The Medical Therapy of Prostate Symptoms (MTOPS) trial and the Combination Avodart and Tamsulosin (CombAT) trial demonstrated that both agents used together improved voiding symptoms (as measured by IPSS) and Q_{max} more than either agent alone (McConnell et al., 2003; Roehrborn et al., 2010). The MTOPS trial also revealed that the combination of both agents is better at preventing the progression of BPH and the need for prostate surgery compared to monotherapy alone. Doxazosin and finasteride reduce the progression of BPH by 39% and 34%, respectively, but together reduce it by 66%. It was also found that men with a PSA >1.5 ng/mL and a prostate volume >40 g benefited the most with the combination of alpha-blockers and 5ARIs (Füllhase et al., 2013). The CombAT study demonstrated a durable 4-year improvement in urinary symptoms with combination therapy.

Combination of Alpha-Blockers and Anticholinergics

When irritative symptoms (i.e., urgency, frequency) in men with BPH do not resolve despite treatment with alpha-blockers, adding an anticholinergic agent may help improve those symptoms. The combination of an alpha-blocker and anticholinergic is ideal for patients with low PVR and irritative symptoms that persist with alpha-blocker monotherapy. It has been shown that this combination provides a greater improvement in QOL, IPSS, urgency, frequency, and nocturia than with either agent alone (Filson et al., 2013). Benefits from the combination can be maintained for at least 1 year (Drake et al., 2015).

Recommendations and Warnings

Care should be taken when prescribing alpha-blockers in patients using a PDE-5 inhibitor, such as sildenafil or vardenafil. The hypotensive effects of alpha-blockers, especially doxazosin or terazosin, can be potentiated with the use of PDE-5 inhibitors. It is recommended that patients space these medications apart by at least 4 h (Viagra, 2014). Furthermore, alpha-blocker monotherapy should be avoided in men with BPH and concurrent cardiovascular comorbidities due to increased risk of congestive heart failure, angina, coronary revascularization, and stroke (Coordinators for the ACRG, 2002).

5-Alpha-Reductase Inhibitors

Action and Indications

5ARIs block the conversion of testosterone to dihydrotestosterone (DHT). DHT, the principal prostatic androgen, contributes to prostatic growth (Bartsch et al., 2000). Instead of reducing smooth muscle tone like alpha-blockers, 5ARIs work by improving LUTS by decreasing prostatic volume. There are two 5-alpha-reductase isoenzymes: type I, found predominately in extra prostatic tissues (i.e., sebaceous glands and liver), and type II, found predominately in genital tissues (Bartsch et al., 2000). Type II 5-alpha-reducatase increases the concentration of DHT in the prostate, hair follicles, and other androgen-sensitive tissues. Finasteride (Proscar) and dutasteride (Avodart) are the only 5ARIs approved for BPH treatment. Finasteride inhibits only type II 5-alpha-reductase and dutasteride inhibits both type I and type II 5-alpha-reductases. However, both medications lead to greater than 80% reduction in intra-prostatic levels of DHT (McVary, 2010).

Efficacy

AUA guidelines recommend the use of 5ARI monotherapy to prevent the progression of BPH and reduce the risk of urinary retention and future prostatic surgery. Due to its primary effect on prostate size, 5ARIs should not be used in men without prostatic enlargement. Prostatic enlargement can be measure by volume measurement (>30 g), PSA level, or DRE (Barry et al., 2017). The Enlarged Prostate International Comparator Study (EPICS) demonstrated that both dutasteride and finasteride are similar in efficacy. 5ARIs have shown to reduce prostate volume by 20%, improve symptom score by 20%, increase Q_{max} by 10%, reduce the risk of urinary retention by 50%, decrease PSA by 50%, and reduce the risk of surgical treatment by 50% (Gormley et al., 1992; Roehrborn et al., 2004). These agents may also help stop hematuria that can occur in BPH (Foley et al., 2000). The Proscar Long-Term Efficacy and Safety Study (PLESS) demonstrated that treatment with finasteride in men with a PSA ≥1.4 and prostate volume >40 g could maintain improved symptom scores, Q_{max}, and prostate volume for more than 4 years. Men with these specific characteristics are appropriate candidates for 5ARIs. In contrast to alpha-blockers, 5ARIs require long-term treatment for efficacy. It usually takes 6–9 months before the prostate size is reduced enough to notice symptom improvements (Wieder, 2010). However, 5ARIs are a reasonable alternative for patient who cannot tolerate alpha-blocker side effects, especially hypotension, and still desire medical therapy. The main difference between finasteride and dutasteride is the serum half-life, which is 6–8 h versus 5 weeks,

