (Donaldson et al., 2018).

Combination therapy A combination of tezacaftor (100 mg) and ivacaftor (150 mg), also known as VX-440, has been approved by FDA in February 2018 under the brand name Symdeko™ (Vertex Pharmaceuticals, 2018). The common ADRs include headache, nausea, sinus congestion, and dizziness. This combination also alters the level of hepatic enzymes and patient can show various symptoms like yellowing of skin or sclera of the eye, dark amber color urine, nausea, vomiting, and

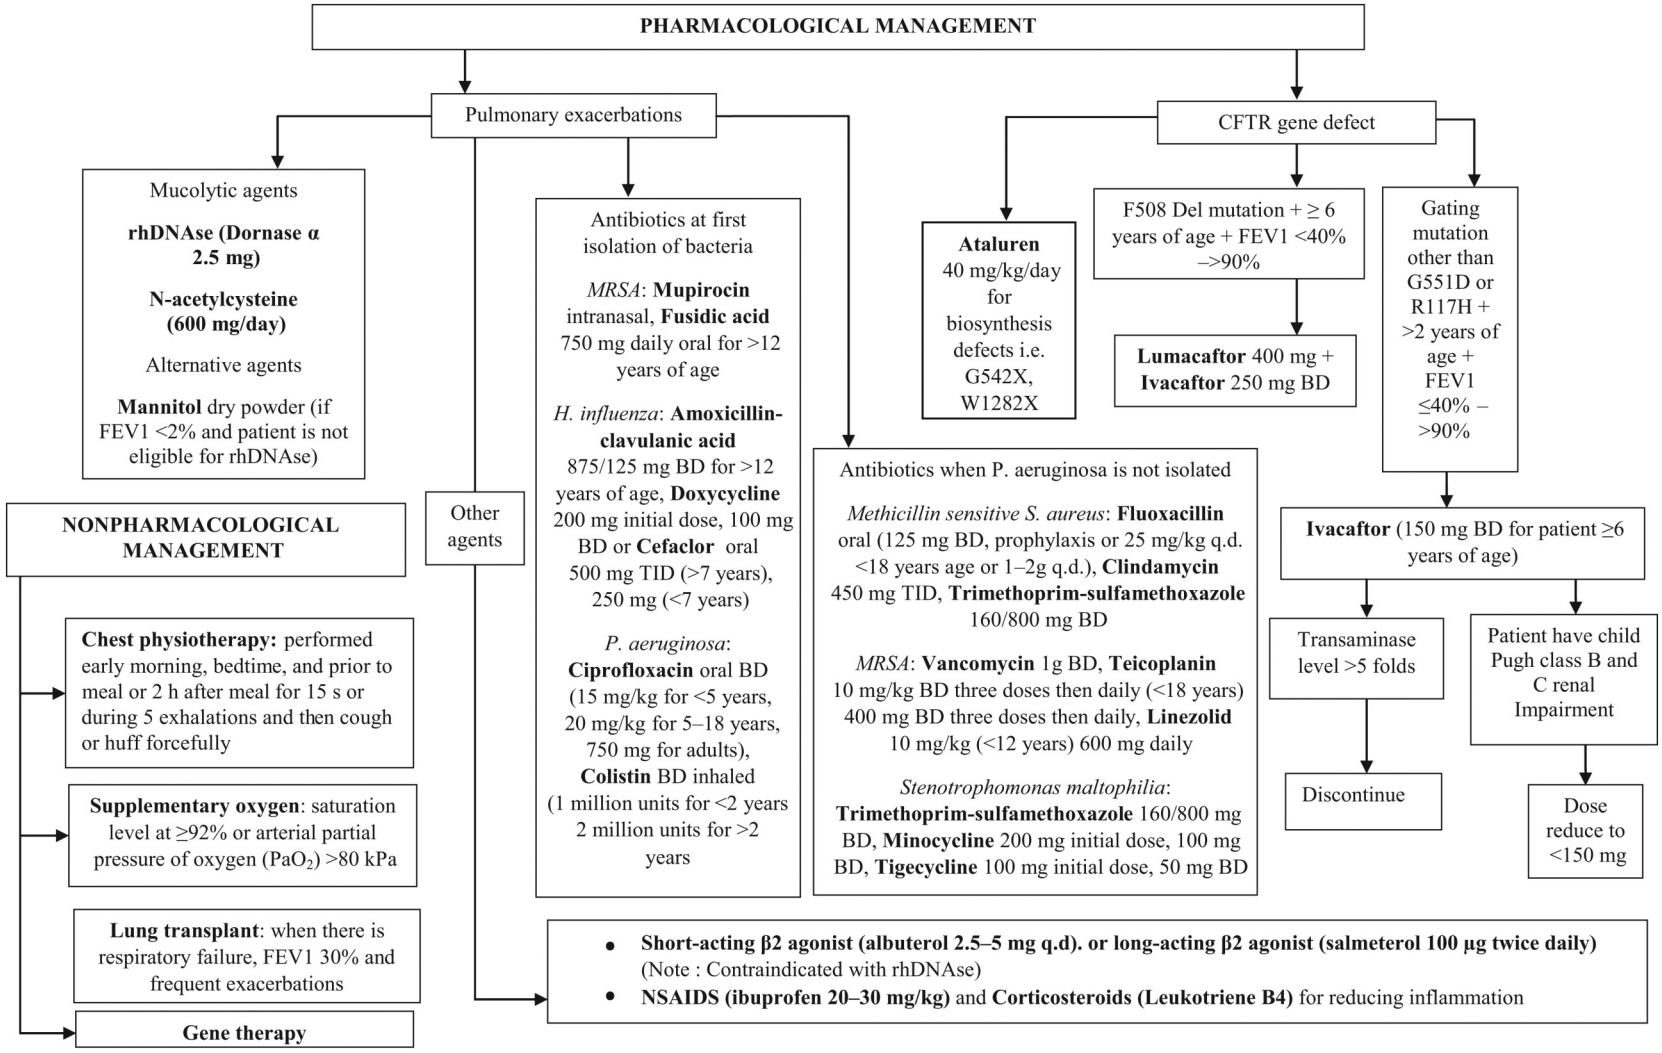

Figure 1 Algorithm of management of CF and associated pulmonary exacerbations.

loss of appetite. As a precautionary measure, an eye examination is mandatory during or after treatment with this combination therapy to check patient for cataract. In phase II studies, this combination shows a reduction in sweat chloride level, improvement in forced expiratory volume (FEV_1) for patients' homozygous for Phe508del. In 2015, FDA approved this combination under the brand name Orkambi™ (lumacaftor 200mg/ivacaftor 125 mg) for CF patients aged ≥12 years who are homozygous for Phe508del mutation (Zhang et al., 2016).

Read-through agents Almost 10% of the CF patients have class I mutation in CFTR gene (Pettit and Fellner, 2014; Rowe et al., 2005; Van Goor et al., 2011). Ataluren 40 mg/kg/day (PTC124) is effective against class I mutations in which premature stop codons (UAA, UAG, or UGA) inhibit the formation of full-length protein (Du et al., 2008). Although it is structurally similar to aminoglycoside antibiotics, Ataluren does not show any similarity with respect to toxicity profile or antibiotics characteristics (Ratjen, 2009).

Antibiotics

In comparison to healthy population, CF patients are more prone to bacterial infections, which mainly include *S. aureus*, *P. aeruginosa*, *B. cepacia* complex, *S. maltophilia*, *Achromobacter* species, and other Gram-negative microorganisms (Coutinho et al., 2008). *S. aureus* is a significant pathogen that is commonly found in respiratory cultures. Sometimes, it shows asymptomatic infections, but it can also initiate immunological responses that may cause lung damage. For symptomatic relief, anti-staphylococcal antibiotics are recommended especially during the first 2 years of life (Hewer and Smyth, 2017). A child must be administered a narrow spectrum anti-staphylococcal antibiotic such as flucloxacillin until 5 years of age. This therapy must be discontinued if there are less than three isolates of *S. aureus* in the preceding year (Gibson et al., 2003). There is no significant evidence that suggests the role of *H. influenza* in the pathogenesis of CF-associated lung diseases (Agrawal and Murphy, 2011). If there are two or more isolates of *H. influenza* in 1 year, then patient should be administered amoxicillin and clavulanic acid prophylactically (Cuthbert, 2011). Oral cephalosporins are not recommended in both *S. aureus* and *H. influenza* infections (Döring et al., 2004). If the patient is chronically infected with *P. aeruginosa*, nebulized colistin or nebulized tobramycin can be given on alternative months. Moreover, azithromycin can be given prophylactically owing to its anti-inflammatory actions and activity against formation of biofilms (G. Davies and Wilson, 2004).

However, there is a need to administer antibiotics in 1–10 pediatric patients despite antibiotic prophylaxis every year (Hewer and Smyth, 2017). Bacterial exacerbation is triggered by viral infections; therefore, the use of antibiotics can be justified. In case of upper respiratory tract infections (URTIs), CF patients should be administered with double dose of flucloxacillin. If there is no relief within 2 days of treatment, then the therapy should be switched to co-amoxiclav (Ciofu et al., 2015; Grimaldi-Bensouda et al., 2014). The antibiotic doses for CF are provided in **Table 3**.

Table 3 Antibiotics for the treatment of bacterial infection in cystic fibrosis

Sl. no.	*Drug*	*Spectrum*	*Dose*	*Frequency*	*Route*	*Age (years)*
1.	Flucloxacillin	*Staphylococcus aureus*	25 mg/kg	6 h	Oral	<18
			1–2 g			>18
2.	Fusidic acid	*Staphylococcus aureus*	500 mg	8 h	Oral	<12
			750 mg			>12
3.	Rifampicin	*Staphylococcus aureus*	10 mg/kg	12 h	Oral	<18
			600 mg			>18
		Mycobacterium avium complex	10 mg/kg	24 h	IV	<12
			450 mg			>12
4.	Clindamycin	*Staphylococcus aureus*	5–7 mg/kg	6 h	Oral	<18
			600 mg			>18
5.	Vancomycin	*Staphylococcus aureus*	15 mg/kg	8 h	IV	<18
			1 g			>18
			4 mg/kg	12 h	Inhaled	<18
			250 mg	6–12 h		>18
6.	Teicoplanin	*Staphylococcus aureus*	10 mg/kg	12 h	IV	<18
			400 mg			>18
7.	Linezolid	*Staphylococcus aureus*	10 mg/kg	8 h	Oral/IV	<12
			600 mg	12 h		>12
8.	Amoxicillin	*Haemophilus influenza*	250 mg	8 h	Oral	<7
			500 mg			>7
9.	Co-amoxiclav (amoxicillin and clavulanic acid)	*Haemophilus influenza*	250 mg	8 h	Oral	All age groups
10.	Doxycycline	*Haemophilus influenza* *Burkholderia cepacia*	200 mg	24 h	Oral	>12
11.	Cefaclor	*Haemophilus influenza*	250 mg	8 h	Oral	<7
			500 mg		Oral	>7

Table 3 Antibiotics for the treatment of bacterial infection in cystic fibrosis (*cont.*)

Sl. no.	*Drug*	*Spectrum*	*Dose*	*Frequency*	*Route*	*Age (years)*
12.	Cefixime	*Haemophilus influenza*	200 mg	24 h	Oral	<10
			400 mg			>10
13.	Chloramphenicol	*Haemophilus influenza*	12.5–25 mg/kg	6 h	Oral	All age groups
14.	Cefuroxime	*Haemophilus influenza*	50 mg	6–8 h	IV	<18
			750 mg			>18
15.	Cefotaxime	*Haemophilus influenza*	50 mg/kg	6–8 h	IV	<18

23.	Ticarcillin—Clavulanic acid	*Pseudomonas aeruginosa*	80–100 mg/kg	6–8 h	IV	<18
			3.2 g			>18
24.	Ceftazidime	*Pseudomonas aeruginosa*	50 mg/kg	8 h	IV	<18
			2–3 g			>18
		Burkholderia cepacia	1 g	12 h	Inhaled	All age groups
25.	Aztreonam	*Pseudomonas aeruginosa*	50 mg/kg	6–8 h	IV	<12
			2 g			>12
26.	Imipenem	*Pseudomonas aeruginosa*	22.5 mg/kg	6 h	IV	<18
27.	Meropenem	*Pseudomonas aeruginosa*	25–40 mg/kg	8 h	IV	<18
			1–2 g			>18
28.	Colistin	*Pseudomonas aeruginosa*	25,000 units/kg	8 h	IV	<18
			2 million units	8 h	IV	>18
29.	Tobramycin	*Pseudomonas aeruginosa*	10 mg/kg	24 h	IV	All age groups
			3.3 mg/kg	8 h		
30.	Fosfomycin	*Pseudomonas aeruginosa*	100 mg/kg	8 h	IV	<12
			5 g	8–12 h		>12
31.	Co-trimoxazole	*Burkholderia cepacia*	480 mg	12 h	Oral	<12
			960 mg			>18
32.	Trimethoprim	*Burkholderia cepacia*	4 mg/kg	12 h	Oral	<12
			200 mg			>12
33.	Temocillin	*Burkholderia cepacia*	1–2 g	12 h	IV	>12
34.	Taurolidine	*Burkholderia cepacia*	4 mL of 2% solution	12 h	Inhaled	>18

(Cystic Fibrosis Foundation, 2009; Edward DeSimone, 2018; Sarath Ranganathan, 2006)

Bronchodilators

Bronchodilators (long- and short-acting β2 agonist) are the most frequently used therapeutic agents among patients with CF (Konstan et al., 1999). These drugs are used to treat the obstruction and hyper-responsiveness of the airways. They also improve mucus clearance (Brand, 2000).

Mucolytic and mucoactive agents

These agents decrease the elasticity and viscosity of mucus by breaking its gel structure. However, they have negative effect on physiological clearance of mucus by ciliary transport, which can efficiently remove thick mucus as compared to viscous mucus (Dulfano and Adler, 1975; Gelman and Meyer, 1979). These secretions are aspired via suction catheters especially in hospitalized patients. Two mucoactive agents, namely N-acetylcysteine (NAC) (600 mg/day) and dornase alpha (2.5 mg), have been administered in CF patients through aerosols to treat abnormal pulmonary secretions (Henke and Ratjen, 2007). NAC is not widely

recommended because of its potential ADR (i.e., bronchospasm). Dornase alpha is not only safe in CF patients having forced ventilatory capacity (FVC) < 40% of predicted value, but is also associated with side effects such as laryngitis, pharyngitis, hypersensitivity reactions, chest pain, rhinitis, sinusitis, dyspnea, pneumothorax, hemoptysis, and conjunctivitis (Fuchs et al., 1994; McCoy et al., 1996).

Anti-inflammatory and antioxidants agents

As CF progresses, pulmonary function declines due to inflammatory response and subsequent tissue damage (Rowe et al., 2005). Thus, therapy with nonsteroidal anti-inflammatory agents (NSAIDs) and corticosteroid gives beneficial outcomes. NSAIDS like propionic acid derivatives (e.g., ibuprofen 20–30 mg/kg twice daily) have been shown to improve disease condition of CF patients with mild type of the disease (Konstan et al., 1995). Ibuprofen gives proinflammatory response at low doses, but is associated with ADRs (e.g., decrease in lung function and kidney injuries) at high doses and consequently increases the lengths of hospital stay (Lahiri et al., 2014; Lands and Stanojevic, 2013). Topical use of corticosteroids (e.g., Leukotriene B4 (LTB4) receptor antagonists) seems to be more beneficial as compared to those formulations, which are designed for systemic use. However, phase II trials were halted due to significant ADRs related to pulmonary exacerbations (PEs) (M. W. Konstan et al., 2014).

Nonpharmacological Management

Chest physiotherapy

This technique is used to drain mucus from five lobes of the lungs. As each position is designed in such a way that a major part of the lung is facing downward, it may be referred to as postural drainage and percussion (Cystic Fibrosis Foundation, 2017a). Devices like drainage tables, electrical and nonelectrical palm precursors, and vibrators are required to carry out this process.

Lung transplantation

It is a surgical procedure in which severely damaged lungs can be replaced with the healthy respiratory organs (Cystic Fibrosis Canada, 2014). Patients have to undergo several pretransplant tests including pulmonary function test, chest and sinus X-ray, arterial blood gas, ventilation-perfusion scan, abdominal ultrasound, blood work, MUGA scan, thallium persantine scan, ECG, bone mineral density scan, 6-min walk test, sputum analysis, and oximetry test.

Supplemental oxygen

Patients with CF may experience hypoxemia either during exercise or sleep (Balfour-Lynn et al., 2005; Urquhart et al., 2005). Supplemental oxygen (1–2 L/min via nasal cannula or 2–4 L/min via venturi mask) may increase daytime function at workplace or school, improve physical function, and decrease mortality rate (Zinman et al., 1989).

Gene therapy

In 1989, the discovery of CFTR gene has brought the expectations that gene therapy could be the new era in CF treatment. In the accomplishment of this goal, two approaches were considered, namely, viral vector and plasmid DNA encapsulated within cationic liposomes. The first method was not widely used due to low transfer efficiency and short retention time within the airways. However, the second approach is giving fruitful results in animal models by correcting CF epithelial chloride transport defect and 100 folds improvement in transfer of genes. UK Gene Therapy Consortium performed phase I clinical trial by using a single dose of PGM169/GL67A. Besides defective CFTR gene, various other genetic factors also impart their role in the pathogenesis of this disease. Therefore, future research is focusing on screening of genetic modifiers.

Cystic Fibrosis-Associated Diabetes

Insulin

Insulin is the drug of choice for CF-induced diabetes mellitus (**Fig. 2**). Insulin not only controls hyperglycemia but also plays an important role in stabilizing respiratory function and nutritional status. **Fig. 2** illustrates the principle for managing CF-associated diabetes mellitus by using insulin therapy. Normally, insulin is required in modest dose (0.5–0.8 units/kg/day) for maintaining the baseline state of health (Sunni et al., 2013). Patients with fasting hyperglycemia are recommended to be managed using basal bolus insulin therapy through insulin pump (continuous subcutaneous infusion) or multiple daily subcutaneous injections (Moran et al., 2010; Nousia-Arvanitakis et al., 2001; O'Riordan et al., 2009b) while in patients without fasting hyperglycemia, pre-meal rapid acting insulin is considered as a standard therapeutic regimen. However, in either case, the goal is to titrate insulin to a highest dose that can be safely tolerated by the patients (Moran et al., 2009).

Cystic Fibrosis-Associated Vitamin Deficiency and Bone Diseases

Multivitamins

Patients with CF often suffer from deficiency of vitamins and essential nutrients. Vitamin D deficiency occurs due to concomitant hepatic disease. Vitamin A deficiency is associated with poor respiratory function, because β-carotene has antioxidant property

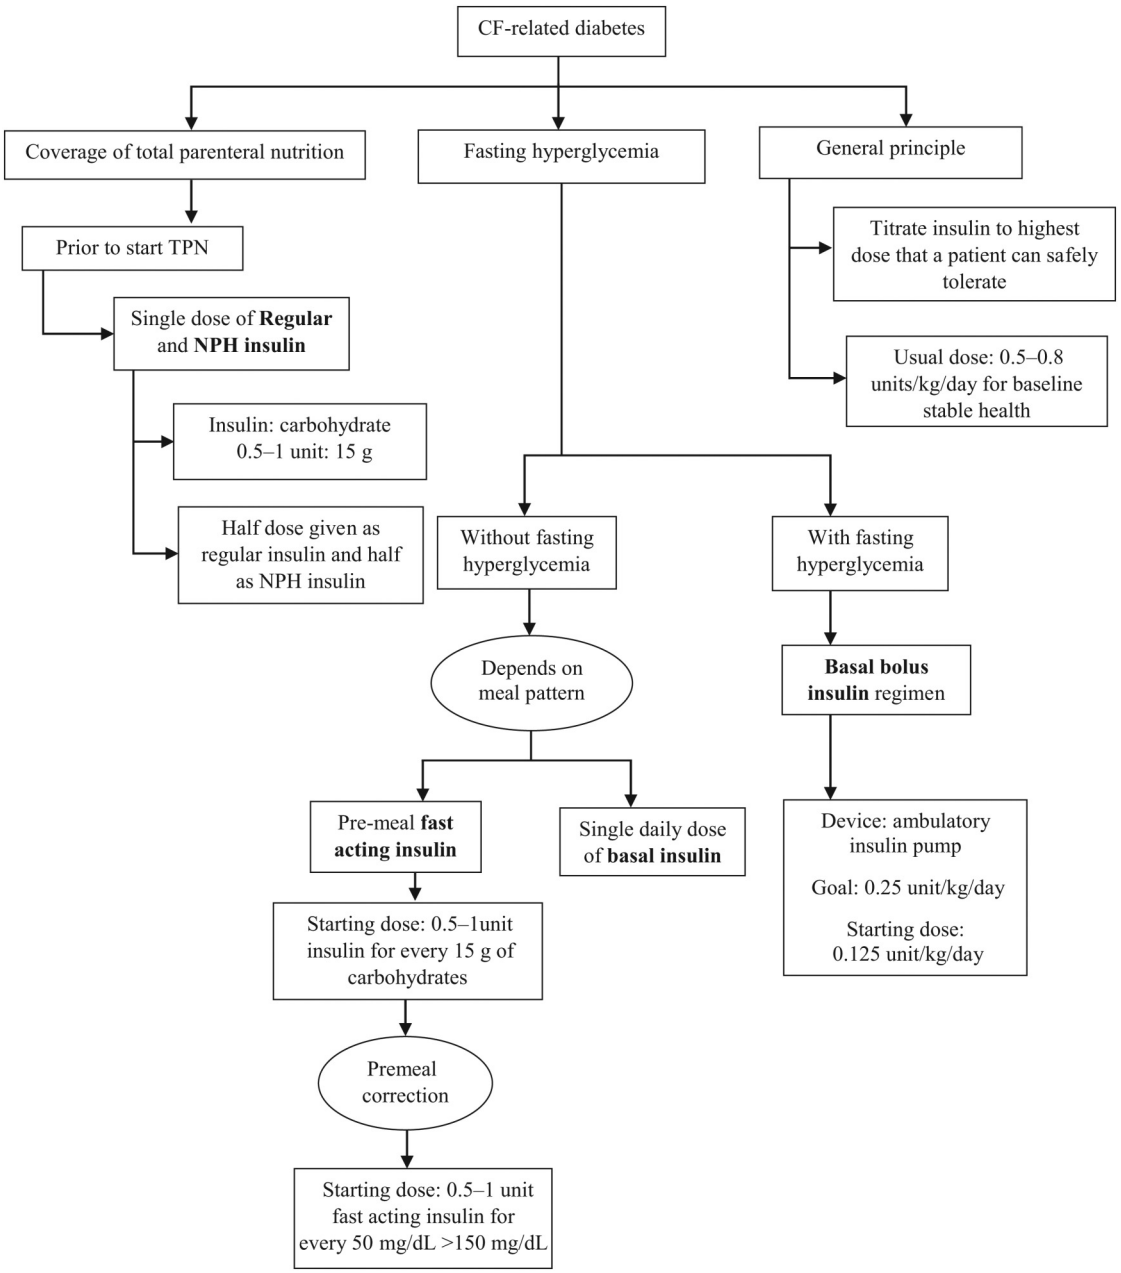

Figure 2 Algorithm for the management of CF-associated diabetes.

and its level becomes very low in patients with CF (Huet et al., 1997; Sinaasappel et al., 2002; Winklhofer-Roob et al., 1996). Similarly, due to increased oxidative stress, the daily requirement of body for Vitamin E also increases soon after birth and consequently gives rise to an impaired secretion of glutathione and low level of selenium (Freedman et al., 2004; Roulet et al., 1997; Thomas et al., 1995). Thus, patients with CF experience an impaired fat metabolism. Irrespective of the pancreatic function, the level of vitamin A and vitamin E must be closely monitored in all patients with CF. Vitamin K is involved in prothrombin synthesis and also acts as a cofactor in the carboxylation of osteocalcin during bone formation. Its deficiency leads to osteopenia especially in CF patients (Aris et al., 2005). The recommended doses of vitamins and calcium supplements for different age groups are outlined in **Fig. 3**.

Moreover, malnutrition, chronic infection, and pulmonary or intestinal bleeding may lead to poor level of serum ferritin, which reflects iron deficiency. Supplements containing iron are not regularly prescribed for patients with CF, because iron acts as an important substrate for the growth of *P. aeruginosa*. Zinc level also decreases and it can be improved by pancreatic enzyme replacement therapy (PERT) (Easley et al., 1998). The daily recommended doses of fat-soluble vitamins and vitamin content in specialty vitamin formulations for patients with CF are provided in **Table 4**.

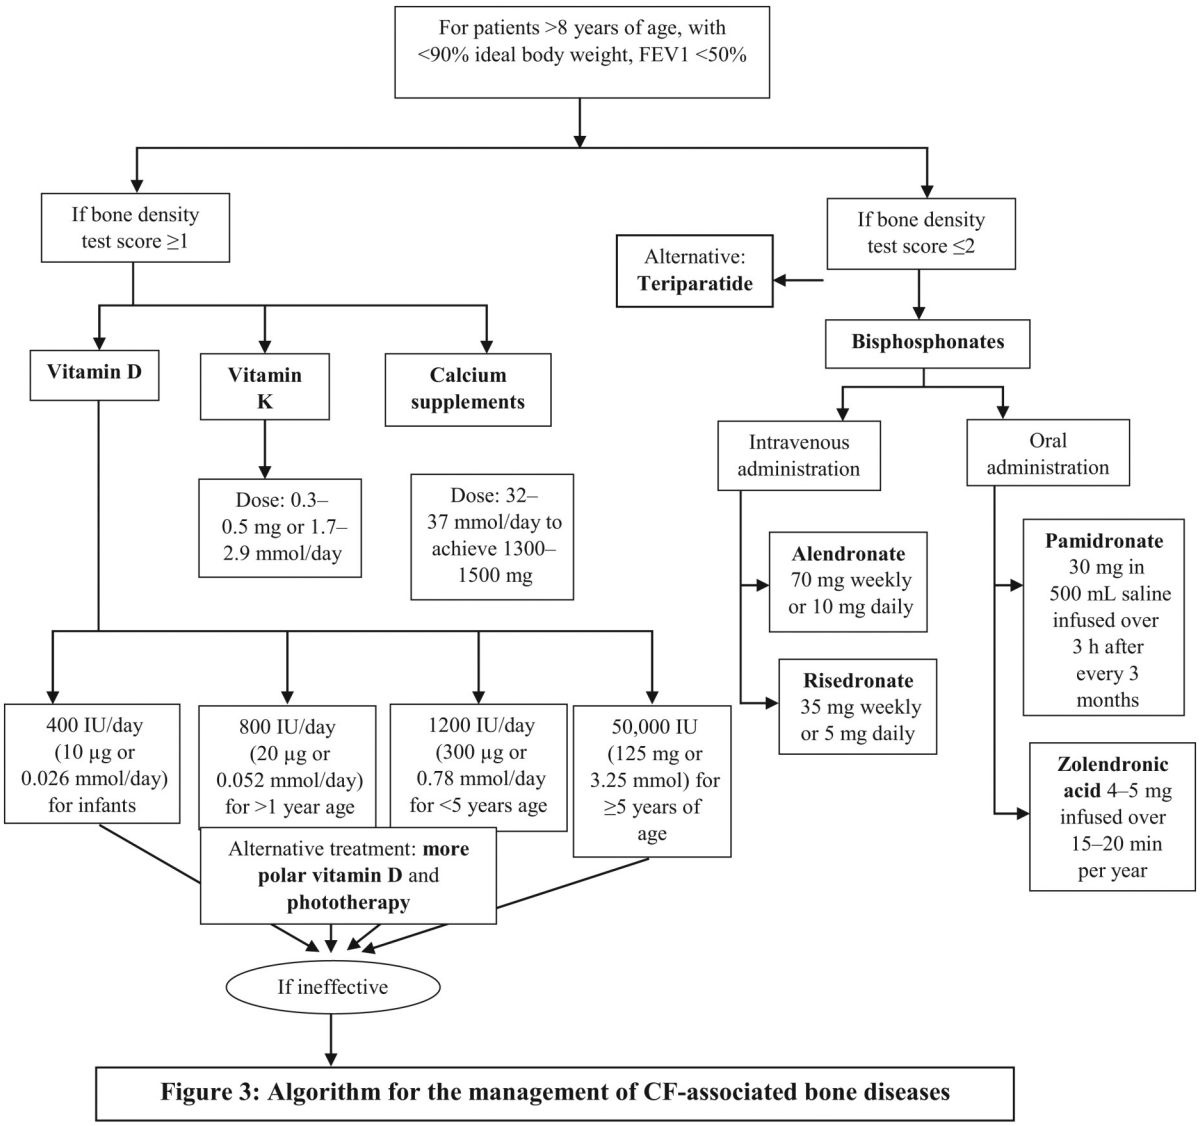

Figure 3 Algorithm for the management of CF-associated bone diseases.

Bisphosphonates

To overcome complications like osteoporosis, bisphosphates are recommended as first-line therapeutic agents for CF-induced osteoporosis (Fig. 3 describes the oral and intravenous administration of bisphosphonates) (Sermet-Gaudelus et al., 2011). This therapy not only leads to a decreased function and recruitment of osteoclasts but also shortens the lifespan of osteoclast and slows down the process of osteoblast apoptosis. However, bisphosphonates have a questionable safety and tolerability; therefore, these can be replaced by teriparatide (Marshall et al., 2014; Neer et al., 2001). If the bone density test score is more than 1, then the CF patients should be prescribed vitamins and calcium supplements (Sermet-Gaudelus et al., 2011).

Prevention of Cystic Fibrosis-Associated Complications

CF is a nonpreventive disease, but its symptoms and other complications can be managed using pharmacotherapy, nutrition, vaccination, exercise, and smoking cessation (B. L. Foundation, 2018). Routine immunization is recommended in children with CF. Influenza vaccine should be administered in children ≥6 months of age. However, it is contraindicated if the child is hypersensitive to egg with the evidence of previous incidence of anaphylactic shock. NHS guidelines suggest that children can receive nasal vaccines in case of mild hypersensitivity (National Health Service, 2018). Since pneumococcus does not have a prominent effect on CF patients, prevnar vaccine is not routinely recommended. Nevertheless, it is a compulsory vaccination course, especially in those pediatric patients (age >5 years) who undergo splenectomy. Furthermore, passive immunization with

Table 5 Major roles of a pharmacist providing care for cystic fibrosis

	Pharmacist's role in the management of cystic fibrosis
1	Counseling of parents on newborn screening
2	Routine review of medications
3	Therapeutic drug monitoring
4	Discussion of patient's medication history
5	Counselling on medication adherence
6	Monitoring the off-label use of medicines in CF
7	Implementation of antimicrobial stewardship
8	Communication with general practitioners and community pharmacists
9	Accessibility of patients towards novel drugs
10	Homecare pharmacy services
11	Medicine information services
12	Reduction in wastage of central intravenous additives
13	Prescription evaluation and dispensing of medicines
14	Medication supplies and cost-effective use of medicines
15	Participation in inpatient ward rounds
16	Medicine optimization and reconciliation

monoclonal antibodies (i.e., Palivizumab) against respiratory syncytial virus (RSV) is available in the market and can be administered intramuscularly five times in a month.

The Role of Pharmacist in the Management of Cystic Fibrosis

CF is a multi-organ system disease that requires multidisciplinary approach for its management. As discussed above, many therapeutic agents are used for the management of CF. Usually, a patient with CF has to take an average of 8–10 medicines on daily basis. It takes an average of 3h to administer this complex medication regimen (Sawicki et al., 2009). As a result, patients experience many problems including nonadherence to drug therapy, therapeutic failure, and poor therapeutic outcomes. Thus, pharmacists can help patients with CF due to their expertise in pharmacotherapy, pharmacokinetics (PK), pharmacodynamics (PD), and drug interactions. In this way, issues such as medication nonadherence, increased incidence of readmission, poor quality of life (QoL), and decreased QALY can be resolved (Prunty and Prunty, 2015). Some of the responsibilities of a CF specialist pharmacist are listed in **Table 5** (Abraham et al., 2018; Mooney et al., 2016).

Counseling of Parents on Newborn Screening

Patients and their families need proper counseling and education at the time of screening and discharge from the health care setting. Newborn screening (NBS) for CF is beneficial for reducing morbidity and mortality associated with CF. Most of the parents support it; however, the psychosocial harm due to NBS process, false positive results, and identification of infant are some of the major concerns. CF centers deal with these issues by giving swift and timely education to improve the impact of diagnosis on the families (Duff and Brownlee, 2008).

Routine Medication Reviews

Patients with CF must actively participate in comprehensive routine reviews of medications. The purpose of CF pharmacist in conducting these reviews is to check medications of each patient and make possible interventions. Philpott et al. reported that a CF pharmacist can make an average of 4.75 interventions per patient and most of these interventions were thought to be significant (Philpott et al., 2007). These interventions may include, but not limited to, changes to inhaled antibiotic formulations, recommending alternative therapeutic agents, and changing the time of administering medications. Review of records such as medication history, patient's most recent clinic visits, and discharge letters is a requisite before conducting the medication reviews. In this way, several issues like irrational prescribing, discrepancies, and nonadherence can be identified and CF pharmacist can discuss these problems during the review process. Problems like poor access to medicines can also be discussed during the review.

Therapeutic Drug Monitoring

Many therapeutic agents such as aminophylline and antifungal agents have to be administered for prolonged period of time among CF patients. A pharmacist can reduce the toxic effects and ensure the safe use of medicines by applying his knowledge of clinical pharmacokinetics (Abraham et al., 2018). The active participation of pharmacist in TDM is associated with: (1) the rapid

achievement of pharmacokinetic and pharmacodynamics targets within short interval of time, (2) increase in frequency of clinical improvement, and (3) a significant reduction in the number of administered doses of drugs, the mean total dose administered, and the alteration of serum creatinine from baseline (Murphy et al., 2007).

Discussion of Medication History with Cystic Fibrosis Patients

CF pharmacist must take medication history from each patient that may include previous medicines, intolerances, and allergic reactions. This discussion enables the pharmacist to include over-the-counter (OTC) drug, and recreational and herbal medicines in the prescription, and counsel the patients about possible ADRs and interactions with other conventional medicines.

Counseling on Medication Adherence

CF is an inexorable disease in which patient's health eventually declines even with complete adherence to therapy. This is because of the fact that its treatment is complex and mostly involves polypharmacy. In order to halt the progression of the disease, it is essential to optimize the patient's adherence by ensuring rational use of resources. In CF, FEV1 and body mass index (BMI) negatively affect the outcome of treatment. The role of a devoted CF pharmacist is to increase patient adherence to treatment. The importance of self-reported adherence has been recognized as a tool to measure medication adherence in routine practice (Mooney et al., 2016). It has also been found that the greater participation of a specialized pharmacist in CF treatment is beneficial in terms of adherence monitoring. On the basis of these findings, CF pharmacist can motivate patients, provide them with the required information, and design strategies to achieve treatment goals. It is also the responsibility of the pharmacist to counsel patients at the time of discharge. Patients must be provided with a list of medicines, purpose, and timings of administration. Pharmacist can communicate with patients about their supply of home medicines. There are circumstances where the patients require fewer drugs (e.g., when they have sufficient stock of medicines at home) or in need of extra supply of therapeutic agents (e.g., when they plan to go somewhere for vocations or work). In this way, the supply given from ward can precisely match with that of the requirements (Redfern and Webb, 2004). A devoted CF pharmacist can assess and monitor the patient's adherence to the dosage form of the drug. She/he may recommend alternative therapeutic agents, change the dosage form, and provide tablet crushers or clutters if needed. Pharmacist can assess the suitability of any therapeutic agent on the basis of patient compliance, and this may be supplied if potential benefits are foreseen. The role of the pharmacist becomes more profound when the patient with CF is a child instead of an adult. It is primarily because of the fact that in such cases, the parents are responsible for managing medications. Thus, the benefits of self-administration schemes are to spread knowledge, autonomy, and make the patient responsible toward therapy of CF.

Monitoring of Off-label Use of Medicines in Cystic Fibrosis

The complexity of CF disease requires the use of therapeutic agents outside their product license. For instance, a novel medication may not have undergone clinical trials, which are prerequisite for gaining the status of being used among pediatric patients, or it may be crucial to alter the dosage form of a drug so that it can be given through an unlicensed route. In this case, appropriate dosing is crucial. Thus, a pharmacist can play a significant role in making these medicines safe and effective by applying pharmacokinetic and pharmacodynamics principles in their formulation. A case study reported the use of posaconazole among CF pediatric patients suffering from allergic bronchopulmonary aspergillosis (ABPA). Although it had not been licensed to be used among patients with CF due to unavailability of data from previously published literature, pharmacist recommended pediatric dosing and evaluated the incidence of ADRs through TDM (Bentley et al., 2015). Furthermore, the limited supply of the unlicensed medicines restricts the physicians to prescribe these agents. In these cases, the CF pharmacist can evaluate the appropriate supply chain (e.g., specialist center or homecare services), which may enable the patients to get their prescribed medicines. The CF pharmacists, especially in those regions of the world where they allow to provide services as independent prescribers, can ensure seamless and timely ongoing supply of medicines to patients.

Implementation of Antimicrobial Stewardship Programs

Antimicrobial stewardship (AMS) program encompasses the selection of dosage and duration of antibiotic regimen for the treatment and prevention of infectious diseases that consequently gives the optimal therapeutic outcomes with limited adverse drug reaction (ADRs) (Gerding, 2001; Leonard et al., 2018). This program is a cascade of interventional strategies for designing the protocols to prescribe antibiotics, improving the rate of antibiotic susceptibilities, and optimizing the cost and utilization of resources across the continuum of care (NICE, 2015). The primary health care provider like pharmacist can play a significant role in this regard (Wickens et al., 2013). Respiratory exacerbations are among the major complications associated with CF; hence, antibiotics especially inhaled formulations are the mainstay agents in reducing these complications and enhancing the longevity of patients with CF (Working, 2009). However, there are several issues associated with the use of aminoglycosides and other antibiotics (Al-Aloul et al., 2005). In such cases, CF pharmacist can design individualized dosing regimens using their knowledge of PK. CF pharmacist is also responsible for observing the process of TDM along with the monitoring of renal, hepatic, blood, and electrolyte indices. CF patients are more prone to antibiotics associated hypersensitivity reactions. It is primarily because of the fact

that antibiotics can give suboptimal therapeutic outcomes in hypersensitive patients (Parmar and Nasser, 2005). Thus, CF pharmacists can identify and document these reactions and recommend alternatives or desensitizing regimens (Dworzynski et al., 2014). In this way, patients can attain optimal therapeutic outcomes with minimal loss of lung functions.

Communication with Community Pharmacists and General Practitioners after the Patient's Discharge from the Hospital

The management of CF in outpatient and inpatient settings requires a multidisciplinary team work because patients suffering from CF are prescribed with many therapeutic agents. Some of these medications are licensed products and are not commonly available. It is the prime responsibility of pharmacists working in CF centers to inform general practitioner and community pharmacist about change in treatment regimen of patients (Smith et al., 2010). Thus, the liaison of CF pharmacist with community pharmacist, clinical commissioning pharmacist, and general practitioner is beneficial in preventing delays to patients receiving their medicines and thus ensuring patients' safety and convenience (O'Riordan et al., 2009a).

Accessibility of Patients Toward Novel Drugs

The inequitable access of novel agents like gene-specific medicines has not only made the treatment regimen complex for CF patients but also economically burden the health care system (Helman, 2007). CF pharmacist is responsible for implementing patient access schemes, formulating guidelines, spreading awareness among patients, and health care professionals about beneficial aspects of optimal delivery of novel drugs, monitoring the adherence and outcomes of these agents, identifying eligible patients that can be treated under local funding agreement (Bucks et al., 2009). Thus, CF pharmacist is liable to gather information about specification of services, funding agreements, and patient's registry data. In this way, proper allocation of budget can be made possible without wastage of resources.

Homecare Pharmacy Services

It is the responsibility of the pharmacists and their coworkers to ensure proper access of therapeutic agents to the patients. The inaccessibility issues arise after the discharge of CF patients from health care settings especially when they are prescribed with orphan drugs. To resolve this issue, there are several homecare companies that provide home delivery services of therapeutic agents to the patients (Fajolle et al., 2004). The pharmacist is responsible to complete the process of registration, supply of prescriptions and liaise with homecare companies regarding delivery of medication and solve the problems of patients when required.

Medicine Information Services

The medication information services must be made available to all CF patients through email or telephone. Pharmacist must educate the patients about their newly prescribed agents, drug–drug interactions, and drug–food interactions (Kerem et al., 2005). This service must be supervised by those pharmacists who are specialized in medication information and work in collaboration with CF pharmacist. Although health care providers can be contacted for attaining medicine information, it is recommended that CF pharmacist must be contacted first (Conway et al., 2014).

Reduction in Wastage of Central Intravenous Additives

The availability of CF pharmacists in units and their active participation in ward rounds is mandatory in reducing the wastage of central intravenous additives (CIVA). Moreover, if the decisions about discharge of patients or change in therapeutic regimen are quickly communicated to the central pharmacy aseptic area, then the medication order can be canceled or changed. In this way, a considerable amount of money can be saved (Fajolle et al., 2004). There are several issues on which the longitudinal studies must be carried out and these mainly include (1) cost-effective analysis before and after the appointment of a devoted CF pharmacist, (2) comparison of outcomes when the pharmacist is available with those when the pharmacist is not available. It was predicted that CIVA wastage per week was reduced from £324 to £30 when the pharmacist was made available. Thus, the potential saving on CIVA is £16,848 annually (Redfern and Webb, 2004).

Medication Supplies and Cost-Effective Use of Medicines

Although the provision of optimal care to the patients can never be compromised while practicing cost-saving strategies, the wastage of health resources must be kept minimum (Institute of Medicine, 2003). Also, medicines free from value-added tax (VAT) can only be dispensed in the community pharmacies because hospitals are not able to pass on VAT to the patients. Thus, the CF pharmacists must encourage the prescribers to prescribe those medicines that can be dispensed in community pharmacies (Redfern and Webb, 2004). In this way, VAT on the expensive medicines can be reduced to a greater extent. It is the duty of pharmacist to reduce the issues of drug supply. The communication between manufacturer and purchaser can be useful in maintaining a constant supply of CF medicines (Narayana et al., 2014).

Participation in Inpatient Ward Rounds

A devoted CF pharmacist can play a vital role in various aspects during the ward rounds which are as follows:

1. He/she can help the physicians in making decisions about therapeutic regimen.
2. He/she can resolve various pharmaceutical problems that may arise due to the involvement of multidisciplinary team.
3. He/she can monitor the upgradation and maintenance of medication records.

Prescription Evaluation and Dispensing of Medicines in Cystic Fibrosis Centers

In CF centers, there is a limited availability of facilities like medicine dispensing. The limited prescriptions must be supplied by the dedicated CF pharmacist who is knowledgeable and experienced in providing services to the CF patients. In this way, number of queries regarding CF medication can be minimized to a greater extent (Moran et al., 2010). This method also ensures that counseling is provided particularly to the patients with respect to the ADRs of therapeutic agents, time of administration, and drug interactions. There is limited opportunity available for the pharmacist to dispense on the unit. However, a devoted CF pharmacist checks the prescription for legibility, completeness, and drug interactions before sending it for dispensing in the main pharmacy. Thus, the process of dispensing speeds up in the main pharmacy area. But such services are not widely available in all health care settings. The presence of a devoted CF pharmacist in the health care centers is acknowledged by many patients and some patients now make requests to see the CF pharmacist for medication advice during clinic visits (Tobacco, 2008).

Medicine Optimization and Reconciliation

It is a patient-centered approach to ensure the rational use of medicines. It is applicable to all patients whether they may or may not be able to take their medicines effectively (Cutler et al., 2011). This can be done retrospectively by using patient's data from the records of inpatient admission, annual reviews, and clinic attendance. The prime focus of this technique is to monitor the patients' adherence toward the prescribed therapeutic regimens and avert the medication errors and possible ADRs (Barton, 2009). A devoted CF pharmacist can counsel patients about the purpose of medication, administration technique, rational use of medicines, storage of drugs, expiry date of medicines, common ADRs, and the ways through which medicine related problems can be subsided. This will help the pharmacists in developing longstanding professional relationship and gives the opportunity to the families to resolve their medication-related doubts (Thomspon et al., 2015).

Management of Gastrointestinal Disorders and the Pharmacist's Role: Coeliac Disease

Wendy Stuart-Smith*, Kim Faulkner-Hogg†,‡, *Charles Perkins Centre, University of Sydney, NSW, Australia; †Gluten-Free Nutrition, Private Dietetic Practice, Sydney, NSW, Australia; ‡Allergy Unit, Royal Prince Alfred Hospital, Sydney, NSW, Australia

Learning Objectives

- Develop an understanding of the role of gluten in coeliac disease and the similarities and differences between this and other syndromes/symptoms associated with wheat/gluten ingestion.
- Develop an ability to recognize the main clinical presentations of coeliac disease.
- Confidently encourage members of the public to seek appropriate diagnosis of wheat/food reaction suspicions, as symptoms may have many etiologies.
- Development of an understanding of the Australian labeling laws regarding gluten and put this in context of labeling in other parts of the world.
- Develop an increased awareness of the sources of gluten in the pharmaceutical area, and when this may be an issue.

Take Home Messages

1. Coeliac disease affects greater than 1 in 100 people in Australia. Much of this goes unrecognized. Untreated coeliac disease may lead to osteoporosis, anemia, certain mental health conditions, infertility (female), and results in an increased risk of bowel cancer. On the other hand, many people unnecessarily follow gluten-free diets with potential long-term adverse health consequences given they often do this without consideration for dietary guidelines, resulting in a diet which may be inadequate in one or more key nutrients.
2. Should coeliac disease be suspected, the person should remain eating gluten and undergo a blood screening test for the condition. If the blood test is positive, a small bowel biopsy is required to confirm the diagnosis. This is the gold standard encouraged by gastroenterologists and other doctors specializing in coeliac disease in Australia.
3. Coeliac disease and dermatitis herpetiformis (a related skin condition) both require strict, lifelong avoidance of gluten, regardless of the presence OR absence of any symptoms.

4. There are a number of other wheat-related medical conditions. It is important to understand the nature of the particular condition under discussion, as this will determine how strictly gluten needs to be avoided. Of these, wheat/gluten intolerance would be the most frequently discussed with the Pharmacist. The mechanism to date is unclear, but may be due to a low tolerance to gluten; indigestible fructo-oligosaccharides (fructans); or to other components of wheat or indeed other grains or foods. Management of these issues is to determine tolerance thresholds for symptoms rather than strict food avoidance, and should only be done in consultation with a Dietitian, as it may not be a component of wheat which is causing the symptoms. It may be other components of the foods in which wheat is consumed, as wheat is not normally eaten in isolation.
5. There are different food standard requirements surrounding allowable concentrations of gluten in food labeled gluten-free, depending on the country where it is made. This will affect both food and pharmaceuticals which may be perceived as acceptable for someone with coeliac disease, as well as what can be sold as gluten-free in Australia.

Introduction to Condition

Whilst this chapter is primarily about coeliac disease (CD), this chapter will take a slightly different tack to some other chapters and will consider some of the common conditions which may present in a similar way to CD and provide context to an understanding of some of the issues around it.

There is in fact, no medication to be prescribed for this condition, management to date being diet alone. However, there are two major issues which the Pharmacist may encounter when assisting a person with CD or suspected wheat reactions. In the first instance the Pharmacist must understand the myriad conditions that may mimic CD and counsel clients to seek an appropriate diagnosis for their suspected wheat reactions.

Self-reported wheat intolerance has increased significantly over the past 10–15 years (Hischenhuber et al., 2006), with these people generally attributing decreased quality of life to gluten- or wheat-induced intestinal and extraintestinal symptoms (Golley et al., 2015). Coeliac disease, Non-Coeliac Gluten Sensitivity (NCGS), Dermatitis Herpetiformis (DH), Wheat Allergy (WA), or Wheat-Dependant Exercise-Induced Anaphylaxis (WDEIA) are all conditions associated with reactions to wheat and or gluten (Pietzak, 2012).

These reactions may be caused by a variety of wheat fractions. In CD, this is the result of gluten (Rubio-Tapia et al., 2013) from wheat, rye, barley, and to a lesser degree, oats (Hardy et al., 2015). Omega-5-gliadin (Palosuo et al., 2003) from wheat may cause WDEIA, while α-gliadin and α-amylase inhibitor (Maruyama et al., 1998; Palosuo et al., 2001) are major wheat allergens. Irritable bowel syndrome (IBS) may be provoked by gluten (Di Sabatino et al., 2015) from gluten-containing grains, or fructo-oligosaccharides (Biesiekierski et al., 2013) from wheat and other foods, or by other food compounds (Faulkner-Hogg et al., 1999).

Given the range of conditions associated with wheat, the pharmacist needs to understand that the diagnosis and management of each condition is unique to that condition. It is therefore crucial to understand the implications in terms of avoidance or exposure to gluten.

The second major role for the pharmacist is ensuring appropriate medications for those with CD, as medications for other conditions may contain gluten as an excipient. It is important to recognize where these small amounts of gluten really are a problem and where they are not.

This chapter will briefly explore other wheat/gluten-related conditions to provide a framework for understanding the management of those with CD and then provide an understanding of the role of the pharmacist within the wider health team of affected people.

Disease/Condition Information

When considering gut symptoms, a pharmacist will most likely find themselves discussing the symptoms suggestive of either CD or wheat intolerance. It is vital that a suggestion to trial gluten avoidance is NOT made, but rather the person is encouraged to pursue a correct diagnosis for their symptoms as current consumption of gluten is foundational to testing outcomes for CD and DH. More information on these two conditions is provided in this section.

Coeliac Disease Epidemiology

Well-known CD researcher, Alessio Fasano has described CD as "one of the most frequent genetically based diseases of humankind" (Fasano, 2003). It is understood that 99.6% of people with CD carry one or more of the human leukocyte antigens, HLA-DQ2 or HLA-DQ8 genotypes (Karell et al., 2003). Anderson estimates that approximately 55% of Australians have one or both of these genes (Anderson et al., 2013). Although roughly 30% of the world's population have these genes, only about 3% of those go on to develop CD (Green and Jabri, 2006). First degree relatives of someone with CD have a 10%–20% increased risk of developing CD (Ludvigsson et al., 2014; Rubio-Tapia et al., 2013).

The prevalence of CD has increased fourfold since the 1950s (Barbero et al., 2014). Today, it is believed that CD occurs in approximately 1% of populations in developed countries. It is estimated that 1 in 80 males and 1 in 60 females in Australia have CD, while Scandinavia and Ireland have the highest global prevalence at 3%. It is quite rare in Asia and Japan, occurs in

approximately 1 in 300 in Germany, and is considered to be common in North Africa and parts of the Middle East (Barbero et al., 2014; Fasano, 2003). It is thought that 80% of Australians who have CD remain undiagnosed (Anderson et al., 2013), leading to a lower quality of life (Gray and Papanicolas, 2010), and the implication of potential future medical issues beyond those mentioned above, due to the malabsorption of nutrients and resulting nutritional deficiencies, even in the presence of what appears to be an adequate diet.

Etiology

Wheat/Gluten-Related Conditions that may be Mistaken for Coeliac Disease

Before discussing the etiology of CD, it is important to have an understanding of conditions that may present in a similar manner to CD. The etiology and management of each of these conditions is uniquely different, and for some of the conditions, failure to appropriately manage the condition may result in a severe reaction or long-term negative health consequences.

Irritable bowel syndrome

Wheat and its components, including gluten, fructo-oligosaccharides, and potentially a number of other compounds, are implicated in provoking IBS symptoms for some people. Fructo-oligosaccharides are also known as fructans—one of the components of FODMAPs [Fermentable oligo-, di-, mono-saccharides and Polyols], a group of short chain sugars that may result in lower gastrointestinal symptoms in susceptible people (Biesiekierski et al., 2013). Specific food intolerances related to IBS and other functional gastrointestinal disorders are idiosyncratic, and there are other food components that may be implicated beyond those under discussion here. Ingestion of wheat and gluten-containing foods in IBS and NCGS does not damage the small intestine but may lead to a range of both intestinal and extraintestinal symptoms. Currently, there are no known diagnostic biomarkers and reduction in wheat/gluten intake, not total avoidance, is suggested for affected individuals.

Food is a complex cocktail of chemicals, and beyond those in wheat itself, natural and added chemicals such as salicylates, amines, glutamates, colors, flavors, and preservatives are also found in many processed wheaten products or foods eaten with wheat, each of which may cause similar symptoms in susceptible people (Faulkner-Hogg et al., 1999).

A formal, structured assessment, followed by a strict elimination diet and systematic challenge protocol should be undertaken under the supervision of an appropriately trained and experienced accredited practicing dietitian (APD) to determine the etiology of any food-related symptoms, and this only after appropriate medical diagnosis to rule out other conditions. An APD will also monitor intake to encourage nutritional adequacy throughout the process. Because of the complexity of food and diet, mistaken attribution is common, and often results in inappropriately restricted diets.

Wheat allergy (IgE-mediated) and wheat-dependent exercise-induced anaphylaxis

There are diagnostic indicators for both wheat allergy and WDEIA (Palosuo et al., 1999, 2001). No damage to the small bowel occurs in either condition. True IgE-mediated wheat allergy tends to be seen in babies and children, presenting with fast-spreading hives/rash, eczema flares, nausea, or vomiting closely following wheat ingestion (Keet et al., 2009). Anaphylaxis is rare, but possible, in this group. Clinical history combined with skin prick tests (SPTs) are used by suitably trained doctors to diagnose a wheat-allergic sensitization. Dietary wheat (not gluten) avoidance is often total when quite young and moderated a little as the child ages, based on subsequent testing and food challenges.

WDEIA is rare and is most commonly found in those working in the beauty industry, where sensitization can occur through damaged and abraded skin. The first presentation of WDEIA occurs mostly in young to middle-aged adults who develop symptoms when they exercise following a meal containing wheat. Symptoms include hives, flushing, nausea, and diarrhea, which may progress to more severe symptoms including angioedema, laryngeal edema, and hypotension, leading to anaphylaxis (Palosuo et al., 1999). Wheat/gluten avoidance is personalized for these people as symptoms severity which relates to exercise intensity and timing after eating wheat, varies from person to person. SPTs are not always positive to wheat, and omega-5-gliadin blood tests are positive in about 80% of those with WDEIA (Matsuo et al., 2008; Palosuo et al., 2003). Some allergists may perform, under supervision, wheat food provocation tests. An epipen is often prescribed. It should be noted that exercise-induced anaphylaxis may occasionally be caused by other food proteins.

Etiology of Coeliac Disease

CD is caused by a complex immunological T-cell response provoking damage to the villi in the small bowel in genetically susceptible people of all ages, by the gluten portion of grain proteins found in wheat (Ludvigsson et al., 2014; Rubio-Tapia et al., 2013), spelt, triticale, rye, barley, and, controversially, oats (Hardy et al., 2015). This small intestinal inflammatory disease was traditionally recognized by its gastrointestinal symptoms and nutritional malabsorption outcomes, such as failure to thrive in children. Today, however, its wide range of presentations see it classified as a multiorgan autoimmune disease, which engages the attention of doctors of many specialties. Undiagnosed CD carries significant potential for future medical complications. CD is also associated with numerous other autoimmune conditions, including autoimmune thyroid disease and type 1 diabetes.

For unknown reasons, in some people with susceptible genotypes, the immune system develops a reaction to gluten leading to inflammation, along with an increase in the number of intraepithelial lymphocytes and the destruction of the villous architecture of the small intestine. Enzymes and helper molecules, generally found on the villi, which aid the absorption of nutrients, are then lost. Malabsorption and nutritional deficiencies ensue and are responsible for many of the presentations of CD.

Table 1 Gluten proteins at the molecular level (Shewry and Tatham, 1990; Thompson, 1997)

	Gluten proteins		
	Prolamin	*% of PROLAMIN in the protein*	*Glutelin*
Wheat	Gliadin	40%–50%	Glutenin
Rye	Secalin	30%–50%	*Rye* glutelin
Barley	Hordein	35%–45%	Hordenin
Oats	Avenin	5%–15%	*Oat* glutelin

Gluten (Haraszi et al., 2011; Shewry and Tatham, 1990), which triggers the process, is not a single molecular structure, as it consists of two protein subfractions: a prolamin and a glutelin. The chemistry of each protein subfraction varies with the different grains. The wheat prolamin is called gliadin, and the wheat glutelin is called glutenin. The gliadin is further subdivided into alpha, beta, gamma, and omega gliadins. The alpha-gliadin is purported to be the most damaging to the small bowel; however, damage can occur with any gliadin or glutenin fraction (**Table 1**).

These protein subfractions are also found in rye and barley. The chemistry in each is slightly different, yet similar enough to provoke damage in the small intestine. On the other hand, oat gluten, called avenin, is significantly different from other forms of gluten, does not contain gliadin-like chemistry, and poorly activates disease (Comino et al., 2011).

The gluten (wheat, rye, barley, but not oats) prolamin portion is rich in the amino acids glutamine and proline. The spacing of these amino acids determines deamidation (Schuppan et al., 2009). For a reaction to occur (**Fig. 1**), tissue transglutaminase (an intracellular enzyme) needs to be extracellular, and gluten needs to be present. It is postulated (Schuppan et al., 2009) that during mechanical or chemical injury or during infection, tissue transglutaminase (tTG) is released from damaged cells and then when dietary gluten peptides reach the subepithelial connective tissue, a reaction could occur. tTG recognizes the spacing between the glutamines and the prolamins on the undigested gliadin and binds to it. The deamidation of the glutamine to glutamic acid creates a negatively charged protein, which enhances its binding via antigen-presenting cells to the HLA-DQ2/HLA-DQ8 molecules. These then display the resulting complexes to other immune helper T-lymphocytes. This triggers a twofold T-cell response. Some cause mucosal destruction leading to villi blunting, and others lead to the production of antibodies to the gliadin (anti-gliadin antibodies) and to tTG (anti-tTG antibodies). Both antibodies are used to screen for CD.

Many people with undiagnosed CD spend years seeking help for mild abdominal symptoms or complaints such as chronic tiredness and fatigue. It has been suggested (Brown, 2012) that classic gastrointestinal presentations such as nausea, vomiting, steatorrhea, diarrhea, bloating, and wind now make up less than 50% of those with CD. Roughly 20% are thought to be asymptomatic, and greater than 50% have weak GI symptoms or extraintestinal manifestations of CD.

Positive serological screening tests for CD require confirmation (Husby et al., 2018; Ludvigsson et al., 2014; Rubio-Tapia et al., 2013) by a duodenal biopsy and, if confirmed, significant, (often ongoing) education, monitoring, and support from a

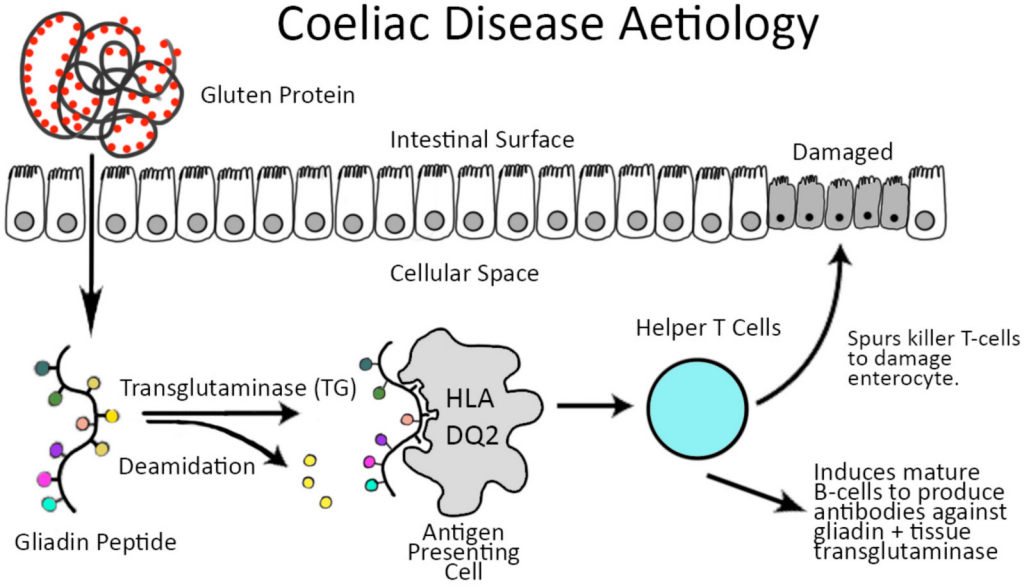

Figure 1 Aetiology of small mucosal injury from gluten in coeliac disease.

Table 2 The National Institute for Health and Care Excellence guidelines suggest testing for CD in these patient groups (National Institutes of Health Consensus, 2005, p. 54).

Offer serological testing for CD to these	*Consider serological testing in these groups*
First degree relatives of people with CD People with any of the following • persistent or unexplained abdominal or gastrointestinal symptoms • prolonged fatigue • faltering growth • unexpected weight loss • severe or persistent mouth ulcers • unexplained iron, vitamin B12 or folate deficiency • type 1 diabetes, at diagnosis • autoimmune thyroid disease, at diagnosis • IBS (in adults)	• metabolic bone disorder (reduced bone mineral density or osteomalacia) • unexplained neurological symptoms (particularly peripheral neuropathy or ataxia) • unexplained subfertility or recurrent miscarriage • persistently raised liver enzymes with unknown cause • dental enamel defects • Down's syndrome • Turner's syndrome

CD, Coeliac disease; *IBS*, irritable bowel syndrome.

specialist dietitian. Patient motivation is crucial, referral to Coeliac Australia is strongly encouraged and medical follow-up is also required (**Table 2**).

Currently, the sole treatment for CD is a lifelong gluten-free diet. Adherence to this is expected to improve not only symptoms, nutritional status, and small bowel villous damage but also to decrease risks from long-term medical complications of gluten ingestion, including infertility, osteoporosis, anemia, gastrointestinal cancers, and reduced life expectancy (Irvine et al., 2017). For these reasons, strict adherence to the gluten-free diet is essential for those with CD.

Dermatitis Herpetiformis (DH) (Cardones and Hall, 2012) is an uncommon skin disease characterized by eruptions of itchy blisters typically in the area of the elbows, knees, and buttocks. It is rare to have DH without having malabsorptive signs of CD (>10%) (Ludvigsson et al., 2014), so patients are advised to undergo testing for CD, if this has not been done. About 25% have normal villi, with increased intraepithelial lymphocytes (Ludvigsson et al., 2014). In many, the bowel symptoms experienced are not as severe, or are silent and there seems to be milder small bowel biopsy changes. The onset of DH is seen more often in people between the ages of 30 and 50 years (Ludvigsson et al., 2014). It is rare for children to have DH, and it occurs more frequently in males than in females, while CD occurs more frequently in females. DH is initially treated with dapsone, which the patient is weaned off over a 2-year period, as the gluten-free diet takes over the management (Ludvigsson et al., 2014). Pharmacists should seek further information on pharmaceutical management of DH as this is beyond the scope of this chapter.

Diagnosis

Symptom response to a gluten-free diet should not be used to diagnose CD, as this does not differentiate CD from IBS or NCGS, nor does it drive home to the patient the significance of CD and the importance of the gluten-free diet to their overall health.

An accurate diagnosis of CD should be established before commencing a life-long gluten-free diet. Coeliac-specific serology and mucosal villous damage need to be evidenced, and these will wane with time on a gluten-free diet.

Blood tests can only screen for the disease, not diagnose it. IgA antibodies to tTG are serological markers with very high sensitivity and specificity, used to screen for CD (Ludvigsson et al., 2014; Rubio-Tapia et al., 2013). People who are IgA-deficient have an increased risk for CD, so IgA testing is used to identify these people, and IgG markers are utilized instead. Many combined IgA/IgG tTG tests are performed.

Gluten must be currently consumed in the diet in order to diagnose CD. The duodenal biopsy remains the gold standard for diagnosis of adults, but there may be circumstances where the blood tests may be used to diagnose CD in children (Husby et al., 2018; Ludvigsson et al., 2014; Rubio-Tapia et al., 2013). The diagnostic process involves 3 steps, and it is essential that significant gluten is in the diet for parts 1 and 2.

If the person has a gluten-free or almost gluten-free intake, and is reluctant to return gluten to the diet, a blood test can be performed to determine if they carry the gene/s associated with CD. The main role for this serogenetic blood test is to rule out CD or make it highly unlikely, given the low chance that someone without these genes will develop CD (Husby et al., 2018). If the tests show that the patient carries one or both genes, the only way to diagnose the disease is to add gluten back to the diet for a period of time, then proceed with the testing as described below.

Gluten loading

It is imperative to ensure adequate gluten is in the diet prior to testing for CD. If the person is already on a gluten-free diet, Coeliac Australia recommend the consumption of four slices of wheat bread each day for at least 6 weeks before testing is performed (Coeliac Australia, 2017). Be aware that quantities and length of ingestion time vary around the world (Husby et al., 2018). Once adequate gluten has been consumed, diagnostic testing may proceed.

Some knowledge is required of gluten ingredients to estimate whether enough pretest gluten is being eaten, and a consultation with a dietitian familiar with the requirements will ensure this is understood by someone intending to undergo testing. Wheat flour products, such as bread, pasta, biscuits, cake, and pizza, are the preferable form of gluten. Spelt, rye, and barley products could also be eaten. Oats should not be used as the major source of gluten, because avenin is thought to activate the disease process in only about 5%–8% of people with CD (Comino et al., 2011; Hardy et al., 2015). The residual gluten alone in wheat starch, wheat thickeners, beer, or malt will not reach the required levels of gluten to stimulate villous changes in the majority of people. Wheat-derived glucose syrup and dextrose can be safely consumed by those with CD so will not contribute to the gluten load.

Diagnosis steps (Husby et al., 2018)

1. Coeliac-specific blood antibody tests
    a. Total Ig A
    b. Tissue transglutaminase IgA & IgG (tTG)
    c. Deamidated gliadin peptide IgA & IgG (DGP)
    d. +/− Endomysial antibodies (EMA)
    e. +/− Serogenetic tests (HLA-DQ2 and HLA-DQ8) (if not done earlier)
2. If antibodies are positive, a small bowel biopsy looking for villous damage is required
    a. Entails a day stay hospital procedure with a gastroenterologist
3. Follow-up biopsy 12–18 months after being on a gluten-free diet
    a. Improvement in the villi confirms the diagnosis

Serogenetic tests

Serogenetic tests determine whether or not the patient carries either or both of the HLA-DQ genes associated with CD. Gluten does not need to be in the diet to conduct this test, and buccal swabs can be offered to young children in order to collect the DNA. As previously mentioned, this test cannot diagnose CD (Husby et al., 2018) as it only screens out those who will *not* have CD, as the absence of HLA-DQ2 and HLA-DQ8 virtually excludes it. Testing for these genetic alleles, in those on self-imposed gluten-free diets, can better define which patients will be required to load gluten back to the diet to undergo usual coeliac-specific antibody tests and which do not.

Coeliac-specific blood antibody tests

- The IgA versions of the tests are preferred. Total IgA is ordered to ensure that the tests are properly interpreted. IgG versions are used in those IgA deficient.
- EMA is the best test but is expensive and not frequently ordered in Australia.
- tTG may be slightly raised for reasons other than CD, so small deviations from normal should not be interpreted as CD. If it is significantly higher than the reference range, this should generate a referral for a small bowel biopsy. This test is considered unreliable in children under the age of five, as their antibodies can fluctuate due to their developing immune system. It is suggested that tests in this age group are repeated 3 months apart (CoeliacAustralia, 2017).
- DGP is thought to be more reliable in the under 5 age group, but not as good as tTG in those over 5.

With concession to exceptional circumstances in some children (Husby et al., 2018), if antibodies are significantly raised, the patient should always be referred to a gastroenterologist for a small bowel biopsy (Ludvigsson et al., 2014; Rubio-Tapia et al., 2013) to diagnose CD.

Clinical Presentations

Clinical presentations of CD are varied, and these days, not often seen is the skinny pot-bellied child, which may have come to mind a number of years ago. Many of the symptoms may be typical of other conditions and diagnosis often now occurs as an adult. Thus, careful investigation is crucial for early diagnosis. **Table 3** outlines the main presenting symptoms of CD.

Management of Coeliac Disease

Place of Pharmacotherapy in Treatment Options

Currently, the only treatment for CD is a strict gluten-free diet. At this time, there are no medications or medical adjunct therapies for this condition. As such, there is no direct pharmacotherapy related to CD. Without hesitation, pharmacists should encourage all

Table 3 Possible disease presentations, or risks of untreated disease (Brown, 2012).

Malabsorption:
- Anemia
- Fatigue or weakness
- Reduced bone mineral density
- Osteoporosis/osteopenia
- Short stature
- Muscle cramps
- Arthritis/bone or joint pain
- Dental enamel defects
- Easy bruising
- Weight loss
- Failure to thrive in infants and children

Gastrointestinal:
- Increased risk of malignancy of the GI tract as well as non-Hodgkin lymphoma
- Nausea
- Wind
- Bloating
- Abdominal pain
- Constipation
- Vomiting

Reproductive: in women only
- Late menarche
- Early menopause
- Infertility
- Miscarriages

Neurological disorders:
- Depression
- Concentration and memory problems (brain fog)
- Decreased school performance
- Headache or migraine
- Mood swings or depression
- Cerebral ataxia
- Seizures
- Early onset dementia
- Peripheral neuropathy

Other
- Heart: Carditis
- Renal: IgA nephropathy
- Liver disorders
- Refractory coeliac disease

Skin:
- Dermatitis herpetiformis
- Hair loss
- Apthous mouth ulcers

clients with this diagnosis to consult a dietitian who specializes in this area if they have not already done so, as management is not only about what to avoid but also what to include in the place of gluten, to ensure nutritional adequacy.

To assist those with CD, local dietitians, skilled in the management of CD, can be found via the Dietitians' Association of Australia (DAA) website (https://daa.asn.au/find-an-apd/) on the "how to find an Accredited Practicing Dietitian" page or direct the person to the DAA website. In Australia, it is imperative that the nutrition health professional consulted carries the accredited practicing dietitian (APD) status, as these people hold appropriate qualifications to adequately assess and provide education and support for people with clinical conditions such as CD. They have university qualifications in nutrition and dietetics and have undertaken their training in a course accredited by the Dietitians' Association of Australia. Only an APD can provide a Medicare rebate with a care plan from their doctor. In other countries, a similarly suitably qualified nutrition professional should be consulted.

While there is no pharmacological management of CD per se, the pharmacist has a vital role to play when a person with CD has other comorbidities requiring medication. While vitamin and mineral supplementation is generally not recommended for the general public, except in certain disease states, at least in the short term, someone diagnosed with CD may be prescribed vitamin and/or mineral supplementation. It is essential for the pharmacist to ascertain that every medication, vitamin, elixir, or jelly bean/lolly sold to them for their use is gluten-free. If the pharmacist is suggesting alternate prescription brands to that being prescribed by the doctor, it is vital that only gluten-free generic brands be offered.

Pharmacological Management

In order to ensure all medications are strictly gluten-free for CD patients, it is vital that the pharmacist has an excellent understanding that the moniker "gluten-free" means different things in different countries according to food labeling regulations. "Gluten-free" refers to a legislated amount of gluten that may be present in a food or product labeled as such. It does not mean zero gluten. Australia has the strictest gluten-free standard in the world. Products declaring themselves to be gluten-free which do not originate in Australia are required to meet the Australian gluten-free standard if they are to be sold here using the "gluten-free" label. This will impact baby formulae, specialized foods and vitamins, minerals and medications sourced from overseas companies.

To call a product gluten-free in Australia, The Food Standards Australia New Zealand mandate that the product must not contain malt, oats, or ingredients derived from them, and it can contain no detectable gluten (FSANZ, 2017). This came into effect in 1994. Assays to detect gluten have become more sensitive so products once called gluten-free (previously up to 30 ppm gluten) may no longer carry the gluten-free label. Currently, the best ELIZA test can detect gluten to levels of 2–5 ppm (Mendez et al., 2005;

Table 4 Symbols used in Coeliac Australia's Ingredient List Phone App here (Coeliac Australia, 2017)

	"Ingredient list" symbols	*Can be eaten by people with coeliac disease*
✓	Gluten-free (GF)	Yes
☑	No detectable gluten even if wheat derived	Yes
✘	Contains detectable gluten	No

Sharma, 2012) and in Australia the current gluten-free limit is 3 ppm (FSANZ, 2017). Australia also has a "low gluten" food standard, allowing a food to contain oats, malt, and up to 200 ppm of gluten. It is rare to see this food label, and these foods are not recommended for people who have CD. They are considered suitable for consumption by those with a wheat intolerance.

The European Codex Alimentarius, and both the United States and Canadian food standards differ in their wording, yet all agree that products that contain up to 20 ppm of gluten can be labeled gluten-free. These nations accept the current research that approximately 50 mg of gluten daily needs to be eaten on a regular basis before damage starts to occur to the small bowel of the majority of people with CD (Catassi et al., 2007). It has been calculated that an average regular intake of foods labeled gluten-free at 20 ppm would contribute ~10 mg of gluten a day to the diet (Akobeng and Thomas, 2008; Collin et al., 2004). This is considered to be a good safety margin from the 50 mg/day "at risk" level of intake, particularly noting that symptoms can occur in the absence of bowel damage.

It is important to be aware of these differing standards and although internationally 20 ppm is accepted as appropriate for people with CD to consume, there is great resistance in Australia to endorse these products at this time as they fall outside the Australian standard, thus cannot be called gluten-free in the Australian context. The Australian public is therefore confused and often uninformed regarding the safety of these 20 ppm products and most do not purchase them.

The pharmacist may run into this issue with European-based baby formulae and baby food ranges, some bulking agents based on wheat starch, vitamins, other supplements, or medications sourced from overseas. Wheat starch was once a popular excipient in many tablets but has now largely been replaced by maize starch.

As an important point of difference, for most people with wheat/gluten intolerance, in the absence of CD, this level of attention to detail is not warranted. These people should be encouraged to liberalize their diet to their tolerance level, as achieving nutritional adequacy is far easier when gluten forms part of the diet. This is quite apart from the decrease in limitations on social situations and drain on finances from higher food costs when gluten must be stringently avoided. There is also emerging evidence of alterations to the gut microbiota when gluten is removed from the diet without consideration of the addition of alternative suitable foods, and the long-term implication of this is as yet unknown.

Reading a food label correctly is an important skill. The following wheat-derived ingredients are considered safe for people with CD because they are highly refined, removing the gluten component: glucose syrup, dextrose, fructose, maltose, caramel color, glucona-delta-lactone (575), MSG, distilled alcohol, and wheat germ oil (a common source and therefore ingredient in Vitamin E preparations).

The Coeliac Australia phone-App can assist the pharmacist to be aware of which wheat-derived ingredients are of concern and which are not. Ingredients are alphabetized, and symbols, as shown in **Table 4**, are used to indicate ingredients that can be safely consumed and those which must be avoided. It is clear and easy to understand and may be a useful resource for pharmacists, in order to check whether products and compounds are safe for use by someone with CD.

Medicine and supplement labeling for gluten differs slightly from food labeling. Food products, such as the packet lollies sold in a pharmacy, need to either:

- list the source grain beside any ingredient derived from wheat, rye, barley, or oats, OR,
- make a bolded allergen statement that the product contains wheat or gluten.

Pharmaceutical medicines and supplements need to declare the presence of wheat or gluten, but do not need to indicate which ingredient is the source.

Oat gluten controversy and food labeling

In Australia, oats are given equal footing with the other gluten-containing grains, when the reality is that the chemistry of the oat gluten barely resembles that of wheat, rye, or barley. Europe, Canada, and the United States allow "pure," "wheat free," or "uncontaminated" oats to be called gluten-free and consumed on a GFD (Gilissen et al., 2016). As such, "pure" oats can be an ingredient in a food labeled gluten-free overseas, but is not allowed in a product labeled gluten-free in Australia (FSANZ, 2017).

The prolamin portion of the oat gluten that triggers disease is called Avenin. It has been shown that a small proportion of people with CD exhibit a small intestinal T-cell response to oat peptides (Ellis and Ciclitira, 2008). Oats are tolerated by the majority because they contain very small amounts of avenin, compared with the proportion of gliadin in wheat, and the chemical structure of avenin is very different to wheat gluten, making it clumsy at activating the disease process. It is debated that about 5%–8% of people with CD react to oats (Comino et al., 2011; Hardy et al., 2015). As there is no way to predict which people with CD can successfully consume oats, they are currently discouraged on a gluten-free diet in Australia and excluded from the gluten-free food standards. People with NCGS should be able to consume oats in their diet on a regular basis.

Uncontaminated, wheat free or pure oats can only be called gluten-free outside Australia and New Zealand. These terms mean that the oats are specially produced so that they are grown from pure oat seed, on land that has not grown wheat, rye or barley for at least 2 years, and the rotational crop, (grown in the off season), is a gluten-free crop, and not the traditional wheat or barley. This ensures that at harvest and storage, gluten-containing grains do not mix with the oats. Australia does not grow these oats, but they can be imported and labeled "wheat free," "contaminant free," or "Pure," but not "gluten-free."

People who do not have many symptoms from CD are less likely to experience symptoms if they eat oats. However, symptomatic tolerance does not mean that the oats are not damaging the small intestine. The usual antibody bloods tests cannot monitor how the body is tolerating the oats. Only a small bowel biopsy can do this. If the client wishes to trial oats, their gastroenterologist must be informed and on board with this decision. It is generally recommended that good health and biopsy markers be restored before commencing a trial with oats (i.e., at least 6–12 plus months on the gluten-free diet and a follow-up biopsy to determine recovery). If all is well, pure oats can be trialed with follow-up biopsies at 3 and 12 months to determine short- and long-term tolerance (Pulido et al., 2009).

Need to supplement

People with newly diagnosed CD could be initially low in iron, folate, B12, zinc, calcium, vitamin D, fiber, protein, and total calories and may require supplementation of some kind. For many, life-long supplementation or dietary vigilance remains in terms of fiber, calcium, and vitamin D. Long-term requirements for other nutrients then depends on diet preferences and intake, just like in most other parts of the population.

Not all countries have mandatory fortification of wheaten products. In Australia, bread flour is fortified with thiamine and iodized salt is used. Wheat-based breakfast cereals are also commonly fortified with a range of nutrients, including B-group vitamins and iron. However, unlike wheat products, there is no mandatory fortification of gluten-free breads and cereals with iron and the B-vitamins, so attention to these is required in a long-term GFD and should be assessed and monitored by a dietitian. Iodine may also be compromised if people don't consume the iodine-fortified commercial gluten-free bread. This is easily remedied by using iodized table salt. Iodine supplements should only be prescribed by a doctor, as excess iodine is contra-indicated in some medical conditions.

What's Coming Up in Pharmacological Management

While there are currently no pharmaceutical options to treat CD, wheat allergy or wheat/gluten intolerance, research addressing these goals is ongoing. Below are short reports of innovative products and potential drugs under investigation.

Innovations to Combat Gluten Contamination

There is mental security in knowing it is possible to tackle the potential trace gluten contamination when served food made out of the control of the person eating it. Whether these innovations are used daily, twice a month, or only twice a year, they can potentially decrease the anxiety associated with gluten contamination when eating out and increase quality of life.

Tablet breaking down contaminant gluten

GluteGuard is an Australian innovation. It is a plant-based dietary enzyme called caricain that can break down proteins, including gluten. It is not a medical treatment for CD and does not allow a person to deliberately eat wheat, bread, or pasta meals. It is designed to be an adjunct to a gluten-free diet (Cornell et al., 2016).

It is intended to be taken just before a supposed gluten-free meal to prevent symptoms of inadvertent gluten ingestion, for example, where cross-contamination may occur, when ingredient labeling is uncertain, or when food preparation is out of the person's control, such as at a restaurant or friend's house (https://glutagen.com/gluteguard). Taking a GluteGuard tablet before eating the offered gluten-free meal may help protect from possible symptomatic consequences of inadvertent gluten contamination. It cannot be taken after the meal, or later that night if symptoms develop. As such, this product acts as a safety measure for gluten-sensitive individuals, helping to decrease the anxiety that often ensues whenever food preparation is out of their control.

Caution: This product can be suggested for those with CD but has the potential to make them complacent about determining if a food is gluten-free. Pharmacists should emphasize that a gluten-free diet is to be eaten and the tablet will give peace of mind about potential contamination. GluteGuard is suitable for those with a gluten intolerance, although they don't generally require strict vigilance with their gluten avoidance and most tolerate well the small amounts of gluten in cross-contamination situations.

Kits to test for gluten contamination

1. *Nima sensor* (NIMA, 2017)
   Nima is a small, portable device, designed by American scientists and CD researchers, to test small, on-the-spot samples of food for any detectable levels of gluten. A food containing up to 20 ppm of gluten is considered to be gluten-free, and therefore acceptable in America. Nima reports whether *any* gluten is present. It does not report the level. It can only be purchased online and has currently made little impact in Australia.

Caution: A limitation is that it only can report the gluten level in the snippet of food chosen to be tested, and this may not represent the entirety of the food on the plate.

2. *BIOHIT Healthcare Coeliac Quick Test* (http://www.biohithealthcare.com/products/diagnostics-tests/products/27/celiac-disease-quick-test.)
   This point of care (PoC) test, developed in Finland, has been available in Australia for a number of years. It proposes to diagnose CD from a fingertip blood sample, within 10 min. It is designed to detect antibodies (IgA/IgG/IgM) against human tissue transglutaminase in the whole blood sample. It has been suggested for "on-the-spot" use with dietitians, GPs, and pharmacists.
3. *Wesley Medical Research PoC Test:*
   Researchers at Wesley Medical Research Centre at Wesley Hospital in Brisbane are currently developing and testing a similar point of care finger prick test to diagnose CD.
   Caution: The use of the above two test kits has not generally been encouraged in Australia. The American Journal of Clinical Pathology (Bond and Richards-Kortum, 2015) reported that blood droplets from a pricked finger contain widely variable contents and only when five combined drops were tested were they able to get results accurate to the venous collected blood. False positives occur in up to 10% of PoC tests, while false negatives have been reported in 15%–20% of cases (https://www.coeliac.org.au/point-of-care-testing-poct/). While pharmacists who use these tests need to have extensive training, the preference is to "drive" patients toward consulting a GP and gastroenterologist for correct diagnosis. If CD is suspected, it is essential that they understand they must continue to eat wheat/gluten until all appropriate testing has been completed.

On the Horizon

The following products are not at the point where they have passed Phase I and/or II trials but are included as potential possible future directions.

Vaccine for those with coeliac disease

Nexvax2 is a vaccine developed in Australia to help those diagnosed with CD tolerate gluten (NEXVAX2, 2017).

The Phase I trials have shown it to be tolerated, safe to use, and has the anticipated bioactive response of being able to desensitize patients to the three specific peptides in gluten that have been identified as troublesome to people with CD.

The vaccine is being further developed by US biotechnology company ImmusanT, with phase 2 trials underway. This company also aims to develop improved serological tests, based on T-cells, to diagnose CD. As it is in the testing phase, this is not an available product.

Drug to reduce inflammation caused by consuming gluten

James Cook University doctors are working to create a drug to treat gluten intolerance and hopefully CD, by studying the way parasites reduce intestinal inflammatory responses. Animal experiments suggest intestinal worm parasites can suppress inflammation, leading to the novel approach of introducing hook worms into humans with CD, to study how they may be used to treat autoimmune or allergic disorders. Currently, trials show a reduced proinflammatory response to gluten in those infected. Small quantities of gluten were tolerated, but as yet, gastrointestinal symptoms could not be prevented with a steady, usual intake of gluten foods (Giacomin, 2015).

Monitoring and Measuring—How do we Know That Treatment is Working?

There are three measurable parameters to monitor the effectiveness of the gluten-free diet in those with CD.

1. Symptom reduction or remission
2. CD-specific antibodies returning to normal levels
3. Improvement or return to normalcy of the villi in the small intestine

Those with newly diagnosed CD will be able to report any improvement in symptoms after commencing a gluten-free diet. However, it is only through tests ordered by a doctor, namely, blood and biopsy results described above, that antibody and histological improvement in disease state can be assessed, which is the crucial part in ongoing management and decreased risk of future complications. It is well understood that while the antibodies may return to normal and symptoms recede, it does not always follow that the small bowel has recovered (Ludvigsson et al., 2014; Rubio-Tapia et al., 2010).

There is a perception by most that a gluten-free diet will rectify all parameters within weeks of initiation of a gluten-free diet. This is a misconception. Tissue transglutaminase antibodies usually take 9–12 months to return to normal serum levels. Small bowel villous recovery time is variable and often slow, taking 2–5 years (Newnham et al., 2016), with a median time of 3.8 years (Rubio-Tapia et al., 2010). Those first diagnosed with CD over the age of 40 (Selby et al., 1999) and those with a highly damaged gut at diagnosis (Rubio-Tapia et al., 2013), often find it difficult to return to a totally normal small bowel. Some struggle with symptoms for 6–12 months and in a proportion, symptoms improve but do not totally subside (Faulkner-Hogg et al., 1999; Newnham et al., 2016). While inadvertent gluten ingestion is principally the main suspect in this, other food intolerances (Faulkner-Hogg et al., 1999) may also be playing a role in some people, who for as yet unknown reasons, seem to have very sensitive guts.

In children, these parameters return to normal within 2 years in 95% of cases (Husby et al., 2018; Rubio-Tapia et al., 2010). Recovery is often faster and more complete than adults, supporting the observation that there is better compliance and fewer medical problems in those who start a gluten-free diet when they are young.

Increased morbidity outcomes are seen in those whose villi do not recover despite at least 12 months on a strict gluten-free diet (van Gils et al., 2015). This is known as refractory CD and is diagnosed after an in-depth dietary analysis from a dietitian and a series of tests with their gastroenterologist. This group has a greater risk of developing small bowel lymphomas (van Gils et al., 2015).

Nonpharmacological Management

As previously mentioned, nonpharmacological management, namely, a strict gluten-free diet is the sole management for this disease. Restoration of health can be a slow process for many. If the pharmacist has an understanding of the timeline of recovery, they can reassure slow-recovering patients and reiterate the need to avoid gluten. If someone with CD appears depressed or is financially constrained, a referral to a social worker or psychologist, or in the first instance, back to their GP for advice is warranted and helpful.

It is not uncommon, considering the damage to the small bowel, that people with newly diagnosed CD may have a transient lactose intolerance, until the villi recover. If gut symptoms remain uncomfortable at the start of the gluten restriction, removing lactose may help to settle symptoms. It's best for the pharmacist to suggest a visit to the dietitian and to stress that this is generally temporary, so as not to worry the patient excessively and to re-affirm that lactose-containing dairy products can often be returned to their diet after a period of avoidance. Avoidance of dairy food is not required. Lactose-free milk and hard cheeses, which are naturally gluten-free, remain good alternatives and lactose-digesting products such as Lacteeze can help enable tolerance of normal dairy foods. Yogurt is naturally low in lactose, and the lactose concentration reduces as the product ages, so this is generally quite well tolerated.

Prevention

Currently, there is no known way to prevent CD. In the last 20 years, several dietary approaches have been suggested when introducing food to babies and toddlers, in the hope that this will decrease the chances of the child developing CD. Although the incidence of CD appeared to decrease in the under 2 age group, absence of disease was not sustainable as childhood progressed, regardless of whether gluten was introduced or not introduced as an early food (Szajewska et al., 2016). Genetics still appears to be the strongest indicator of disease likelihood (Liu et al., 2014; Szajewska et al., 2016).

Parents may only be aware of the old dietary advice and many are reluctant to introduce gluten to their child's diet, with the hope that they may prevent the disease from developing. The recommendations in 2008 were to introduce gluten to the diet between 4 and 7 months of age, while the baby was being breastfed. New evidence prompted a revision of these guidelines by the European Society for Paediatric Gastroenterology, Hepatology, and Nutrition (ESPGHAN) in 2016 (Szajewska et al., 2016). The revised ESPGHAN guidelines are applicable to all infants, as outlined later especially those who carry at least one CD-risk genetic allele, not just those who have one or more parents with CD.

Neither breastfeeding alone nor breastfeeding during gluten introduction has been shown to decrease the risk of developing CD, but breast feeding should still be promoted for its otherwise well-established health benefits, according to the Australian Dietary Guidelines (AustralianDietaryGuidelines, 2018), and this is echoed in the ESPGHAN guidelines (Szajewska et al., 2016). Gluten can be introduced at any time between 4 and 12 months of age. Consumption of large quantities of gluten should be avoided during the first few weeks after gluten introduction and during infancy. The optimal quantity and type of gluten to introduce have not been determined.

Consumption of large amounts of gluten may potentially result in infants developing CD earlier than they otherwise might but is unlikely to change the inevitable outcome. The issue in developing CD in infancy rather than later in life is the potential for associated malabsorption resulting in failure to thrive. The only benefit of an early diagnosis is that it generally leads to better compliance and less long-term complications. Most people enquiring about timing of gluten introduction would have a family history of CD so someone in the family is consuming gluten-free foods. Feeding the infant both gluten-free and gluten-containing foods in order to both eat gluten and yet not eat large amounts of it appears to be a good option (Andren Aronsson et al., 2016).

The Role of the Pharmacist in the Health-Care Team

In CD, the main roles of the pharmacist can be mostly summed up as follows:

Evidence for role of pharmacist

- It is essential that the pharmacist supporting a person with CD is cognizant of the requirement for that person to be strictly gluten-free and be aware of the excipients in various drugs, supplements, nutritional formulae, and so on. They should ensure the client is receiving appropriate medications, suggesting alternatives if there is a problem. An understanding of Australia's strict laws

surrounding gluten-containing products is important. This comes to the fore particularly when a new medication is prescribed, when generic medications have the potential to be substituted for branded ones, and in nutritional supplement formulae (both food and micronutrients).

Medication management

- There is evidence that drug absorption may be impaired in those with undiagnosed or newly diagnosed CD, so it is important to identify those people who have CD and other comorbidities and monitor the efficacy of drugs.
- Every person is different, and dietary compliance and choice of nutritious food are variable. While it is preferable that a person gain their required nutrition from foods, sometimes supplementation is required, particularly in the early stages or if the person is very underweight and/or undernourished on diagnosis. Once the person has been assessed by a dietitian and has an understanding of additional supplementation required, if any, the pharmacist is important to ensure appropriate gluten-free products are selected.

Counseling/listening skills

- Where a client asks for gluten-free products and does not have CD, it is important to be able to counsel them around those products that contain little gluten and point them back to a dietitian if there is a concern about nutrition, and first and foremost to a GP if there are concerns the client may indeed have undiagnosed CD.
- Using effective listening skills is also important. It is obviously the doctor's role to diagnose, and the dietitian's role to manage the diet and prescribe nutritional supplements, both in terms of energy and micronutrients; but it is useful for the pharmacist to be aware of questions being asked and refer back to the dietitian, the doctor or another member of the health-care team if they are concerned.

Role in the interprofessional team

- Understanding the science and being able to assist a client who may present with either a self-diagnosis (especially IBS or NCGS) or misleading, inaccurate, or nonevidence-based information from an alternative practitioner is important, followed by referring back to an appropriate health-care team member. The pharmacist is potentially the first health-care professional to become aware of the person's symptoms, so has an important role here.
- Being aware of and understanding of quality of life issues. There are times when a person diagnosed with CD may suffer some kind of mental health issue as a result of the isolation they may feel following a long search for solutions, or dealing with coming to grips with their diagnosis and the inevitable lifestyle changes which ensue. Anxiety and depression are not out of the question for some. Food is at the center of our social fabric, and it can make socializing difficult when you have to be on guard around shared food. Gluten-free foods are also more expensive than regular foods, which can be a significant financial burden for those of lower income groups. Recognizing mood changes in a person with CD and using effective counseling skills can be helpful in pointing the client toward an appropriate member of the health-care team, such as a psychologist or social worker.

Triage

- This role should not be underestimated. Given people will present to the pharmacy looking for medications, as well as pre and probiotics to manage symptoms caused by possible IBS or NCGS, the pharmacist is in a unique role to be able to ask a few questions and encourage those who have not been adequately diagnosed to see their GP to ensure appropriate diagnosis and long-term management of their condition. The outcomes of this action may decrease the risk of a person undertaking tests or therapies, which are not validated, often expensive, and which may result in them either restricting their diet unnecessarily or, more importantly, failing to have CD identified.

Thus, the role of the pharmacist may be nontraditional and quite different from most other conditions, but it is nonetheless valuable and not to be trivialized.

Constipation

Ben Basger, The University of Sydney, NSW, Australia

Learning Objectives

- Understand the factors most likely to contribute to constipation
- Know that the consequences of constipation may affect many different body systems and cause a wide variety of symptoms
- Have knowledge of medicines and medical conditions that may contribute to or cause constipation
- Be able to take a comprehensive medical history
- Understand the patient barriers that may occur when discussing constipation
- Be aware of alarm symptoms
- Deliver nonpharmacological and pharmacological counseling and treatments
- Be aware of the onset of action and precautions/contraindications of laxatives
- Be aware of new treatments for constipation

Take Home Messages

- People may have many misconceptions about constipation and the medicines used to treat it. It is important that health-care professionals have a clear understanding to correct these misconceptions
- Constipation may cause a wide variety of intestinal and extra-intestinal symptoms
- It may not be possible to deprescribe medicines suspected of contributing to constipation
- Many older people may consider bowel health a private matter, which they find difficult to discuss. Conversely, many health-care professionals may feel uncomfortable in asking questions and discussing the issue, which requires a proactive approach and appropriate communication skills
- Constipation in children occurs for different reasons than in older people and treatments may differ
- Appropriate treatment for certain groups of patients includes the prophylactic use of laxatives

Introduction

Constipation is a common functional gastrointestinal disorder (FGID) and refers to a change in bowel habit that involves the passage of hard stools less frequently than is normal for the patient (APF, 2015). Although abdominal pain and/or bloating may be present, they are not predominant symptoms and should not meet criteria applicable to irritable bowel syndrome (IBS) (Lacy et al., 2016)—see chapter on IBS. The term "functional" has been used to describe a disorder that affects function or performance, causing signs or symptoms of an organic disease, but with no obvious evidence of structural or physiologic abnormalities. Other FGIDs include functional dyspepsia, gastroparesis (delayed stomach emptying), IBS, and functional diarrhea. Diagnosis is based on

symptoms, with minimal tests and investigations unless the patient has clinical features that warrant further investigation (eTG complete, 2016).

Functional disorders can be classified according to the Rome criteria, whose development began in 1988 when a team of experts worked to develop consensus criteria for the diagnosis of IBS (Drossman, 2016). The Rome Foundation classification of FGIDs is based primarily on symptoms rather than physiological criteria. This is because of limited evidence that physiological disturbance (e.g., motility) fully explained patient symptoms and that symptoms are what bring patients to health-care providers. While IBS was not the only FGID, at that time there existed no overarching operational definition or classification for them. The first set of criteria ("Rome I") for 21 functional GI disorders were compiled into a book in 1994. Studies began being published using these criteria, which progressed their acceptance and further use and development through Rome II (1999–2000), III (2006), and IV (2016). Rome III differed from Rome I and Rome II with the use of more evidence-based rather than consensus-based data. This was because a greater number of research studies published using the Rome criteria allowed for more precise patient selection and presented data more representative of these disorders (Drossman, 2016).

To advance the field of FGIDs, Rome IV had to address limitations and make changes which have included an improved definition of FGIDs that is positive (rather than by the exclusion of other disease), reflective of current scientific knowledge and nonstigmatizing. Rome IV now defines FGIDs as disorders of gut–brain interaction (Lacy et al., 2016).

There is an increased prevalence of constipation in older (greater than 60 years) adults, believed to be due to reduced physical activity and polypharmacy rather than age-related physiological changes (Emmanuel et al., 2017). The people with sedentary life style are three times more likely to report constipation (Rao and Go, 2010). Whole gut transit time is prolonged in immobile people (AMH Aged Care Companion, 2016), and it may not be possible to deprescribe medicines suspected of contributing to constipation. However, it has also been stated that there are two main causes of constipation in the elderly—age-related slow colonic transit time and pelvic floor dysfunction causing a functional defecation disorder (Roque and Bouras, 2015).

Many older people may consider bowel health a private matter, which they find difficult to discuss. Consequently, many patients may resort to self-medication and therefore do not benefit from the experience of health-care professionals (Emmanuel et al., 2017). Conversely, many health-care professionals may feel uncomfortable in asking questions and discussing the issue, which requires a proactive approach and appropriate communication skills.

In children, most constipation is functional or idiopathic and related to behavioral withholding after an unpleasant stool event (Waterham, 2017). Constipation may also occur secondary to other medical conditions.

Misconceptions About Bowel Habits

There are many misconceptions about bowel habits and what is viewed as normal. Normal stool frequency can vary between 3 motions per day and 3 motions per week (Gandell et al., 2013). However, a hard stool passed with difficulty (straining) once or twice daily indicates constipation, while a soft stool passed comfortably every 2–3 days does not (APF, 2015). Some may believe that having a daily bowel movement is necessary for health, rationalizing that toxins arising from prolonged residence of undigested food may be absorbed, resulting in illness and a variety of nonspecific symptoms. There are also many misconceptions about which laxatives are safe and effective. Some falsely believe that stimulant-type laxatives damage the colon with chronic use (Wald, 2006). The availability of over-the-counter laxatives and fiber supplements means that without intervention, idiosyncratic beliefs may perpetuate irrational self-treatment. Patients need to understand that bowel habits vary considerably between individuals and for individuals over time (Australian Medicines Handbook, 2018).

Although not normally life threatening, the impact of constipation can be as great in older patients as other common chronic conditions such as diabetes and osteoarthritis (Emmanuel et al., 2017). In susceptible older people who are frail, excessive straining can trigger a syncopal episode or coronary or cerebral ischemia (Gandell et al., 2013). Laxatives (also known as aperients) are used to prevent straining, particularly for those at increased risk such as during the postoperative period, in those who have ischemic (coronary) heart disease, and in those with hemorrhoids. In addition to gastrointestinal symptoms, constipation in children may cause reduced appetite and irritability (eTG complete, 2016).

Effective management of childhood functional constipation depends on securing a therapeutic alliance with the parents, particularly through the first years when children cannot accurately report symptoms. Clinicians may depend on the reports and interpretations of the parents, who know their child best, in addition to their own training and experience, to differentiate between health and illness (Gordon et al., 2016).

Incidence and Burden of Disease

The prevalence of constipation has been estimated to be 16%–20% in the general population (Emmanuel et al., 2017; Roque and Bouras, 2015). Its prevalence rises with age, with some estimates as high as 50% in those over 80 years old. Up to 40% of older people living in the community and 50%–60% of those in aged care facilities may be affected (Gandell et al., 2013). It should be noted that prevalence varies with the definition used. Severe constipation is more common in elderly women, with rates two to three times higher than their male counterparts. Chronic constipation negatively impacts health related quality of life, with psychological and social consequences (Roque and Bouras, 2015). Improperly diagnosed "overflow" incontinence resulting from impaction with

leakage of liquid stool can be a trigger for nursing home admission (Emmanuel et al., 2017). Constipation is a common reason for primary care visits and referrals to gastroenterologists (Selby and Corte, 2010).

Chronic constipation can lead to bowel obstruction, urinary incontinence, urinary tract infection, hemorrhoids, rectal bleeding, and anal fissures (APF, 2015) and may cause or contribute to delirium in older people (AMH Aged Care Companion, 2016). Constipation has been reported to occur in greater than 50% of patients taking opioid analgesics for noncancer pain (APF, 2015) and to become almost universal in palliative care patients (eTG complete, 2016). In a study of adverse events associated with the combined effects of multiple medicines in elderly inpatients, constipation was one of the most commonly occurring events (in addition to events such as arrhythmia, bleeding, orthostatic hypotension, sedation, and seizures (Bottiger et al., 2018).

Children—Constipation is a common problem in children, with up to 1 in 10 seeking medical attention. Incidence has been reported to be up to 30% in some settings (Waterham, 2017). Constipation in children can cause abdominal pain, perianal pain on passage of stools, reduced appetite, and irritability. It may present with soiling due to overflow incontinence. Urinary tract infections are more common in children with constipation (eTG complete, 2016).

Etiology of Constipation

Normal defecation has been stated to require several factors—a diet adequate in fiber and fluid, normal peristalsis, adequate power in the abdominal and pelvic musculature, normal rectal and perianal sensation, and patient mobility (eTG complete, 2016).

The elderly exhibit age-related cellular dysfunction such as decreased number of gastrointestinal contractions and delayed transit time; neuronal loss; dysfunctional myenteric ganglia and altered control of the pelvic floor. Pelvic floor dysfunction may frequently occur in elderly women, particularly those with a history of anorectal or pelvic surgery and other pelvic floor trauma such as childbirth. Such dysfunction may result in inadequate relaxation of the pelvic floor muscles and inadequate propulsive forces during attempted defecation (Roque and Bouras, 2015). However, while age-related changes have been acknowledged, others do not consider them to be major contributors to chronic constipation (Emmanuel et al., 2017; Gandell et al., 2013).

Causes of constipation more easily identified include certain medicines, metabolic abnormalities, disease states, and some general factors. These factors include lower socioeconomic class, non-white race, regular medication use, female sex, older age, a history of sexual abuse, and symptoms of anxiety and depression. They have all been associated with increased prevalence of constipation (Gandell et al., 2013; Selby and Corte, 2010).

Lifestyle factors that have been reported to predispose people to constipation include inadequate fluid intake, insufficient dietary fiber, insufficient physical activity, suppressing the urge to defecate, and social conditions (such as lack of privacy, reliance on others for toileting assistance, a change in surroundings) (AMH Aged Care Companion, 2016; APF, 2015). However, while exercise and consumption of dietary fiber and fluids represent healthy choices, deficiencies in any or all these factors do not seem to be major causes of chronic constipation (Wald, 2006). In those with fiber deficiency, fiber and water intake (to maximize the benefit of fiber) increase stool bulk and frequency and a dietary history will reveal whether there is sufficient fiber in the diet from cereals, grains, fruit, and vegetables. Increasing dietary fiber to approximately 30 g/day may therefore be effective in such patients. Increasing fiber intake beyond the required amounts may result in bloating and flatulence without relieving (or even aggravating) constipation (Selby and Corte, 2010).

In opioid-induced constipation, opioids bind to mu opioid receptors leading to a decrease in propulsive peristalsis, a reduction in pancreatic and biliary secretions, and an increase in intestinal fluid absorption. This effect is dose related. Unlike other opioid side effects, tolerance to constipation rarely develops (APF, 2015).

Medicines commonly associated with constipation appear in **Table 1**.

Medical conditions commonly associated with constipation appear in **Table 2**.

Children

Functional fecal retention and stool withholding behavior are the most common causes of constipation in children (eTG complete, 2016). Other causes are listed in **Table 2**. Constipation occurs after an unpleasant or painful stool event. Stool builds up within the colon and rectum, leading to the absorption of water and, therefore, accumulation of hard fecal matter. This stretches the lower bowel and rectum. Over time, the sensation of needing to defecate diminishes with persistent rectal stretching from chronic stool loading. The rectum becomes less sensitive, which can lead to involuntary soiling and will persist until chronic stretching is alleviated and prevented from recurring. Soiling is unpleasant and embarrassing (Waterham, 2017).

Diagnosis

The following information is based on clinical history but not physical examination, which may form part of the medical practitioner's assessment.

Table 1 Medicines commonly associated with constipation (AMH Aged Care Companion, 2016; APF, 2015; Clinical Practice Guideline, 2018; Gandell et al., 2013; Roque and Bouras, 2015; Selby and Corte, 2010; Waterham, 2017).

- Analgesics—NSAIDs, opiates including tramadol and tapentadol
- Antacids containing calcium or aluminum
- Anticholinergic agents (which include antihistamines, antispasmodics, and antidepressants—aclidinium, amantadine, amitriptyline, atropine, belladonna, benzhexol, benztropine, biperiden, brompheniramine, chlorpheniramine, clomipramine, cyclizine, cyproheptadine, darifenacin, dexchlorpheniramine, dimenhydrinate, diphenhydramine, disopyramide, dothiepin, doxepin, glycopyrronium, hyoscine butylbromide or hydrobromide, hyoscyamine, imipramine, ipratropium (nebulized), mianserin, nortriptyline orphenadrine, oxybutynin, phenelzine, pheniramine, pizotifen, prochlorperazine, promethazine, propantheline, solifenacin, tiotropium, tolterodine, tranylcypromine, trimeprazine, triprolidine, umeclinidium
- Anticonvulsants—carbamazepine, oxcarbazepine, zonisamide
- Antihypertensives—calcium channel blockers (mainly verapamil), clonidine, diuretics
- Antiparkinson agents—dopamine agonists (apomorphine, pramipexole, ropinirole, rotigotine, bromocriptine, cabergoline), COMT inhibitors (entacapone)
- Antipsychotics—aripiprazole, asenapine, brexpiprazole, chlorpromazine, clozapine, droperidol, flupentixol, haloperidol, lurasidone, olanzapine, paliperidone, periciazine, quetiapine, risperidone, trifluoperazine, ziprasidone, zuclopenthixol
- Calcium channel blockers—verapamil most commonly
- Bile acid binder—colestyramine
- Calcium supplements
- Dopamine agonist—quinagolide
- Iron supplements
- Sucralfate
- Vinca alkaloids
- 5HT3 antagonists—granisetron, ondansetron, palonosetron, tropisetron

Table 2 Medical conditions commonly associated with constipation (AMH Aged Care Companion, 2016; APF, 2015; eTG complete, 2016; Gandell et al., 2013; Roque and Bouras, 2015).

- Chronic renal disease
- Connective tissue—amyloidosis, scleroderma
- Dehydration
- Electrolyte disturbances—hypercalcemia, hypokalemia, hypermagnesemia
- Endocrine—diabetes, hypothyroidism, hyperparathyroidism
- Dyssynergic defecation— difficulty in expelling stool due to failure of recto-anal coordination
- Gastrointestinal—celiac disease, colorectal carcinoma, diverticulosis, hemorrhoids, IBS, perianal conditions, rectal prolapse, slow transit, stricture
- General disability
- Neurologic—autonomic neuropathy, dementia, multiple sclerosis, Parkinson's disease, spinal cord lesions, stroke
- Pelvic floor dysfunction (e.g., as a consequence of childbirth)
- Pregnancy
- Psychiatric—anorexia nervosa, anxiety, depression, somatization

Children

- Anatomic malformations of anus
- Allergy to cow's milk protein
- Celiac disease
- Reduced stool volume and dry stools caused by poor diet
- Slow-transit constipation
- Pelvic floor muscle dyssynergia
- Sexual abuse
- Hirschsprung disease, metabolic disease (hypercalcemia, hypothyroidism), and spinal cord abnormalities (rare)

The Rome III criteria have been used to define chronic functional constipation in adults, when the presence of two or more of the following occur (Gandell et al., 2013; Selby and Corte, 2010);

- Straining during at least 25% of bowel movements
- Lumpy or hard stools in at least 25% of bowel movements
- Sensation of incomplete evacuations for at least 25% of bowel movements
- Sensation of anorectal obstruction/blockage for at least 25% of bowel movements
- Manual maneuvers to facilitate at least 25% of bowel movements (such as digital evacuation or support of the pelvic floor
- Fewer than 3 spontaneous bowel motions per week
- Loose stools are rarely present without the use of laxatives
- There are insufficient criteria for IBS (added in Rome IV)

The last point was added by Rome IV to specify that abdominal pain and/or bloating may be present but are not predominant symptoms. That is, the patient does not meet criteria for IBS. This supports the concept that functional constipation (FC) and IBS with constipation-predominant symptoms (IBS-C) are disorders that exist on a continuous spectrum (Lacy et al., 2016).

These criteria must have been present for the last 3 months, with symptom onset at least 6 months before diagnosis. However, many people who complain of constipation do not meet all these criteria. Older patients may not always present with the expected decreased bowel frequency and altered consistency, but with almost daily bowel movements that require excessive straining, rectal digitation to facilitate stool expulsion, and accompanied by a sensation of incomplete evacuation and abdominal discomfort (APF, 2015; Roque and Bouras, 2015). Severe constipation may lead to upper gastrointestinal (GI) symptoms due to alterations in GI motility such as abdominal cramping, bloating, flatulence, nausea, and dyspepsia (Roque and Bouras, 2015).

A method to identify clinical factors that impact bowel function in the elderly consist of looking for nine "D"s; drugs (side effects), defecatory dysfunction, degenerative disease, decreased dietary intake, dementia, decreased mobility/activity, dehydration, depression, and dependence (on others for assistance) (Roque and Bouras, 2015).

In older people, constipation may present as confusion, overflow diarrhea, abdominal pain, urinary retention, nausea, or loss of appetite (APF, 2015). In patients where urinary incontinence is present, it may be exacerbated by constipation. Conversely, treatment in those with urinary incontinence may contribute to constipation through use of fluid restriction and anticholinergic drugs (AMH Aged Care Companion, 2016).

In taking a medical history, the following points could be considered (Rao and Go, 2010);

- What does the patient mean by constipation? Why do they think they have constipation?
- Has there been a change in the patient's bowel movements?
- Has the type of stool changed? This relates to stool frequency and consistency (with reference to the Bristol stool chart (Continence Foundation of Australia, 2018. Types 3–4 represent ideal stools).
- Ask if they ever need to strain on the toilet
- Have there been circumstances requiring postponing or ignoring a call to defecate? This may reflect upon difficult social conditions or poor access to toileting facilities
- Ask about diet to assess fiber and water intake
- List all medical conditions and all medications (prescription and nonprescription)
- Assess mobility
- Has there been previous use of laxatives and if so, what was their effectiveness?
- If using a laxative, for how long has this occurred and are you satisfied with the results?

It has been suggested that an accurate bowel chart be kept recording time, amount, and consistency of stool. This will facilitate assessment of laxative requirements and if so, response to treatment (AMH Aged Care Companion, 2016).

Children and Infants

Most children pass stools every 2–3 days, whereas breastfed babies may only pass stool once a week. Common times for constipation to occur in children and infants include transition to solids, toilet training, and school entry. Other causes may consist of painful bowel actions due to anal fissures or perianal skin conditions, change of diet, and psychosocial stressors (Waterham, 2017).

The Rome IV criteria are used for the diagnosis of functional constipation in children and must include two or more of the following criteria for at least 1 month (Clinical Practice Guideline, 2018);

- Two bowel movements or less per week
- A history of withholding or incomplete evacuation
- A history of large-diameter stools
- Presence of a large fecal mass in the rectum

In toilet-trained children, there is one additional criteria; at least one episode per week of incontinence which, after evaluation, cannot be fully explained by another medical condition.

In taking a medical history in children, the following points could be considered (Clinical Practice Guideline, 2018; Waterham, 2017)

- What has been the stool consistency (per Bristol stool chart)?
- Has there been straining?
- Has there been blood on wiping and/or in the nappy?
- Have bowel actions been painful?
- Has there been an event (painful, frightening, or challenging such as school entry) prior to onset of constipation?
- Has there been toilet refusal or withholding behaviors (e.g., crossing legs)?
- Has fecal or urinary incontinence occurred?
- For children with fecal incontinence, what has been the frequency of soiling episodes and what was their relationship to bowel motions

- Is there a family history of celiac disease?
- Have laxatives been used previously and if so, what has been their effectiveness?
- With the introduction of solids, has there been adequate fiber and water intake?
- Has general growth and development been within normal parameters?

Need for Referral

The presence of alarm symptoms may indicate an underlying organic cause such as colorectal neoplasia or inflammatory bowel disease (Selby and Corte, 2010). Referral has been recommended when constipation is accompanied by any of the following symptoms (APF, 2015; Australian Medicines Handbook, 2018; Selby and Corte, 2010);

- Blood and/or mucus in the stools
- Persistent or severe abdominal pain
- Anorexia, nausea, vomiting, or fever
- Unintentional or unexplained weight loss
- Obstipation (obstructive constipation)—stool cannot be passed
- Tenesmus—a continuous feeling of the need to defecate
- A sudden change in bowel habits lasting two weeks or longer
- A family history of inflammatory bowel disease or colorectal cancer
- Constipation persisting after appropriate treatment with laxative(s)

Children

In children, the following alarm symptoms have been identified (Clinical Practice Guideline, 2018; Waterham, 2017);

- Ribbon/pencil-thin stools (may indicate an anorectal malformation)
- Delay in general growth and development
- Other physical signs; lethargy, fever, vomiting, weight loss
- Blood in stool

Treatment—Nonpharmacologic

Fluid and exercise—While adequate water intake and exercise have been recommended, there is little evidence for their effectiveness (Rao and Go, 2010; Wald, 2006). The small intestine handles 7–10 L of fluid each day, so it should not be surprising that extra fluid intake makes little difference, except to increase urinary output. Fluid restrictions should be noted in those with medical conditions such as heart or renal failure.

Fiber—it has been shown that increased consumption of fiber increases stool weight and frequency in healthy individuals and decreases colonic transit time (Wald, 2006). However, the prescription of many medicines (**Table 1**) and the presence of multimorbidity (**Table 2**) in patients may result in little or no benefit from fiber supplementation. Notwithstanding this, constipated patients without a motility disorder have been reported to improve or become symptom free with fiber supplementation (Rao and Go, 2010). A dietary history will reveal whether there is sufficient fiber in the diet. Fiber is the indigestible parts of plant foods such as vegetables, fruits, grains, beans, and legumes (peas, beans, chickpeas, lentils, soybeans, peanuts). Both soluble (which includes some grains (e.g., oats, rye, barley, millet, buckwheat), some fruit and vegetables (e.g., artichoke, onion, garlic), seed husk (e.g., psyllium husk), and cooked (from dried) or canned legumes, and insoluble fiber (which include most whole grains (e.g., whole wheat, wheat bran, brown rice, rye, quinoa, wholegrain cereals [barley, buckwheat, oat, rye, rice, spelt], wholemeal or mixed-grain products), skins of fruits and vegetables, nuts and seeds, raw lentils, kidney beans, and chickpeas have been recommended, with benefits generally seen within 3–5 days (APF, 2015; Selby and Corte, 2010). However, evidence for any benefit has been found to be unclear (Ford, 2012). The recommended daily fiber intake for adults is 25–30 g. For children, the number of grams should be their age in years plus 5—for example, 10 g/day in a 5 year old (APF, 2015). Fiber content should be increased gradually to avoid adverse effects such as bloating or flatulence.

Regularity— colonic motor activity increases after waking and after a meal (the gastrocolonic reflex). This suggests that constipated patients may establish a regular pattern of defecation by ritualizing a bowel habit that takes advantage of this normal physiologic stimulus (Rao and Go, 2010).

Position—When seated on the toilet, correct positioning (i.e., with knees above the level of the hips to reduce the rectal angle—a footstool may be needed) is recommended (eTG complete, 2016).

Urge—People should be encouraged to respond to an urge to defecate rather than delay (eTG complete, 2016).

Infants and children (Clinical Practice Guideline, 2018)—use of a footstool has been recommended to ensure knees are higher than hips. The child should lean forward and put their elbows on their knees. A toilet ring can be placed over the toilet seat if needed. Toilet sits should be organized of up to 5 min three times a day, preferably after meals. Encouragement should be given so that the exercise is treated as a positive experience. A toileting diary may reinforce positive behavior and record frequency of bowel actions. Toilet training attempts should be delayed until the child is painlessly passing soft stool.

Treatment—pharmacologic (AMH Aged Care Companion, 2016; APF, 2015; Australian Medicines Handbook, 2018; Clinical Practice Guideline, 2018; Ford, 2012; Gandell et al., 2013; Selby and Corte, 2010; Serrano-Falcon and Rey, 2017; Wald, 2006)

The term "laxative" is an imprecise term, since it encompasses drugs with different mechanisms of action, thus implying heterogeneity in their efficacy and safety and rendering comparison difficult. Further, the exact mechanism of action of most laxatives is unknown because there are complex factors involved in colon function. Determination of the influence of factors such as cyclic-AMP, electrolyte transportation, hormones, and enzymes may change currently accepted mechanisms. However, some general classes of mechanism of action can be described (below).

Evidence is insufficient to assess the relative effectiveness or tolerability of laxatives. Drug choice may therefore be based on onset of action, patient preference, adverse effects, effectiveness of previous treatments, and cost (Australian Medicines Handbook, 2018).

Laxatives (aperients) have been described as foods or drugs that, when ingested, act directly on the gut (or gut contents) to increase stool frequency or to ease stool passage. They differ from motility agents such as metoclopramide, domperidone, and prucalopride, which exert a promotility effect after systemic absorption (Ford, 2012). Long-term laxative use is not necessary unless constipation or fecal impaction is likely to recur. This may occur in opioid-induced constipation; where there are progressive neurological conditions; in immobility due to old age or illness and in some children to prevent relapse (Australian Medicines Handbook, 2018).

Patients approaching the end of life may tolerate food and fluid poorly, have little or no mobility, inadequate power of abdominal and pelvic musculature, or reduced rectal and perianal sensation, such that constipation becomes almost universal (eTG complete, 2016). Despite this, a recent Cochrane review was unable to determine the effectiveness and differential efficacy of laxatives used to manage constipation in people receiving palliative care, although a previous review identified the effectiveness of the peripherally acting opioid antagonist methylnaltrexone (Candy et al., 2015), which is administered subcutaneously once every 24–48 h.

Laxative use is contraindicated in intestinal obstruction (Australian Medicines Handbook, 2018). The use of fiber supplements may worsen constipation in those patients with constipation-predominant IBS, slow transit constipation, or primary defecation disorder (Wald, 2006).

Opioid-induced constipation is largely the result of reduced peristalsis and hardened feces, so the most useful laxatives are those that increase peristalsis and soften the stool (APF, 2015). The effect of opioids on peristalsis can be reduced by the concomitant use of naloxone (an opioid antagonist commonly used together with oxycodone [Targin] in moderate to severe pain), which undergoes extensive first-pass metabolism resulting in a systemic bioavailability of less than 3% and no significant effect on the central nervous system at approved doses (Ward et al., 2017).

Because most laxatives are not absorbed and none cross the blood–brain barrier, there appears to be no pharmacologic basis for addiction. Those individuals who do abuse laxatives are often individuals with psychiatric disorders. As with any substance, laxatives may be abused because of psychologic dysfunction (Wald, 2006).

In children, osmotic and lubricant laxatives are usually required on a long-term basis (months to years). Parents should be reassured that this is safe and will not produce a "lazy bowel." Laxative should be titrated to obtain one soft, easy to pass bowel action per day. A common cause of recurrence is stopping laxatives too early (Waterham, 2017).

Serotonin (or 5-hydroxytryptamine [5-HT]), commonly viewed as a central neurotransmitter, is most abundant in the gastrointestinal tract where it is synthesized and stored in enterochromaffin cells. Serotonin is involved in intestinal secretion, motility, and sensation and is therefore a natural target for treatment of chronic constipation. Of its various receptors, serotonin 5-HT3 and 5-HT4 receptors have attracted the greatest attention in the intestine; the former for their role in visceral sensation, the latter for their role in motor activity. Consequently, 5-HT4 receptor agonists have been developed as prokinetic agents (Quigley and Neshatian, 2016).

A stepwise approach has been suggested in the management of constipation in older people (Gandell et al., 2013);

(1) Identify the predominant symptoms, (2) identify possible secondary causes (medications, disease states), (3) exclude fecal impaction, (4) optimize behavioral factors (seating position, timing), (5) trial dietary modification (fiber) for 2–4 weeks, (6) trial a previously preferred laxative for 2–4 weeks, (7) trial macrogol or lactulose if not in, (6) for 2–4 weeks, (8) trial a combination of agents from different classes for 2–4 weeks, and (9) refer to a gastroenterologist or geriatrician.

There are four major groups of laxatives (AMH Aged Care Companion, 2016; APF, 2015; Australian Medicines Handbook, 2018; Clinical Practice Guideline, 2018; Ford, 2012; Gandell et al., 2013; Selby and Corte, 2010; Serrano-Falcon and Rey, 2017; Wald, 2006).

Bulk forming laxatives—includes isphagula, psyllium, and sterculia

- Onset of action is 2–3 days. Full effect may take 3–4 days
- Act to sequester extra water in the stool, increasing stool weight and colonic distention to stimulate intestinal activity and increase the speed of transit. Adequate fluid intake should be ensured.
- Fermentation by colonic bacteria may cause bloating and flatulence. A gradual increase in quantity will minimize these effects
- May worsen constipation in immobile or fluid restricted patients. They have no role in nonambulant patients or those taking opioids or other constipating drugs
- Contraindicated in obstruction, impaction, colonic atony, and dysphagia

Osmotic laxatives—includes glycerol, lactulose, macrogol, saline laxatives (containing magnesium, sodium citrate, sodium phosphate), and sorbitol

- Onset of action for lactulose, macrogol, and sorbitol is 1–3 days. Saline laxatives ½—3 h. Rectal (glycerol—used for stool in the lower rectum) 5–30 min
- Ions such as magnesium, sulfate, phosphate, and citrate are poorly absorbed and retain fluid in the colon through an osmotic effect. Other molecules such as lactulose, macrogol, and sorbitol are completely unabsorbed and to maintain an iso-osmolar state, draw water into the intestinal lumen. The increase in intraluminal pressure stimulates peristalsis. Water ingested with them is retained in the gut
- Fluid augments their osmotic effect
- Some brands of macrogol contain approximately 8 mmol (186 mg) of sodium per sachet. This should be considered in patients who may have heart or kidney failure or hypertension or who are taking diuretics—which aim to eliminate sodium
- Fluid and electrolyte disturbances are less of a risk with macrogol laxatives than with other osmotic laxatives
- Common adverse effects include nausea, abdominal distention, flatulence, cramps, or pain
- Tolerance may be limited by the taste of lactulose and sorbitol
- Laxatives containing sodium phosphate may cause serious fluid and electrolyte disturbance in the elderly, which are more likely in dehydrated patients or those taking diuretics, angiotensin
- -converting enzyme inhibitors, angiotensin-2-receptor antagonists, or nonsteroidal anti-inflammatory drugs. They should not be used in heart failure or renal impairment
- Lactulose or macrogol laxatives have been recommended for use in infants 1–12 months old. Macrogol (and/or liquid paraffin) has been recommended for use in children
- Macrogol has the best and most recent evidence base of all laxatives for efficacy. It is generally recommended as first choice

Stimulant laxatives—includes bisacodyl, frangula, senna, and sodium picosulfate

- Onset is 6–12 h
- May act to increase peristalsis by a direct effect on the smooth intestinal musculature by stimulation of intramural nerve plexi. They have also been shown to promote fluid and ion accumulation in the colon. Bisacodyl may inhibit water absorption through an action on endogenous esterases; sodium picosulfate through an action on colonic flora; senna following mucosal contact
- They are contraindicated in inflammatory bowel disease
- They do not damage the neuromuscular apparatus of the colon
- May cause abdominal discomfort and cramping
- They are recommended in combination with a stool softener as the best initial choice in palliative care patients and in opioid-induced constipation

Stool softening laxatives—include docusate, liquid paraffin, and poloxamer (or poloxalkol)

- Onset is 24–72 h
- Docusate and poloxamer are detergents (surfactants) and act to facilitate penetration of water into feces. Liquid paraffin is a lubricant to facilitate passage of feces
- Evidence for their efficacy when used alone is lacking
- Poloxamer can be used in children less than 3 years old and mixed with fruit juice or in bottle feeds. Docusate can be used in children older than 3 years. Other guidelines recommend poloxamer use only in infants less than one month old
- Liquid paraffin may cause anal leakage, reduce absorption of fat-soluble vitamins with regular use, and may be aspirated in those with predisposing factors (e.g., gastro-oesophageal reflux, Parkinson's, and other neurological diseases). It should not be administered immediately before lying down
- It is recommended in combination with a stimulant as the best initial choice in palliative care patients and in opioid-induced constipation

Prokinetic Agents

Cisapride was one of the first serotonin receptor agonists shown to have some efficacy in constipation. Lack of selectivity for the 5-HT4 receptor and resultant interactions with the human ether-a-go-go-Related Gene (hERG) channel (resulting in cardiac arrhythmias) led to worldwide withdrawal of the drug. After this came tegaserod, a 5-HT2B receptor agonist, which was also withdrawn due to the occurrence of cardiovascular ischemic events (Quigley and Neshatian, 2016).

Prucalopride is an agent that has highly selective agonist activity and high affinity for 5-HT4 receptors. This results in reduced colonic transit time due to longitudinal smooth muscle contraction and propulsion of luminal contents. A decrease in the resistance potentially produced by circular smooth muscle contractions also occurs. Prucalopride neither interacts with the hERG potassium channel (such as cisapride) nor with the 5-HT2B receptors (such as tegaserod), resulting in the selective stimulation of gastrointestinal motility without arrhythmogenic side effects (Bassotti et al., 2016).

Prucalopride is indicated for chronic idiopathic constipation when other regular laxatives are inadequate. It is taken once a day. The tablets have a high oral bioavailability and can be taken with or without food. There is little metabolism of prucalopride. Most of

the dose is excreted unchanged in the urine. A bowel movement occurs within a median of 50–54 h (Bassotti et al., 2016). Benefit should be evident within 4 weeks and if not, the medicine should be ceased. It has been recommended that further studies are needed to establish efficacy in the elderly, in patients with secondary causes of constipation, with long term use and in combination with other laxatives (Australian Medicines Handbook, 2018). This is because prucalopride has been mainly tested on patients recruited for clinical trials and data on "real-life" patients, or those with different subtypes of constipation, are scarce (Bassotti et al., 2016). The cost of prucalopride may represent a considerable barrier —approximately 75 (Australian) dollars per month (2 mg tablets × 28).

Velusetrag, Naronapride, and Mosapride are other highly selective 5-HT4 agonists, which are undergoing development, with the latter also being a partial 5-HT3 antagonist.

Prosecretory agents (secretagogues)—Modulation of epithelial ion channels promote intestinal secretion and therefore facilitates stool passage and enhances GI transit. Lubiprostone, the first secretogogue introduced for the treatment of chronic constipation, is a fatty acid derived from prostaglandin-1. It activates a specific chloride channel located on the enterocyte, thereby increasing water secretion in the intestinal lumen. It may also act through prostaglandin E4 receptors (Quigley and Neshatian, 2016). It may cause nausea in up to 30% of patients, limiting its effectiveness (Roque and Bouras, 2015).

Linaclotide is a 14-amino acid peptide that binds to and activates the guanylate cyclase-C (GC-C) receptor, which generates cyclic guanosine monophosphate (cGMP). Intracellular cGMP activates the cystic fibrosis transmembrane conductance regulator (CFTR), which increases the secretion of chloride and bicarbonate into the lumen, thereby increasing colonic secretion and intestinal motility (Gandell et al., 2013).

Plecanatide, a uroguanylin analog, is a GC-C receptor agonist. Uroguanylin is a naturally occurring intestinal hormone that has its downstream effects through the activation of the GC-C receptor (Quigley and Neshatian, 2016).

Pregnancy —Fiber supplements, sorbitol, lactulose, and docusate have been recommended, with occasional macrogol if necessary. Stimulant laxatives should be avoided (Australian Medicines Handbook, 2018; Selby and Corte, 2010).

Role of the Pharmacist

- Many older people may consider bowel health a private matter which they find difficult to discuss. Consequently, many patients may resort to self-medication and therefore do not benefit from the experience of health-care professionals. Conversely, many health-care professionals may feel uncomfortable in asking questions and discussing the issue, which requires a proactive approach and appropriate communication skills. Asking open-ended questions (that is, those beginning with "how," "when," "where," "why" or "what") may open communication and allow better assessment of the problem. For example, "for how long have you experienced this problem?"; "what kind of change have you experienced in your bowel motions?" and "what have you tried in the past to fix it?"
- It may not be possible to deprescribe medicines suspected of contributing to constipation. It is therefore important that patients' misconceptions about constipation and the medicines used to treat it are addressed. For example, there appears to be no pharmacologic basis for addiction. A medication review may be necessary to investigate the possibility of medication adjustment or cessation.
- The availability of over-the-counter laxatives means that without intervention, idiosyncratic beliefs may perpetuate irrational self-treatment. This includes use of complementary and alternative (CAMs) medicines. Idiosyncratic beliefs may be able to be changed, depending upon the behavioral stage-of-change that the patient may be currently experiencing—are they in a precontemplation, contemplation, preparation, action, or maintenance stage?) A patient in a precontemplation stage will be resistant to correction of erroneous beliefs.
- The significant consequences of inadequately treated constipation should be explained to patients. These include the effects of excessive straining, occurrence of overflow fecal incontinence, bowel obstruction, urinary incontinence, urinary tract infection, hemorrhoids, rectal bleeding, anal fissures, abdominal pain, nausea, anorexia, upper gastrointestinal symptoms, and delirium in older people. They should be considered when assessing patients' medical history/presenting symptoms. These issues can be communicated by explaining that we are very much concerned about people becoming constipated because, apart from constipation being uncomfortable and slow to reverse, it can affect other parts of the body like the urinary system.
- In patients where urinary incontinence is present, exacerbation by constipation should be considered.
- In children, reduced appetite and irritability may be associated with constipation
- The frequency of occurrence of constipation in patients taking opioid analgesics for non-cancer pain, those approaching the end of life and in palliative care patients means that appropriate treatment includes prophylactic laxative use for all such patients. Addition of naloxone to oxycodone in combined preparations for analgesia may often not be enough to prevent constipation and additional laxatives may often be required.
- Familiarity with alarm symptoms is important, as certain symptoms may indicate an underlying organic cause such as colorectal neoplasia or inflammatory bowel disease, requiring referral to a doctor for investigation.
- Counseling regarding nonpharmacological advice and treatment such as appropriate fiber intake, attention to regularity, defecation position, and avoidance of delaying urge should be considered in all patients.
- In children, osmotic and lubricant laxatives are usually required on a long-term basis. This means that appropriate counseling of parents/carers is important with respect to the safety of laxatives.

It should be explained to patients that laxatives do not cause tolerance or dependence or damage the gut. For example, it could be explained that macrogol, one of the most effective laxatives available, is a chemical that keeps fluid inside the gut. This pushes out or distends the gut wall, which causes it to push back, thus moving along gut contents. The chemical itself never enters the body. Simplified explanations such as this appear likely to deal with the common issue of inadequate health literacy.

There should be an awareness that older people in the community or in low-level care facilities may have difficulty with nonpharmacologic options because they are afraid to exercise (walk) alone, fruit and vegetables may be difficult to access or too expensive and they may be concerned that increased fluid intake may worsen urinary incontinence. Awareness of these issues will allow them to be discussed.

Management of Gastrointestinal Disorders and the Pharmacist's Role: Gastroesophageal Reflux Disease

Jorabar Singh Nirwan, Maria Yousaf, Barbara R. Conway, Muhammad Usman Ghori, University of Huddersfield, Huddersfield, United Kingdom

Gastroesophageal Reflux Disease

According to a Montreal consensus panel, the globally accepted definition of gastroesophageal reflux disease (GERD) is "a condition which develops when the reflux of stomach contents causes troublesome symptoms and/or complications" (Vakil et al., 2006). Although there is no standard criterion for the symptoms exhibited, heartburn and regurgitation are the most prevalent indicators of GERD, and a weekly occurrence of these symptoms is typically sufficient to make a clinical diagnosis (Fock and Poh, 2010). This definition of GERD may be further classified as nonerosive reflux disease (NERD) and erosive reflux disease (ERD) depending on whether esophageal erosion is absent or present, respectively (Kroch and Madanick, 2017).

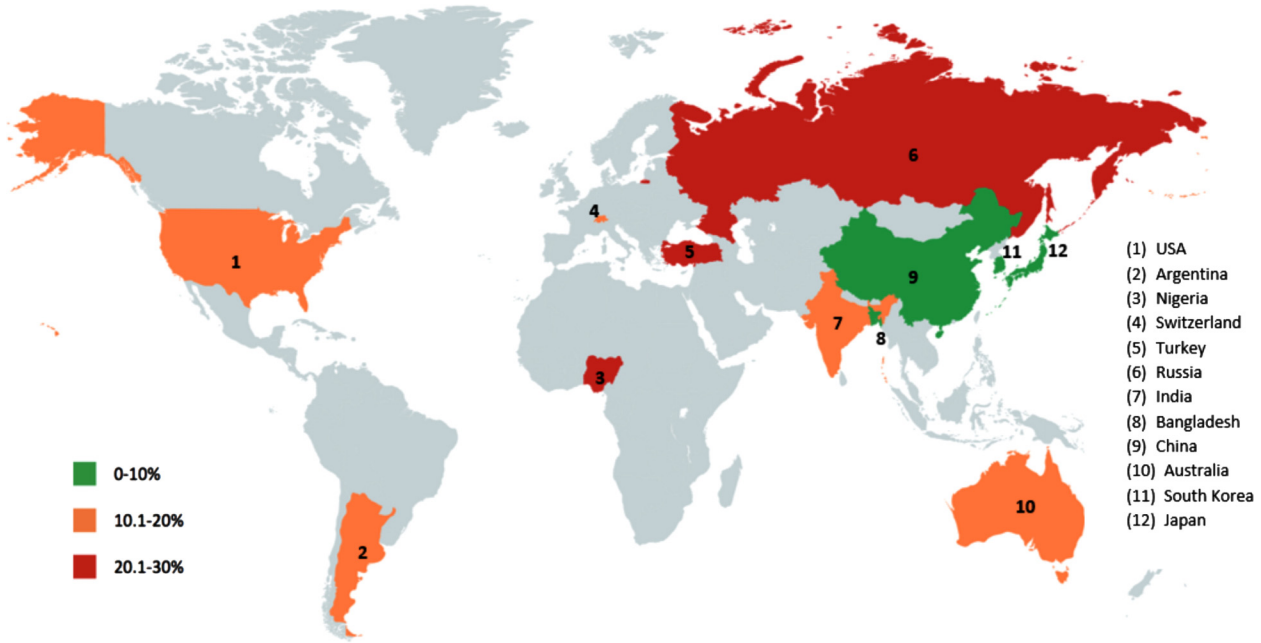

Figure 1 World map showing the global prevalence of GERD. *(1) Jung et al. (2007); (2) Chiocca et al. (2005); (3) Nwokediuko (2009); (4) Schwenkglenks et al. (2004); (5) Mungan (2012); (6) Bor et al. (2015); (7) Kumar et al. (2011); (8) Shaha et al. (2012); (9) Wang et al. (2009); (10) Eslick and Tallet (2009); (11) Watanabe et al. (2003); (12) Kim et al. (2012).*

Besides causing a significant decrease in the quality of life of patients, GERD may also facilitate the development of more serious and potentially life-threatening conditions (Nwokediuko, 2012).

Epidemiology

GERD is a highly prevalent condition worldwide, although language and cultural differences in symptom interpretation make it difficult to determine an accurate global estimate of its prevalence (Ronkainen et al., 2005). Nevertheless, prevalence estimates of GERD vary significantly between regions and are more prevalent in western societies than other societies (8.8%–25.9% in Europe and 17.6%–28.8% in US) (Darbà et al., 2011; El-Serag et al., 2013; Orlando, 2000; Ronkainen and Agréus, 2013). A similar prevalence of the disease has also been found in Middle Eastern and West Asian societies (8.7%–27.6%) (El-Serag et al., 2013; Ronkainen and Agréus, 2013). However, East Asian societies have consistently shown a low prevalence of GERD (2.5%–7.27%), although evidence has shown that this is rapidly rising (Cheung et al., 2009; Kim et al., 2012; Wong et al., 2003, 2004). The distributions of prevalence estimates around the world are displayed in **Fig. 1**.

Etiology

Excessive retrograde movement of acid-containing gastric secretions or bile and acid-containing secretions from the duodenum and stomach into the esophagus is the etiologic effector of GERD. A functional (transient lower esophageal sphincter relaxation (TLESR)) or mechanical (hypotensive LES) problem of the lower esophageal sphincter (LES) is the most common cause of GERD. Transient relaxation of the LES could also be due to food (coffee, alcohol, chocolate, and fatty meals), medications (beta-agonists, nitrates, calcium channel blockers, and anticholinergics), hormones (e.g., progesterone), and nicotine.

Pathophysiology

Early understanding described hiatus hernia as the main pathophysiological factor for GERD. This theory was replaced when a hypotensive LES was consistently observed in GERD patients and there was a theory that a hypotensive LES pressure may contribute toward GERD via strain-induced reflux (Herregods et al., 2015). Strain-induced reflux is caused by an abrupt increase in intragastric pressure and mainly occurs when LES pressure is less than 10 mmHg. Alternatively, free reflux is identified by a fall in intraesophageal pH without a change in intragastric or LES pressure and mainly occurs when LES pressure is less than 4 mmHg (Orlando, 2000).

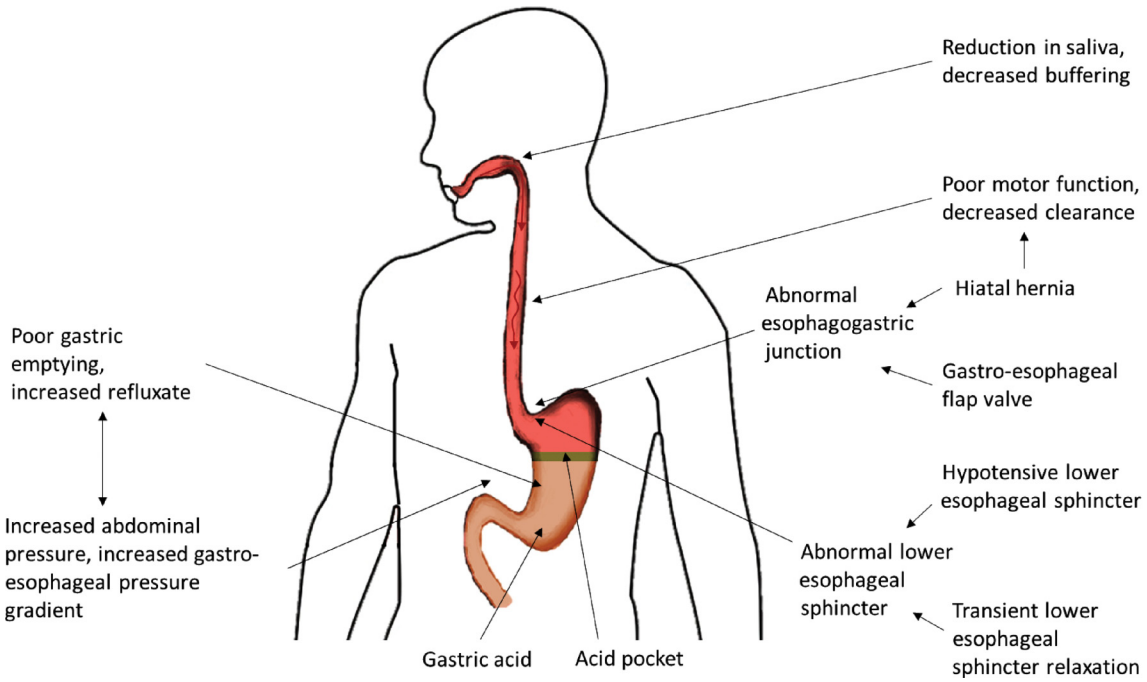

Figure 2 Pathophysiology of GERD.

However, further developments in the techniques available to measure LES pressure lead us to our current understanding, which describes the pathophysiology of GERD as multifactorial (**Fig. 2**) (Lee and McColl, 2013). TLESR is the main cause of gastroesophageal reflux leading to 70% of the cases. Although the rate of TLESRs in healthy individuals is similar to those with GERD, the latter are more likely to suffer from acid reflux during the process (Herregods et al., 2015). Therefore, TLESR is not responsible for causing reflux but instead a pathway to allow reflux to occur. A number of mechanisms have been suggested which may cause acid reflux during TLESR. These include (1) an increase in compliance of the LES, (2) a higher-pressure gradient across the esophagogastric junction (EGJ), and (3) differences in the meal distribution or the localization of the acid pocket on top of the meal (Hershcovici et al., 2011).

Natural Barriers Against Gastroesophageal Reflux Disease

In healthy individuals, reflux of gastric contents is prevented by a number of natural barriers including the LES, the angle of His, the diaphragm, and the length of the intraabdominal esophagus (**Table 1**) (Menezes and Herbella, 2017). The most important of these barriers are the LES and the crural diaphragm that, along with the anatomical flap valve, make up the EGJ, which acts as a defense system against reflux.

Lower Esophageal Sphincter

The LES is a composite of tonically contracted muscles with multiple functions spanning 2.4–4.5 cm in length located at the distal end of the esophagus (Menezes and Herbella, 2017). One function of the LES is to prevent the flow of acid secreted by the most

Table 1 Description and functions of the barriers against GERD

Barrier	*Description*	*Functions*
Lower esophageal sphincter	A composite of tonically contracted muscles with multiple functions spanning 2.4–4.5 cm in length located at the distal end of the esophagus	Behaves as a "one-way system" by allowing ingested food and liquids into the stomach from the esophagus while inhibiting the reflux of gastric contents and gastric juice
Crural diaphragm	An external sphincter on the esophagus. It wraps around the proximal 2–4 cm of the LES and augments pressure during inspiration	Contracts to augment the LES pressure and prevent reflux
Angle of His	The acute angle between the cardia and the esophagus	Forms a valve that prevents the reflux of gastric contents and gastric juice into the esophagus

proximal gastric mucosa into the esophagus and ensures the flow is directed toward the stomach, thus preventing damage to its squamous mucosa. It also behaves as a "one-way system" by allowing ingested food and liquids into the stomach from the esophagus while inhibiting the reflux of gastric contents and gastric juice (Lee and McColl, 2013).

One of the most complicated and least-understood functions of the LES also happens to be the most common cause of GERD. This is defined as simultaneous spontaneous relaxation of the LES and crural diaphragm lasting 10–60 s and independent of swallowing (Hershcovici et al., 2011). During this period, the LES and crural diaphragm are completely relaxed, and the longitudinal smooth muscle of the esophagus contracts. The EGJ ascends 2–8 cm into the chest causing a temporary hiatal hernia, which disfigures the flap valve, opening the LES, and allowing air located in the proximal stomach to escape via the esophagus (Lee and McColl, 2013).

Crural Diaphragm

The crural diaphragm also plays an important role in preventing GER by acting as an external sphincter on the esophagus (Hershcovici et al., 2011). In fact, it has been suggested that simultaneous crural diaphragm inhibition and LES relaxation are essential for GER to occur. The pressure gradient between the stomach and esophagus is increased during inspiration due to the production of a negative intraesophageal pressure. The pressure gradient is further increased by the contraction of the abdominal wall. These two processes favor GER; therefore, the crural diaphragm contracts to augment the LES pressure and prevent GER (Mittal, 2011).

Angle of His

The angle of His is the acute angle between the cardia and the esophagus. The acute angle forms a valve, which prevents the reflux of gastric contents and gastric juice into the esophagus and an obtuse angle would facilitate recurrent regurgitation (Menezes and Herbella, 2017).

Risk Factors

Obesity

A higher body mass index (BMI) is linked to an increase in the prevalence of GERD due to disruption of the EGJ resulting in a hiatal hernia caused by a change in pressure morphology across the EGJ, an increase in intragastric pressure, and an increase in the gastroesophageal pressure gradient (Pandolfino et al., 2006). Obese patients are also twice as likely to possess a defective LES compared to healthy individuals (Ayazi et al., 2009).

However, abdominal obesity is more important than general obesity as symptoms of GERD are positively associated with abdominal obesity independent of BMI. Therefore, improvement of GERD symptoms can be achieved by weight loss and improvement of diet (Park et al., 2016).

Age

Infants and Children

Reflux of gastric contents is a common occurrence in the pediatric population with 75% of infants experiencing GER. Fortunately, 65%–95% of the patients experience spontaneous resolution of their symptoms by 2 years of age. However, 7%–20% of the pediatric population suffers from GERD with high-risk groups including those with prematurity, esophageal atresia, congenital diaphragmatic hernia, neurologic impairment, obesity, and specific genetic disorders (Barnhart, 2016).

The high prevalence of GERD in infants may be attributed to underdeveloped barriers against reflux. For instance, the LES in infants only measures a few millimeters compared to 2.4–4.5 cm in adults (Menezes and Herbella, 2017). Additionally, the angle of His in infants is less acute than in adults and may even direct the flow of gastric contents into the esophagus. Furthermore, the behavior of infants also increases the risk of GER. Crying and awkward movements due to poor trunk control can increase intragastric pressure, therefore, causing GER (Di Lorenzo and Vandenplas, 2012).

Diagnosis of GERD may be difficult due to infants being unable to communicate their symptoms accurately or at all. However, many common symptoms are clear and easy to recognize such as regurgitation and vomiting. Other visible symptoms may include coughing, wheezing, choking, apnea, and apparent life-threatening events (Slater and Rothenberg, 2017).

Elderly

It is believed that there is a positive correlation between the incidence of GERD and age, possibly due to anatomical and physiological degradation of GER barriers at the EGJ (Becher and Dent, 2010). Symptoms of GERD have also shown to be atypical in elderly patients compared to young or adult patients. These atypical symptoms include vomiting, dysphagia, anorexia, anemia, weight loss, belching, and respiratory problems (Pilotto et al., 2006).

Pregnancy

GERD is very common during pregnancy with 40%–85% of pregnant women suffering from the condition. A combination of hormonal imbalances and anatomical alterations causes GERD favoring changes such as lowering of LES pressure, increased abdominal pressure, and slow gastric emptying. The predominant factor of GERD during pregnancy is the reduction of LES tone caused by progesterone and estrogen. Moreover, the resting LES pressure is lower than normal during all three trimesters of pregnancy, reaching a nadir at 36 weeks of pregnancy (Fill Malfertheiner et al., 2012).

Smoking

Smoking significantly exacerbates GERD symptoms and a strong dose-dependent association between smoking and GERD exists (Nilsson, 2004). Activation of nicotinic receptors on the enteric neurons of the EGJ smooth muscle results in the release of substances, such as nitric oxide, norepinephrine, and GABA, which relax the gastric clasp and sling fibers, and LES smooth muscle. Additionally, individuals who smoke exhibit a decrease in LES pressure, as well as a decrease in the secretion of salivary bicarbonate. An increase in coughing and deep inspiration in smokers is also responsible for increasing intraabdominal pressure, thus, favoring reflux (Kahrilas and Gupta, 1990).

Hiatal Hernia

Hiatal hernia is caused by the weakening or rupture of the phrenoesophageal ligament and it has been observed that almost all patients with severe GERD and many with mild GERD have evidence of hiatal hernia (Lee and McColl, 2013). Four types of hiatal hernia have been identified (**Fig. 3**):

1. Sliding hiatal hernia (type I)
2. Paraesophageal hiatal hernia (type II)
3. Mixed hiatal hernia (type III

Giant paraesophageal hiatal hernia (IV). The mechanism leading to reflux is different in patients with hiatal hernia who also experience more frequent and prolonged TLESRs. It is believed that one of the ways a hiatal hernia facilitates GERD is by hindering LES function. A sudden increase in intraabdominal pressure, such as during inspiration or coughing, increases the possibility of reflux, which is related to both low LES pressure and hiatal hernia. Reflux can also be caused by an acid pocket becoming trapped in the hiatal hernia sac during esophageal acid clearance, which then refluxes into the esophagus during LES relaxation (Savas et al., 2008).

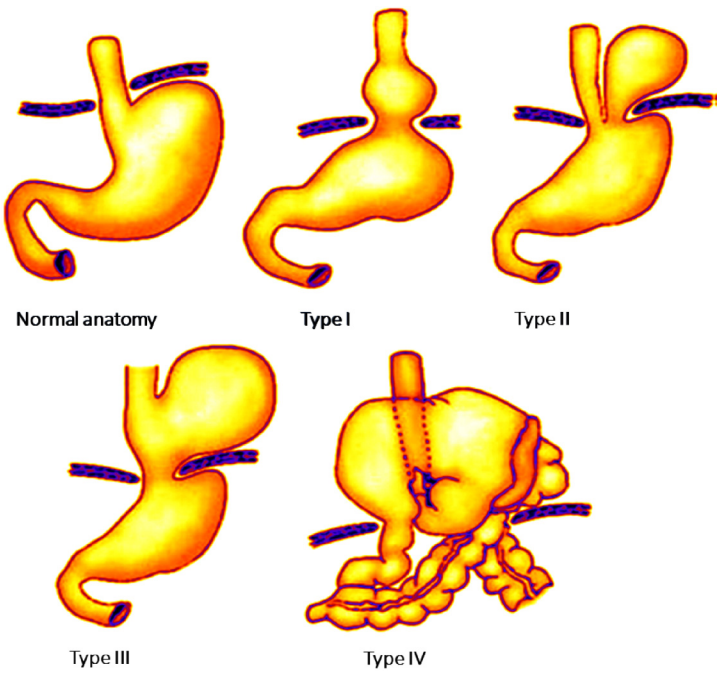

Figure 3 The four types of hiatal hernias.

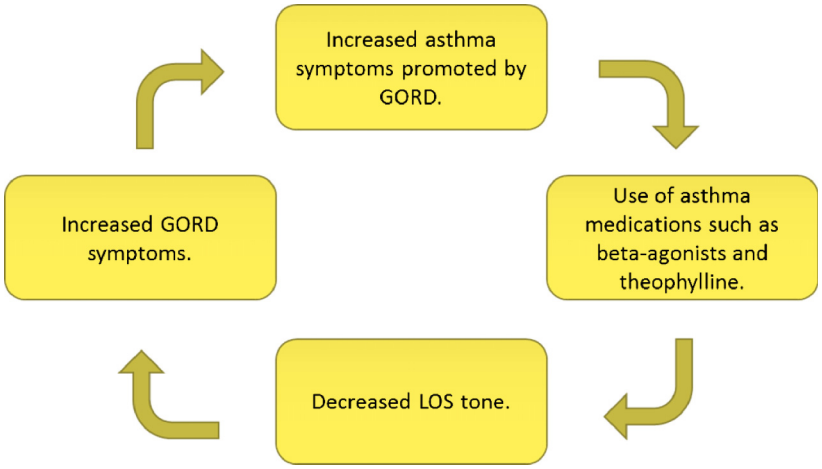

Figure 4 Illustration showing the relationship between asthma medications and GERD.

Asthma

The prevalence of GERD in individuals with asthma is a common occurrence with up to 82% of the adult population with asthma also suffering from GERD (Aras et al., 2012). Potential causes of this relationship include an increase in the rate of TLESRs caused by bronchial obstruction and herniation of the LES into the chest due to lung hyperinflation in asthmatic patients (McCallister et al., 2011).

However, GERD has also shown to cause and exacerbate asthma symptoms via two theorized mechanisms: (1) exposure to acid refluxate causing damage to the pulmonary tree (reflux theory) and (2) stimulation of vagal nerve endings in the esophagus causing bronchial constriction (reflex theory). Additionally, a vicious cycle between the two conditions has also been discovered (Fig. 4). Asthma medicines, such as beta-agonists and theophylline, have been shown to promote GERD by decreasing LES tone. This results in an increase in asthma symptoms promoted by GERD which, in turn, lead to an increase in the use of asthma medications (McCallister et al., 2011).

Prognosis

Most patients with GERD respond well to medications, although a relapse after cessation of medical therapy is common and indicates the need for long-term maintenance therapy. Identifying the subgroup of patients who may develop the most serious complications of GERD and treating them appropriately is important. Surgery at an early stage is most likely indicated in these patients. After a laparoscopic Nissen fundoplication, symptoms resolve in approximately 92% of patients. The LOTUS trial—a 5-year, exploratory randomized, open, parallel-group trial—demonstrated that with antireflux therapy for GERD, either using drug-induced acid suppression with esomeprazole or laparoscopic antireflux surgery, most patients achieve remission and remain in remission at 5 years.

Most cases of GER in infants and very young children are benign and respond to conservative nonpharmacologic treatment (developmental disabilities represent an important diagnostic exception); 80% resolve by age 18 months (55% resolve by age 10 months). Some patients require a "step-up" to acid-reducing medications, and only a very small minority requires surgery. Because symptomatic GER after 18 months of age likely represents a chronic condition, long-term risks are increased. For patients whose GER persists into later childhood, long-term therapy with antisecretory agents is often required.

In refractory cases or when complications related to reflux disease are identified (e.g., stricture, aspiration, airway disease, Barrett's esophagus), surgical treatment (fundoplication) is typically necessary, and the prognosis with surgery is considered excellent. The surgical morbidity and mortality are higher in patients who have complex medical problems in addition to GER.

Signs and Symptoms

The signs and symptoms of GERD may vary from individual to individual and can be categorized into typical and atypical symptoms (Table 2). However, typical symptoms, such as heartburn and acid regurgitation, are most common and are sufficient to make a diagnosis of GERD with high specificity (Klauser et al., 1990).

Table 2 Typical and atypical symptoms of GERD

Typical symptoms	*Atypical symptoms*	*Symptoms of possible complicated GERD*
Heartburn	Chest pain	Vomiting
Acid regurgitation	Chronic cough	Weight loss
	Globus	Early satiety
	Asthma	Dysphagia
	Recurrent laryngitis	Odynophagia
	Subglottic stenosis	Iron deficiency anemia
	Recurrent sore throat	Gastrointestinal bleeding
	Dental enamel loss	

Typical Esophageal Symptoms

Heartburn is the most common typical symptom of GERD and is felt as a retrosternal sensation of burning or discomfort that usually occurs after eating, when lying supine or bending over. Regurgitation refers to reflux of gastric and/or esophageal contents into the pharynx. This may also lead to respiratory complications if gastric contents enter the tracheobronchial tree. Additionally, dysphagia occurs in approximately one-third of the patients. These patients experience a sensation of food being stuck, particularly in the retrosternal area. Dysphagia can be an advanced symptom and may be due to a primary underlying esophageal motility disorder.

Atypical Esophageal Symptoms

Atypical symptoms of GERD can be severe and may lead to further complications. Coughing and/or wheezing are respiratory symptoms resulting from the inspiration of gastric contents into the tracheobronchial tree or from the vagal reflex arc producing bronchoconstriction. Hoarseness results from irritation of the vocal cords by gastric refluxate and is often experienced by patients in the morning. Furthermore, reflux is the most common cause of noncardiac chest pain, accounting for approximately 50% of cases. Additional atypical symptoms from abnormal reflux include damage to the lungs (e.g., pneumonia, asthma, idiopathic pulmonary fibrosis), vocal cords (e.g., laryngitis, cancer), ear (e.g., otitis media), and teeth (e.g., enamel decay) (Heidelbaugh et al., 2003).

Diagnosis of Gastroesophageal Reflux Disease

The diagnosis of GERD is typically carried out using a combination of clinical symptoms, response to acid suppression, and a set of diagnostic tests. The most commonly used tests are empirical trials, upper endoscopy, ambulatory pH monitoring, barium esophagram, and esophageal manometry (**Table 3**) (Kahrilas, 2003).

Empirical Trial

In many cases, patients exhibit typical symptoms of uncomplicated GERD. For these patients, an initial empiric medical therapy can be used before other invasive tests are employed. An empirical trial is a presumptive diagnosis of GERD, which can be conducted in the setting of existing typical symptoms of heartburn and regurgitation for the empirical management of the symptoms. Based on these symptoms, a therapeutic trial of high-dose proton pump inhibitors (PPIs) is administered for 2–4 weeks. This test has shown sensitivity and specificity to GERD as compared to the other diagnostic methods (Fox and Forgacs, 2006).

Table 3 Diagnostic tests for GERD, explanation of indications, evidence, and recommendation

Diagnostic test	*Indication*	*Highest level of evidence*	*Recommendation*
Proton pump inhibitor Trial	Atypical symptoms, no alarm symptoms	Metastudies	Negative results shows absence of GERD
Endoscopy	Warning signs, chest pain, screening of patients at a high risk	Randomized controlled studies	Early for elderly, those who doesn't respond to PPI trial
Esophageal biopsy	Must not include non-GERD patients	Case control	Not indicated for GERD diagnosis
Esophageal manometry	Preoperative, surgery evaluation	Observational	Rule out hypomotility, preoperatively, not recommended for GERD
Ambulatory reflux monitoring	Preoperatively, for nonerosive GERD	Observational	Monitoring enhanced to 90% when impedance is added

Upper Endoscopy

Endoscopy is the best diagnostic method for patients experiencing typical symptoms such as heartburn and acid regurgitation and is preferred when the patient does not respond to the empiric therapy or in the presence of alarm symptoms of complicated GERD. This method is also preferred for analyzing alarm symptoms such as dysphagia, bleeding, weight loss, anemia, and recurrent vomiting (Shaheen et al., 2012). Additional factors that can lead to the need of upper endoscopy are nocturnal reflux symptoms, hiatal hernia, elevated BMI, and detection of esophageal adenocarcinoma and Barrett's esophagus (Lichtenstein et al., 2007).

However, it is not suitable to undergo endoscopic studies in every patient with uncomplicated reflux symptoms. Therefore, patients experiencing long-term, mild, typical reflux, and no alarm symptoms may be given an empiric trial. Patients exhibiting symptoms that progress during therapeutic trials may indicate the presence of severe or complicated esophagitis (DeVault and Castell, 2005).

Ambulatory pH or Reflux Monitoring

Esophageal pH monitoring is a method used to measure the extent of acidic reflux into the esophagus from the stomach. This is one of the best methods used to measure abnormal esophageal acid exposure and to determine whether the acidic reflux is occurring during the day or night. It is necessary to remember that 70%–80% of patients continue to secrete some acid despite the administration of PPIs twice daily and some proportion of the acid is susceptible to reflux back into the esophagus.

This test is also used to determine the occurrence of abnormal acid exposure, reflux frequency, and some symptoms that are linked to reflux episodes. In a consensus statement, it has been suggested that the addition of impedance for reflux monitoring increased the sensitivity to around 90% as it has the capability to distinguish between acid and nonacid GER (Sifrim et al., 2004).

Esophageal Manometry

Esophageal manometry is a technique that does not play any role in the diagnosis of GERD but plays an important key role in determining the preoperative condition of the esophagus. This procedure is recommended before undergoing antireflux surgery with the aims of ruling out severe hypomotility and some conditions that may be contraindicatory to fundoplication. This method is also used to measure the strength and function of the esophagus and plays a significant role in determining the functionality of the esophagus when any food or liquid passes through it (Katz et al., 2013; Murray et al., 2003).

Barium Esophagram

Barium esophagram was once recommended as a screening test for GERD, but is no longer a part of the diagnostic evaluation. The sensitivity and specificity of barium radiography for abnormal degrees of acid reflux have been found to be insufficient and therefore this test is no longer recommended for the diagnosis of GERD. On the other hand, it is frequently used in the evaluation of complications related to GERD (e.g., peptic stricture) as well as in the evaluation of dysphagia in the post antireflux surgery patient.

Management of Gastroesophageal Reflux Disease

The aim of the treatment is to relieve and prevent symptoms, heal esophagitis, and prevent further complications (Heidelbaugh et al., 2003). As the GERD severity varies from patient-to-patient, treatment also varies depending upon the pathophysiological factors. The treatment of GERD can be classified into two categories: nonpharmacological interventions and pharmacological interventions.

Nonpharmacological Interventions

Nonpharmacological interventions primarily include lifestyle modifications, which assist in the reduction of esophageal acid exposure, promoting gastric emptying, and to prevent symptomatic relapses (Kaltenbach et al., 2006). These lifestyle modifications include modifications in diet, behavior, sleeping body position, and weight reduction (**Fig. 5**) (Kang and Kang, 2015).

Dietary modifications can also include avoidance of high fat food, which exacerbate the gastric emptying from the stomach, decreasing mucosal injury by avoiding spicy foods, and avoidance of coffee or chocolate for the reduction of reflux. Based on the individual physiology, maintenance of gastric pH and by avoiding citrus foods and carbonated beverages (Dutta and Moayyedi, 2013; Fox et al., 2007; Johnson et al., 2010).

Furthermore, modifications of behavior include avoidance of alcohol intake and smoking cessation. There are a number of reasons why alcohol and smoking cessation has a significant role in the management of GERD. Alcohol increases acid secretion

Figure 5 Illustration showing the different life style options for managing GERD.

through stimulation of gastrin, decreasing LES pressure, increasing LES relaxation, impaired emptying of the stomach, and impaired gastric motility. Whereas, smoking prolongs the esophageal acid clearance, reduces the pressure of the LES, and decreases the secretion of salivary bicarbonate (Dua et al., 1998; Smit et al., 2001).

Additional life style modifications include weight reduction to decrease intragastric pressure, and elevation of the head of the bed by approximately 4–8 in. in patients experiencing nocturnal GERD, which helps to reduce acid reflux symptoms, it also helps to increase the esophageal pH (Khan et al., 2012).

Pharmacological Interventions

Pharmacological interventions applicable for the management and treatment interventions of GERD include nonraft-based formulations (Table 4) and alginate-based raft formulations. Common pharmacological therapy of GERD includes administration of antacids, proton pump inhibitors, sucralfate, histamine-2 receptor antagonists (H_2RAs), and alginate-based raft formulations (Savarino et al., 2012).

Two therapeutic approaches for the management of GERD exist. First strategy is the "Step Up" approach, which includes life style modifications and use of antacids, followed by H_2RA (Ranitidine 150 mg × 2) and, if symptoms still persist, then switch to proton pump inhibitors (PPIs). Alternatively, the treatment may begin with the most effective regimen and stepped down gradually, which is known as the "Step Down" approach. In this approach, treatment is initiated with a PPI such as Omeprazole 20 mg to help control the patient's symptoms (Katsanos et al., 2003).

Table 4 Nonraft-based pharmaceutical formulations used in the treatment of GERD

Drugs	*Dose*	*Mechanism of action*	*Adverse effects*	*Recommendation*	*Level of evidence*
		Antacids			
Aluminum hydroxide/magnesium hydroxide combinations	30 mL 1 h after meals and at bedtime	Neutralizes stomach acid	Constipation, diarrhea, nausea, headache	Conditional recommendation	Low level of evidence
Calcium carbonate (single or in combination with magnesium hydroxide and simethicone)	10–20 mL of suspension, or 2–4 regular strength tablets takes four times a day 20–60 min after meals and at bedtime	Neutralizes stomach acid	Diarrhea, constipation, nausea, belching. Risk of drug interaction, use concurrently with some drugs	Conditional recommendation	Low level of evidence
		Histamine 2 antagonists			
Cimetidine	600 mg twice daily	Blocks H_2-receptor to reduce acid production	Diarrhea, constipation, headache, fatigue, confusion, cardiac effects, rash	Conditional recommendation	Low level of evidence
Famotidine	10–20 mg twice daily	Blocks H_2-receptor to reduce acid production	Diarrhea, constipation, headache, fatigue, confusion, cardiac effects, rash	Conditional recommendation	Low level of evidence
Nizatidine	150 mg twice daily	Blocks H_2-receptor to reduce acid production	Diarrhea, constipation, headache, fatigue, confusion, cardiac effects, rash	Conditional recommendation	Low level of evidence
Ranitidine	75–150 mg twice daily	Blocks H_2-receptor to reduce acid production	Diarrhea, constipation, headache, fatigue, confusion, cardiac effects, rash	Conditional recommendation	Low level of evidence
		Proton pump inhibitors			
Esomeprazole	20–40 mg once daily 30 min before food; usual: 40 mg once daily before food	Inhibition of active proton pumps to reduce acid production	Abdominal pain, diarrhea, headache. Potential for cytochrome P450-mediated drug interactions	Strong recommendation	Moderate level of evidence
Lansoprazole	30 mg once daily 30 min before food	Inhibition of active proton pumps to reduce acid production	Diarrhea, abdominal pain, headache. Cytochrome P450-mediated	Strong recommendation	Moderate level of evidence
Omeprazole	20 mg once daily 30 min before food	Inhibition of active proton pumps to reduce acid production	Abdominal pain, nausea, headache. Mediated by CYP450	Strong recommendation	Moderate level of evidence
Pantoprazole	40 mg once daily 30 min before food	Inhibition of active proton pumps to reduce acid production	Diarrhea, headache, dizziness, pruritus. Mediated by CYP450	Strong recommendation	Moderate level of evidence
Rabeprazole	20 mg once daily 30 min before food	Inhibition of active proton pumps to reduce acid production	Diarrhea, headache. Mediated by CYP450	Strong recommendation	Moderate level of evidence

Nonraft-Based Pharmaceutical Formulations

Antacids

Antacids are basic in nature and are composed of different combinations of acid-neutralizing agents such as aluminum and magnesium hydroxide, calcium carbonate, sodium citrate, and sodium bicarbonate. These bases combine with acid in the stomach and result in the neutralization of gastric acid, providing relief from the acidity.

Over-the-counter acid suppressants and antacids are usually administered for the initial therapy for GERD and are primarily used on demand for episodic heartburn which is most commonly postprandial heartburn (Jones, 2000). Antacids have been used for the management of GERD for a long period of time and are very popular among consumers of over-the-counter (OTC) medications.

Sucralfate

Sucralfate is a prescription medicine, which is used to treat peptic ulcers and acts by stimulating the secretion of growth factors implicated in ulcer healing. It also works as a binding agent and binds to the ulcer base in conditions when the pH of the stomach is reduced (Isolauri and Laippala, 1995.

Histamine-2 receptor antagonists

H_2RA therapy results in reliable healing of peptic ulcers along with the healing of mild to moderate erosive esophagitis. H_2RAs suppress the secretion of gastric acid from the parietal cells of the stomach by competitively inhibiting the histamine at H_2-receptors. H_2RAs also reduce the volume of gastric acid in the stomach by an unidentified mechanism as a result of reduction in pepsin output (Wolfe and Sachs, 2000).

Proton pump inhibitors

Proton pump inhibitors are the cornerstone of treatment for GERD owing to their consistent inhibitory effect on acid secretion. The introduction of PPIs revolutionized the treatment related to acid reflux and they are currently considered the best therapeutic option for GERD and the most successful antisecretory agent in terms of symptom relief and mucosal healing (Chiba et al., 1997; Howden, 1994). PPIs are also considered to be the most efficient suppressants of gastric acid and they act by inhibiting the common pathway of gastric acid secretion also known as H^+/K^+ ATPase pump (Dean et al., 2004; Moayyedi et al., 2007).

Alginate-Based Raft Pharmaceutical Formulations

Alginate-based raft formulations work on the principle of floating drug delivery systems. The bulk density of these systems is lower than that of the gastric fluid and hence they remain floating on the surface of the stomach where they swell and form a raft, which remains floating on the surface of the stomach contents. This system contains a gel-forming agent (e.g., sodium alginate), alkaline bicarbonates, or carbonates for generating the carbon dioxide, which helps in making the system less dense and help the formulation float on the surface of gastric fluid, along with the presence of an acid neutralizer (Fabregas et al., 1994; Shah et al., 2009).

In cases in which therapeutic agents such as H_2RAs, PPIs, and antacids act by acid neutralization while interfering in the normal physiology of the stomach, raft-forming antireflux formulations can prove to be an ideal therapeutic class, which exhibit a unique nonsystemic mechanism. The therapeutic effect is achieved by protecting the esophageal mucosa by forming a viscous, gelatinous neutral barrier on the top of the stomach contents (Mandel et al., 2000).

This raft prevents the acidic gastric content from getting refluxed into the esophagus, giving symptomatic relief to GERD patients (Mandel et al., 2000; Sun et al., 2015; Wang et al., 2013).

Surgical Treatment

Justifications for surgery include failed medical management, patient preference for surgery despite successful management, complications of GERD, medical complications attributable to a larger hiatal hernia, or atypical symptoms with reflux documented on 24-h pH monitoring (Heidelbaugh et al., 2003).

The basic principle of surgery includes the reduction of hiatal hernia, repair of diaphragmatic hiatus, strengthening of the EGJ-posterior diaphragm attachment, and strengthening of the antireflux barrier through placement of a gastric wrap around the EGJ (fundoplication) (So et al., 1998).

Mild symptoms of GERD such as heartburn and regurgitation can be eliminated by surgery more effectively (beneficial in 75%–90% of patients), whereas moderate and severe symptoms of GERD, such as coughing, asthma and laryngitis, can be eliminated to a lesser degree by the use of surgery (beneficial in 50%–75% of patients) (So et al., 1998).