respectively. Patients should, therefore, be aware of the possible prolonged duration of side effects after cessation of dutasteride. Finasteride is also indicated for male pattern hair loss (androgenic alopecia).

Side Effects

The side effects of 5ARIs are generally sexual. Adverse effects include erectile dysfunction (ED) (<5%), decreased libido (<4%), decreased volume of ejaculate (<3%), and gynecomastia (<1%) (Gormley et al., 1992). However, it has been shown that adverse sexual effects are only increased during the first year of therapy (Wessells et al., 2003). Another potential side effect of 5ARIs includes increased risk of self-harm and depression, particularly during the initial 18 months of treatment (Welk et al., 2017). 5ARI therapy should be discontinued if depression develops.

Combination of 5ARIs and Alpha-Blockers

As discussed previously with alpha-blockers, the combination of 5ARIs and alpha-blockers is an appropriate treatment for men with severe LUTS (AUASS or IPSS >20), enlarged prostates (>40 g), and inadequate response to monotherapy.

Recommendations and Warnings

Women, especially those who are pregnant or may become pregnant, should not handle crushed or broken tablets as they may be absorbed and cause potential harm to a male fetus. Another concern with the use of 5ARIs is the increased risk of high-grade prostate cancer. However, it has also been found through the Prostate Cancer Prevention Trial (PCPT) and the Reduction by Dutasteride of Prostate Cancer Events (REDUCE) trial that 5 ARIs can reduce the incidence of prostate cancer. Based on these findings, the FDA recommends evaluating men for prostate cancer before initiating 5 ARIs but does not approve them for the prevention of cancer.

Anticholinergic Agents

Action and Indications

Anticholinergic agents work by competitively inhibiting the binding of neurotransmitter acetylcholine to muscarinic receptors in smooth muscle throughout the body, including the bladder. Involuntary bladder contractions are under the control of the parasympathetic nervous system, which is hyperactive in overactive bladder (OAB). Of the five subtypes of muscarinic receptors (M1–M5) found in the bladder, M2 and M3 receptors make up the majority, while M3 receptors are the predominate type associated with bladder contraction (Caulfield and Birdsall, 1998). Inhibition of the M3 receptors in the bladder reduces detrusor overactivity. Anticholinergic medications are considered first-line therapy for OAB, which often coexists with BPH. Thus, the irritative symptoms (i.e., frequency, urgency, nocturia, and urinary incontinence) of BPH can be reduced with the use of these agents. The AUA recommends anticholinergic agents as alternative monotherapy in men with LUTS secondary to BPH who have predominately irritative symptoms without elevated PVR. Anticholinergic agents approved for use in OAB include tolterodine, oxybutynin, darifenacin, solifenacin, fesoterodine, and trospium. However, none are currently approved by the FDA for the treatment of BPH.

Efficacy

Anticholinergic monotherapy has demonstrated to be safe and efficacious in men with predominantly OAB symptoms (Athanasopoulos et al., 2011). Studies have shown that these agents can reduce AUASS or IPSS by 6 points. With anticholinergic monotherapy, patients with smaller prostatic volume, higher IPSS, and higher Q_{max} have greater treatment success rates (Liao et al., 2013). Although PVR tends to increase significantly, patients rarely develop acute urinary retention (<3%) (Kaplan et al., 2011). It has been found, however, that risk of acute urinary retention is highest in the first month of treatment. Anticholinergics may improve urinary symptoms within 1 week, but maximal improvements are usually achieved by 3 months (Kaplan et al., 2011). The durability of effectiveness cannot be assessed due to lack of studies with greater than 12 weeks of follow up.