Role of Pharmacist in the Management of Gastroesophageal Reflux Disease

Pharmacists are one of the most accessible and trusted health-care professionals and are the first point of contact for many patients. Therefore, it is necessary for them to be aware of typical and atypical GERD symptoms and to be able to determine the relevant course of action to ensure that patients receive effective and individualized treatment (Fig. 6). Additionally, pharmacists must have

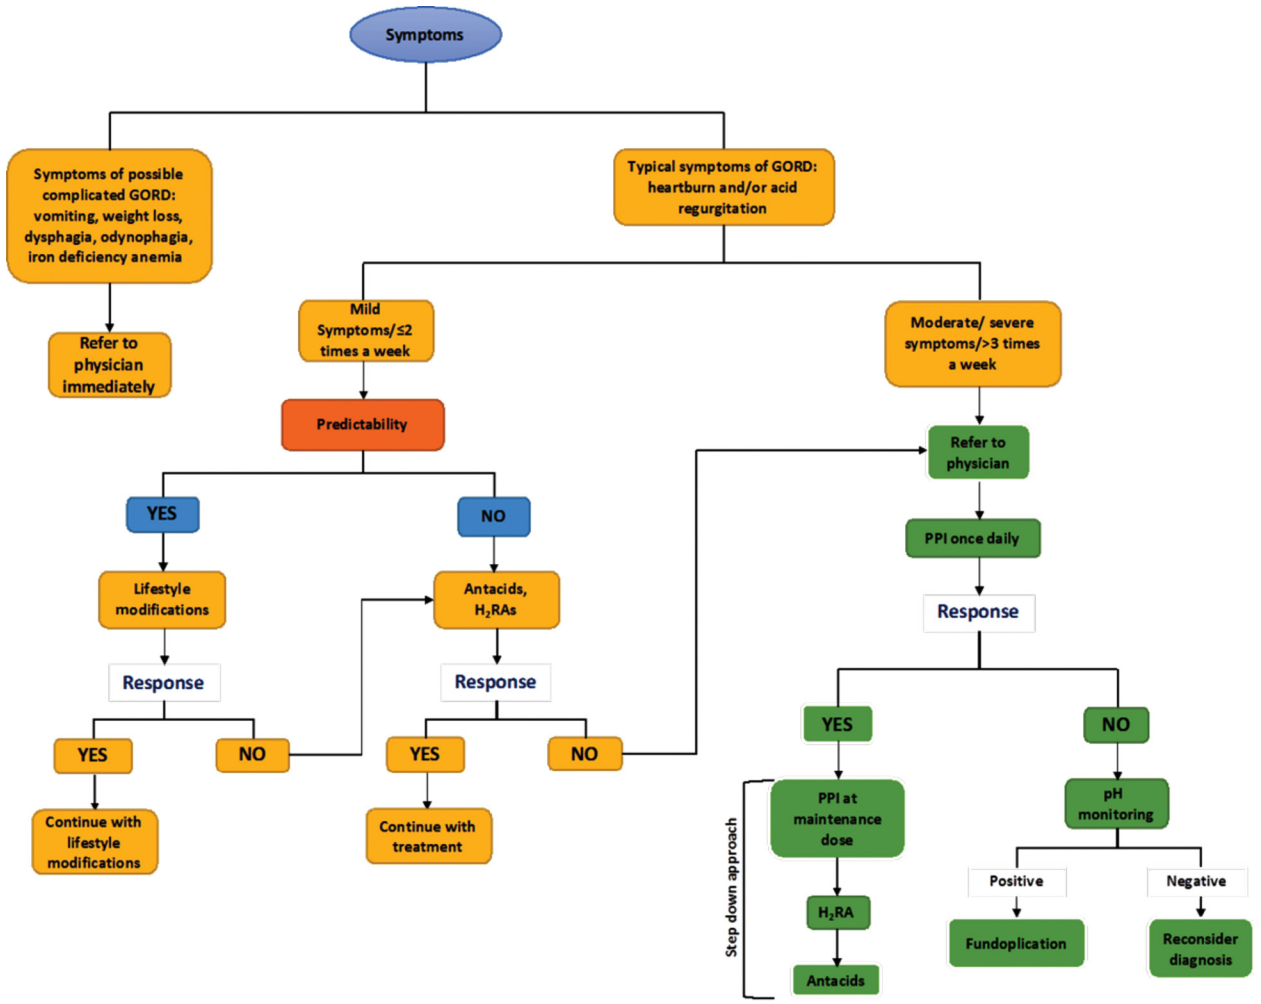

Figure 6 Flow diagram detailing the diagnosis and treatment methods for GERD.

knowledge of possible risk factors, clinical presentations, adverse drug interactions, adverse effects, dosage intervals, dosage titration, complications, and most important of all, therapeutics of GERD (Zeid and Confer, 2016).

Pharmacist's Initiative to Treat Different Gastroesophageal Reflux Disease Conditions

In cases where the patient visits the pharmacy and complains of symptoms consistent with GERD, diagnosis begins with a short interview to determine the characteristics of their symptoms including the nature, frequency, and severity of symptoms (Veldhuyzen van Zanten et al., 2000).

For patients presenting with mild GERD symptoms (symptoms ≤2 times a week), treatment typically begins with lifestyle modifications. This includes advice on smoking cessation, avoiding alcoholic drinks, losing weight, avoiding acidic drinks, elevating the head of the bed, and avoiding foods that may trigger symptoms such as food high in spices or fat (Nilsson, 2004; Pandolfino et al., 2006). However, although effective, lifestyle modifications alone are not sufficient to completely control symptoms in most cases. Therefore, pharmacological treatment of patients exhibiting mild symptoms of GERD begins with an initial OTC therapy of H_2RA or a PPI inhibitor to be taken 30–60 min before the first meal of the day (Colin-Jones, 1995; des Varannes et al., 2010).

If the patient is experiencing typical symptoms of GERD frequently (>3 times a week) and these symptoms affect their quality of life, it becomes evident that the patient is suffering from moderate to severe symptoms of GERD (Moayyedi and Talley, 2006). In this case, the pharmacist should refer the patient to a physician immediately.

The treatment strategy for moderate to severe symptoms of GERD includes gastric acid suppression, which will ultimately suppresses the acidic reflux contents. There are two categories of drugs, which can significantly lower the pH of stomach contents; H_2RAs and PPIs. Patients with moderate to severe GERD are likely to require long-term treatment with PPIs or even surgery in certain circumstances (Sheikh et al., 2014).

Pharmacists are advised to ask questions regarding alarm symptoms in a short interview with the patient. Patients presenting any alarm symptoms should be referred to their physician or to a hospital emergency room immediately.

Pharmacists can treat patients with a family history of GERD displaying mild symptoms. However, if symptoms become uncontrollable or severe, it is the responsibility of the pharmacist to refer the patient to a physician (Flook et al., 2008).

Approximately half of all pregnant women experience GERD during their second or third trimester. If a woman visits a pharmacy and complains of GERD symptoms, pharmacists should educate the patient on appropriate lifestyle modifications (Akbari and Wolf, 2017; Patti, 2016).

Education and Counseling Approaches on Medicine Usages

It is the duty of the pharmacist to provide information to patients regarding available treatment options. Patients should also be made aware of lifestyle changes they could implement to manage GERD symptoms (NICE Guideline Draft, 2014). Other information pharmacists should give includes use of OTC medication, duration of therapy, proper route of administration, dosages, and dosage intervals between consecutive medication (NICE Clinical Guidelines, 2004; Wagner, 2000).

Pharmacists should educate patients on potential adverse reactions of prescribed medications. For example, general adverse effects of PPIs are headaches, diarrhea, and dyspepsia (Katz et al., 2013). Furthermore, long-term use of PPIs may lead to conditions such as B12 deficiency, iron deficiency, hypomagnesemia, increased susceptibility to pneumonia, enteric infections, and hypergastrinemia (Sheen and Triadafilopoulos, 2011). Adverse effects of H_2RAs may include hepatotoxicity and nephrotoxicity (Fisher and Le Couteur, 2001; McGuigan, 1981).

Pharmacists should also examine the medical history of the patient to determine any potential drug interactions. Commonly, ketoconazole, simvastatin, vitamins, and digoxin show drug interactions when administered with PPIs (Blume et al., 2006). Antacids also show drug interactions with a few classes of drugs such as quinolones, NSAIDs, and cephalosporin (Sadowski, 1994). Some other common possible adverse drug interactions of drugs used for the treatment of GERD are presented in **Table 5**.

Pharmacist's Role in Treatment Follow-up

Patients visiting a pharmacist after undergoing treatment for moderate to severe GERD symptoms should have a follow-up with the patients regarding the recovery from GERD. If GERD symptoms persist, the pharmacist should refer the patient to the physician again. If the symptoms are subsiding and the patient is healing, the same treatment regimen of PPIs once daily should be continued unless the treatment is suspended by the physician (Marchetti and Chan, 2009). Pharmacists should also check whether patients are taking medicines properly hence they can evaluate the extent pharmacist-led counseling is helping in controlling the symptoms of

Table 5 Summary of common drug–drug interactions associated with antacid, PPIs, and H_2RAs

	Antacids	*PPIs*	*H_2RAs*
Antivirals	Aluminum and magnesium containing antacids cause a small decrease in exposure to antiviral drugs	PPIs are life threatening or contraindicated with rilpivirine and administered with closed monitoring in some combinations	Dose adjustment and close monitoring are needed
Antidiabetics	No interaction or no interaction of clinical significance	No interaction of clinical significance	Dose adjustment and closed monitoring are needed
Antiasthmatics	No interaction or no interaction of clinical significance	No interaction of clinical significance	Dose adjustment and closed monitoring are required in very few cases otherwise no clinical interaction is found
Anticholinergics	No interaction or no interaction of clinical significance	Dosage adjustment, closed monitoring, and guidance are needed in few cases	Dose adjustment and closed monitoring are required
Antiarrhythmic	Contraindicated or administered with closed monitoring and dose adjustment	No interaction of clinical significance	Dose adjustment and closed monitoring are required
Antibiotics	Dose adjustment and close monitoring are required	Dose adjustment or closed monitoring is needed in few case, administer with guidance	Dose adjustment and closed monitoring are required
NSAIDs	Monitoring and guidance about suitable adverse effects need to be given when antacids are administered with salicylic acid derivatives of NSAIDs, no clinically significant interaction is evident with other NSAIDs	The antiplatelet activity and pharmacokinetic properties are not affected at all	No interaction of clinical significance
Alcohol	No clinical evidence	No interaction of clinical significance	No interaction of clinical significance
Food	Dosage adjustment and closed monitoring are required	No interaction of clinical significance, dose adjustment, and close monitoring is required in few cases	No potential or clinical significance

GERD. Getting the prescription reviewed helps pharmacists maintain a record regarding the improvement of the disease condition (NICE Guideline Draft, 2014).

Management of Gastrointestinal Disorders and the Pharmacist's Role: Inflammatory Bowel Disease

Mohammad Ismail*, Zahid Ali*, Faiza Shahid*, Ejaz Cheema†, *Department of Pharmacy, University of Peshawar, Peshawar, Khyber Pakhtunkhwa, Pakistan; †University of Birmingham, Birmingham, United Kingdom

Learning Objectives

At the end of this chapter, the reader would be able to:

- Develop a basic understanding of the etiopathogenesis and epidemiology of different forms of inflammatory bowel disease (IBD).
- Describe the main clinical features and complications associated with ulcerative colitis and Crohn's disease.
- Discuss various pharmacological approaches and their selection criteria.
- Explain the roles and activities of pharmacists in the pharmacotherapy of IBD.

Introduction

Inflammatory bowel disease (IBD) is an idiopathic immune-mediated chronic inflammatory condition of the gastrointestinal (GI) tract that involves episodes of relapse and periods of remission. The two main forms of IBD are ulcerative colitis (UC) and Crohn's disease (CD) that are characterized by continuous mucosal and intermittent transmural inflammation, respectively. UC affects the colorectal part of the GI tract; whereas CD primarily affects the terminal ileum and cecum (ileocecal CD), however esophagus, small intestine, large intestine and rectum may also be affected.

Epidemiology

The epidemiology of IBD varies substantially over time and across various geographical regions. Although the incidence and prevalence of IBD has stabilized in high-incidence areas including North America and Europe, it continues to rise in previously low-incidence areas such as Eastern Europe and Asia (Ng, 2014; Sharara et al., 2018). A recent systematic review has reported the highest prevalence rates of IBD in Europe (UC: 505 per 100,000 people in Norway; CD: 322 per 100,000 people in Germany) and North America (UC: 286 per 100,000 people in the United States; CD: 319 per 100,000 people in Canada). On the contrary, an increased prevalence of IBD has been reported in recently developed countries across Africa, Asia, and South America (Ng et al., 2018). The incidence of IBD peaks at the second and third decade of life (during 20s and 30s) with a subsequent peak at the age of 60–80 years, but it may occur in individuals of any age (Duricova et al., 2014; Jeuring et al., 2016). Compared to males, the risk of CD is lower in females till the age of 10–14 years, however the risk of the disease increases thereafter. The incidence of UC is similar in both males and females until the age of 45 years, but increases in men afterwards (Shah et al., 2018).

Etiology and Pathophysiology

The exact cause of IBD remains unclear but abnormal immune system, intestinal microbiota, and various genetic and environmental factors are believed to play an important role in its pathogenesis (Ray and Longworth, 2019; Rohr et al., 2018). Intestinal microbiota in the presence of damaged GI mucosal barrier and impaired immune response may result in chronic inflammation. An increased secretion of interferon-γ by the T_1-helper cells and cytokines by the T_{17}-helper cells has been detected in CD. Whereas, an increased secretion of cytokines by the T_2-helper cells has been reported in UC (Yadav et al., 2016). Furthermore, the abundance of proinflammatory microbiota (dysbiosis) has been proved to play an important role in the pathogenesis of IBD and related complications (Rohr et al., 2018; Yadav et al., 2016).

Genetic predisposition is well established in the first-, second-, and even third-degree relatives of patients with IBD. Genetic predisposition is primarily associated with polymorphism of the caspase recruitment domain family member 15 (CARD15) gene in CD and human leukocyte antigen class-II gene in UC (Cho and Brant, 2011; Yadav et al., 2016). Polymorphism of numerous other genes has also been associated with the increased risk of IBD.

Lifestyle factors including diet, cigarette smoking, and stress can significantly affect the pathogenesis of IBD. An increased consumption of fast food, fats, proteins, milk, and refined sugars has also been associated with IBD (Rohr et al., 2018). In addition, the use of nonsteroidal anti-inflammatory drugs (NSAIDs), oral contraceptives, isotretinoin, and several antibiotics may increase the risk of IBD (Ananthakrishnan et al., 2012; Rohr et al., 2018). Cigarette smoking has been reported to increase the risk of CD by twofold but is suspected to reduce the risk of UC (Yadav et al., 2016).

Clinical Presentation

The clinical manifestations of IBD are related to the nature and severity of the disease. Typically, UC is presented with bloody diarrhea, tenesmus, and fecal incontinence (Magro et al., 2017). Nocturnal defecation and fatigue have also been frequently reported. Rectal inflammation results due to passage of frequent, but small volumes of loose stools that is associated with abdominal

pain (Matsuoka et al., 2018). In severe cases, anorexia, weight loss, fever, tachycardia, nausea, vomiting, dehydration, hypokalemia, and hypoalbuminemia can also occur.

Patients with CD may present with abdominal pain, fatigue, low-grade fever, intermittent nonbloody diarrhea, and weight loss (Gomollón et al., 2016). Malabsorption and weight loss are common in patients with CD involving the small intestine. Patients with perianal disease may experience severe perirectal pain, foul-smelling discharge from the fistula, and disfiguring scars of active disease or prior surgery. Growth retardation and delayed or failed sexual maturation may also be manifested in children with CD (Yangyang and Rodriguez, 2017).

Diagnosis

IBD is best diagnosed by a collective assessment of the clinical signs and symptoms, and findings of hematological, histologic, colonoscopic, and radiologic investigations (Gomollón et al., 2016; Magro et al., 2017; Rohr et al., 2018).

Sigmoidoscopy and colonoscopy allow direct visualization of the rectum and colon. They also permit tissue biopsy for histopathological assessment (Gomollón et al., 2016; Magro et al., 2017). Sigmoidoscopy is primarily used for the diagnosis of UC or proctitis due to its limited length of scope (i.e., 60 cm), while colonoscopy can examine the whole large intestine. However, these procedures increase the risk of bleeding and perforations.

Radiological imaging including computed tomography scan and magnetic resonance imaging are noninvasive alternatives of sigmoidoscopy and colonoscopy (Rohr et al., 2018). They permit visualization of the large and small intestine and offer initial diagnosis (particularly when the small intestine is involved) and evaluation of related complications (Rohr et al., 2018). Radiolabeled leukocyte scans may also be used to identify the site and severity of disease.

Hematological and biochemical assays involving complete blood count, liver function tests (LFTs), erythrocyte sedimentation rate (ESR), and C-reactive protein (CRP) are all useful to assess the extent and severity of disease as well as its extraintestinal manifestations (Gomollón et al., 2016; Magro et al., 2017). Altered LFTs are common in patients with hepatic complications. ESR and CRP levels are markers of inflammation and are useful in monitoring the disease activity and response to therapy (Gomollón et al., 2016; Magro et al., 2017).

Serologic tests such as the perinuclear antineutrophil cytoplasmic antibodies (pANCA) and anti-*Saccharomyces cerevisiae* antibodies (ASCA) tests ascertain the type of IBD. A positive pANCA test with negative ASCA test is highly specific for patients with UC, whereas a positive ASCA with a negative pANCA is suggestive of CD (Gomollón et al., 2016; Magro et al., 2017; Mitsuyama et al., 2016). However, serologic tests are associated with false-positive results and should not be used exclusively for the diagnosis of IBD.

Stool tests cannot be used for the diagnosis of IBD, but they can be used to rule out alternative conditions (Gomollón et al., 2016; Magro et al., 2017). Microscopic examination of stool can help identify occult blood or other infective cells such as amoeba, whereas stool culture and toxin assay can be used to identify *Clostridium difficile* infection (Mowat et al., 2011).

Complications

IBD is associated with a number of intestinal and extraintestinal complications. The intestinal complications include strictures, fistulae, abscesses, perforations, toxic megacolon, and superinfections (Matsuoka et al., 2018). Fistulae and abscesses, strictures, and perianal complications are commonly found in patients with CD, whereas toxic megacolon, perforations, and superinfections are frequent in patients with UC. IBD also increases the risk of GI malignancies.

The extraintestinal complications are more frequent in patients with CD. They commonly affect the liver, joints, eyes, skin, and blood (Yangyang and Rodriguez, 2017). The hepatobiliary complications include fatty liver, pericholangitis, autoimmune hepatitis, cirrhosis, cholelithiasis, and cholangiocarcinoma. Severe asymmetric arthritis affecting one or few large joints and osteoporosis can be seen. Ocular complications comprise iritis, uveitis, and conjunctivitis (Vavricka et al., 2015). The mucocutaneous complications include erythema nodosum, pyoderma gangrenosum, and aphthous ulcer. Anemia is a common complication possibly because of chronic blood loss, malnutrition, or drug-induced bone marrow suppression (Vavricka et al., 2015).

Treatment

The primary aim of therapy is to induce and maintain remission of symptoms, promote mucosal healing, and prevent the occurrence of complications. For this purpose, various nonpharmacological and pharmacological strategies are employed.

Nonpharmacological Therapy

Incessant use of elemental, semi-elemental, and defined diets have been demonstrated to reduce inflammation and promote mucosal healing (Alastair et al., 2011). Therefore, they are recommended for the treatment of mild CD along with proper monitoring of disease progression (Lichtenstein et al., 2018). Enteral dietary supplements have also been recommended as adjuvant

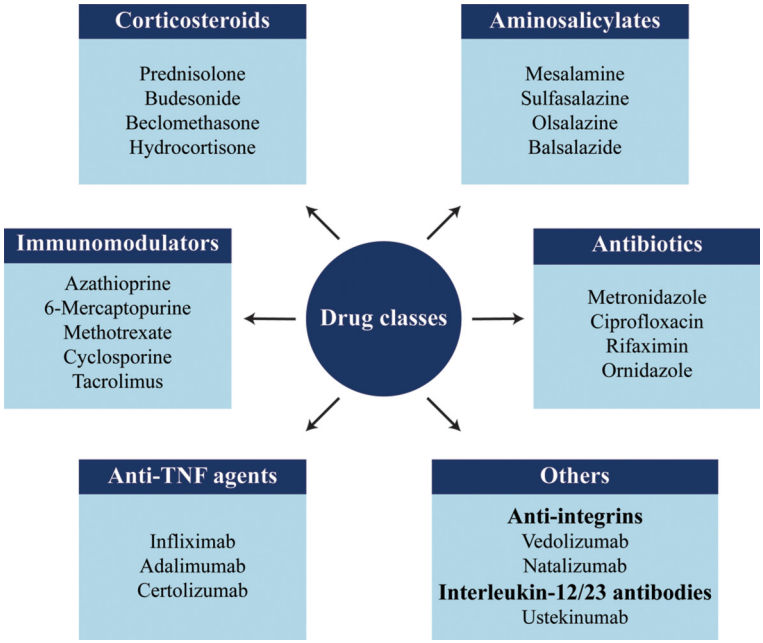

Figure 1 Drugs used for the treatment of inflammatory bowel disease.

therapy. They are mainly used in patients with severe CD involving the small intestine because of significant malnutrition and weight loss (Alastair et al., 2011). Consumption of low-residue diet can prevent intestinal obstruction in patients with small bowel strictures. However, dairy products (a low-residue diet) may cause diarrhea in lactose-intolerant patients (Bitton et al., 2012). Parenteral nutrition therapy is costly and associated with an increased risk of infections. Therefore, it is typically reserved for patients with severe malnutrition or intolerance to enteral therapy (Alastair et al., 2011). Probiotics have been demonstrated to be of some benefit and are recommended as an adjuvant therapy in selected patients considering their efficacy and cost (Wasilewski et al., 2015).

Surgery is one of the recommended options in patients with an advanced IBD. Common surgical procedures involve resection of the affected segment of intestine, closure of fistula or perforation, and drainage of abscess. Colectomy (resection of a segment of large intestine) may be necessary in patients with UC who do not respond to the recommended pharmacotherapy, have signs of premalignant changes, or present with complications such as toxic megacolon (Biondi et al., 2012; Kornbluth et al., 2010). Colostomy is performed in patients with severe perianal or rectal disease. Surgery may also be performed for treating strictures (stricturoplasty) (Lichtenstein et al., 2018).

Pharmacological Therapy

The pharmacological therapy involves the use of various drugs such as aminosalicylates, corticosteroids, immunomodulators, anti-TNF agents (TNF-α antibodies), anti-integrins (integrin antibodies), interleukin-12/23 antibodies, and antibiotics (**Fig. 1**). Their recommended doses are given in **Table 1**.

Although a variety of guidelines are available for the management of IBD (see further reading for details), the ones published by the American College of Gastroenterology and the European Crohn's and Colitis Organization are widely used (Gomollón et al., 2016; Harbord et al., 2017; Kornbluth et al., 2010; Lichtenstein et al., 2018).

Aminosalicylates

Aminosalicylates are the recommended first-line agents for the treatment of IBD because of their local (intestinal) anti-inflammatory activity and better safety profile. They include sulfasalazine, mesalamine, balsalazide, and olsalazine. Several formulations of aminosalicylates such as suppositories, enema, foam, and oral tablets/capsules are available. The choice of a specific dosage-form depends on the severity and location of the disease (Harbord et al., 2017).

Corticosteroids

Corticosteroids are rapid acting, potent anti-inflammatory agents. They are recommended for induction of remission. In IBD, both topical and systemic corticosteroids are used. Topical corticosteroids are administered as enema or foam and systemic corticosteroids are administered via oral (prednisolone) or intravenous route (hydrocortisone). Topical preparations and ileal release budesonide are preferred in patients with mild to moderate disease, whereas systemic preparations are commonly used in severe disease.

Table 1 Recommended doses for the pharmacotherapy of inflammatory bowel disease

	Dosage		
Drugs	*Ulcerative colitis*	*Crohn's disease*	*Special considerations*
Sulfasalazine	**Remission**: Oral 1–2 g/day in three divided doses (maximum 4 g/day) **Maintenance**: Oral 2 g/day	**Remission**: Oral 3–6 g/day in divided doses (off-label)	**CI**: Hypersensitivity, intestinal or urinary obstruction and porphyria **DA**: In GI intolerance, discontinue for few days and reintroduce therapy with 50% daily dose then gradually increase.
Mesalamine	**Remission**: Oral 2.4–4.8 g/day; the dosage and cumulative daily dose depends on available formulations **Maintenance**: Oral 1.5–2.4 g/day; the dosage and cumulative daily dose depends upon the available formulations	**Remission**: Oral 1 g every 6–8 h	**CI**: Hypersensitivity **DA**: None required **Precautions**: Do not administer delayed release mesalamine with antacids
Balsalazide	**Remission**: Oral 2.25 g three times daily **Maintenance**: Oral 1.5–2 g twice daily	–	**CI**: Hypersensitivity **Precautions**: Effectiveness and safety of use >12 weeks is not established
Budesonide	**Remission**: Oral 9 mg once daily; rectal foam 2 mg twice daily; rectal enema 100–125 mL (2 mg/100 mL) once daily	**Remission**: Oral 9 mg once daily **Maintenance**: Oral 6 mg once daily	**CI**: Hypersensitivity to budesonide, milk proteins, and primary treatment of asthma **DA**: Reduce dose in moderate or severe hepatic impairment; use lowest effective dose in geriatrics
Prednisolone	**Remission**: Oral 5–60 mg once daily	**Remission**: Oral 5–60 mg once daily	**CI**: Systemic infections **DA**: None required; use lowest effective dose in geriatrics **Precautions**: Do not stop abruptly, taper dose gradually
Hydrocortisone	**Remission**: IV 100–500 mg every 2, 4, or 6 h; Oral 20–240 mg/day	**Remission**: IV 100–500 mg every 2, 4, or 6 h; Oral 20–240 mg/day	**CI**: Hypersensitivity, systemic infections **DA**: Reduce dose in hepatic impairment **Precautions**: Do not stop abruptly, taper dose gradually
Azathioprine	**Remission**: Initiate 20–40 mg/kg infusion over 36 h then oral 2 mg/kg/day **Maintenance**: Oral 1.5–2.5 mg/kg/day (off-label)	**Remission/Maintenance**: Oral 1.5–4 mg/kg/day	**CI**: Hypersensitivity, Pregnancy **DA**: Reduce dose or discontinue therapy in bone marrow suppression; reduce dose in lower doses by 25% in moderate renal impairment and 50% in ESRD
6-Mercaptopurine	**Remission/Maintenance**: Oral 50 mg daily; adjust dose according to response (off-label)	**Remission/Maintenance**: Oral 1–1.5 mg/kg daily (off-label)	**CI**: Hypersensitivity, resistance to 6-mercaptopurine **DA**: Use the lowest effective dose in renal or hepatic impairment and geriatrics; adjust dose to maintain WBC >4500 and platelets >100,000
Methotrexate	–	**Remission/Maintenance**: IM 15–25 mg once weekly	**CI**: Pregnancy, breast-feeding, chronic liver disease, hypersensitivity, kidney failure, compromised immunity and bone marrow suppression **DA**: Reduce dose by half in moderate renal impairment; reduce dose by 25% if bilirubin is 3.1–5 mg/dL or avoid use if bilirubin is >5 mg/dL
Infliximab	**Remission**: IV 5 mg/kg over 2 h at weeks 0, 2, and 6 **Maintenance**: IV 5 mg/kg over 2 h every 8 weeks	**Remission**: IV 5 mg/kg over 2 h at weeks 0, 2, and 6 **Maintenance**: IV 5 mg/kg over 2 hours every eight weeks	**CI**: Hypersensitivity **DA**: Use doses ≤5 mg/kg in moderate or severe heart failure **Precautions**: Infusion reaction, infuse slowly, and consider preventive therapy with corticosteroids, acetaminophen and antihistamines; discontinue if sepsis or infection develops during therapy
Vedolizumab	**Remission/Maintenance**: Infuse 300 mg over 30 min at weeks 0, 2, and 6 followed by 300 mg every 8 weeks	**Remission/Maintenance**: Infuse 300 mg over 30 min at weeks 0, 2, and 6 followed by 300 mg every 8 weeks	**CI**: Active and severe infection, hypersensitivity **Precautions**: Discontinue if jaundice or hepatic injury develops

(*Continued*)

Table 1 Recommended doses for the pharmacotherapy of inflammatory bowel disease (*cont.*)

	Dosage		
Drugs	*Ulcerative colitis*	*Crohn's disease*	*Special considerations*
Ustekinumab	–	**Remission/ Maintenance**: Initiate ~55 kg weight: Infuse 260 mg over 1 h, 55–85 kg weight: Infuse 390 mg over 1 h, >85 kg weight: Infuse 520 mg over 1 h followed by subcutaneous 90 mg every 8 weeks	**CI**: Active infection, hypersensitivity **Precautions**: Discontinue ustekinumab if infection develops during therapy
Metronidazole	Oral or IV 500 mg thrice daily	Oral or IV 500 mg thrice daily	**CI**: Hypersensitivity, alcohol consumption, first trimester of pregnancy. **DA**: Reduce dose by half in severe hepatic impairment
Ciprofloxacin	Oral 500–750 mg twice daily or IV 400 mg twice or thrice daily	Oral 500–750 mg twice daily or IV 400 mg twice or thrice daily	**CI**: Hypersensitivity **DA**: Administer 200–400 mg every 18–24 h in moderate or severe renal impairment Renal impairment (CrCl 5–29 mL/min): 200–400 mg intravenous every 18–24 h

CI, Contraindications; CrCl, creatinine clearance; DA, dose adjustments; ESRD, end-stage renal disease; GI, gastrointestinal; IM, intramuscular; IV, intravenous; WBC, white blood cells.
Sources: ASHP (2018), Lexicomp (2018), and Micromedex Drugdex (2018)

Guidelines do not recommend the long-term use of corticosteroids as a maintenance therapy because of limited proven efficacy and increased risk of serious adverse effects (Harbord et al., 2017; Lichtenstein et al., 2018).

Immunomodulators

Immunomodulators suppress the immune system by disrupting the cellular signaling processes, which result in apoptosis of immune cells. They include azathioprine, 6-mercaptopurine (6-MP), methotrexate, cyclosporine, and tacrolimus. Immunomodulators exhibit corticosteroid sparing effect and are used for maintenance of remission (particularly in corticosteroid-dependent patients). They are not recommended for induction of remission because of delayed onset of clinical effect (Gomollón et al., 2016; Lichtenstein et al., 2018).

Immunomodulators such as azathioprine or 6-MP are also used in combination with infliximab because they attenuate the development of antibodies against infliximab and maintain its efficacy for an extended period of time (Harbord et al., 2017; Lichtenstein et al., 2018). Methotrexate is an effective alternative to azathioprine and 6-MP (thiopurines) for the maintenance of remission and is used in a similar manner as thiopurines. Parenteral formulations of methotrexate are more effective than oral preparations but the latter are preferred by practitioners because of better treatment adherence (Herfarth et al., 2015). Cyclosporine and tacrolimus are reserved for patients with severe refractory disease (Harbord et al., 2017; Lichtenstein et al., 2018).

Anti-TNF Agents

Monoclonal anti-TNF agents include infliximab, adalimumab, and certolizumab. They effectively reduce inflammation and promote mucosal healing, and are recommended for induction as well as maintenance of remission (Harbord et al., 2017; Lichtenstein et al., 2018). The choice of a specific agent is based on its cost, availability, and route of administration. Combination therapy of infliximab with immunomodulator has greater efficacy than either agents alone (Gomollón et al., 2016; Harbord et al., 2017). A number of more affordable biosimilar products of infliximab and adalimumab have also been approved (Danese et al., 2016; Lichtenstein et al., 2018).

Anti-Integrins

Anti-integrins include natalizumab and vedolizumab. They reduce inflammation by preventing the adhesion of leukocytes surface integrins to endothelial cell adhesion molecules. Anti-integrins are indicated for the maintenance of remission either alone or in combination with immunomodulators (Harbord et al., 2017; Lichtenstein et al., 2018).

Interleukin-12/23 Antibodies

Ustekinumab is recommended for patients who do not respond to immunomodulators and anti-TNF agents (Lichtenstein et al., 2018). Ustekinumab is considered safe with no apparent risk of opportunistic infections and malignancies (Papp et al., 2015).

Novel Agents

An estimated one-third patients with CD do not respond to anti-TNF agents, whereas one-third of patients lose response to biologics over time (Lichtenstein et al., 2018). To fulfill the therapeutic needs of such patients, various novel agents are under investigation. They include etrolizumab, ozanimod, risankizumab, brazikumab, filgotinib, upadacitinib, tofacitinib, and mongersen (Chan and Ng, 2017; Lichtenstein et al., 2018; Sands, 2017).

Others

Antibiotics such as metronidazole and ciprofloxacin are primarily used for the prevention and treatment of septic complications (Lichtenstein et al., 2018). They have no direct effect on remission of symptoms; however, they may help suppress the immune response by eliminating bacterial antigenic triggers (Nitzan et al., 2016). Moreover, an enteric formulation of rifaximin may be of some benefit in mild disease (Prantera et al., 2012).

Treatment Approaches: Ulcerative Colitis

Induction of Remission

Remission therapy for UC aims to alleviate symptoms. The selection of pharmacotherapy for the induction of remission depends on the site and severity of disease (Fig. 2). Treatment algorithm for the induction of remission in patients with UC is presented in Fig. 3.

Mild–Moderate Distal Colitis

Oral aminosalicylates (sulfasalazine, mesalamine, olsalazine, or balsalazide), topical aminosalicylate (mesalamine), or topical corticosteroids are recommended in patients with mild to moderate distal colitis (Kornbluth et al., 2010). Topical mesalamine is considered to be more effective than oral aminosalicylates (Hanauer, 2016). Whereas, combination therapy with oral and topical aminosalicylates has been reported to be more effective than monotherapy with either agents alone (Ford et al., 2012). Oral prednisolone or infliximab may be considered in patients who present with systemic manifestations or who do not respond to aminosalicylates or topical corticosteroids (Kornbluth et al., 2010).

Mild–Moderate Extensive Colitis

Oral aminosalicylates (sulfasalazine or mesalamine) either alone or in combination with topical aminosalicylates are the recommended first-line therapy in mild to moderate extensive colitis. Alternatively, oral corticosteroids (prednisolone) may be considered in patients who do not respond to the combination of aminosalicylates (oral and topical) or whose condition demand speedy remission. Following failure of oral corticosteroids, immunomodulators (azathioprine or 6-MP), or anti-TNF agents (infliximab)

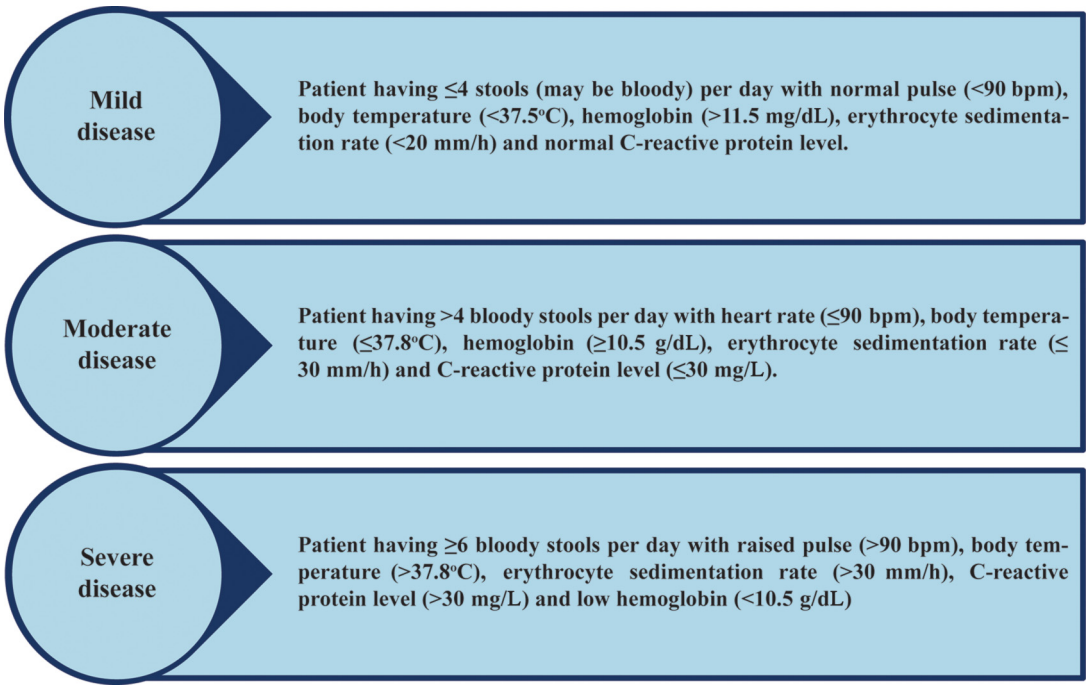

Figure 2 Classification of ulcerative colitis on the basis of severity.

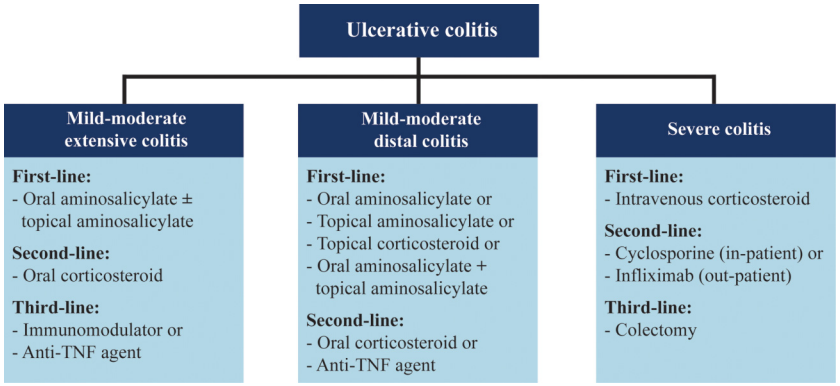

Figure 3 Treatment algorithm for the remission of ulcerative colitis.

should be used (Harbord et al., 2017; Kornbluth et al., 2010). Adjuvant therapy with probiotics, fecal transplant, modified release phosphatidylcholine and *Andrographis paniculata* (herbal remedy) has been shown to improve the clinical response (Karner et al., 2014; Rossen et al., 2015; Sandborn et al., 2013b; Shen et al., 2013).

Severe Colitis

Patients with severe colitis should be hospitalized. Supportive therapy needs to be administered that includes intravenous fluids (as fluid replenishment), low molecular weight heparin (for thromboprophylaxis), electrolytes (for electrolyte imbalance), and blood transfusion (for anemia) (Dignass et al., 2015; Harbord et al., 2016; Nguyen et al., 2014). A collaborative management by medical and surgical experts is highly recommended for timely selection of appropriate therapy and improved health outcomes (Bartels et al., 2013; Harbord et al., 2017). Intravenous corticosteroids (hydrocortisone) are recommended as first-line treatment for severe UC (Bossa et al., 2007). Response to corticosteroid therapy is best assessed after three days. Cyclosporine (in hospitalized patients) or infliximab (in outpatients) may be considered as salvage therapy (Harbord et al., 2017; Järnerot et al., 2005). Whereas, colectomy is recommended provided patient's condition does not improve following 4–7 days of salvage therapy (Harbord et al., 2017). Antibiotics such as metronidazole or ciprofloxacin are indicated in septic complications. Total parenteral nutrition may be considered in malnourished patients (Harbord et al., 2017; Kornbluth et al., 2010).

Maintenance of Remission

Patients with UC require long-term pharmacotherapy for the maintenance of remission in order to delay or prevent the relapse of symptoms.

Mild–Moderate Distal Colitis

Topical mesalamine (enema or suppository) is the recommended first-line therapy for the maintenance of remission. Combination therapy with oral (sulfasalazine) and topical (mesalamine) aminosalicylates is more effective and may be used in patients who can tolerate them. Alternatively, immunosuppressants (azathioprine or 6-MP) or infliximab may be considered in patients who do not respond to aminosalicylates (Harbord et al., 2017; Kornbluth et al., 2010).

Mild-Moderate Extensive Colitis

Oral aminosalicylates including sulfasalazine, mesalamine, or balsalazide are effective for the maintenance of remission. The long-term use of corticosteroids should be avoided. Azathioprine or 6-MP is recommended for maintenance of remission in corticosteroid-dependent patients and for those who fail to respond to aminosalicylates (Kornbluth et al., 2010). Infliximab should be used in patients who have achieved remission with its use (Kornbluth et al., 2010).

Therapy for Refractory Disease

Patients with persistent active disease, despite the use of combination therapy consisting of oral corticosteroids combined with oral and rectal aminosalicylates, are considered refractory (Harbord et al., 2017). Such patients should be carefully evaluated for nonadherence or resistance to previous drug therapy, inadequate delivery of drug to the inflamed tissue, undiagnosed or misdiagnosed conditions, and the presence of complications (Gecse and Lakatos, 2014; Harbord et al., 2017). Hospital admission is indicated in patients with systemic manifestations for intravenous therapy, whereas patients without systemic manifestations can be treated as out-patients (Harbord et al., 2017; Mehta et al., 2013). Intravenous corticosteroids are the recommended first-line therapy (Harbord et al., 2017). Alternatively, azathioprine/6-MP or infliximab/adalimumab may be used (Archer et al., 2016; Gecse and Lakatos, 2014; Harbord et al., 2017). Limited evidence also supports the use of oral/rectal cyclosporine or tacrolimus (Harbord

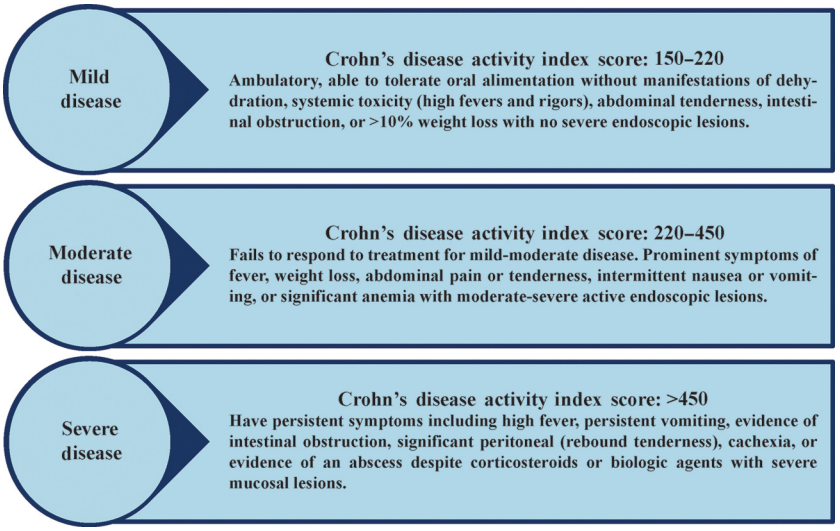

Figure 4 Classification of Crohn's disease on the basis of severity.

et al., 2017; Schmidt et al., 2013). Rectal tacrolimus (ointment) in a dose of 1–1.5 mg twice daily has been proven to be effective in patients resistant to aminosalicylates, corticosteroids, immunosuppressants, and infliximab (Lawrance et al., 2017). If symptoms persist, surgery (colectomy or proctocolectomy) should be considered (Harbord et al., 2017).

Treatment Approaches: Crohn's Disease

The selection of therapy depends on the site, severity (Fig. 4), and prognosis of disease. In addition, previous drug use and the presence of complications are also considered. Patients with extensive disease, young age (<40 years), perianal disease, and those requiring corticosteroids as initial therapy usually show poor prognosis (Miheller et al., 2013). Current practice involves rapid addition of potent agents when the first-line therapy fails to achieve the desired outcome in expected time (accelerated bottom-up approach) (Gomollón et al., 2016). Alternatively, potent agents may be used at an early stage in some patients (top-down approach) (D'Haens et al., 2008; Lichtenstein et al., 2018).

Induction of Remission

The primary aim of remission therapy is to swiftly alleviate the symptoms (Lichtenstein et al., 2018). In general, aminosalicylates and corticosteroids are used in mild or moderate disease, whereas anti-TNF agents either alone or in combination with immunomodulators are preferred in patients with severe disease and/or poor prognosis (Fig. 5) (Terdiman et al., 2013).

Ileocecal Disease

Ileocecal disease is the most common form of CD affecting the terminal ileum and cecum. It can be further divided into mild, moderate, and severe disease.

Mild disease

In mild disease, ileal release budesonide (corticosteroid) is the recommended first-line therapy. Alternatively, oral aminosalicylate (sulfasalazine) may be used. Dietary therapy may be considered in patients who refuse to take medications; however, proper monitoring for disease progression would be required. Anti-TNF agents can be used, but they are not preferred due to their high cost and adverse effects (Lichtenstein et al., 2018).

Moderate disease

Ileal release budesonide or systemic corticosteroids (prednisolone) are recommended as initial therapy in moderate disease (Gomollón et al., 2016; Lichtenstein et al., 2018). Systemic corticosteroids are alternative options; however, they should be sparingly used for remission and their dose must be tapered down (Ho et al., 2006). Patients refractory to corticosteroids should be treated with an anti-TNF agents or combination of a corticosteroid and an immunomodulator (azathioprine or methotrexate) (Gomollón et al., 2016; Lichtenstein et al., 2018; McDonald et al., 2014). Vedolizumab may be considered in patients who fail to respond to systemic corticosteroids and/or anti-TNF agents (Gomollón et al., 2016; Lichtenstein et al., 2018). Whereas, ustekinumab is suggested for patients refractory to corticosteroids, immunomodulators, or anti-TNF agents (Feagan et al., 2016).

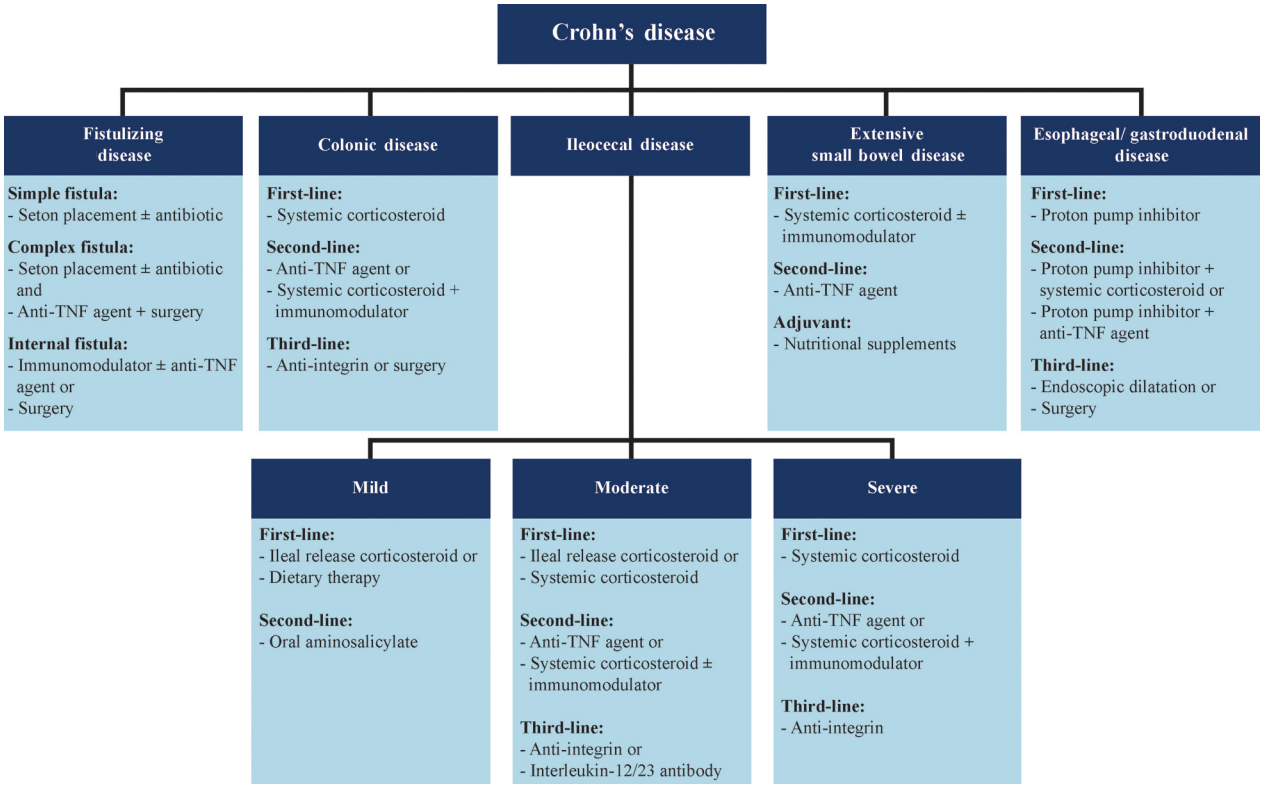

Figure 5 Treatment algorithm for the remission of Crohn's disease.

Severe disease

Systemic corticosteroid (prednisolone or hydrocortisone) is the recommended first-line therapy in severe disease. Alternatively, anti-TNF agents (infliximab) or restarting systemic corticosteroids in combination with immunomodulators (azathioprine) may be used in patients who do not respond to monotherapy with systemic corticosteroids (Gomollón et al., 2016; Lichtenstein et al., 2018). Combination therapy comprising anti-TNF agents and immunomodulators has greater efficacy than either agents alone. Patients with poor prognosis may benefit from early initiation of infliximab and immunomodulator combination therapy (Feagan et al., 2008). Vedolizumab should be used in patients refractory to corticosteroids and/or anti-TNF agents (Gomollón et al., 2016). Whereas, cyclosporine or tacrolimus is ineffective and should not be used (Lichtenstein et al., 2018).

Fistulizing/Perianal Disease

Around one-third of the patients present with fistula predominantly in the perianal region. Treatment of fistulizing disease requires collaborative input from medical and surgical experts. Patients with asymptomatic simple fistula do not require treatment. Whereas, symptomatic simple fistula is initially drained by seton placement followed by treatment with metronidazole or ciprofloxacin (Lichtenstein et al., 2018). Complex fistulizing disease is treated with a combination of surgery and anti-TNF agent (infliximab); however, prior drainage of abscess by seton placement and treatment of infection are needed. Internal fistula (rectovaginal, enterovesical or enteroenteric) is treated with an immunomodulator (azathioprine) either alone or in combination with anti-TNF agent (infliximab). Typically, pharmacological therapy is given prior to surgery in order to improve the patient's condition to enable surgical intervention (Lichtenstein et al., 2018).

Colonic Disease

Systemic corticosteroid (prednisolone) is the recommended first-line therapy for colonic disease. Anti-TNF agents (infliximab) are used in patients refractory to prednisolone. Alternatively, combination therapy comprising a systemic corticosteroid (prednisolone) and an immunomodulator (azathioprine or 6-MP) may be used. Vedolizumab (anti-integrin) or surgery should be considered in patients who do not respond to anti-TNF agents (Gomollón et al., 2016).

Extensive Small Bowel Disease

Extensive small bowel CD is associated with increased inflammation and malabsorption, which often leads to nutritional deficiencies. Systemic corticosteroid is the recommended first-line therapy. Combination therapy with a systemic corticosteroid and an immunomodulator (for steroid-sparing effect) may be considered. Anti-TNF agents should be used in patients refractory to

corticosteroids (Gomollón et al., 2016). Whereas, nutritional supplements are recommended as an adjunctive therapy (Wall et al., 2013).

Esophageal and Gastroduodenal Disease

Mild esophageal and/or gastroduodenal disease should be treated with proton pump inhibitors. A combination of proton pump inhibitor with either systemic corticosteroid or anti-TNF agent is recommended for severe disease. Endoscopic dilatation or surgery may be considered for the treatment of symptomatic strictures (Gomollón et al., 2016).

Maintenance of Remission

The currently approved drugs for CD merely provide symptomatic relief. Once remission has been achieved, maintenance therapy is required in patients who are at risk of recurrence (Gomollón et al., 2016; Lichtenstein et al., 2018). In general, thiopurines (azathioprine, 6-MP), methotrexate, anti-TNF agents (infliximab), and anti-integrins (vedolizumab), either alone or in combination are effective and recommended for the maintenance of remission (Gomollón et al., 2016; Lichtenstein et al., 2018).

For corticosteroid-induced remission, azathioprine, 6-MP, or methotrexate is the recommended first-line agent (Gomollón et al., 2016; Lichtenstein et al., 2018; Terdiman et al., 2013). Dose escalation may be considered in the case of relapse (Gomollón et al., 2016). Alternatively, an anti-TNF agent (infliximab) either alone or in combination with azathioprine/6-MP should be used (Gomollón et al., 2016; Lichtenstein et al., 2018).

For biologics-induced remission, maintenance therapy with the same agent that was used for the induction of remission is recommended (Gomollón et al., 2016). Biological agents including anti-TNF agents (infliximab), anti-integrins (vedolizumab), and interleukin-12/23 antibodies (ustekinumab) are effective options for use as maintenance therapy (Lichtenstein et al., 2018; Terdiman et al., 2013). Furthermore, if remission has been achieved with the combination of anti-TNF agent (infliximab) and immunomodulator (azathioprine), the same combination should be used as maintenance therapy (Gomollón et al., 2016).

In extensive disease, azathioprine or 6-MP is recommended for maintenance of remission. Alternatively, methotrexate may be considered. Anti-TNF agents (infliximab) should be used in patients with aggressive disease and/or poor prognosis (Gomollón et al., 2016).

Postsurgery Maintenance

Postsurgery recurrence significantly increases with the presence of a number of risk factors such as cigarette smoking, associated complications (abscess or fistula), aggressive phenotype, and multiple prior surgeries. Maintenance therapy is recommended in patients with moderate/severe disease or those presented with risk factor(s) (Lichtenstein et al., 2018).

In low-risk patients (moderate/severe disease with no risk factor), azathioprine or 6-MP is recommended as initial maintenance therapy (Doherty et al., 2009; Lichtenstein et al., 2018). Alternatively, mesalamine may be considered in the case of intolerance to azathioprine/6-MP (Ford et al., 2011). Anti-TNF agents (infliximab) should be used in patients refractory to azathioprine/6-MP (Lichtenstein et al., 2018; Sorrentino et al., 2012).

In high-risk patients (with one or more risk factors), an anti-TNF agent (infliximab) is recommended as first-line therapy. It should be initiated within four weeks after surgery (Lichtenstein et al., 2018; Singh et al., 2015). Alternatively, combination therapy with an anti-TNF agent (infliximab) and azathioprine/6-MP may be used that has greater efficacy as compared with either agent alone (Colombel et al., 2010; Renna et al., 2014).

Therapy for Refractory Disease

Several factors such as response to previous therapies, time to relapse, and patient's preferences (affordability, convenience, and adherence) need to be considered prior to selection of therapy for the management of refractory disease. Azathioprine is recommended as initial therapy in patients with an early relapse. Adherence must be checked in the case of poor response to azathioprine. Dose escalation may improve response to azathioprine in patients with better adherence. Infliximab may be used as an alternate option; however, it is preferred in patients with either a moderate/severe disease or those refractory to corticosteroids (Gomollón et al., 2016). Vedolizumab is recommended in patients who fail to respond to azathioprine and infliximab (Sandborn et al., 2013a). Surgery may be considered in patients with localized disease. Whereas, nutritional supplements may be used as an adjuvant therapy in malnourished patients (Gomollón et al., 2016).

Role of Pharmacist

The pharmacists' role in the management of IBD mainly focuses on efforts to rationalize pharmacotherapy, educate patients, improve treatment adherence, minimize cost, and accomplish therapeutic goals.

A study reported inadequate baseline knowledge about disease/medications and poor treatment adherence among patients with IBD. A significant improvement was reported in the disease-related knowledge of patients as well as in their medication adherence following the intervention of clinical pharmacists (Ashok et al., 2017). Another study suggested that medication adherence can be

improved and further sustained through a personalized counseling session led by a pharmacist (Tiao et al., 2017). Pharmacist as a member of the GI team monitors the efficacy and safety of self-injectable biological preparations, provides education to patients regarding their proper use and administration, and optimizes adherence to such preparations (Bhat et al., 2015). A pharmacist-led methotrexate self-injection training program can ensure appropriate and safe use of methotrexate for patients with CD (Clark et al., 2006). A study that assessed the impact of a pharmacist involvement on the prophylaxis of venous thromboembolism (VTE) reported a significant improvement in the rates of VTE prophylaxis (Ra et al., 2013). The availability of various drugs that are costly but used in the management of IBD requires the involvement of pharmacists in both financial and clinical management of patients who are receiving such drugs (Mullican and Francart, 2016). Pharmacist-led evaluation of medication therapy can effectively identify the drug-related problems (DRPs) such as dosage errors, drug without indication, and drug–drug interactions (Cerveny et al., 2007; Chellangi et al., 2015).

Pharmacists' Patient Care Process

A team-based patient-centered care is vital for achieving the desired therapy outcomes for patients in a cost-effective manner. Pharmacists' Patient Care Process (PPCP) is a comprehensive approach as part of pharmacists' collaborative work with other healthcare professionals in the delivery of optimized patient care. The main components of PPCP include collect, assess, plan, implement, and follow-up (monitor/evaluate) (Gonyeau et al., 2018; JCPP, 2014). In PPCP, pharmacists' specific activities for patients with IBD are described in **Fig. 6**.

Patient Education

Inflammatory bowel disease is a chronic medical condition that requires lifelong treatment. Therefore, patient education is an essential component of therapeutic management in order to achieve the desired outcomes. Patient education improves shared decision making, medication use, disease knowledge, and adherence. Education about disease, its therapy, and associated complications should be provided to every patient. The need for continued therapy despite remission of symptoms must be stressed to patients (Lichtenstein et al., 2018). Patients must be informed about the importance and need for preventive therapy in addition to taking adequate dietary supplements (Farraye et al., 2017). The significance of various dietary supplements such as low-residue, elemental, semi-elemental, and defined diets must be covered in patient education (Abegunde et al., 2016; Farraye et al., 2017;

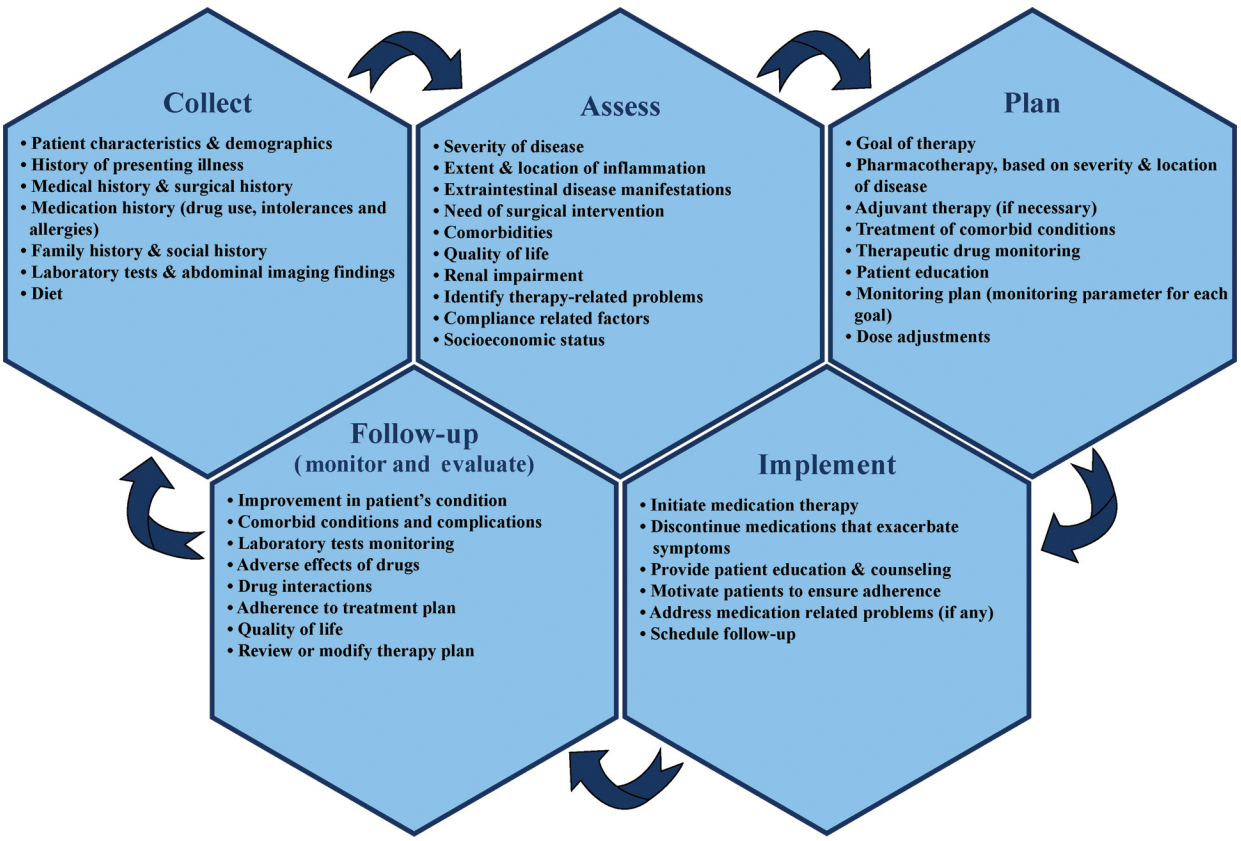

Figure 6 Pharmacists' patient care process for inflammatory bowel disease.

Lichtenstein et al., 2018). Furthermore, information about the safety of drugs in pregnancy or breastfeeding and their effects on fertility should be provided to pregnant patients or those who wish to conceive (Beaulieu and Kane, 2011; Sands et al., 2015). Regular exercise and abstinence from smoking and alcohol should be encouraged. Patients should be advised to seek medical attention if they experience worsening of symptoms such as signs of weight loss, dehydration, fever, abdominal pain, and bloody stools. Moreover, patients must be advised to undergo regular laboratory and other diagnostic tests for the timely identification and rectification of metabolic, hematologic, or other abnormalities.

Treatment Adherence

Treatment adherence is a challenging issue in patients with IBD. Nonadherence to therapy may result in aggravated disease activity, poor response to therapy, increased hospitalization and cost of treatment, and poor patients' quality of life (Herman and Kane, 2015; Lenti and Selinger, 2017; Tae et al., 2016). An estimated one-third of patients with IBD show nonadherence to prescribed therapy (Coenen et al., 2016; Tae et al., 2016). A pooled analysis reported nonadherence to anti-TNF therapy in 17% of patients with IBD (Lopez et al., 2013). Whereas, another study reported nonintentional and intentional nonadherence in around 42% and 57% of patients, respectively (Campos et al., 2016).

Nonadherence to drug therapy is a multifaceted issue that cannot be addressed by focusing on a single aspect only (Lenti and Selinger, 2017; Lopez et al., 2013). Some common predictors of nonadherence include smoking, anxiety or depression, use of syringes, forgetfulness, family and social insecurities, limited knowledge about medicines, and influence of drugs on daily activities (Coenen et al., 2016; Lopez et al., 2013; Spekhorst et al., 2016; Tae et al., 2016). The selection of an appropriate interventional approach should be based on addressing the patient-specific barriers to medicine adherence (Lenti and Selinger, 2017; Lopez et al., 2013). Studies suggest that patient education, simplification of therapeutic regimen, use of reminder systems, and organizational strategies (e.g., pill boxes) are useful for patients with accidental nonadherence. Whereas, addressing motivational issues, teaching skills for problem solving, and addressing problematic patterns of family functioning are beneficial for patients with intentional nonadherence (Chan et al., 2017; Greenley et al., 2013; Herman and Kane, 2015).

Self-Management

Patient's self-management of the disease is another important area for pharmacists to utilize their knowledge and skills. Patients with IBD often experience difficulty in managing various aspects of their disease. Pharmacists can help guide patients and their attendants about various self-management strategies including proper administration of therapy, nutritional supplementation, and management of stress and social relations (Bhat et al., 2015; Tran and Mulligan, 2018; Wong et al., 2011).

Monitoring Therapy Outcomes

The effectiveness of therapy, disease progression, and occurrence of complications should be vigilantly monitored in patients with IBD. Patient reported complaints, patient's history, physical examination, diagnostic tests, and patients' quality of life are all effective tools for the assessment of therapeutic outcomes (El-Matary, 2014). Diagnostic tests including serum transferrin, serum albumin, and markers of inflammation such as ESR and CRP can be used to monitor disease activity. Patients should be monitored for fluid or electrolyte imbalances because of diarrhea. Patients often develop microcytic anemia as a result of malabsorption or chronic blood loss; therefore, proper assessment is recommended. Patients' quality of life can be assessed with the help of an IBD questionnaire that can be used in order to evaluate bowel function, emotional status, systemic symptoms, and social function (Chen et al., 2017).

Therapeutic Drug Monitoring

Several guidelines recommend therapeutic drug monitoring (TDM) of selected therapies in order to ensure maximal efficacy with minimal adverse effects and treatment failure. TDM can also assess patients' adherence or resistance to therapy (Guidi et al., 2018; Hoseyni et al., 2018; Sheasgreen and Nguyen, 2017). In IBD, TDM is typically performed for biological therapies including anti-TNF agents and thiopurines because of loss of efficacy overtime (Hoseyni et al., 2018; Mitrev and Leong, 2017; Restellini et al., 2018; van Hoeve et al., 2018).

Adverse Drug Effects

Adverse drug effects (ADEs) associated with pharmacotherapy of IBD may result in increased morbidity, premature discontinuation of therapy, nonadherence, and poor therapy outcome (Godat et al., 2018; McLean and Cross, 2014). Particular attention should be given to frequent or serious ADEs (**Table 2**).

Aminosalicylates are well-tolerated by most of the patients but they may cause minor GI-related ADEs, arthralgia, anemia, hepatitis, or bone marrow suppression. Among aminosalicylates, sulfasalazine has a higher incidence of ADEs because of systemic absorption of its sulfapyridine moiety. The adverse effects of aminosalicylates can be managed by initiating therapy with a lower dose followed by gradual dose escalation to achieve the desired response (Troncone and Monteleone, 2017).

Table 2 Adverse drug effects associated with pharmacotherapy of inflammatory bowel disease

Drugs	*Dermatological*	*Gastrointestinal*	*Cardiovascular*	*Hematological*	*Immunological*	*Neurological*	*Miscellaneous*
Sulfasalazine	Pruritus, rash, urticaria, *SJS, TEN, skin discoloration, alopecia*	Abdominal pain, vomiting, stomatitis, abnormal LFTs, *fulminant hepatic failure, hepatotoxicity*	Cyanosis, *myocarditis, vasculitis*	Hemolytic anemia, heinz body anemia, leukopenia, *agranulocytosis, aplastic anemia*	Immunoglobulin suppression, *hypersensitivity, SLE*	Dizziness, headache, insomnia, *depression*	**Respiratory:** Cough, *pulmonary fibrosis, pneumonia, dyspnea,* **Others:** Fever, s*epsis*
Mesalamine	Rash, alopecia, urticaria, pruritus, acne, *increased sweating, SJS, facial edema*	Abdominal pain, vomiting, flatulence, abdominal distension, gastroenteritis, GI hemorrhage, hepatotoxicity, e*xacerbation of UC, pancreatitis*	Hypertension, vasodilation, *myocarditis, pericarditis, tachycardia, hypotension,*	*Agranulocytosis, aplastic anemia, leukopenia, neutropenia, pancytopenia, thrombocytopenia*	*Hypersensitivity*	Asthenia, headache	**Respiratory:** Nasopharyngitis, rhinitis **Genitourinary:** *Renal impairment, oligospermia, UTI* **Others:** Arthralgia, *infectious disease*
Balsalazide	Rash, *Erythema nodosum, facial edema*	Abdominal pain, diarrhea, vomiting, flatulence, dyspepsia, xerostomia, stomatitis, exacerbation of UC, *pancreatitis, hepatotoxicity*	*Hypertension, tachycardia, myocarditis, vasculitis*	Anemia	Infectious diseases	Headache, insomnia, *dizziness, depression*	**Respiratory:** Nasopharyngitis, rhinitis, influenza, cough, *pneumonia, pleural effusion* **Genitourinary:** Renal impairment, dysmenorrhea, interstitial nephritis, UTI **Others:** Fever, arthralgia
Budesonide	Acne, rash, eczema, pustular rash, pruritus	Diarrhea, nausea, abdominal pain, flatulence, *pancreatitis, hemorrhoids*	Fluid retention, palpitations, *hypertension, syncope*	Leukocytosis, *anemia*	Oral candidiasis, *anaphylaxis, immunosuppression, angioedema*	Headache, dizziness, insomnia, *smell disturbances*	**Respiratory:** RTIs, sinusitis, *pneumonia* Genitourinary: UTI **Others:** Weight gain, conjunctivitis, *glaucoma, Cushing's syndrome, bone fracture*
Prednisolone	Acne, superinfections, *Kaposi's sarcoma, impaired wound healing*	Superinfections, ulcerative esophagitis, abdominal pain, GI *perforation, pancreatitis*	Fluid retention, hypertension, *CHF, Bradycardia, arrhythmias, hypertrophy, cardiac arrest*	*Leukocytosis*	Opportunistic infections, activation of latent tuberculosis	Headache, psychotic disorder, *seizures*	**Respiratory:** Pulmonary tuberculosis, *hiccups* **Others:** Muscle weakness, osteoporosis, glaucoma, hyperglycemia, *diabetic ketoacidosis*
Hydrocortisone	*Acne, allergic dermatitis, erythema, impaired wound healing, increased sweating, rash*	*Abdominal distention, pancreatitis, peptic ulcer, GI perforation and hemorrhage, elevated LFTs*	*Arrhythmias, CHF, syncope, thromboembolism, thrombophlebitis, vasculitis*	–	Impaired resistance to infections, *Anaphylactoid reaction, anaphylaxis, angioedema*	Psychotic disorder, *depression, mood swings*	**Respiratory:** *Pulmonary tuberculosis* **Others:** Osteoporosis, *Cushing's syndrome, hyperglycemia, cataract, glaucoma*

Azathioprine	*Skin cancer, alopecia*	Nausea, vomiting, *diarrhea, pancreatitis, hepatotoxicity*	*Pericarditis*	Bone marrow suppression, *anemia, thrombocytopenia, pancytopenia*	*Hypersensitivity, malignant lymphoma, T-cell lymphoma*	*Progressive multifocal leukoencephalopathy*	**Respiratory:** *Pulmonary adenocarcinoma* **Others:** *Infectious disease, Neoplastic disease*
6-Mercaptopurine	Rash, *hyperpigmentation, alopecia*	Diarrhea, appetite suppression, vomiting, intestinal ulceration, *hepatic encephalopathy, hepatotoxicity pancreatitis*	–	*Myelosuppression*	*Lymphoproliferative disorder, T-cell lymphoma*	–	**Others:** Fever, hyperuricemia
Methotrexate	Alopecia, photosensitivity, rash, itching, e*rythema, SJS, TEN*	Abdominal pain, diarrhea, stomatitis vomiting, abnormal LFTs, *liver cirrhosis, hepatitis, pancreatitis*	*Thromboembolic disorder, vasculitis*	Thrombocytopenia, leukocytopenia, a*granulocytosis, aplastic anemia, pancytopenia*	Disseminated herpes zoster, *anaphylactoid reaction, malignant lymphoma, opportunistic infection*	Headache, drowsiness, e*ncephalopathy, leukoencephalopathy, seizures, confusion*	**Respiratory:** Bronchitis, nasopharyngitis, *pneumonia* **Genitourinary:** Renal failure, dysuria, hematuria **Others:** Fever, impaired wound healing
Cyclosporine	Hirsutism, acne, brittle fingernails, alopecia, skin ulceration, increased sweating	Gingival hyperplasia, hyperbilirubinemia, *hepatotoxicity*	Hypertension, flushing, arrhythmia cardiac failure, peripheral ischemia	Leukopenia, *thrombocytopenia, anemia*	Hypersensitivity, septicemia, fungal infections, wound and skin infections, viral infections	Headache, neuropathy, depression, insomnia, *progressive multifocal leukoencephalopathy, seizure*	**Respiratory:** Pneumonia, bronchitis, cough, dyspnea, pharyngitis **Genitourinary:** UTI, frequent micturition *nephrotoxicity* **Others:** Muscle cramps, conjunctivitis, abnormal vision, cataract, hyperglycemia, hyperuricemia, *hyperkalemia, hypomagnesemia*
Infliximab	Rash, e*rythema multiforms, SJS, TEN*	Abdominal pain, nausea, *bowel obstruction, hepatotoxicity*	*Acute coronary syndrome, bradyarrhythmia, heart failure, hypertension, myocardial Infarction, systemic vasculitis*	*Hemolytic anemia, leukopenia, pancytopenia, thrombocytopenia, neutropenia*	*Anaphylaxis, infusion reactions, malignant lymphoma, sarcoidosis*	Headache, *cerebrovascular accident*	**Respiratory:** Cough, pharyngitis, sinusitis, upper respiratory infection, *pulmonary edema, tuberculosis* **Genitourinary:** *Cervical cancer* **Others:** Fatigue, *cancer, infectious disease, mycosis*
Vedolizumab	Rash, pruritus	Nausea, *hepatitis, elevated bilirubin, abnormal LFTs*	–	–	*Anaphylaxis, infusion reaction*	Headache, *progressive multifocal leukoencephalopathy*	**Respiratory:** Nasopharyngitis, upper RTI, *tuberculosis* **Others:** Fatigue, fever, *cancer, infectious disease, sepsis*
Ustekinumab	Erythema, pruritus, *non-melanoma skin cancer*	Vomiting, diarrhea	–	–	*Anaphylaxis, angioedema*	Headache, *posterior reversible encephalopathy syndrome*	**Genitourinary:** Mycosis, UTI **Respiratory:** Upper RTI, nasopharyngitis, bronchitis, *pneumonia* **Others:** Fatigue, infectious diseases, *cancer*

(*Continued*)

Table 2 Adverse drug effects associated with pharmacotherapy of inflammatory bowel disease (*cont.*)

Drugs	*Dermatological*	*Gastrointestinal*	*Cardiovascular*	*Hematological*	*Immunological*	*Neurological*	*Miscellaneous*
Metronidazole	Pruritus, *SJS, TEN*	Abdominal discomfort, metallic taste, diarrhea, nausea, *hepatotoxicity*	*Flat T-wave, flushing, QT interval prolongation*	*Leukopenia, neutropenia, thrombocytopenia, pancytopenia*	Jarisch-Herxheimer reaction	Dizziness, headache, *aseptic meningitis, encephalopathy, peripheral neuropathy, seizures*	**Respiratory:** Upper RTIs **Genitourinary:** Vaginal candidiasis, vaginal discharge, vaginitis, hemolytic uremic syndrome **Others:** Optic nerve disorder
Ciprofloxacin	Rash, *photosensitivity, SJS, TEN*	Diarrhea, vomiting, *CDD, hepatotoxicity, GI hemorrhage, pancreatitis*	*Aortic aneurysm, cardiorespiratory arrest, prolonged QT interval, myocardial infarction, Torsades de pointes*	*Agranulocytosis, aplastic anemia, bone marrow depression, hemolytic anemia, thrombocytopenia*	*Hypersensitivity*	Headache, irritability, *memory impairment, psychotic disorder, Guillain-Barré syndrome, paranoid disorder*	**Respiratory:** nasopharyngitis **Genitourinary:** Hemorrhagic cystitis, acute renal failure **Others:** Tendons rupture, myasthenia gravis, hypoglycemia

CDD, *Clostridium difficile* diarrhea; CHF, congestive heart failure; GI, gastrointestinal; LFT, liver function test; RTI, respiratory tract infection; SJS, Stevens-Johnson syndrome; SLE, systemic lupus erythematosus; TEN, toxic epidermal necrolysis; UC, ulcerative colitis; UTI, urinary tract infection.

Note: Serious adverse effects are presented in italics.

Sources: ASHP (2018), Lexicomp (2018), and Micromedex Drugdex (2018).

Short-term use of corticosteroids is well-tolerated. However, their prolonged use is associated with a number of serious ADEs such as osteoporosis, impaired immunity, peptic ulcer, and dysglycemia. Patients receiving long-term corticosteroids therapy should be carefully monitored. Moreover, abrupt discontinuation of corticosteroids is associated with adrenal insufficiency and should therefore be gradually discontinued (Lichtenstein et al., 2018).

Immunomodulators may cause bone marrow depression, hypersensitivity reactions, and secondary infections. Predisposition to development of ADEs may be related to polymorphisms of the enzyme thiopurine methyltransferase, which is partially responsible for activation and metabolism of thiopurines. Anti-TNF agents may cause hypersensitivity reactions, cardiovascular problems, bone marrow suppression, and secondary infections (Farraye et al., 2017).

Drug–Drug Interactions

Patients with IBD often receive multiple drugs simultaneously. Most of these drugs are used for an extended period of time. Moreover, additional therapies are required for the treatment of a variety of comorbid conditions. Therefore, drug–drug interactions are more likely to occur in patients with IBD that may lead to toxicity or impaired therapeutic response (Irving et al., 2008). Patient medication therapy should be reviewed for all possible drug interactions in order to manage them accordingly. Important drug–drug interactions related to pharmacotherapy of IBD, and their adverse outcomes and management are presented in **Table 3**.

Table 3 Drug–drug interactions in inflammatory bowel disease

Interacting drugs	*Adverse outcomes*	*Management/monitoring guidelines*
Mesalamine		
Celecoxib, diclofenac, indomethacin, ibuprofen, naproxen	Bleeding	Monitor for bleeding signs, PT, APTT, INR; consider alternate therapy
Azathioprine, 6-mercaptopurine, thioguanine	Bone marrow suppression	Reduce dose in combination; monitor CBC
Insulin	Hypoglycemia	Monitor glucose levels; adjust insulin dose
Aluminum carbonate/hydroxide/phosphate, magnesium carbonate/hydroxide/trisilicate	Reduced mesalamine therapeutic efficacy	Consider alternate therapy
Sulfasalazine		
Celecoxib, diclofenac, etoricoxib, indomethacin, ibuprofen, naproxen, piroxicam, warfarin	Bleeding	Monitor for bleeding signs, PT, APTT, INR; consider alternate therapy
Azathioprine, 6-mercaptopurine, thioguanine	Bone marrow suppression	Reduce dose in combination; monitor CBC
Methotrexate	Hepatotoxicity	Monitor LFTs; discontinue combination
Insulin	Hypoglycemia	Monitor glucose levels; adjust insulin dose
Cyclosporine, digoxin, warfarin	Reduced interacting drug's efficacy	Increase interacting drug dose when use in combination and monitor its level; in case of warfarin monitor for thrombosis, PT, APTT, and INR
Prednisolone		
Vaccines	Vaccine-induced infection	Avoid concomitant administration, can be used with an interval of two to three months
Amphotericin, hydrochlorothiazide	Electrolyte abnormalities	Monitor electrolytes; consider alternate therapy
Celecoxib, diclofenac, etoricoxib, ibuprofen, indomethacin, ketorolac, naproxen, piroxicam, warfarin	Bleeding	Monitor for bleeding signs, PT, APTT, INR; consider alternate therapy
Ciprofloxacin, levofloxacin, moxifloxacin, norfloxacin	Tendon rupture	Discontinue combination
Ritonavir	Cushing syndrome	Monitor signs of Cushing syndrome
Testosterone	Edema	Monitor signs/symptoms of edema in patients more at risk
Bupropion	Seizures	Use low dose of bupropion
Atracurium, warfarin	Reduced interacting drug's efficacy	Avoid concomitant administration; adjust dose
Phenobarbital, phenytoin, rifampin	Reduced prednisolone efficacy	Adjust dose of corticosteroids
Cyclosporine	Interacting drug's toxicity	Avoid or use with caution; adjust dose if necessary
Contraceptives, fluconazole, ketoconazole	Prednisolone toxicity	Use with caution and decrease dose of corticosteroids
Budesonide		
Celecoxib, diclofenac, indomethacin, ketorolac, mefenamic acid, naproxen, piroxicam	Bleeding	Monitor for bleeding signs, PT, APTT, INR; consider alternate therapy
Ciprofloxacin, levofloxacin, moxifloxacin, norfloxacin	Tendon rupture	Discontinue combination
Ritonavir	Cushing syndrome	Monitor signs of cushing syndrome
Testosterone	Edema	Monitor signs/symptoms of edema in patients more at risk
Bupropion	Seizures	Use low dose of bupropion

(*Continued*)

Table 3 Drug–drug interactions in inflammatory bowel disease (*cont.*)

Interacting drugs	*Adverse outcomes*	*Management/monitoring guidelines*
Clarithromycin, erythromycin, fluconazole, ketoconazole	Budesonide toxicity	Use with caution and decrease dose of corticosteroids
Azathioprine		
Vaccines	Vaccine-induced infection	Consider administration interval of three months
Balsalazide, lisinopril, olsalazine, ramipril, sulfamethoxazole/trimethoprim	Bone marrow suppression	Reduce dose in combination; monitor CBC
Doxorubicin, methotrexate	Hepatotoxicity	Monitor LFTs; discontinue combination
Warfarin	Reduced warfarin efficacy	Avoid concomitant administration; monitor PT, APTT, INR
Allopurinol, febuxostat, sulfamethoxazole/trimethoprim	Azathioprine toxicity	Avoid combination or reduce dose; monitor signs/symptoms of toxicity
Cyclosporine		
Live vaccines	Vaccine-induced infection	Consider administration interval of three months
Atorvastatin, lovastatin, rosuvastatin, simvastatin	Myopathy or rhabdomyolysis	Reduce statins dose; discontinue concomitant administration
Amikacin, aspirin, celecoxib, diclofenac, indomethacin, ketorolac, lisinopril, mefenamic acid, naproxen, piroxicam, ramipril, streptomycin	Nephrotoxicity or electrolyte abnormalities	Monitor RFTs and electrolytes; consider alternative or reduce dose
Furosemide	Gouty arthritis	Monitor signs/symptoms of gouty arthritis; discontinue concomitant administration
Warfarin	Reduced warfarin efficacy	Avoid concomitant administration; monitor PT, APTT, INR
Carbamazepine, cyclophosphamide, famotidine, infliximab, phenobarbital, phenytoin, pyrazinamide, quinine, rifampin, sulfasalazine, warfarin	Reduced cyclosporine efficacy	Avoid concomitant administration; adjust dose if necessary
Alprazolam, colchicine, doxorubicin, methotrexate, morphine, valsartan	Interacting drug's toxicity	Avoid combination or reduce dose; monitor signs/symptoms of toxicity
Amlodipine, aspirin, ceftriaxone, celecoxib, chloroquine, cimetidine, clarithromycin, colchicine, diclofenac, diltiazem, fluconazole, glyburide, indomethacin, ketoconazole, ketorolac, mefenamic acid, metoclopramide, metronidazole, naproxen, piroxicam, rabeprazole, ritonavir, verapamil	Cyclosporine toxicity	Avoid combination or reduce dose; monitor signs/symptoms of toxicity
Infliximab		
Vaccines	Vaccine-induced infection	Avoid concomitant administration, can be administer at an interval of 3 months
Cyclosporine, fentanyl, phenytoin, paclitaxel, theophylline, thioridazine, warfarin	Reduced interacting drug's efficacy	Avoid concomitant administration; monitor drug's efficacy
Adalimumab, anakinra, rituximab, vedolizumab	Increased immunosuppression and risk of infection	Avoid concomitant administration
Vedolizumab		
Biologic agents (vaccines, antibodies, interleukins)	Increased immunosuppression and risk of infection	Avoid concomitant administration
Metronidazole		
QT interval prolonging drugs (amiodarone, cisapride, hydroxychloroquine, saquinavir, tacrolimus, thioridazine)	QT interval prolongation	Discontinue combination; monitor ECG and serum electrolytes
Warfarin	Bleeding	Monitor for bleeding signs, PT, APTT, INR; consider alternate therapy
Cholestyramine, phenytoin	Reduced metronidazole efficacy; phenytoin toxicity	Avoid concomitant administration, can be used with an interval
Cholera vaccine	Reduced immune response to vaccine	Avoid concomitant administration, can be used with an interval
Carbamazepine, cyclosporine, lithium	Interacting drug's toxicity	Adjust interacting drug dose; monitor signs of toxicity
Disulfiram	Psychotic reactions, confusion	Avoid combination, can be used with an interval of 14 days

(*Continued*)

Table 3 Drug–drug interactions in inflammatory bowel disease (*cont.*)

Interacting drugs	*Adverse outcomes*	*Management/monitoring guidelines*
Ciprofloxacin		
QT interval prolonging drugs (amiodarone, amitriptyline, domperidone, droperidol, fluoxetine, ondansetron, saquinavir, thioridazine)	QT interval prolongation	Discontinue combination; monitor ECG and serum electrolytes
Warfarin	Bleeding	Monitor for bleeding signs, PT, APTT, INR; consider alternate therapy
Betamethasone, budesonide, dexamethasone, hydrocortisone, prednisolone	Tendon rupture	Avoid concomitant administration; consider alternate therapy
Simvastatin	Myopathy or rhabdomyolysis	Reduce statins dose; discontinue combination
Gliclazide, glimepiride, glyburide, insulin, metformin, sitagliptin	Hypoglycemia or hyperglycemia	Monitor glucose levels; adjust dose of antidiabetic agents
Iron, sucralfate	Reduced ciprofloxacin efficacy	Avoid concomitant administration, can be used with an interval
Cholera/ typhoid vaccine	Reduced immune response to vaccine	Avoid concomitant administration, can be used with and interval
Doxorubicin, methotrexate, theophylline, tramadol	Interacting drug's toxicity	Adjust interacting drug dose; monitor signs of toxicity

APTT, Activated prothrombin time; CBC, complete blood count; ECG, electrocardiogram; INR, international normalized ratio; LFTs, liver function tests; PT, prothrombin time; RFTs, renal function tests.