Side Effects

Due to the wide distribution of muscarinic receptors throughout the body, anticholinergic agents have a broad side-effect profile. In the bladder, inhibition of M receptors can cause severe urinary retention. Outside of the bladder, M receptors are located in the eyes, salivary glands, intestines, heart, and brain. Inhibition of M3 receptors in the eyes causes pupil dilation, which leads to blurry vision. Inhibition of M3 receptors in the salivary glands reduces saliva production leading to dry mouth. Dry mouth is the most common side effect experienced with anticholinergics. It can be decreased, however, with the use of extended release rather than immediate release formulations. Inhibition of the M3 receptors in the intestines reduces motility, which leads to constipation. Inhibition of M2 receptors in the sinus nodes of the heart can cause tachycardia.

Combination of Anticholinergics and Alpha-Blockers

As discussed previously with alpha-blockers, the combination alpha-blocker and anticholinergic therapy may be used in patient with predominantly irritative symptoms with concomitant BOO. The addition of an alpha-blocker is recommended in patients who have persistent LUTS with anticholinergic monotherapy.

Recommendations and Warnings

Contraindications to the use of anticholinergics include urinary retention, gastric retention, intestinal obstruction, angle closure glaucoma, and myasthenia gravis. Due to the peripheral side effects and need for prolonged use to achieve maximal benefits, many patients become noncompliant. Management of bothersome side effects, such as dry mouth and constipation, may help maintain patient compliance. Dry mouth can be managed with oral lubricants, sipping water, sucking on sugar-free hard candy, chewing sugar-free gum, or avoiding alcohol-based mouth wash. Constipation can be managed by increasing fluid and fiber intake, stool softeners, laxatives, and regular exercise. Side effects may also be reduced by using M3-specific anticholinergics, such as darifenacin and solifenacin, but these agents have been noted to have higher rates of constipation (Chapple et al., 2008).

Phosphodiesterase-5 Inhibitors

Action and Indications

PDE-5 inhibitors block the degradation of cyclic guanosine monophosphate (cGMP) by cGMP-specific PDE-5 in smooth muscle cells. This increases levels of cGMP leading to relaxation of smooth muscle in the bladder neck, urethra, and prostate and in their vascular supply. PDE-5 inhibitors are first-line treatments for ED. There is a concomitant increase in the prevalence of ED and LUTS secondary to BPH in aging men, which may be due to a shared pathophysiology (Kaplan and Gonzalez, 2007). It has been found that sexual dysfunction is strongly related to the severity of LUTS due to BPH (Rosen et al., 2003). Although AUA guidelines do not mention PDE-5 inhibitors for the management of BPH, European Association of Urology (EAU) guidelines state that PDE-5 inhibitors (i.e., tadalafil, sildenafil, and vardenafil) are appropriate to use for the concomitant treatment of BPH and ED. Tadalafil (Cialis) is the only PDE-5 inhibitor approved by the FDA for BPH. PDE-5 inhibitors are ideal for men who have both obstructive symptoms and ED.

Efficacy

A meta-analysis demonstrated significant improvements in IPSS despite no difference in urodynamic parameters in men with symptomatic BPH after >12 weeks of treatment with tadalafil compared to placebo (Liu et al., 2011). Compared to alpha-blockers, PDE-5 inhibitor monotherapy also showed significant improvements in IPSS and Q_{max}, while being the only treatment to improve ED and QOL in men with BPH (Oelke et al., 2012). Tadalafil can improve IPSS by greater than 25% within 1–4 weeks of use in most patients (Oelke et al., 2015). Maximal improvements in LUTS may take up to 2 months. Long-term safety and effectiveness of these agents have not been assessed in men with symptomatic BPH with concurrent ED.

Side Effects

The most common side effects with PDE-5 inhibitors include headache and facial flushing, which is due to the vasodilatory effect of these agents. Other less common side effects include nasal congestion, back pain, myalgia, dyspepsia, diplopia, blurry vision, and impaired color vision (blue or purple hues). While extremely rare, priapism, loss of vision, and loss of hearing may occur. Most side effects experienced by patients often decrease or resolve after several weeks of use.

Combination of PDE-5 Inhibitors and Other Benign Prostatic Hyperplasia Medications

PDE-5 inhibitors may be combined with other BPH medications when monotherapy is inadequate in treating BPH-related symptoms. The combination of PDE-5 inhibitors and alpha-blockers has shown to significantly improve IPSS, Q_{max}, and ED more than with alpha-blockers alone (Gacci et al., 2012). The combination of PDE-5 inhibitors and 5ARIs has also shown to improve symptom scores more than with 5ARIs alone (Elkelany et al., 2015).

Recommendations and Warnings

PDE-5 inhibitors should be avoided in men with extreme hypotension (blood pressure <90/50) or hypertension (blood pressure >170/110), men who are taking drugs that prolong the half-life of PDE-5 inhibitors, or in patients with retinitis pigmentosa. PDE-5 inhibitors are contraindicated in men taking nitrates for chest pain since these agents potentiate the effect of nitrates and may cause life-threatening hypotension. Caution should be taken when co-administering PDE-5 inhibitors with alpha-blockers as hypotension may occur when taken together. It is recommended to start a PDE-5 inhibitor at the lowest dose if the patient is stable on an alpha-blocker, and vice versa. In addition, a dose of sildenafil >25 mg should not be taken within 4 h of taking an alpha-blocker (Viagra, 2014).

Surgical Therapy

While being a highly invasive option, surgery is the most effective treatment for BOO due to BPH. It is strongly indicated in patients with acute urinary retention, recurrent UTIs, refractory gross hematuria, recurrent or large bladder stones, hydronephrosis, or renal insufficiency from BPH. Patients with an enlarged median lobe are unlikely to respond to medical therapy and should be treated surgically. In addition, patients who fail lifestyle modifications and combination medical therapy after 12 months should be considered for surgical management. AUA guidelines state that surgical intervention is an appropriate treatment option for patients

with moderate to severe LUTS. While initial medical therapy is recommended in these men, patients may choose to pursue surgery as the primary treatment. In general, the decision to proceed with surgery depends on the effectiveness of medical therapy, the development of complications from BPH, and patient preference. Surgical therapies for BPH include minimally invasive, endoscopic, open, and robotic surgery.

Endoscopic Approaches

Transurethral Resection of the Prostate

TURP is considered the "gold standard" surgical therapy for treating BPH. Obstructing prostatic tissue is resected transurethrally via a resectoscope with an electrical loop, allowing urine to flow more easily. It is most suitable for men with prostate volumes <80 g. This procedure is performed in an operating room under general or spinal anesthesia.

Most patients experience substantial improvements with TURP. Compared to medical therapy with alpha-blockers, TURP has the most significant improvements in IPSS (15 vs. 6 points) and Q_{max} (11 vs. 2 mL/s) (Wieder, 2010). Despite the great results, the procedure is associated with a significant risk of morbidity (11.1%) and a small risk of mortality (0.10%) (Reich et al., 2008). The most common postoperative complication is bleeding, which may be reduced with the use of bipolar TURP (compared to monopolar TURP) or the preoperative administration of a 5ARI (McVary, 2010). There is also a risk of blood transfusion and prolonged hospital stay. Other complications include bladder wall injury, bladder neck stenosis, urinary incontinence, ED, or retrograde ejaculation. Transurethral resection syndrome (TUR syndrome), which comprises of hyponatremia and water intoxication due to excess fluid absorption, is a possible adverse effect that may lead to hypertension, mental confusion, nausea, vomiting, and visual changes.