Conclusions

IBD is an idiopathic, debilitating life-long condition that adversely affects the patients' health-related quality of life. The pathogenesis of IBD is multifactorial and is governed by an interplay of the immune system, intestinal microbiota, and various genetic and environmental factors. Monitoring of maintenance therapy for safety and efficacy is essential to ensure prolonged remission and improved patients' quality of life. Pharmacist involvement can promote treatment adherence, medication safety, and effective therapeutic outcomes.

Glossary

Adjuvant therapy Therapy given in addition to the primary therapy in order to maximize effectiveness.
Colostomy It is a surgical procedure performed for the diversion of fecal stream to excrete feces through the abdominal wall.
Fistula An abnormal passage between two organs or an organ and the exterior of the body.
Fulminant Abrupt and extremely intense onset of symptoms.
Refractory The presence of symptoms despite pharmacological therapy.
Relapse The return of symptoms after its apparent cessation.
Remission The period during which the symptoms of a disease subside.
Seton A surgical grade thread or wire passed through the fistula or subcutaneous tissue for drainage of abscess.
Strictures Abnormal narrowing of the small or large intestine due to inflammation and scarring.
Tenesmus Painful spasm of the rectum or bladder with a failed attempt to urinate or defecate.

Management of Gastrointestinal Disorders and the Pharmacist's Role: Nausea and Vomiting

Mohammad Ismail*, Sidra Noor*, Hira Sajid*, Nadia Bukhari†, *University of Peshawar, Peshawar, Pakistan; †UCL School of Pharmacy, London, United Kingdom

Learning Objectives

At the end of this chapter, the reader will be able to:

- Describe the basic concepts and etiopathogenesis of different types of emesis.
- Discuss available pharmacotherapeutic approaches for specific clinical situations.
- Develop a patient-oriented care plan and monitor the therapeutic outcomes.
- Assess and manage the potential adverse drug effects associated with pharmacotherapy of emesis.
- Discuss the role of pharmacist in the effective management of nausea and vomiting.

Introduction

Nausea can be the precursor for vomiting and is defined as a subjectively unpleasant wavelike sensation in the back of the throat or epigastrium. Nausea may also be associated with other symptoms such as pallor, flushing, tachycardia, sweating, excessive salivation, and feeling either hot or cold. Vomiting can be described as the forceful expulsion of stomach contents through the mouth, which is preceded by relaxation of the esophageal sphincter, contraction of the abdominal muscles, descent of the diaphragm, and temporary suspension of breathing (Babic and Browning, 2014; Pleuvry, 2012; Smith et al., 2012).

Etiology and Pathophysiology

Nausea and vomiting are associated to a variety of conditions such as chemotherapy, pregnancy, gastrointestinal (GI) disorders, allergy, or surge. The main causes for nausea and vomiting are listed in **Table 1**.

The sequential process of emesis comprising nausea, retching (rhythmic spasmodic contractions without expulsion of gastric contents), and vomiting is initiated and coordinated by involvement of the central nervous system, the peripheral nervous system, and the GI system (Babic and Browning, 2014; Bashashati and McCallum, 2014).

Table 1 Causes of nausea and vomiting

Gastrointestinal causes	*Non-gastrointestinal causes*	*Drugs/radiations/toxins*
Inflammatory/infectious/allergic conditions	*Cardiovascular diseases*	*Drugs/radiations*
Hepatitis	Myocardial infarction	Radiotherapy
Appendicitis	Cardiomyopathy	Cancer chemotherapy
Cholecystitis	Angina	Antibiotics
Pancreatitis	*Metabolic diseases*	Anticonvulsants
Peptic ulcer disease	Nephrolithiasis	Cardiac antiarrhythmics
Gastroenteritis	Addison's disease	Digoxin
Inflammatory bowel disease	Diabetic ketoacidosis	Oral hypoglycemics
Food protein-induced enterocolitis syndrome	Hereditary fructose intolerance	Oral contraceptives
Gastrointestinal tract obstruction disorders	Galactosemia	Antidepressants
Mesenteric artery syndrome	Thyroid hormone abnormalities	*Drug withdrawal*
Colonic obstruction	*Neurologic diseases*	Benzodiazepines
Pyloric obstruction	Migraine	Opioids
Small bowel obstruction	Vestibular disorders	*Toxins*
Malignancy	Increased intracranial pressure	Ethanol
Functional gastrointestinal disorders	Meningitis	Cyanide
Irritable bowel syndrome	Hemorrhage	Lead
Gastroparesis	*Psychological disorders*	Iron
Gastrointestinal reflux	Anxiety	Carbon monoxide
Rumination syndrome	Anorexia and bulimia nervosa	Food poisoning
Cyclic vomiting syndrome	*Postoperative vomiting*	
Gastroesophageal reflux disease	*Pregnancy-induced vomiting*	
Hirschsprung disease	Vomiting up to first trimester	
Malrotation	Hyperemesis gravidarum

Esp. Anestesiol. Reanim 64, 223–232 (Veiga-Gil et al., 2017)

The vomiting center (VC) located in the medulla oblongata of the brain, coordinates emesis by receiving afferent signals from sensory organs, and sending efferent signals to effector organs. Neurotransmitter receptors play an important role in the process of emesis regulation and therefore are the main targets of pharmacotherapy (Shinpo et al., 2012). These include serotonin ($5HT_3$), dopamine (D_2), histamine (H_1), neurokinin-1 (NK_1), and cholinergic (muscarinic M_1) receptors. These neurotransmitter receptors are inhibited for the control of nausea and vomiting (Bashashati and McCallum, 2014; Flake et al., 2004; Navari, 2015; Quigley et al., 2001).

A number of afferent signals might be responsible for initiating an emetic response. The chemoreceptor trigger zone (CTZ) present in the brainstem just outside the blood brain barrier, senses toxins, and noxious substances in the blood or cerebrospinal fluid and triggers an emetic response by sending neurotransmitters (serotonin, dopamine, and NK_1) to the VC and the nucleus tractus solitarius (NTS) (Pleuvry, 2012).

The GI system initiates an emetic response when the enterochromaffin cells of the GI mucosa are damaged by exposure to either chemotherapy, radiation, anesthetics, or mechanical irritation. Serotonin is released, which in turn stimulates vagal afferent signals as well as directly acts on the VC and the NTS (Bashashati and McCallum, 2014).

The cerebral cortex and the limbic system stimulate the emetic center in response to emotional states such as anxiety, pain, and conditioned responses (anticipatory nausea and vomiting). The neurotransmitters involved in this pathway are not clearly known (Pleuvry, 2012). Vestibular system disorders (vertigo and motion sickness) stimulate the VC by releasing acetylcholine and histamine (Babic and Browning, 2014; Smith et al., 2012).

Clinical Features

Emesis is caused by many disorders; therefore, its clinical presentation varies. The patient either experiences a simple, self-limiting episode that subsides by itself or suffers persistent debilitating vomiting that necessitates antiemetic therapy. Simple emesis may present as abdominal pain/cramps, pale skin, heartburn, vertigo, tinnitus, headache, and fever (Balaban and Yates, 2017; Koch and Hasler, 2017). Whereas, persistent vomiting may cause dehydration with electrolyte imbalance, malnutrition, weight loss, dental

caries, dental erosions, and aspiration pneumonia, thus significantly affecting patient's quality of life and their ability of self-care. Rarely, persistent vomiting may lead to esophageal tear, which is either partial (Mallory Weiss) or complete (Boerhaave syndrome) (Hasler, 2018; Koch and Hasler, 2017).

Diagnosis

Patients who present with nausea and vomiting are initially assessed for the nature of symptoms (onset, severity and duration), triggering factors, dietary intake, hydration status, current medical conditions, medications used, and surgical status. Furthermore, the underlying etiology must be identified for tailoring therapy.

Taking a full patient history can help identify the underlying cause of emesis. Acute emesis is often associated with drugs, toxins, and infections. Whereas, delayed emesis occurs as a result of chronic diseases such as GI obstruction. Physical examination further strengthens the diagnosis and findings of the patient's history (Keeley, 2015; Singh et al., 2016). Orthostatic hypotension and reduced skin turgor are signs of dehydration. Abdominal tenderness can be an indication of inflammation, whereas presence of fecal blood may indicate GI mucosal injury or tumor (Koch and Hasler, 2017).

Differential diagnosis through selected screening tests might be necessary in some patients particularly in patients with persistent emesis. Laboratory tests will be helpful to identify hypokalemia, azotemia, or metabolic alkalosis that might occur due to loss of gastric content. Endoscopy or computed tomographic (CT) imaging is helpful in identifying gastric and intestinal obstruction (Keeley, 2015; Singh et al., 2016). Abnormal pancreatic and liver biochemistries indicate pancreaticobiliary disease. Central nervous system causes are best evaluated with either head CT imaging or magnetic resonance imaging (MRI). Similarly, for every suspected underlying etiology, its specific differential diagnostic tests should be performed (Koch and Hasler, 2017; Quigley et al., 2001).

Nonpharmacological Management

Various nonpharmacological approaches comprising dietary, physical, and psychological strategies may be used in the management of nausea and vomiting. Dietary modifications such as avoiding or decreasing the consumption of foods or beverages that trigger emesis, eating smaller meals, avoiding spicy or fried foods, and preferably eating bland foods such as BRAT (bananas, rice, apple sauce and toast) help improve the condition (Koch and Hasler, 2017; Stern et al., 2011). Ginger is also effective in the treatment of emesis related to pregnancy, surgery, and motion sickness (Ernst and Pittler, 2000; Saberi et al., 2013; Sheikhi et al., 2015). An example of physical strategy is attaining a stable position that relieves motion sickness. Psychological strategies include relaxation, biofeedback, hypnosis, cognitive distraction, optimism, guided imagery, acupuncture, yoga, and systemic desensitization (Cheong et al., 2013; Kamen et al., 2014; Sheikhi et al., 2015).

Pharmacological Management: General Approaches

Prevention or complete elimination of nausea and vomiting with no or minimal adverse effects is the desired goal of pharmacotherapy. A number of important issues need to be considered that include correction of fluid, electrolyte, or nutritional imbalances; identification and elimination of the underlying cause where possible; and suppression or elimination of the symptoms (Quigley et al., 2001).

A simple episode of nausea and vomiting may be self-limiting. If the condition does not improve and symptoms persist, pharmacotherapy with antiemetics is needed. A single agent or combination therapy (agents from different pharmacological classes of antiemetics) is initiated depending upon the severity and complexity of presenting condition (Flake et al., 2004; Quigley et al., 2001; Singh et al., 2016). Besides the effectiveness of pharmacotherapy, economic impact should also be considered especially in the case of long-term management such as nausea and vomiting induced by chemotherapy, pregnancy, or surgery (Haiderali et al., 2011; Piwko et al., 2013).

Antiemetic Drugs

Antiemetic drugs mainly produce their effect by antagonizing the neurotransmitters that are involved in the regulation of emesis. The main classes of antiemetic drugs include serotonin $5HT_3$ receptor antagonists ($5HT_3$RAs), neurokinin-1 receptor antagonists (NK_1RAs), dopamine D_2 receptor antagonists, and antihistamines/anticholinergics (**Fig. 1**) (Kenward et al., 2015; Pleuvry, 2012; Singh et al., 2016). Selection of an appropriate antiemetic(s) depends on certain factors such as the underlying cause; frequency, duration, and severity of emetic episodes; ability of patient to use certain dosage form; and response to previously used antiemetic medications (Flake et al., 2004; Quigley et al., 2001).

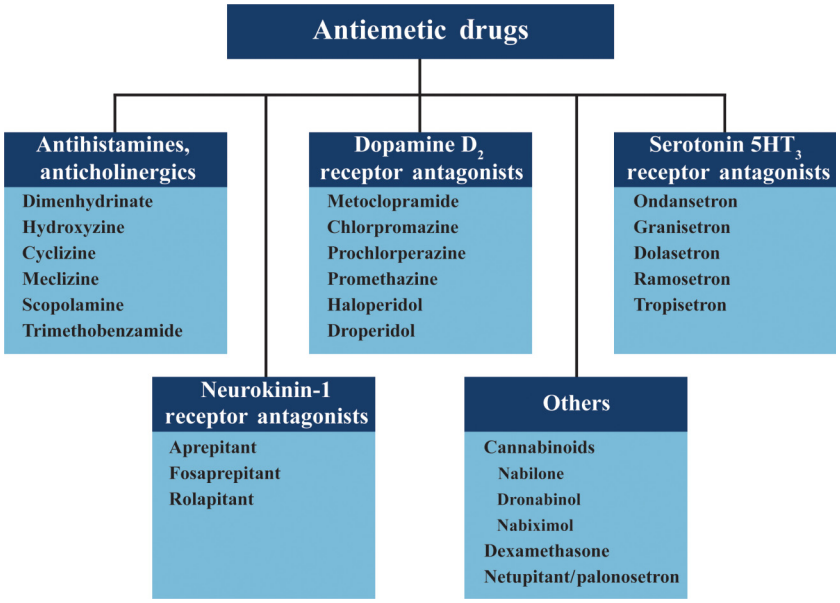

Figure 1 Classes of antiemetic drugs.

Specific Clinical Situations

The following sections describe the management of nausea and vomiting in specific clinical situations such as chemotherapy-induced nausea and vomiting (CINV), postoperative nausea and vomiting (PONV), radiotherapy-induced nausea and vomiting (RINV), nausea and vomiting of pregnancy (NVP), and motion sickness.

Chemotherapy-Induced Nausea and Vomiting

CINV is one of the major causes of nonadherence, increased anxiety and depression, and poor quality of life in cancer patients (Navari, 2015). CINV has been categorized into five different types: acute, delayed, anticipatory, breakthrough, and refractory (**Fig. 2**) (Jordan et al., 2014; Navari and Aapro, 2016).

Even though milestones have been achieved in the management of acute CINV; anticipatory and delayed CINV still remains a major problem to be managed. Of the patients who experience nausea and vomiting during earlier chemotherapy sessions, 30% have reportedly experienced nausea, whereas 20% have experienced vomiting during subsequent chemotherapy sessions (Mustian et al., 2011). CINV can be prevented in up to 70%–80% of the patients with appropriate use of prophylactic antiemetics (Jordan et al., 2014; Tageja and Groninger, 2016).

Chemotherapeutic agents differ in their emetogenic potential. They are classified into four different groups based on their emetogenicity: high, moderate, low, and minimal that possess an incidence risk of emesis in >90%, 30%–90%, 10%–30%, and <10% of patients, respectively (**Fig. 3**) (Grunberg et al., 2005; Navari and Aapro, 2016). Antiemetic regimens are selected on the basis of emetogenicity of chemotherapeutic agents (Jordan et al., 2014).

Acute and Delayed Chemotherapy-Induced Nausea and Vomiting

Pharmacotherapy of acute and delayed CINV is summarized in **Table 2**. CINV should preferably be controlled through prophylaxis. The prophylaxis of acute CINV is initiated prior to the start of chemotherapy and continued up to 24 h, whereas prophylaxis of delayed CINV is continued till fourth day following administration of chemotherapy (Berger et al., 2017; Jordan et al., 2014).

In patients receiving high emetogenic chemotherapy, acute CINV is managed with a combination of a $5HT_3$RA, dexamethasone and aprepitant/fosaprepitant (NK_1RAs) within first 24 h of chemotherapy. For delayed CINV, dexamethasone and aprepitant/fosaprepitant (NK_1RAs) are recommended in combination (**Table 2**) (Jordan et al., 2014; Navari and Aapro, 2016).

Patients undergoing moderately emetogenic chemotherapy are recommended a combination of a $5HT_3$RA (preferably palonosetron) and dexamethasone for acute CINV. Addition of aprepitant to this combination is recommended in selected patients. Whereas for delayed CINV, dexamethasone is the drug of choice. Alternatively, aprepitant can also be used provided that it had been used in prophylaxis of acute CINV (Jordan et al., 2014) (**Table 2**).

Patients receiving low emetogenic chemotherapy can be effectively managed with a single agent such as a low-dose corticosteroid. Antiemetic prophylaxis is usually not required in the case of minimal emetogenic chemotherapy (Jordan et al., 2014).

Other Types of Chemotherapy-Induced Nausea and Vomiting

For the management of breakthrough and refractory CINV, repeated administration of the same agent that was already used prophylactically is hardly effective (Navari and Aapro, 2016). Other options should be considered such as a dopamine receptor antagonist (e.g., metoclopramide), a benzodiazepine, or a neuroleptic agent (e.g., olanzapine) (Jordan et al., 2014).

Anticipatory nausea and vomiting is usually managed through prophylaxis, which includes nonpharmacological approaches such as behavioral therapy, hypnosis, and acupuncture/acupressure, and pharmacological therapy with benzodiazepines. These prophylactic approaches might lose their efficacy over the course of time. For treatment of anticipatory nausea and vomiting, either oral alprazolam 0.5–1 mg or oral lorazepam 0.5–2 mg are recommended, starting the evening prior to chemotherapy (Navari and Aapro, 2016).

Postoperative Nausea and Vomiting

PONV is experienced by 20%–30% of patients undergoing surgery and generally occurs within 24 h of anesthesia administration (Wiesmann et al., 2015). PONV decreases patient's comfort and satisfaction, and can cause/prolong hospitalization, stress on the surgical closure, hematomas, dehydration, electrolyte imbalances, and aspiration pneumonitis. A number of risk factors related to patient, anesthesia, and surgery predispose patient to PONV (Wiesmann et al., 2015).

All patients undergoing surgery do not experience PONV; therefore, prophylaxis is not a rational approach in every patient. For this purpose, a risk scoring system has been suggested based on four factors: female gender, history of PONV/motion sickness, non-smoker, and use of opioid during surgery (Stoicea et al., 2015). Each of these risk factors increases the incidence risk by around 20% (Wiesmann et al., 2015). This tool is very useful for the identification of high-risk patients in order to apply various antiemetic strategies accordingly (Weilbach et al., 2006).

Management strategies involve reduction of baseline risk and use of antiemetic drugs for the prophylaxis and treatment of PONV. Baseline risk can be minimized using local instead of systemic anesthesia; adequate hydration; intraoperative supplemental oxygen; and using less emetogenic induction agents, anesthetic agents, and analgesics.

Antiemetic drugs used for the management of PONV include $5HT_3$RAs, NK_1RAs, corticosteroids, droperidol, haloperidol, antihistamines, and anticholinergics (Stoicea et al., 2015; Wiesmann et al., 2015). As prophylactic therapy for PONV, various antiemetic drugs are used at specified timings as shown in **Table 3**. A combination therapy, involving drugs from different classes, is recommended for high-risk patients (Wilhelm et al., 2007).

Rescue therapy is recommended for patient experiencing PONV even after receiving prophylactic therapy. In this therapy, an agent should be administered from a pharmacologic class other than that already used for prophylaxis. In cases where no prophylactic therapy was given initially, any of the following may be used: ondansetron (or other $5HT_3$RAs), dexamethasone, droperidol, and promethazine (Gan et al., 2014).

Radiotherapy-Induced Nausea and Vomiting

RINV occurs in around 50%–80% of patients undergoing radiotherapy (Li et al., 2017). The incidence of RINV depends on various factors such as the site of irradiation, the dosing, fractionation, irradiated volume, and radiotherapy techniques. The incidence risk is very high in patients receiving a total body irradiation (~90%) and those receiving radiations to the upper abdominal area (50%–80%). Whereas radiotherapy of other body parts have a decreased incidence risk (Feyer et al., 2015). RINV significantly affects the quality of life (Poon et al., 2016). Nausea seems to impact the patient more directly, whereas vomiting affects those closest to the patient (Yee et al., 2018). Clinical practice guidelines have classified radiotherapy receiving patients into four groups with respect to incidence risk of RINV: at high risk are the patients receiving total-body or -nodal irradiation (TBI/TNI); moderate risk occurs in patients receiving upper body or abdomen and hemibody radiotherapy; low risk exists in patients receiving cranial, craniospinal, head and neck, lower thorax, and pelvic radiotherapy; and patients undergoing extremities and breasts irradiation are at minimal risk (Feyer et al., 2015; Ruhlmann et al., 2017).

Prophylactic therapy is administered to patients who are at high or moderate risk of RINV. For patients at high emetic risk, prophylaxis with a combination of a $5HT_3$RA and dexamethasone is recommended (**Table 4**) (Li et al., 2017). In patients with moderate emetic risk, prophylaxis with a $5HT_3$RA is usually recommended; however, the use of dexamethasone is optional. In patients with low emetic risk, a $5HT_3$RA agent is used either as prophylaxis or as rescue therapy (Li et al., 2017). In patients with minimal emetic risk, no prophylaxis is administered rather a rescue therapy may be opted among dexamethasone, dopamine receptor antagonists, or $5HT_3$RAs. Limited data are available on recommendations of rescue therapy; however, $5HT_3$RAs are considered effective as antiemetic treatment of RINV (Feyer et al., 2015; Ruhlmann et al., 2017).

Nausea and Vomiting of Pregnancy

NVP affects a majority (70%–80%) of pregnant women. The symptoms occur predominantly during the first trimester, but some women may experience symptoms throughout the entire pregnancy (Bustos et al., 2017; Lee and Saha, 2011). The exact etiology of NVP is not known, but it is widely agreed that a variety of factors including physiological, hormonal, psychological, genetic, and cultural components are involved (Furneaux et al., 2001). The severity of symptoms for NVP ranges from mild to moderate nausea and vomiting, but a small percentage of women develop a severe form of NVP called hyperemesis gravidarum (HG). If not treated,

Table 3 Pharmacotherapy of postoperative nausea and vomiting

Class of drugs	*Drug*	*Remarks*	*Adult dose for prophylaxis*	*Pediatric dose (IV) of prophylaxis*	*Timing of prophylaxis dose*	*Treatment or rescue dose*
$5HT_3$RAs	Ondansetron	Gold standard	4 mg IV, 8 mg OD	50–100 mcg/kg up to 4 mg	At the end of surgery	1 mg IV every 8 h
	Palonosetron	Prolonged half-life	0.075 mg IV	–	Immediately before induction	0.075 mg IV single dose
	Granisetron	Might not be equally effective in ultra-metabolizers of CYP2D6 pathway	0.35–3 mg IV	40 μg/kg up to 0.6 mg	At the end of surgery	0.1 mg
NK_1RA	Aprepitant	As effective as ondansetron in achieving complete response	40 mg orally	Not labeled for use in pediatrics	Within 3 h prior to induction	None
Corticosteroid	Dexamethasone	Monitor glucose levels in diabetic patients	4–5 mg IV	150 mcg/kg up to 5 mg	At induction	2–4 mg IV
Butyrophenones (Dopamine D_2 receptor antagonists)	Droperidol	High risk of QTIP/TdP	0.625–1.25 mg IV	10–15 mcg/kg up to 1.25 mg	At the end of surgery	0.625–1.25 mg IV or IM every 4–6 h
	Haloperidol	High risk of QTIP/TdP	0.5–2mg (IM or IV)	Not mentioned	Not specified	–
Antihistamines-Anticholinergics	Promethazine	Contraindicated in children less than 2 years	6.25–12.5 mg IV	Not mentioned	Not specified	12.5–25 mg IV or IM every 4–6 h
	Dimenhydrinate	Adequate hydration is recommended	1 mg/kg IV	0.5 mg/kg up to 25 mg	Not specified	–
	Scopolamine	Monotherapy not affective in prophylaxis	Transdermal patch	Not mentioned	Prior evening or 4 h before surgery	–

$5HT_3RA$, serotonin $5HT_3$ receptor antagonist; *CYP2D6*, cytochrome P450 2D6; *IM*, intramuscular; *IV*, intravenous; *NK_1RA*, neurokinin-1 receptor antagonist; *OD*, once daily; *QTIP*, QT interval prolongation; *TdP*, torsades de pointes.

HG may result in significant maternal morbidity and adverse birth outcomes (Bustos et al., 2017; Lee and Saha, 2011). NVP significantly affects the quality of life of the pregnant woman and imparts a negative impact on employment, household duties, parenting, and family relationships (Bustos et al., 2017). In addition, NVP also exerts a large economic burden on patients, caregivers, and society. The estimated total economic burden of NVP was $1.77 billion in the United States in 2012 (Piwko et al., 2013).

Management of NVP involves dietary changes, intravenous fluid rehydration (including electrolytes and vitamins), and pharmacological treatment. Dietary changes include eating smaller and more frequent meals and avoiding foods, odors, or supplements that trigger nausea, especially fatty or spicy foods and iron tablets. Some other strategies that might help include drinking fluids between meals or eating bland, dry, and high-protein foods. Ginger and acupuncture are also shown to be effective (Herrell, 2014; Saberi et al., 2013).

In the case of persistent nausea and vomiting, drug therapy is recommended. However, the teratogenic potential of each drug should be considered. Approximately 10% of women with nausea and vomiting in pregnancy require medication. The American College of Obstetricians and Gynecologists recommends a combination of vitamin B6 (10–25 mg every 8 h) and doxylamine (25 mg at bed time and 12.5 mg each in the morning and afternoon) as first-line therapy in NVP (ACOG, 2018). This combination has been associated with a 70% reduction in nausea and vomiting with no reports of teratogenicity. Patients that are refractory to this combination can successively be treated with any of the following options: dopamine receptor antagonists (e.g., metoclopramide and various phenothiazines), antihistamines (e.g., dimenhydrinate and diphenhydramine), or serotonin $5HT_3RA$ (e.g., ondansetron) (ACOG, 2018). Metoclopramide is rarely associated with tardive dyskinesia. However, the risk increases with prolonged use and the total cumulative dose. Therefore, the treatment duration should not exceed 12 weeks (Herrell, 2014; Wijemanne et al., 2016). Corticosteroids, such as methyl prednisolone, have shown beneficial results in patients of HG (ACOG, 2018). The use of methyl prednisolone is associated with a three- to four-fold higher risk for cleft lip with or without cleft palate, thus its use should be avoided till first 10 weeks of gestation (Herrell, 2014). Severe NVP can cause dehydration and lead to increased level of ketones. This can be treated with IV fluid replenishment and multivitamins, especially thiamine. Antiemetics can be administered intravenously, if needed. However, follow-up measurement of urinary ketones and electrolytes will be required. Women with continued vomiting even after therapy should be hospitalized (ACOG, 2018).

Motion Sickness

Motion sickness is a syndrome that occurs as a result of exposure to certain types of motion. It is believed to be caused by conflict between the vestibular, visual, and other proprioceptive systems (Brainard and Gresham, 2014). Although vomiting is a typical presentation of motion sickness, it is often preceded by stomach awareness, malaise, drowsiness, and irritability. Management involves nonpharmacological (behavioral) and pharmacological strategies. Patients should be educated about the situations that might lead to motion sickness and strategies to minimize the amount of unpleasant motion. Scopolamine is recommended as a first-line drug for prevention of motion sickness (Spinks and Wasiak, 2011). Its transdermal patch is administered several hours before the anticipated motion exposure. In the case of poor response with usual dose, the dose can be doubled (Bar et al., 2009). First-generation antihistamines (cyclizine, meclizine, dimenhydrinate, etc.) are also effective. However, they often have sedative and

other side effects. Nonsedating antihistamines and ondansetron are not effective in the prevention and treatment of motion sickness (Brainard and Gresham, 2014).

Role of Pharmacist

Pharmacists are important members of the multidisciplinary health-care team and are experts in medicines. Their active involvement is needed in order to rationalize medication use and achieve the desired patient outcomes. For this purpose, pharmacists have a huge role to play in the pharmacotherapy of nausea and vomiting.

Pharmacists contribute to improving patients' health by providing pharmacotherapy-related patient-care services. In this connection, Pharmacists' Patient Care Process (PPCP) is a contemporary and comprehensive approach to patient care. In PPCP, pharmacists use a patient-centered model of care and work in collaboration with other members of multidisciplinary health-care team (Gonyeau et al., 2018; JCPP, 2014; Jupp et al., 2016). The following are the main components of PPCP: collect, assess, plan, implement, and follow-up (monitor/evaluate). PPCP for nausea and vomiting is illustrated in Fig. 4.

Pharmacists provide comprehensive patient education and counseling, which is one of the main strategies used for the management of nausea and vomiting. A study has demonstrated that education provided by pharmacists resulted in proper use of antiemetic drugs and led to improved control of chemotherapy-induced nausea with reduction in the cost for antiemetics by 16% (Iihara et al., 2012).

Many patients are persistently affected by nausea and vomiting. They suffer, not only physically and mentally but also financially. In such situations, treatment adherence becomes a major concern. The pharmacist role is to evaluate patients by identifying all considerable factors such as patient's health literacy, the convenience or complexity of the prescribed regimen, and pinpointing the factors that may affect adherence. Patients should be properly educated, and all issues that might lead to nonadherence should be addressed (McCullough, 2017).

Patients should be provided with accurate information regarding the condition and other therapy-related issues such as its outcome, potential harms, cost, duration, and proper administration. Patient education regarding the appropriate use of medications with special emphasis on adherence to antiemetic therapy should be provided. Adequate verbal and written information should be provided to each patient about the timing of drug administration, its duration, and possible adverse effects and their management (Tilleman et al., 2018). Other issues can also be addressed while educating a patient, which may have an impact on

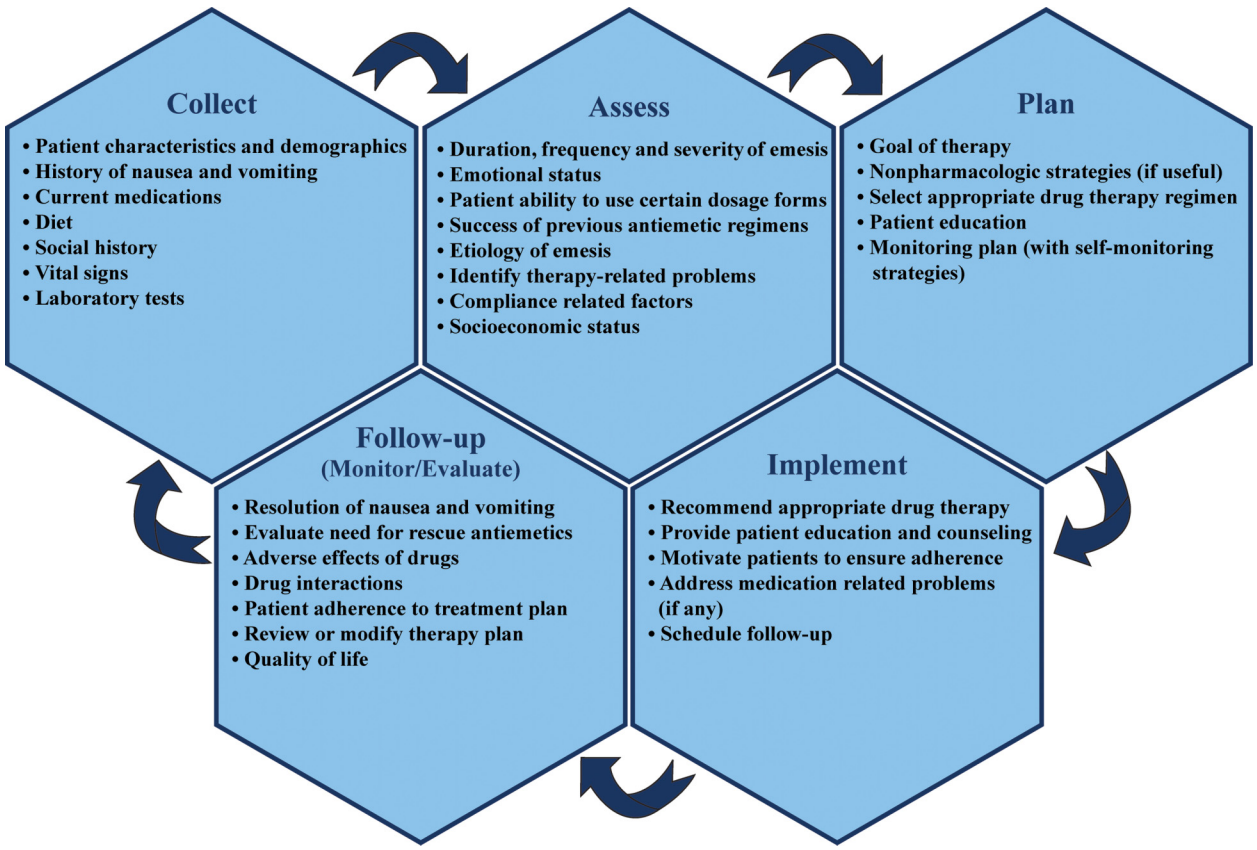

Figure 4 Pharmacists' patients care process for nausea and vomiting.

the condition such as dietary and lifestyle modifications; avoiding foods that may trigger emesis; eating soft bland foods; taking adequate amount of water; use of ginger; and psychological strategies.

Monitoring of therapy outcome is another important activity undertaken by pharmacists. Prevention or complete elimination of nausea and vomiting with no or minimal adverse effects are the desired outcomes of pharmacotherapy of nausea and vomiting. A patient receiving antiemetic therapy should be evaluated for resolution of symptoms and decrease in severity of nausea and number of emetic episodes per day. Moreover, patient evaluation for fluid and electrolyte imbalance is necessary. Therefore, parameters such as change in weight, estimated fluid loss, acid–base balance, and serum electrolytes should be regularly measured. Patient should also be evaluated for improvement of the underlying cause of nausea and vomiting. Physical assessment involving evaluation of mucous membrane and skin turgor should also be performed. Patients undergoing chemotherapy should be assessed after each chemotherapy session as most of the patients experience emetic episodes on the third day of the chemotherapy session. Documenting the experiences can help the health-care providers to modify the next management plan (Gravatt et al., 2017).

Antiemetic therapy is associated with many adverse drug effects (ADEs); therefore, their monitoring and management are also among the prime responsibilities of pharmacists (Husband and Worsley, 2007; Iihara et al., 2012). ADEs unceasingly place patients at risk and are a major source of health-care mishaps. They are not unexpected in the highly complex antiemetic therapy. ADEs deteriorate a patient's health-related quality of life, which already is poor in patients receiving antiemetic therapy as emesis itself is an adverse outcome of a number of underlying etiologies. Some of the frequently occurring ADEs associated with antiemetic therapy are discussed as follows (**Table 5** for more details). Antihistamine-anticholinergic class of drugs work by blocking H_1 receptors in the brain and muscarinic receptor M_1 both peripherally and centrally, which not only increase its efficacy but also its adverse effects. The commonly associated adverse effects with these drugs include sedation, xerostomia, dilated pupils, blurred vision, decreased GI motility/secretions, and urinary retention (ACOG, 2018; Veiga-Gil et al., 2017). Serotonin $5HT_3$RAs are fairly safer drugs and pose a risk of mild ADEs that include headache, constipation, diarrhea, and transient elevation of liver enzymes. Rarely, they may cause QT interval prolongation (ACOG, 2018; Veiga-Gil et al., 2017). The short-term use of dexamethasone is well-tolerated in most patients. Despite that, its use is associated with adverse effects such as hypertension, depression, conjunctivitis and steroid-related hyperglycemia. Diabetic patients are more prone to the steroid-related hyperglycemia; therefore, they should be advised to regularly monitor their glucose level (Wiesmann et al., 2015). Aprepitant is usually a well-tolerated drug and is associated with mild side effects such as fatigue, hiccups, headache, and diarrhea (Navari and Aapro, 2016). Stevens–Johnson syndrome is a rare but severe adverse effect associated with the use of aprepitant. Apart from these well-known and widely used pharmacologic agents, drugs from other classes have been used as antiemetics. Their ADEs are listed in **Table 5**. Moreover, a variety of drug interactions (DIs) are also possible in

Table 5 Adverse drug effects associated with pharmacotherapy of nausea and vomiting

Drugs	*Cardiovascular*	*Gastrointestinal*	*Neurological/psychiatric*	*Others*
Dimenhydrinate	–	Nausea, vomiting, epigastric distress, xerostomia	Sedation	Genitourinary: urinary retention
Hydroxyzine	*QTIP*	Xerostomia	Sedation	Dermatologic: *injection site reaction*
Meclizine	–	Xerostomia	Sedation	Immunologic: a*naphylactoid reaction* Ophthalmic: *blurred vision*
Scopolamine	*Tachyarrhythmia*	Xerostomia	*Confusion, hallucinations*	Dermatologic: *dry skin* Ophthalmic: mydriasis Genitourinary: urinary retention
Trimethobenzamide	–	*Hepatotoxicity, jaundice*	Dizziness, sedation, *coma, disoriented, extrapyramidal signs, seizure, depressed mood*	Ophthalmic: blurred vision
Diphenhydramine	–	Xerostomia	Dizziness, dyskinesia, sedation	Respiratory: dryness of nasopharyngeal mucosa, thick sputum Immunologic: *anaphylaxis*
Dolasetron	Bradyarrhythmia, *cardiac arrest, myocardial ischemia, QTIP, syncope, TdP, ventricular arrhythmia*	Diarrhea, *pancreatitis*	Dizziness, headache	Immunologic: *anaphylaxis,* Others: fatigue, *serotonin syndrome*
Granisetron	*QTIP*	–	Asthenia, headache, sedation	Immunologic: *hypersensitivity reactions* Other: fever
Ondansetron	*ECG abnormalities, QTIP, TdP*	Constipation, diarrhea	Headache	Respiratory: hypoxia Other: fatigue, malaise, *serotonin syndrome*
Palonosetron	Bradyarrhythmia, *QTIP*	Constipation	Headache, *seizure*	Immunologic: *anaphylaxis, hypersensitivity reactions* Other*: serotonin syndrome*

(*Continued*)

Table 5 Adverse drug effects associated with pharmacotherapy of nausea and vomiting (*cont.*)

Drugs	*Cardiovascular*	*Gastrointestinal*	*Neurological/psychiatric*	*Others*
Aprepitant	Hypotension	Abdominal pain, constipation, diarrhea, indigestion, loss of appetite, hepatotoxicity	Asthenia, dizziness, headache	Dermatologic: *SJS* Respiratory: cough, hiccups Hematologic: anemia, neutropenia Others: dehydration, fatigue
Fosaprepitant	–	Diarrhea	Asthenia	Dermatologic: *SJS* Hematologic: *neutropenia,* Immunologic: *hypersensitivity reaction, infusion reaction* Others: *fatigue*
Rolapitant	–	Loss of appetite	Dizziness	Respiratory: cough, hiccups Hematologic: neutropenia
Chlorpromazine	Orthostatic hypotension, tachycardia, *QTIP*	Nausea, xerostomia, *obstipation, paralytic ileus, jaundice*	Akathisia, dizziness, parkinsonism, sedation, tardive dyskinesia	Dermatologic: *erythroderma* Endocrine/metabolic: ineffective thermoregulation, hyperthermia Hematologic: *agranulocytosis, aplastic anemia, leukopenia*
Prochlorperazine	*QTIP*	–	*Tardive dyskinesia, NMS*	
Promethazine	*QTIP*	Nausea and vomiting, xerostomia, *jaundice*	CNS depression, dizziness, extrapyramidal disease, convulsion, sedation, *NMS*	Dermatologic: dermatitis, phototoxicity, urticaria, *injection site reaction* Respiratory: *apnea* Hematologic: *agranulocytosis, leukopenia, thrombocytopenia*
Metoclopramide	–	Nausea, vomiting	Asthenia, headache, sedation, *NMS, tardive dyskinesia*	Endocrine/metabolic: fluid retention Other: fatigue
Dexamethasone	Hypertension, *cardiomyopathy*	*Pancreatitis*	Depression, euphoria	Respiratory: tuberculosis Endocrine/metabolic: Cushing's syndrome, growth retardation, *hyperglycemia* Ophthalmic: abnormal vision, cataract, conjunctivitis, *conjunctival hemorrhage, glaucoma, uveitis* Musculoskeletal: *osteoporosis* Immunologic: *infectious disease*
Haloperidol	Hypotension, *QTIP, sudden cardiac death, TdP*	Constipation, xerostomia, *paralytic ileus*	Akathisia, extrapyramidal disease, sedation, *dystonia, NMS, seizure, tardive dyskinesia*	Ophthalmic: blurred vision Hematologic: *agranulocytosis* Reproductive: *priapism*
Droperidol	Hypotension, tachycardia, *cardiac arrest, QTIP, TdP, ventricular tachycardia*	–	Sedation, anxiety, dysphoric mood, restlessness, *NMS*	Immunologic: *anaphylaxis*
Dronabinol	Palpitations, tachyarrhythmia, vasodilation, *hypotension*	Abdominal pain, nausea, vomiting, xerostomia	Amnesia, ataxia, confusion, dizziness, sedation, anxiety, euphoria, hallucinations, d*epression, mania, schizophrenia*	Dermatologic: flushing Immunologic: *hypersensitivity reactions*
Nabilone	Hypotension	Xerostomia	Asthenia, ataxia, sedation, headache, poor concentration, vertigo, euphoria, *psychotic disorder*	Ophthalmic: visual disturbance
Olanzapine	Orthostatic hypotension, *sudden cardiac death*	*Acute hemorrhagic pancreatitis*	Personality disorder, *akathisia, asthenia, dizziness, sedation, tremors, cerebrovascular disease, dystonia, seizure, status epilepticus,* s*uicidal intent*	Respiratory: *pulmonary embolism* Endocrine/metabolic: hypercholesterolemia, hyperglycemia, hyperprolactinemia, increased appetite, weight gain, *hyperglycemic hyperosmolar state* Immunologic: *eosinophilia*

CNS, central nervous system; *ECG*, electrocardiogram; *NMS*, neuroleptic malignant syndrome; *QTIP*, QT interval prolongation; *SJS*, Stevens–Johnson syndrome; *TdP*, torsades de pointes. Note: Serious adverse effects are presented in italics.

patients with nausea and vomiting as they are usually exposed to polypharmacy (Umar, 2018). Antiemetic drugs are frequently used simultaneously with many other drugs for underlying problems and comorbidities. Therefore, patients' drug therapy may be associated with DIs leading to adverse outcomes. DIs are considered preventable causes of morbidity and mortality. Pharmacists should screen every patient's therapy for DIs in order to manage them accordingly.

Extensive literature is available regarding the role of the pharmacist in the pharmacotherapy of nausea and vomiting. Various studies have reported a significant impact of pharmacists on optimizing patient outcomes and improving medication safety. According to a systematic review, pharmacist interventions can improve outcome measures such as rates of nausea and vomiting control, medication adherence, and patient satisfaction (Colombo et al., 2017). A study found that pharmaceutical consultations substantially improve the outcome of antiemetic therapy, management of adverse effects, and patient satisfaction (Monfort et al., 2015). Impact of a clinical pharmacist-led guidance team was assessed in a prospective, multicenter, double-arm, controlled study. Clinical pharmacist produced a significant impact on various outcome parameters including reduction in the incidence of drug-induced nausea ($P = 0.028$) and vomiting ($P = 0.035$) (Chen et al., 2014).

Interprofessional collaboration is of great value in the management of nausea and vomiting. With the changes in scope of practice, more pharmacists proactively and collaboratively involve in direct patient care services in both inpatient and ambulatory settings (Jupp et al., 2016). Literature supports that collaborative disease therapy management can improve therapy outcomes, enhance medication adherence and medication safety, and minimize health-care expenditures (Jackson et al., 2018; Jupp et al., 2016). A study found that implementation of collaborative disease therapy management for CINV has shown favorable results, in which, the pharmacists have made a substantial number of clinical interventions and provided patient education to patients undergoing chemotherapy (Jackson et al., 2018). A successful reduction in the cost of antiemetic therapy was reported as result of a treatment algorithm developed by a team comprising pharmacists, oncologists, and oncology nurses (Berard and Mahoney, 1995). Another study showed that oncology pharmacists' collaboration with medical oncologists improved the management of CINV. Pharmacists successfully identified areas related to the use of antiemetics that needed refinement (Chan et al., 2008). As many cases of nausea and vomiting are drug induced, therefore proper monitoring of drug therapy will be helpful to detect such cases. Pharmacist–physician joint monitoring of chemotherapy was found very effective in identifying cases with adverse drug effects (Holle et al., 2016).

Various guidelines are available for the appropriate management of nausea and vomiting. These guidelines provide evidence-based standardized approaches. A key role of pharmacists is to ensure that treatments are consistent with these guidelines (Tilleman et al., 2018; Wood et al., 2015). A study has demonstrated that adherence to antiemetic guidelines resulted in significant reduction in the incidence of nausea/vomiting and side effects, and improvement of the patient's quality of life (Abunahlah et al., 2016). An educational intervention involving emphasis on the current guidelines was also found very effective to decrease markedly the incidence of PONV in a population of adult surgical patients (Sigaut et al., 2010). A randomized trial assessed the impact of pharmacist intervention involving evaluation of drug-use based on hospital guidelines. Pharmacist significantly contributed to promoting appropriate drug-use and controlling unnecessary hospital costs (Dranitsaris et al., 1995). Moreover, pharmacists significantly enhance care of the patients with CINV by making formulary considerations using patient-centered and evidence-based treatment (McCullough, 2017).

Pharmacists' contribution to pharmacotherapy of nausea and vomiting has been reported by many other studies as follows: supportive care provided by pharmacists in community- and hospital-pharmacies (Jansen and Ortland, 2017); pharmacist prescribing of antiemetic agents for nausea and vomiting with improved compliance to treatment-algorithm, drug safety, and patients/professionals acceptance (Martin and Norwood, 1988); evaluation of quality of life in patients with nausea and vomiting (de Souza et al., 2015); community pharmacists' roles/services (Albassam and Awad, 2018; Maesschalck, 2011); role of hospital pharmacist in the management of nausea and vomiting (Breton et al., 2011); and outpatient approach to nausea and vomiting (Prunty and Prunty, 2013).

Glossary

Akathisia A movement disorder characterized by a feeling of inner restlessness and inability to stay still.
Asthenia Loss of strength and energy.
Emetogenicity The potential of an agent to cause nausea and/or vomiting.
Extrapyramidal signs Forms of abnormal body movements that are caused by blockade of normal dopamine functions in the brain.
Neuroleptic malignant syndrome A life-threatening idiosyncratic reaction to antipsychotic drugs (neuroleptics) characterized by fever, altered mental status, muscle rigidity, and autonomic dysfunction.
Radiotherapy Therapy using ionizing radiation, generally as part of cancer treatment to control or kill malignant cells.
Retching Spasmodic movements of thoracic and abdominal muscles without emesis; also called dry heaves.
Stevens-Johnson syndrome (SJS) A severe inflammatory eruption of the skin and mucous membranes, which usually occurs as an allergic reaction to drugs or other substances.
Tardive dyskinesia A disorder associated with the use of neuroleptic drugs that results in involuntary, repetitive body movements.

Torsades de pointes (TdP) A specific form of polymorphic ventricular tachycardia characterized by rapid, irregular QRS complexes, which appear to be twisting around the ECG (electrocardiogram) baseline.
Xerostomia An abnormal dryness of mouth due to insufficient secretions.

Management of Gastrointestinal Disorders and the Pharmacist's Role: Peptic Ulcer Disease

Mohammad Ismail*, Fahadullah Khan*, Sidra Noor*, Anjum Shafi†, *University of Peshawar, Peshawar, Khyber Pakhtunkhwa, Pakistan; †Health Canada, Ottawa, ON, Canada

Learning Objectives

At the end of this chapter, the reader will be able to:

- Develop a basic understanding of the epidemiology and pathophysiologic of peptic ulcer disease (PUD).
- Describe the main clinical features and complications of PUD.
- Discuss various pharmacological approaches available for PUD and the rationale for their use.
- Design a patient-specific care plan to ensure effective therapeutic outcomes.
- Educate patient about the proper administration of medications.
- Identify and manage adverse drug effects and drug interactions associated with pharmacotherapy of PUD.

Introduction

Peptic ulcer disease (PUD) refers to defects or breaks in the inner lining of the stomach and/or duodenum that penetrates through the muscularis mucosa leading to inflammation of the underlying tissue. *Helicobacter pylori* (*H. pylori*) infection and the use of nonsteroidal anti-inflammatory drugs (NSAIDs) are the most common causes of PUD.

Epidemiology

Peptic ulcer disease remains a relatively common condition worldwide (Sung et al., 2009). Its overall incidence has changed over the past few decades (Azhari et al., 2018; Sung et al., 2009). The global annual incidence of PUD ranges from 0.10% to 0.19% based on physician diagnosis and 0.03% to 0.17% based on hospitalization data (Sung et al., 2009). According to a recent systematic review, the incidence of PUD varies in different parts of the world (Europe, Asia, and North America), with the highest in Spain (141.8 per 100,000 persons) and the lowest in the United Kingdom (23.9 per 100,000 persons) (Azhari et al., 2018). The incidence of PUD is related to gender and age. Males and older persons are more susceptible to PUD than females and younger persons, respectively (Garrow and Delegge, 2010). The prevalence of PUD is also variable, which exceeds its incidence mainly because of recurrence. The 1-year global prevalence is 0.12%–1.5% for physician-diagnosed PUD and 0.10%–0.19% for PUD diagnosed during hospitalizations (Sung et al., 2009). In a large population-based study in the United States, the estimated prevalence of peptic ulcers is 8.4% (Garrow and Delegge, 2010). Similarly, a large endoscopic study of a population sample from Sweden reported a prevalence of 4% (2% gastric and 2% duodenal ulcers) (Aro et al., 2006).

Etiology

Infection with *H. pylori* and use of NSAIDs are the most common causes of PUD. Among NSAIDs, the risk of ulcer is highest with full doses of nonselective NSAIDs, followed by low-dose aspirin and cyclooxygenase-2 (Cox-2)-selective NSAIDs (Masclee et al., 2014). Duodenal ulcer is almost always (>90%) associated with *H. pylori* infection, whereas gastric ulceration is associated with both *H. pylori* infection and the use of NSAIDs (Dovjak, 2017). Other less common causes of peptic ulcer include Zollinger–Ellison syndrome, cigarette smoking, stress, chronic illnesses, infections other than *H. pylori*, radiations, and concomitant administration of anticoagulants, selective serotonin reuptake inhibitors or corticosteroids with NSAIDs. The risk of PUD increases with old age (>60 years), previous history of ulcer, and alcohol consumption (**Table 1**). Individuals with multiple risk factors are at a higher risk for peptic ulcer-related bleeding (Nagata et al., 2015; Sostres et al., 2015; Venerito et al., 2018). Lately, the prevalence of idiopathic ulcer (*H. pylori* and NSAID-negative peptic ulcer) has increased, accounting for up to 10%–30% of PUD cases. In such patients, the less common causes of ulcer must be considered (Charpignon et al., 2013; Iijima et al., 2014). The ulcerogenic potential of diet and nutrition such as spicy food, carbonated drinks, coffee, tea, milk, and beer is uncertain; however, they may cause dyspepsia.

Pathophysiology

Peptic ulcers develop as a result of imbalance between aggressive factors (acid and pepsin) and defensive factors (synthesis of prostaglandins, ischemia), irrespective of the causative agent. *H. pylori* infection causes gastritis in almost all infected individuals, but only a fraction of them (~10%) actually develop PUD. The incidence of PUD depends on a myriad of host and bacterial factors. Host-related factors include genetic predisposition, duration of infection, smoking, and the use of NSAID. The most notable bacterial factors are the expression of CagA (cytotoxin-associated gene-A) and VacA (vacuolating toxin) virulence factors (proteins) (Amieva and Peek, 2016). The CagA protein disrupts various epithelial cell signaling processes involved in cell replication and cell death, whereas the VacA gene protein introduces a large pore-forming protein in the epithelial cell membrane that results in an increased efflux of micronutrients and apoptosis (Costa et al., 2009). Bacterial surface proteins (Hop and BabA proteins) facilitate bacterial adhesion and act as a chemotactic for neutrophils and monocytes, which further augments cellular injury. Additionally, *H. pylori* infection alters the secretion of gastrin (hypersecretion of gastrin in duodenal ulcer) mainly because of the reduced number of somatostatin secreting antral "D" cells and the stimulation of gastrin release by cytokines during active inflammation, that result in hyperchlorhydria. In gastric ulcers, hypochlorhydria may allow the growth of other bacteria that may cause chronic inflammation.

NSAIDs cause ulcers by local irritation as well as systemic inhibition of prostaglandins synthesis that are essential for mucosal integrity and repair (Bhatt et al., 2008). All NSAIDs including aspirin are weak acids. They remain unionized in the acidic pH of the stomach and diffuse into the gastric epithelium. In the epithelial cells, the neutral pH ionizes NSAIDs resulting in irritation and inflammation, which may subsequently cause epithelial injury. Systemically, NSAIDs inhibit the cyclooxygenase (Cox) enzymes involved in the synthesis of prostaglandins. The Cox-1 enzyme synthesizes protective prostaglandins that regulate normal physiologic processes and is present in the stomach, kidney, intestine, and platelets. While, the inducible Cox-2 enzyme is generated during acute inflammation and synthesizes prostaglandins involved in inflammation, fever, and pain (Bhatt et al., 2008). The nonselective NSAIDs inhibit both the Cox-1 and Cox-2 isoforms. They have a higher risk of gastrointestinal (GI) toxicity as compared to the Cox-2-selective NSAIDs, which only inhibit the Cox-2 enzyme. NSAIDs can also cause mucosal injury through the production of proinflammatory mediators such as tumor necrosis factors and leukotrienes.

Cigarette smoking not only induces ulcers but also impairs ulcer healing and increases the risk of ulcer complications. The exact mechanism of smoking-induced ulcer is unknown. The association of genetic factors and ulcers remains unclear, however a higher incidence of ulcers has been reported in first degree relatives and patients with blood group "O" (Malfertheiner et al., 2009).

Table 1 Risk factors for peptic ulcer disease

Patient's characteristic
• Old age (>60 years)
Infections
• *Helicobacter pylori* • Cytomegalovirus (particularly in AIDS and transplant patients) • Herpes simplex virus (particularly in AIDS and transplant patients) • Helicobacter heilmannii
Medications
• NSAIDs (including Cox-2-selective NSAIDs and low-dose aspirin) • Anti-coagulants (alone or in combination with NSAIDs) • Corticosteroids (in combination with NSAIDs) • Selective serotonin reuptake inhibitors (in combination with NSAIDs) • Bisphosphonates • Potassium chloride • Chemotherapy • Iron preparations
Diseases
• Zollinger–Ellison syndrome • Stress (burns, multiorgan failure, CNS trauma) • Crohn's disease • Chronic kidney disease • Chronic heart failure • Arthritis • Coronary artery disease • Liver cirrhosis • Chronic obstructive pulmonary disease • Pancreatitis • Lymphoma • Bile reflux disease

Risk Factors for the Presence of Symptoms in Peptic Ulcer Disease. Clin. Endosc. 50, 578–584 (Lee et al., 2017).

Clinical Features

The clinical features of PUD vary with the severity of the disease. Patients may present with mild epigastric discomfort to life-threatening complications. Epigastric pain is the most frequent presentation of ulcer, but it is nonspecific and might be present in patients with other GI conditions including nonulcer dyspepsia. The patient may point at the site of pain with one finger commonly known as the pointing sign. Generally, the pain is expressed as a burning, gnawing, aching sensation and is localized to the epigastrium. In complicated cases, it may radiate toward the back or lower abdomen. Severe nocturnal pain that awakens the

patient may also be reported by some patients (Lanas and Chan, 2017; Narayanan et al., 2018). In duodenal ulcers, food intake often diminishes pain that recurs after 1–3 h, whereas food intake worsens pain in gastric ulcers. Dyspepsia, an uncomfortable feeling may be present in some patients, but it is common with other GI conditions as well. Moreover, patients may experience dyspepsia, following intake of NSAIDs, spicy food, or milk.

Peptic ulcer-related bleeding is a serious complication. Bleeding may be occult, which can only be ascertained following fecal occult blood test, or it may present as melena or hematemesis. Chronic bleeding may result in anemia, while significant acute blood loss can cause shock (Budimir et al., 2017; Lanas and Chan, 2017; Venerito et al., 2018). Mild epigastric tenderness may be observed with deep palpitations in patients with noncomplicated ulcers whereas, severe "board-like" abdominal tenderness is suggestive of perforation. Moreover, early satiety, nausea, vomiting, pain precipitating with meals, weight loss, and bloating indicate gastric obstruction.

Diagnosis

The main objective of diagnosis is to ascertain the cause of ulcer and to rule out gastric malignancy. The patient's history, being quick and easy, provides important information about the severity and potential cause(s) of PUD. Information regarding the use of NSAIDs, prior history of PUD, failure of *H. pylori* therapy, smoking, and age guides the selection of the appropriate diagnostic procedure and treatment. In physical examination, epigastric tenderness may be found between the umbilicus and the xiphoid process that less commonly radiates to the back.

Routine laboratory tests such as full blood count and fecal occult blood test may assist in the evaluation of bleeding ulcers, while rare specialized tests such as fasting serum gastrin concentration and gastric acid analysis may be performed for patients who are unresponsive to therapy or suspected to have Zollinger–Ellison syndrome.

Endoscopy is the gold-standard method for investigating the upper GI tract and ulcers. It permits direct inspection, photographic documentation, tissue biopsy, and employment of therapeutic interventions (e.g., epinephrine injection and placement of hemostatic clips). Endoscopy is recommended for high-risk patients, particularly elderly patients having alarm features (e.g., weight loss, bleeding, vomiting, dysphagia) and patients who do not respond to therapy. For patients who undergo endoscopy, biopsies should be taken and tested for the presence of *H. pylori* infection and malignancy (Chey et al., 2017).

Barium radiography is a less expensive and widely available method of ulcer detection. It is used as an alternate method to endoscopy. In this technique, the patients receive a barium meal that improves ulcer detection.

Detection of *H. pylori* infection is recommended in all patients having active ulcers, prior history of PUD (except successful eradication), and individuals starting chronic NSAIDs therapy. A number of invasive and noninvasive methods have been developed for the detection of *H. pylori* (**Table 2**). The accuracy and sensitivity of invasive tests (except histology) are greatly affected with the use of antibiotics, bismuth salts, and proton pump inhibitors (PPIs); therefore, they should be withdrawn at least 4 weeks (2 weeks for PPIs) before performing these tests (Chey et al., 2017).

Treatment

The main goals of PUD treatment include symptomatic relief, eradication of *H. pylori* infection, healing the ulcer, and preventing ulcer complications and recurrence. Various non-pharmacological and pharmacological options may be used. In non-pharmacological treatment, diet and lifestyle modifications are recommended. Although no specific diet promotes or augments ulcer healing, intake of spicy food and carbonated or caffeinated beverages may increase gastric acid secretion or cause dyspepsia. Therefore, they should be avoided or used in moderation. Regular small meals are encouraged and late-night snacks are better avoided because they increase nocturnal acid secretion. Moreover, cigarette smoking and the use of NSAIDs should be avoided. Pharmacological treatment includes various regimens for the eradication of *H. pylori* related ulcers and the treatment and prevention of NSAIDs-related ulcers (Chey et al., 2017; Lanza et al., 2009).

Treatment of *H. pylori*-induced Ulcer

H. pylori eradication therapy aims to completely eliminate *H. pylori* infection and heal the ulcer by selecting a cost-effective drug regimen. The type and duration of therapy, antibiotic resistance, and patient adherence are key factors responsible for the success of treatment. In the following sections, various treatment options and their selection criteria are discussed. Drugs doses, precautions, use in pregnancy and lactation, and renal/hepatic dose adjustments are presented in **Tables 3 and 4**.

Treatment Options

Therapy against *H. pylori* infection comprises multiple drugs (**Fig. 1**) in order to achieve successful eradication and minimize the emergence of resistance (Chey et al., 2017).

Triple therapy: The conventional triple therapy is a combination of a PPI and two antibiotics (metronidazole with clarithromycin or amoxicillin) and is recommended for a duration of 10–14 days (Chey et al., 2017; Fallone et al., 2016; Luther et al., 2010). Triple

Table 2 Diagnostic approaches for the detection of *Helicobacter pylori*

Tests	*Description*	*Sensitivity*	*Specificity*	*Merits*	*Demerits*	*Guidelines recommendations*
Invasive endoscopic tests (requires tissue biopsy)						
Rapid urease test	Change in color (pH sensitive indicator) is detected because of ammonia production due to urease enzyme	80%–95%	95%–100%	Test of choice; easy to perform on biopsy sample; rapid	Potential false-negative result with drugs; expensive; reduced accuracy in ulcer; 13-carbon test requires expensive mass spectrometer	Sensitivity can be improved with increasing number of biopsy samples
Histology	Microbial examination using various stains	>90%	>95%	Test of choice to rule out malignancy; permits classification of gastritis	Takes several days; expensive; requires skilled expert	Performed to exclude gastric malignancy
Culture	Culture of biopsy particularly for antibiotic susceptibility	Variable	100%	Enables antibiotic susceptibility testing	Time consuming; expensive; technically demanding	Limited to patients who fail initial treatment
Polymerase chain reaction	Detection of *H. pylori* DNA in gastric tissue	High	High	High specificity and sensitivity	High rates of false-positive or -negative; positive DNA does not correlate with the presence of organism	–
Noninvasive tests (does not require tissue biopsy)						
Urea breath test	*H. pylori*'s urease enzyme converts ingested radiolabeled urea into ammonia and carbon dioxide, the latter is exhaled and detected in breath	>90%	>90%	Determines active *H. pylori* infection; simple; rapid; recommended for confirmation of eradication	Exposure to low-dose radiations with 14-carbon test; potential false-negative with drugs; results take around two days	Test of choice
Fecal antigen test	Detects *H. pylori* antigen in stool by enzyme immunoassay using polyclonal antibody	>90%	>90%	Identifies active *H. pylori* infection, comparable to urea breath test; inexpensive; convenient	Potential false-negative with drugs	Alternate for initial screening and eradication confirmation to urea breath test; convenient in children; some individuals may be reluctant to obtain stool samples
Office-based antibody serologic test	Detects IgG antibodies against *H. pylori* in blood using strips	>80%	>90%	Quick (under 15 min); inexpensive; convenient; not affected by drugs; widely available	Qualitative; cannot differentiate between active or previous infection; less sensitive and specific than laboratory-based test; not recommended for eradication confirmation	Not recommended for initial screening except in patients with no prior history of ulcer
Laboratory-based antibody serologic test	Detects IgG antibodies against *H. pylori* in serum using ELISA and latex agglutination techniques	>80%	>90%	Quantitative; more accurate than office-based serologic test; inexpensive; convenient; not affected by drugs	Cannot differentiate between active or previous infection; less sensitive and specific than invasive tests; not recommended for eradication confirmation	May be performed in patients with no prior history of ulcer

Table 3 Recommended drugs' doses and precautions

Therapeutic class	*Drug*	*Adult dosage*	*Cautions*
Proton pump inhibitors	Omeprazole	Oral 20–40 mg once or twice daily for 4–8 weeks[a]	Avoid in patients with known hypersensitivity. May induce CDAD, CLE, SLE, fundic gland polyps, osteoporosis, hypomagnesemia, vitamin B_{12} deficiency, acute interstitial nephritis and hepatic toxicity
	Esomeprazole	Oral 20–40 mg once or twice daily for up to 6 months[a]	
	Pantoprazole	Oral 40–80 mg once or twice daily for 4–8 weeks[a]	
	Rabeprazole	Oral 20 mg once or twice daily for up to 4 weeks[a]	
	Lansoprazole	Oral 30–60 mg once or twice daily for up to 8 weeks[a]	
Histamine-2 receptor antagonists	Ranitidine	Oral 150 mg twice daily	Avoid in patients with known hypersensitivity. May induce vitamin B_{12} deficiency, hepatotoxicity, acute porphyria, confusion in elderly patients, prolongation of QT interval and gynecomastia (cimetidine)
	Famotidine	Oral 40 mg once daily at night for up to 8 weeks	
	Cimetidine	Oral 800 mg once daily at night or 400 mg twice daily or 300 mg four times daily	
Anti-infective agents	Clarithromycin	Oral 500 mg twice daily in combination with other drugs	Avoid in patients with known hypersensitivity, cholestatic jaundice, cardiac arrhythmia. May induce SJS, TEN, prolongation of QT interval, hepatotoxicity, CDAD and exacerbation of myasthenia gravis
	Amoxicillin	Oral 1 g twice daily in combination with other drugs	Avoid in patients with known hypersensitivity. May induce anaphylaxis and CDAD
	Metronidazole	Oral 500 mg thrice daily as triple or quadruple regimen or Oral 500 mg twice daily as non-bismuth quadruple regimen	Avoid in patients with known hypersensitivity, first-trimester, concomitant intake of disulfiram or alcohol. May induce seizures, encephalopathy, peripheral neuropathy, CDAD, hepatotoxicity and blood abnormalities
	Tetracycline	Oral 500 mg four times daily in combination with other drugs	Avoid in patients with known hypersensitivity, hepatic impairment, second and third trimester. May induce photosensitivity, intracranial hypertension, retardation of bone growth and teeth discoloration
	Levofloxacin	Oral 500 mg once daily in combination with other drugs	Avoid in patients with known hypersensitivity. May induce anaphylaxis, blood abnormalities, renal toxicity, phototoxicity, hypoglycemia, CDAD, prolongation of QT interval and torsade de pointes
	Furazolidone	Oral 200 mg twice daily in combination with other drugs	Avoid in infants, with concomitant intake of disulfiram and patients with known hypersensitivity. May induce hemolytic anemia in G6PD deficient patients
	Rifabutin	Oral 150–300 mg twice daily in combination with other drugs	Avoid in patients with known hypersensitivity. May induce blood abnormalities, ocular inflammation, arthralgia and brown-orange discoloration of body fluids
Mucosal protectants	Misoprostol	Oral 200 mcg four times daily for 4 weeks	Avoid in patients with known hypersensitivity. May induce diarrhea, anaphylaxis, chills and teratogenicity
	Bismuth subsalicylate	Oral 300 mg four times daily in combination with other drugs	Avoid in patients with known hypersensitivity, diarrhea, gastrointestinal bleeding, children with chicken pox and influenza. May induce black discoloration of tongue
	Sucralfate	Oral 300 mg four times daily in combination with other drugs; Oral 1 g four times daily for stress ulcer	Avoid in patients with known hypersensitivity. May induce hyperglycemia in diabetics or alter drugs absorption

CDAD, *Clostridium difficile* associated diarrhea; *CLE*, cutaneous lupus erythematosus; *G6PD*, glucose-6 phosphate dehydrogenase; *SJS*, Stevens–Johnson syndrome; *SLE*, systemic lupus erythematosus; *TEN*, toxic epidermal necrolysis.

[a]Twice daily dosing is prescribed for shorter duration of therapy in treating *H. pylori* infection and the duration often varies with specific regimen.

therapy containing amoxicillin should be avoided in individuals with an allergy to β-lactam antibiotics (Chey et al., 2017). *H. pylori* strains resistant to clarithromycin can significantly affect the efficacy of clarithromycin-based triple therapy; thus, they are not recommended in areas with a high prevalence (>15%) of clarithromycin resistance. Alternatively, levofloxacin-based triple therapy may be used (Chey et al., 2017; Fallone et al., 2016; Luther et al., 2010).

Bismuth quadruple therapy: The bismuth quadruple therapy is a combination of bismuth, PPI, and two antibiotics (e.g., metronidazole with tetracycline, amoxicillin, or clarithromycin) (Chey et al., 2017). It is recommended for a duration of 14 days and is preferred over the triple therapy especially in areas with high clarithromycin resistance (Chey et al., 2017; Fallone et al., 2016; Venerito et al., 2013). The addition of bismuth can increase eradication rates by 30%–40% (Dore et al., 2016; Zhang et al., 2015b). Adherence, however, is a major issue with this therapy due to the increased number of drugs and a complex dosing schedule.

Table 4 Drugs use in pregnancy and lactation and dose adjustment

			Dose adjustment	
Drug	*Pregnancy*	*Lactation*	*Kidney impairment*	*Liver impairment*
Omeprazole	Uncertain risk	Uncertain risk	Not necessary	Reduce dose to 10 mg OD for maintenance therapy
Esomeprazole	Uncertain risk	Uncertain risk	Not necessary	Maximum daily dose of 20 mg in severe hepatic impairment
Pantoprazole	Uncertain risk	Uncertain risk	Not necessary	Not necessary
Rabeprazole	Uncertain risk	Uncertain risk	Not necessary	Severe hepatic impairment, use with caution
Lansoprazole	Uncertain risk	Uncertain risk	Not necessary	Severe hepatic impairment, maximum 15 mg daily
Ranitidine	Uncertain risk	Uncertain risk	CrCl <50 mL/min: Reduce the usual dose by half	Not necessary
Famotidine	Uncertain risk	Uncertain risk	CrCl <50 mL/min: 150 mg Oral OD	Not necessary
Cimetidine	Uncertain risk	Minimal risk	CrCl < 30 mL/min: 300 mg Oral BD	Severe hepatic impairment, reduce the usual dose by half
Clarithromycin	Minimal risk	Uncertain risk	CrCl <30 mL/min: Reduce the usual dose by half	Not necessary
Amoxicillin	Uncertain risk	Minimal risk	CrCl < 30 mL/min: Avoid extended release formulations; Use immediate release formulation 250–500 mg BD	Not necessary
Metronidazole	Established risk	Uncertain risk	Not necessary	Severe hepatic impairment, reduce the usual dose by half
Tetracycline	Established risk	Minimal risk	CrCl <50 mL/min: Extend dose interval: administer every 12–24 h	Not necessary
Levofloxacin	Minimal risk	Uncertain risk	CrCl <50 mL/min: Reduced the usual dose by half	Not necessary
Furazolidone	Minimal risk	Uncertain risk	–	–
Rifabutin	Uncertain risk	Uncertain risk	CrCl <30 mL/min: Reduce the usual dose by half	Not necessary
Misoprostol	Established risk	Uncertain risk	Caution is advised	Not necessary
Bismuth subsalicylate	Minimal risk (1st and 2nd trimester); established risk (3rd trimester)	Established risk	Not necessary	Not necessary
Sucralfate	Uncertain risk	Uncertain risk	Not necessary	Not necessary

BD, twice daily; *Crcl*, creatinine clearance; *OD*, once daily.

Source: ASHP, 2018. Drug Information Monographs. AHFS DI Essentials. American Society of Health-System Pharmacists, Inc. Available from: https://www.drugs.com/monograph (ASHP, 2018); Lexicomp, 2018. Adherence can be improved by utilizing a fixed-dose combination formulation, pharmacist-assisted blister packaging, and proper patient education (Gisbert, 2011; Graham and Dore, 2016; Malfertheiner et al., 2011).

Nonbismuth quadruple therapy: A number of nonbismuth quadruple therapies have been used for *H. pylori* eradication. The nonbismuth quadruple therapies comprise a PPI and three antibiotics used for varying duration (Liu et al., 2018; Malfertheiner et al., 2016). Nonbismuth quadruple therapies are costly, complex, and have low adherence. The concomitant therapy contains a PPI and three antibiotics (clarithromycin, amoxicillin, and metronidazole), administered for a duration of 10–14 days (Gisbert and Calvet, 2012b). Concomitant therapy is superior to other non-bismuth therapies in terms of efficacy and compliance (Molina-Infante et al., 2012). Optimized concomitant therapy with a high dose of PPI may achieve higher eradication rates (Molina-Infante et al., 2015). The sequential therapy includes a PPI and amoxicillin, administered for 5–7 days, followed by clarithromycin and metronidazole for an additional 5–7 days (Chey et al., 2017). In hybrid therapy, a PPI and amoxicillin are administered for initial 5–7 days, followed by a combination of PPI, amoxicillin, clarithromycin, and metronidazole for an additional 5–7 days (Chey et al., 2017).

Rescue therapy: Rescue therapy or salvage therapy is a type of therapy given after the failure of standard therapies. Some notable examples of rescue therapies for PUD include levofloxacin containing triple therapy with a PPI, levofloxacin, and amoxicillin; or quadruple therapy with a PPI, bismuth, levofloxacin, and amoxicillin. Their use for 10–14 days effectively achieves eradication in sensitive strains. Alternately, furazolidone or rifabutin may be used as rescue therapy for sensitive strains (Fallone et al., 2016; Liao et al., 2013; Liou et al., 2010).

Use of acid suppression agents in H. pylori regimens: PPIs (e.g., omeprazole, esomeprazole, pantoprazole, and rabeprazole) are an integral part of all eradication therapies. The primary aim of administering a PPI is to inhibit or reduce gastric acid secretion in order

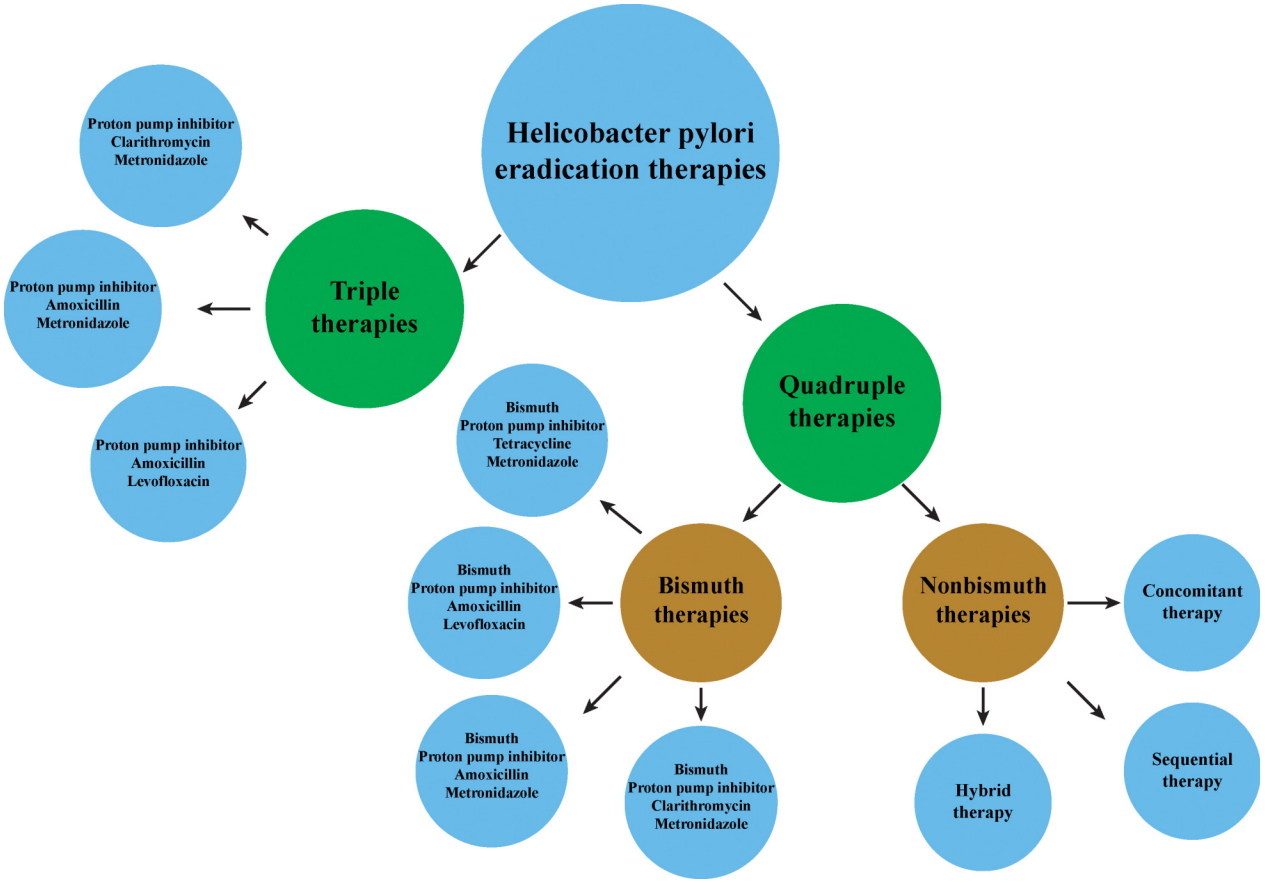

Figure 1 Various therapeutic regimens for the eradication of *Helicobacter pylori* infection.

to promote bacterial growth (*H. pylori*), thus predisposing them to the action of antibiotics. Moreover, PPIs reduce acid-induced mucosal injury. The appropriate selection and optimum efficacy of PPI are influenced by the CYP2C19 genotype. Higher doses of PPIs may be required in fast metabolizers (Kuo et al., 2014; Lee et al., 2014). Alternatively, a novel potassium competitive acid blocker (vonoprazan) may be used (Murakami et al., 2016).

Probiotic adjuvant therapy: Lately, the use of probiotics as an adjuvant therapy has gained popularity. Probiotics such as the lactobacillus, bifidobacterium, and saccharomyces genus have been reported by some studies to improve eradication rates and reduce the incidence of adverse effects (Jung et al., 2018; Losurdo et al., 2018; Zhang et al., 2015a).

Treatment Selection Criteria

The selection of an appropriate therapeutic regimen for a particular patient is mainly based on recent antibiotic use and resistance patterns (Fig. 2). Other factors include contraindication/intolerance, availability, cost, and patient adherence (Chey et al., 2017; Malfertheiner et al., 2016). In general, resistance against tetracycline and amoxicillin is low. Resistance against metronidazole can be overcome by increasing its dose. Resistance against clarithromycin, levofloxacin, and rifabutin can significantly alter their therapeutic outcome (Graham and Fischbach, 2010).

Low-clarithromycin resistance: In areas where the prevalence of clarithromycin resistance is low (<15%) or when patient has no recent exposure to clarithromycin, clarithromycin triple therapy is recommended as first-line treatment for 10–14 days (Fallone et al., 2016). Alternatively, amoxicillin may be used in combination with metronidazole in areas where resistance to metronidazole is low (<15%). The addition of bismuth to clarithromycin triple therapy can increase eradication by 30%–40%. As far as the use of amoxicillin is concerned, it is an important component of eradication regimens due to lower resistance. However, it should be avoided in patients who are allergic to penicillin. If first-line therapy fails, repeated use of clarithromycin should be avoided. The recommended second-line empirical therapy is bismuth quadruple therapy for a duration of 14 days (Chey et al., 2017; Fallone et al., 2016). If second-line therapy fails, the selection of third-line rescue therapy must be based on findings of the antibiotic susceptibility test (Lim et al., 2016; Liu et al., 2018; Malfertheiner et al., 2016; Sugano et al., 2015). Levofloxacin-based triple or quadruple therapy is recommended for susceptible strains. If resistance against levofloxacin is high, bismuth-based therapy containing furazolidone or rifabutin is used (Fallone et al., 2016; Gisbert and Calvet, 2012a; Liao et al., 2013; Liou et al., 2010).

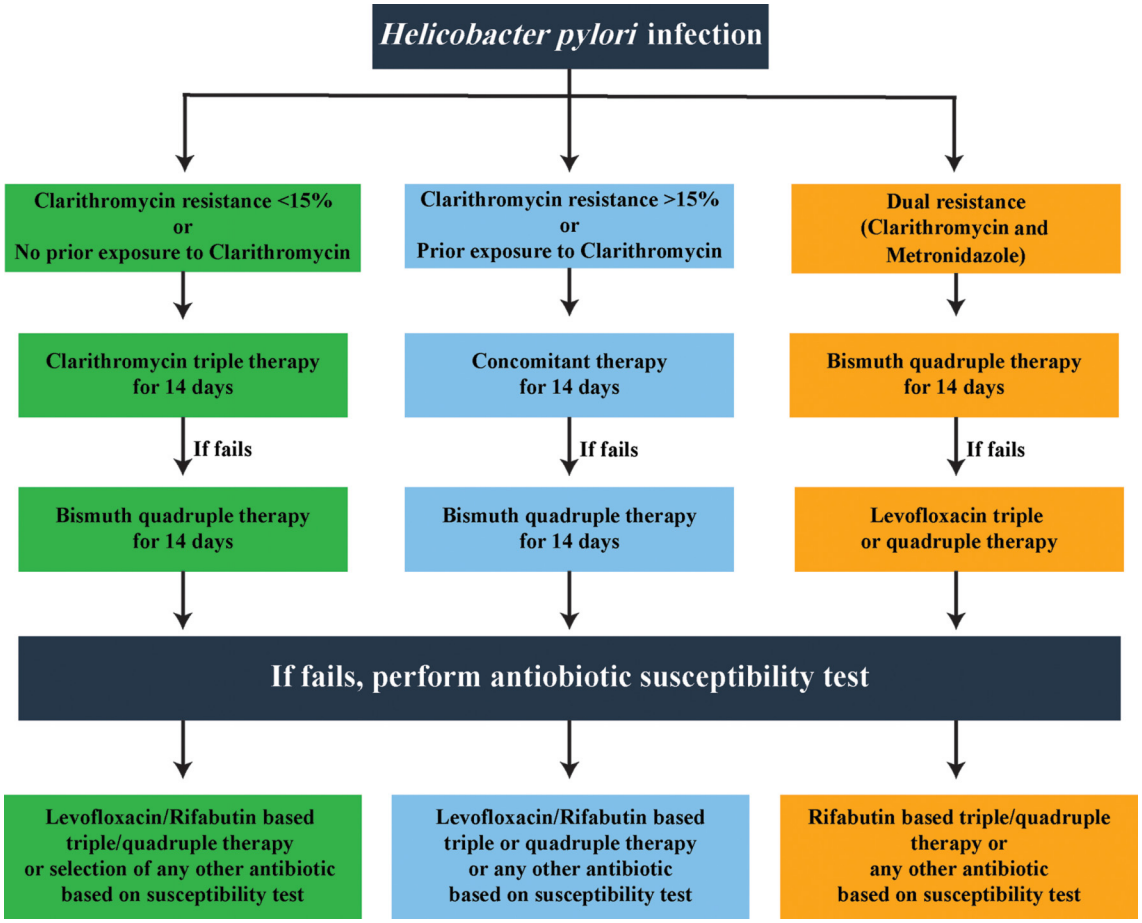

Figure 2 Treatment algorithm for the eradication of *Helicobacter pylori* infection.

High clarithromycin resistance: In patients with recent exposure to clarithromycin or areas where clarithromycin resistance is high (>15%), but metronidazole resistance is low (<15%), nonbismuth quadruple therapy (especially the concomitant therapy) is recommended for a duration of 14 days. If first-line therapy fails, bismuth quadruple therapy for a duration of 14 days should be used (Chey et al., 2017; Chung et al., 2011; Lee et al., 2011). Following failure of second-line therapy, selection of appropriate antibiotic must be based on antibiotic susceptibility test. Levofloxacin-based triple or quadruple therapy is recommended for susceptible strains (Chuah et al., 2012; Fallone et al., 2016; Marin et al., 2013). In the case of levofloxacin resistance, furazolidone- or rifabutin-containing regimen may be used following the susceptibility test.