Endoscopic Laser Treatments for Benign Prostatic Hyperplasia

Holmium Laser Enucleation and Holmium Laser Resection of the Prostate

The holmium:yttrium-aluminium garnet (Ho:YAG) laser is a pulsed solid-state laser, which is absorbed by water and any tissue containing water. Secondary to the laser's wavelength (2140 nm), the depth of the penetration is limited to 3–4 mm. The procedure uses the laser to enucleate the prostatic adenoma within the tissue planes. The Laser cuts and instantaneously provides tissue hemostasis. Secondary to excellent hemostatic properties and the fact that the procedure uses isotonic saline solution, the procedure is ideal for men with BPH and larger prostate glands. A Compared to TURP, HOLEP has similar symptoms improvement, potency, continence, and major morbidity but shorter hospitalization and catheterization. HOLEP may also be safely performed in men being treated with anticoagulant and/or antiplatelet agents (El Tayeb et al., 2016; Westenberg et al., 2004).

Open Simple Prostatectomy

An open simple prostatectomy is the most radical surgical option available and the standard of care for large (>80 g) prostate glands. It involves surgical removal of the inner core (transition zone) of the prostate, leaving behind the peripheral zone.

Similar to TURP, an open simple prostatectomy provides better improvements in IPSS (10 vs. 6 points) and Q_{max} (14 vs. 2 mL/s) than with medical management (Wieder, 2010). However, it is the most invasive procedure and is associated with an increased risk of longer hospital stay, larger amounts of blood loss, and possible blood transfusions (McVary, 2010). The side-effect profile is similar to TURP with the exception of an increased risk of bladder neck stenosis and urinary incontinence (Wieder, 2010).

Role of Pharmacist

The process leading to the diagnosis and management of BPH is often initiated following symptomatic presentations to general practice. Medical therapy is the first step of management. Patients who do not respond to this medical therapy are subsequently refereed for specialist urology assessment. There are no studies, which have specifically assessed the pharmacist's role in this setting. However, the pharmacist can play a key part in ensuing successful implementation of treatment, provide continuous monitoring, and evaluate for ongoing response. Pharmacist-initiated patient education with regard to timing of administration, drug interactions, and side effects can maximize the likelihood of successful medical therapy. In addition, as mentioned earlier in the chapter, BPH is a progressive condition and despite initial response to treatment, a proportion of patients will continue to deteriorate. As healthcare professionals who interact with patients on regular basis, the pharmacist should enquire about recurrence of symptoms and make subsequent recommendations for further medical assessment.

BPH is almost exclusively diagnosed in older men who are often concurrently treated with multiple other therapeutic agents. The pharmacist is in a prime position to assess and review possible drug interactions. Medication side effects are often the main reason for poor compliance and consequently lead to failure of medical therapy for BPH.

Lastly, pharmacists should be aware of all available options for management of BPH and LUTs. They should be able to reassure their patients that failure of one agent or combination therapy does not translate to life-long symptoms and that surgery remains an option for many men with LUTs.

Conclusion

BPH is undoubtedly one of the most prevalent conditions seen in elderly men, especially as the population is rapidly aging. While it is not usually a life-threatening condition, BPH can significantly impact a patient's QOL and may eventually lead to complications such as renal failure. While surgical management is extremely effective in relieving LUTS due to BPH, medical management has emerged to become the predominant method for treating BPH. Thus, pharmacists play a crucial role in the management of patients with BPH.

Due to the comorbidities and polypharmacy often associated with BPH, pharmacists need to ensure that patients are adequately educated on the disease process associated with BPH and receiving the optimal treatment for their symptoms. There are many drug classes that have shown to be effective in treating LUTS in BPH, but it is important to consider the patient's symptoms, risk of disease progression, coexisting conditions, and other medications before deciding on which medical therapy to pursue. Alpha-blockers are recommended as first-line treatment for patients with BPH. 5ARIs are only recommended in men with prostatic enlargement. PDE-5 inhibitors can be used in men with concomitant ED. Lastly, anticholinergics are recommended in patients with symptoms of OAB. These classes of medications may be combined depending on severity of the disease and the presence of concurrent symptoms.

Phytotherapy may also have a potential benefit in patients with BPH, but these products have not shown to be entirely safe and efficacious in controlled studies. Pharmacists may also counsel men with BPH on behavioral modifications and screen their profiles for medications that can exacerbate LUTS. If patients are unsuccessful with behavioral and medical management, surgery may be an appropriate option. It should also be emphasized to patients that nonadherence to medical therapy may increase the need for surgery. The ultimate goal of BPH treatment is to reduce LUTS and improve QOL. Pharmacists are essential in the management of patients with BPH by ensuring their therapy is safe and effective, providing realistic treatment expectations, and stressing medication compliance.

Glossary

Phytotherapy Phytotherapy is the study of the use of natural extracts as medicines or health-promoting agents. Phytotherapy medicines differ from plant-derived medicines in standard pharmacology

LUTS (lower urinary tract symptoms) LUTS is a term used to describe a number of symptoms related to issues related to the lower urinary tract (urethra, prostate, and bladder). LUTS are grouped into obstructive symptoms (during voiding) or irritative (also called storage e.g., frequency, urgency) symptoms.

IPSS Score The International Prostate Symptom Score (I-PSS) is based on patient answers to seven questions (scored from 0 to 5) concerning urinary symptoms and one question assessing quality of life. The total score (0–35) indicated the severity of the symptoms.

Bladder outflow obstruction (BOO) BOO is a blockage of urine flow from the bladder which can lead to LUTS symptoms. This is often related to BPH.

Management of Erectile Dysfunction and the Pharmacist's Role

Natalie J. Gauld[*,†], **Rhiannon Braund**[‡], [*]The University of Auckland, Auckland, New Zealand; [†]Natalie Gauld Ltd, Auckland, New Zealand; [‡]New Zealand Pharmacovigilance Centre, University of Otago, Dunedin, New Zealand

Learning Objectives

After reading this chapter, the reader should be able to:

1. Define erectile dysfunction, and understand its prevalence, common causes, and effect on the sufferer.
2. Discuss the management of erectile dysfunction including lifestyle and pharmacological management, and risk management for pharmacological treatment.
3. Discuss the current and future roles of the pharmacist in the identification and management of erectile dysfunction, including the evidence for these roles.

Key Concepts

- Erectile dysfunction (ED) is a common condition, increasing in prevalence with age.
- ED can be an early indicator of more widespread cardiovascular disease, with the small vessels being occluded earlier.
- The risk of ED increases with many medical conditions, such as diabetes, hypertension and hyperlipidemia, and the use of some medicines.
- ED can be from physical causes (e.g., blood vessel occlusion), and from psychological causes, such as depression, or performance anxiety. Even where the cause of ED is physical, a psychological component is common, for example, with reduced confidence in their sexual performance.
- Treatment options include vacuum devices intercavernosal injections and intraurethral pellets.
- PDE5 inhibitors are considered first line therapy. These inhibit PDE5, preventing the breakdown of cyclic guanosine monophosphate. This causes smooth muscle relaxation, and increased blood flow which compresses the veins and maintains an erection.
- Contraindications to the use of PDE5 inhibitors include use of nitrates or alkyl nitrites, use with a recent myocardial infarction (MI), stroke, or life-threatening arrhythmia, particularly low or high blood pressure, unstable angina, angina with sexual intercourse, severe cardiac failure, loss of vision in one eye, and hereditary degenerative retinal disorder.
- PDE5 inhibitors are the most commonly counterfeited of all medicines, and many herbal products can be adulterated with PDE5 inhibitors, sometimes combined with other pharmaceuticals.

- Sourcing PDE5 inhibitors without health professional involvement is common, particularly in younger men (under 40 years), mostly through internet purchase.
- In some countries, pharmacists may be able to supply PDE5 inhibitors without a prescription.
- Protocols or checklists should aid safe supply, and help identify men needing a medical check-up. Advice is an important aspect of this supply.
- There are still many considerations that need to be evaluated for the advanced role of the pharmacist in this field and more research needs to be undertaken to evaluate the scope, protocols, and effectiveness.

This chapter particularly concentrates on aspects of ED that are most relevant to the pharmacist. It focuses on potential causes, particularly conditions or medications where pharmacists might be able to make a difference, on counterfeit medicines and remedies with undeclared ED prescription medicines, and on counseling points. It also provides information on pharmacists' models of care for ED outlined in the literature.