High clarithromycin and metronidazole resistance: In areas where resistance to both clarithromycin and metronidazole is high (dual resistance), bismuth quadruple therapy for a duration of 14 days is the recommended first-line treatment (Fallone et al., 2016; Luther et al., 2010; Malfertheiner et al., 2016). If bismuth quadruple therapy fails, clarithromycin triple therapy should be avoided as second-line therapy. Levofloxacin-based triple or quadruple therapy is the recommended second-line therapy in such cases (Fallone et al., 2016; Marin et al., 2013). If second-line treatment fails or resistance to levofloxacin is high, a bismuth quadruple therapy containing susceptible antibiotics such as furazolidone or rifabutin, determined by antibiotic susceptibility testing, should be used (Fallone et al., 2016; Gisbert and Calvet, 2012a).

Treatment of NSAID-Induced Ulcers

Patients must be tested for *H. pylori* infection because NSAID-associated ulcers may be *H. pylori* positive. Eradication is generally recommended in *H. pylori* positive cases. In patients with confirmed NSAID-induced ulcers, nonselective NSAIDs should be discontinued (when possible). A standard 4–8 weeks' therapy preferably with a PPI can achieve satisfactory ulcer healing. They can also be substituted with sucralfate or histamine-2 receptor antagonists (H_2RAs) such as ranitidine or famotidine. Ulcer healing may be impaired if use of NSAIDs is continued. In such situations, the following measures may be considered such as reducing the NSAID dose, switching to acetaminophen or non-acetylated salicylate or a Cox-2-selective NSAID, and co-therapy with a PPI. If co-therapy with a PPI/H_2RAs is employed, they need to be used for a longer duration of around 8–12 weeks (Melcarne et al., 2016; Satoh et al., 2016).

Prevention of NSAID-Induced Ulcers

Generally, NSAIDs are not recommended in patients who are at risk for GI toxicity. Long-term NSAID treatment may be needed in some situations such as chronic rheumatological conditions; therefore, prevention of the NSAID-associated ulcer and GI complications should be considered. Ulcer preventive therapy with a PPI or misoprostol or high dose H_2RA is recommended for patients using nonselective NSAIDs (e.g., aspirin, diclofenac, and naproxen). Alternatively, selective Cox-2 NSAID (celecoxib) may be used that are safer and are less likely to cause ulcers (Melcarne et al., 2016; Satoh et al., 2016).

Ulcer preventive therapy is very useful if the risk of ulcer and GI toxicity is high (**Table 1**). It may not be needed in low-risk situations. However, some guidelines recommend preventive therapy in all individuals taking nonselective NSAIDs irrespective of ulcer risk. PPIs are the therapy of choice for the prevention of NSAID-induced ulcer or ulcer complications (Satoh et al., 2016; Yang et al., 2017). Alternatively, misoprostol or high-dose H_2RA may be used. Misoprostol has comparable efficacy to PPI but they have poor patient compliance and increased incidence of adverse effects (e.g., abdominal pain and diarrhea). High-dose H_2RA (ranitidine or famotidine) may be used effectively for the prevention of ulcer; however, their low doses are ineffective (Melcarne et al., 2016; Scally et al., 2018; Scheiman, 2016).

Cox-2-selective NSAIDs have significantly lower risk of GI adverse effects, whereas they have similar anti-inflammatory activity like nonselective NSAIDs. The risk of ulcer with Cox-2-selective NSAIDs appears similar to that associated with combination of a nonselective NSAID and PPI. While co-therapy of PPI with Cox-2-selective NSAIDs further decreases the risk of ulcers. A Cox-2-selective NSAID alone or in combination with PPI may be the preferred option in order to prevent ulcer or ulcer complications. The risk for cardiovascular events is considerably higher with Cox-2-selective NSAIDs; therefore, caution is advised (Melcarne et al., 2016; Scheiman, 2016).

Maintenance Therapy

Chronic acid-suppression (maintenance) therapy for the prevention of ulcer or ulcer complications is recommended for patients with a history of ulcer complications, frequent recurrence, heavy smoking, and NSAID use. PPIs at lowest effective doses are the preferred therapy. Alternatively, misoprostol may be used, but they often cause diarrhea (Satoh et al., 2016).

Idiopathic Ulcers

The increasing occurrence of idiopathic ulcers (i.e., *H. pylori*-negative and NSAID-negative ulcers) is a growing concern. The exact cause of idiopathic ulcers remains unknown, but several studies have reported hypersecretion of gastrin and gastric acid as the main cause. Despite no significant reduction in the incidence of bleeding or mortality with acid suppression therapy, guidelines recommend the use of PPIs for the management of idiopathic ulcers (Satoh et al., 2016; Wong et al., 2012).

Personalized Pharmacotherapy

Genetic polymorphism of the CYP2C19 isoform can cause significant difference in the metabolism of PPIs. For instance, almost all Asians are poor metabolizers of PPIs and thus require a low dose of PPIs. In contrast, majority of Caucasians are rapid metabolizers of PPIs and require higher doses. Prior knowledge of CYP2C19 genotype may help adjust the dose of PPIs, thus reducing the chances of treatment failure (Kuo et al., 2014). Moreover, increased drug plasma concentration in poor metabolizers may increase the risk of adverse events (Ma and Lu, 2011). Obese individuals may require higher doses of antibiotics (due to drug accumulation in fat tissues) in order to achieve optimum concentration at the gastric mucosal level. In addition, allergy to a specific antibiotic may prohibit its use in some patients. Patients with genetic predisposition, such as family history of ulcer or blood type "O," have a higher risk of ulcer and may require ulcer preventive therapy.

Role of Pharmacist

Patient care is an integrated collaborative process and pharmaceutical care is an essential component of patient care. In this regard, a pharmacist has a variety of roles and professional responsibilities in the pharmacotherapy of PUD. Some notable pharmacist's activities include development of a patient care plan, selection of an appropriate therapy, prevention of irrational drug use, patient education and counseling, monitoring of therapeutic outcome, dose adjustments, and identification/management of adverse drug reactions and drug interactions.

Successful and safe therapy always requires the active involvement of a pharmacist. According to the American Society of Health-System Pharmacists (ASHP), pharmacists are key to ensure that patients use prescribed regimens appropriately so that the clinical outcomes of associated PUD are optimal (ASHP, 2001). Many studies are available regarding the pharmacist's specific role in PUD as discussed below. Most of these have mainly targeted stress-ulcer prophylaxis. Pharmacist-managed programs involving educational intervention and medication reconciliation on patient-care rounds and at hospital discharge have shown a significant decrease in irrational drug use during hospitalization and upon discharge along with substantial cost savings (Buckley et al., 2015; Hatch et al., 2010). In intensive care settings, pharmacist-based quality improvement programs, educational initiatives and interactions

with physicians during ward rounds successfully reduce inappropriate drug use with a significant economic impact (Hammond et al., 2017; Masood et al., 2018). In nonintensive care settings, studies report that pharmacist-led educational sessions have shown to improve the appropriateness of prescribing by family practice resident physicians, resulting in minimization of patient risk and cost savings (Agee et al., 2015). Interprofessional collaboration among clinical pharmacists and hospital services can significantly reduce inappropriate drug use (Belfield et al., 2017). Standard treatment guidelines improve rational drug use. The pharmacist has a vital role in improving adherence with these guidelines (Rafinazari et al., 2016; Sanders et al., 2012). In specialized settings such as nephrology, the active involvement of a clinical pharmacist as a team member significantly contributes to reducing inappropriate prescribing of antiulcer drugs and their related cost (Mousavi et al., 2013). In the community pharmacy setting, the pharmacist can provide a verity of services about antiulcer medications such as PPIs. They can guide patients about the proper administration of medications, prescription refills, over-the-counter medications, treatment of minor ailments, physician referrals, and informed self-care decisions (Armstrong and Nakhla, 2016; Boardman and Heeley, 2015). A pharmacist-managed *H. pylori* clinic is also described by some studies (Morreale, 1995; Ravnan et al., 2002). A variety of services can be provided in these clinics to ambulatory patients such as overall patient assessment, screening for the presence of *H. pylori*, treatment of positive cases, adjustment of acid-suppressive drug regimens, patient education, and monitoring of adverse drug effects and therapeutic outcomes. The studies have shown that pharmacist-managed telephone-based clinics are also very effective to improve the overall outcome of *H. pylori* eradication therapy (Morreale, 1995; Ravnan et al., 2002).

Pharmacists' Patient Care Process

Pharmacists in collaboration with other healthcare professionals can optimize pharmacotherapy of PUD and improve therapeutic outcomes. These activities can be better described by applying the Pharmacists' Patient Care Process (PPCP), developed by the Joint Commission of Pharmacy Practitioners (Gonyeau et al., 2018). The main components of PPCP include the following: collect, assess, plan, implement, and follow-up (monitor and evaluate). Throughout this process, the pharmacist needs to collaborate, document, and communicate with physicians, other pharmacists, and other health care professionals for the purpose of providing safe, effective, and coordinated care. For PUD, specific pharmacists' activities related to each component of PPCP are presented in **Fig. 3**.

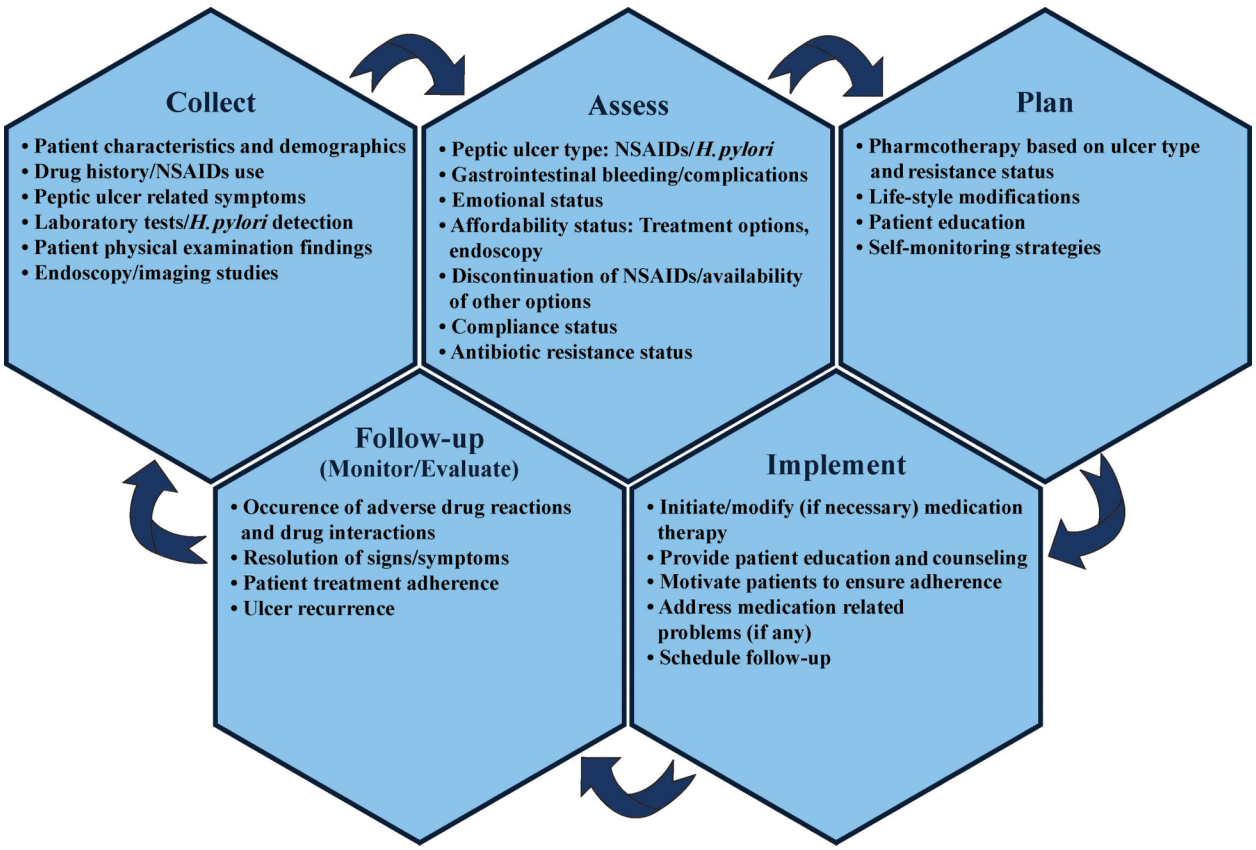

Figure 3 Pharmacists' patient care process for peptic ulcer disease.

Patient Education

Pharmacist-led patient education is one of the important interventions that contribute to improve medication adherence (Blom and Krass, 2011; Kini and Ho, 2018). Patient education should cover various areas related to pharmacological and non-pharmacological management. Appropriate administration of prescribed medicine is essential in order to minimize treatment failure and antibiotic resistance. Adherence to eradication therapy is a major challenge due to an increased number of drugs and frequent dosing. Patients must be educated to complete the treatment course even if symptoms disappear, seek pharmacist's advice when purchasing over-the-counter analgesics, and avoid over the counter NSAIDs and aspirin (paracetamol-based products are preferred). If NSAID therapy is necessary, then they should be administered with or after meals to reduce the risk of dyspepsia. Patients need to be well informed about the optimum time of administration of PPIs, the dose, and duration. PPIs should be administered 30–60 min before breakfast (if prescribed once daily) and dinner (if prescribed twice daily) along with other drugs. In the case of bismuth quadruple therapy, all medicines should be taken with meals except the PPI (Chey et al., 2017). Pregnant women should be warned against the use of misoprostol (Auffret et al., 2016). Patients need to be informed about the most common and/or serious potential adverse effects of therapy (**Table 5**). Drugs commonly employed for the treatment of ulcers may interact with other drugs (**Table 6**) when coadministered, thereby increasing the risk of adverse effects or treatment failure. Patients must be informed to avoid contraindicated and serious drug interacting combinations (**Table 6**). Patients should be advised to visit physicians if they develop blood in stools, black tarry stools, vomiting or abdominal pain. Patients with dyspepsia or reflux-like symptoms should be advised to take antacids and raise the head of the bed to improve nocturnal symptoms. Patients should be advised to avoid cigarette smoking, alcohol, spicy food, carbonated or caffeinated beverages, and NSAIDs (Bear et al., 2017).

Monitoring of Therapy Outcomes

The outcome of therapy in patients with uncomplicated ulcers is assessed through symptomatic relief, while patients having complicated or refractory ulcers may undergo *H. pylori* testing or endoscopy. At present, monitoring of ulcer healing following successful treatment through endoscopy is not recommended by most of the guidelines. However, monitoring the outcome has increased significantly, particularly in patients treated for *H. pylori*-associated ulcer due to the increasing prevalence of resistance and treatment failure. *H. pylori* infected individuals should be evaluated for eradication at least 4 weeks after completion of therapy (Lim et al., 2013). The urea breath test and fecal antigen test are the preferred noninvasive tests for confirmation of successful eradication. Monitoring is needed for persistent or recurrent symptoms of ulcer after completion of eradication therapy to ascertain the cause of treatment failure (resistance or nonadherence). Ulcer complications, particularly bleeding should be monitored as well (Laursen et al., 2012).

Adverse Drug Effects

Although PPIs are effective and safe, their use may be associated with headache, abdominal pain, nausea, and diarrhea. The use of antibiotics may cause nausea, diarrhea, abdominal pain, and oral or vaginal candidiasis (in women). Clarithromycin and metronidazole may cause taste disturbances. Metronidazole may cause disulfiram-like reactions in individuals who consume alcohol. Thus, alcohol must be avoided in patients prescribed metronidazole. Tetracycline causes photosensitivity and tooth discoloration (Drucker and Rosen, 2011; Vennila et al., 2014). Bismuth may cause dark discoloration of the tongue or stool. A detailed overview of adverse drug reactions associated with drugs used for the management of PUD is given in **Table 5**.

Drug Interactions

Drugs used for the management of PUD are associated with a variety of drug interactions (**Table 6**). PPIs increase the gastric pH, thereby affecting the absorption and bioavailability of a number of orally administered drugs such as ketoconazole and digoxin. PPIs also alter the absorption of a number of antiviral drugs including those used for the treatment of human immune virus infection (HIV), which may result in treatment failure. Therefore, caution is advised about the use of PPIs in HIV-positive individuals. PPIs and clarithromycin are potent inhibitors of the CYP2C19 enzyme, which may result in increased plasma levels and toxicity of a number of drugs such as warfarin, phenytoin, and diazepam. Rabeprazole may be prescribed if other drugs that are substrates of the CYP2C19 are coadministered. Similarly, antibiotics when coadministered with other drugs may also interact and result in treatment failure or drug-related adverse events. Important drug–drug interactions, their adverse outcomes, and management are given in **Table 6**.

Conclusions

A number of pharmacological approaches are available for the management of the disease. A thorough patient's assessment is needed in order to select appropriate therapy. Pharmacist involvement is vital for effective management of PUD. Some of the main pharmacist's roles include the development of a care plan, patient education, monitoring of therapeutic outcomes, dosing adjustment, and the management of adverse drug reactions and drug interactions.

Table 5 Adverse effects of drugs used for the management of peptic ulcer disease

Drugs	*Dermatological*	*Gastrointestinal*	*Genitourinary*	*Neurological*	*Others*
Omeprazole	Rash, *CLE, erythema multiforms, SJS, TEN*	*Gastritis, pancreatitis, CDD*, abdominal pain, constipation, diarrhea, flatulence, nausea, acid regurgitation, vomiting, *hepatic encephalopathy, hepatic necrosis, liver failure*	*Acute interstitial nephritis*	Asthenia, dizziness, headache	Hematologic: *Hemolytic anemia* Musculoskeletal: *Bone fracture, rhabdomyolysis* Respiratory: Upper respiratory tract infection Others: *Hypomagnesemia, angioedema*, fever
Esomeprazole	*CLE, erythema multiforms, SJS, TEN*	Abdominal pain, constipation, diarrhea, flatulence, nausea, xerostomia, *CDD, fundic gland polyposis of stomach*	*Acute interstitial nephritis*	Headache, somnolescence	Musculoskeletal: *Bone fracture, rhabdomyolysis* Others: *Anaphylaxis, angioedema, hypomagnesemia, cyanocobalamin deficiency*
Pantoprazole	*CLE, SJS, TEN*	Abdominal pain, diarrhea, flatulence, *atrophic gastritis, CDD, fundic gland polyposis of stomach*	*Acute interstitial nephritis*	Headache	Hematologic: *Thrombocytopenia* Musculoskeletal: *Bone fracture, rhabdomyolysis*
Rabeprazole	*CLE, erythema multiforms, SJS, TEN*	Abdominal pain, diarrhea, nausea, vomiting, *CDD, fundic gland polyposis of stomach*	*Acute interstitial nephritis*	Headache	Musculoskeletal: *Bone fracture, rhabdomyolysis* Others: *Anaphylaxis, SLE*
Lansoprazole	*CLE, erythema multiforms, SJS, TEN*	Abdominal pain, diarrhea, nausea, vomiting, *CDD, fundic gland polyposis of stomach, pancreatitis*	*Acute interstitial nephritis*	Headache	Musculoskeletal: *Bone fracture, rhabdomyolysis* Others: *Hypomagnesemia, anaphylaxis*
Ranitidine	*SJS, TEN*	Abdominal pain, constipation, diarrhea, *necrotizing enterocolitis in fetus, pancreatitis, cholestatic hepatitis, liver failure, abnormal LFT's*	–	Headache	Cardiovascular: *Bradyarrhythmia* Hematologic: *Agranulocytosis, aplastic anemia, pancytopenia, thrombocytopenia*
Famotidine	*SJS, TEN*	Constipation, diarrhea, *necrotizing enterocolitis in fetus*	–	Dizziness, headache, *seizure*	Musculoskeletal: *Rhabdomyolysis* Others: *Anaphylaxis, angioedema, pneumonia*
Cimetidine	–	*Gastric cancer, necrotizing enterocolitis in fetus, pancreatitis*	–	Psychotic disorder	Gynecomastia
Clarithromycin	*SJS, TEN, Henoch-Schonlein purpura*	Abdominal pain, diarrhea, taste alteration, indigestion, nausea, vomiting, CDD, *hepatitis, liver failure*		Headache, *cerebrovascular disease*	Cardiovascular: *Cardiovascular death, prolonged QT interval* Others: *Anaphylaxis, drug-induced eosinophilia and systemic symptoms, all cause death*
Amoxicillin	Rash, *erythema multiforms, SJS, TEN*	Diarrhea, nausea, vomiting, *CDD*	*Mycotic vulvovaginitis*	Headache	*Anaphylaxis*
Metronidazole	*SJS, TEN*	Abdominal discomfort, altered taste, diarrhea, nausea, *hepatotoxicity, hepatic failure*	Genital candidiasis, vaginal discharge, vaginal irritation, vaginitis, *hemolytic uremic syndrome*	Dizziness, headache, *seizure, aseptic meningitis, encephalopathy, peripheral neuropathy*	Hematologic: *Leukopenia* Others: Jarisch–Herxheimer reaction, *disorder of optic nerve, ototoxicity*
Tetracycline	Phototoxicity	–	–	*Bulging fontanelle, pseudotumor cerebri*	Tooth discoloration, *acidosis, azotemia, raised serum blood urea nitrogen*

(*Continued*)

Table 5 Adverse effects of drugs used for the management of peptic ulcer disease (*cont.*)

Drugs	*Dermatological*	*Gastrointestinal*	*Genitourinary*	*Neurological*	*Others*
Levofloxacin	*Erythema multiforms, SJS*	Diarrhea, nausea, *hepatitis, liver failure*	*Acute renal failure*	Dizziness, headache, insomnia, *disorientation, disturbed attention, Guillain-Barre syndrome, memory impairment, peripheral neuropathy, raised ICP, seizure, delirium, depression, hallucinations, paranoid disorder, suicidal psychotic disorder*	Cardiovascular: *Aortic aneurysm, cardiac arrest, prolonged QT interval, torsade de pointes, ventricular tachycardia* Hematologic: *Aplastic anemia, pancytopenia, thrombocytopenia purpura* Musculoskeletal: *Exacerbation of myasthenia gravis, tendon rupture, tendinitis* Others: Hypersensitivity reaction, anaphylaxis, retinal detachment, *hypoglycemia*
Furazolidone	Rash, *erythema multiforms*	Abdominal pain, diarrhea, GI bleeding, nausea, vomiting, hepatotoxicity, jaundice	Abnormal urinalysis, discolored urine, nephritis, oliguria	Dizziness, headache, insomnia, neuropathy, neurotoxicity, somnolescence, vertigo, giddiness, hypomania, agitation, psychotic disorder	Cardiovascular: Hypertension Hematologic: Agranulocytosis, anemia, raised eosinophil count, hemolysis, hemolytic anemia, leukopenia Others: Hypersensitivity reaction, disulfiram-like reaction, malaise, serum sickness, dyspnea, pulmonary eosinophilia, hypoglycemia
Rifabutin	Rash	CDD, altered taste	Discolored urine	Ocular discoloration, uveitis	Hematologic: *Neutropenia, thrombocytopenia* Others: *SLE*
Misoprostol	–	Abdominal pain, diarrhea, *gastrointestinal hemorrhage*	*Uterus rupture*	–	Cardiovascular: *Cardiac dysrhythmia, chest pain, myocardial infarction* Hematologic: Anemia, thromboembolic disorder Others: *Anaphylaxis, deafness, toxic shock syndrome, abortion related clostridial infection*
Bismuth subsalicylate	Rash, skin discoloration	Dark stool, black hairy tongue, nausea, diarrhea, gastralgia, constipation, GI bleeding, melena, hepatotoxicity	Nephrotoxicity	*Neurotoxicity*, headache, dizziness, encephalopathy, tinnitus	Cardiovascular: Mild hypotension Hematologic: Elevated hemoglobin Others: Anaphylaxis, hypercalcemia
Sucralfate	–	Constipation, *bezoar*	–	–	Aluminum toxicity in patients with renal failure, hyperglycemia

CDD, *Clostridium difficile* associated diarrhea; *CLE*, cutaneous lupus erythematosus; *GI*, gastrointestinal; *ICP*, intracranial pressure; *LFTs*, liver function tests; *SJS*, Stevens–Johnson syndrome; *SLE*, systemic lupus erythematosus; *TEN*, toxic epidermal necrolysis.

Note: Serious adverse effects are presented in italics.

Table 6 Important drug interactions

Interacting drugs	*Potential adverse outcome*	*Remarks*
Omeprazole, esomeprazole, pantoprazole, rabeprazole and lansoprazole		
Cilostazol	May result in cilostazole toxicity	Consider reducing the dose of cilostazole
Citalopram	Increased risk of QT interval prolongation	Monitor patients for ECG changes and discontinue citalopram in patients with QTc interval >500 ms
Clopidogrel	Diminished efficacy of clopidogrel	Consider administration of rabeprazole or pantoprazole
Ketoconazole	Diminished efficacy of ketoconazole	Consider administration of ketoconazole with acidic beverage and monitor antifungal activity
Rilpivirine	Diminished efficacy of rilpivirine	Avoid concomitant use of both drugs
Saquinavir	May result in saquinavir toxicity	Monitor patients for GI symptoms, QT interval prolongation and DVT
Clarithromycin		
Cisapride	Increased risk of QT interval prolongation	Avoid concomitant use of both drugs
Fluconazole	Increased risk of QT interval prolongation and torsade de pointes	Avoid concomitant use of both drugs
Ketoconazole	Increased risk of QT interval prolongation	Avoid concomitant use of both drugs or monitor patients for ECG changes
Simvastatin	Increased risk of myopathy or rhabdomyolysis	Consider reducing the dose of simvastatin or administer fluvastatin
Ziprasidone	Increased risk of QT interval prolongation	Avoid concomitant use of both drugs
Amoxicillin		
Tetracyclines	Diminished efficacy of amoxicillin	Avoid concomitant use of both drugs
Venlafaxine	Increased risk of serotonin syndrome	Monitor for tremors, muscle rigidity, tachycardia, diaphoresis, diarrhea, agitation or delirium. Avoid concomitant administration of both drugs
Warfarin	Increased risk of bleeding	Consider monitoring of INR and corresponding dose adjustment
Metronidazole		
Hydroxychloroquine	Increased risk of QT interval prolongation	Avoid concomitant use of both drugs or monitor patients for ECG changes
Mebendazole	Increased risk of Stevens–Johnson syndrome or toxic epidermal necrolysis	Avoid concomitant administration of both drugs
Saquinavir	Increased risk of QT interval prolongation	Monitor patients for ECG changes and discontinue one or both drugs in patients with QT interval >480 ms
Warfarin	Increased risk of bleeding	Monitor INR or prothrombin time and sign/symptoms of bleeding
Tetracycline		
Cholera vaccine	Diminished efficacy of cholera vaccine	Avoid concomitant use of both drugs
Digoxin	Increased risk of digoxin toxicity	Monitor digoxin serum concentration with corresponding dose adjustment
Methoxyflurane	Increased to renal toxicity including fatality	Avoid concomitant administration of both drugs
Penicillin	Diminished efficacy of amoxicillin	Better to avoid concomitant use of both drugs
Levofloxacin		
Cisapride	Increased risk of QT interval prolongation	Avoid concomitant use of both drugs or monitor patients for ECG changes
Fluoxetine	Increased risk of QT interval prolongation	Avoid concomitant use of both drugs or monitor patients for ECG changes
Hydroxychloroquine	Increased risk of QT interval prolongation	Avoid concomitant use of both drugs or monitor patients for ECG changes
Theophylline	Increased risk of theophylline toxicity	Monitor theophylline concentration and make appropriate dose adjustment
Warfarin	Increased risk of bleeding	Consider monitoring of INR, no dose reduction of warfarin is required
Furazolidone		
Carbamazepine	Increased risk of serotonin syndrome	Monitor for tremors, muscle rigidity, tachycardia, diaphoresis, diarrhea, agitation or delirium. Avoid concomitant administration of both drugs
Fluoxetine	Increased risk of serotonin syndrome	Monitor for tremors, muscle rigidity, tachycardia, diaphoresis, diarrhea, agitation or delirium. Avoid concomitant administration of both drugs
Levodopa	Increased risk of significant hypertension	Avoid concomitant use of both drugs
Metoclopramide	Increased risk of significant hypertension	Avoid concomitant use of both drugs
Tramadol	Increased risk of serotonin syndrome or opioid toxicity	Avoid concomitant use of both drugs

(*Continued*)

Table 6 Important drug interactions (*cont.*)

Interacting drugs	*Potential adverse outcome*	*Remarks*
Rifabutin		
Artemether/lumefantrine	Diminished efficacy of artemether/lumefantrine	Avoid concomitant use of both drugs
Clarithromycin	Diminished efficacy of clarithromycin and increased risk of rifabutin adverse effects including uveitis	Consider decreasing rifabutin dose and monitoring for ocular inflammation
Hormonal contraceptives	Diminished efficacy of hormonal contraceptives	Consider alternate method of conception
Tramadol	Diminished efficacy of tramadol	Consider increasing the dose of tramadol
Voriconazole	Increased plasma concentration of rifabutin and decreased voriconazole plasma concentration	Avoid concomitant use of both drugs
Misoprostol		
Antacids	Diminished efficacy of misoprostol	Monitor for diarrhea, particularly with magnesium containing antacids. Consider reducing misoprostol dose or discontinue antacid
Phenylbutazone	May cause headache, dizziness and ataxia	If adverse effects occurs consider another NSAID
Bismuth subsalicylate		
NSAIDs	Increased risk of bleeding due to salicylate	Avoid concomitant use of both drugs
Sucralfate		
Digoxin	Diminished efficacy of digoxin	Consider increasing the dose of digoxin by 20%–40%
Ketoconazole	Diminished efficacy of ketoconazole	Avoid concomitant use of both drugs. Consider antifungal efficacy of ketoconazole

DVT, deep vein thrombosis; *ECG*, electrocardiogram; *INR*, international normalized ratio; *ms*, millisecond; *NSAIDs*, nonsteroidal anti-inflammatory drugs.

Glossary of Terms

Duodenal bulb It is the portion of the duodenum closest to the stomach.
Gastric metaplasia Transformation of the intestinal epithelial cells into an epithelium that resembles gastric epithelium.
***Helicobacter pylori* eradication therapy** Multidrug therapy comprising an acid-suppressing agent and at least two antibiotics intended to completely eliminate *Helicobacter pylori* infection.
Hyperchlorhydria A state of increased gastric acid level due to increased secretion of gastric acid.
Idiopathic ulcer Peptic ulcer disease in which the cause of ulceration is unknown.
Maintenance therapy Long-term acid suppression therapy in order to prevent the recurrence of peptic ulcer or its complications.
Melena Dark sticky feces containing partially digested blood.
Occult bleeding Bleeding that is not visible to the patient or physician.
Penetration A type of peptic ulcer complication in which ulceration develops a hole in the gastrointestinal lining and affects another organ.
Perforation A complication of peptic ulcer in which a hole develops in the lining of the gastrointestinal tract typically in the stomach or duodenum that opens into the peritoneal cavity.
Quadruple therapy A multidrug regimen comprising a proton pump inhibitor with three antibiotics; or a proton pump inhibitor with two antibiotics and bismuth salt.
Refractory ulcer Peptic ulcer that does not heal after 8–12 weeks of standard treatment.
Triple therapy A multidrug treatment regimen comprising a proton pump inhibitor with two antibiotics intended for the eradication of *Helicobacter pylori* infection.
Virulence The ability of *Helicobacter pylori* to infect a host.
Xiphoid process The cartilage at the lower end of the sternum.
Zollinger–Ellison syndrome A condition of abnormal production of gastrin that results in increased production of gastric acid.

Management of Renal Disorders and the Pharmacist's Role: Acute Kidney Injury

Ronald Castelino[*,†], **Li Shean Toh**[‡], [*]University of Sydney, Sydney, Australia; [†]Blacktown Hospital, Sydney, NSW, Australia; [‡]University of Tasmania, Hobart, TAS, Australia

Learning Objectives

- Categorize AKI as pre-renal, intrinsic, or post-renal based on patient history, laboratory values and results of physical examination.
- Identify risk factors for AKI.
- Formulate preventive strategies to decrease the risk of developing AKI in high risk populations.
- Formulate a therapeutic plan to manage AKI.
- Identify medications/medications classes including herbal medicines associated with AKI.

Key concepts

- Acute Kidney Injury (AKI) is a common condition and is associated with high morbidity and mortality.
- AKI has been traditionally categorized based on three types of injury; pre-renal: renal hypoperfusion; intrinsic: structural damage to the kidney; and post-renal: obstruction within the urinary tract.

- There is no compelling evidence for any drugs to prevent or reverse AKI and the most effective strategies to prevent AKI include: maintaining adequate hydration and avoiding nephrotoxic medications; whilst supportive therapies such as renal replacement therapy, nutritional support, avoiding nephrotoxins, blood pressure, fluid and electrolyte management remain the mainstay of treatment.
- Dosing of drugs during AKI remain challenging as serum creatinine (SCr) and estimated glomerular filtration rate (eGFR) are unreliable. Therapeutic drug monitoring is recommended for drugs with narrow therapeutic index or predominantly renally cleared medications.
- Hospital and community pharmacists can play huge role in AKI management. Pharmacists can help prevent AKI by assessing risk, optimizing drug therapy, adjusting drug dosages related to kidney function, monitoring of drugs and response to treatment, patient and other health care professionals' education and medication reconciliation.

Introduction

Acute Kidney Injury (AKI), is a common, harmful, potentially treatable disorder that is often under-recognized and is increasing in incidence globally (KDIGO, 2012). AKI manifests as an abrupt decline (hours to days) in glomerular filtration rate (GFR) and results in an accumulation of nitrogenous waste products such as blood urea nitrogen (BUN), serum creatinine (SCr), and commonly, a reduction in urine output (NICE, 2013). It is not a single disease entity, but a broad clinical syndrome encompassing various etiologies (specific kidney diseases, extra renal causes, etc.). The manifestations and clinical consequences of AKI can be quite similar regardless of the etiology. AKI is the new consensus term for acute renal failure (ARF) (NICE, 2013). The change in terminology is to standardize the definition of the syndrome as well as recognize that even small rises in serum creatinine are associated with important clinical consequences including increased risk of death (KDIGO, 2012; NICE, 2013).

However, despite the standardization in the definition and staging, progress in understanding the underlying pathophysiology, AKI continues to be associated with poor outcomes and remains a major unmet medical need without any pharmacological treatments that directly reverses the injury (Australian Institute of Health and Welfare, 2015; Lameire et al., 2013). AKI is strongly associated with serious short- and long-term complications, in particular increased mortality and morbidity, the development of chronic kidney disease (CKD) and high financial health care costs (Australian Institute of Health and Welfare, 2015; Lameire et al., 2013). Although AKI is increasingly being seen in primary care in people without any acute illness, it is much more common in the setting of acute or critical illness. It affects approximately 20% of hospitalized patients (older adults and critically ill being particularly affected) of whom 10% require renal replacement therapy (RRT) (Bellomo et al., 2012; Lameire et al., 2013).

Hence there is a need to increase an awareness of the condition among health care professionals (including primary care professionals) as early recognition along with supportive therapy is the focus of the management for those with AKI. Individuals at risk of an AKI, for example those with CKD, need to have their hemodynamic status closely monitored with exposure to nephrotoxins minimized (Bellomo et al., 2012). Assessments of individuals should include medical and surgical history, physical examination, medication use and laboratory tests. Pharmacists have an important role to play when it comes to AKI, both in terms of prevention and treatment, that is, reducing risk and avoidable harm, medication optimization in AKI, advising about drug dosing, and identifying and monitoring drugs that can cause kidney damage.

In this chapter, the definition and classification, incidence, clinical features, and etiologies of AKI are presented. Methods to recognize AKI, preventative strategies for patients at risk and management strategies for established AKI, and the role of pharmacist in AKI identification and management will also discussed.

Definition and Classification of Acute Kidney Injury

In recent years, there has been a paradigm shift in the understanding of AKI. Initially described and defined as a complete loss of kidney function (acute kidney failure (ARF)), it is now widely recognized that lesser degrees of kidney impairment have significant consequences (KDIGO, 2012; NICE, 2013). The significant re-examination of the definitions used in recent years is to recognize that AKI represents a heterogenous clinical syndrome with multiple causes rather than a specific disease and to encompass the entire spectrum of the syndrome from minor changes in kidney function to kidney failure which can influence prognosis and management (KDIGO, 2012; NICE, 2013).

The acute dialysis quality initiative first defined AKI with the RIFLE criteria (risk, injury, failure, loss, end stage) in 2004. The acute kidney injury network (AKIN) later supported the RIFLE criteria with minor modifications (Bellomo et al., 2004a; Mehta et al., 2007). **Table 1** lists an overview of all classification systems. The kidney disease: improving global outcomes (KDIGO) clinical practice guidelines working group in 2012 merged the two definitions in a recent guideline update and proposes a staging system that is extended to include pediatric patients (younger than 18 years) (KDIGO, 2012). AKI is now defined as an increase in SCr of $\geq$26.5 μmmol/L within 48 h of observation or 1.5 times baseline or greater, which is known to have occurred within 7 days, or a reduction in the urine volume below 0.5 mL/kg/h for 6 h (**Table 1**) (KDIGO, 2012).

All three staging systems have been validated across different patient populations with the staging correlated with mortality, cost, and length of stay. The KDIGO classification has shown to identify more patients with AKI and more predictive of

Table 1 RIFLE, AKIN and KDIGO Classification Schemes for AKI (KDIGO, 2012; NICE, 2013; Bellomo et al., 2012)

RIFLE category	*SCr and GFR criteria*	*Urine output criteria*
Risk	SCr increase to 1.5-fold or GFR decrease >25% from baseline	Urine output <0.5 mL/kg/h for ≥6 h
Injury	SCr increase to twofold or GFR decrease >50% from baseline	Urine output <0.5 mL/kg/h for ≥12 h
Failure	SCr increase to twofold or GFR decrease >75% from baseline, or SCr ≥4 mg/dL (≥354 μmmol/L) with an acute increase of at least 0.5 mg/dL (44 μmmol/L)	Anuria for ≥12 h
Loss	Complete loss of function (RRT) for >4 weeks	
ESKD	RRT >3 months	
AKIN criteria	*SCr criteria*	*Urine output criteria*
Stage 1	Increase in SCr of ≥0.3 mg/dL (≥26.4 μmmol/L) within 48 h; or increase 1.5–1.9 times from baseline	Urine output <0.5 mL/kg/h for ≥6 h
Stage 2	Increase in SCr 2.0–2.9 times from baseline	Urine output <0.5 mL/kg/h for ≥12 h
Stage 3	Increase in SCr ≥3.0 times from baseline or SCr ≥4.0 mg/dL (≥354 μmmol/L) or RRT treatment	Urine output <0.3 mL/kg/h for ≥24 h OR anuria for ≥12 h
KDIGO criteria	*SCr criteria*	*Urine output criteria*
Stage 1	Increase in SCr of ≥0.3 mg/dL (≥26.4 μmmol/L) within 48 h; or increase 1.5–1.9 times from baseline	Urine output <0.5 mL/kg/h for 6–12 h
Stage 2	Increase in SCr 2.0–2.9 times from baseline	Urine output <0.5 mL/kg/h for ≥12 h
Stage 3	Increase in SCr ≥ 3.0 times from baseline or SCr ≥4.0 mg/dL (≥354 μmmol/L) or RRT treatment or in if <18 years decrease in eGFR to <35 mL/min/1.73 m^2	Urine output <0.3 mL/kg/h for ≥24 h OR anuria for ≥12 h

in-hospital mortality than RIFLE and AKIN classification (Fujii et al., 2014; Luo et al., 2014; Zeng et al., 2014). However, despite the significant contributions of these definitions towards the definition and management of AKI, they have limitations. All three staging systems suffer from the same inherent weakness as they rely on SCr and urine output to identify AKI and several factors can affect SCr and urine output. Firstly, there is a lag time for the increase in SCr which usually takes 24–48 h to increase following injury. Secondly, although urine output reduction occurs earlier it is a very nonspecific marker as it depends upon several factors. Furthermore, patients with AKI can have a 24 h urine output less than 50 mL (anuric), less than 500 mL/day (oliguric) or more than 500 mL/day (nonoliguric) (Bellomo et al., 2012). Lastly, the definitions depend on a reference value to describe 'baseline' renal function. Ideally, this value should reflect the patient's steady state kidney function just before the episode of AKI. However, this SCr value may not be available for all patients at the time of diagnosis and various surrogate estimates are frequently used (such as back calculating a baseline SCr using an assumed normal eGFR of 75 mL/min/1.73 m^2 in cases of missing data). This method needs to be interpreted with caution as it can overestimate incidence of AKI (Siew et al., 2010; Zavada et al., 2010). Hence, significant research is currently underway with new biomarkers (such as Cystatin C) for AKI to replace or complement SCr. In addition to diagnosing AKI earlier, these markers may also provide information about the etiology of AKI (Koyner, 2012; Spahillari et al., 2012).

Epidemiology

The incidence of AKI is increasing worldwide (Evans et al., 2017; Lameire et al., 2013; Mesropian et al., 2016; Siew and Davenport, 2015; Waikar et al., 2006). The epidemiology of AKI varies widely depending upon the patient population studied and the criteria used to evaluate the patients. Differences in data capture, AKI awareness, monitoring, recognition, and clinical practice make comparisons between health care settings and periods difficult.

AKI occurs much more commonly in the hospital as compared to the community setting (Evans et al., 2017). Community-acquired AKI has an incidence of approximately 1%. Most of these patients develop AKI on the background of CKD and is referred as "acute" on chronic renal impairment (Wonnacott et al., 2014). Pre-renal AKI accounts for most of these cases (~70%), followed by obstructive uropathy and intrinsic AKI due to various etiologies (~17% and 11%, respectively) (Meola et al., 2016). In contrast, hospital-acquired AKI has an incidence ranging from about 4% to 7.2% with pre-renal and intrinsic AKI from nephrotoxic medications accounting for most cases (Liangos et al., 2006). The incidence of AKI is much higher in patients who are critically ill ranging from 30% to 60% with high mortality rates reported especially among those who require RRT (~50%) (Bellomo et al., 2012; Goldberg and Dennen, 2008; Hoste et al., 2015). Common risk factors for AKI are listed in **Table 2** (KDIGO, 2012). The high incidence and substantial morbidity and mortality of AKI demand a logical approach to its early diagnosis, prompt recognition and management of its complications (Wonnacott et al., 2014).

Table 2 Risk factors for AKI (KDIGO, 2012)

Exposure:
- Critical illness
- Sepsis
- Circulatory shock
- Burns
- Trauma
- Cardiac surgery
- Major non-cardiac surgery
- Nephrotoxic medications (angiotensin-converting enzyme [ACE] inhibitors, angiotensin receptor blockers [ARBs], aminoglycosides)
- Iodinated contrast media

Susceptibility factors
- Volume depletion
- Older age
- Female sex
- Black race
- Chronic kidney disease
- Other chronic disease (heart, lung, liver)
- Diabetes mellitus
- Cancer
- Anemia

Etiology

Once AKI is discovered it is important to determine the underlying cause of AKI because the initial evaluation and management is tailored to the particular cause. AKI most frequently results of tubular and vascular factors and can be divided into three broad categories based upon the anatomical location of the injury associated with the precipitating factors. The terms "pre-renal", "intrinsic" and "post-renal" have been traditionally used to narrow the differential diagnosis of AKI (Glassock et al., 2001). Pre-renal AKI results from decreased renal perfusion in the setting of undamaged parenchymal tissue; Intrinsic AKI, results from structural damage to the kidney and is considered under different anatomical components of the kidney (vascular supply, glomerular, tubular, and interstitial disease); and post-renal AKI results from obstruction of urine downflow from the kidney (Glassock et al., 2001).

Pre-renal AKI

Pre-renal AKI caused by an under perfusion of an otherwise normal kidney. It is a normal physiological response to hypotension or hypovolaemia, resulting in intense renal conservation of sodium and water at the expense of a decreased GFR. The hallmark of pre-renal AKI is that renal function is reversible with appropriate therapy and once underlying cause is corrected. Pre-renal AKI represents the most common form of AKI cases (Badr and Ichikawa, 1988).

Impaired renal perfusion with a resultant fall in glomerular capillary filtration pressure is the most common cause of pre-renal AKI. The kidneys are usually adept at regulating their blood supply over a variety of perfusion pressures, and such regulation is highly effective in healthy individuals. However, a marked reduction in renal perfusion may overwhelm autoregulation and precipitate an acute fall in GFR (Badr and Ichikawa, 1988). It is important to note that with lesser degrees of renal hypoperfusion, glomerular filtration pressures and GFR are maintained by afferent arteriolar vasodilation (mediated by vasodilatory prostaglandins) and efferent arteriolar vasoconstriction (mediated by angiotensin II).

In this setting AKI, may be precipitated by drugs that impair afferent arteriolar dilation or efferent arteriolar vasoconstriction (nonsteroidal antiinflammatory drugs [NSAIDs] and ACEI or ARBs, respectively) (Ungprasert et al., 2015; Zhang et al., 2006). Some common causes for pre-renal AKI are presented in **Table 3**. These include extracellular fluid volume depletion resulting from renal losses (diuretics, osmotic diuresis in hyperglycemia) or extrarenal losses (gastrointestinal losses) fluid sequestration in liver failure or other edematous states, or inadequate perfusion pressure caused by heart failure. Treatment is imperative, as failure to restore the renal blood flow can lead to intrinsic renal AKI with tubular cell injury (Glassock et al., 2001).

Intrinsic AKI

Intrinsic AKI results from direct damage to the kidney, it involves the renal parenchyma and is categorized based on the injured structures within the kidney; vasculature, glomeruli, tubules, and interstitial (Bellomo et al., 2012). **Table 4** lists some of the causes that can damage the renal parenchyma and lead to intrinsic AKI.

Table 3 Common causes for pre-renal AKI (Workeneh and Batuman, 2018)

- *Volume depletion:*
  - Renal losses (diuretics, osmotic diuresis in hyperglycemia)
  - Gastrointestinal losses-vomiting, diarrhea
  - Cutaneous losses-burns, Steven–Johnson syndrome
  - Hemorrhage
  - Pancreatitis
- *Decreased cardiac output:*
  - Heart failure
  - Pulmonary embolism
  - Acute myocardial infarction
  - Sever valvular disease
  - Abdominal compartment syndrome (tense ascites)
- *Systemic vasodilation:*
  - Sepsis
  - Anaphylaxis
  - Anesthetics
  - Drug overdose
- *Afferent arteriolar vasoconstriction:*
  - Hypercalcemia
  - *Drugs** - NSAIDs, amphotericin B, calcineurin inhibitors, radiocontrast agents*
  - Hepatorenal syndrome
- *Diseases that decrease effective arterial blood volume:*
  - Hypovolemia
  - Heart failure
  - Liver failure
  - Sepsis

Table 4 Causes of intrinsic AKI (Basile et al., 2012; Brivet et al., 1996; Praga and Gonzalez, 2010; Waikar et al., 2006)

- *Vascular*
  - Atheroemboli,
  - Malignant hypertension,
  - Scleroderma crisis,
  - Renal artery or vein thrombosis,
  - Trauma,
  - Microangiopathy [thrombotic thrombocytopenic purpura (TTP), hemolytic uremic syndrome (HUS)]
- *Glomerular*
  - Nephritic
    - Goodpasture's syndrome,
    - Lupus nephritis,
    - Acute post infectious glomerular nephritis
  - Nephrotic
    - Focal segmental glomerulosclerosis (FSGS)
    - Minimal change disease
- *Tubular*
  - Ischemic ATN
    - Hemorrhage,
    - Sepsis,
    - Shock,
    - Trauma,
    - Hypotension,
    - Pre-renal azoetemia
  - Nephrotoxic ATN[a] (aminoglycosides, radiocontrast, amphotericin B[a])
  - Endogenous toxins
    - Hemoglobinuria,
    - Myoglobinuria
- *Interstitial*
  - Drugs[a] (Penicillin antibiotics, omeprazole[a])
  - Infection (Staphylococcal, Streptococcal)
  - Systemic Disease (Sjögren syndrome, systemic lupus nephritis)

[a]Drug induced kidney disease is discussed in detail in Table 10.

Post-renal AKI

Post-renal AKI or obstructive nephropathy accounts for less than 5% of all cases of AKI and may develop as a result of obstruction at any level with the urine collection system (Lameire et al., 2013). This results in an increased pressure within the renal collecting systems and resulting in a reduced GFR, reduced tubular reabsorption of sodium and water, and also acquire renal tubular acidosis, and other abnormalities of tubular function. Bladder outlet obstruction is the most common cause of obstructive nephropathy, and

Table 5 Causes of obstructive nephropathy (Workeneh and Batuman, 2018)

- *Bladder outflow obstruction*
  - Benign prostatic hypertrophy
  - Prostate cancer
  - Infiltrative bladder cancer
  - Neurogenic bladder
- *Ureteric obstruction*
  - Bilateral stone disease
  - Crystal deposition (urate, sulphonamides, acyclovir, cisplatin, indinavir**)
  - Pelvic tumors
  - Papillary necrosis
  - Retroperitoneal fibrosis
  - Radiation fibrosis
  - Renal calculi
  - Urethral strictures

is often a result of a prostatic process (hypertrophy, cancer, or infection) (Basile et al., 2012). Blockage can also occur at the ureters secondary to blood clots or nephrolithiasis or due to crystal precipitation by some medications; however, these are relatively uncommon (Workeneh and Batuman, 2018). **Table 5** lists some of the causes for obstructive nephropathy. Most causes of post-renal AKI are amenable to therapy, and the prognosis is generally good depending upon the underlying disease (Workeneh and Batuman, 2018).

Clinical Presentation and Diagnosis

The initial signs or symptoms of AKI are highly variable and dependent on the underlying etiology. Early recognition and cause identification are critical, as they directly affect the outcome of AKI. One of the first steps in the diagnostic process is to determine whether the change in renal function is acute, chronic or acute in a patient with known CKD (acute on chronic renal failure) (Bellomo et al., 2012). Early or mild AKI may be asymptomatic. Frequent presenting symptoms include weakness, anorexia, generalized malaise, and nausea. Patients should be evaluated for their change in fluid and electrolyte status. Patients may exhibit signs of hypovolemia or hypervolemia. Signs of hypovolemia may include tachycardia, orthostatic hypotension, dry mucous membranes, decreased skin turgor, cool extremities, and sunken eyes. Signs of hypervolemia may include edema and weight gain. Reduced urine output may present as anuria (<50 mL/24 h) or oliguria (50–500 mL/24 h) in hospitalized patients, although some patients may be nonoliguric (>500 mL/24 h) (Workeneh and Batuman, 2018). Some additional signs of AKI include; confusion or altered mental status, fever, signs of uremic encephalopathy (asterixis, stupor, papilledema, or coma), arrhythmias (due to electrolyte imbalances and acidosis), rash (indicative of AKI as a result of an allergic reaction), uremic odor, pruritis, flank pain, fasciculations, muscle cramps, pericardial effusion or pericardial rub (pericarditis), distended bladder or enlarged prostate (post-renal cause). Livedo reticularis or blue toe syndrome, indicative of AKI caused by atheroembolism. The classic triad of fever, rash and eosinophilia suggest allergic interstitial nephritis and should prompt a review of medications. However, the triad occurs uncommonly (Workeneh and Batuman, 2018).

Laboratory studies, complemented by history and physical examination, form the foundation for the diagnosis. An elevated SCr and decreased urine output are primary indicators for AKI (**Table 1**). Laboratory tests for diagnosis and initial evaluation include: serum chemistry, urine chemistry and sediment analysis assessment to ascertain concentration: albuminuria and total proteinuria; and the presence or absence of hematuria, pyuria, renal tubular epithelial cells, granular and cellular casts (Bellomo et al., 2012). Renal ultrasonography of the kidneys may be warranted if obstruction is suspected. Additional tests may be required to assess complications, systemic diseases or diseases in other organ systems, and hemodynamic status in critically ill patients (Workeneh and Batuman, 2018).

Albuminuria is preferred over total protein for the evaluation of kidney diseases, is a marker of glomerular damage and frequently occurs in parenchymal kidney diseases other than ATN (KDIGO, 2012; NICE, 2013). Increased red or white blood cells in the urine may indicate urinary tract lesion while the presence of renal tubular epithelial cells or granular or cellular casts in the sediment indicates localized lesion in the kidney. Renal ultrasonography is the preferred imaging study (>90% sensitivity) as it is not associated with radiation exposure or contrast administration, may be performed to assess the size and shape of the kidney and to determine if there is any obstruction (Bellomo et al., 2004a, 2012; Carrero et al., 2017; KDIGO, 2012; NICE, 2013). Tests for urine concentration may help distinguish between decreased kidney perfusion from ATN. The glomerular filtrate is isotonic with plasma; concentration of the urine requires intact tubular function. Concentration of the urine in the setting of AKI indicates decreased kidney perfusion and preserved tubular function. Absence of urine concentration indicates decreased kidney perfusion and preserved tubular function.

Table 6 Characteristics of different types of AKI (Burke, 2016)

	Pre-renal	*Intrinsic (ATN and AIN)*	*Post-renal*
History and clinical presentation	Volume depletion CHF Drugs: NSAIDs, ACEI and ARBs	Prolonged pre-renal state Nephrotoxins (Aminoglycosides, contrast) Vasculitis Glomerulonephritis	Kidney stones BPH cancer
Physical examination	Hypotension Dehydration Ascites	Rash, fever (with AIN)	Distended bladder Enlarged prostate
Serum BUN/SCr ratio	>20:1	15:1	15:1
Urine sodium	<20 mEq/L	>40 mEq/L	>40 mEq/L
FENa	<1%	>2%	>2%
Urine osmolality	High urine osmolality	Low urine osmolality	Low urine osmolality
Urine sediment	Normal	Muddy brown granular casts; tubular epithelial casts	Variable; may be normal
Urine WBC	Negative	2–4+	Variable
Urine RBC	Negative	2–4+	1+
Proteinuria	Negative	Positive	Negative

Other tests are also frequently required to assess for causes and complications of AKI. Blood urea nitrogen (BUN):creatinine ratio may also be useful to provide additional information on the underlying type of AKI (Bellomo et al., 2004a, 2012; Carrero et al., 2017; KDIGO, 2012; NICE, 2013). Patients electrolytes (sodium, potassium, magnesium, calcium, phosphorous, and bicarbonate) levels should be measured to identify complications (KDIGO, 2012; NICE, 2013). Other additional investigations may include venous or arterial blood gases for interpretation of acid–base disorders, complete blood count, liver function tests, muscle enzymes; imaging of the heart and lungs; and blood and body fluids cultures for infectious diseases (KDIGO, 2012; NICE, 2013). A summary of the characteristics of different types of AKI is presented in **Table 6**.

Prevention and Management

AKI can contribute significantly to the dysfunction of other organs, such as heart, lung, brain, and liver, and is associated with significant mortality. Hence primary prevention and early diagnosis of AKI are of central clinical importance. Once AKI is detected then secondary prevention to attenuate the effects of injury and treatment of consequences of injury are necessary (KDIGO, 2012; Bellomo et al., 2012).

Risk Assessment

The first step in preventing AKI is an adequate risk assessment. The initial care of patients at risk should be focused on identification, and if possible reversal of risk factors. **Table 2** summarizes the risk factors in different settings (KDIGO, 2012).

Ensure Adequate Hydration

Regardless of the nature of the insult, hemodynamic stabilization with optimization of cardiac output and blood pressure is a key factor in the prevention of AKI. The general aim is to optimize volume status based on physiological measurements, to maintain adequate hemodynamic status and cardiac output to ensure renal perfusion, and to avoid further insults such as hypotension or hypovolemia (KDIGO, 2012; NICE, 2013). Hence, fluid management is an important intervention for patients both in the initiation and extension phase of AKI. However, it is important to note that assessing the volume status is not without challenges, particularly in patients in the ICU or those with severe congestive heart failure where it can lead to worsening of symptoms (KDIGO, 2012; NICE, 2013). Therefore, the extent of fluid volume expansion needs to be balanced against the unwanted consequences of fluid accumulation and overload (KDIGO, 2012).

Prevention of Contrast Medium Nephropathy

Patients at risk of contrast induced AKI (CI-AKI) should receive intravenous hydration, the morning of the procedure or immediately before the intervention in case of emergency interventions (Trivedi et al., 2003). The prevention of CI-AKI consensus working panel recommends that preventative measures should be initiated in those with eGFR <60 mL/min/1.73 m^2 (KDIGO, 2012). The volume of the contrast administered should be lowered as much as possible as it has been shown to be a risk factor and independent predictor of CI-AKI. It is also important to avoid administration of contrast within 48–72 h of previous contrast administration (Taylor et al., 1998; Trivedi et al., 2003).

N-Acetylcysteine (NAC) is a tripeptide analogous to glutathione able to cross cellular membranes (Inda-Filho et al., 2014). NAC may reduce vasoconstriction and oxygen free radical generation after the administration of contrast material thereby reducing some of the cellular damage associated with post ischemic and nephrotoxic AKI (Inda-Filho et al., 2014). Several meta-analyses have concluded that NAC can lower the risk of CI nephropathy in high-risk patients and is recommended due to its low cost and excellent safety. In practice both hydration and NAC are combined in patients at high-risk for CI nephropathy (KDIGO, 2012; Mueller et al., 2002).

Glycemic Control

Glycemic control in critically ill patients is important as stress hyperglycemia and insulin resistance are common during critical illness and are associated with increased mortality (KDIGO, 2012; NICE, 2013). However, studies investigating aggressive blood glucose control have reported conflicting results with some studies showing no benefit, increased hypoglycemia and increased mortality whilst others are showing a reduction in the incidence of AKI. Whether there is any clear benefit in preventing or ameliorating AKI is still unclear and current KDIGO guidelines recommend maintaining appropriate control of blood glucose concentration in the range of 6.1–8.3 mmol/L (KDIGO, 2012; NICE, 2013).

Prevention of Nephrotoxin-Induced AKI

Amphotericin

Nephrotoxicity due to amphotericin occurs in one-third of the patients treated with amphotericin with the risk significantly higher in those treated with high doses. It is important to note that lipid formulation of amphotericin have less nephrotoxicity compared to conventional form (Australian Medicines Handbook, 2018). However, further studies are needed to clarify the nephrotoxicity across different formulations as available studies are not directly comparable with differences in definitions of nephrotoxicity, patient groups and study designs. Moreover, alternative antifungal agents such as caspofungin, voriconazole are recommended to be used in high risk patients rather than conventional amphotericin (Australian Medicines Handbook, 2018).

Angiotensin-Converting Enzyme Inhibitors, Angiotensin Receptor Blockers, Non-Steroidal Anti-Inflammatory Drugs

NSAIDs should be avoided in patients with compromised renal function as they inhibit cyclooxygenase and block prostaglandin induced vasodilation of the afferent arteriole, thereby reducing GFR and renal blood flow.

Angiotensin-Converting Enzyme Inhibitors (ACEI) and Angiotensin Receptor Blockers (ARBs) despite their benefits can cause deterioration of kidney function through the efferent arteriolar vasodilation and reducing the intraglomerular pressure in renal impairment can result in reduced GFR. In patients with impaired renal function, SCr may increase after starting treatment or increasing the dose (usually stabilizes within the first 2 months). If increase is <30% or GFR reduction is <25%, there is no need to adjust dose. However, if increase is >30% (or GFR reduction >25%), in addition to investigating other causes a dose modification or discontinuation of the medication is recommended (Australian Medicines Handbook, 2018; Chronic Kidney Disease (CKD), 2012; Ludlow et al., 2017). It is also important to avoid combination of ACE/ARBs with NSAIDs as it contributes towards further deterioration of kidney function with along with diuretics (commonly known as "triple whammy"). It can result in pre-renal AKI in high risk patients (Australian Medicines Handbook, 2018; Chronic Kidney Disease (CKD), 2012).

Aminoglycosides

Aminoglycosides typically results in nonoliguric AKI with decreased urine concentration ability in AKI. Nephrotoxicity usually occurs 5–10 days after the initiation of the drug. Because of its toxicity KDIGO recommend avoiding the use of aminoglycosides in patients with AKI and those at risk of AKI unless no suitable alternative exists. In general, multiple daily administration of aminoglycosides correlates with nephrotoxicity, hence once daily administration of aminoglycosides should be considered in people with risk of AKI (Hughes et al., 2018; KDIGO, 2012).

Summary of Medications Used in the Prevention of AKI

A variety of drugs have been trialled in preventing AKI with most of them not showing any significant benefit in preventing AKI or improving health outcomes. A summary of some of the drugs used in the prevention of AKI is listed in **Table 7** (Bellomo et al., 2012; KDIGO, 2012; NICE, 2013).

Treatment of AKI

General Management

Appropriate management requires timely diagnosis of the clinical condition as there is no specific treatment that can reverse AKI or speed up the recovery. Another key question is whether AKI can be managed with non-dialytic therapies or if RRT is necessary. Initial management of established AKI includes careful assessment of the cause of renal dysfunction and the patient's volume status. The

Table 7 Summary of drugs used in the prevention of AKI

Drugs	*Rationale*	*Evidence*	*Results*
Dopamine	To increase renal blood flow to the kidney	RCTs	No effect on kidney function or mortality *Currently not recommended to prevent or treat AKI* (KDIGO, 2012)
Fenoldopam	Increase renal blood flow to the renal cortex and outer medulla	• Small RCTs • Meta-analysis	• No effect on Kidney function • Beneficial effect on kidney function Fenoldopam was shown to reduce the risk of AKI in postoperative or critically ill patients. However further studies are required. *Currently not recommended to prevent or treat AKI* (Aravindan et al., 2006; KDIGO, 2012)
Loop diuretics	Diuretic use is associated with worsening of kidney function and should be stopped if AKI is due to pre-renal causes.	• RCTs • Meta-analysis	Does not reduce in-hospital mortality associated with AKI, risk of requiring dialysis or the number of dialysis sessions required *Not recommended to prevent or treat AKI except to manage hypervolemia* (Ho and Sheridan, 2006; Karajala et al., 2009; KDIGO, 2012)
N-Acetyl cysteine	NAC may reduce vasoconstriction and oxygen free radical generation after the administration of contrast material thereby reducing some of the cellular damage associated with post-ischemic and nephrotoxic AKI	RCTs Meta-analysis	Variable beneficial effect in contrast induced nephropathy 600–1200 mg BID before and the day of contrast administration along with saline or IV bicarbonate (Inda-Filho et al., 2014; KDIGO, 2012; Mueller et al., 2002)
Natriuretics (Nesiritide)	Increase renal blood flow, urine production and reduce inflammation	RCT	AKI rates were lower in those undergoing cardiac surgery, however, no effect on RRT requirement or length of stay Further studies are required. *Currently not recommended to prevent or treat AKI* (Ejaz et al., 2009; KDIGO, 2012; NICE, 2013)

main goal is to maintain adequate hemodynamic status to ensure renal perfusion, avoidance of further kidney injury, reducing extrarenal complications, maintaining other organ functions and try to restore patient's renal function to pre-AKI baseline function (KDIGO, 2012; NICE, 2013).

Identification and management of AKI should be prompt. Pre-renal AKI should be managed by hemodynamic support and volume replacement. Post-renal AKI should be managed by removing the cause of obstruction. Loss of kidney function associated with other clinical conditions such as heart failure and liver failure include management of the comorbid precipitating event. In patients with acute or chronic renal impairment full recovery of kidney function to pre-AKI levels is unlikely (Bellomo et al., 2012; KDIGO, 2012; Kshatriya et al., 2012; NICE, 2013).

Hydration and Management of Volume Status

It is important to note that AKI may develop in the setting of volume depletion or overload and either condition may occur during the course of AKI. Oliguric AKI is more likely to result in volume overload and has been associated with poor outcomes (Godin et al., 2013). It is also important to avoid volume overload to prevent life threatening pulmonary edema, increased intra-abdominal pressure, renal venous congestion and decreased eGFR. On the other hand, volume depletion should be avoided because it can delay recovery from AKI (Godin et al., 2013; KDIGO, 2012). Hence, maintaining and managing the volume status is imperative and challenging at the same time particularly in those who are critically ill. Frequent monitoring of fluid intake and output, bodyweight, volume status, electrolytes with administration or restriction of fluid depending on the results are important (Godin et al., 2013; KDIGO, 2012).

The main goal of fluid therapy is to maintain or restore effective intravascular volume to ensure adequate tissues perfusion. First line therapies of volume resuscitation consist of crystalloids such as isotonic saline or balanced solutions. Colloids may be used for patients with burns or liver disease (Bellomo et al., 2004b; Finfer et al., 2004; Perel and Roberts, 2007; Young et al., 2015). Treatment of volume overload in patients with AKI can sometimes include using high doses of loop diuretics, these are given as multiple doses throughout the day or as infusion. In critically ill patients with vasomotor shock, vasopressors such as dopamine or norepinephrine may be used in conjunction with fluids in order to maintain adequate hemodynamics and renal perfusion (Bellomo et al., 2004b; Finfer et al., 2004; KDIGO, 2012; NICE, 2013; Perel and Roberts, 2007; Young et al., 2015).

Electrolyte Management

The initial management of electrolytes should start with medical management and proceed to RRT when medical management is no longer satisfactory.

Sodium Disorders

Hypernatremia and fluid retention are common complications of AKI. Total daily sodium intake should be monitored since excessive amounts may contribute to diuretic therapy failure (KDIGO, 2012; NICE, 2013). Several commonly administered medications especially antibiotics contain significant amount of sodium and can contribute to hypernatremia.

Hyponatremia is more common in AKI associated with heart failure, liver failure or diuretics. In these settings, water restriction to below output levels is important. Sodium restriction is usually necessary to treat fluid overload and edema. In patients with true volume depletion with associated pre-renal AKI, isotonic saline will need to be administered to correct both disorders (Bellomo et al., 2012; KDIGO, 2012; NICE, 2013).

Acid–Base Balance

Metabolic acidosis is the most common acid–base abnormality caused by reduced regeneration of sodium bicarbonate and failure to eliminate ammonium ions. In addition, accumulation of phosphate and anions such as sulphate, urate, hippurate, hydroxy propionate, furan propionate, and oxalate are contributory (KDIGO, 2012; NICE, 2013). However, despite the retention of anions in many patients' anion gap remains within normal limits. Sodium bicarbonate may be administered to treat metabolic acidosis as a complication of AKI if serum bicarbonate levels fall below 15–18 mmol/L. However, care should be taken to avoid volume overload (KDIGO, 2012; NICE, 2013).

Potassium Disorders

The most common electrolyte disorder encountered in patients with AKI is hyperkalemia, as more than 90% of potassium is renally excreted (Bellomo et al., 2012; KDIGO, 2012; NICE, 2013). Hyperkalemia can affect the cardiac conduction and can result in life threatening cardiac arrhythmias, so frequent monitoring of potassium is essential. It is important to identify and remove all other oral or IV sources of potassium including dietary restriction of potassium and drugs which retain potassium (e.g., ACEI/ARBs). Treatment of severe hyperkalemia (serum potassium >6.5 mmol/L or with electrocardiographic changes), IV administration of calcium gluconate to reduce the risk of arrhythmias is urgently needed followed by insulin plus dextrose/beta-adrenergic-agonists or sodium bicarbonate (if there is no concern of fluid overload) to shift extracellular potassium intracellularly (KDIGO, 2012; NICE, 2013). These effects are temporary and must be accompanied by measured to remove potassium from the body. The onset of action with insulin and dextrose is usually within 20–30 min and the effect last for about 2–6 h. Sodium bicarbonate-potassium lowering effects is most prominent in patients with metabolic acidosis (Hewitt et al., 2012). Beta-adrenergic agonists are less preferred for hyperkalemia as they have more side effects (KDIGO, 2012; NICE, 2013).

The potassium lowering must be sustained by administration of saline, loop diuretics and cation exchange resins such as sodium polystyrene sulphonate or calcium resins (KDIGO, 2012; NICE, 2013). For patients without oliguria, high dose of loop diuretics can be used to increase urine output and enhance potassium excretion. For patients with oliguria sodium polystyrene sulphonate or calcium resins can be used to induce osmotic diarrhea and fecal potassium loses (KDIGO, 2012; NICE, 2013). A summary of the drugs used in the management of hyperkalemia is presented in **Table 8** (Bellomo et al., 2012; KDIGO, 2012; NICE, 2013).

Calcium, Phosphorous and Magnesium Disorders

High phosphate and low calcium is common in patients with AKI. Hyperphosphatemia results due to reduced elimination of phosphate by the kidney, which in turn reduces the calcium levels resulting in hypocalcaemia. Other causes for low calcium could include low calcitriol production or increases resistance to parathyroid hormone (PTH). However, in most cases the levels of calcium reduction are mild to moderate and can be corrected easily (KDIGO, 2012; NICE, 2013; Workeneh and Batuman, 2018). The first step to correct calcium is to control phosphate by dietary phosphate restriction and oral phosphate binders (KDIGO, 2012; NICE, 2013). Calcium-based phosphate binders and other phosphate binders can be used in this setting.

Nutritional Considerations

AKI often results in protein energy malnutrition because of poor intake and high catabolic rate. Loss of the normal physiological and metabolic functions of the kidney and hypercatabolic response to stress and injury often has a significant impact on the metabolism of nutrients. Nutrition support should provide adequate calories with restricted potassium and phosphate, preventing protein-energy wasting with concomitant metabolic complications, promoting wound healing and tissue repair, supporting immune system function, and reducing mortality (Dellinger et al., 2008).

Table 8 Summary of the drugs used in the management of hyperkalemia

Treatment	*Onset of action*	*Reduction in potassium*	*Duration of action*	*Action*
Calcium gluconate	1–3 min	Nil	30–60 min	Stabilize the heart
Insulin (+dextrose)	15–30 min	0.65–1 mmol/L	4–6 h	Intracellular potassium uptake
Salbutamol (nebulized/IV)	30 min	0.6–1.0 mmol/L	2–4 h	Intracellular potassium uptake
Ion exchange resins	2–3 h	0.5–1.0 mmol/L	4–6 h	Potassium excretion
Hemodialysis	Immediate	≤1.5 mmol/L/h	While dialysis is ongoing	

Table 9 Indications for RRT (Bertsche et al., 2009; KDIGO, 2012; NICE, 2013)

Indications for RRT	*Clinical setting*
A: acid–base abnormalities	Metabolic acidosis
E: electrolyte disturbance	Hyperkalemia
I: Intoxication	Lithium, salicylates etc
O: Fluid overload	Pulmonary edema not responding to diuretics
U: Uremia	Symptoms of uremia or complications (e.g., encephalopathy, pericarditis)

KDIGO guidelines for patients with AKI recommend a total energy intake of 20–30 kcal/kg/day, preferably provided via the enteral route. Minimal nitrogenous waste production is desirable in AKI; however, protein restriction is no longer recommended in the management of AKI. KDIGO guidelines recommend protein goals of 0.8–1.0 g/kg/day in non-catabolic patients, 1.1–1.5 g/kg/day in patients receiving RRT, and a maximum of 1.7 g/kg/day in hypercatabolic patients or those who are receiving continuous RRT (KDIGO, 2012).

Renal Replacement Therapy

RRT is used to manage the complications of AKI. Common indications include life-threatening change in fluid, electrolyte, and acid-base balance that require urgent correction (**Table 9**) (Workeneh and Batuman, 2018). RRT should be discontinued as soon as it is no longer required, because the kidney function has recovered enough to meet the patient's needs or life sustaining therapy is no longer the goal (Bellomo et al., 2012; KDIGO, 2012; NICE, 2013; Workeneh and Batuman, 2018).

The four main modalities of acute RRTs are acute intermittent hemodialysis (iHD); continuous renal replacement therapy (CRRT); prolonged intermittent renal replacement therapy (PIRRT); sustained low-efficiency dialysis (SLED); and acute peritoneal dialysis (Levey and James, 2017).

CRRT is the most popular, however, practice patterns may vary depending upon cost, technology and reimbursement policies. It is a slow, continuous form of therapy delivered 24 h a day in the ICUs and is usually used for hemodynamically unstable patients (Levey and James, 2017). In patients who are hemodynamically stable, conventional intermittent HD may be used. However, more frequent sessions may be required to correct some of the fluid and electrolyte abnormalities. PIRRT provides prolonged dialysis using slower flow rates over longer sessions (>6 h/session). Studies comparing continuous versus intermittent HD in critically ill patients have found no significant differences in clinical outcomes such as length of hospitalization, and mortality (Palevsky, 2009; Pannu et al., 2008; Vinsonneau et al., 2006).

Drug Dosing in AKI

Optimizing drug dosing during AKI is often very challenging. SCr and eGFR are less accurate to guide dosing in the non-steady state than in the steady state (Levey and James, 2017). Other factors that could influence drug dosing include patients' residual drug clearance, fluid accumulation, and RRT. Expert consensus recommend close monitoring of drug response in patients with known nephrotoxicity or other toxicities and for renally eliminated drugs serum drug concentrations (Levey and James, 2017). It is also important to note that renal impairment can also independently impair non-renal drug elimination (Vilay et al., 2008). Further, the use of dosing guidelines based on the data derived from patients with stable CKD may not affect the clearance and volume of distribution in critically ill AKI patients. It is also important to note that in AKI adverse effects of many medications are increased. For example; bleeding risk of anticoagulants is increased in AKI due to the uremic platelet dysfunction; decreased clearance of low molecular weight heparins and direct oral anticoagulants. Pharmacists have a huge role to play in determining the drug dosing and determining the dosing interval in patients with AKI and those on dialysis (Levey and James, 2017).

Pharmacist's Role in AKI

Pharmacists being medication experts are in an ideal position to contribute to reduce the burden of AKI. Community pharmacists are often the first point of contact for most patients as they are easily accessible and are in an excellent position to identify patients who are at high risk of developing AKI (**Table 2**); engaging with them, supporting and developing their understanding of medication risks, and monitoring medicines that can cause kidney problems (CPPE, in press). Community pharmacists should be aware that drug-induced nephrotoxicity can often be predicted because it is more common in certain patients and in specific clinical situations. An example of such an intervention is with use of "triple whammy", that is, the use of ACEI/ARBs, diuretics and nonsteroidal antiinflammatory drugs (NSAIDs) in combination increases the risk of AKI in patients with risk factors for AKI (**Table 2**). Australian adverse drug reactions bulletins have highlighted "triple whammy" as a cause for community-acquired AKI (Thomas, 2000).

In the hospital setting, pharmacists play an essential part of the inter-professional team supporting prescribing decisions for patients with AKI, optimizing drug therapy, adjusting drug dosages related to kidney function, laboratory monitoring, patient and other health care professionals' education and medication reconciliation (Baum and Harder, 2010; Bourne and Choo, 2012; Gharekhani et al., 2014; St Peter et al., 2013; Such Díaz et al., 2013; Thomas, 2000). Pharmacists play an important role in

Table 10 Nephrotoxic agents leading to AKI

• Pre-renal azotaemia	Antihypertensives NSAIDs	
• Small vessel disease	NSAIDs ACEI/ARBs Radiocontrast agents Cyclosporine Tacrolimus Cocaine	Renal vasoconstriction
	Cyclosporine Tacrolimus Mitomycin C Quinine Clopidogrel	Thrombotic microangiopathy
• Glomerular disease	Penicillamine Hydralazine Propylthiouracil	Rapidly progressive GN
• Acute tubular necrosis	Amphotericin B Aminoglycosides Foscarnet Tenofovir, ciclofovir, adefovir Cisplatin Carboplatin Cyclosporine Tacrolimus zoledronate Ifosfamide Acetaminophen Herbal medications Radiocontrast agents Lithium	
• Acute interstitial nephritis	Antibiotics (Penicillins, cephalosporins, ciprofloxacin, sulphamethoxazole) NSAIDs Proton pump inhibitors Loop diuretics Cimetidine Allopurinol Phenytoin Mesalazine	
• Intratubular obstruction	Acyclovir Sulphonamides Indinavir Foscarnet Methotrexate Oral phosphate (high dose)	Crystal nephropathy
• Post-renal obstruction	NSAIDs, compound analgesics Anticholinergics, tricyclic antidepressants	Papillary necrosis Urinary retention

identifying drugs associated with nephrotoxicity and educating patients, health care professionals about drug-induced AKI and recommending alternatives to nephrotoxic medicines (Kane-Gill and Bauer, 2017).

Several diagnostic and therapeutic agents have been associated with drug-induced AKI and identification and avoidance of nephrotoxic agents in AKI is critical in the management of AKI. Nephrotoxicity is often reversible upon discontinuation of the individual drug, however in some cases it can lead to AKI or CKD. There are many mechanisms of nephrotoxicity and include alterations in the renal hemodynamics, direct tubular toxicity, generation of allergic reactions resulting in interstitial nephritis, and intratubular obstruction. Although the list is extensive the more common medications associated with AKI are listed in **Table 10** (Levey and James, 2017; Workeneh and Batuman, 2018).

In recent years, the use of herbal medicines and dietary supplements to promote health and treat chronic diseases has increased significantly. Many of these products are available as over the counter (OTC) in pharmacies and some may harm kidneys. Hospital pharmacists are also vital in liaising with community pharmacists and general practitioners (GPs) to ensure a continued supply of medication, monitoring or introduction of compliance aid as needed to ensure quality use of medicines in renal impairment patients (Saran et al., 2016).

Table 11 highlights some of the potential renal side effects of herbal medicines (Isnard Bagnis et al., 2004).

Table 11 Examples of kidney syndromes induced by herbal medicines (Isnard Bagnis et al., 2004)

Hypertension	*Glycyrrhiza* species (Chinese herbal teas, gancao, boui-ougi-tou)
	Ephedra species (ma huang)
Acute tubular necrosis	Traditional African medicine: toxic plants (*Securidaca longepedunculata*, *Euphoria matabelensis*, *Callilepis laureola*, Cape aloes), or adulteration by dichromate
	Chinese medicine: *Taxus celebica*
	Morocco: Takaout roumia (paraphenylenediamine)
Acute interstitial nephritis	Peruvian medicine *(Uno degatta)*
	Tung Shueh pills (adulterated by mefenamic acid)
Fanconi syndrome	Chinese herbs containing Aristolochic acids (AAs) (*Akebia* species, boui-ougi-tou, Mokutsu)
	Chinese herbs adulterated by cadmium
Papillary necrosis	Chinese herbs adulterated by phenylbutazone
Chronic interstitial renal fibrosis	Chinese herbs or Kampo containing AAs (*Aristolochia* species, *Akebia* species, Mu Tong, Boui, Mokutsu)
Urinary retention	*Datura* species, *Rhododendron molle* (atropine, scopolamine)
Kidney stones	Ma huang (ephedrine)
	Cranberry juice (oxalate)
Urinary tract carcinoma	Chinese herbs containing AAs

Management of Renal Disorders and the Pharmacist's Role: Chronic Kidney Disease

Ronald Castelino[*,†], **Li Shean Toh**[‡], [*]Faculty of Medicine & Health, University of Sydney, Sydney, Australia; [†]Blacktown Hospital, New South Wales, Australia; [‡]University of Tasmania, Hobart, Tasmania, Australia

Learning Objectives

- Classify the stage or category of CKD based on patient history, physical examination, and laboratory values
- Identify risk factors for the progression of CKD and formulate management strategies to slow down the progression of CKD
- Assess for the presence of common complications of CKD
- Develop a plan to manage common complications of CKD
- Identify medications/medications classes that are associated with nephrotoxicity and required dosage adjustment in kidney disease

Key Concepts

- Chronic kidney disease (CKD) is defined by a decline in kidney function (i.e., an estimated glomerular filtration rate (eGFR) of < 60 mL/min/1.73 m^2) and/or at least 3 months of structural or functional kidney damage (presence of albumin in urine).
- GFR is estimated through measuring serum creatinine (SCr) via GFR estimating equations, with chronic kidney disease epidemiology collaboration (CKD-EPI) equation the currently preferred equation. Albuminuria is measured by urine albumin/creatinine ratio: >30 mg/g indicating albuminuria.
- CKD is commonly associated with hypertension, diabetes, and cardiovascular disease (CVD).
- Early stages of CKD are often asymptomatic, causing CKD to be untreated, leading to further progression of kidney damage and worse prognosis.
- Although many patients with CKD progress to end-stage kidney disease (ESKD) and require renal replacement therapy (RRT), the majority die of nonrenal causes, particularly premature CVD.
- In patients with CKD it is important to monitor electrolyte levels, parathyroid hormone, and sodium bicarbonate levels to detect complications of CKD, including CVD, anemia, bone mineral disease, and acidosis.

- A growing body of evidence indicates that pharmacist services for CKD patients, including medication reconciliation and medication therapy management, positively affect clinical and cost outcomes, including lower rates of decline in glomerular filtration rates, reduced mortality, and fewer hospitalizations and hospital days, but more robust research is needed.

Introduction

Chronic kidney disease (CKD) is increasingly being recognized as a significant and growing public health problem, especially as our population ages (Radhakrishnan et al., 2014; Bruck et al., 2015; Khanal et al., 2015; Bruck et al., 2016). It is defined as a decline in kidney function (i.e., an eGFR of < 60 mL/min/1.73 m^2) and/or kidney damage (presence of albumin in the urine) lasting for 3 months or more (Kidney Disease: Improving Global Outcomes (KDIGO) CKD Work Group, 2013). Currently, more than 322 million individuals are affected by CKD worldwide, and the number of patients with end-stage kidney disease (ESKD) treated with dialysis or transplantation globally exceeds 2.6 million people (Anand et al., 2013; Jha et al., 2013).

In Australia, around 1.7 million Australians (1 in 10) aged ≥18 years have clinical evidence of CKD (Chronic Kidney Disease, 2012; Australian Institute of Health and Welfare, 2017). However, CKD typically has no symptoms, with less than 10% of the people with CKD being aware that they have CKD. This means that over 1.5 million Australians are unaware that they have indicators of CKD. CKD is associated with an increased mortality rate, as well as an elevated risk of several comorbidities and adverse outcomes, including anemia, acute kidney injury, falls, and heart failure (Australian Institute of Health and Welfare, 2017). People with CKD also require extensive hospital services, particularly those with ESKD who need regular dialysis or a kidney transplant to survive (Chronic Kidney Disease, 2012; Australian Institute of Health and Welfare, 2017).

Definition and Staging of CKD

The definition of CKD has evolved over the past decade with advances in the knowledge of the prognosis (Chronic Kidney Disease Prognosis Consortium et al., 2010; Matsushita et al., 2010) According to the National Kidney Foundation Kidney Disease Outcomes Quality Initiative (KDOQI) guidelines published in 2002, CKD is defined by structural and functional abnormality of the kidney (manifested by abnormalities in the composition of blood or urine or abnormalities in imaging tests), with or without decreased GFR (<60 mL/min/1.73 m^2) for 3 months (National Kidney Foundation, 2002). The staging system was modified by kidney disease improving global outcomes (KDIGO) in 2012 to reflect independent contributions of eGFR, albuminuria, and cause of CKD (Kidney Disease: Improving Global Outcomes (KDIGO) CKD Work Group, 2013). According to KDIGO, CKD is defined as abnormalities of kidney structure or function for more than 3 months. These abnormalities may be seen as persistent markers of kidney damage or GFR <60 mL/min/1.73 m^2 (Kidney Disease: Improving Global Outcomes (KDIGO) CKD Work Group, 2013).

Serum creatinine (SCr) is the most common filtration marker used to estimate GFR and carry out staging of CKD. The best available and currently most widely used equation to estimate GFR is the CKD epidemiology collaboration equation (CKD-EPI) (Johnson et al., 2012a,b). Urine albumin is recommended over urine protein assessment and is generally standardized to urine creatinine to normalize to 24-h excretion and account for any differences in concentration (albumin-to-creatinine ratio [ACR]) (Johnson et al., 2012a,b). The criteria for the definition of CKD is summarized in **Table 1**.

Epidemiology

Patients with CKD experience high morbidity and mortality rates, which result in a huge economic burden to the healthcare system due to hospitalization and the high costs of RRTs such as dialysis and transplantation (World Health Organization, 2013). The age-adjusted death rates attributable to CKD increased by 36.9% in 188 countries (1990–2013) and are now the 19th leading cause of life lost (World Health Organization, 2013). It is estimated that 8%–16% of the general population has CKD around the world and over 2.6 million people globally are undergoing RRT (dialysis or transplantation) (Anand et al., 2013; Jha et al., 2013; Australian Institute of Health and Welfare, 2017).

Table 1 Summary criteria for the definition of chronic kidney disease (CKD) (Kidney Disease: Improving Global Outcomes (KDIGO) CKD Work Group, 2013)

CKD is defined as abnormalities in kidney function or structure, present for 3 months or more with implications for health. These may include:	
Decreased GFR	GFR < 60 mL/min/1.73 m^2
Markers of kidney damage	• Albuminuria (AER ≥30 mg/24 h; uACR ≥30 mg/g [≥3 mg/mmol]) • Urine sediment abnormalities • Electrolyte and other abnormalities caused by tubular disorders • Abnormalities detected through histology • Structural abnormalities detected through imaging • History of kidney transplantation

The prevalence of CKD increases disproportionately in older people because of the age-related decline in GFR of approximately 8 mL/min with each decade of life after the age of 40 years (Hanlon et al., 2011). People with CKD have the highest prevalence of CVD, diabetes, and hypertension, and is strong risk factor for future cardiovascular events including stroke and death (Chronic Kidney Disease, 2012; Tonelli et al., 2012; Australian Institute of Health and Welfare, 2017). It is reported that in people with CKD, the risk of dying from cardiovascular events is 20 times higher than the risk of requiring dialysis or transplantation (Keith et al., 2004; Mathew and Corso, 2009; Chronic Kidney Disease, 2012; Tonelli et al., 2012). Research suggests that people with CKD have 20% higher mortality than the general population (Chronic Kidney Disease, 2012). Hence, focusing on factors contributing to the decline in renal function, rather than on whether the decline is inevitable with age, helps in the prevention and treatment of the disease.

Evidence-based guidelines demonstrate that early recognition, proper management, and early referral have the greatest effect on slowing the progression of CKD (Kidney Disease: Improving Global Outcomes (KDIGO) CKD Work Group, 2013; National Institute for Health and Care Excellence, 2014). These strategies include better management of comorbidities such as hypertension, and diabetes and discontinuation of medications that are nephrotoxic or considered problematic in renal impairment (Kidney Disease: Improving Global Outcomes (KDIGO) CKD Work Group, 2013; National Institute for Health and Care Excellence, 2014). It is reported that if CKD is detected early and managed appropriately, then the deterioration in kidney function can be reduced as much as 50%, and in some cases may be reversible (Johnson, 2004). Hence, many countries (e.g., the United States and Australia) have now implemented public health initiatives to reduce the proportion of people with CKD by increasing awareness; increase the proportion of the people with CKD who know they have impaired kidney function; reduce the rate of new cases of ESKD, and reduce mortality associated with CKD (World Health Organization, 2013).

Etiology and Risk Factors

Globally, diabetes mellitus (DM) is the most common cause for CKD responsible for 40%–50% of new cases of ESKD (Chronic Kidney Disease, 2012; National Kidney Foundation, 2012). Hypertension has shown to be responsible for about 25% of new cases of CKD, with glomerulonephritis accounting for 10% of the cases. Some of the other causes of CKD include urinary tract disease, polycystic kidney disease, and lupus (Chronic Kidney Disease, 2012; Phoon, 2012; Kidney Disease: Improving Global Outcomes (KDIGO) CKD Work Group, 2013; National Institute for Health and Care Excellence, 2014). A summary of the risk factors for susceptibility and initiation of CKD is presented in **Table 2** (Inker et al., 2014).

Pathophysiology

Progression of CKD occurs gradually over several years and largely depends upon the main cause of the disease (Chronic Kidney Disease, 2012). Patients with diabetes often have glomerular mesangial expansion, while in patients with hypertension,

Table 2 Risk factors for susceptibility to, initiation, and progression of CKD (Inker et al., 2014)

Susceptibility/initiation risk factors	
Diabetes	Obesity
Hypertension	Systemic infections/inflammation
Cardiovascular disease	Urinary tract infections
Dyslipidemia	Urinary stones
Obesity	Urinary tract obstruction
Hyperuricemia	Neoplasia
Smoking	Family history
Low socioeconomic status	Acute kidney injury
Autoimmune diseases	Reduced kidney mass
Polycystic kidney disease	Exposure to drugs, e.g., analgesics
Nephrotoxins (NSAIDs, heavy metal exposure)	
Advanced age	
Racial or ethnic minority: Aboriginal and Torres Strait Islander people, African American	
Low income/education	
Low birth weight	
Exposure to chemical	
Progression risk factors	
Hyperglycemia	
Elevated blood pressure	
Proteinuria	
Smoking	

nephrosclerosis is often the problem (Tomino, 2014). However, the key elements to the progression of ESKD includes loss of nephron mass, glomerular capillary hypertension, and proteinuria. Exposure to the initiation risk factors can result in loss of nephron mass. However, a normal kidney consists of approximately 1 million nephrons, each of which contributes to the total GFR. In face of a renal injury, the kidney has an innate ability to maintain GFR. Despite progressive destruction of nephrons, the remaining nephrons compensate through the process of autoregulation. This nephron adaptability allows for continued normal clearance of plasma solutes. Plasma levels of substances such as urea and creatinine start to show measurable increases only after the total GFR has decreased to 50%.

After the initial loss of nephrons and the reduced perfusion pressure and GFR, renin release from the juxtaglomerular apparatus increases and converts angiotensinogen to angiotensin 1, which is then converted to angiotensin 2 (AT2). AT2, although a potent vasoconstrictor of both afferent and efferent arterioles, preferentially affects the efferent arterioles leading to increased pressure within the glomerular capillaries and resultant increased filtration. The higher intraglomerular capillary pressure impairs the size selective function of glomerular permeability barrier, resulting in increased urinary excretion of proteins. Furthermore, development of intraglomerular hypertension may also result in the development of systemic hypertension, which along with proteinuria is a risk factor for cardiovascular mortality and morbidity (Lopez-Novoa et al., 2010; Tomino, 2014; Gajjala et al., 2015).

Filtration of proteins (albumin, immunoglobulins, and cytokines) can further promote loss of nephrons through toxicity to the kidney tubular cells. Studies have shown that these proteins increase the production of inflammatory and vasoactive cytokines such as endothelin and monocyte chemoattractant protein (MCP1) and activate complement in the tubules. These events ultimately can result in scarring of the interstitial and progressive loss of nephrons and further reduced GFR (Lopez-Novoa et al., 2010; Tomino, 2014; Gajjala et al., 2015).

Clinical Presentation and Assessment

CKD is usually asymptomatic until later stages of stages 4–5 and is usually detected by routine blood testing (Chronic Kidney Disease, 2012; Phoon, 2012). Patients need to be asked about symptoms as they are often non-specific. Early identification and management have shown to reduce the progression of CKD as well as the risk of CVD (Chronic Kidney Disease, 2012; Phoon, 2012). A detailed medical history that includes medical conditions, family history of kidney disease, use of medications, and other risk factors listed in **Table 3** is warranted. Patients are often required to repeat blood tests (SCr, eGFR, and ACR) within 3 months to confirm the chronicity of kidney disease. Elevated blood urea nitrogen (BUN), creatinine, and low GFR are the best overall indicators of poor kidney function. eGFR is estimated by multivariable (SCr, age, sex, and race) prediction equations normalized to body surface area (Kidney Disease: Improving Global Outcomes (KDIGO) CKD Work Group, 2013; National Institute for Health and Care Excellence, 2014).

The modification of diet in renal disease (MDRD) equation has been commonly used in clinical laboratories until recently but following KDIGO recommendations this has been replaced by the CKD-EPI which is the preferred reporting equation (Johnson et al., 2012a). Direct GFR clearance methods or Cystatin C measurement may confirm CKD in situation when SCr-based GFR is less accurate. Serum chemistries may also show hyperkalemia, hyperuricemia, hypocalcemia, hyperphosphatemia, hyperglycemia, and decreased bicarbonate (Richards et al., 2008; Phoon, 2012; Kidney Disease: Improving Global Outcomes (KDIGO) CKD Work Group, 2013; National Institute for Health and Care Excellence, 2014). Proteinuria is an important diagnostic and prognostic marker, and its presence indicates a higher risk of progression of CKD and CVD (Chronic Kidney Disease, 2012; Phoon, 2012; Kidney Disease: Improving Global Outcomes (KDIGO) CKD Work Group, 2013). KDIGO recommends that the preferred method for assessing proteinuria is by the measurement of urine ACR using the early morning urine sample (Kidney Disease: Improving Global Outcomes (KDIGO) CKD Work Group, 2013). Albuminuria is graded according to the A1 to A3 criteria highlighted in **Table 4**. Urinalysis may also reveal hematuria or formed elements such as casts.

Imaging of the kidneys may be required to identify the cause, taking into account the risk of administered contrast media. Structural abnormalities such as polycystic kidney disease, renal artery stenosis, and small kidney size can be detected by imaging studies such as ultrasound and magnetic resonance imaging (Kidney Disease: Improving Global Outcomes (KDIGO) CKD Work Group, 2013; National Institute for Health and Care Excellence, 2014).

Table 3 KDOQI stages in CKD (Kidney Disease: Improving Global Outcomes (KDIGO) CKD Work Group, 2013)

Stage of renal disease	*Damage*	*GFR (mL/min/1.73 m^2)*
Increased risk of developing kidney disease	Risk factors for CKD (diabetes, HTN, family history)	≥90
Stage 1	Kidney damage with normal GFR	≥90
Stage 2	Kidney damage with mild decrease in GFR	**60–89**
Stage 3	Moderate decrease in GFR	**30–59**
Stage 4	Severe decrease in GFR	**15–29**
Stage 5	Kidney failure	<**15**

Table 4 KDIGO categories of albuminuria (Kidney Disease: Improving Global Outcomes (KDIGO) CKD Work Group, 2013)

Category	*Classification*	*ACR (mg/g)*	*Daily excretion (mg/24 h)*
A1	Normal to mildly increased	**<30**	**<30**
A2	Moderately increased	**30–300**	**30–300**
A3	Severely increased albuminuria	**>300**	**>300**
	Nephrotic-range proteinuria		**>3000**

Management of CKD

Patients with CKD should be frequently evaluated to assess the progression of CKD, identify complications, and manage the complications to reduce morbidity and mortality. Both pharmacological and non-pharmacological recommendations are applied as part of the general approach to the management of CKD and should include a multidisciplinary approach to address these. Multidisciplinary teams include renal physicians, general practitioners, social workers, dieticians, nurses, and pharmacists, and depend upon the severity of CKD (Chronic Kidney Disease, 2012).

Non-Pharmacological Therapy for CKD

Non-pharmacological management of CKD includes diet and lifestyle interventions aimed to reduce the risk factors for CKD progression or development of comorbidities such as CVD. These include smoking cessation, weight loss if appropriate, and physical activity of at least 30 min daily 5 times a week similar to other chronic disease states (Chronic Kidney Disease, 2012). People with CKD >30 mL/min should be encouraged to eat and adequate diet according to the energy requirements in line with dietary recommendations for other chronic disease states (Chronic Kidney Disease, 2012). However, depending upon the severity of CKD, dieticians should be involved to provide appropriate advice regarding nutrition for patients with eGFR <30 mL/min/1.73 m^2. The nutritional recommendations as per KDIGO are highlighted in **Table 5** (Kidney Disease: Improving Global Outcomes (KDIGO) CKD Work Group, 2013).

General Approach to the Management of CKD

Treatment of CKD is aimed at reducing the progression of CKD by treatment specific to the underlying disorders and alleviating the electrolyte and hormonal abnormalities that can lead to symptoms or complications.

Factors Causing Progression of CKD

It is well known that once CKD is developed kidney function decline usually occurs at a predictable rate in the absence of further insult to the kidney. Hence, management of factors causing progression of CKD is critical (Johnson, 2004).

Diabetes

The management of diabetes in patients with CKD includes reduction of proteinuria and achievement of desired blood pressure and HbA1c to slow down the progression of CKD (Chronic Kidney Disease, 2012; National Kidney Foundation, 2012; Phoon, 2012). All patients with Type 1 DM should begin annual monitoring for albuminuria 5 years after diagnosis while in Type 2 DM patients should have annual monitoring of albuminuria immediately after diagnosis (Chronic Kidney Disease, 2012; National Kidney Foundation, 2012; Phoon, 2012). Angiotensin converting enzyme inhibitors (ACEIs) or angiotensin receptor blockers (ARBs)

Table 5 Nutritional recommendations in patients with CKD (Kidney Disease: Improving Global Outcomes (KDIGO) CKD Work Group, 2013)

Daily intake	*Predialysis CKD*	*Hemodialysis*	*Peritoneal dialysis*	*Comments*
Protein (g/kg/IBW)	0.6-1.0 1.0 for patients with NS	1.1-1.2	1.0-1.3	Patients protein intake is often individualized depending upon the nutritional status, phosphate levels, dialysis adequacy
Energy (kcal/kg BW)	35 (<60 years) 30–35 (>60 years)	35 (<60 years) 30–35 (>60 years)	35 (<60 years) 30–35 (>60 years)	For PD patients including dialysis calories
Sodium (mmol)	<100 (more if salt wasting)	<100	<100	
Potassium	Reduce if hyperkalemic			
Calcium	In CKD stages 3–5 total intake of calcium should not exceed 2000 mg/day			Includes dietary calcium
Phosphorous	Reduce: level dependent on protein intake			

Table 6 BP target in patients with CKD and albuminuria

Severity of albuminuria	*Goal BP*	*Level of evidence*
Normal to mild albuminuria	140/90 mmHg	1B
Moderate to severe albuminuria	130/80 mmHg	2D

should be used with any degree of proteinuria, even if the patient is not hypertensive. ACEIs/ARBs are also the preferred agents for the management of blood pressure in patient's diabetic nephropathy (Chronic Kidney Disease, 2012; National Kidney Foundation, 2012; Phoon, 2012). The goal BP reading in patients with diabetic nephropathy as per KDIGO is highlighted in **Table 6** (National Kidney Foundation, 2012).

It is important to monitor patient's potassium levels and kidney function closely once an ACEI/ARBs are initiated as these agents can worsen kidney function or aggravate hyperkalemia in CKD. Providing the reduction in kidney function is < 25% within 2 months of starting therapy, the ACEI/ARB should be continued (Chronic Kidney Disease, 2012; Australian Medicines Handbook, 2018). If the reduction in GFR is more than 25% below the baseline value, the ACEI or ARB should be ceased and consideration given to referral to a nephrologist. Combined therapy with ACEI and ARB should be avoided except with specialist advice. Similarly, caution should be exercised if baseline K+ is ≥5.5 mmol/L, as rises in serum K+ of approximately 0.5 mmol/L are expected. Most patients will need diuretic in combination with an ACEI/ARB (thiazide with stages 1–3 and loop diuretics in stages 4–5). If BP is higher than 160/100 mmHg, consideration may be given to start with a two-drug regimen. However, combination therapy with ACEIs and ARB should be avoided (Chronic Kidney Disease, 2012; KDIGO Blood Pressure Work Group, 2012; National Institute for Health and Care Excellence, 2014; Australian Medicines Handbook, 2018).

The HbA1c target in patients with diabetic nephropathy should be about 7% (53 mmol/mol). However, higher targets may be considered in patients at a higher risk of hypoglycemia, limited life expectancy, or advanced CKD (National Kidney Foundation, 2012). It is important to note that HbA1c values may be falsely low in CKD patients as red blood cell life is decreased in patients with CKD. Metformin is the drug of choice for the management of Type 2 DM. However, it requires dosage adjustment in CKD and is contraindicated in unstable CKD or severe CKD (<15 mL/min) (Chronic Kidney Disease, 2012; Australian Medicines Handbook, 2018). Most of the oral antidiabetic agents such as gliptins (except linagliptin), sodium glucose cotransport inhibitors, and glucagon-like-peptide 1 (GLP-1) analogues do require dosage adjustment in CKD and contraindicated in CKD depending upon the severity of CKD. **Table 13** lists some of the drugs that need to be used with caution in CKD. Furthermore, the requirement of insulin in patients with CKD is generally less because of reduced metabolism of insulin by the kidney as GFR declines (Chronic Kidney Disease, 2012; Australian Medicines Handbook, 2018).

Blood Pressure Management

ACEIs/ARBs are an essential part of the best care approach for many patients in all stages of CKD with hypertension even in the absence of diabetes. Patients often need more than one drug and calcium channel blockers or diuretics are often used for that purpose. Beta-blockers may be useful in people with coronary heart disease, tachyarrhythmias, and heart failure, but are contra-indicated in asthma and heart block (Chronic Kidney Disease, 2012; KDIGO Blood Pressure Work Group, 2012; Kidney Disease: Improving Global Outcomes (KDIGO) CKD Work Group, 2013; Australian Medicines Handbook, 2018). The BP goals as per KDIGO are listed in **Table 7** (KDIGO Blood Pressure Work Group, 2012).

Dyslipidemia

Patients with CKD often have abnormalities in lipoprotein metabolism. The KDIGO guidelines recommend assessing the fasting lipid profile in all adult patients with newly identified CKD (grade 1C recommendation). Follow-up lipid levels are generally not recommended unless the information is likely to alter the management (e.g., adherence to therapy). Only statin therapy has shown to reduce CV events in patients with CKD or a statin plus an ezetimibe combination. Treatment recommendations from KDIGO (Kidney Disease: Improving Global Outcomes (KDIGO) CKD Work Group, 2013; National Kidney Foundation, 2014) are in **Table 8**.

Cardiovascular Disease in CKD

CVD is an important risk factor for CKD as well as a consequence of CKD and the major reason for mortality in CKD patients (Saran et al., 2015; Australian Institute of Health and Welfare, 2017). Recent studies have shown that CKD is a more important

Table 7 Goals of BP management in patients with CKD

Target group	*Severity of albuminuria*	*Goal blood pressure (maximum)*	*Level of evidence*
Nondiabetic CKD	Normal to mild albuminuria	140/90 mmHg	1B
Nondiabetic CKD	Moderate to severe albuminuria	130/80 mmHg	2D moderate 2C severe

Table 8 Recommendations for dyslipidemia management in patients with CKD

Target group	*Treatment recommendations*	*Grade*
Age ≥50 years, stages 1–2	Statin	1B
Age ≥50 years, stages 3a–5	Statin or statin + ezetimibe	1A
Adults 18–49 years of age with CKD before dialysis or transplant with CAD, diabetes, stroke, or estimated CVD risk >10%	Statin	2A
Adults on therapy when dialysis initiated	Continue treatment	2C
Adults with dialysis-dependent CKD	Do not start therapy[a]	2A
Adult kidney transplant recipients	Statin	2A

[a]Studies have failed to show any great benefit in terms of CV outcomes in patients on dialysis when initiated with statins. Some studies have shown worse outcomes (Wanner et al., 2005; Palmer et al., 2013; Palmer et al., 2012).

risk factor for CKD than diabetes (Go et al., 2004; Vanholder et al., 2005; Ardhanari et al., 2014). For people with CKD, the risk of dying from cardiovascular events is up to 20 times higher than the risk of requiring dialysis or transplantation. The prevalence of any form of CVD is double in CKD patients compared to patients without CKD (70% vs. 35%) (Australian Institute of Health and Welfare, 2010). Risk factors for CVD in CKD patients include both traditional risk factors such as diabetes, dyslipidemia, hypertension, left ventricular hypertrophy, smoking, and obesity, and nontraditional risk factors such as anemia, proteinuria, inflammation, and abnormal calcium and phosphate metabolism resulting in vascular calcification (Ardhanari et al., 2014).

However, there is a shortage of RCTs concerning the efficacy and safety of interventions to reduce risk of CVD in patients with CKD (Choi et al., 2014). Available evidence supports recommendations that patients with CKD should stop smoking, achieve excellent blood pressure control (but avoid an SBP less than 120 mmHg), and receive statin therapy for dyslipidemia (Chronic Kidney Disease, 2012; Kidney Disease: Improving Global Outcomes (KDIGO) CKD Work Group, 2013; National Institute for Health and Care Excellence, 2014). Further, RCTs are required to determine the relative safety and efficacy of aspirin and other platelet inhibitors.

Treatment OF CKD Complications

Anemia

Anemia is a common complication of CKD (stages 3a–5) caused by a relative deficiency of erythropoietin, although several other factors such as reduced availability of iron, chronic inflammation, bone marrow suppression by uremic toxins, and reduced nutrition may also play a role (Jelkmann, 2011; Kidney Disease: Improving Global Outcomes (KDIGO) Anemia Work Group, 2012). Anemia may have multiple adverse effects including worsening cardiac dysfunction by increasing cardiac output and exacerbating left ventricular hypertrophy, exacerbating the decline in kidney function, and reducing cognition and concentration (Chronic Kidney Disease, 2012). The desired outcomes of anemia management are to increase oxygen-carrying capacity, decrease signs and symptoms of anemia, and decrease the need for blood transfusions (Kidney Disease: Improving Global Outcomes (KDIGO) Anemia Work Group, 2012).

Hemoglobin (Hb) is the preferred marker for monitoring red blood cell production and as per KDIGO guidelines should be monitored annually in patients with stage 3a CKD, twice a year in patients with stage 4, and every 3 months in patients with stage 5 CKD (**Table 9**) (Kidney Disease: Improving Global Outcomes (KDIGO) Anemia Work Group, 2012). Patients should also have an assessment of their iron stores, vitamin B-12 and folate levels to rule out other causes of anemia (Kidney Disease: Improving Global Outcomes (KDIGO) Anemia Work Group, 2012). Anemia is diagnosed when Hb is <130 g/L in men and <120 g/L in women. Patients are often commenced with treatment for anemia when Hb levels fall below 100 g/L. The main goals of anemia treatment are to decrease morbidity and mortality, reduce left ventricular hypertrophy, increase exercise tolerance, and increase quality of life (Kidney Disease: Improving Global Outcomes (KDIGO) Anemia Work Group, 2012).

Table 9 KDIGO guidelines for frequency of laboratory monitoring in CKD stages 3–5 (KDIGO, 2009)

	Stage 3 CKD	*Stage 4 CKD*	*Stage 5 CKD*
Calcium	Every 6–12 months	Every 3–6 months	Every 1–3 months
Phosphorus	Every 6–12 months	Every 3–6 months	Every 1–3 months
PTH	Baseline	Every 6–12 months	Every 3–6 months
Alkaline phosphatase	Baseline	Every 12 months	Every 12 months
25-hydroxyvitamin D	Baseline	Baseline	Baseline

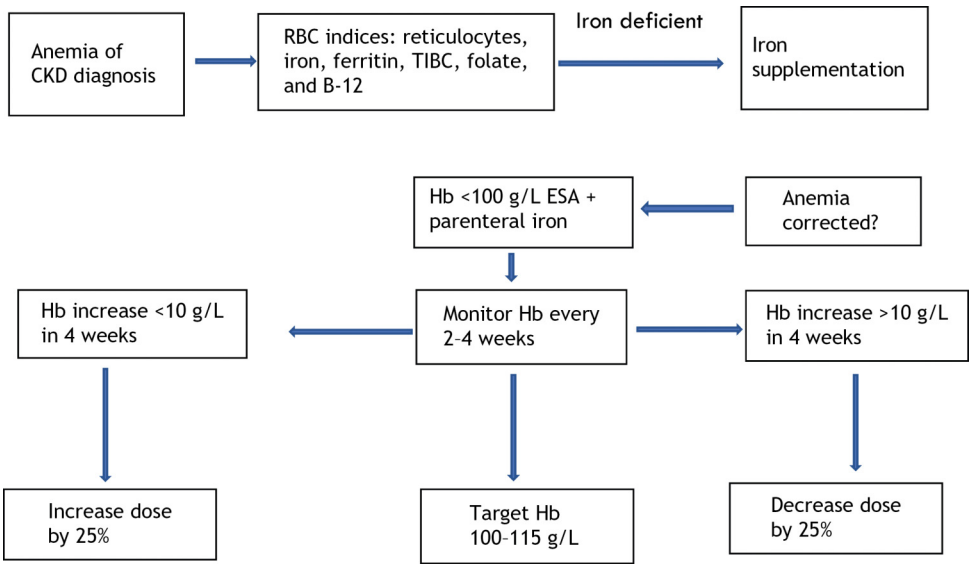

Figure 1 Algorithm for the management of anemia of CKD (Kidney Disease: Improving Global Outcomes (KDIGO) Anemia Work Group, 2012).

Erythropoiesis stimulating agents (ESAs) (e.g., epoetin alfa and beta, and darbepoetin alfa) are administered to reduce transfusions in anemic CKD patients. A target Hb of 100–115 g/L is reasonable to avoid premature and excessive ESA use (Kidney Disease: Improving Global Outcomes (KDIGO) Anemia Work Group, 2012). Higher Hb concentrations are associated with adverse CVD events and it is recommended that Hb concentrations should not exceed 130 g/L (Phrommintikul et al., 2007; Pfeffer et al., 2009; Kidney Disease: Improving Global Outcomes (KDIGO) Anemia Work Group, 2012). It is also important not to correct Hb rapidly, with current recommendations targeting to correct Hb no >10 g/L every 2–4 weeks (Phrommintikul et al., 2007; Kidney Disease: Improving Global Outcomes (KDIGO) Anemia Work Group, 2012). Additionally, iron sufficiency should be present, defined as transferrin saturation > 20% and ferritin >100 ng/mL, before ESA therapy is initiated (Kidney Disease: Improving Global Outcomes (KDIGO) Anemia Work Group, 2012). Maintenance of ESAs includes individualized dosing and using the lowest dose of ESA enough to reduce the need for red blood cell transfusions and adjusting dose as appropriate.

It is important that ESA dosing should be monitored with Hb monitoring every 2–4 weeks during the initiation phase and monthly during the maintenance phase in dialysis patients and every 3 months in non-dialysis patients (Kidney Disease: Improving Global Outcomes (KDIGO) Anemia Work Group, 2012). Patients BP and iron studies should also be monitored. Dosing adjustments should be made in increments of 25% upward or downward according to the current dose. In practice practitioners often consider spacing out the ESAs to counter the rapid rise in Hb (Kidney Disease: Improving Global Outcomes (KDIGO) Anemia Work Group, 2012). For example, darbepoetin may be administered every 3 weeks at the same dose instead of every 2 weeks if the rise in Hb is rapid or approaching 115 g/L rather than withholding treatment (**Fig. 1**).

ESAs: Four ESAs are available in Australia—Epoetin alfa, beta, darbepoetin, and methoxy PEG epoetin beta (Australian Medicines Handbook, 2018). All ESAs are clinically equivalent and different only in their frequency of administration (Australian Medicines Handbook, 2018). Iron deficiency is the most common cause of erythropoietin resistance; however, the increased use of intravenous iron products has reduced this problem. Infection and inflammation, chronic blood loss, hyperparathyroidism, aluminum toxicity, folate or vitamin B-12 deficiency, malignancies, malnutrition, hemolysis, and vitamin C deficiency may also be some of the factors associated with ESA resistance (Kidney Disease: Improving Global Outcomes (KDIGO) Anemia Work Group, 2012).

Bone and Mineral Disorders

Disturbances in bone and mineral metabolism is common in CKD patients and include abnormalities in the parathyroid hormone, calcium, phosphorous, vitamin D, fibroblast growth factor-23 (FGF-23), bone turnover, as well as soft tissue calcification (KDIGO, 2009). These abnormalities historically were known as renal osteodystrophy (ROD). However, the clinical, biochemical, and imaging abnormalities identified as correlates of ROD are defined more broadly these days by the syndrome CKD-mineral and bone disorder (CKD-MBD) (KDIGO, 2009). The spectrum of skeletal abnormalities seen in ROD includes the following: the bone abnormalities include osteitis fibrosa cystica (high bone turnover disease), osteomalacia (low bone turnover disease), adynamic bone disease, osteopenia/osteoporosis, combination of these abnormalities termed as mixed ROD, and other abnormalities with skeletal manifestations (chronic acidosis, β2-mircoglobulin amyloidosis). CKD-MBD is the main cause of morbidity and mortality in patients undergoing dialysis (KDIGO, 2009).

Table 10 KDIGO categories in CKD (Kidney Disease: Improving Global Outcomes (KDIGO) CKD Work Group, 2013)

GFR category	*Terms*	*GFR (mL/min/1.73 m^2)*
G1	Kidney damage with normal or high GFR	≥90
G2	Kidney damage with mildly decreased GFR	**60–89**
G3a	Mildly to moderately decreased GFR	**45–59**
G3b	Moderately to severely decreased GFR	30–44
G4	Severely decreased GFR	15–29
G5	Kidney failure	<15

The pathophysiology of CKD-MBD is complex and is typically apparent in categories G3 to G5 (KDIGO, 2009) (**Table 10**). Calcium and phosphorous homeostasis is mediated through calcitriol, FGF-23 on the bone, GI tract, kidney, and parathyroid gland (Gutierrez, 2010). CKD results in reduced phosphate elimination, which results in hyperphosphatemia and in turn reduces serum calcium concentration. Hypocalcemia stimulates the secretion of PTH by the parathyroid glands, while hyperphosphatemia increases PTH synthesis and release through its direct effects on the parathyroid gland. PTH increases calcium reabsorption by the distal tubules, reduces phosphate reabsorption in the proximal tubules of the kidney, and increases calcium mobilization from bone (Roberts and Singer, 2010). FGF-23 production in bone also increases in response to high phosphate levels and promotes phosphate excretion by the kidney. The result is a relative normalization of calcium and phosphorus, in the early stages of CKD. The increase in PTH, although notable when GFR is <60 mL/min/1.73 m^2 (0.58 mL/s/m^2), worsens as kidney function further declines. As kidney function declines further, the initial adaptive increments in FGF-23 and PTH become maladaptive and abnormalities in calcium and phosphorus worsen. Over time the negative effects of sustained hyperparathyroidism on bone results in a spectrum of bone and other mineral disorders together known as CKD-MBD (Gutierrez et al., 2008; Gutierrez, 2010; Roberts and Singer, 2010).

It is also important to note the role of calcitriol (1-α, 25-dihyroxycholecalicferol) in CKD-MBD. As kidney disease progresses the concentration of calcitriol, which is the active form of vitamin D, also reduces due to the loss of 1-α-hydroxylase activity in the kidney (Roberts and Singer, 2010). Calcitriol promotes intestinal absorption of calcium and also has a direct suppressive action on PTH production.

The resultant vitamin D deficiency leads to reduced intestinal calcium and phosphorus absorption and worsening hyperparathyroidism (Roberts and Singer, 2010). Calcitriol deficiency can also occur due to increase in FGF-23. Deficiency in 25(OH) vitamin D is also common in patients with CKD due to decreased dermal synthesis of vitamin D, decreased exposure to sunlight, and reduced dietary intake of vitamin D (Gutierrez et al., 2008; Gutierrez, 2010; Roberts and Singer, 2010). These abnormalities of CKD-MBD lead to alterations in the structural integrity of bone and other associated consequences. Disturbances in phosphate metabolism have been linked to adverse clinical outcomes, including CVD and death among patients undergoing dialysis (KDIGO, 2009). Several studies have reported an increase in calciphylaxis or rapid calcification of subcutaneous tissues, in patients with CKD-MBD, elevated phosphate, and warfarin use (Nigwekar et al., 2015). Medications used as phosphate binders, in particular calcium-based binders, have been associated with coronary artery calcification. Hence, it is important to consider all consequences of elevated PTH, calcium, and phosphorus, not just their effects on bone (KDIGO, 2009; Roberts and Singer, 2010; Nigwekar et al., 2015).

Clinical management of CKD-MBD is based on repeated measurement of circulating laboratory values, specifically PTH, calcium, and phosphorus concentrations, and therapeutic interventions using combinations of phosphate binders, cholecalciferol and calcitriol, and calcimimetic agents that are dose adjusted to keep these biochemical parameters within specific target ranges, while minimizing potential side effects of the various therapies (KDIGO, 2009). Treatment considerations also depend on the stage of CKD, the mechanism of action.

CKD-MBD-related symptoms are insidious in onset where patients may experience fatigue and musculoskeletal and GI pain, calcification may be visible on radiography, and bone pain and fractures can occur if progression is left untreated (KDIGO, 2009; Roberts and Singer, 2010). Treatment goals are summarized in **Table 11** (KDIGO, 2009).

Nondrug therapies for CKD-MBD include dietary phosphate restriction of 800–1000 mg/day in stage 3 or higher (KDIGO, 2009). Parathyroidectomy is generally reserved for patients with unresponsive hyperthyroidism. Patients generally require phosphate-binding agents despite being on dialysis (depending upon the modalities) as it would be insufficient to maintain phosphate balance (KDIGO, 2009). Common phosphate binders used include calcium-based phosphate binders such as caltrate

Table 11 CKD-MBD treatment goals

	CKD stage 3	*CKD stage 4*	*CKD stage 5*	*CKD stage 5 on dialysis*
Corrected calcium	Normal	Normal	Normal	Normal
Phosphorus	Normal	Normal	Normal	Near normal
Intact PTH	Normal	Normal	Normal	2–9 times upper normal

or cal-sup, and sevelamer (Renagel), while lanthanum (Forenol), sucroferric oxyhydroxide, and aluminum hydroxide may also be used (Australian Medicines Handbook, 2018). Occasionally, phosphate-binding agents may be combined for their additive effect and achieve the desired target levels (KDIGO, 2009).

Calcium-based phosphate-binding agents are widely used as phosphate binders especially in the pre-dialysis patients as they are cheaper. They act by binding to phosphorus in the gut. Hence, they are to be taken with meals to be effective (Australian Medicines Handbook, 2018). Occasionally, calcium may also be used as a supplement as hypocalcemia occurs sometimes in patients with CKD which typically is prescribed away from meals. However, it has to be used with caution to avoid hypercalcemia.

Sevelamer, a nonabsorbable phosphate binder, is one of the most commonly prescribed drugs in patients with CKD. It binds to dietary phosphate and is consider primary therapy in patients on dialysis. It is generally well tolerated and can also lower LDL-cholesterol and increase HDL-cholesterol while in some patients may worsen metabolic acidosis (Australian Medicines Handbook, 2018). Lanthanum, a flavorless chewable tablet, is another phosphate-binding agent that has similar indications to sevelamer but is not widely used as sevelamer. It can be considered if the patient has hypercalcemia. Sucroferric oxyhydroxide is made up of iron-oxyhydroxide complex, sucrose, and starches. The iron complex is insoluble and binds to phosphate. It is a newer drug with no long-term safety data (Australian Medicines Handbook, 2018). Aluminum hydroxide is best avoided because of the risk of aluminum toxicity (encephalopathy, adynamic bone disease, and erythropoietin resistance). However, it may be used as a short-term (4-week) course when serum phosphate is not adequately controlled by other measures. Currently, there is no data indicating that one phosphate binder is superior over the other in terms of reducing mortality or hospitalizations. However, sevelamer and lanthanum have shown to cause less hypercalcemia and reduce calcium burden (KDIGO, 2009).

Vitamin D and vitamin D analogues are often used in the management of CKD-MBD mainly to suppress PTH synthesis and concentrations. However, they have to be used with caution as they can increase hypercalcemia (KDIGO, 2009; Roberts and Singer, 2010). Calcitriol, which is the pharmacologically active form of vitamin D (1,25-dihydroxy cholecalciferol), is used in the management of CKD-MBD mainly to treat hypocalcemia and to prevent and treat secondary hyperparathyroidism. Studies have shown that calcitriol is effective in reducing hypocalcemia; however, it does not significantly reduce PTH concentration. The major limitation of using calcitriol is hypercalcemia that will have to be monitored closely (Australian Medicines Handbook, 2018). Paracalcitriol, which is a Vitamin D analogue, is indicated for the prevention and treatment of secondary hyperparathyroidism has a lower incidence of causing hypercalcemia compared to calcitriol but is used less often (Australian Medicines Handbook, 2018).

Calcimimetics such as cinacalcet that attach to the calcium receptor on the parathyroid gland with resultant increase in sensitivity of the receptors to serum calcium concentrations thereby reducing PTH concentrations is indicated for secondary hyperparathyroidism in dialysis patients with high calcium, phosphate, and PTH. Studies in dialysis patients have shown that cinacalcet is effective in significantly reducing PTH, calcium, and phosphate. However, a recent trial (EVOLVE) has shown that cinacalcet did not significantly reduce all-cause mortality or CV events in patients with stage 5 CKD (Chertow et al., 2012). Hence, the drug has been delisted from the pharmaceutical benefits scheme (PBS) in Australia. Cinacalcet is partially metabolized by cytochrome P450 CYP3A4, and there is potential for drug–drug interactions. It also can cause hypocalcemia, hence close monitoring of serum calcium levels are indicated (Australian Medicines Handbook, 2018).

Electrolyte Imbalance in CKD

The ability to concentrate or dilute the urine is usually retained until GFR falls to less than 30%. However, both hyponatremia and hypernatremia can occur in patients with CKD depending upon whether they are fluid overloaded or dehydrated as in the case of elderly patients (Chronic Kidney Disease, 2012; National Institute for Health and Care Excellence, 2014).

The kidneys play a huge role in potassium balance and hyperkalemia is a common problem in patients with CKD. Potassium levels need to be monitored closely and managed appropriately. The management of hyperkalemia is summarized in the previous chapter.

Patients with CKD have a fall in the serum bicarbonate concentration in association with a reduced pH (metabolic acidosis), when GFR falls typically below 20%–25%. The metabolic acidosis results from reduced acid excretion, leading to positive proton balance (Chronic Kidney Disease, 2012; National Institute for Health and Care Excellence, 2014). The electrolyte pattern seen with metabolic acidosis of CKD is often of the high anion gap variety, but frequently a hyperchloremic (nonanion gap) or combined high anion gap and nonanion gap pattern can be observed. The degree of acidosis is usually mild to moderate but in most cases serum bicarbonate concentration remains stable unless there is a significant decline in kidney function. It is important to note that acidosis can worsen hyperkalemia and depending upon the severity of CKD sodium bicarbonate may be supplemented to correct acidosis (Chronic Kidney Disease, 2012; National Institute for Health and Care Excellence, 2014).

Treatment Options for ESKD

The progression of CKD to ESKD would necessitate either dialysis or transplant to survive. Indications for commencing RRT include (Chronic Kidney Disease, 2012; Chen et al., 2018):

- A: Acidosis (not responsive to bicarbonate)
- E: Electrolyte abnormality (hyperkalemia, hyperphosphatemia)
- I: Intoxication (e.g., lithium, salicylate)

Table 12 Different treatment options for patients at Stage 5 CKD

Treatment	*Types*	*Involves*	*Lifestyle impact/outcomes*
Transplant	Living donor	Surgery	Freedom to work and travel once stabilized
	Deceased donor	Lifetime immunosuppressants	Less dietary restriction
		May involve long waiting times	High infection rates and cancer
Peritoneal dialysis (PD)	Continuous ambulatory peritoneal dialysis (CAPD)	Four exchanges daily, performed manually	Need PD catheter Freedom to work and travel Good quality of life Risk of peritonitis
	Automated peritoneal dialysis (APD)	Overnight exchange by machine	Not suitable for everyone
Hemodialysis (HD)	Home HD	Need to create permanent access (arteriovenous fistula)	Long training Good flexibility with work Slightly better outcomes
		Can be performed daytime (4–6 h each) or nighttime (8 h each) 3–5 treatments weekly	
	Center-based HD	Need to create permanent access (arteriovenous fistula)	Strict routine Dietary restriction
		Hospital/satellite-based treatment	Transport to hospital/satellite center
		3 times a week (4–6 h each)	Less flexibility with work and travel
Supportive care	No dialysis or transplant Palliative care team Managed in the community	Medication and diet control	In older people with comorbidities no greater benefit with dialysis compared to supportive care

- O: Fluid overload (pulmonary edema)
- U: Uremia (pericarditis and weight loss)

Patients and their families/carers should receive sufficient information and education regarding the nature of stage 5 CKD, and the options for the treatment to allow them to make an informed decision about the management of their condition. Dialysis initiation and its timing should be a shared decision between physician, patients, and family members, and should be tailored to the individual patient's needs. Patients need to be referred to a nephrologist in a timely fashion to allow adequate pre-dialysis care and planning. Planning is required for dialysis initiation when a patient's kidney function declines to CKD stage 4 (eGFR < 30 mL/min/1.73 m^2). While the intent of this chapter is not to exhaustively compare and contrast the different options, a brief overview of the different options available is presented in **Table 12** (Chronic Kidney Disease, 2012).

Role of Pharmacist

Drug therapy problems (DTPs) are very common in patients with stages 1–5 CKD and patients undergoing dialysis. On average patients with end-stage renal diseases undergoing hemodialysis are prescribed 12 medications and present with around six comorbidities (Manley et al., 2003; Manley et al., 2004). Additionally, the rates of nonadherence to prescribed oral medication are as high as 67% (Schmid et al., 2009).

Pharmacists being medication experts are in an ideal position to contribute in this area of management for CKD patients. Pharmacists' activities that have strong association with improved patient outcomes include participating in ward rounds, interviewing patients, performing medication reconciliation (prescription, nonprescription, herbal, and nutritional supplements), discharge patient counseling, and post-discharge follow-ups (Kaboli et al., 2006). Calculation of creatinine clearance and adjusting the dose of renally cleared medications (**Table 13** [Chronic Kidney Disease, 2012]) based on the degree of kidney function is a routine activity clinical pharmacists' carryout on a day-to-day basis in hospitals. Appropriate measures should also be taken for patients with CKD to decrease the risk of nephrotoxicity from radiocontrast agents, antibiotics such as aminoglycosides, as well as nonsteroidal anti-inflammatory drugs and ACEIs. Specialist renal pharmacists are also involved in providing education to other healthcare professionals on management of some of the complications of CKD (Stemer and Lemmens-Gruber, 2011a,b; Qudah et al., 2016). A systematic review of eight controlled trials involving CKD patients demonstrated that clinical pharmacist interventions improved the management of anemia, blood pressure, and lipids, as well as calcium and phosphate parameters (Salgado et al., 2012). These studies showed that clinical pharmacists' interventions in CKD patients were able to reduce hospital admissions and length of hospital stay (Stemer and Lemmens-Gruber, 2011a,b; Salgado et al., 2012; Qudah et al., 2016).

Although not mandated to be part of the care team, renal pharmacists are active members of the care team in some CKD and especially dialysis settings in the United States, Australia, and the UK inclusion of renal pharmacists have resulted in reduction in DTPs. Pharmacists involvement in the management of patients with CKD is very well defined and standardized in Canada as listed in **Tables 14 and 15**.

Table 13 Some examples of medications/medication classes that require dosage adjustment or are to be avoided in renal impairment (Chronic Kidney Disease, 2012)

Drugs/drugs class	*Agents requiring dosage adjustment*
Antibiotics	Almost all parenteral antibiotics require dosage adjustment (exceptions: ceftriaxone, clindamycin, linezolid, metronidazole, macrolides, nafcillin)
Anticoagulants	Enoxaparin, fondaparinux, apixaban, rivaroxaban, dabigatran
Cardiac medications	Atenolol, ACEI, ARBs, digoxin, Spironolactone[a], fibrates, rosuvastatin
Pain medications	Codeine, tramadol, pethidine, morphine, hydromorphone, and other agents may also require adjustment
Neurological agents	Gabapentin, pregabalin, lithium, topiramate, vigabatrin, levetiracetam
Antidiabetic drugs	Gliptins (except linagliptin), exenatide, insulins, metformin, gliflozins, glibenclamide+, glimepiride+
Others	Allopurinol, H_2 receptor antagonists, NSAIDs[a]

[a]Avoid if <30 mL/min; + does not require dosage adjustment but shorter acting ones are preferred.

Table 14 Standard of clinical practice for renal pharmacists (Raymond et al., 2013)

The pharmacist *must* perform these core clinical activities on fully staffed weekdays[a] (in order of priority):

1. Attend all MRP clinics (includes PD, home and rural HD, and CKD stages 1–5 clinics, total of 24 half-day clinics per week):
   a. Review laboratory test result and medication for all patients
   b. Document in health record any recommendations, suggestion, or further patient information required for patients not seen by a pharmacist
   c. For patients seen by a pharmacist, generate best possible medication history and perform medication reconciliation (National Kidney Foundation, 2002) by a pharmacist
2. Attend multidisciplinary patient care rounds (twice weekly for HD and PD patients):
   a. Contribute to interprofessional discussion about patients.
   b. Identify admitted patients for discharge medication reconciliation.
   c. Identify patients for medication review by a pharmacist.
3. Perform discharge (and transfer) medication reconciliation for admitted patients receiving dialysis before discharge or at first subsequent dialysis session (HD patients only) (National Kidney Foundation, 2002):
   a. Reconcile inpatient medication with home and in-center HD medications.
   b. Perform detailed medication review and document recommendation in the patient's medical record.
   c. Write discharge prescription for medication, including appropriate medications for in-center HD and new medications started in hospital contact prescribing nephrologist to make recommendations and confirm prescription
   d. Provide patient with medication card and counseling.
4. Review monthly laboratory test results for HD patients.
5. Perform detailed medication review for new starts to HD or PD within 2 weeks.
6. Perform detailed medication review for other patients.

The pharmacist will perform the following "must do activities" (prioritized according to pharmacist's professional judgment):

- Ensure follow-up laboratory tests are ordered, according to pharmacist's recommendation.
- Ensure patient have adequate prescriptions and refills.
- Liaise with community pharmacy as appropriate (e.g., to facilitate prescription delivery, compliance aid, and drug coverage)
- Liaise with patient, caregivers, family members, and other healthcare professionals as appropriate to provide medication-related information to or for patients.
- Provide drug information for immediate patient care that day.
- Provide education to pharmacy students and residents.
- Provide monitoring and follow-up for recommendation.[b]
- Provide communication between MRP and other pharmacists within the facility.[b]

The pharmacist shall perform the following desirable activities as appropriate and as pharmacist is available:

- Participate in MRP and pharmacy program initiatives (e.g., development of drug protocols review of preprinted orders, participation on committees, development of policy and procedures, and responses to drug shortages).
- Provide education-related activities to healthcare professionals.
- Provide communication between MRP and other pharmacists at other facilities.
- Provide drug-use management activities, including prospective audits.
- Participate in projects or research.
- Investigate medication incidents or errors.
- Review or triage medication orders to identify drug therapy problems related to appropriateness, duration, and dosing of each medication, as well as drug interaction (as an activity separate from medication review, medication reconciliation, or MRP clinic visit).

CKD = chronic kidney disease, HD = hemodialysis, PD = peritoneal dialysis.

[a]Evening HD patients are reviewed and seen by pharmacists who work later shifts periodically, in order that all patients are seen by a pharmacist. Weekend pharmacist coverage consists of centralized dispensary pharmacist coverage at each site.

[b]When the pharmacy is short-staffed, these are considered "should do" (rather than "must do") activities.

Table 15 Steps in review of patients with chronic kidney disease for drug therapy problems (Raymond et al., 2013)

General medication review:
- For new dialysis patients, before nephrologist review or clinic visit (every 6 months to 1 years) or at the request of another healthcare professional
- Interview patient, caregivers, family members, and other healthcare professionals
- Generate best possible medication history and perform medication (National Kidney Foundation, 2002)
- Review laboratory test results, investigations, physical findings, and medications to identify DTPs
- Documents medication review, DTP, and recommendation in the medical record
- Identify and resolve actual/potential DTPs during discharges, medication reviews, clinic visits, between clinics visits (after review of laboratory test results), on medication order review, or detailed medication review

Assess patient for general DTP (Mathew and Corso, 2009; Hanlon et al., 2011; Johnson et al., 2012a,b; Tonelli et al., 2012; World Health Organization, 2013; Keith et al., 2004)
- Allergies and intolerances
- Drug–drug interaction
- Adverse drug reactions
- Medication causing or exacerbating a symptom
- Duplication of pharmacological or therapeutically similar medications
- Appropriate dosage form and route of administration
- Medication therapy not indicated
- Medication indicated but not utilized
- Medication adherence
- Problems related to IV administration
- Medication that require renal dose adjustments
- Medications that are contraindicated in CKD or that should be minimized
- Medication that are no longer required in dialysis

Assess patient for DTPs specific to CKD by assessing the following:
- *Anemia*: assess hemoglobin, transferring saturation, ferritin, use of erythropoietic-stimulating agent, iron, and renal multivitamin consider erythropoietin hyporesponsiveness (Johnson, 2004; National Kidney Foundation, 2012; Phoon, 2012; Inker et al., 2014; National Institute for Health and Care Excellence, 2014; Tomino, 2014).
- *Mineral and bone disease*: Assess corrected calcium, serum phosphate, parathyroid hormone, alkaline phosphatase, albumin, calcium bath concentration, phosphate and calcium additives to the dialysate, surgical history (for parathyroidectomy), use of phosphate binders, vitamin D analogue, or cinacalcet. Liaise with dietitian about diet (Lopez-Novoa et al., 2010; Gajjala et al., 2015).
- *Cardiovascular risk*: Assess for presence of cardiovascular disease and risk factors, and therapies to reduce this risk (antiplatelets, proteinuria, antihypertensives, statins, antianginal therapies, and antiarrhythmics) (Richards et al., 2008; Gajjala et al., 2015; Australian Medicines Handbook, 2018).
- *Hypertension and proteinuria*: Assess blood pressure before, during, and after dialysis, in clinic and at home, assess dry weight, proteinuria, antihypertensives, and antiproteinuric therapies (KDIGO Blood Pressure Work Group, 2012; Richards et al., 2008; Gajjala et al., 2015; Australian Medicines Handbook, 2018).
- *Diabetes mellitus*: Assess glucose monitoring before and after dialysis, in clinic and at home, as well as glycated hemoglobin and use of hypoglycemic agents (Wanner et al., 2005; Palmer et al., 2012; National Kidney Foundation, 2014; Gajjala et al., 2015).
- *Pain*: Assess source of pain, its quantity and quality, and use of opioids, NSAIDs, and adjunctive therapies (Palmer et al., 2013; Saran et al., 2015).
- *Peripheral neuropathy*: Assess source of pain, its quantity and quality, and use of antidepressants, anticonvulsants, and opioids (Ardhanari et al., 2014).
- *Restless leg syndrome*: Assess symptom severity and frequency, sleep disturbance, daytime fatigue, and use of dopamine agonists, gabapentin, levodopa, benzodiazepines, and opioids (Go et al., 2004; Vanholder et al., 2005).
- *Smoking status*: Assess readiness to quit and use of nicotine replacement therapy, bupropion, or varenicline provide education (Australian Institute of Health and Welfare, 2010).
- *Cramps*: Assess symptom severity and frequency, as well as use of quinine or vitamin E (Choi et al., 2014).
- *Pruritus*: Assess symptom severity and use of topical or systemic agents.
- *Gastrointestinal issues (e.g., reflux, history of bleeding, ulcer, dyspepsia, constipation, diarrhea)*: Assess signs and symptoms, as well as use of antacids, laxatives, stool softeners, agents to treat diarrhea, NSAIDsor corticosteroids.
- *Infectious diseases (e.g., IV catheter-related infection, skin infection, peritonitis) requiring treatment or prophylaxis, including antibiotic locks and intraperitoneal antibiotics*: Assess signs and symptoms, as well as culture and sensitivity results (Phrommintikul et al., 2007; Jelkmann, 2011; Kidney Disease: Improving Global Outcomes (KDIGO) Anemia Work Group, 2012).
- *Hyperkalemia (for stages 1–5 CKD patients)*: Assess serum potassium, presence of hemolyzed sample, and use of potassium supplements, ACE inhibitors, ARBs, potassium-sparing diuretics, and other agent known to increase serum potassium. Assess use of potassium-binding resins and diuretics. Liaise with dietitian regarding diet (Pfeffer et al., 2009)
- *Metabolic acidosis (for stages 1–5 CKD patients)*: Assess serum bicarbonate concentrations and use of supplementation (Gajjala et al., 2015).
- *Depression, anxiety, and insomnia*: Assess consultations with other healthcare professionals and use of antidepressants, antipsychotics, benzodiazepines, and sedatives (KDIGO, 2009).
- *Gout (for patients with stages 1–5 CKD)*: Assess serum uric acid level, frequency and severity of gout attacks, and use of xolchicine, NSAIDs or corticosteroids, allopurinol, and febuxostat (Gutierrez, 2010).
- *Review patient for the use of the following high-alert medication*: Digoxin, lithium, phenytoin, and immunosuppressive therapy.
- Assess serology and vaccination status for hepatitis B, pneumonia, and influenza (Roberts and Singer, 2010; Gajjala et al., 2015).

ACE, angiotensin-converting enzyme; ARB, angiotensin receptor blockers; CKD, chronic kidney disease; NSAID, nonsteroidal anti-inflammatory drug.

Currently, although there are some studies that demonstrate the evidence of pharmacist' interventions in CKD patients, the literature is sparse, of variable quality and with heterogeneous outcomes. With the best available evidence, pharmacists' intervention may have a positive impact on CKD patient outcomes (Salgado et al., 2012). Therefore, future pharmacists' intervention in CKD patients should be well documented and conducted in robust study designs to demonstrate the actual benefit on clinical outcomes.

Management of Endocrine Disorders and the Pharmacist's Role: Adrenal Insufficiency

Arianne N. Sweeting[*,†], **Elizabeth L. Chua**[*,†], [*]Royal Prince Alfred Hospital, Sydney, Australia; [†]University of Sydney, Sydney, Australia

Learning Objectives

- Understand the critical role of the adrenal gland in regulating energy, salt, and fluid homeostasis via the production of the glucocorticoid cortisol and the mineralocorticoid aldosterone.
- Understand the need for lifelong glucocorticoid and mineralocorticoid replacement therapy in adrenal insufficiency and the clinical signs and symptoms suggestive of under-replacement or over-replacement of therapy.
- Understand the necessity of increasing the glucocorticoid dose in times of medical and surgical stress to prevent adrenal crisis.
- Understand that acute adrenal crisis is a life-threatening medical emergency requiring immediate treatment.
- Understand the importance of patient, family, medical and other health care providers education on sick day management planning and glucocorticoid stress dosing to prevent acute adrenal crisis and optimize quality of life.

Take Home Messages

- Adrenal insufficiency is defined as primary, secondary, or tertiary depending on whether the problem arises at the level of the adrenal gland, pituitary gland, or hypothalamus, respectively.
- Primary adrenal insufficiency is defined by loss of cortisol, aldosterone, and androgen production.
- Secondary or tertiary adrenal insufficiency is defined by loss of cortisol production only.
- Treatment involves adequate replacement of deficient hormones to prevent acute adrenal crisis, associated complications, and improve quality of life.
- Acute adrenal crisis is a life-threatening medical emergency requiring immediate treatment and glucocorticoid replacement is the most important aspect of initial resuscitation.
- Ongoing education of the patient, their family and clinical practitioners on glucocorticoid replacement, appropriate sick day management, including instructions on glucocorticoid dose increases during intercurrent illness, stress or surgery, use of emergency hydrocortisone injector kits in an emergency, when to present to the Emergency Department, and the importance of wearing a Medic-Alert or equivalent identification at all times, forms the cornerstone of management of adrenal insufficiency.

Introduction

Adrenal insufficiency is an important endocrine disorder, characterized by deficient glucocorticoid (cortisol) production by the adrenal cortex. Deficient mineralocorticoid (aldosterone) and adrenal androgen production is also a feature of primary adrenal insufficiency (PAI or Addison's disease). Adrenal insufficiency can be either primary (PAI), secondary (SAI), or tertiary (TAI), depending on whether the cause arises at the level of the adrenal gland, pituitary gland, or hypothalamus. Regardless of the etiology, untreated adrenal insufficiency is lethal given the central role of cortisol and aldosterone in energy, salt, and fluid homeostasis. Consequently, acute adrenal crisis is a life-threatening medical emergency. Despite the seriousness of this condition, the diagnosis of adrenal insufficiency is often missed or delayed due to its generally subacute, nonspecific clinical features. Importantly, once diagnosed, adrenal insufficiency can be treated with lifelong replacement pharmacotherapy. The central role of pharmacotherapy in the management of adrenal insufficiency includes the appropriate dose of oral glucocorticoid and mineralocorticoid maintenance therapy and ongoing patient, family, medical, and other health care provider education on sick day management planning and glucocorticoid stress dosing to prevent acute adrenal crisis and optimize quality of life.

Epidemiology and Etiology

Primary Adrenal Insufficiency

PAI has a reported incidence of approximately 4 per 1 000 000 per year (Bornstein et al., 2016). Up to 90% of PAI in developed countries is due to autoimmune adrenalitis (Bornstein et al., 2016). Autoimmune adrenalitis is characterized by autoimmune destruction of the adrenal cortex, with sparing of the adrenal medulla. Steroid 21-hydroxylase antibodies are detected in most patients with PAI (Betterle et al., 2002).

Congenital adrenal hyperplasia (CAH) is a group of autosomal recessive disorders generally caused by mutations in *CYP21A2*, the gene that encodes adrenal steroid 21-hydroxylase. As this enzyme is needed for the conversion of the precursors for cortisol and aldosterone production, mutation results in impaired cortisol synthesis and adrenal insufficiency (Speiser et al., 2018).

X-linked adrenoleukodystrophy (X-ALD) is another rare genetic disorder caused by mutations in the *ABCD1* gene that result in accumulation of very long chain fatty acids in various tissues, including the central nervous system, testes and adrenal cortex (Suryawanshi et al., 2015). Involvement of the adrenal cortex results in impaired steroidogenesis, leading to PAI.

Infectious adrenalitis is the most common cause of PAI in developing countries (Melmed et al., 2016). Tuberculosis, cytomegalovirus, acquired immunodeficiency syndrome (AIDS) and fungal infections are all associated with PAI.

Hemorrhage or adrenal vein thrombosis leading to bilateral adrenal infarction is another important cause of PAI (Rao et al., 1989). This is most commonly iatrogenic in the context of critical illness, for example, due to coagulopathies including the heparin-induced thrombocytopenia syndrome, and in those with underlying sepsis or trauma. The antiphospholipid syndrome and meningococcal sepsis are also strongly associated with adrenal hemorrhage (Caron et al., 1998).

Metastases to the adrenal gland, most commonly from primary lung and breast neoplasms or lymphoma, may lead to PAI if there is sufficient destruction of the adrenal gland, although this is uncommon. Infiltrative diseases such as sarcoidosis, amyloidosis, and hemochromatosis have also been associated with PAI.

Pharmacotherapies including the anticonvulsant aminoglutethimide, the anesthetic etomidate, the antifungal ketoconazole, in addition to metyrapone and mitotane, may also cause PAI by inhibiting glucocorticoid synthesis (Jabre et al., 2009; Schoneshofer and Claus, 1985; Sonino, 1987; Wagner et al., 1984). In addition, pharmacotherapy that activates or accelerates glucocorticoid metabolism by inducing hepatic cytochrome P450 enzymes, such as the anticonvulsant phenytoin and carbamazepine, the barbiturate phenobarbital, the antibiotic rifampicin, and St John's wort can also cause adrenal insufficiency in the setting of impaired or borderline hypothalamic-pituitary-adrenal (HPA) axis function, for example concomitant exogeneous glucocorticoid therapy (Bornstein, 2009).

Secondary and Tertiary Adrenal Insufficiency

Conditions that disturb the HPA axis (**Fig. 1**) at the level of the pituitary gland or hypothalamus can lead to SAI or TAI by disrupting adrenocorticotropic hormone (ACTH) and corticotropin-releasing hormone (CRH) secretion, respectively. The HPA axis deficiency may be isolated or occur in association with other pituitary hormone deficits.

Pituitary adenomas arising within the sella are the most common cause of hypopituitarism and are generally benign (Regal et al., 2001). Most adenomas are either nonfunctioning or prolactin-secreting (prolactinomas). Hypopituitarism may be apparent at presentation due to mass effect of the adenoma or be iatrogenic following pituitary surgery. Craniopharyngiomas are the most common suprasellar tumors and are associated with panhypopituitarism and diabetes insipidus. Other space occupying lesions such as gliomas, metastases, and primary hematological malignancies such as leukemia and lymphoma can also lead to hypopituitarism—either via direct infiltration and destruction or secondarily due to treatment.

Infiltrative disease, for example sarcoidosis and hemochromatosis, are also associated with hypopituitarism. Lymphocytic infiltration causing autoimmune (lymphocytic) hypophysitis is an increasingly important cause of SAI. This is associated with isolated destruction of the ACTH producing cells of the pituitary gland. The advent of immunomodulatory therapy such as the human anticytotoxic T-lymphocyte-associated protein-4 (anti-CTLA-4) antibody ipilimumab and the antiprogrammed cell death 1

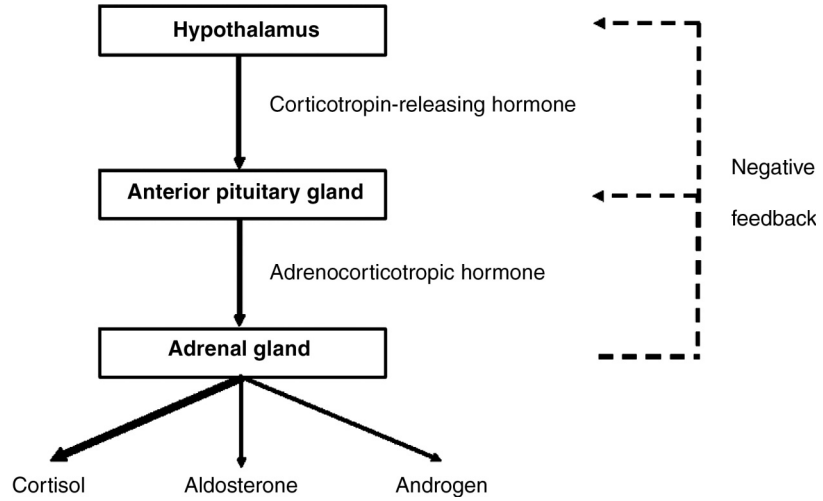

Figure 1 The hypothalamic-pituitary-adrenal axis.

(anti-PD-1) antibody pembrolizumab for metastatic melanoma and other solid organ malignancies has been associated with a significantly increased incidence of autoimmune hypophysitis (Faje et al., 2014; Faje, 2016; Lam et al., 2015; Sweeting and Chua, 2015).

Sheehan's syndrome is classically associated with pregnancy and postpartum hemorrhage causing severe hypotension and resultant pituitary ischemia and hypopituitarism. Pituitary apoplexy similarly results from hemorrhage or infarction, generally arising from a preexisting pituitary adenoma. Most cases occur spontaneously; however, reported precipitating factors include closed head trauma, hypo- or hyper-tension, previous cranial irradiation, anticoagulant therapy, and dopamine agonists (Nawar et al., 2008).

Traumatic brain injury and cranial irradiation for tumors or hematological malignancy distant to the hypothalamic-pituitary axis is associated with significant rates of irreversible and progressive hypopituitarism, with a reported prevalence of any degree of hypopituitarism of 66% (Appelman-Dijkstra et al., 2011).

Pharmacotherapy is another important cause of SAI and TAI. The most common cause is long-term administration of exogenous glucocorticoid therapy, which can include oral, inhaled and even long-term dermal routes (Lee et al., 2015; Woods et al., 2015). Opioids have multiple acute and chronic effects on several endocrine axes, primarily mediated via κ-receptors in the hypothalamus and pituitary. Opioids are associated with both isolated reversible ACTH deficiency and gonadal hormone deficiency, with time to recovery dependent on duration of opioid exposure (Vuong et al., 2010). The causes of adrenal insufficiency are summarized in Table 1.

Table 1 Causes of adrenal insufficiency

Primary adrenal insufficiency
Autoimmune adrenalitis
Infection
• Tuberculosis, AIDS, fungal—cryptococcosis, histoplasmosis
Hemorrhage
• Meningococcal sepsis, antiphospholipid syndrome
Infiltrative disease
• Lymphoma, amyloidosis, and hemochromatosis
Bilateral adrenalectomy
Genetic
• Adrenoleukodystrophy, congenital adrenal hyperplasia, and adrenal hypoplasia congenita
Drug-induced
• Anticoagulants (heparin, warfarin)
• Tyrosine kinase inhibitors (sunitinib)
• Aminoglutethimide
• Ketoconazole, fluconazole, and etomidate
• Phenobarbital
• Anticonvulsants (phenytoin, carbamazepine)
• Rifampicin

(*Continued*)

Table 1 Causes of adrenal insufficiency (*cont.*)

Secondary adrenal insufficiency
Space occupying lesions or trauma • Pituitary tumors, sella or suprasellar tumors—adenomas, Rathke's cleft cyst, craniopharyngiomas, and gliomas • Malignant infiltration/Neoplasm—brain tumors, hematological malignancy (leukemia, lymphoma), and lung/breast metastases • Trauma (pituitary stalk lesions)
Pituitary surgery for pituitary tumors or other neurological tumors
Irradiation • Cranial, pituitary, nasopharyngeal carcinoma
Autoimmune • Immunomodulatory therapy (Ipilimumab, Pembrolizumab, and Nivolumab), classic lymphocytic hypophysitis
Infection • Tuberculosis, meningitis
Infiltration • Granulomatous diseases (Sarcoid, Wegener's granulocytosis), Langerhan's cell histiocytosis, hemochromatosis
Infarction • Apoplexy, Sheehan's syndrome
Traumatic brain injury • Acute insult, subarachnoid hemorrhage, and cerebrovascular event
Congenital • Pituitary hypoplasia/aplasia, genetic mutations (Prader-Willi Syndrome)
Drug-induced • Abrupt withdrawal of glucocorticoid therapy (systemic or topical), opioids
Tertiary adrenal insufficiency
Space occupying lesions or trauma • Craniopharyngiomas or metastases • Surgery or irradiation for central nervous system or nasopharyngeal tumors
Infection • Tuberculosis, meningitis
Infiltration • Lymphocytic hypophysitis, hemochromatosis, sarcoidosis, and histiocytosis X
Trauma, injury (fracture of skull base)
Drug-induced • Abrupt withdrawal of glucocorticoid therapy (systemic or topical) • Mifepristone • Chlorpromazine • Imipramine

Clinical Presentation of Adrenal Insufficiency

The clinical presentation of adrenal insufficiency may be either acute or chronic depending on its severity, rate of onset, and underlying cause. In general, the development of adrenal insufficiency is gradual, and its clinical features are nonspecific. Thus, the diagnosis is often delayed until an intercurrent illness precipitates an acute adrenal crisis.

The signs of chronic adrenal insufficiency predominantly arise from glucocorticoid and mineralocorticoid deficiency—the latter a feature of PAI only, as mineralocorticoid production by the zona glomerulosa of the adrenal gland is preserved in SAI. Signs include orthostatic hypotension due to dehydration, and electrolyte abnormalities such as hyponatremia, hyperkalemia, metabolic acidosis, and increased urea concentration. Abnormalities in the full blood count including anemia, lymphocytosis and eosinophilia may occur, in addition to hypoglycemia and increased liver transaminases.

As the mineralocorticoid activity of the adrenal gland is intact in SAI and TAI, hypotension is generally less severe, and hyperkalemia does not occur. Hypoglycemia is however common, due to the ACTH deficiency and associated growth hormone deficiency. Other pituitary hormone deficiencies may also be present. Mass effect signs and symptoms such as headaches or visual field deficits arising from a space occupying lesion, hemorrhage or infiltrative disease may also be present.

Table 2 Clinical presentation of adrenal insufficiency

- Lethargy
- Dizziness
- Postural hypotension
- Nausea and vomiting
- Weight loss
- Hypoglycemia

Symptoms of adrenal insufficiency include salt craving, anorexia, weakness, malaise, fatigue, muscle cramps, arthralgia, nausea, vomiting, abdominal pain, and diarrhea or constipation. Adrenal insufficiency may also be associated with psychiatric symptoms including depression, anxiety, memory impairment and psychosis. Hyperpigmentation of the skin, particularly in sun exposed areas and mucous membranes, is a characteristic feature of PAI, reflecting the stimulation of the melanocortin-1 receptor resulting from the increased secretion of ACTH and other pro-opiomelanocortin peptides. Deficiency of adrenal androgen secretion in PAI is clinically more apparent in women, and results in loss of axillary and pubic hair, loss of libido, amenorrhea, dry skin, and pruritus. The clinical symptoms and signs of adrenal insufficiency are summarized in Table 2.

Acute adrenal insufficiency, or an adrenal or Addisonian crisis, is a medical emergency. Acute adrenal crisis is defined primarily by hypotension and shock, altered level of consciousness, marked biochemical derangement, and often low-grade fever. Other symptoms of chronic adrenal insufficiency including anorexia, nausea and vomiting, abdominal pain and malaise may also occur. Epidemiological studies suggest an incidence of between 5 and 10 adrenal crises per 100 patient years, which is lethal in 1 in every 200 patients (Allolio, 2015). It most commonly occurs in PAI. In patients with undiagnosed PAI, acute adrenal crisis may occur when they are subjected to serious infection or acute, major stress. In patients with known PAI, acute adrenal crisis may occur in those who do not take additional glucocorticoid during infection, major illness or surgery; due to persistent vomiting caused by gastroenteritis or other gastrointestinal disorders; in patients who are abruptly withdrawn from both oral and inhaled doses of glucocorticoid; or following bilateral adrenal hemorrhage or infarction. Acute adrenal crisis is an increasingly common presentation of immunomodulatory therapy-related autoimmune lymphocytic hypophysitis. Acute adrenal crisis may also complicate SAI during acute stress or surgery.

Diagnosis of Adrenal Insufficiency

The diagnosis and type of adrenal insufficiency is established by the presence of low serum cortisol in combination with plasma ACTH, which may be either elevated in PAI or inappropriately normal or low in SAI and TAI. Subsequent investigations should confirm the diagnosis and determine the underlying cause.

It is important to note that the approach to the diagnosis of adrenal insufficiency is guided by the clinical presentation. In acute adrenal crisis, treatment should be initiated immediately even before the results of plasma ACTH and cortisol measurement are available, as delayed treatment is a significant contributor to the excess mortality in acute adrenal insufficiency complicating PAI (Bornstein et al., 2016; Cooper, 2017).

Evidence suggests that adrenal insufficiency can be excluded at early morning cortisol concentrations >450 nmol/L and is likely at levels <100 nmol/L (Grossman, 2010). PAI is defined by raised plasma ACTH and low serum cortisol. Specifically, this should be assessed by simultaneous measurement of morning (0600–0800) serum cortisol and plasma ACTH, as cortisol concentrations are greatest in the early morning and are lowest in the afternoon. A morning cortisol concentration <140 nmol/L and ACTH concentration greater than two-fold above the upper limit of the reference range is consistent with PAI (Bornstein et al., 2016).

The recommended gold standard diagnostic test for PAI is the standard-dose ACTH stimulation test or short synacthen test (Bornstein et al., 2016). This involves the administration of 250 mcg of intravenous (IV) or intramuscular (IM) synthetic ACTH (1–24) with simultaneous measurement of serum cortisol and plasma ACTH at baseline (0 min), followed by serum cortisol measurement at 30 min and at 60 min to assess the response of the adrenal glands poststimulation. Although assay dependent, peak cortisol concentration <500 nmol/L at 30 or 60 min is suggestive of PAI.

In addition, simultaneous measurement of plasma renin and aldosterone can be performed, with increased plasma renin concentration or activity and normal or low aldosterone concentration confirming the presence of mineralocorticoid deficiency in PAI.

Imaging, specifically with a computed tomography (CT) scan of the adrenal glands, should be performed in the absence of adrenal (steroid 21-hydroxylase) antibodies. X-ALD should be considered in males who present with adrenal insufficiency with negative adrenal antibodies.

The diagnosis of SAI is suggested by an inappropriately normal or low plasma ACTH in combination with a low serum cortisol. The presence of other pituitary hormone deficiencies or panhypopituitarism is also supportive of SAI, although isolated ACTH deficiency is a feature of autoimmune hypophysitis. If early morning cortisol concentrations are within the equivocal range (i.e. cortisol concentration greater than 100 nmol/L but less than 450 nmol/L), referral to an Endocrine Centre for a stimulation test such as an Insulin Tolerance Test is recommended to determine if there is an appropriate cortisol rise to stress, in the absence of

contraindications (i.e., seizures or ischemic heart disease) (Grossman, 2010; Sweeting and Chua, 2015). Adequate response is defined as a peak cortisol concentration >550 nmol/L which has doubled from baseline in response to hypoglycemia (blood glucose level <2.2 mmol/L) (Dons, 1998). A short synacthen test may also be undertaken with the caveat that it may fail to detect SAI and TAI of recent onset as the adrenal glands have not yet atrophied. The underlying cause of SAI should be further assessed with a pituitary MRI.

Management of Adrenal Insufficiency

Pharmacotherapy replacement of glucocorticoid deficiency (and mineralocorticoid deficiency in PAI) is the mainstay of treatment for adrenal insufficiency. PAI can be lethal if left untreated - prior to the widespread availability of glucocorticoid therapy, most patients with PAI died within 2 years of diagnosis (Esposito et al., 2017). There are several important considerations regarding the appropriate formulation of pharmacotherapy, dosing regimen, education and monitoring of treatment efficacy.

Acute Adrenal Insufficiency

Acute adrenal insufficiency (adrenal crisis) is a life-threatening complication of adrenal insufficiency and accounts for a significant proportion of mortality associated with this condition (Rushworth et al., 2017). Acute adrenal insufficiency is therefore an emergency requiring immediate treatment. The aim of initial management is to treat the hypotension and electrolyte abnormalities (i.e., hyponatremia and hyperkalemia), and to reverse the glucocorticoid deficiency (Gargya et al., 2016). Immediate administration of parenteral preferably IV hydrocortisone, or IM if no IV access is immediately available, is required. Fifty to 100 mg of IV hydrocortisone 6–8 h is generally recommended (Melmed et al., 2016). Rapid infusion of normal saline is also required, given the associated significant deficit in both sodium and water. Five percent dextrose saline should be added if hypoglycemia is present. Specific mineralocorticoid replacement is not necessary with a total daily hydrocortisone dose ≥50 mg, as this provides adequate mineralocorticoid cover (Charmandari et al., 2010). The presence of an intercurrent illness which may have precipitated the acute adrenal insufficiency (frequently gastroenteritis and flu-like illness) should also be investigated and treated.

Hydrocortisone therapy should be weaned over 3–4 days once the clinical condition has stabilized. A typical regimen would be 50 mg IV 6 h, then 8 h, then 12 h, followed by oral hydrocortisone 40 mg in the morning and 20 mg at 1500–1600. This can then be rapidly weaned to an oral maintenance dose in PAI such as 20 mg in the morning and 10 mg at 1500–1600. In PAI, fludrocortisone 50–100 mcg should be commenced once the total daily dose of hydrocortisone is less than 50 mg.

Chronic Adrenal Insufficiency

Lifelong glucocorticoid and mineralocorticoid replacement therapy is required in PAI, while only glucocorticoid replacement therapy is required in SAI (and TAI). In addition, replacement of other pituitary hormone deficiencies may also be needed in SAI.

Glucocorticoid Replacement

Chronic oral glucocorticoid maintenance therapy should preferably be administered at a dose and timing that mimics the normal cortisol production rate and pattern. A range of possible glucocorticoid preparations and dosages may be used. Either the natural glucocorticoid hydrocortisone or cortisone acetate, which is converted to hydrocortisone in the liver, is preferred. Glucocorticoid formulations such as prednis(ol)one or dexamethasone are not recommended because their longer duration of action has been associated with complications associated with chronic glucocorticoid excess, including reduced bone mineral density, and increased adiposity (Bleicken et al., 2008). The exception is in situations where higher glucocorticoid doses are needed to treat co-existing medical conditions (e.g., rheumatoid arthritis); with prednisone the recommended maintenance therapy. The prednisone dose can be increased during a flare in the underlying medical condition (Electronic Therapeutic Guidelines, 2018). The relative potency and half-life of these various glucocorticoid formulations is summarized in **Table 3**.

Hydrocortisone is generally administered in two to three divided doses with one half to two thirds of the total daily dose taken in the morning, mirroring the physiological diurnal cortisol secretion pattern (Bornstein et al., 2016). Given SAI is associated with some endogenous glucocorticoid production, a low dose twice daily regimen is generally appropriate.

Table 3 Relative potency and half-life of glucocorticoid formulations

Glucocorticoid	*Relative glucocorticoid potency*	*Relative mineralocorticoid potency*	*Equivalent dose for glucocorticoid effect*	*Estimated biological half-life (hours)*
Hydrocortisone	1	1	20 mg	8–12
Cortisone acetate	0.8	0.8	25 mg	8–12
Prednisone	4	0.8	5 mg	18–36
Methylprednisone	5	0.5	4 mg	12–36
Dexamethasone	25–50	0	400–800 mcg	36–54

In a twice daily dosing regimen, two-thirds of the daily dose should be administered in the morning, immediately upon waking, and one-third of the dose should be administered between 1400 and 1500 (Electronic Therapeutic Guidelines, 2018). In a three-daily dosing regimen, 40%–60% of the dose should be administered in the morning, immediately upon waking, 25%–35% of the dose should be taken at midday, and 15%–25% of the dose should be taken in the late afternoon, prior to 1700 (Electronic Therapeutic Guidelines, 2018). It is not necessary to take hydrocortisone with food, and it should not be taken after 1700 as this may cause insomnia and physiological glucocorticoid levels are lower in the evening.

There is no strictly objective clinical or biochemical measure to ascertain the optimal dose of oral maintenance hydrocortisone therapy, and thus this is associated with significant controversy (Torpy, 2017). The standard hydrocortisone tablets available in Australia are 20 mg and 4 mg. The equivalent strengths of cortisone acetate tablets are 25 mg and 5 mg. The traditional fixed hydrocortisone dose of 30 mg daily or cortisone acetate dose of 37.5 mg daily is now considered to be excessive for most adults with PAI and may be associated with reduced bone mineral density (Bornstein et al., 2016).

As patients with SAI may still have some endogenous glucocorticoid production, the replacement dose is generally lower than in PAI. Hydrocortisone doses of 10 mg in the morning and 10 mg in the afternoon, or even lower (e.g., 8 mg in the morning and 4 mg in the afternoon), are frequently used (Sweeting and Chua, 2015).

Studies have shown mean endogenous cortisol production rates of between 5 and 8 mg/m^2 daily, depending on age and body composition, equivalent to oral hydrocortisone replacement of 15–25 mg daily or cortisone acetate 20–35 mg daily (Purnell et al., 2004). Accordingly, weight-based dosing for hydrocortisone and cortisone acetate is increasingly recommended in both PAI and SAI (Mah et al., 2004). Specifically, hydrocortisone maintenance doses of approximately 0.24 mg/kg daily or an equivalent cortisone acetate dose of 0.3 mg/kg daily for PAI, with less required in SAI, is advised (Electronic Therapeutic Guidelines, 2018).

There is no laboratory test to assess the adequacy of glucocorticoid replacement and thus clinical assessment is key. However, serum cortisol day curves may aid glucocorticoid dose adjustment for hydrocortisone or cortisone acetate, although they are not useful for prednisone therapy. Peak cortisol concentration can be measured 2 h postdose. A peak cortisol concentration greater than 700 nmol/L may suggest that the dosage should be reduced (Electronic Therapeutic Guidelines, 2018).

Clinical assessment includes weight and body composition, blood pressure, skin pigmentation, evidence of Cushing's syndrome, and overall well-being (Bornstein et al., 2016). Inadequate replacement may be associated with reduced energy levels, postural hypotension, nausea, abdominal pain, and progressive pigmentation in PAI, whilst over-replacement will lead to weight gain, insomnia, peripheral edema, Cushingoid features and osteoporosis. Bone mineral density should be monitored for osteoporosis.

Mineralocorticoid Replacement Pharmacotherapy

Mineralocorticoid replacement therapy is essential in PAI to maintain intravascular euvolemia and prevent hyponatremia and hyperkalemia. In addition, adequate mineralocorticoid replacement facilitates a lower glucocorticoid replacement dose, thus attenuating the long-term adverse effects of glucocorticoid excess (Esposito et al., 2017).

Fludrocortisone (9-alpha-fluorohydrocortisone) therapy is the treatment of choice, usually at a dose of 100 mcg daily (range 50–200 mcg daily) (Bornstein et al., 2016). Fludrocortisone should be administered as a single dose in the morning, mimicking the peak daily physiological serum aldosterone concentration (Williams et al., 1972).

The dose titration of fludrocortisone is based on more specific clinical signs and biochemical findings than that of glucocorticoid therapy, and includes assessment of body weight, postural blood pressure, serum electrolytes and plasma renin activity. Specifically, blood pressure, serum sodium, and potassium concentrations should be maintained in the normal range, and plasma renin at the upper end of the normal range. For example, postural hypotension, salt craving, elevated plasma renin activity and electrolyte abnormalities indicate inadequate dosing of fludrocortisone therapy; conversely, hypertension, peripheral edema and decreased plasma renin activity suggests that the dose of fludrocortisone should be reduced. Acute adjustments of mineralocorticoid dose are not required for stress or intercurrent illness.

The appropriate dose of fludrocortisone therapy is also dependent upon the concomitant glucocorticoid therapy being used. Specifically, higher doses of fludrocortisone may be needed with prednisone or dexamethasone, due to their lack of mineralocorticoid activity. In contrast, a lower dose of fludrocortisone would be expected when combined with hydrocortisone therapy, given hydrocortisone has some mineralocorticoid activity (**Table 3**).

The dose of fludrocortisone may need to be temporarily increased by 50%–100% in warmer weather or in situations associated with excessive sweating, such as intensive exercise, and increased salt intake should also be recommended (Bornstein et al., 2016). Moreover, in the setting of persisting hypertension where the fludrocortisone dose has already been reduced and/or seems appropriate, antihypertensive pharmacotherapy should be commenced in combination with fludrocortisone (Inder et al., 2015).

Dehydroepiandrosterone

The need for dehydroepiandrosterone (DHEA) or adrenal androgen replacement is not routine in PAI. Nevertheless, it may be considered in premenopausal women with PAI, given the adrenal cortex is the primary source of the androgen precursors DHEA, DHEA sulfate (DHEAS) and androstenedione. A trial of morning oral DHEA replacement dose of 25–50 mg is recommended, titrated by measuring serum DHEAS concentrations in the morning pre-DHEA dose (Bornstein et al., 2016). Some studies report beneficial effects on mood, sexual function, and general well-being in women with PAI treated with DHEA, given androgen deficiency in women may be associated with decreased libido, mood disorders and fatigue (Binder et al., 2009). However, in a meta-analysis and systematic review, DHEA treatment was not associated with any substantial clinical benefit (Alkatib et al., 2009).

Education, Sick Day Management and Stress Dosing

Patient and family education is a critical aspect of the management of adrenal insufficiency, with the primary aim being the prevention of acute adrenal crisis. Even with treatment, the health-related quality of life in those with adrenal insufficiency is often reduced (Løvås et al., 2002), underscoring the importance of appropriate management and education.

Education should be regularly revised and should focus on the need for life-long replacement therapy and the importance of increasing the dose of glucocorticoid therapy during illness and stress. Patients must wear a medical alert (Medic Alert) bracelet or necklace. Patients should also be provided with parenteral glucocorticoid injector kits (i.e., "Acto-O-Vial" 100 mg hydrocortisone IMI) for use in emergencies, such as nausea and vomiting in which oral therapy is unable to be tolerated. The patient and their family should also be taught how to administer these glucocorticoid injector kits, and when to present to the Emergency Department, and this should be discussed at each visit. Useful resources include:

http://slhd-intranet.sswahs.nsw.gov.au/SLHDintranet/videos.html?l=1;
http://www.addisoncrisis.info/emergency-injection/emergency-injection-cortico-steroids-solu-cortef-act-o-vial-two-chamber-ampul/;
https://www.addisons.org.uk/;
https://addisons.org.au/.

A sick day management plan is a useful resource in this regard, detailing the recommended dose increases of glucocorticoid therapy in specific situations and advising when parenteral hydrocortisone should be administered, and when to present to casualty for urgent medical assessment. The "Addison's Angle" is a simple tool which illustrates these important concepts and is shown in Fig. 2.