Introduction to Erectile Dysfunction

Erectile dysfunction (ED) is a very common complaint in men, particularly associated with increased age, and arising from many medical conditions, medicines, and psychological factors. It can have a profound impact psychologically and on relationships. While there are a variety of mechanical devices and locally administered options, the treatment of ED was "revolutionized" with the advent of sildenafil in 1998. This "Viagra" era and the associated "little blue pill" have heralded a new stage of ED conversation and therapy options. This has led to ED becoming increasingly discussed, with over 100 million men thought to have sought treatment for ED since then (Perelman and Watter, 2016).

Erectile Dysfunction—An Overview

Erectile dysfunction (ED) is defined as the persistent inability to achieve and maintain a penile erection adequate for satisfactory sexual performance (NIH Consensus Conference, 1993; Tsertsvadze et al., 2009).

Sexual stimulation leads to the release of nitric oxide from nerve endings and the endothelium of the penis, stimulating an increase in levels of cyclic guanosine monophosphate (cGMP), which causes relaxation of the cavernosal smooth muscle. This causes dilatation of the cavernosal arterioles allowing blood to flow into the corpus cavernosum. It is this increased blood flow that causes the engorgement of the penis and results in an erection. Cyclic guanosine monophosphate is degraded by phosphodiesterase 5 (PDE5) (Andersson, 2018).

Prevalence and Etiology

ED is a common condition, increasing by age (Feldman et al., 1994; Schouten et al., 2005). The prevalence varies by study according to definition, sampling, and survey tools. In men under 40 years, various studies have suggested a prevalence of 1%–10%, from 40 to 49 years the prevalence has been found to be 2%–9%, increasing then to 20%–40% in men 60–69 years, and 50%–100% above 70 years (Shamloul and Ghanem, 2013). However, some men with ED are unperturbed by it, with a Dutch study finding only around a quarter of men with ED particularly concerned by their ED, with greater concern in those with more significant ED (Schouten et al., 2005).

While ED can be caused by organic causes in which the physiology is affected, or by psychological causes such as performance anxiety or relationship issues, in many cases it is a mix of both (Hatzimouratidis et al., 2016).

> "In men aged <60 years and in men with diabetes or hypertension, ED can be a critical warning sign for existing or impending cardiovascular disease and risk for death." (Meldrum et al., 2011)
>
> "ED significantly increases the risk of CVD, coronary heart disease, stroke, and all cause mortality, and the increase is probably independent of conventional cardiovascular risk factors." European Association of Urologists 2018 (Hatzimouratidis et al., 2016)

ED can be "the canary in the coal mine," being an important independent marker of heightened cardiovascular (CV) risk (Hatzimouratidis et al., 2016; Meldrum et al., 2011; Shah et al., 2016). Vascular ED is strongly linked with cardiovascular disease, often coexisting with silent CV disease. It shares the same risk factors of obesity, smoking, dyslipidemia, physical inactivity, and diabetes. ED symptoms typically occur before CV symptoms, and have an independent association with CV disease and CV events. In men presenting to an emergency department with chest pain and angiographically confirmed coronary artery disease (CAD), half had ED, with ED occurring before CAD symptoms in 67%, by a mean of 39 months (Montorsi et al., 2003). Therefore it is recommended that all men with vascular ED have a CV risk assessment, unless done recently (Shah et al., 2016). We want patients to consult doctors early when it occurs so they can be checked for CV risk and preventative measures started early if necessary, helping both their CV risk and their ED.

Smoking increases the risk of getting ED, up to twofold, with a dose dependent relationship (longer duration and higher frequency increases the risk) (Kovac et al., 2015). Men quitting smoking before middle age can have some improvement in their

ED, and improvement in erectile function can be seen even after a short smoking absence (Kovac et al., 2015). However, regaining erectile function is less likely if the ED was severe and/or the man over 50 or 60 years of age. There is good evidence to advise men to quit smoking early to protect their erectile function.