In general, appropriate glucocorticoid stress dosing for mild illness or surgery, for example febrile illness, mental stress, or dental extraction, is considered two to three times the usual oral maintenance dose. The three by three rule is a useful guide, advising tripling the usual maintenance dose for 3 days or for the duration of mild illness, after which the patient resumes their usual replacement therapy dose (Nieman, 2013). An example of a sick day management plan is shown in **Table 4**.

In addition, 50–100 mg IV hydrocortisone administered immediately prior to minor surgery may also be appropriate. In contrast, regular high dose IV hydrocortisone is required during major illness or surgery, generally at doses of 50–100 mg every 6–8 h (Arlt, 2009), although others advocate lower dosing regimens (Nenke and Torpy, 2014). This dosing regimen can be weaned to the usual maintenance regimen based on the clinical course as detailed in the management of acute adrenal crisis.

Finally, in women with adrenal insufficiency during pregnancy, hydrocortisone should be increased in the later stages of pregnancy, for example by 20%–40% from 24 weeks' gestation, mimicking the physiological increase in serum cortisol during pregnancy due to both increased free cortisol and cortisol binding globulin levels (Bornstein et al., 2016). Fludrocortisone may also need to be increased due to the progressive rise in maternal progesterone concentration during pregnancy, which acts as a mineralocorticoid antagonist, although the increase in hydrocortisone replacement may be sufficient (Lebbe and Arlt, 2013). Intrapartum, women require IV saline and a similar IV hydrocortisone regimen as for major illness and surgery. Hydrocortisone can, however, be rapidly weaned to maintenance doses immediately postpartum.

Current and Future Trends

Given that adrenal insufficiency remains associated with increased morbidity and mortality even with treatment, the potential of glucocorticoid formulations that may better reflect physiological diurnal cortisol patterns have recently been evaluated. A novel once-daily oral hydrocortisone dual-release tablet, compared with the standard formulation and dosing regimen for oral

Table 4 An example of a sick day management plan for patients with adrenal insufficiency

Issue	*Symptoms*	*Temperature*	*Dose adjustment*	*Duration of oral dose adjustment*
Trivial illness	e.g. mild cold	No temperature (less than 37.4°C)	No change	N/A
Mildly unwell	e.g. mild infection (such as cystitis) with low grade temperature	37.5–38.5°C	2× normal oral dose	Until recovery plus 1–2 days
More unwell	e.g. high fevers	>38.5°C	3× normal oral doset	Until recovery plus 2 days
	e.g. gastroenteritis with vomiting ± diarrhoea or pneumonia etc	Could be normal or raised	Early parenteral hydrocortisone (50–100 mg IV bolus followed by 25–50 mg IV every 8 h till the condition stabilizes) then 2–3× normal oral dose	Until recovery plus 2 days
Minor dental procedure (>I h under local anesthetic), significant injury or major emotional stress			2× normal oral dose	24 h
Major surgery or procedure with general anesthetic			Parenteral hydrocortisone (50–100 mg IV bolus at induction followed by 25–50 mg IV every 8 h till stable) then 2× normal oral dose	Continue for 48 h post procedure

From (Gargya et al., 2016)

hydrocortisone, provided a sustained serum cortisol profile 0–4 h-post dose, with decreased late afternoon and evening and 24-h cortisol exposure (Johannsson et al., 2012; Nilsson et al., 2017). Furthermore, the novel formulation was associated with a small but significant reduction in mean weight, blood pressure, and improved glucose and lipid metabolism in patients both with and without preexisting diabetes. Based on these findings, the modified release oral hydrocortisone formulation (Plenadren) is now available in Europe as both 5 and 20 mg modified release tablets.

However, it is important to note that the modified release formulation does not mimic the gradual cortisol increase before wakening, associated prandial increases or frequent pulses of cortisol, and thus only partly mimics the physiological profile of cortisol. Further, the improvements in glucose and lipid metabolism were generally not maintained during 6 months' follow-up (Johannsson et al., 2012). There is also not enough evidence that the novel modified release formulation reduces the excess morbidity or mortality associated with adrenal insufficiency. Thus, further research is needed to determine the optimal glucocorticoid replacement therapy.

Role of Pharmacist

Given the critical role of pharmacotherapy in the treatment of adrenal insufficiency, the pharmacist has an important role in the management of this condition. In particular, the pharmacist should play an active role in patient education, emphasizing the importance of adherence, including the appropriate timing of glucocorticoid replacement. In the setting of concomitant pharmacotherapy that may inhibit steroidogenesis or accelerate glucocorticoid metabolism, or when the patient with adrenal insufficiency is unwell, the pharmacist should advise the patient of the need to increase their glucocorticoid dose. It is also important to educate the patient regarding the fact that their glucocorticoid therapy is in fact replacement therapy, rather than being used as anti-inflammatory therapy, ensuring that can be taken on an empty stomach, and thereby alleviating concern over possible adverse effects associated with chronic glucocorticoid use. The pharmacist should ensure that the patient has an emergency hydrocortisone injector kit, is confident in its administration, and that it is not expired. Furthermore, it is important to understand the difference between hydrocortisone vials for general parenteral use as compared with an emergency hydrocortisone injector kit, which is specifically designed for the treatment of acute adrenal crisis.

Conclusions

Adrenal insufficiency is an important endocrine disorder in which lifelong pharmacological glucocorticoid and (in PAI) mineralocorticoid replacement therapy is required to avoid associated morbidity and mortality. The aims of treatment in adrenal insufficiency are to provide physiological glucocorticoid replacement, minimize over- or under-replacement of glucocorticoid therapy and associated adverse sequelae; improve patient quality of life, and most importantly, prevent life-threatening acute adrenal crisis. Accordingly, education of the patient, family, medical and other health care providers, including the pharmacist, on the importance of compliance with replacement therapy, sick day management and stress dosing of glucocorticoid therapy is essential to achieving these treatment goals. Nevertheless, even with treatment, patients with adrenal insufficiency have increased morbidity and mortality, underscoring the importance of ongoing education in managing this condition and the need to further optimize glucocorticoid replacement formulations, dosing and administration regimens to greater replicate physiological diurnal cortisol patterns.

Management of Endocrine Disorders and the Pharmacist's Role: Diabetes

Ines Krass*, Kreshnik Hoti†, Kevin Mc Namara‡, *University of Sydney, Sydney, Australia; †University of Prishtina, Prishtina, Kosovo; ‡Deakin University, Geelong, Australia

Introduction

Diabetes has been described as an escalating global epidemic, which imposes a huge cost burden on families, communities, and health-care systems. The most recent estimates suggest that worldwide approximately 425 million adults have diabetes and that this will increase to 642 million by 2040 (International Diabetes Federation, 2017). The prevalence is rising rapidly in both developed and developing countries with one in 11 adults diagnosed with type 2 diabetes (T2DM), and over 1 million children and adolescents affected by type 1 diabetes (T1DM) (International Diabetes Federation, 2017). However, the most dramatic increases in diabetes have occurred in Pacific island nations and in the Middle East and North Africa region, which now have the highest prevalence rates in the world. In Polynesia and Micronesia, where prevalence is highest, more than one in five adults have diabetes. In 2014, the annual global health-care costs associated with diabetes were estimated to be 825 billion dollars, disproportionately experienced in middle- and lower-income countries where, between 1980 and 2014, prevalence of diabetes increased by 35% (NCD Risk Factor Collaboration (NCD-RisC), 2016). Much of this burden is driven by the costs of managing the long-term complications such as cardiovascular disease (CVD), kidney and eye disease, and amputations.

The first section of this chapter will present a brief overview of current understandings of the pathophysiology and complications of the various forms of diabetes, the rationale and role of early screening for T2DM and the role of the pharmacist, contemporary evidence-based approaches for the management of diabetes including lifestyle modification, pharmacotherapy, diabetes education, and self-management support. This is followed by an overview of pharmacist roles in the care of people with diabetes, focusing on the elements of pharmaceutical care and disease management support that may be delivered in community pharmacies and other health-care settings and how these may be incorporated into routine practice. The final part of the chapter will examine the evidence of efficacy, effectiveness, and cost-effectiveness of pharmacists' interventions for people with diabetes.

What Is Diabetes?

Disease Definitions

Diabetes is a complex metabolic disorder with varying clinical presentations. The clinical and diagnostic feature common to all is hyperglycemia resulting from damaged or dysfunctional β pancreatic cells.

The current classification of diabetes distinguishes four categories (American Diabetes Association, 2018a).

1. *T1DM is due to autoimmune destruction of β cells leading to absolute deficiency in insulin;*
2. *T2DM; the most common form of diabetes mellitus, characterized by insulin resistance and progressive loss of insulin secretion.*
3. *GDM—carbohydrate intolerance resulting in hyperglycemia of variable severity, with onset, or first recognition, during pregnancy.*
4. *Diabetes due to other causes, for example, MODY; other endocrine diseases, pancreatic diseases (e.g., cystic fibrosis), or iatrogenic causes, for example, corticosteroid therapy.*

Pathophysiology of T1DM and T2DM

T1DM: In a predisposed individual, environmental triggers encountered early in life such as infections, chemicals, and nutrients, are able to activate an autoimmune cascade against pancreatic islet β cells, involving production of both cellular (T lymphocytes) and humoral autoantibodies. The presence of antibodies alone, however, is not diagnostic or prognostic of T1DM since some individuals who are antibody positive will not develop T1DM. In those who will progress to T1DM, early destruction of β cells may be initially compensated through pancreatic reserve. Over time, the progressive destruction of β cells heralds the development of hyperglycemia. Only once the majority of β cells have been destroyed will T1DM develop (Zaccardi et al., 2016).

T2DM: The hallmarks of T2DM are insulin resistance and β cell dysfunction. It has long been believed that insulin resistance predates β cell dysfunction such that early in T2DM, insulin resistance leads to β cell hypersecretion of insulin to compensate ("hyperinsulinemia") and thus maintain glucose homeostasis. Over time, as insulin resistance worsens, the pancreatic cells are unable to compensate leading to frank hyperglycemia, that is, T2DM (Kahn et al., 2014). More recently, it has been understood that because of the operation of a feedback loop between β cells and insulin sensitive tissues, β cell dysfunction is already present at the preclinical stages of T2DM (Kahn et al., 2014). It is the magnitude of reduction of β cell function that determines the degree of hyperglycemia. In T2DM, there are also other types of dysfunction in organs such as the liver, which produces too much glucose, the pancreas where α cells increase glucagon secretion and the gut with reduction in GLP-1 levels and increased intestinal transit time for food and the kidney with increased glucose reabsorption. In adipose tissue (visceral fat), dysregulation of hormones such as adiponectin and the production of inflammatory cytokines contribute to insulin resistance (Cornell, 2012).

Long-Term Complications

Chronic uncontrolled hyperglycemia causes damage to blood vessels and nerves, which leads to long-term complications among people with any form of diabetes. The complications are classified as "microvascular" (due to damage to small blood vessels) and "macrovascular" (due to damage to the arteries). Microvascular complications include eye disease or "retinopathy," kidney disease termed "nephropathy," and neural damage or "neuropathy". In diabetic retinopathy, vascular leakage and ischemia in the retina can lead to blindness and is a leading cause of the condition in adults aged 20–74 years. Diabetic nephropathy is the most common cause of end-stage renal disease in developed countries and also an independent risk factor for cardiovascular morbidity and mortality. Neuropathy is a highly variable complication initially affecting the peripheral nerves. Its associated complications cause significant morbidity and include foot ulceration, amputations, gangrene, sexual dysfunction, and even cardiac arrhythmia leading to sudden death.

The major macrovascular complications include myocardial infarction and stroke. An individual with diabetes has a threefold greater risk of myocardial infarction compared to someone without diabetes (Forbes and Cooper, 2013). The atheroma and myocardial damage are likely to occur at least in part as consequences of hypertension, altered vascular permeability, and ischemia. However, long-term glycemic control remains the best predictor of CVD risk in people with both T1DM and T2DM. Other complications include depression and dementia (Forbes and Cooper, 2013).

Diagnosis

Diabetes may be diagnosed using either a fasting plasma glucose (FPG) or the 2-h plasma glucose (2-h PG) after a 75 g oral blood glucose tolerance test (OGTT) or HbA1c. Criteria for diagnosis are as follows: FPG≥126 mg/dL (7.0 mmol/L); or 2-h PG≥200 mg/dL (11.1 mmol/L) or HbA1C ≥6.5% (48 mmol/mol); or random plasma glucose (RPG) ≥200 mg/dL (11.1 mmol/L) in patient with symptoms of hyperglycemia). Unless there is a clear clinical diagnosis, a second test is required for confirmation (American Diabetes Association, 2018a) HbA1c testing should not be used as the basis for diagnostic testing if any condition is present that leads to a short red blood cell survival time (e.g., anaemia, chronic renal failure, and hemolysis), as this increases the risk of a false negative result.

Diabetes Screening and Prevention

This section will focus on screening for T2DM. For a variety of reasons including the absence of appropriate screening tests for other forms of diabetes, the mainstay of pharmacist screening is with T2DM.

Risk Factors for Diabetes

T2DM develops over time as a result of multiple biomedical, lifestyle, and social risk factors. Nonmodifiable risk factors such as increasing age, ethnicity, genetic variation, and male gender play an important role. A range of modifiable risk factors also act as key risk factors for diabetes onset. Key established risk factors at a population level include obesity, inadequate physical inactivity, suboptimal diet, and gestational diabetes (Bellamy et al., 2009; Wilmot and Idris, 2014). Effective interventions to prevent diabetes typically emphasise lifestyle modification within a structured program (Diabetes Prevention Program Research, 2002; Kosaka et al., 2005; Li et al., 2008; Tuomilehto et al., 2001). Adoption of key goals for modifiable risk behaviors by participants, such as the following evidence-based goals from the benchmark Finnish Diabetes Prevention Study (Tuomilehto et al., 2001), supports improved outcomes:

- losing body weight (typically 5% or more)
- achieving moderate physical activity on a daily basis (30 min or more)
- increasing fiber intake (e.g., 15 g/1000 calories)
- reducing total calories from fat (30% or less energy derived from dietary fat, 10% or less from saturated fats)

A recent meta-analysis suggests that lifestyle interventions lasting 6–24 months can reduce the average risk of diabetes onset long-term by 31% (Barry et al., 2017), with further gains possible from longer interventions (3–6 years' duration). Metformin also appears to also have a significant protective effect against diabetes during short and longer term (Barry et al., 2017), but there are fewer trials compared with lifestyle interventions and it is unclear if a beneficial effect persists after withdrawal of metformin.

The role of certain drugs in stimulating cardiometabolic disturbances and potentially causing increased rates of new-onset diabetes is well known. This is classified as secondary diabetes. Key drug groups implicated include corticosteroids, thiazide diuretics, beta-blockers, atypical antipsychotics (esp. olanzapine, clozapine), and antiretroviral therapies (Anyanwagu et al., 2016). The last two groups have come increasingly under the spotlight—as the life expectancy of patients taking these therapies has increased in recent years, a greater need to consider long-term risks and conduct cardiometabolic monitoring has evolved. Statins have also been implicated, with the level of risk possibly dependent on the dose and individual statin's potency (Anyanwagu et al., 2016). Currently, it is felt that the relative risk of diabetes onset is low, and the clinical benefit of statin use usually warrants continued treatment.

Evidence suggests that a range of other highly prevalent clinical and other factors, for which associations with diabetes incidence are established, may actually have causal relationships with diabetes. Such factors include poor sleep quality and obstructive sleep apnoea, shift work, smoking, socioeconomic status, and low birth weight (Anothaisintawee et al., 2016; Wannamethee et al., 2001; Whincup et al., 2008). The role of social determinants of health such as lack of availability of fresh food and physical activity opportunities at a neighborhood level are increasingly acknowledged as having adverse consequences for risk factor prevalence. More recent research is actively exploring the potential additional role of factors such as environmental pollutants (particularly persistent organic pollutants from pesticides) (Henríquez-Hernández et al., 2017) and the gut microbiome (Moreno-Indias et al., 2014) in diabetes onset.

Screening Tools

Several options now exist to screen for diabetes risk and for undiagnosed diabetes. A number of countries have validated noninvasive diabetes risk scores—either bespoke or adapted—for use in their population to determine likelihood of future diabetes onset, including China, Finland, France, Mauritius, Mexico, the United States, Germany, United Kingdom, India, and Australia (Kengne et al., 2014). These risk scores are largely based on patient self-reported attributes and anthropometric measures of obesity (e.g., BMI, waist circumference). They identify people at elevated risk of diabetes with reasonable accuracy and are highly cost-effective by not requiring use of laboratory or point of care testing. However, it is only appropriate to use such a score if it has been validated for the population of interest. Such scores are widely used as the initial basis for referral to diabetes prevention programs, but clinical judgment needs to be exercised. For example, some who exceed the threshold score largely as a result of points stemming from increased age and gender may already have quite a healthy lifestyle and little to gain from a lifestyle intervention. Attributes of some key international risk assessment tools are outlined in **Table 1** as examples of the similarities and variation that many occur.

It is important to understand the specific attributes of the particular risk assessment tool in use for several reasons. A key consideration is that tools are typically designed or validated for use in particular settings, which may affect feasibility in a pharmacy setting (Noble et al., 2011). Some have been developed for self-administration by patients, others to be administered by health professionals, and some will be designed for population-level use that draws on database information. The score development should be scrutinized to determine what exactly the score is measuring—for example, is it undiagnosed diabetes, high-risk of diabetes, or a combined outcome? Levels of sensitivity (percent with diabetes who receive a positive test result) and specificity

Table 1 Core attributes of several common diabetes risk assessment tools used internationally (adapted from Krass and Armour, 2011; Noble et al., 2011 and individual validation studies). (Bang et al., 2009; Gray et al., 2010; Lindström and Tuomilehto, 2003)

Risk scale	*Country*	*Validation age range*	*Factors included*	*Sensitivity (Se) Specificity (Sp) Receiver operating curve (ROC)*
ADA Diabetes screening score (Bang et al., 2009) Cut point ≥4 (undiagnosed diabetes or prediabetes) Cut point ≥5 (undiagnosed diabetes) Score range −1 to −9	USA	≥20 years	Age, sex, family history of diabetes, history of hypertension, obesity, and physical activity	73% (Se) 57% (Sp) 0.72 (ROC) (using values cut-point ≥4 as the more comparable with diabetes risk scores)
Leicester Diabetes Risk Score (Gray et al., 2010) Cut point ≥12 Score range 0–47	United Kingdom	40–75 years	Age, ethnicity [white European vs. other (predominantly South Asian)], sex, first-degree family history of diabetes, antihypertensive therapy or history of hypertension, waist circumference and body mass index	81% (Se) 45% (Sp)_ 0.72 (ROC)
Finnish Diabetes Risk Score (FINDRISC) (Lindström and Tuomilehto, 2003) Score cut-point >11 Score range 0–26	Finland	35–64 years	Age, BMI, waist circumference, physical activity, daily consumption of fruits, berries and vegetables, history of anti-hypertensive drug treatment, history of blood glucose, and family history of diabetes	66% (Se) 69% (Sp) 0.73 (ROC) (females) 70%(Se) 61% (Sp) 0.72 (ROC) (males)
The Australian Type 2 Diabetes Risk Assessment Tool (AUSDRISK) (Noble et al., 2011) Score cut point >12 Score range 0–36	Australia	≥25 years	Age, gender, ethnicity, and family history of diabetes, hypertension, smoking, fruit and vegetable consumption, history of blood glucose, waist circumference, physical activity	78%(Se) 58% (Sp) 0.75 (ROC)

(percent without diabetes who are correctly identified as such) vary widely and should be understood so that a result can be correctly interpreted for the screening participant (Noble et al., 2011). It is also important to realize that such tools are typically not validated for ongoing monitoring, for example, to determine the effect of an intervention on an individual's risk. If nonmodifiable factors such as demographics are heavily weighted in calculating a risk score, diabetes risk scores may not improve substantially for many making health gains. Similarly, the items included in the final tools may or may not have a direct causal relationship with the diabetes outcome; they are included on the basis of their predictive value alone. Conversely, some items are added to self-administration tools even if they do not add to the discrimination power of the tool—for example, questions about physical activity and vegetable consumption are only added to the Finnish FINDRISC tool to emphasise their importance in diabetes prevention (Lindström and Tuomilehto, 2003).

Tests to screen for undiagnosed diabetes involve measurement of glucose abnormalities using HbA1c, 2-h plasma glucose levels following oral glucose tolerance testing, or fasting plasma glucose (see Section 2.4, diagnostic criteria) (Siu, 2015; The Royal Australian College of General Practitioners, 2016). Where impaired fasting glucose, impaired glucose tolerance, or T2DM is detected, a repeat test should be used to confirm the diagnosis. While increasingly accepted, there remains some concerns about the validity of HbA1c as a population screening tool and so country-specific guidelines should be followed (Incani et al., 2015). Laboratory-standard screening tests are not accessible by pharmacists in most countries, but the availability of point of care HbA1c and capillary blood glucose testing as a preliminary screening tool is increasingly common, particularly in developed countries.

Guidelines for Screening

The most appropriate mechanism for screening will depend upon the national or local health system. In a pharmacy context, best practice for screening typically involves a two-stage process. The first step is to establish if a patient falls into a high-risk group, using one of the risk scores described above where validated for the patient population. Where a risk stratification tool does not exist, local guidelines may recommend other approaches to identifying high-risk groups within the population (e.g., previous history of CVD, aged 45 years or over and obese) (American Diabetes Association, 2018b; The Royal Australian College of General Practitioners, 2016). Step two involves a point of care test for those identified as belonging to a high-risk group. Krass et al. (2007) demonstrated the superiority of two-step sequential screening in pharmacy compared with risk stratification only, with respect to detection of undiagnosed diabetes.

Use of capillary, nonfasting tests in pharmacies often uses random rather than fasting glucose concentrations. If testing regimens are likely to produce less reliable results than their laboratory equivalents, a more conservative referral threshold is probably necessary. Few head-to-head comparisons of different screening models in community pharmacy exist to confirm the key attributes of effective screening, however the Pharmacy Diabetes Screening Trial underway in Australia may provide insights in key areas such as the type of capillary screening test performed (Krass et al., 2017) and performance of certain referral thresholds for diagnostic testing.

Pharmacists' Role in Screening

Globally, it is estimated that over 45% of people with diabetes remain undiagnosed—a large majority (83%) of such individuals are in low- and middle-income countries, but it also remains a challenge in developed countries (Beagley et al., 2014). Given the frequency with which undiagnosed and at-risk individuals visit pharmacies, including those who are otherwise healthy, pharmacists can play an important role in increasing access to screening (Mc Namara et al., 2012).

In general terms, screening intervals for diabetes should adhere to guidelines for the health system. Typically, key international guidelines recommend annual screening for those with prediabetes (American Diabetes Association, 2018c; The Royal Australian College of General Practitioners, 2016), while other individuals without prediabetes should be screened every 3 year from about 40–45 years of age. Country-specific variation regarding screening frequency and when to commence screening often exists for a range of at-risk social and clinical subgroups (e.g., ethnic minorities, history of cardiovascular disease or gestational diabetes, obese individuals, elevated diabetes risk score, or using antipsychotic medication). Pharmacists have a responsibility to provide a professional level of service in terms of ensuring patient privacy and handling of blood products. They should also take the time to interpret the result for patients, indicating the level of risk implied by the results and the reliability of the test. At a minimum, pharmacists should provide brief advice regarding health behaviors to prevent diabetes, and factors that might be implicated in any positive screening or elevated risk score. Because most pharmacists do not have direct access to medical advice or diagnostic testing, assuring continuity of care is especially important if offering screening services. This may extend to direct communication of results in writing to a nominated doctor if the patient consents, especially for positive screenings (Krass et al., 2017)—a large proportion of referred patients fail to attend medical services for further investigation if referral support is not provided. Pharmacists should consider effective referral as an integral part of the screening process. Further training may be required for pharmacists seeking to deliver lifestyle interventions.

Psychosocial Issues

Clear communication including a discussion of the benefits and risk of screening is valued by patients and supports an informed decision to participate. Potential harms from screening include associated time and costs, incorrect diagnosis, and distress associated with a positive screening or diagnosis (Thoolen et al., 2006). Stigma associated with diabetes may also need to be addressed for some individuals—this may be more prevalent in culturally and linguistically diverse groups, or other vulnerable communities. In such communities, challenges with screening may stem from factors such as misunderstanding of the disease, treatment options and prognosis, or where a culture of prevention is not commonplace (Alzubaidi et al., 2015). Poor patient–provider relationships can often delay diagnosis further, even when symptomatic (Alzubaidi et al., 2015). Effective health awareness messages and counseling to complement screening programs may be necessary in such situations.

Guidelines for Diabetes Management

Current Goals of Therapy

Goals of therapy in patients with diabetes are customized and dictated by patients' individual factors such as age, lifestyle, comorbid conditions, lifestyle, and well-being (Endocrinology Expert Group, 2017). This has followed growing awareness of the high prevalence of mental health/well-being issues such as depression, feelings of stigma, and diabetes-related distress. These have adverse consequences in their own right but can negatively impact an individual's capacity to undertake vital self-care activities and need to be adequately managed. However, regardless of these factors, the key goals of therapeutic management for patients with diabetes are to relieve symptoms such as polyuria and polydipsia, control blood glucose levels, prevent acute diabetes complications such as hyperosmolar hyperglycemia and diabetic ketoacidosis, and also prevent and treat chronic complications such as neuropathy, nephropathy and retinopathy, and ischaemic cardiovascular disease (American Diabetes Association, 2018c; Endocrinology Expert Group, 2017). Current best practice recommends that all HCPs involved in caring for people with diabetes adopt a patient-centred approach. Furthermore, choice of therapy is also dependent on drug characteristics and patient preferences. This orients the goal of diabetes pharmacological management toward minimizing medication side effects while ensuring adequate glycemic control (American Diabetes Association, 2018c; Endocrinology Expert Group, 2017; Rossi, 2017). Avoiding hypoglycemia is a priority when designing and reviewing diabetes therapy and its goals. The potential effect of therapy on patients' weight and cost considerations are also important factors that drive the individualization of diabetes therapy and the development and implementation of a diabetes management plan.

Table 2 Treatment targets for patients with diabetes (Endocrinology Expert Group, 2017; The Royal Australian College of General Practitioners, 2016)

T1DM	
HbA1c	≤53 mmol/mol ≤7%
Blood glucose concentration	4–7 mmol/L (fasting and preprandial) 5–10 mmol/L (postprandial)
T2DM	
HbA1c	<53 mmol/mol (7%)[a]
Blood glucose concentration	4–8 mmol/L (fasting and preprandial)[b] <10 mmol/L (postprandial)
LDL-C	<2 mmol/L (primary prevention) <1.8 mmol/L (secondary prevention)
HDL-C	≥1 mmol/L
TC	<4 mmol/L
TG	<2 mmol/L
BP (adults)[c]	≤140/90 mmHg

[a]In patients at high risk of hypoglycemia levels of 64 mmol/mol [8.0%] is appropriate.
[b]In patients at high risk of hypoglycemia levels of 6–8 mmol/L is appropriate.
[c]The target for patients with diabetes and albuminuria/proteinuria is <130/80 mmHg.

Goals of therapy in diabetes should consider individualization of treatment targets and take account of key contributors to diabetes complications. Addressing CVD risk and also improving cardiovascular outcomes are important factors influencing drug choice and goals in patients with diabetes. This is particularly relevant since CVD is the leading cause of death in patients with diabetes (The Royal Australian College of General Practitioners, 2016). Because the majority of patients with diabetes actually die from cardiovascular complications, early and effective management of CVD risk factors, as described in Chapter XX, are also a core focus of management. CVD risk factors are typically already present upon diagnosis of diabetes (Herman et al., 2015).

In both T1DM and T2DM, glycemic targets should be individualized to patients, while ensuring that hypoglycemia is avoided. Treatment targets are summarized in **Table 2**.

Lifestyle Modification

Lifestyle modifications are important in the overall management of all patients with diabetes. In T1DM the dietary principles focus on adequate caloric intake for normal growth and ideal body weight and maintenance of near normal blood glucose levels by balancing food intake with insulin and physical activity. In T2DM lifestyle modification also centres on nutrition and physical activity, but for many people with T2DM weight loss is required to address insulin resistance. As previously discussed, smoking cessation and psychological care are also recommended as part of lifestyle modification interventions where applicable (American Diabetes Association, 2018b).

Following diagnosis of T2DM diabetes, the initial management usually commences with lifestyle modification focusing on both carbohydrate and energy restriction and increase in physical activity for a period of three months, since lifestyle changes alone may result in glycemic control. However, it should be emphasized that for patients with underlying symptoms, those unlikely to achieve goals with lifestyle modifications alone or in patients with consistently high glucose levels, it may be appropriate to commence pharmacotherapy earlier than 3 months. Lifestyle modifications continue to play a significant role in the management of diabetes patients throughout course of disease management, especially in relation to glycemic control and management of CVD risk (The Royal Australian College of General Practitioners, 2016).

Various studies indicate that nutritional interventions based around calories restriction result in HbA1c reductions between 0.3% and 2.0%. Modest persistent weight loss, defined as sustained reduction of 5% of initial body weight, can delay the need for initiation of pharmacotherapy. However, to achieve optimal outcomes in control of glycemia, blood pressure, and lipids, a sustained weight loss of 7% is recommended. This weight loss can be achieved with various programs that result in energy deficit of 500–760 kcal/day (or programs tailored at 1200–1500 kcal/day for women and 1500–1800 kcal/day for men adjusted based on individual baseline body weight) (American Diabetes Association, 2018c).

In relation to physical activity, current recommendations suggest that patients with T2DM benefit from a total of 30 min of physical activity in most days per week (if not all days) (The Royal Australian College of General Practitioners, 2016). In children and adolescents, 60 min/day over 3 days/week of moderate to vigorous intensity activity is recommended. Aerobic exercise has been associated with similar reduction of HbA1c levels (0.73%) compared to single medication use alone (0.9%). Resistance-based exercises are associated with smaller reductions (The Royal Australian College of General Practitioners, 2016). Other major lifestyle modifications are based around reduced sodium intake (especially in patients with comorbidities such as hypertension) and limited

alcohol consumption (≤2 drinks for men and ≤1 drink for women per day). The above lifestyle modifications should be considered in all treatment plans designed for diabetes patients. It should be emphasized that a patient-centred approach toward lifestyle modifications in patients with diabetes should be tailored to achieve realistic goals (American Diabetes Association, 2018c; The Royal Australian College of General Practitioners, 2016).

Pharmacotherapy and Treatment Algorithms

All people with T1DM require insulin replacement therapy either with multiple daily injections (MDI) including basal and bolus inulin or insulin delivered by an insulin pump. In this section, the focus is on T2DM since this is the most common form of diabetes that pharmacists encounter in practice. Pharmacotherapy in T2DM is usually initiated when patients fail to achieve glycemic control approximately 3 months after introduction of lifestyle modification. Short-term insulin to stabilize blood glucose levels may be needed in patients with particularly high levels of blood glucose concentrations and/or in patients displaying significant symptoms (Endocrinology Expert Group, 2017). It is important to note that the risk of irreversible microvascular complications such as glomerular damage and retinopathy can be prevented with a timely initiation of pharmacotherapy in patients with T2DM. To achieve this, it is pivotal not to delay pharmacotherapy, and this can be facilitated by patient motivation to start treatment (Bailey, 2015).

Pharmacotherapy initiation does not replace lifestyle modifications and they should be complementary to each other.

The emergence of new classes of diabetes drugs has resulted in the availability of a wider range of glucose-lowering medicines. The mechanism of action of currently available antihyperglycemic agents is based around eight underlying pathophysiological mechanisms (i.e., "ominous octet"). These are reduction of insulin secretion from pancreatic β cells, increased liver production of glucose, increased secretion of glucagon from α cells in the pancreas, increased reabsorption of renal glucose, impaired glucose uptake by peripheral tissues, insulin resistance in the brain and neurotransmitter dysfunction, heightened lipolysis, and diminished small intestinal incretin effect (Chaudhury et al., 2017). Currently used types of antihyperglycemic agents in T2DM are summarized in **Table 3** including their mode of action, risk of hypoglycemia, weight gain, and considerations in relation to key side effects.

Initiating Pharmacotherapy in T2DM

Provided there are no contraindications, metformin is the drug of choice as monotherapy in patients who have failed to achieve glycemic control after initial introduction of lifestyle modifications. As a drug choice, metformin is safe and can be very useful in

Table 3 Antidiabetic drug classes: their mode of action and key effects (American Diabetes Association, 2018c; Chaudhury et al., 2017; Cornell, 2012)

Class	*Mode of action*	*Hypoglycemia risk*	*HbA1C reduction (%)*	*Weight*	*Adverse effects and considerations*
Biguanides *Metformin*	insulin sensitiser; effects on inhibition of glucose production	No	1–2	Neutral	GI effects common: nausea, diarrhea vitamin B12 deficiency
Sulphonylureas (SU) *glyburide, glipizidem, gliclazide, glimepiride*	increases pancreatic insulin secretion	Yes	1–2	Gain	Nausea, diarrhea, metallic taste, headache, rash
Acarbose	Delay of intestinal absorption of carbohydrates in the small intestine	No	0.5–0.8		Flatulence, diarrhea, abdominal pain
Thiazolidinediones *pioglitazone, rosiglitazone*	Insulin sensitizer; decrease free fatty acid accumulation, reduce inflammatory cytokines, increase adiponectin levels, and preserve β-cell integrity and function	No	0.5–1.4	Gain	Peripheral oedema, headache, dizziness, arthralgia, congestive heart failure, bone fracture, increased LDL (rosiglitazone), bladder cancer (pioglitazone)
GLP-1 analogs *exenatide, liraglutide, albiglutide, lixisenatide, dulaglutide*	Promote glucose-mediated insulin secretion; reduces glucagon secretion and slows gastric motility	No (only in combination with SU)	0.5–1.5	Loss	Thyroid C-cell tumors, nausea, vomiting diarrhoea (common), pancreatitis risk (?)
DPP-IV inhibitors *sitagliptin, saxagliptin, linagliptin, alogliptin*	Reduces degradation of endogenous GLP-1 and GIP	Low (when used with insulin or a SU)	0.5–0.9	No effect	Joint pain, acute pancreatitis runny nose, sore throat, headache, musculoskeletal pain
SGLT-2 inhibitors *canagliflozin, dapagliflozin, empagliflozin*	Inhibits sodium-glucose co-transporter 2, reducing glucose reabsorption in the kidney	Low (when used with a sulfonylurea or insulin)	0.5–0.7	Loss	Genitourinary infections, increased LDL, amputation canagliflozin), bone fracture risk (canagliflozin)

patients who are overweight. It is not expensive and reduces the risk of cardiovascular events. Additionally, compared to the usual next antihyperglycemic choice (i.e., sulfonylureas), metformin also has a better outlook on cardiovascular mortality and impact on patients HbA1c levels and weight (Maruthur et al., 2016). Because it is renally excreted, patients with diabetes who experience decline in renal function while taking metformin need close monitoring. Declining renal function is often present in ageing patients who have had diabetes for a number of years. Leading international guidelines recommend withdrawal of metformin when eGFR declines below 30 ml/min per 1.73 m^2, to avoid the risk of lactic acidosis resulting from a build-up of metformin.

Intensifying Pharmacotherapy in T2DM

There is a chronological decline in the efficacy of oral antihyperglycemic monotherapy, which parallels a decline β cell function. Following failure to achieve glycemic control with metformin monotherapy at optimized doses, a second antihyperglycemic agent is added. Current ADA guidelines suggest that, if metformin is contraindicated or not tolerated, a dual combination therapy may be initiated in newly diagnosed patients with HbA1c levels ≥9% (American Diabetes Association, 2018c). When patients have markedly high blood glucose levels (e.g., in patients with HbA1c levels of ≥10% or 86 mmol/mol or with hyperglycemic symptoms), insulin should be considered as part of any of the combination regimen leaving open the possibility that as the clinical outlook improves, the regimen may be simplified accordingly (American Diabetes Association, 2018c). A meta-analysis comparing the effects of four antihyperglycemic drug-classes introduced as initial therapy (sulfonylurea, basal insulin, GLP-1 analog, and DPP-4 inhibitor) indicated that HbA1c levels are reduced by 0.9%–1.1%, with the second addition (Nathan et al., 2013). If glycemic control is not achieved within 3 months of dual therapy, a third agent is added and if this escalation fails to achieve HbA1c target with another 3 months, then combination injectable therapies are considered (**Fig. 1**). It should be noted that, regardless of addition of other antihyperglycemic agents, metformin therapy should be continued (if tolerated and not contraindicated) due to further glycemic benefits of this continuation.

To guide the initiation and escalation of pharmacotherapy in patients with T2DM, a number of algorithms have been proposed by various professional organizations. In all cases, it is important to note that principles of a patient-centred approach underpin the application of these algorithms. Patient preferences, drug-related adverse effects, comorbidities, body weight, risk of hypoglycemia, and medication cost must all be factored into designing the treatment plan. The continuing emergence of new pharmacological agents and a lack of high-quality studies investigating combination therapies represent important challenges in the development and application of algorithms. **Fig. 1** represents an algorithm that is based around algorithms from the American Diabetes Association (ADA) algorithm for the management of T2DM and the Australian algorithm for blood glucose treatment (American Diabetes Association, 2018c; The Royal Australian College of General Practitioners, 2016).

Self-Management Support

Self-management education and support are essential components of diabetes care. The extent to which an individual is active and able to self-manage their condition positively contributes to the achievement of glycemic targets. The ADA recommends all patients with diabetes should participate in self-management-based activities aimed at facilitating knowledge and skills required in diabetes self-care (American Diabetes Association, 2018c).

Generally, self-management support facilitates patient's self-care behaviors and informed decision-making process through programs which empower patients to engage in their health management and takes into account their preferences (Marrero et al., 2013). These programs should also take into account patients' health literacy level. Providing active patient support is focused on four key stages of transition for patients with diabetes: at point of disease diagnosis, at regular assessments, when patients experience factors with detrimental effects on diabetes (e.g., other health conditions, physical limitations), and also during the transition of care.

Evidence suggests that self-management education and support programs in patients with diabetes result in better HbA1c control, lower weight, and reduced mortality, better coping, improved quality of life, disease knowledge and self-care behaviors, as well as cost savings (American Diabetes Association, 2018c; Chrvala et al., 2002; Cooke et al., 2013; Frosch et al., 2011; Haas et al., 2014; Malanda et al., 2012; Norris et al., 2002; Steinsbekk et al., 2012).

There are various programs aimed at facilitating patients' self-management and education. These programs are usually focused around optimal nutrition, physical activity, hypoglycemia management and avoidance, smoking cessation if applicable, alcohol, blood pressure, lipid management, foot care, sick day management, as well as medication management (American Diabetes Association, 2018c).

An important component of diabetes self-management is self-monitoring of blood glucose (SMBG). SMBG allows patients to review response to therapy and can also guide them in relation to nutrition and physical activity programs. At the time of diagnosis, it serves to enhance an individual's understanding of how their diet, lifestyle, and medication influence their blood glucose levels. Ongoing SMBG is not generally recommended in low-risk patients on oral antihyperglycemics. A Cochrane review concluded that there are limited clinical benefits to continuing SMBG in patients with T2DM (Malanda et al., 2012). SMBG is recommended in patients on insulin and oral antidiabetic drugs causing hypoglycemia (e.g., sulphonylureas), during pregnancy and prepregnancy planning, when major pharmacotherapy and lifestyle modifications occur and when actively monitoring hyperglycemia due to a condition and in situations where HbA1c results are not reliable (The Royal Australian College of General Practitioners, 2016). SMBG monitoring regimens may be intensive involving preprandial and 2-h post prandial measurements with each meal and a

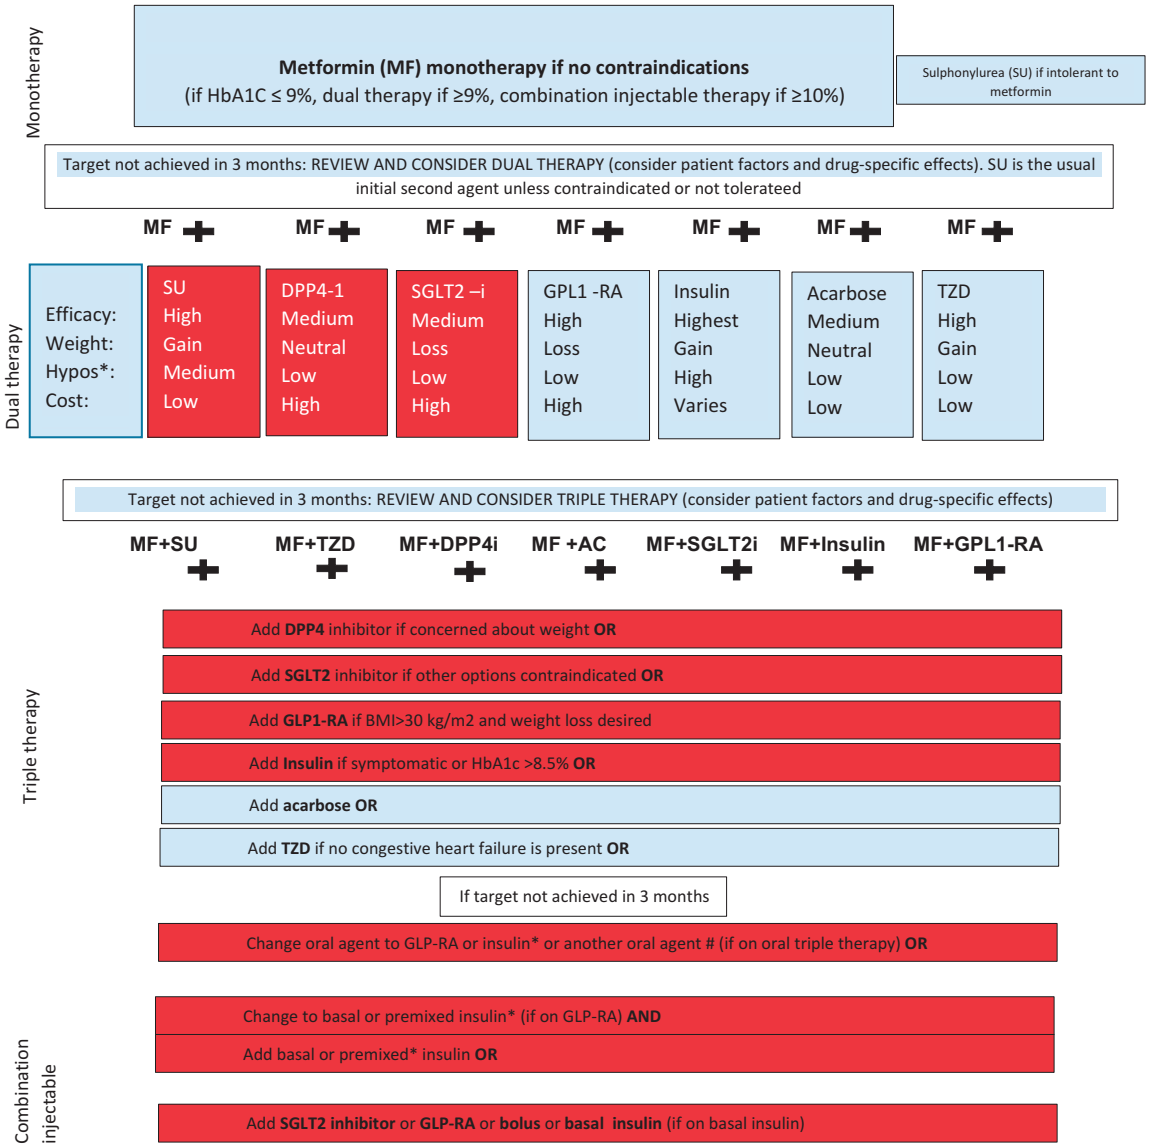

Figure 1 Treatment algorithm for patients with T2DM (American Diabetes Association, 2018c; Hoti, 2016; The Royal Australian College of General Practitioners, 2016). *Note: Red boxes indicate usual therapeutic strategy. MF*, metformin; *SU*, sulfonylurea; *TZD*, thiazolidinedione; *DPP4-i*, DPP-4 inhibitor; *AC*, Acarbose; *SGLT2-i*, SGLT2 inhibitor; *GLP1-A*, GLP-1 analogs (receptor agonists). #smallest effect; *Metformin is usually continued in combination with insulin.

night-time level. Another approach is to vary the time of measurement to different times of the day and repeat measurements on subsequent days at times when BGL is not controlled (pattern management) to determine if this is a pattern and to identify the cause (International Diabetes Federation, 2009).

Pharmacists Role in Diabetes Disease Management Support Through Pharmaceutical Care

Pharmacist Interventions in Diabetes

As a chronic condition, diabetes provides a suitable context through which pharmacists can actively engage in the care of people with diabetes. Pharmacists' medication expertise coupled with easy accessibility of pharmacies places them in an ideal position to assist diabetes patients through active monitoring and provision of pharmaceutical care.

Pharmacist interventions within a pharmaceutical care plan should be systematic because this allows achievement of optimal patient outcomes and fulfillment of treatment goals (Hughes et al., 2017). This approach starts with activities focused around patient assessment (i.e., medical history, physical, laboratory results status, allergies and contraindications, health literacy, and diabetes risk factors), followed by patient treatment plan (i.e., drug-related problem (DRP) screening, individualization,

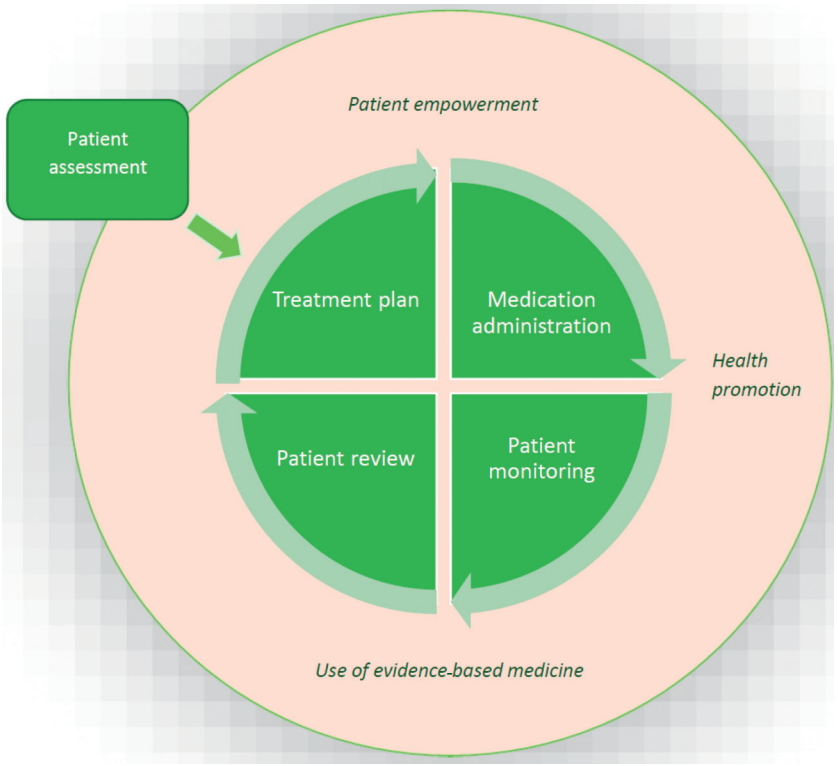

Figure 2 Key steps in delivering systemic pharmaceutical care in patients with diabetes (adapted from Hughes et al., 2017)

and development of treatment plan, patient education), medication administration (including preparation, accurate dispensing and counselling), monitoring (focus on adherence, adverse effects, treatment outcomes, and diabetes complications) and regular review (i.e., results, need for treatment adjustment and referral). These steps are illustrated in **Fig. 2** (Hughes et al., 2017).

Throughout the delivery of pharmaceutical care, pharmacists must ensure that their activities support patient empowerment, incorporate health promotion, and evidence-based medicine. The use of motivational interviewing and collaborative goal setting by pharmacists as complementary strategies to facilitate self-management support have been shown to be effective in improving health outcomes in T2DM (Mitchell et al., 2011). Pharmacists should also endeavour to pursue a multidisciplinary collaborative approach as part of the patient's diabetes care team. A further requirement for delivering diabetes interventions is to provide appropriate conditions and resources to patients with diabetes, including (but not limited to): counseling areas, patient privacy, and necessary accurate equipment such as glucometers, blood pressure meters, and BMI readers.

A number of pharmacist interventions have been documented to improve the overall management of T2DM. Overall, the evidence suggests that pharmacist interventions result in improved patient support and better management and improved glycemic control (Deters et al., 2018; Hughes et al., 2017). More details about the evidence regarding the impact of pharmacists' interventions have been provided in the next section.

Evidence for Impact of Pharmacy Diabetes Interventions Applying the ECHO Model

Any comprehensive evaluation of a pharmacy diabetes intervention requires the ECHO (economic, clinical, and humanistic outcomes) approach, which determines its value as a combination of traditional clinical-based outcomes with more contemporary measures of economic efficiency and quality (Kozma et al., 1993). Evidence for the efficacy and effectiveness of pharmacy diabetes interventions is therefore considered in terms of the ECHO model (Kozma et al., 1993). Clinical outcomes refer to a range of intermediate measures such as HbA1c, FPG, SBP and DBP, BMI, lipids including TC, LDL-C, HDL-C, TG and 10 year absolute CVD risk. Other clinically related impact measures include changes in medication adherence, screening for complications, and/or resolution of drug-related problems (Hughes et al., 2017). Evidence of impacts on more meaningful long-term clinical outcomes such as such as hospitalizations, micro and macrovascular complications is lacking due to the short times frames of pharmacy diabetes intervention studies. Humanistic/social outcomes comprise patient-centred impacts such as health-related quality of life (HRQoL) and diabetes-specific related quality of life, well-being, patient satisfaction, and self-management activities. Economic evaluations typically consider incremental cost-effectiveness of pharmacy diabetes care intervention relative to "usual care" from a third part payer perspective (i.e., government, health insurer).

Clinical Outcomes

Glycemic control

The accumulated evidence for the benefit of pharmacist diabetes interventions on glycemic control comes from several systematic reviews published in the last decade (Hughes et al., 2017). The most comprehensive review, published in 2016, included 36 RCTs conducted across a range of both developed and developing countries and diverse health-care settings including community pharmacy, outpatient clinics, and hospitals. In the 26 studies, which reported an impact on $HbA1_C$, the difference between intervention and "usual care" groups ranged from −1.8% to −2.1% (Pousinho et al., 2016). In this review, 23 studies reported significant reductions in blood glucose (random, fasting, or post prandial) in intervention groups from baseline to follow-up and 20 reported greater improvements in this outcome in intervention compared to control groups (Pousinho et al., 2016). More recently, a meta-analysis of six RCTs of pharmacist diabetes interventions implemented in community pharmacies, which included 670 patients, showed a mean difference in $HbA1_C$ of −0.66% (95% CI −0.86%–0.45%) between intervention and "usual care" groups (Deters, 2018). The differences in effect size between studies may reflect variations in the scope of interventions themselves. The systematic review of community pharmacist diabetes interventions by Deters et al., conducted an analysis of the effectiveness of the different components of pharmacist diabetes interventions. Based on data from 11 RCTs, the most successful components were found to be sending feedback to physicians, individual goal setting, review of medications, and assessing and addressing patient health beliefs and medication knowledge (Deters, 2017). However, the successful components were incorporated to varying extents in each of the studies included in the systematic review. Differences in effect size may also reflect differences in the trial subject characteristics. For example, the higher the baseline glycemic levels and the younger the patient cohort, the greater the impact of the intervention on glycemic control (Hughes et al., 2017).

Cardiovascular—BP, lipids, BMI, absolute CVD risk

On the whole, there is some evidence of positive impacts of pharmacist diabetes interventions on CVD risk factors (Pousinho et al., 2016; Santhschi et al., 2012). In the systematic review by Pousinho et al., there were mixed findings of benefit with statistically significant differences between intervention and "usual care" groups in reductions of SBP and DBP found in only 9/18 studies which measured SBP, 5/15 which measured DBP and 4/15 studies measuring LDL-C and 2/12 studies which included triglycerides. However, a meta-analysis that provides a more robust measure of impact through pooling of data, found that compared with "usual care," pharmacist diabetes interventions were associated with statistically significant reductions in SBP (12 studies with 1894 patients; −6.2 mmHg [95% CI −7.8 to −4.6]); DBP (9 studies with 1496 patients; −4.5 mmHg [−6.2 to −2.8]); TC (8 studies with 1280 patients; −15.2 mg/dL [−24.7 to −5.7]); LDL-C (9 studies with 8084 patients; −11.7 mg/dL [−15.8 to −7.6]); and BMI (5 studies with 751 patients; −0.9 kg/m(2) [−1.7 to −0.1]). No significant change was found in HDL cholesterol. The included studies involved solo delivery of the intervention by pharmacists in 8 studies and in collaboration with physicians, nurses, dietitians, or physical therapists in 7 studies.

Impact on absolute CVD risk was reported in only 6 studies included in the review by Pousinho et al. (2016). The studies used different methods of estimation including UKPDS risk engine, Framingham prediction methods and other prediction charts, which estimate the risk of a cardiovascular event over a 10 year period. An overall decrease in CVD risk was reported in all 6 studies for the pharmacist intervention group between baseline and follow-up and greater improvements compared to the control groups. However, the difference in changes between groups was only statistically significant in 2 studies. Because of different methods of estimation a range of impact cannot be defined (Pousinho et al., 2016).

Medication adherence

Medication adherence has also been shown to improve as a result of pharmacist diabetes interventions; however, a corresponding impact on health outcomes is inconclusive (Omran et al., 2012). A systematic review of RCTs of pharmacist interventions to improve adherence to antidiabetic medication found that while compared to "usual care," 5 of the 8 included studies reported significant improvements in adherence rates with the pharmacist intervention, improvements in glycemic control were found in only 2/8 studies (Omran et al., 2012).

Humanistic/social outcomes

The key humanistic outcome is health-related quality of life (HRQoL). Overall there is conspicuous lack of RCTs of pharmacist diabetes interventions which have included measurement of HRQoL and when included there has been a notable variation in the HRQoL instruments used.

A systematic review evaluating interventions delivered by a pharmacist either alone or as part of a team care arrangement for patients with T2DM found that of the 17 included studies, 12 used generic nonvalidated instruments; and the remainder used a validated generic HRQoL instrument such as the SF-36 or the EQ-5D (Krass and Dhippayom, 2013). Only 6 studies used diabetes-specific HRQoL scales; and one study used both a generic and diabetes specific measure. Thirteen of the 17 studies reported significant improvements in overall or subscale scores post intervention. The effect size varied as did the detail in reporting of overall vs. subscale scores. This variation in effect may be due to the different instruments used, lack of sensitivity of the instruments to subtle effects of the intervention, and/or differences in the nature of the pharmacist diabetes intervention. Because of the different scales used and the level of detail, it is also difficult to compare between studies. Overall, the findings of this (Krass and Dhippayom, 2013) and a subsequent review (Pousinho et al., 2016) suggest some preliminary evidence that pharmacist diabetes

interventions can improve HRQoL with the evidence pointing to a greater effect on mental rather than physical health. Pharmacist diabetes interventions have also been shown to increase patients' knowledge of their condition and its complications and self-management of diabetes (Wubben and Vivian, 2008).

Economic outcomes

Even fewer studies of pharmacist diabetes interventions have examined the economic benefits of this type of pharmacist activity. A recent systematic review identified 25 studies that had conducted some form of economic evaluation in the period between 2006 and 2014. Only 11 were full economic evaluations, which were of moderate quality and most adopted a third-party payer or provider perspective. The studies used a variety of settings, but most were either in community pharmacy or clinic-/hospital-based outpatient facilities. The most common pharmacist diabetes interventions comprised targeted education and general pharmacotherapeutic monitoring. However, variation in the type, mix, and intensity of pharmacist's interventions delivered would necessarily influence the costs (such as labor costs associated with the pharmacist time, costs of medication, which typically increases as a result of medication review, etc.), and thereby affect cost savings or cost-effectiveness. In general, these increased costs are offset by reductions in medical care costs from fewer emergency room visits and hospitalizations. According to the findings of this review, pharmacist-managed services resulted in cost savings ranging from $7 to $65,000 ($8 to $85,000 in 2014 US dollars) per person per year, and generated higher quality-adjusted life years with lower costs, compared with usual care (Wang et al., 2016).

A summary of pharmacists' ley interventions in relation to clinical outcomes and the effect of individual intervention component on HbA1c level have been provided in **Table 4**.

Table 4 A summary of key pharmacists' interventions (Deters et al., 2018; Hughes et al., 2017)

Pharmacist intervention (54)	*Clinical outcome*
Clinical review based around goal setting, HbA1c monitoring, education sessions, adherence sessions	60% vs. 40% controlled HbA1C, −0.3% improvement in HbA1c
Lifestyle education, self-care, and therapy review	HbA1c: +0.2% to −2.1% (vs Control); SBP: −0.5 to −18.6 mmHg; DBP: −0 to −17.4 mmHg; TC: 0 to −39 mg/dL [0 to −1.0 mmol/L]; LDL: −6 to −15.6 mg/dL [−0.16 to −0.40 mmol/L]; HDL: +1.95 to −4.3 mg/dL; TG: −13.0 to −53.4 mg/dL [−0.15 to −0.60 mmol/L]
Education on diabetes, diet and exercise, medication counseling, adherence assessment, and pharmacotherapy adjustment	HbA1c: −0.76% (vs control); FBG: −29.32 mg/dL [−1.62 mmol/L];
Education, communication, regular follow-up, feedback on BG; improved pharmacist–physician communication strategies	Significant improvements in adherence
Medication management, educational interventions to patients, feedback to health-care professional (e.g., DRP identification, recommendation and discussion)	SBP: WMD −6.2 mmHg ([−7.8 to −4.6], studies conducted in community pharmacy greater reduction in SBP (–10.0 mmHg vs –5.5 mmHg); DBP: WMD −4.5 mmHg (−6.2 to −2.8); TC: WMD −15.2 mg/dL (−24.7 to −5.7) [−0.39 mmol/L (−0.64 to −0.15)], LDL: WMD −11.7 mg/dL (−15.8 to −7.6), [−0.30 mmol/L (−0.41 to −0.20)]
Medication management and adherence based interventions, measurement of CVD risk factors	HDL: WMD +0.2 mg/dL (−1.9 to 2.36) [−0.005 mmol/L (−0.049 to 0.061)], BMI: WMD −0.9 kg/m^2 [−1.7 to −0.1]
Counseling and education on diabetes, medication, lifestyle modification, and self-monitoring, medication adherence strategies, screening, DRPs, pharmacotherapy adjustments	HbA1c: −0.18% to −2.1% (vs control); SBP: −3.3 to −23.05 mmHg; DBP: −0.21 to −9.1 mmHg; TC: +18.95 to −32.48 mg/dL [0.49 to −0.84 mmol/L]; LDL: +7.35 to −30 mg/dL [+0.19 to −0.78 mmol/L]; HDL: −5.8 to +11 mg/dL [−0.15 to +0.28 mmol/L]; TG: +12 to −62 mg/dL [0.14 to 0.70 mmol/L]; BMI: Reduced; Adherence: Improved; 10-Year CVD risk: improved

Individual intervention component (55)	*Mean HbA1c (%) reduction*
Medication review and DRP identification	−0.79
Diabetes-related complications (DM)	−0.60
Health beliefs and medication knowledge (DM)	−0.74
Nutrition, exercise, and smoking recommendations (DM)	−0.66
Goal setting (individual)	−0.81
Diabetes knowledge	−0.54
Review of diabetes record books (DM)	−0.74
Blood glucose measurements	−0.70
Medication adherence	−0.60
Patients' satisfaction with pharmacists' interventions	−0.67
Health status	−0.74
Feedback and recommendations to the physician	−0.81

DRP, Drug-related problem; *BG*, blood glucose; *SBP*, systolic blood pressure; *DBP*, diastolic blood pressure; *TC*, total cholesterol; *LDL*, low-density lipoprotein; *HDL*, high-density lipoprotein; *TG*, triglyceride; *FBG*, fasting blood glucose; *BGM*, blood glucose monitoring; *CVD*, cardiovascular disease; *WMD*, weighted mean difference; *BMI*, body mass index; *DM*, disease management.

Documentation of Interventions

When delivering pharmaceutical interventions, it is recommended that pharmacists engage in documentation of patient care. This is crucial to ensure not only continuity of care and patient safety but also to achieve good quality of interventions delivered. Given that diabetes is a progressive condition and also due to the fact that oral diabetes therapy diminishes in efficacy over time, documentation of interventions by pharmacists, in a timely manner, is essential to support the decision making processes during these key stages of diabetes care. Furthermore, documenting these interventions also assists pharmacists in communicating and disseminating patient results to other health-care professionals (HCPs) involved in the patient's diabetes care.

Documentation of pharmacist's care can be achieved through preparation of patient treatment plans, monitoring forms and drug and clinical problem identifications. In general, these documents should enable accurate recording and easy legibility of interventions provided by pharmacists through all stages of intervention and should allow for documentation of all components involved in the documentation, for example, education, patient assessment information, details of treatment plan, medication assessments, medication counseling and administration, DRP identification and other clinical issues identified, action taken and resolution steps, monitoring and regular follow-up details, health promotion activities, screening and risk assessments, and other disease state management details. Various pharmacy professional organizations provide templates or guidelines for pharmacists documenting the above activities aimed at improving patient' diabetes care (Australian Government Department of Health, 2015; Pharmaceutical Care Network Europe, 2017). These are important considerations for inclusion into all forms of design of pharmacists care plans when delivering interventions for diabetes patients.

Conclusion

Pharmacists have a valuable contribution to make to improving health outcomes for people at risk of diabetes, with undiagnosed diabetes and/or those with established disease. Opportunistic screening of "at-risk" people visiting the pharmacy is key to enabling early intervention to prevent the onset of subsequent diabetes and its complications. For people with established diabetes, optimizing the benefits of pharmacotherapy therapy through medication counseling and monitoring for DRPs is a core pharmacist activity. There is, however, a much wider scope for pharmacists' interventions, including self-management education, supporting SMBG, and providing continuity of care and support over time. At each visit to the pharmacy, there is an opportunity to review patient progress, troubleshoot problems, and thereby assist the patient to achieve better control and prevent downstream complications. There is also an opportunity for pharmacists to seek to become a part of the diabetes care team in a model of multidisciplinary health care.

Glossary

Prediabetes The presence of either IFG or IGT
Receiver Operating Curve It is a plot of the true positive rate against the false positive rate for the different possible cut points of a diagnostic test
Sensitivity The ability of a screening test to correctly identify individuals with the condition
Specificity The ability of a screening test to correctly identify individuals who do not have the condition

Abbreviations

ADA	American Diabetes Association
BMI	Body Mass Index
BP	Blood pressure
CVD	Cardiovascular disease
DBP	Diastolic blood pressure
DRP	Drug-related problem
ECHO	Economic, clinical, and humanistic outcomes
FPG	Fasting plasma glucose
GDM	Gestational diabetes mellitus
GLP-1	Glucagon-like peptide-1
HbA1c	Glycated hemoglobin
HCP	Health-care professional
HDL-C	High-density lipoprotein cholesterol
HRQoL	Health-related quality of life
IFG	Impaired fasting glucose

IGT	Impaired glucose tolerance
LDL-C	Low-density lipoprotein cholesterol
MDI	Multiple daily injections
MODY	Mature-onset diabetes of the young
NCD	Noncommunicable disease
OGTT	Oral blood glucose tolerance test
RPG	Random plasma glucose
ROC	Receiver operating curve
Se	Sensitivity
Sp	Specificity
SBP	Systolic blood pressure
SMBG	Self-monitoring of blood glucose
TC	Total cholesterol
TG	Triglycerides
T1DM	Type 1 diabetes mellitus
T2DM	Type 2 diabetes mellitus

Management of Endocrine Disorders and the Pharmacists' Role: Thyroid Disorders

Louise E. Curley*, Joanne C. Lin*, Timothy F. Chen†, *The University of Auckland, Auckland, New Zealand; †The University of Sydney, Sydney, Australia

Learning Objectives

After reading this chapter, the reader should be able to:

- Understand the importance of the hypothalamic–thyroid–pituitary axis and the thyroid hormones triiodothyronine (T_3) and thyroxine (T_4).
- Define the thyroid disorders hypothyroidism and hyperthyroidism and list the common causes of these conditions.
- Discuss the management of hypothyroidism and hyperthyroidism, including the place of medications available for their treatment and side effects, including any pharmaceutical formulation considerations.
- Discuss the current role and the future roles of the pharmacist in the management of thyroid disorders.

Key Concepts

- The thyroid gland and the hormones T_3 and T_4 have an integral role in the functioning of many important systems and processes within the human body, working alongside the nervous system to regulate metabolic processes and heart rate.
- Thyroid function tests (TFTs) are often undertaken if symptoms and signs of thyroid disorder are present.
- As pharmacist roles in independent prescribing become more common, their involvement in management of thyroid disorders is becoming more common.
- In both the community and hospital setting, pharmacists should work with patients to the management of the condition. Pharmacists can support medication taking and encourage patient medicine adherence.
- Advice regarding the management of side effects is also a role of the pharmacist. Advising patients on what to do if a patient experiences side effects will allow medication-related problems to be addressed promptly.

- If the patient wishes, the pharmacist can advise and liaise with the patient's doctor or endocrinologist if further support is needed.
- Pharmacists have a strong role to play in the future of thyroid disorder management. Pharmacists are playing an important role in thyroid clinics and as part of a multidisciplinary team. The role in this area has mainly been around the initiation, maintenance, and modification of medicines for specific individuals who have been diagnosed with thyroid disorders. This role has been conducted under the guidance of written protocols by the chief endocrinologist of the hospital or within an established team.
- The advanced role of the pharmacist in this field is yet to be well-defined; further research needs to be undertaken to evaluate the scope, protocols, and effectiveness of pharmacists in this role.

Introduction to the Thyroid and Thyroid Disorders

The thyroid is the largest endocrine gland in the body; it is a butterfly-shaped gland located at the front of the neck inferior to the Adam's apple (American Association of Clinical Endocrinologists, 2015). It is responsible for a number of functions, including the regulation of metabolism, growth, and homeostasis (American Association of Clinical Endocrinologists, 2015; Jonklaas and Talbert, 2011). The gland consists of two lobes, connected by bridge called an isthmus (Hulisz, 2018). The gland secretes the hormone thyroxine (T_4) and triiodothyronine (T_3) (Jonklaas and Talbert, 2011; Hulisz, 2018; Rousset et al., 2015) and calcitonin (Hulisz, 2018). Reservoirs of these hormones in the gland and in the blood ensure that there is constant availability (Jonklaas and Talbert, 2011). Under- or over-activity of the thyroid gland may negatively affect a number of integral systems and processes within the body, including the cardiovascular, skeletal, and metabolic systems (DeEugenio and Smith, 2004; Freeman, 2009; Jonklaas and Talbert, 2011). Calcitonin has a number of roles including the regulation of calcium homeostasis (Felsenfeld and Levine, 2015; Hulisz, 2018).

Thyroid disorders can range from those that are subclinical and require no intervention, to those that are life-threatening and so requiring immediate intervention. According to the World Health Organization's International Statistical Classification of Diseases and Related Health Conditions 10th revision (ICD-10), *Thyroid gland and Thyroid hormone disorders* sits within the *Endocrine, nutritional and metabolic diseases classification (E00-E07)* (World Health Organisation, 2016). Within this classification, the ICD-10 further differentiates eight thyroid conditions (World Health Organisation, 2016):

- Congenital iodine-deficiency syndrome
- Iodine deficiency-related thyroid disorders
- Subclinical iodine-deficiency hypothyroidism
- Other hypothyroidism
- Other nontoxic goiter
- Thyrotoxicosis (hyperthyroidism)
- Thyroiditis
- Other disorders of the thyroid

The most common of the thyroid disorders and those that the pharmacist is most likely to encounter in daily practice are hypothyroidism and hyperthyroidism. Ultimately the goal of treatment of both hypothyroidism and hyperthyroidism is to achieve a euthyroid state (The Royal College of Physicians, 2011); the background, management, and the role of the pharmacist within hypo- and hyperthyroidism will be discussed in this chapter.

To understand these conditions more fully, it is firstly important to understand the importance of the hypothalamic–thyroid—pituitary axis and the thyroid hormones T_3 and T_4.

The hypothalamic–pituitary–thyroid axis is responsible for the production and the release of thyroid hormones and is sensitive to small changes in circulating levels, which subsequently drive alterations in secretion to ensure that circulating levels are maintained within a narrow range (DeEugenio and Smith, 2004; Freeman et al., 2009; Jonklaas and Talbert, 2011). The hypothalamus produces thyrotropin-releasing hormone (TRH), which subsequently promotes the synthesis and release of thyroid-stimulating hormone (TSH) from the anterior pituitary (Freeman et al., 2009; Jonklaas and Talbert, 2011). The synthesis and release of the main thyroid hormones (T_3 and T_4) occurs when TSH acts on the thyroid gland (Best Practice NZ, 2010; DeEugenio and Smith, 2004). While the thyroid gland produces all of the body's T_4, the majority of T_3 is produced in the liver and the kidney by removing an iodide from the T_4 structure. T_3 is two to three times more potent than T_4, and, therefore, there is less T_3 in circulation (DeEugenio and Smith, 2004; Jonklaas and Talbert, 2011). The axis is controlled and maintained by negative feedback from thyroid hormones at both the hypothalamic and the pituitary levels (DeEugenio and Smith, 2004; Jonklaas and Talbert, 2011). In a person who has a normally functioning system, as T_4 and T_3 concentrations increase, the pituitary and the hypothalamus decrease production of TSH and TRH. This ensures the regulation of thyroid hormone production (DeEugenio and Smith, 2004; Jonklaas and Talbert, 2011).

Thyroid Disorders—An Overview

Prevalence and Etiology

Thyroid disorders have been estimated to represent 30%–40% of presentations in endocrine practice (Garmendia Madariaga et al., 2014). However, the prevalence of abnormal thyroid function is still debated (Canaris et al., 2000), this is mainly due to

differences in the definitions of these disease states and the sample populations that have been evaluated in studies (Canaris et al., 2000). A recent meta-analysis of nine studies in Europe found that there was a 3.82% mean prevalence (when both diagnosed and undiagnosed was taken into consideration) (Garmendia Madariaga et al., 2014). While a US-based study reported the incidence to be 4.78% (Garber et al., 2012). In NZ, it is estimated that 5% of women and 1% of men are affected by thyroid disorders (Best Practice NZ, 2010). Despite this variation, what *is clear* from research is that prevalence is higher in women than in men and the prevalence increases with age (American Association of Clinical Endocrinologists, 2015; Eggertsen et al., 1988; Okamura et al., 1989; Sawin et al., 1979; Vanderpump, 2011).

Hypothyroidism has been strongly associated with dietary iodine (Vaidya and Pearce, 2008); goiter (swelling of the thyroid) and congenital hypothyroidism are prevalent in areas where daily intake of iodine is less than 50 μg and per 25 μg, respectively (Vanderpump, 2011). Remote and mountainous areas of South-East Asia, Latin-America, and Central Africa are areas that are deemed high risk for thyroid disorders (Vanderpump, 2011). Iodization programs have proven beneficial (Rousset et al., 2015); for example, the use of iodized salt in bread became mandatory in Australia and New Zealand in 2009, which rendered the countries iodine sufficient (Walsh, 2016), although there have been reports of iodine deficiency reemerging (Foundation TAT, 2018).

In areas where dietary iodine is sufficient, a common cause of thyroid disorders is thought to be autoimmune (Walsh, 2016). Antithyroid antibodies have been identified and appear to vary across sex, age, and ethnicity. The prevalence of antibodies is greater in females, increases with age, and is greater in whites and Mexican Americans than in African Americans (Canaris et al., 2000; Hollowell et al., 2002). While the presence of antibodies to thyroid peroxidase (TPOAb) and thyroglobulin (TgAb) does not determine whether a patient needs to be treated, it does increase the risk of thyroid dysfunction (Åsvold et al., 2012; Walsh et al., 2010).

Additionally, patients who are at higher risk of thyroid disease include those with other autoimmune diseases, dyslipidemia, past history of neck surgery or irradiation, suspicious thyroid symptoms postpartum or a previous episode of postpartum thyroiditis, chronic cardiac failure, coronary heart disease, arrhythmias, hypertension, elevated pulse of >90 bpm, menstrual disturbance or unexplained infertility, some genetic conditions, and patients who are taking certain medications, for example, lithium, amiodarone (NZ BP, 2005).

In the case of amiodarone, this medication can induce both hypo- and hyperthyroidism, due to its high iodine content and also its ability to have a toxic effect on the thyroid gland. Guidelines vary withregard to the type of monitoring that should be conducted (Best Practice NZ, 2010); however, most do suggest monitoring of TSH while on this medication. An initial rise in TSH may occur in the first 6 months of therapy with iodine, but this should then return to normal range (Best Practice NZ, 2010; NZ BP, 2005). Monitoring should occur prior to starting therapy, every 6 months during treatment and continue for a year after the cessation of the medication, due to its long half-life (Best Practice NZ, 2010).

Lithium can also affect the thyroid and lead to hypo- or hyperthyroidism, although the latter is rare (Best Practice NZ, 2010). Hypothyroidism induced by lithium is common and can occur abruptly. Baseline monitoring of TSH and fT_4 and annual monitoring of TSH are recommended (Best Practice NZ, 2010; NZ BP, 2005).

Consequences of Poorly Managed Thyroid Disorders

Patients whose thyroid disorders are not well managed may be at higher risk of developing associated health problems, including cardiovascular disorders and arrhythmias (Sawin et al., 1994), and have lower bone mineral density and quality (Ross et al., 1987). There has been clear evidence, for example, for poorer outcomes for patients with hypothyroidism and heart failure; hypothyroidism is associated with decreased inotropy, decreased cardiac output, reduced vascular compliance, and hyperlipidemia (Canaris et al., 2000; Heeringa et al., 2008; Iacoviello et al., 2008; Klein and Danzi, 2008; Rodondi et al., 2008; Ziman et al., 2012). The Colorado Thyroid Disease Prevalence study was a study of 25,862 individuals that aimed to determine the prevalence of abnormal thyroid function and the relationship between abnormal thyroid function and lipid levels and symptoms. The authors reported only 60% of patients taking thyroid medication had TSH levels in the appropriate range (Canaris et al., 2000). Additionally, there have been some (albeit preliminary) data that have pointed to subclinical hypothyroidism being associated with hyperlipidemia, cardiovascular disease, and low bone mineral density (Iacoviello et al., 2008; Rodondi et al., 2008; Ross et al., 1987). Hyperthyroidism is also associated negative health outcomes, including an increased risk of atrial fibrillation (Heeringa et al., 2008).

Diagnosis

Diagnostic tests are not warranted if there are no clinical symptoms. In a report by Bandolier (1997), people were categorized based on their clinical presentation as high, moderate, and low risk of hypothyroidism. Subsequently, these individuals' thyroid function was assessed; 78%, 2.9%, and 0.45% of people in the respective groups were found to have a thyroid disorder (NZ BP, 2005; White and Walmsley, 1978).

Serum TSH has been promoted to be the sole initial test for monitoring thyroid dysfunction (American Association of Clinical Endocrinologists, 2012; Best Practice NZ, 2010; NZ BP, 2005, 2007). In normal patients, when TSH is within the reference range (0.4–4.0 mU/L), the free-T_4 (fT_4; the metabolically available moiety of T_4 that is not protein-bound) will in most cases also be within the reference range, and there is no further need to check other hormone or antibody levels (Best Practice NZ, 2010; NZ BP, 2005, 2007).

TSH levels change with age, and some laboratory measurements will take age into account when reporting TSH reference levels (Best Practice NZ, 2010; NZ BP, 2005, 2007). For example, mild elevations in TSH may be normal in the elderly (American

Association of Clinical Endocrinologists, 2012). Due to the vague and often nonspecific symptoms that are associated with thyroid disorders, diagnostic tests are warranted if a thyroid disorder is suspected.

If TSH is not within the reference range, then further testing is warranted. If TSH is high, fT_4 should be checked and if this is normal, antibodies testing could be warranted. Low fT_4 is indicative of hypothyroidism. If TSH is low, then testing of both free-T_3 (fT_3) and fT_4 should be conducted. Elevated fT_3 and/or fT_4 could indicate hyperthyroidism. Normal fT_3 and fT_4 would warrant a clinical review and consider repeating testing in 6 months (Best Practice NZ, 2010; NZ BP, 2005, 2007).

There are some cases when initial testing of TSH alone is *not appropriate*. First, when the patient is suspected of having central hypothyroidism, due to pituitary gland failure (NZ BP, 2005). In this case, TSH will be normal, and fT_4 will be low (NZ BP, 2005). Patients who are suspected of being nonadherent to thyroxine replacement medication and those in early stages of therapy; these patients should also have both TSH and fT_4 tested (NZ BP, 2005). In the latter case, it will take approximately 2 months for the TSH and fT_4 to reach an equilibrium (Best Practice NZ, 2010; NZ BP, 2005, 2007). In the case of hyperthyroidism, positive TSH-receptor antibodies establish a diagnosis of Grave's disease (a disorder of the immune system that results in the overproduction of thyroid hormones). Radionuclide thyroid scanning is seldom warranted and can lead to further confusion of diagnosis (Best Practice NZ, 2010; NZ BP, 2005, 2007). Additionally, an endocrinologist's advice should be sought in those patients who are acutely ill and pregnant patients (Best Practice NZ, 2010; NZ BP, 2005, 2007).

Management of Hypothyroidism

In countries where there is sufficient dietary iodine, the major causes of hypothyroidism are Hashimoto's thyroiditis, thyroiditis (subsequent to hyperthyroidism), thyroidectomy, postpartum thyroiditis, irradiation, and medication related (Best Practice NZ, 2010; Garber et al., 2012; Hulisz, 2018; Kostoglou-Athanassiou and Ntalles, 2010). Hypothyroidism can also occur secondary to pituitary or hypothalamus disorders (Garber et al., 2012; Kostoglou-Athanassiou and Ntalles, 2010).

Symptoms

Hypothyroidism (high TSH, low-fT_4) has been described as an endocrine condition that occurs when the thyroid gland is underactive, resulting in a deficiency in the production of thyroid hormones (The National Institute of Diabetes, 2016; Yvette, 2012); this may subsequently affect integral systems within the body. Hypothyroidism is characterized by symptoms of goiter, bradycardia, fatigue, weight gain, constipation, menorrhagia, pale, dry skin and hair, and cold intolerance (American Association of Clinical Endocrinologists, 2015; Garber et al., 2012; Malaty, 2018; Roberts, 2004; The National Institute of Diabetes, 2016; Yvette, 2012). The most common symptoms of hypothyroidism are listed in **Table 1**. Hypothyroidism can be

Table 1 Common signs and symptoms of hypo and hyperthyroidism, table reproduction permission required unless modified (Best Practice NZ, 2010; NZ BP, 2005)

	Common signs and symptoms of hypothyroidism	*Common signs and symptoms of hyperthyroidism*
Symptoms highly indicative of condition	• Goiter • Delayed reflexes	• Goiter • Thyroid bruit (sound that can be heard over the thyroid mass) • Lid lag • Proptosis
Symptoms intermediately indicative of condition	• Fatigue • Weight gain/difficulty in losing weight • Cold intolerance • Dry, rough, pale skin • Constipation • Family history • Hoarseness	• Fatigue • Weight loss despite increased appetite • Heat intolerance/sweating • Fine tremor • Family history • Increased bowel motions • Fast heart rate/palpitations • Staring glaze
Symptoms that are lesser indicative of condition	• Coarse dry hair • Hair loss • Muscle cramps/aches • Depression • Irritability • Memory loss • Abnormal menstrual cycles • Decreased libido	• Nervousness • Insomnia • Breathlessness • Light or absent menstrual periods • Weight loss • Muscle weakness • Warm moist skin • Hair loss

differentiated into primary and secondary hypothyroidism (Garber et al., 2012). It is estimated that 95% of cases of hypothyroidism are of primary origin (Malaty, 2018). Secondary or central hypothyroidism is sometimes differentiated (into secondary and tertiary) depending on whether it relates malfunctions of the pituitary or the hypothalamus, respectively.

Rarely, a very severe form of hypothyroidism may occur called myxedema coma (Kostoglou-Athanassiou and Ntalles, 2010; Malaty, 2018). Patients present with low or normal temperature, shallow breathing, low blood pressure, low blood glucose, and unresponsiveness (DeEugenio and Smith, 2004). This can be caused by an infection, illness, exposure to cold, and from certain medications in patients who have untreated hypothyroidism (DeEugenio and Smith, 2004). This is a medical emergency and immediate hospitalization is required (DeEugenio and Smith, 2004).

Treatment

Confirmed overt primary hypothyroidism can usually be managed well with standard guideline treatment. In the case where there is an elevated TSH, but normal fT_4, this may indicate subclinical hypothyroidism. In those with mildly elevated TSH (up to 10 mU/L), in half of cases this normalizes itself and thus no immediate treatment is required. Instead, testing should be repeated in 6–8 weeks.

Subclinical hypothyroidism, where there is a substantially elevated TSH (>10 mU/L), is associated with adverse effects on the cardiovascular system. Therefore, treatment in these cases may be warranted.

Levothyroxine

Standard treatment for hypothyroidism is levothyroxine sodium (American Association of Clinical Endocrinologists, 2012; Best Practice NZ, 2010, in press; Garber et al., 2012; McDermott, 2009; Roberts, 2004); this is a synthetic form of T_4 used to replace the lack of endogenous T_4 and normalize blood levels. Levothyroxine treatment is usually warranted for life (Malaty, 2018; Truter, 2011). Regional guidelines vary slightly in terms of the starting and titration increments. Most adults will achieve euthyroidism with a dose of approximately 1.6 micrograms (μg)/kg/day orally (Best Practice NZ, 2010). Evidence has indicated that most patients should be started on the full replacement dose of levothyroxine (Malaty, 2018; Roberts, 2004) but should be given at the lower end of the anticipated dose requirement (Roberts, 2004). Usually, the initial dose is 50–100 μg/day (New Zealand Formulary, in pressa), and titration by 25–50 μg every 3–4 weeks (New Zealand Formulary, in pressa) is based on thyroid function tests. Some literature has indicated that ideal (lean) body weight, rather than actual body weight, is a better predictor of levothyroxine dose, and this is summarized and discussed by Jonklaas et al. (2014).

If patients are elderly or frail or in those with heart disease, a smaller initial dose of 25 μg/day should be used and titration by 12.5–25 μg every 6–8 weeks (Davoren, 2008; Kim, 2017; Malaty, 2018; New Zealand Formulary, in pressa; Roberts, 2004). In those patients who have undergone a thyroidectomy or radioiodine treatment for thyrotoxicosis but are otherwise healthy, an immediate dose of thyroxine at (or just below) their predicted daily replacement dose of 100–200 μg may be initiated (Davoren, 2008).

According to the American Association of Clinical Endocrinologists and the American Thyroid Association, treatment of special populations should be undertaken with an endocrinologist (Garber et al., 2012); these special populations include the pediatric populations, women who are pregnant or those planning to conceive, people with cardiovascular disease, and people with other endocrine diseases such as adrenal and pituitary disorders (American Association of Clinical Endocrinologists, 2012; Garber et al., 2012; Yvette, 2012). Specific guidelines for the management of thyroid disease in pregnant and postpartum women have been released by a number of endocrinology associations worldwide, for example, the American Association of Clinical Endocrinologists; however, these will not be discussed as they are outside the scope of this chapter.

Dosing can be administered once daily, due to the long half-life (approximately 7 days) (Davoren, 2008); dosing requirements may be necessary in the elderly, for a number of reasons (Kim, 2017). If there needs to be a dose adjustment at a smaller increment than available tablets, then alternate or variable day dosing should be used, as this alleviates the need for patients to need to cut tablets (Davoren, 2008). Tablets should not be cut in half, unless the manufactured brand states; otherwise, there are some brands that enable tablets to be crushed and sprinkled, for those patients who are unable to swallow—individual manufacturers advice should be sought (New Zealand Formulary, in pressa).

Levothyroxine is slowly incorporated into body organs; therefore, it usually takes up to 6 weeks before symptom improvement is observed (Davoren, 2008; Truter, 2011). However, many patients may experience improvement after 2–3 weeks of treatment (Davoren, 2008; Truter, 2011). The rate at which specific symptoms improve varies (Truter, 2011). Early in treatment, there can be an improvement in pulse rate, a reduction in weight and puffiness, while skin hair and voice tone may take a few months. A slower improvement occurs in cholesterol. Reduction in the size of the goiter may require high-dose thyroid hormone for a short period of time (Truter, 2011).

The recommendation is to administer levothyroxine an hour prior to breakfast (as bran and fiber may delay absorption) (Yvette, 2012), but in some cases, this may result in poor adherence (Jonklaas et al., 2014). Consistent daily dosing is adhered to with regard to meals (including types of foods consumed, especially in the case of foods that may affect absorption) and time of day should, therefore, be encouraged (Garber et al., 2012; Yvette, 2012). To date, no long-term studies have investigated the effect of adherence and timing regimens and the consequence on TSH levels (Jonklaas et al., 2014).

Levothyroxine is available generically and in a number of brands throughout the world. Many of these brands are not interchangeable (Best Practice NZ, 2010; Garber et al., 2012; Jonklaas et al., 2014).

In patients where unusually high doses of levothyroxine are required, the patient should be investigated for underlying gastrointestinal conditions (Jonklaas et al., 2014). A number of studies have identified conditions that could affect levothyroxine

absorption or serum TSH levels, for example, *Helicobacter pylori*-related gastritis. This is thought to be mediated via changes in acidity. The evidence for this has been summarized and discussed by Jonklaas et al. (2014). If the underlying condition is identified and treated, TFTs may need reviewing with the view to adjust the dosing of the levothyroxine (Jonklaas et al., 2014).

Monitoring of Therapy

After starting levothyroxine, patients should have their TSH measured every six to eight weeks until the levels become stable and within normal limits (0.4–4.0 mU/L) (Best Practice NZ, in press; Garber et al., 2012; NZ BP, 2005). Subsequent to the levels being attained, TSH should be checked every four to six months and then annually (Best Practice NZ, in press; NZ BP, 2005). Monitoring should become more frequent if the situation changes; for example, switching to a brand that is not bioequivalent (Best Practice NZ, 2010), if a drug that interacts with levothyroxine is added to the patient's medication regimen, for example, amiodarone, antacids, anticonvulsants, or if there is marked weight gain or planned pregnancy (NZ BP, 2005).

Poor Outcomes of Treatment

Levothyroxine is generally well tolerated (Roberts, 2004); however, it has a narrow therapeutic window (Roberts, 2004) and thus there is a substantial number of patients who are either being over and undertreated (Hulisz, 2011). Both over and undertreatment can cause adverse health consequences (Hulisz, 2011). As mentioned earlier, lack of adequate treatment can lead to cardiovascular disease (Hulisz, 2011). Overtreatment can lead to adverse effects including symptomatic thyrotoxicosis (Roberts, 2004) and can result in long-term sequelae, including atrial fibrillation, lower bone mineral density, and fracture and cardiovascular disease (Hulisz, 2011).

The Colorado Thyroid Disease Prevalence Study reported that 60% of people taking thyroid medication had TSH within reference values (Canaris et al., 2000). In a study in older Australian adults, abnormal TSH was found in 25% of people taking levothyroxine (Empson et al., 2007). High rates of abnormal measurements have also been reported by Canaris et al. (2000). These findings could be due to a number of reasons, which must be investigated in the patient: (1) adherence issues (Ramadhan and Tamilia, 2012), (2) a reduced absorption of levothyroxine, which could be due to drug–drug interactions or inconsistency with dosing in relation to food (Ramadhan and Tamilia, 2012), or (3) if patients switch from one brand to another that are not bioequivalent.

Adherence issues can be an important factor in poor response to treatment (Centanni et al., 2017), and due to the long half-life of the medication, missing a dose can have effects that last a number of days (Centanni et al., 2017). The pharmacist has a vital role to play in education of the patient (Hulisz, 2011), including why adherence is imperative for treatment. Explanation of the life-long nature of therapy, time to observe symptomatic changes, and consistency with dosing (emphasizing the relation to meals being consistent) is important not only at the introduction of therapy but also on an ongoing basis. Medication organizers, such as pill dosette boxes, may be of assistance in patients when adherence is an issue (Jonklaas et al., 2014).

Reduced gut absorption of levothyroxine is another reason for poor response. This may be due to drug–drug interactions, timing with meals, or a malabsorptive disorder, such as celiac disease and inflammatory bowel disease (Centanni et al., 2017; Jonklaas et al., 2014; Roberts, 2004). A study by McMillan et al. (2016) surveyed 925 individuals with hypothyroidism undergoing treatment and reported that a high proportion of patients do not take levothyroxine as directed. Patients should be advised to consulting the pharmacist if starting any new medication, including those purchased over-the-counter (OTC) medications (Hulisz, 2011) (including dietary supplements and iodine-containing products), and medications that have the potential to alter the absorption of levothyroxine, for example, calcium carbonate, cholestyramine, ferrous sulfate, proton pump inhibitors, and sucralfate (Roberts, 2004; Trifirò et al., 2015; Truter, 2011). Additionally, the metabolism of levothyroxine may be altered by some medications, including some antidepressants, antiepileptic drugs, and enzyme-inducing antibiotics (Roberts, 2004).

Explaining why brands cannot be interchanged to a patient is integral. If a prescriber decides to swap the brand, additional monitoring of thyroid levels will be required (Jonklaas et al., 2014).

Appropriate storage conditions of the levothyroxine should be explained, as this can lead to malabsorption if the preparation is affected (Centanni et al., 2017). The medicine should be kept below 25°C and away light.

In some patients, despite normalized TSH, ill health may persist. This may be due to the symptoms being unrelated to the thyroid, for example, depression. There have been reports, although there is a lack of evidence to prove this, that some patients have improved symptoms when TSH levels are in the lower end of the reference range (NZ BP, 2007). Reports have suggested that this appears to be safe, in young healthy patients, as long as the level does not become suppressed below 0.1 mU/L (Flynn et al., 2010; Walsh, 2016).

Other Therapies

Unlike current thyroid medications, which are synthetic, natural thyroid medications were once prepared from the thyroid glands of cows, hogs, and sheep (DeEugenio and Smith, 2004; Jonklaas and Talbert, 2011). These products provided both T_3 and T_4; however, the levels of T_3 and T_4 varied greatly (DeEugenio and Smith, 2004; Jonklaas and Talbert, 2011). In addition, as these medications were protein derived, they may be antigenic in allergic or sensitive patients (DeEugenio and Smith, 2004; Jonklaas and Talbert, 2011). The current use of these medications should not be encouraged (American Association of Clinical Endocrinologists, 2012; Best Practice NZ, 2010; Davoren, 2008; DeEugenio and Smith, 2004).

Liothyronine (triiodothyronine or T_3) is rarely used orally for maintenance therapy. Most patients respond well to T_4 alone, which is converted in the body to T_3. When a rapid response is required, T_3 may be used, that is, in severe hypothyroid states (New Zealand Formulary, in pressb).

Management of Hyperthyroidism

Hyperthyroidism and thyrotoxicosis are terms that are often used interchangeably (Topliss and Eastman, 2004). Hyperthyroidism is less common than hypothyroidism and is most frequently caused by Grave's disease (60%–80%) (Association et al., 2011; Best Practice NZ, 2010; Walsh, 2016), toxic multinodular goiter (nodules that develop in the thyroid gland and secrete thyroid hormone, also known as Plummer's disease) (Association et al., 2011; Best Practice NZ, 2010; Walsh, 2016), or toxic adenoma (Association et al., 2011).

Thyroiditis can also lead to hyperthyroidism; in thyroiditis, there is generally a three-stage course, that is, hyperthyroidism followed by hypothyroidism and finally euthyroidism. Depending on the type of thyroiditis the condition may resolve, or hypothyroidism may ensue and require treatment (Walsh, 2016).

It is essential in hyperthyroidism to establish the cause prior to the commencement of treatment, as this will alter the management (Association et al., 2011; Walsh, 2016).

Subclinical hyperthyroidism should be monitored as it often resolves without treatment (Meyerovitch et al., 2007), in some patients with persistent (i.e., longer than 3–6 months), subclinical hyperthyroidism treatment may be warranted to avoid altered skeletal health and atrial fibrillation (Association et al., 2011). Again, in persistent subclinical hyperthyroidism, the underlying cause should be identified (Association et al., 2011).

Rarely, a life-threatening condition called thyrotoxicosis (thyroid storm) can develop, even with treatment the mortality rate of thyroid storm is reported to be 30%. It presents as hyperthermia, severe tachycardia, disorientation, and severe agitation and may be accompanied with heart failure (Association et al., 2011; DeEugenio and Smith, 2004). This can lead to stupor and coma (Association et al., 2011; DeEugenio and Smith, 2004). This is a serious condition and requires treatment and monitoring in an intensive care unit. Treatment is supportive and thyroid specific and is discussed in detail in the Guidelines by the American Thyroid Association and American Association of Clinical Endocrinologists (Association et al., 2011; Jonklaas and Talbert, 2011).

Symptoms

In hyperthyroidism, there is low/nonexistent TSH and high fT_4 (Best Practice NZ, 2010; NZ BP, 2005). Clinical symptoms are characteristic (see **Table 1**) and include increases in blood pressure and heart rate, arrhythmia, enlarged thyroid (goiter; seen in both hypo and hyperthyroidism), bulging eyes, tremor, increased sweating, heat intolerance, irritability, anxiety, weight loss, and loss of sleep (Best Practice NZ, 2010; Hulisz, 2018; Jonklaas and Talbert, 2011; NZ BP, 2005; Walsh, 2016).

Treatment

There are three main avenues for treatment in patients with hyperthyroidism: surgery, antithyroid medications, and radioactive iodine. The route chosen depends on the cause of the hyperthyroidism. Furthermore, additional factors that affect the choice of treatment include preference in the region that the patient is being treated, that is, due to local guidelines, size and nature of the goiter, other medication or medical conditions, and (particularly in the case of patients with Grave's disease) patient preference (Best Practice NZ, 2010; Topliss and Eastman, 2004).

There are three treatment options for Grave's disease: (1) blocking the synthesis of thyroid hormones with antithyroid medication, (2) radioactive iodine, or (3) surgery (Association et al., 2011; Razvi and Perros, 2018; Topliss and Eastman, 2004; Walsh, 2016).

In toxic nodular goiter, radioactive iodine or surgery is generally the treatment of choice. Antithyroid medications are often not the treatment of choice, as it will need to be lifelong (Association et al., 2011; Pearce, 2018; Walsh, 2016).

If thyroiditis is the cause, often this does not need medication therapy, unless it is autoimmune thyroiditis and hypothyroidism may persist (Walsh, 2016). As mentioned previously, thyroiditis generally progresses in three parts: hyperthyroidism, hypothyroidism and then euthyroid (Walsh, 2016). TSH should be monitored, and if the hypothyroidism persists, then treatment should be commenced with levothyroxine (Association et al., 2011).

Symptom control may be necessary as an adjunct to treatment, and this is often attended to by the use of β-adrenergic blocking agents, for example, to alleviate tremor and tachycardia (Association et al., 2011; Best Practice NZ, 2010), as these medications are able to reduce the effects of T_4 on the sympathetic system (Michael et al., 2012).

Surgery

A thyroidectomy involves some or all of the thyroid gland being surgically removed. Patients must be rendered euthyroid prior to surgery with thionamide therapy (Association et al., 2011; Topliss and Eastman, 2004). In some special populations, this is the treatment of choice (Association et al., 2011; Best Practice NZ, 2010; Topliss and Eastman, 2004), including patients who are noncompliant to treatment, refuse to have radioactive iodine treatment, or where therapy fails, this may be used as an alternative

(Michael et al., 2012). Subsequently, the patient is likely to need thyroid replacement treatment thereafter (Association et al., 2011).

Antithyroid Medications

Antithyroid medications consist of thiouracils and sulfur-containing derivatives (thioamides: propylthiouracil and carbimazole). These medications work is by interfering with thyroxine synthesis in the thyroid gland (Razvi and Perros, 2018). The initial dose is dependent on the severity of the condition, and once a euthyroid state is achieved, the dose is lowered (Best Practice NZ, 2010). It has been reported that use for 12–18 months is the best course length for sustained remission in Grave's disease (Best Practice NZ, 2010; Razvi and Perros, 2018). Relapse can occur in approximately 50% of patients (Topliss and Eastman, 2004). Side effects of the medication include rash, fever, and gastrointestinal disorders. Rarely, agranulocytosis can occur (NZ BP, 2005).

Radioactive Iodine

This option is usually chosen when antithyroid medications are not effective (after relapse) or not able to be used (Topliss and Eastman, 2004). Additionally, this may be the treatment of choice in toxic nodular goiter (Pearce, 2006). Between 80% and 90% of patients become euthyroid after a single dose (Holm et al., 1981). There are some populations that this treatment is contraindicated in, for example, in pregnancy and breastfeeding, or of the patient is planning on becoming pregnant in the near future (Association et al., 2011; Pearce, 2006). The medication is administered as a single dose in a hospital environment (Association et al., 2011). Side effects include transient neck soreness, flushing, decreased sensation of taste, radiation thyroiditis, and potential exacerbation of ophthalmopathy (Pearce, 2006; Razvi and Perros, 2018). Worsening hyperthyroidism has been reported by some patients, which occurs shortly after the treatment due to thyroid hormone leaking from the damaged gland and, thus, may be administered an antithyroid drug prior to treatment or shortly afterward (Best Practice NZ, 2010).

Other Therapies

As mentioned, symptomatic treatment with beta-blockers is an option, for example, with propranolol (Best Practice NZ, 2010). This is sometimes useful at the start of therapy as it helps with palpitations, sweating, and anxiety (DeEugenio and Smith, 2004); however, it does not ameliorate the underlying condition. There are some populations in which these medications should be used with caution; for example, asthmatics (Association et al., 2011).

Monitoring

TSH may remain suppressed for 3–6 months after treatment with antithyroid medication begins (NZ BP, 2005); therefore, until TSH normalizes and the clinical presentation of symptoms has improved in the patient, it is recommended that thyroid function (TSH and fT_4) be monitored every 4 weeks (Best Practice NZ, 2010; NZ BP, 2005). Subsequently, the patient should be monitored every 2 months using TSH only (NZ BP, 2005). In some cases, patients will need to have the fT_3 monitored in addition, this is due to T_3 toxicosis and they should be under the care of an endocrinologist (Best Practice NZ, 2010).

Role of Pharmacist in Health-Care Team—Current and Future Roles in Pharmacotherapy and Management

The pharmacist can benefit the management of thyroid disorders in three main avenues: as an educator, an advisor, and potentially in an advanced role, with the latter being an avenue that still needs further research.

Understanding of the thyroid condition and its management is essential for patient engagement with their ongoing treatment. Pharmacists are in an ideal position, as the easiest to access health-care professional, to educate patients of these factors both when a patient is newly diagnosed and prescribed treatment, and on an ongoing basis when picking up repeat prescriptions for medications.

Suggestions for Counseling Patients with Hypothyroidism

The amount and type of counseling required to be provided to individuals will depend on the individual needs and their level of understanding; however, some suggestions include:

1. That there is no "cure" for hypothyroidism, but the condition can be appropriately and effectively managed using a synthetic version of the thyroid hormone (Yvette, 2012).
2. Treatment is in most cases lifelong but this should not prevent them from taking part in normal life activities (Yvette, 2012).
3. Adherence to treatment is crucial for effective treatment and this includes taking the medication at the same time each day in relation to food and other medications and not stopping taking the medication (even if they are feeling the symptoms are better) unless told to do so by their doctor. The recommendations for levothyroxine state that the medication should be taken with water on an empty stomach 30 min prior to food or at bedtime 4 h after their last meal. However, this may reduce adherence for some patients (Jonklaas et al., 2014). If the individual has been stabilized on a dose for some time, advising of a new routine in relation

to meals may significantly affect their levels and they will have to be dose-adjusted after tests by the prescriber. Patients should also not take the medication within 4 h of any fiber supplements or calcium, iron, multivitamins, aluminum hydroxide antacids, or any medications that bind bile acids.
4. If starting new medications (including ones that they can purchase without a prescription or herbal supplements), they should advise their prescriber and pharmacist that they are taking their medication for thyroid dysfunction, so that any interactions or considerations can be evaluated.
5. Individuals can be advised that usually the dose will be adjusted after blood tests, to ensure the right dose for the patient is being prescribed; these blood tests typically are every 4–8 weeks as that is the required period for hormone stabilization (Best Practice NZ, 2010).
6. It is helpful for individuals to be educated about the potential side effects of the medicine, as these can affect many vital systems within the body. This can be particularly worrisome for patients; therefore, being aware of which side effects to seek additional medical attention and how long to improvement of symptoms is integral to treatment. Patients should be advised to report any signs of palpitations, rapid weight loss, restlessness or shakiness, sweating, and insomnia to their prescriber straight away. Alarm symptoms, such as dizziness, lack of consciousness, slow heartbeat, and difficulty breathing should be reported to their emergency department (Yvette, 2012).
7. Lastly, patients should be advised that the brand of medication is very important; many brands are not interchangeable and therefore they must not switch brands, unless advised to do so by their prescriber (Jonklaas et al., 2014).

Main Factors to Include in Counseling for Hyperthyroidism

1. That hyperthyroidism can be appropriately and effectively managed using medication or surgery (Association et al., 2011).
2. Patients should be made aware of the time to symptomatic relief.
3. If symptomatic relief is prescribed by the doctor, it should be made clear which medication is for what purpose.
4. That even after clinical symptoms have resolved, it is important to continue to take the medication for the duration specified by the prescriber.
5. In addition to general side effects, all patients who are administered antithyroid medication should be told about the rare but serious complication of agranulocytosis and the appropriate management. If symptoms of fever, sore throat, or other infection develop, patients should stop treatment and seek immediate medical treatment (Best Practice NZ, 2010; NZ BP, 2005).
6. Monitoring will be conducted on a monthly basis, as this is the time necessary for there to be a change in hormone levels, once levels are within the reference range, the doctor may extend this to every other month (NZ BP, 2005).

When considering the importance of the pharmacist in patient education in thyroid disorders, only a small number of studies have explored this role. Singh et al. used a cross-sectional designed study to evaluate knowledge in patients diagnosed with hypothyroidism (Singh et al., 2014). They reported poor knowledge and misconceptions. In a separate study, better outcomes were associated with knowledge, appropriate use of medication, and dosage adjustment (Kannan et al., 2010). The pharmacist's role in this regard has been evaluated by a prospective case-controlled study of 118 individuals diagnosed with hypothyroidism (Maharjan and Chhetri, 2015). The authors found that education by the pharmacist in hypothyroidism improved patient knowledge, attitudes, and practice score. However, the study had a relatively small sample size and was based in one region of Nepal, limiting the generalizability of the results and no clinical outcomes were assessed (Maharjan and Chhetri, 2015). Future research could further explore knowledge, attitudes, and clinical outcomes to further evaluate this role.

The second major role of the pharmacist within the management of thyroid disorders is the role of the advisor. There is a huge potential for medication contribution to the development of thyroid disorders and also in affecting the management of thyroid disorders. As discussed previously, increasing age is associated with an increased prevalence of thyroid disorders; this also increases the likelihood that patients are on one or more medications. Pharmacists can act as an important resource within the health-care team to advise on which medications could be contributing to thyroid dysfunction, for example, amiodarone and lithium (Best Practice NZ, 2010). Additionally, pharmacists can also act in an advisory role to patients and other health-care professionals on the many interactions that could affect the management of these conditions and provide evidence-based advice on interactions and information about other complementary medicines in thyroid disorder. While no evidence has been reported specifically on the role of the pharmacist in the advisory role in thyroid disorders *in the community setting* to our knowledge, there has been a study by Ziman and colleagues that has evaluated the role of the pharmacist within a health-care team within outpatient pharmacy setting (Ziman et al., 2012). The pharmacist has been found to be a beneficial addition in this role (Ziman et al., 2012).

Traditionally, the role of the pharmacist has been the compounder and dispenser of medicines; however, more recently, due to many factors including an ageing population and subsequent increases in those with long-term conditions, their role is evolving. It has been said that the future role of the pharmacist will be a clinical one, including aspects of medication review and moving toward independent prescribing (Babar et al., 2018). Evidence for pharmacist's role in thyroid disorders in this respect is scant. There have been small-scale studies that have looked at an advanced role of the pharmacist in novel roles. Ziman et al. (2012) focused on the role of the pharmacist in the clinical context, in patients with heart failure and a thyroid dysfunction. They reported that there was a positive impact on patient adherence to thyroid testing in heart failure. This was a small study, but provides some baseline evidence to promote further research in this area (Ziman et al., 2012). Dong (1990) published a study that centered on pharmacist involvement in a thyroid clinic in a 500-bed university hospital. Within this hospital setting, there had been an established role

for a pharmacist within the thyroid clinic for 10 years. The report by Dong described how the pharmacist initiated, maintained, or modified the drug therapy of selected patients, under the guidance of a protocol approved by the chief endocrinologist (Dong, 1990). This study did state boundaries that the pharmacist operated within, that is, that major changes in the thyroid status and drug therapy, were always discussed with the chief endocrinologist. It was reported was that in a clinical audit, the role of the pharmacist was found to be effective (Dong, 1990). No economic assessment was made. To our knowledge, no further research since this has been published from this facility. Cleary, there are some grounds to warrant further research within this sphere. What needs to be addressed is what this role is, the guidance that this role would operate within, how to manage this expansion of scope, that is, whether this is through a pharmacist prescriber role within a dedicated team and the assessment of patient clinical outcomes and whether there is any clear benefit.

Contraception and the Pharmacist's Role

Natalie J. Gauld[*,†], **Rhiannon Braund**[‡], [*]The University of Auckland, Auckland, New Zealand; [†]Natalie Gauld Ltd, Auckland, New Zealand; [‡]New Zealand Pharmacovigilance Centre, University of Otago, Dunedin, New Zealand

Learning Objectives

After reading this chapter, the reader should be able to:

1. Understand the different contraception options, their efficacy, contraindications, and precautions and adverse event profiles.
2. Consider the most suitable contraceptive choice for an individual patient based on the respective pros and cons of each method of contraception.
3. Be familiar with the efficacy of each contraceptive method and aware of the failure rate (even when used optimally).
4. Discuss the current and future roles of the pharmacist in the management of contraception, including the evidence for these roles.

Contraception is a large topic that is always changing, and there can be important differences in contraindications, precautions, and duration of use between products and countries. Therefore, this chapter aims to provide an introduction to the field. Product literature and up-to-date contraceptive Medical Eligibility Criteria (MEC) should be consulted. World Health Organisation (WHO), United States (US) and United Kingdom (UK) versions of MEC are readily available.

Key Concepts

Appropriate contraceptive choice is important for a significant proportion of women during their "childbearing" years. An increasing number of options each have their own pros and cons. The age of the woman, frequency of intercourse, other medical factors, and personal preference can influence the suitability of contraception.

In general, the longer the contraception is designed for, the more effective it is. Condoms, emergency contraceptive (EC) pills, and diaphragms are designed and used for single events and are less effective than ongoing hormonal contraception (Trussell, 2011). Oral contraceptives (OCs) (used daily) are less effective than the three-monthly progestogen injection, which is less effective than the long-acting reversible contraceptives (LARCs) of implants and intrauterine devices (IUDs). Finally, vasectomy and tubal ligation are the most effective of all.

Given the breadth of this topic, this chapter starts with an introduction to the area and the historical developments of contraception, before considering the various categories of contraceptives and their mechanisms of action, advantages and disadvantages and then a discussion of their effectiveness and usage. Given the increasing role pharmacists have with emergency contraception, this focuses most on the forms pharmacists can usually supply and their role in that supply. The chapter finishes with a noncomprehensive discussion of pharmacist-supply of contraceptives with a focus on professional interactions.

Introduction to Contraception

From the start of being sexually active and for the majority of the next 30 years or more (nearly a third of their life time), most women in many countries will be trying to avoid pregnancy. There are many options to help them do this, with variation in failure rates, ease of use, permanency, benefits, risks, and accessibility.

In the US, the age of first sexual intercourse has changed over time, dropping steadily to a low in the 1990s, then increasing by one year, with sexual intercourse experienced by 50% of people by their 18th birthday (Finer and Philbin, 2013). However, a reasonable proportion of 15 and 16 year olds (19% and 32%, respectively) has had sexual intercourse, and has barriers to accessing contraception. While less than a fifth of unintended pregnancies occur in adolescents, over 80% of pregnancies in ages 15–19 are unintended, and 64% in women 20–24 years old (Finer and Zolna, 2011).

Conception is highest in sexually active women aged in their 20s, with about a 25% pregnancy rate in a month without contraception (Johnson et al., 2012). It declines to about 20% per month around the age of 32 years then less than 5% per month by the age of 41 years and 1% per month by about 45 years. However, the messages about declining fertility may be leading to increased unplanned pregnancy rates in these groups (Finer and Zolna, 2011), and increasing termination rates in older age groups in England and Wales (contrasting to declining termination rates in under 25 year olds) (Abortion Statistics, 2017).

With the wide range of contraceptives available, high rates of unintended pregnancy (Finer and Zolna, 2014; Hohmann-Marriott, 2018) are surprising. Increasing use of LARCs should help given their high efficacy, but many women use options with lower efficacy, or underestimate their chances of pregnancy (Bellizzi et al., 2015). The range of contraceptives includes combined hormonal methods which contain an estrogen and a progestogen, including oral, transdermal, and vaginal rings. Progestogen-only methods include oral, injection, implant, or IUDs. Nonhormonal options include the copper IUD, barrier methods (condoms, diaphragms, cervical caps), and withdrawal and fertility awareness. Finally, there are permanent sterilization methods, male and female.

The WHO regularly provides updated Medical Eligibility Criteria (MEC) for the range of contraceptives. This may differ from the sponsor's licensed prescribing information. The UK and US produce their own MEC, which are more suited to developed countries (e.g., including bariatric surgery). These are important documents for appropriate prescribing of contraceptives with four levels of risk:

1. A condition for which there is no restriction for the use of the method.
2. A condition where advantages generally outweigh the theoretical or proven risks.
3. A condition where the theoretical or proven risks usually outweigh the benefits of using the method. The provision of a method requires expert clinical judgment or a specialist contraceptive provider since the method is not usually recommended unless other more appropriate methods are not available or not acceptable.
4. A condition which represents an unacceptable medical risk if the method is used.

In general, MEC categories 1 and 2 are reasonable for provision, but 3 and 4 are not.

Pharmacists have an important role to play with contraception: in dispensing it pursuant to a prescription (with advice); in making recommendations for prescribers; and in recommending non-prescription contraception. In all cases there is a need to consider safety, adherence, education and patient-centered care.

History

Methods to avoid pregnancy, and sometimes sexually transmitted infections, have been described for hundreds of years (Amy and Thiery, 2015; Quarini, 2005). Early methods from the 17th century or earlier included male condoms made from animal intestines (reportedly used by Casanova), withdrawal, douching after intercourse, and sponges moistened with brandy or water, or paper inserted into the vagina. Cervical caps, IUDs, and fertility awareness became more common in the 1920s. Combined oral contraceptives (COCs) launched in the 1960s, initially contained 150 μg of mestranol (a pro-drug of ethinylestradiol, converting to about 70% of the mestranol dose) (Melo and Creinin, 2016). Gradual lowering of estrogen doses followed, as did development of new progestogens, progestogen-only pills, transdermal patches, and vaginal rings. Hormones were developed in longer-lasting forms, depot progestogen injections, and more recently in IUDs and implants. A goat's bladder female condom dates back to 150 AD, and 2000 years on, female condoms are marketed in some countries.

Nonpharmacological Contraceptive Options

Withdrawal of the penis before ejaculation reduces pregnancy risk because preejaculatory fluid has little or no motile sperm, but still has a one year failure rate of 22% (Trussell, 2011). Postcoital vaginal douching might heighten the risk of pregnancy by washing sperm into the uterus (Quarini, 2005).

Fertility awareness methods vary. Detection of cervical mucus changes has high levels of pregnancy (35% after 13 cycles), even where intensive training has taken place and with "perfect" use (Goldsmith, 2016). Adding body temperature monitoring reduces the failure rate, e.g., 2% over 13 months in clinical studies.

Breast-feeding on demand at least four hourly during the day, and at least six hourly at night, in the first six months postpartum has a 2% pregnancy rate (Alsharaydeh et al., 2017). Sterilization includes fallopian tube occlusion for women, and vasectomy for men.

Copper IUDs are discussed under LARCs.

Male Condoms

Condoms protect against pregnancy and sexually transmitted infections, and may prevent premature ejaculation (Batár and Sivin, 2010). Originally from animal membranes, rubber condoms became more popular and more available in the 19th century (Amy and Thiery, 2015). Nowadays, latex is usually used, with a teat end to capture the ejaculate to avoid a reflux of sperm. Polyurethane condoms (for latex allergy) and animal membrane condoms (skins) are also available (Amy and Thiery, 2015; Batár and Sivin, 2010). Polyurethane condoms may break more and be less effective than latex, and are not biodegradable. Animal membrane condoms are expensive and may not protect against STIs, nor be sufficiently robust for anal intercourse.

The challenge with condoms is ensuring they are used every time. Men and women have expressed dislike (Amy and Thiery, 2015). Effectiveness against STIs transmitted through skin-to-skin contact, such as human papilloma virus is less than for infections spread through fluid contact such as HIV, chlamydia, and gonorrhea (Amy and Thiery, 2015). Mineral oil lubricants, some vaginal candidiasis products, and excessive temperatures can damage latex condoms.

Female Barrier Methods

Female barrier methods, diaphragms, cervical caps, and female condoms, prevent spermatozoa reaching the egg. They are hormone-free for those with contraindications or wanting to avoid hormones, and for women who do not have intercourse often. They have unknown effectiveness in preventing most STIs, but the diaphragm provides some protection against HPV infection, and their use is low and in decline (Batár and Sivin, 2010).

Female condoms are a soft disposable sheath made of polyurethane with an outer ring, and inner ring inserted in the vagina up to eight hours before intercourse (Alsharaydeh et al., 2017; Amy and Thiery, 2015). They are expensive, can be noisy, can stick to male condoms, be uncomfortable and tricky to insert, and have low usage (Batár and Sivin, 2010).

Diaphragms (a latex shallow dome) and cervical caps (small and thimble shaped, fitting over the cervix) (Amy and Thiery, 2015), were popular in Europe and the US until the OC became available (Batár and Sivin, 2010). Diaphragms vary in size and need to be fitted by someone qualified for first usage, and after childbirth or significant weight changes (Batár and Sivin, 2010). They typically fold to be inserted, are used with spermicide owing to leakage of sperm, and are not felt during intercourse. The diaphragm remains in place for six to eight hours after intercourse, then is washed with lukewarm water and mild soap, rinsed, dried, and stored carefully. Checks for damage and replacement 1–2 yearly are important. Women with vaginal fistulae or latex allergy cannot use them, and toxic shock syndrome has been reported with delayed removal.

Cervical caps are very uncommonly used (Batár and Sivin, 2010). They also need fitting and are coated in spermicide, but can remain in place for more than 24 hours for repeated sexual intercourse. They are relatively rigid, may cause discomfort during intercourse, and insertion and removal can be difficult.

Spermicide-impregnated single-use sponges are available in some countries, but have reasonably high failure rates (Batár and Sivin, 2010).

Long-Acting Reversible Contraceptives

LARCs are contraceptives administered less frequently than once a month (The Faculty of Sexual & Reproductive Healthcare Clinical Effectiveness Unit, 2014). They include IUDs (copper and hormonal), medroxyprogesterone acetate (MPA) injections and progestogen implants. Low opportunity for user error provides high efficacy. Their benefits and risks differ markedly from estrogen-containing contraceptives (Anon, 2016; Shoupe, 2016). Low use of LARCs arises from various reasons, including insufficient knowledge in women, cost concerns (Rose et al., 2011; Sweeney et al., 2015), insufficient familiarity and skill in providers, and overestimation by providers of women's adherence to OCs (Sweeney et al., 2015).

Medroxyprogesterone Acetate Injection

MPA injection, a progestogen, inhibits the secretion of gonadotropins, preventing follicular maturation and ovulation. It also thickens the cervical mucus limiting sperm penetration, and changes the endometrium, discouraging implantation (Pfizer Limited, 2018a; The Faculty of Sexual & Reproductive Healthcare Clinical Effectiveness Unit, 2014). MPA is available as a deep IM injection (DMPA, Depo Provera® containing 150 mg medroxyprogesterone acetate) or the more recently available subcutaneous injection (Sayana Press®, 104 mg MPA) self-administrable with training (Pfizer Limited, 2018b).

Some African countries, e.g., Uganda, Malawi, and Swaziland have usage in 20%–30% of married or in-union women of reproductive age. High usage occurs in some South American and developing Asia Pacific countries, while other similar countries in these areas, and highly developed countries have minimal or no use.

MPA is initiated within the first five days of a normal menstrual cycle, or additional contraceptive cover is needed (Pfizer Limited, 2018a). The injections are administered every 12 weeks (Pfizer Limited, 2018a) (Depo-Provera) or every 13 weeks (Sayana Press) (Pfizer Limited, 2018b).

Unpredictable bleeding lessens satisfaction, so warn of changes (Hoopes et al., 2018). It cannot be discontinued immediately, and full fertility may take up to one year after discontinuation (Pfizer Limited, 2018a,b). Weight gain sometimes occurs, particularly in obese women under 18 years of age (The Faculty of Sexual & Reproductive Healthcare Clinical Effectiveness Unit, 2014). A small loss in bone mineral density, particularly in the first year of use, typically recovers after discontinuation, but provides a caution for young women or those approaching menopause. The manufacturer advises that it is only indicated in women under 18 years of age when other contraceptive methods are considered unsuitable or unacceptable (Pfizer Limited, 2018b), and women at particular risk of osteoporosis should consider other contraceptives (Pfizer Limited, 2018a).

Amenorrhea (in 50% at one year) or reduced bleeding may be beneficial (The Faculty of Sexual & Reproductive Healthcare Clinical Effectiveness Unit, 2014), particularly in women with heavy menstrual bleeding, dysmenorrhea or endometriosis pain, or in wheelchairs, and it can be used immediately postpartum. MPA users have nearly an 80% reduction in endometrial cancer (Shoupe, 2016).

Intrauterine Devices

IUDs are inserted into the uterus. The copper IUD shortens the sperm's survival and affects its passage into the fallopian tubes (Mishell, 2011a). It is made of polyethylene with fine copper wire, and lasts for 3–10 years (Anon, 2016), depending on the product. Few contraindications and precautions exist. Copper IUDs can be used when hormones are contraindicated, e.g., with breast cancer. Because copper IUDs can cause painful heavy bleeding, discontinuation is common (Alsharaydeh et al., 2017), and iron deficiency anemia is a precaution for use (Anon, 2016). About 5% of women will have the IUD displaced or expelled (Alsharaydeh et al., 2017).

IUDs should not be inserted if there is pelvic inflammatory disease or sepsis, and uterine perforation, bleeding, discomfort and infection can occur on insertion (Alsharaydeh et al., 2017).

The levonorgestrel (LNG) IUD prompts release of leukocytes and prostaglandins by the endometrium and thickens the cervical mucus, preventing proliferation of the endometrium, inhibiting sperm passage, and sometimes suppressing ovulation (Bayer PLC, 2018). It lasts 3–5 years depending on the product (Alsharaydeh et al., 2017). It has more contraindications and precautions than the copper IUD (Alsharaydeh et al., 2017; Anon, 2016), but causes lighter periods or amenorrhea, which can help in dysmenorrhea, and has very low failure rates (**Fig. 1**).

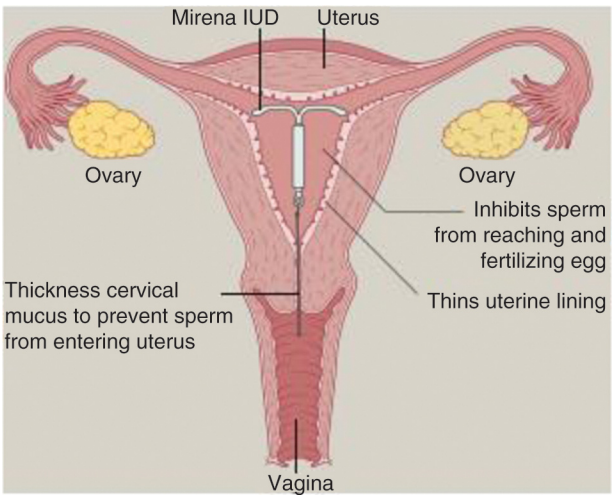

Figure 1 Mirena IUD. *Source: Reprinted from Alsharaydeh, I., Gallagher, M., Mahmood, T.A., 2017. Non-oral contraception. Obstet. Gynaecol. Reprod. Med. 27(5), 158–165, with permission from Elsevier.*

Progestogen Implants

The progestogen implant is increasingly used, with the lowest failure rate of all reversible contraceptives (Trussell, 2011), fewer contraindications and precautions than the COC (Anon, 2016), and high rates of continuation at 12 months (Diedrich et al., 2015; Trussell, 2011). It can be removed. Progestogen implants primarily prevent ovulation, and change the cervical mucus to inhibit sperm penetration (French and Darney, 2016). Currently there are two different progestogens used in small subdermal implanted rods, levonorgestrel or etonogestrel (a metabolite of desogestrel), with similar profiles (French and Darney, 2016). A higher dose is released initially, declining over time, and this is affected by bodyweight (Bayer OY, 2016; Merck Sharp and Dohme Limited, 2016).

The implant is inserted surgically, preferably by a person who has been appropriately trained. If inserted in the first five days of the menstrual period, no back-up contraception is needed (French and Darney, 2016). However, it can be inserted at other times if there is reasonable certainty that the woman is not pregnant and back-up contraception is used for seven days.

Check the latest product information for duration of effect (currently three (Merck Sharp and Dohme Limited, 2016) or five years (Bayer OY, 2016)), and recommendations in women who are "heavier." Migration of the implant is possible, particularly with deep insertion, manipulation of the implant or contact sports. At insertion and removal, vascular or nerve damage can occur (Alsharaydeh et al., 2017). Ovulation and fertility returns promptly after removal (Alsharaydeh et al., 2017).

Menstrual bleeds may change in frequency, intensity, and duration. About 20% of users become amenorrhoeic and a similar number have frequent and/or prolonged bleeding (Merck Sharp and Dohme Limited, 2016). Unscheduled bleeding is the most common reason for discontinuation (French and Darney, 2016).

Oral Contraceptives

One of the most commonly used forms of contraceptive is the OC. These are noninvasive, and allow short-term use with easy discontinuation when desired, e.g., with side effects or change in relationship status, without needing a health professional (Castaño and White, 2013). This does not help continuation though.

OCs contain an estrogen and a progestogen (COCs), or are progestogen-only pills (POPs) often referred to as the mini-pill. This section will first discuss the COCs and then the POPs.

The estrogen in COCs was initially mestranol, later replaced by ethinylestradiol, and with gradually reducing doses (Melo and Creinin, 2016). Ethinylestradiol is usually used in 20 μg to 35 μg strengths, and occasionally 50 μg. The lower estrogen dose is associated with greater break-through bleeding, but has been recommended if nausea or breast tenderness is attributed to the COC (Darney, 1997).

The originally used progestogens (first generation) in COCs included norethisterone (norethindrone) and lynestrol, however, attempting to improve the side effect profile, new progestogens were developed including LNG (second generation). Third generation progestogens, gestodene, desogestrel, norgestimate (Stegeman et al., 2013) were designed for lower androgenicity. The fourth generation progestogen, drospirenone is structurally related to spironolactone and has antiandrogenic activity (Melo and Creinin, 2016). COCs containing third and fourth generation progestogens may have higher thrombosis risks than with the second generation progestogens (Stegeman et al., 2013), although this is controversial (Faculty of Sexual & Reproductive Healthcare Clinical Guidance, 2012). Cyproterone acetate is also a first generation progestogen and antiandrogen. It reduces hirsutism and acne, but increases the risk of thrombosis (Stegeman et al., 2013).

The COCs work primarily by preventing ovulation, and also thicken the cervical mucus to make sperm passage more difficult They reduce uterine and oviduct motility, hinder egg and sperm movement, and have effects in the endometrium that affect sperm survival (Mishell, 2011b).

Despite being one of the most widely used and widely studied medicines in the world, with good safety and well-defined contraindications and precautions, many women have misconceptions about effects on fertility and potential to cause cancer (Hamani et al., 2007; Küçük et al., 2012; Mishell, 1989). Myths perpetuated by media make it a surprise to learn that COC users live longer than never-users (Hannaford et al., 2010). COC users have a reduced risk of ovarian cancer of 40%–50%, and endometrial cancer of 40%–70% depending on treatment duration, with a significant effect remaining long after stopping (Collaborative Group on Epidemiological Studies of Ovarian Cancer, 2008; Shoupe, 2016). Other benefits of COCs include reduced menstruation irregularities, cycle blood loss and anemia, and improving acne (Faculty of Sexual & Reproductive Healthcare Clinical Guidance, 2012; Melo and Creinin, 2016; Petitti, 2003).

Effectiveness is substantially lower than other forms of contraception, being prone to user error, particularly in adolescents (Melo and Creinin, 2016). Thus, some organizations, e.g., The American Congress of Obstetricians and Gynecologists and the American Academy of Pediatrics, recommend IUDs and the progestogen implant first-line, even in adolescents, rather than OCs (Melo and Creinin, 2016). Contraceptive failure is most likely with missed pills at the start of the cycle (Melo and Creinin, 2016). While contraindications, precautions, and drug interactions affect COC suitability for some women, most healthy young women can take them (Anon, 2016).

Side-effects include rare but serious effects (Faculty of Sexual & Reproductive Healthcare Clinical Guidance, 2012; Melo and Creinin, 2016; Petitti, 2003). These can include increased risk of thrombosis (risk depends on estrogen dose and progestogen), myocardial infarction, and stroke (Faculty of Sexual & Reproductive Healthcare Clinical Guidance, 2012; Petitti, 2003).

The risk of venous thromboembolism (VTE, including deep vein thrombosis and pulmonary embolism) is about 9–10/10,000 woman-years, twice the background risk, and highest in the first few months of use (Faculty of Sexual & Reproductive Healthcare Clinical Guidance, 2012). This rate is lower than the 29/10,000 woman-years in pregnancy, and 300–400/10,000 woman-years immediately postpartum. Therefore, a personal history of VTE or known thrombogenic mutation is COC contraindications. Immobility is a risk factor and should be avoided, e.g., by changing contraception in cases of prolonged immobility. For flights over three hours, the woman should try to move regularly (Faculty of Sexual & Reproductive Healthcare Clinical Guidance, 2012). For travel to high altitude areas for more than a week another contraceptive may be preferred. The risk of VTE increases as BMI increases, so a BMI of 30–34 kg/m^2 has an MEC of 2, while a BMI of 35 kg/m^2 or over has an MEC of 3 (Anon, 2016). Other risk factors may make the risks outweigh the benefits, see the MEC for details.

A 2015 Cochrane review found that COCs increase the risk of a myocardial infarction or stroke by about 60%, particularly in smokers, and with increasing estrogen (Roach et al., 2015). Increase in absolute risk is low (Faculty of Sexual & Reproductive Healthcare Clinical Guidance, 2012). There was no association with the progestogen used. For women with a history of migraine, COCs at least double the risk of stroke, and even higher risk occurs in migraine with aura (Anon, 2016). Use in women with migraine with aura (even if long ago) is contraindicated. Other risk factors such as high blood pressure and obesity may increase myocardial infarction or stroke with the COC and the presence of some risk factors are contraindications. Even adequately controlled hypertension without other risk factors has an MEC of 3 (Anon, 2016). The risk is likely to outweigh the benefit with multiple risk factors such as smoking in women aged 35 years or over (Anon, 2016; Faculty of Sexual & Reproductive Healthcare Clinical Guidance, 2012). See the MEC for details.

Meta-analyses have shown a small elevated risk of breast cancer of 8%–24% with COCs (Anon, 2017). This disappears within 5–10 years of stopping (Iversen et al., 2017; The Faculty of Sexual & Reproductive Healthcare Clinical Effectiveness Unit, 2014), and the Royal College of Obstetrics and Gynaecology (UK) states that *"use of COCs have not been found to be associated with increased mortality from breast cancer"* (The Faculty of Sexual & Reproductive Healthcare Clinical Effectiveness Unit, 2014). The American College of Obstetricians and Gynecologists (ACOG) notes that the low baseline numbers of cancer in premenopausal women makes the absolute numbers small, and an increase of 20% equates to 1 additional case per 7690 women, or in women under 35 years, 1 in 50,000 (Anon, 2017). Because COCs prevent other cancers (endometrial, ovarian, and colon), overall cancer risk may be slightly lower in COC users (Anon, 2017). Alcohol increases breast cancer much more—British women drinking up to 250 mL of 12% wine daily have an extra 5 in 1000 lifetime risk of breast cancer versus nondrinkers (Hyde, 2017). Women with current or past breast cancer should not have COCs, but a family history of breast cancer is not a contraindication (Anon, 2016).

Cervical cancer might increase in COC users, but any increase disappears 5–10 years after stopping (Iversen et al., 2017; The Faculty of Sexual & Reproductive Healthcare Clinical Effectiveness Unit, 2014), and vaccination for human papillomavirus will make this disease rare in the future.

Research on links between COCs and depression are variable with some studies showing no effect (Duke et al., 2007; O'Connell et al., 2009). A recent Danish study found a 23% increase in first use of an antidepressant versus nonusers (Skovlund et al., 2016). Commentary on this latter study noted the increase would equate to 0.5% more women beginning hormonal contraception developing depression who might not have otherwise (Bitzer, 2017). In addition to other questions about the study, this commentator noted that increased use of antidepressants could occur because these women had more contact with health care services.

More minor side effects can include irregular bleeding, breast tenderness, nausea, and bloating. These can often be reduced with lower estrogen doses (Rosenberg et al., 1999), but this is associated with more breakthrough bleeding. Many of these side effects diminish with ongoing use. For example, women with irregular bleeding should continue the COC for three months before considering a change (Faculty of Sexual & Reproductive Healthcare Clinical Guidance, 2012). COCs occasionally cause a small increase in blood pressure (Steenland et al., 2013).

The POP is used much less commonly than the COC, despite having a fewer contraindications and precautions and less risk of serious adverse effects. There are three different progestogens used: norethisterone, LNG, or desogestrel.

The POPs suppress ovulation, although this varies between the different progestogens—50%–60% of cycles with norethisterone, 72% in LNG users, and 97% for desogestrel users (Renner and Jensen, 2011). They make the cervical mucus thick, reducing sperm penetration. POPs also affect sperm and egg transportation by affecting tubal motility and cilia. Finally, they lead to an inactive endometrium, which possibly affects sperm transportation or implantation. They are taken daily with no break.

Norethisterone and LNG need to be taken within 3 hours of the due time; a dose over 27 hours after the last dose may reduce the effect on the cervical mucus (Faculty of Sexual & Reproductive Healthcare Clinical Guidance, 2015). For desogestrel, up to 12 hours late is acceptable because of the greater suppressive effect on ovulation. With few contraindications (Faculty of Sexual & Reproductive Healthcare Clinical Guidance, 2015), the POP is often suitable when the COC is not. It is often used for lactating women.

Mood changes have been reported with POPs (Faculty of Sexual & Reproductive Healthcare Clinical Guidance, 2015), but a systematic review published in 2018 found no clear relationship between progestogen contraceptives and depression (Worly et al., 2018). Ectopic pregnancy may be a risk, and changes in bleeding patterns are common (Faculty of Sexual & Reproductive Healthcare Clinical Guidance, 2015).

Other Hormonal Contraceptives

Hormonal Vaginal Rings

The vaginal ring works in a very similar way to the COC with estrogen and progestogen for three weeks of a four week cycle. It releases 15 μg ethinylestradiol and 120 μg etonogestrel daily (Alsharaydeh et al., 2017). A ring is inserted (an applicator can be used, but is not essential) and then removed after three weeks for seven days allowing a withdrawal bleed before inserting a new ring. Alsharaydeh et al. (2017) and the product literature (Merck Sharp and Dohme Limited, 2018) report that the ring can release sufficient hormones for up to four weeks, providing extra cover for women who delay the removal (which is not recommended). The ring is considered to have similar effectiveness to the combined OC (Trussell, 2011). Women find the ring easy to insert and remove, it does not interfere with sexual intercourse, and satisfaction is high (Alsharaydeh et al., 2017). For the first use with no current hormonal use, the ring is inserted on day 1 of the cycle (first day of menstrual bleed), or days 2–5 if necessary, but then the woman may not be protected for the first seven days of use and needs contraceptive cover.

The vaginal ring can fall out, especially if poorly inserted, while removing a tampon, during sexual intercourse, or with severe or chronic constipation (Merck Sharp and Dohme Limited, 2018). It should be replaced within 3 hours to maintain contraception (Alsharaydeh et al., 2017; Merck Sharp and Dohme Limited, 2018). Vaginal discharge can increase occasionally, and vaginal infection may be a risk. Contraindications, precautions, interactions, and side effects are like the COC. However, it has the advantages of only needing to be remembered once a month, and achieving steady low hormonal levels which should aid tolerability.

The ring is refrigerated before dispensing, then stored at room temperature, up to 30 °C for up to four months (Merck Sharp and Dohme Limited, 2018).

Combined Hormonal Patches

The transdermal patch also releases estrogen and progestogen for three weeks, with seven days off and a withdrawal bleed (Alsharaydeh et al., 2017). It releases 203 μg of norelgestromin and 33.9 μg of ethinylestradiol every 24 hours. Contraceptive efficacy can be lower in women 90 kg or heavier (Janssen-Cilag Ltd, 2017).

The patch is applied weekly to clean, dry, hairless, intact health skin on the buttock, abdomen, upper outer arm or torso, where tight clothes will not rub (Janssen-Cilag Ltd, 2017). The site is rotated to minimize irritation. In the absence of previous hormonal treatment, the patch is started on day 1 of the cycle. See the product information for instructions on switching from other hormonal contraceptives. Complete or partial detachment may result in insufficient levels and contraceptive failure. See the product information for the action to take.

Alsharaydeh et al. (2017) reports 10% of users develop application site reactions, and that breakthrough bleeding is more common with the patch than COC in the first two cycles but not after that.

Effectiveness of Contraceptives

The failure rate of contraception is affected by a woman's underlying fertility, frequency of intercourse, the contraceptive method, and compliance (Goldsmith, 2016). A woman who has previously used hormonal contraceptives will have a lower failure rate than a new user, possibly through more awareness of correct use. Women who are satisfied with the OC have more correct use and fewer missed pills. Contraceptive failure is higher in people with low socioeconomic status, some ethnic groups, and obese women (who have been found to have lower compliance) (Goldsmith, 2016). Women need clear advice to understand the effectiveness of various contraceptives.

For women attempting to become pregnant, around 80%–85% will become pregnant within 12 months (Goldsmith, 2016; Trussell, 2011). In married women not trying to become pregnant, but also not using contraception, the 12 month rate of pregnancy is 46% (Goldsmith, 2016), but it is likely that these will be self-selecting for having low fertility (e.g., required help to become pregnant previously), or low frequency of intercourse (Trussell, 2011). The estimated rates of failure for various methods based on US data are outlined in **Table 1**. The data from Trussell (2011) reflects the first year after initiation (or restart) of the method, but these estimates arise from 1995 and 2002, so newer numbers are provided from a 2006–2010 US survey (Sundaram et al., 2017). The POP and the COC are combined in **Table 1**, primarily because the data comes from studies in which people reported being on "the pill" without identifying which pill. Trussell (2011) suggests that the POP might have a greater failure than the COC given the smaller window for taking it. A Cochrane review in 2011 found the different COCs to be comparable in preventing pregnancy (Lawrie et al., 2011).

Failure rates can vary. The failure rate for the implant is higher (0.23%) in women who are obese (Goldsmith, 2016). The MPA injection has recently been used subcutaneously, with an unknown failure rate, but a study over 24 months reported no pregnancies (Goldsmith, 2016). Condom users will sometimes use the EC when failure occurs, which drops the failure rate back to 1.0%–2.1% where used consistently. Latex condoms have lower failure rates than polyurethane condoms, possibly through less slippage or breakage (Goldsmith, 2016). The Choice study, in which women not on contraception chose an OC, vaginal ring, contraceptive patch, DMPA, implant, or IUD and were followed for three years, found a failure rate of around 5% for the group using the OC,

Table 1 Percentage of women experiencing an unintended pregnancy (Sundaram et al., 2017; Trussell, 2011)

	Sundaram et al. (2017) *From 2006 to 2010 data*	*Trussell (2011)* *During 1st year of use, mostly from 1995 and 2002 data*[a]	*Trussell (2011)* *During 1st year of use, mostly from 1995 and 2002 data*[a]

Condoms	43%	N/A	N/A	

COC, combined OCs; *DMPA*, depot medroxyprogesterone acetate; *IUD*, intrauterine devices.

patch, or vaginal ring, at one year, increasing to around 9% at three years (Winner et al., 2012). The failure rate almost doubled in young women under 21 years. In comparison, the IUD or implant group had just under 1% failure rate at three years.

For adolescents, barrier methods are not usually recommended alone to prevent pregnancy because of higher failure rates compared with OCs, MPA, or LARCs, unless they are particularly mature and motivated, but even with perfect use pregnancy risk remains more elevated than other options (**Table 2**) (Greydanus et al., 2012).

Even after deciding to initiate DMPA, delaying initiation to rule out pregnancy can cause failure. In a US clinic, 7% of adolescents asked to return for the injection (day 1–5 of menses) became pregnant before returning. Despite needing no appointment, they took a median 28 days (average 104 days) to return, with 19% taking at least six months and 8% not returning (Ohlemeyer, 2003). In young women up to 26 years of age, immediate progestogen injection after a negative pregnancy test, regardless of the day of cycle, resulted in better progestogen injection continuation and significantly fewer pregnancies than using bridging hormonal contraception for 21 days then the injection (Rickert et al., 2007).

Immediate starting of contraception is recommended, particularly in young women, to avoid the risk of nonreturn to the clinic, or loss of motivation to use contraception (Whiteman et al., 2014).

The younger a woman starts having sex the longer it takes to initiate contraceptive use (Finer and Philbin, 2013). Furthermore, young women (e.g., up to 20 years old) have lower OC continuation rates than older women (Diedrich et al., 2015; White and Westhoff, 2011). A US study found that, despite most young women surveyed having used OCs, most did not like the idea of using them for themselves (Hoopes et al., 2018). DMPA was even less desirable to these women, few of whom had used it. The IUD and contraceptive implant were considered very acceptable by a larger group, although a significant minority considered these "very

unacceptable." Women seemed influenced by someone who had become pregnant on that particular contraceptive, and the views of friends and family. The young women in this study with a history of pregnancy were less interested in OCs and more interested in implants versus nulliparous women.

In women for whom a pregnancy may be particularly risky physically, e.g., stroke, certain cardiac conditions, some cancers, or transplant, the most effective methods of contraception should be used, i.e., LARCs (Anon, 2016). Women taking teratogenic medicines, e.g., oral retinoids, or methotrexate also have a particularly strong need for effective contraception, including for a period of time after discontinuation, depending on the medicine.

Continuation and Gaps in Therapy

Effectiveness depends on continuation, but the rates (**Table 2**) are based on consumers choosing their method, not being randomized to the different options. Self-reported continuation is overestimated, with a study finding 59% continuation at one year by self-report versus 38% by pharmacy claims (Triebwasser et al., 2015).

LARCs have higher rates of continuation generally as these are designed for use for years without needing to arrange interim prescriptions. It may reflect selection by women who wanted long-term contraception, e.g., being in a long-term relationship or particularly motivated to avoid pregnancy. Presumably it also reflects a lack of bothersome side effects. However, many women seeking short-term contraception do not want to try LARCs and those randomized to it had a discontinuation rate of 35% at two years, typically citing adverse effects (Hubacher et al., 2018). Around 6% of women fitted with an IUD postabortion had a repeat abortion within the next 24 months (Rose and Lawton, 2012).

A US study using administrative claims found when women started on hormonal contraception (first time or a restart), 55% refilled their prescriptions at three months indicating continuation (Murphy and Brixner, 2008).

For OCs, providing longer cycles (seven months (White and Westhoff, 2011) or one year (Foster et al., 2006)) significantly increases the continuation rate compared with shorter cycles of supply, particularly in women under 18 years (White and Westhoff, 2011). Longer supply also reduces the risk of pregnancy and abortion compared with shorter supply periods (Foster et al., 2011).

Availability without prescription might help continuation (Castaño and White, 2013). A study from El Paso, Texas, found women going to Mexico to get OCs without prescription had higher continuation rates than those going to local clinics (Potter et al., 2011). While counseling should help continuation, Castaño and White (2013) found no evidence for this. They reported that apart from one randomized controlled study with a positive effect on injection continuation, others had negative findings, but were limited by small sample sizes, variable interventions, and high loss to follow-up. Advising women when initiating the OC of the transient nature of most side effects might be helpful (Castaño and White, 2013).

US women's reasons for a gap in contraception use commonly include infrequent sexual activity; problems accessing or using methods, including cost, lack of time to get it, side effects, and not liking any method; ambivalence about becoming pregnant; or believing they could not get pregnant (Potter et al., 2011). Women who think they have experienced side effects are more likely to discontinue OCs, but also might switch to another OC or a less effective method (Castaño and White, 2013). Women without underlying concerns about hormones tend to switch to another highly effective contraceptive if they had side effects, while those with underlying concerns tended to stop contraception completely or move to condoms. In the mid-1990s, VTE reports resulted in many women discontinuing their OC, increasing abortions without any reduction in VTE incidence (Castaño and White, 2013). Women discontinuing IUDs or implants within three years commonly cite bleeding changes, or not liking how it made them feel. For OCs the most common reason was logistical reasons, e.g., remembering to take it, or barriers to access (Diedrich et al., 2015). DMPA discontinuers commonly cite side effects (Diedrich et al., 2015).

Missing occasional pills is common (e.g., 68% of women self-reported missing one or more pills in three months) (Smith and Oakley, 2005), and sometimes missing multiple pills inadvertently leads to discontinuation. While most missed pills do not increase pregnancy risk, some do, particularly where the woman runs out of tablets (Smith and Oakley, 2005). Poor OC compliance is associated with having no established routine for pill taking, not reading or understanding the written information provided, insufficient information from the health care professional, and perceived adverse effects (Smith and Oakley, 2005). The top reasons women missed a pill include being away from home, forgetting, not having a new pill pack, being late taking it, travel, work pressures, or school pressures (Smith and Oakley, 2005). Pharmacy could address these concerns through advance discussion with the woman about how she is going to remember taking it (e.g., mobile phone reminder, putting by the toothbrush, making it part of her routine), considering the unexpected night away or travelling (e.g., have a spare card in a wallet or at a house she stays at often), and how to ensure she does not run out. US women can get a free text reminder service for contraceptives (Castaño and White, 2013). To help maximize continuation and minimize gaps in therapy it is important to inform women about LARCs and offer from first starting contraception.

Use of Contraception Around the World

Contraceptive usage varies considerably by country (**Table 3**) (Department of Economic and Social Affairs Population Division, 2017). This is likely to reflect access including cost and health care worker availability, desire to avoid pregnancy within a population, social norms and other cultural effects. While variation is particularly marked between highly developed countries and

Dates provided above are the last date of data collection for the data in the table. Methods of data collection will vary between countries.

developing countries, there is also considerable variation between countries with similar development status. For example, IUDs are twice as commonly used in France than across the Channel in the UK, and Australia has much lower usage than either country.

Emergency Contraception

A copper IUD is 99% effective in preventing pregnancy if used within one week of unprotected intercourse (Alsharaydeh et al., 2017). However, oral hormonal methods are more convenient than an IUD insertion (Gemzell-Danielsson, 2010).

The Yuzpe method introduced in the late 1970s consisted of 0.1 mg ethinylestradiol and 0.5 mg LNG given within 72 hours post intercourse and repeated after 12 hours (Gemzell-Danielsson, 2010). Reduced side effects and higher efficacy saw LNG alone (at a higher dose) superseding the Yuzpe method (Cameron et al., 2017).

LNG can be given as 0.75 mg twice, 12 hours apart or as a single 1.5 mg dose (Gemzell-Danielsson, 2010) when administered within 72 hours of unprotected sexual intercourse. Failure rates increase with later dosing. In a large multicentre study, LNG had a pregnancy rate of 0.4% with dosing up to 24 hours after unprotected intercourse, versus 1.2% for 25–48 hours, and 2.7% at 49–72 hours (Task Force on Postovulatory Methods of Fertility Regulation, 1998). Overall, this represents prevention of 85% of the expected pregnancies. An increase up to 120 hours may have reduced effectiveness (Cameron et al., 2017; Gemzell-Danielsson, 2010) and is not licensed.

LNG appears to have no direct impact on sperm function or motility when used as an EC (Cameron et al., 2017; Gemzell-Danielsson, 2010; Gemzell-Danielsson et al., 2013). LNG can impact on follicular development, if used before the normal luteinizing hormone surge (Gemzell-Danielsson et al., 2013). Inhibiting the luteinizing hormone surge delays or prevents ovulation (Sznajder and Jamshidi, 2016). LNG mainly works by delaying ovulation long enough for any viable sperm to be rendered inactive (Cameron et al., 2017).

More recently available is ulipristal acetate (UPA) as a single 30 mg dose (Cameron et al., 2017). It is slightly more effective, and importantly can be used up to 120 hours after unprotected sexual intercourse (Cameron et al., 2017). A noninferiority study with LNG and UPA found a 1.8% observed rate of pregnancy with UPA (versus 5.5% expected rate), and 2.6% for LNG (versus 5.4% expected) (Glasier et al., 2010). There were 3 pregnancies in 106 LNG users 72–120 hours after sexual intercourse, versus none in 97 UPA users in the same time frame, a significant difference.

UPA is a progesterone receptor modulator that inhibits or delays ovulation and may have some effect on sperm function (Cameron et al., 2017). A theoretical concern has been noted when UPA is used by women already taking an OC. As UPA acts as a receptor modulator, this may make the progestogen contained in an OC unable to bind and therefore decrease the efficacy of the OC (Salcedo et al., 2013). Therefore, an additional barrier method is recommended for the remainder of the menstrual cycle.

LNG may be less effective in women with obesity (BMI $\geq$ 30 kg/m^2) than in normal/underweight women (Jatlaoui and Curtis, 2016). While the evidence is limited, there is some evidence to suggest that women over 80 kg are at increased risk of LNG failure and indeed experience pregnancy rates comparable to those with no contraception (Jatlaoui and Curtis, 2016). In these women, consideration of another method (i.e., UPA or IUD) may be appropriate.

Given the importance of "timely" access to emergency contraception (i.e., efficacy decreases the longer time from unprotected sexual intercourse), increasing access has been a key priority internationally. Pharmacy access may aid uptake due to the distribution of pharmacies, longer opening times and no appointment needed. For example, demand increased in Germany nearly 50% for the EC after reclassifying from prescription to nonprescription (Kiechle and Neuenfeldt, 2017). As early as 1997 community pharmacists in the USA were involved in increasing access (Anderson and Blenkinsopp, 2006), and by around 2000 many countries were supplying ECs via pharmacies (Anderson and Blenkinsopp, 2006). Service users rate pharmacists highly for quality of personal interaction and the quality of information provided (Anderson and Blenkinsopp, 2006). Young people have expressed positive

interactions accessing sexual health products from pharmacy and note specifically longer hours and accessible location (Gonsalves and Hindin, 2017).

A Canadian qualitative study found pharmacists poorly informed on the EC option of a copper IUD, and were unlikely to discuss it with patients, even with delayed presentation or bodyweight above 75 kg (Wong et al., 2017). Many felt reluctant to discuss bodyweight. Mystery shopping in private pharmacies in Kinshasa, Democratic Republic of Congo, found pharmacy staff were mostly knowledgeable and helpful, although some knowledge gaps existed, for example, in time window for use, and a fifth were out of stock of the EC (Hernandez et al., 2018).

Privacy is a common concern, with an Australian study finding many consultations took place at the dispensary counter, albeit that usually the mystery shopper found privacy to be maintained (Collins et al., 2018). More questions were asked when the counseling room was used than at the dispensary, although the number of counseling points did not differ. Some lacked knowledge about the new hormonal contraceptive, UPA, and regulatory matters (supply to a third party). The patient was usually not given a choice of LNG or UPA, despite increased efficacy with UPA.

In a small minority of cases, LNG was supplied outside of the 72 hour window in an Australian mystery shopping study, despite UPA being available (Collins et al., 2018).

Requests for emergency contraception also present an opportunity for pharmacists to provide ongoing contraception or education about it. In Jamaica, only 15% of women getting the EC pill who were not using regular contraception (except condoms in some cases) went on to regular contraceptive measures in the following 3–6 months (Chin-Quee et al., 2010).

Pharmacists' Roles with Ongoing Contraception

Pharmacists can have a variety of roles with ongoing contraception beyond dispensing prescriptions. This includes provision of information; continuation supply; initiation of oral contraceptives, transdermal contraceptives or vaginal rings; and administration or provision of injections.

Rural women in India had limited knowledge about contraceptive methods, which increased substantially following a pharmacist intervention (Chandrasekhar et al., 2018). A simple measure of a pharmacist providing a book improved knowledge immediately after the supply and three months later compared to before the intervention, versus a control group, in a study in Jordan (Akour et al., 2017). There may be other opportunities for contraception provision or advice in pharmacy, for example, a survey in Kuwait found that most pharmacists reported providing contraception advice to lactating women (Albassam and Awad, 2018), probably because they supply OCs without prescription (Shah et al., 2001).

Where hormonal contraceptives other than emergency contraception are available through pharmacy without prescription, the models can vary considerably. Requirements can include previous prescribing by a doctor, age restrictions, additional training by pharmacists, and use of screening tools (Gauld et al., 2016). Sometimes the availability expands through a continuation supply provision, as in Australia and the Netherlands, through reclassification as in New Zealand, or statewide legislation as in some states in the US. Some countries simply have pharmacy or drugstore availability (Grindlay et al., 2013; Ratanajamit et al., 2002).

While much research on the EC availability in pharmacy has been conducted, little research exists on the provision of other contraceptives by pharmacists without prescription. Two key pilot studies were conducted in London (UK) (Parsons et al., 2013) providing OCs and Washington State (US) (Gardner et al., 2008), providing OCs, contraceptive patches or vaginal rings (**Table 4**). In the London study, 11% of women surveyed said they would not have accessed contraception elsewhere, and users were often first-time hormonal contraceptive users. The London pharmacists were self-selecting, potentially being particularly motivated, received a lot of training, and knew they would be audited and mystery shopped. Therefore, this study may not represent a real-world model. In the Washington study, 9% of women were ineligible for supply, primarily because of blood pressure and/or bodyweight over the allowable limit. Some ineligible women did get supplied, typically those already taking it from another provider.

Another pharmacy study found that providing one month of POP to women at the EC consultation saw more women on contraceptives at 6–8 weeks later than those invited to take their empty EC pack to the family planning clinic (Michie et al., 2014).

Table 4 An overview of the two pilot studies conducted (Gardner et al., 2008; Parsons et al., 2013)

	London study	*Washington state study*
Pharmacists and pharmacies involved	16 pharmacists in 8 pharmacies trained; 7 pharmacists from 5 pharmacies provided the service	26 pharmacists in 8 pharmacies; all pharmacies recruited patients
Number of participants	741	214
Proportion of participants with previous use	41% had previously used OCs	87% had previously used hormonal contraceptives
Accuracy of the pharmacist on audit	100%	96% of supplies were within the guideline
Proportion supplied following an EC supply	45%	7%
Time in the consultation	19 minutes	23 minutes for an initial supply
Satisfaction ratings for women	All responding were satisfied or very satisfied	High or very high 98%

A US pilot saw pharmacists with additional training administer DMPA injections to women who were previous users (Maderas and Landau, 2007). Pharmacist enthusiasm or prioritization of the service, and a close relationship with and referrals from the local health clinic appeared to aid uptake, but some clinicians preferred their clinics delivered the injections.

Some real-life research exists of provision of ongoing contraception by pharmacists. One year after opening pharmacist-supply, only 11% of Californian pharmacies provided the service, but a further third expected to (Gomez, 2017). Barriers include lack of reimbursement by insurers and insufficient payment, time constraints, and liability concerns (Vu et al., 2017). Pharmacy purchase of OCs is common in Kuwait (Shah et al., 2001). A quarter of women started it without a physician's consultation. Most women sent another person to collect their OC, and instructions on usage or adverse effects in the pharmacy were rarely reported. OC discontinuation typically occurred with plans to become pregnant. The authors noted the high rate of obesity in women of child bearing age, and the need for improvements in pharmacy staff and packaging to provide better information. In Thailand (Ratanajamit and Chongsuvivatwong, 2001), mystery shopping and survey research with drugstores published in 2001 found deficiencies with history-taking and advice-giving with OCs, but good drug selection. EC provision also had room for improvement. Most drugstores are not pharmacist-owned, and there were some better practices seen with the pharmacists or staff in pharmacist-owned drugstores versus nonpharmacists and staff in drugstores not owned by pharmacists. An educational intervention improved the EC provision (Ratanajamit et al., 2002).

Further real world research is necessary to ascertain the safety, workability, and uptake with the various models.

Conclusion

Pharmacy has an important and increasing role to play in aiding safe and effective contraceptive choices and ensuring women are informed about contraception and how to use it effectively. There is a wide range of contraception, so pharmacists need to be well-informed, and access WHO, UK, or US MEC for the latest information on best practice recommendations.

Management of Urologic Disorders and the Pharmacist's Role: Benign Prostatic Hyperplasia

Pranav Sharma*, Hannah Pham*, Kamran Zargar-Shoshtari†, *Texas Tech University Health Sciences Center, Lubbock, TX, United States; †University of Auckland, Auckland, New Zealand

Introduction

Benign prostatic hyperplasia (BPH) is a noncancerous enlargement of the prostate gland due to proliferation of smooth muscle and epithelial cells within the prostatic transitional zone (McVary, 2010). The nonmalignant, uncontrolled growth of the prostate leads to bothersome lower urinary tract symptoms (LUTS). LUTS consist of both obstructive voiding symptoms and irritative storage symptoms. Common manifestations of obstructive symptoms include decreased force of stream, intermittent urinary stream, straining, hesitancy, post-voidal dribbling, and incomplete bladder emptying. Irritative symptoms present as increased daytime

frequency, nocturia, urgency, and urinary incontinence. BPH can also cause microscopic or gross hematuria. If left untreated, BPH may lead to more serious medical complications such as acute urinary retention, recurrent urinary tract infections (UTIs), bladder calculi, hydronephrosis, or renal insufficiency/renal failure.

Benign prostatic hyperplasia is the most common benign neoplasm found among men, which increases in incidence and prevalence with advancing age (McConnell et al., 1994). The prevalence of BPH increases from 8% in men aged 31–40, to approximately 50% in men aged 51–60, to over 80% in men older than age 80 (Berry et al., 1984). Black men are more likely to have BPH with moderate to severe LUTS than white men, while Asian men are less likely to have BPH-related symptoms (Martin et al., 2014). Other risk factors associated with an increased risk of BPH-induced LUTS include higher free prostate-specific antigen (PSA) levels, obesity, heart disease, diabetes mellitus, use of beta-blockers, and lack of physical exercise (Meigs et al., 2001).

The exact etiology of BPH remains incompletely understood although several theories exist. Due to the similarity between BPH and the embryonic morphogenesis of the prostate, it has been hypothesized that BPH may result from prostatic tissue reverting back to an embryonic-like state in which it is unusually sensitive to various growth hormones (McVary, 2010). Other possible explanations for the development of BPH may include a change in prostatic androgen receptors or an increase in the ratio of estrogen to androgen with advancing age (Chodak et al., 1992; Krieg et al., 1993). It is certain, however, that as men age, there will be an increase in the amount of prostatic stroma (fibroblast, myofibroblasts, and smooth muscle cells), which further increases the density of alpha-1 receptors in the prostate. Growth of the prostate stroma into the prostatic urethral lumen and increase in smooth muscle tone via the receptors within the prostate create a bladder outlet obstruction (BOO) that contributes to the clinical symptoms seen in BPH. Detrusor overactivity, due to bladder irritability from an overworked bladder trying to overcome an obstruction, is thought to cause irritative symptoms in LUTS.

Although symptoms of BPH are generally not life-threatening, they can be immensely bothersome and significantly affect quality of life (QOL). Thus, it is important to correctly diagnose BPH in order to provide the most effective therapy. The recommended diagnostic evaluation for BPH includes a patient history of LUTS, physical examination, urinalysis, PSA testing, and occasionally urodynamics. The patient's history should include the presence of obstructive and/or irritative symptoms. The severity of LUTS can be assessed using a self-completed questionnaire, such as the American Urologic Association Symptom Score (AUASS) or the International Prostate Symptom Score (IPSS) (Barry et al., 2017). Patients with scores of 0–7 have mild symptoms, 8–19 have moderate symptoms, and 20–35 have severe symptoms. A voiding dairy, which is utilized to record the frequency and volume of urination, may be useful in the evaluation of BPH, especially in men with nocturia or polyuria (>3 L/day) (McVary, 2010). During the physical exam, the bladder is palpated for distention and a digital rectal exam (DRE) is performed to evaluate prostate size, symmetry, and consistency. The presence of blood or a UTI can be detected by urinalysis. A serum PSA, which can be an indicator of prostatic volume, should only be obtained if the patient has greater than 10–15-year life expectancy and if a diagnosis of prostate cancer would modify management (Nickel et al., 2010). Uroflowmetry and post-void residual volume (PVR) are optional diagnostic tests that may be used to assess urine flow rates and identify obstruction. Cystoscopy may be indicated in patients undergoing surgery or in whom urethral stricture, bladder stone, or bladder cancer are suspected. Although BOO may appear severe on diagnostic tests, the degree of BOO or prostate size does not always correlate with the severity of BPH symptoms experienced by the patient.

Treatments for Benign Prostatic Hyperplasia

The primary goals of treatment are to improve patient QOL by relieving LUTS, slowing disease progression, and preventing secondary complications. The need for therapy depends on the severity of symptoms (as assessed by the AUASS or IPSS), its effect on the patient's QOL, and the extent of urinary tract damage. The treatment options for BPH include behavioral modifications, phytotherapy, medicine, and surgery.

Medical Therapy

Behavioral Modification

The American Urologic Association (AUA) recommends that patients with mild LUTS (AUASS or IPSS <8) or patients with moderate to severe LUTS (AUASS or IPSS >8) who are not bothered by their symptoms should be managed with watchful waiting or active surveillance and reexamined yearly. Patients with symptoms that are beginning to affect their QOL but have no evidence of complications (e.g., recurrent infections, urinary retention, or renal insufficiency) may be monitored and treated conservatively with behavioral modifications. Patients should be advised to avoid substances that make urinary symptoms worse. Reducing consumption of spicy food, acidic food, caffeine, and alcohol in the diet may help minimize urinary symptoms. Certain medications that exacerbate symptoms (e.g., diuretics) or induce urinary retention (e.g., alpha-agonists, antihistamines) should also be avoided. If nocturia is a major symptom, men should avoid diuretics in the evening, decrease fluid intake in the evening, and elevate legs an hour before bedtime (to help redistribute and eliminate excess fluid before sleeping) if they have lower extremity edema (McVary, 2010). Lastly, men can try voiding in a sitting position rather than standing or use the double voiding technique to help empty the bladder more completely (de Jong et al., 2014). These lifestyle modifications may be helpful for all patients, regardless of

BPH severity. LUTS may also be relieved by clean intermittent self-catheterization (CIC). This is an appropriate option for men who fail to respond to medical therapy and are not candidates for surgical therapy.

Phytotherapy

The use of phytotherapy (plant-based or herbal medications) for BPH treatment may benefit some men. The current AUA guidelines do not recommend using alternative medicines for the management of LUTS secondary to BPH, due to the lack of data on safety and efficacy of these agents (McVary, 2010). Saw palmetto (*Serenoa repens*) is the most widely used and studied phytotherapy for BPH. The extract from its berries is believed to have antiandrogenic effects, 5-alpha-reductase inhibition, and antiinflammatory effects. However, there is currently conflicting data concerning the efficacy of this extract, with most studies stating saw palmetto has no benefit in the treatment of BPH (Barry et al., 2011; Tacklind et al., 2009). Other phytotherapies marketed for BPH treatment include African plum tree (*Pygeum africanum*), stinging nettle *(Urtica dioica*), pumpkin seed (*Cucurbita pepo*), South African star grass (*Hypoxis rooperi*), and rye grass pollen (*Secale cereale*). The extract from the bark of the African plum tree, which is suggested to inhibit fibroblast proliferation and have antiinflammatory and antiestrogenic effects, has been demonstrated to improve urinary symptoms two times more than placebo and increase maximum urinary flow (Q_{max}) rates (Wilt and Ishani, 1998). Pumpkin seeds have also been shown to have antiinflammatory effects and reduce urinary urgency and frequency in men with LUTS (Damiano et al., 2016). Cernilton, which is extracted from rye grass pollen, has shown to provide symptomatic improvement in BPH, but does not affect urinary flow rates, PVR, or prostate volume (Wilt et al., 1998). Its proposed mechanism of action involves alpha-blockade and 5-alpha-reductase inhibition. Beta-sitosterol, a sterol found in these many of these phytotherapies, has been identified as the ingredient that improves LUTS in men with BPH (Wilt et al., 1999). While some men find benefit in using phytotherapies, there may be a considerable placebo effect with these agents.

Oral Medications

If LUTS continue to negatively affect the patient's QOL despite conservative management, initiation of medical therapy may be indicated. Pharmacotherapy can be considered in men with moderate to severe BPH symptoms (AUASS or IPSS ≥8) who do not have an absolute indication necessitating surgery. Before medically treating BPH, the severity of the patient's symptoms and the potential side effect of therapy should be weighed. Oral medications commonly used for treatment of BPH include alpha-adrenergic antagonists (alpha-blockers), 5-alpha-reductase inhibitors (5ARIs), anticholinergic agents, phosphodiesterase-5 (PDE-5) inhibitors, or combination therapy (**Table 1**).

Alpha-Blockers

Action and Indications

American Urologic Association guidelines recommend the use of alpha-blockers as first-line treatment for moderate to severe symptomatic BPH. Alpha-blockers work by inhibiting alpha-1 adrenergic receptors on the smooth muscle cells of the bladder neck, prostate, and prostatic urethra, leading to the reduction in urethral resistance and bladder obstruction. Alpha-blockers prevent the sympathetic activation of these receptors by the neurotransmitter norepinephrine. Alpha-1 adrenergic receptors consist of 3 subtypes: alpha-1A, located in the smooth muscle of the prostate, bladder neck, seminal vesicles, and vas deferens; alpha-1B, located in blood vessels; and alpha-1D, located in nasal passages, bladder, and spinal cord. Alfuzosin (Uroxatral), doxazosin (Cardura), tamsulosin (Flomax), terazosin (Hytrin), and silodosin (Rapaflo) are long-acting alpha-blockers approved by the US Food and Drug Administration (FDA) for BPH treatment. Alfuzosin, doxazosin, and terazosin are nonsubtype selective alpha-blockers, while tamsulosin and silodosin are selective alpha-1A blockers.

Efficacy

All five alpha-blockers appear to have equal efficacies when administered at the appropriate doses (Jung et al., 2017; McVary, 2010). The alpha-blockers allow for long-term improvement in IPSS and urinary flow rates, decreasing 30%–40% and increasing 16%–25%, respectively (Djavan and Marberger, 1999). Alpha-blockers have also proved to be more effective in improving maximal urine flow and nocturia than finasteride, a 5ARI (Tacklind et al., 2010). Maximal urinary flow rates can be achieved within 8 h of the first dose of a selective alpha-1A blocker and up to 4 weeks with nonselective alpha-blockers. Urinary improvements may be evident within a few days and maximal improvement may take up to 1–3 months (Marks et al., 2013). While older alpha-blockers, such as terazosin and doxazosin, are more cost-effective choices, they require dose titration over several weeks and administration at bedtime to avoid hypotension. Alpha-blockers such as doxazosin can also prevent the progression of BPH (by 39% compared to placebo) (McConnell et al., 2003).

Side Effects

While similar in their efficacies, alpha-blockers can be distinguished by their side-effect profiles due to their differences in affinity for the various alpha-1 receptor subtypes. Some adverse effects experienced by patients include fatigue, nasal congestion, dizziness, orthostatic hypotension, syncope, and retrograde ejaculation. Agents that block alpha-1B receptors can cause hypotension,

Table 1 Oral medications for treating BPH

Class	*MOA*	*Generic name*	*Brand name*	*Selectivity*	*Titration/used for HTN*	*Supplied*	*Directions*	*Maximum daily dose*	*Adverse effects*
α-blocker	Relax smooth muscle in the bladder neck and prostate by inhibiting α-receptors	Alfuzosin	Uroxatral	α-1 non-selective	No/No	Tabs: 10 mg	po q day after a meal	10 mg	Fatigue, nasal congestion, dizziness, orthostatic hypotension, syncope, retrograde ejaculation
		Doxazosin	Cardura	α-1 non-selective	Yes/Yes	Tabs: 1, 2, 4, 8 mg	po q day	8 mg	
		Silodosin	Rapaflo	α-1A selective	No/No	Caps: 4, 8 mg	po q day with a meal	8 mg	
		Tamsulosin	Flomax	α-1A selective	Sometimes/No	Caps: 0.4 mg	po q day after a meal	0.8 mg	
		Terazosin	Hytrin	α-1 non-selective	Yes/Yes	Tabs: 1, 2, 5, 10 mg	po q HS	10 mg	
5α-Reductase Inhibitor (5-ARI)	Reduce prostate volume by inhibiting 5-α reductase enzyme and	Dutasteride	Avodart	Types 1 and 2	No/No	Caps: 0.5 mg	po q day	0.5 mg	Erectile dysfunction, decreased libido, decrease volume of ejeculate, gynecomastia
		Finasteride	Proscar	Type 2	No/No	Tabs: 5 mg	po q day	5 mg	
Phosphodiesterase-5 Inhibitor (PDE5I)	Decrease bladder, prostate, and urethra smooth muscle tone by increasing intracellular cGMP	Tadalafil	Cialis	Type 5	No/No	Tabs: 5 mg	po q day	5 mg	Headache, flusing, back pain, nasal congestion, myalgia, dyspepsia, diplopia, blurry vision, impaired color vision
Anticholinergic Agents	Reduce bladder smooth muscle contractions via inhibiting muscarinic receptors	Tolterodine	Detrol	M receptor non-selective	No/No	Caps: 2, 4 mg	po q day	4 mg	Urinary retention, blurry vision, dry mouth, constipation, cognitive impairments
α-blocker + 5-ARI	Combination MOA of α-blocker and 5-ARI	Dutasteride + Tamsulosin	Jalyn	Type 1 and 2 5α-Reductase Inhibitor + α-1A adrenergic receptor inhibitor	No/No	Caps: 0.5 mg dutasteride + 0.4 mg tamsulosin	po q day after a meal	0.5 mg dutasteride + 0.4 mg tamsulosin	Combination side effects of α-blocker and 5-ARI

dizziness, and syncope. Doxazosin and terazosin cause more hypotension than alfuzosin, tamsulosin, and silodosin (Marks et al., 2013; Roehrborn et al., 2003). However, the hypotensive side effects of doxazosin and terazosin may be favorable in patients with both BPH and hypertension. Agents that block alpha-1D receptors may cause nasal congestion.

Combination of Alpha-Blockers and 5ARIs

The combination of an alpha-blocker and a 5ARI is an appropriate and effective treatment for patients with LUTS and demonstrable prostatic enlargement (>40 g) (McVary, 2010). This combination treatment is also ideal for patients with severe symptoms (AUASS or IPSS >20) or those who do not have an adequate response to maximal monotherapy. Jalyn (0.5 mg dutasteride and 0.4 mg tamsulosin) is the combination pill approved for use in the United States. Based on their respective mechanisms of action, alpha-blockers provide rapid relief of urinary symptoms, and 5ARIs alter the underlying disease process.