Men with hypertension, with no other medical conditions, have at least double the risk of ED compared with men without hypertension, with longer and more severe hypertension increasing the incidence further (Meldrum et al., 2011).

Comorbidities are common, for example, a Spanish study (Martín Morales et al., 2010) found many men getting ED medication had hypertension (64%), diabetes mellitus (43%), hypercholesterolemia (55%), hypertriglyceridemia (34%), or depression (38%). Men with diabetes are three to four times as likely as men without diabetes to have ED (Burke et al., 2007; Maiorino et al., 2014; Colson and Roussey, 2013), with risk increasing with age, and a longer duration of disease (type 1 or 2). ED occurs 10–15 years earlier in men with diabetes, who tend to have more severe ED and are less likely to respond to oral therapy. Microvascular and macrovascular damage, and concomitant conditions that diabetes is often associated with, are likely to contribute to this increased risk.

Panel 1

Contributing factors to erectile dysfunction include (Shamloul and Ghanem, 2013; Hatzimouratidis et al., 2016; Meldrum et al., 2011; Rai and Terry, 2018):

- Sedentary lifestyle
- Obesity
- Cigarette smoking
- Cycling more than three times per week
- Atherosclerosis
- Hypertension
- Hypercholesterolemia
- Diabetes mellitus
- Metabolic syndrome
- Degenerative disorders, e.g., Parkinson's disease, multiple sclerosis
- Stroke
- Multiple sclerosis
- Hormones, e.g., testosterone deficiency, hyperprolactinemia, excess or insufficient thyroid hormones or cortisol
- Pelvic surgery
- Radiotherapy or brachytherapy for prostate cancer
- Penile trauma or abnormality, e.g., from priapism, Peyronie's disease
- Excessive alcohol
- Recreational drug use
- Spinal cord injury
- Renal failure
- Poor health
- Depression
- Relationship difficulties
- Performance anxiety
- Disorders of sexual intimacy

ED is common in men on opioid replacement therapy, with around half of such men being sexually inactive or having ED, increasing in prevalence as the dosage increases (Lugoboni et al., 2017). In Parkinson's disease, 43%–79% report ED (Bhattacharyya and Rosa-Grilo, 2017).

Some medicines may cause ED (Panel 2).

Panel 2

Drugs known to cause erectile dysfunction (Shamloul and Ghanem, 2013; Hatzimouratidis et al., 2016; NICE, 2017; Aronson, 2016)

Beta blockers
Thiazide and thiazide-like diuretics
Spironolactone
Disopyramide, flecainide
Tricyclic antidepressants
Monoamine oxidase inhibitors
Selective serotonin reuptake inhibitors
Venlafaxine
Chlorpromazine, haloperidol, thioridazine
Risperidone, clozapine, ziprasidone

Digoxin
Amiodarone
Cimetidine, ranitidine
Finasteride
Antiandrogens, e.g., flutamide, cyproterone acetate
Gonadorelin and analogues
Corticosteroids
Bromocriptine
Interferon alfa
Sulfasalazine
Opioids
Naltrexone
Recreational drugs

Some care may need to be taken about mentioning ED as a possible side effect of a new medicine started as at least some of the effect is psychological. Men taking atenolol 50 mg per day for three months were twice as likely to have ED when told about possible side effects than when only told that they were getting atenolol (Silvestri et al., 2003). They were even less likely to report ED when they did not know what they were given (3%), and placebo seemed nearly as effective as sildenafil in solving the problem, further suggesting a psychological component.

More lipophilic beta blockers may be more likely to cause ED, and new generation beta blockers, e.g., nebivolol less likely (Aronson, 2016). Meyler's Side Effects of Drugs (Aronson, 2016) suggests that the likelihood of ED with thiazides is elevated but still reasonably low.

Sexual dysfunction including ED is common with antidepressants, with ED occurring in 14%–40% of men taking selective serotonin reuptake inhibitors or selective serotonin-norepinephrine reuptake inhibitors, depending on the agent, but most of those suffering do not report it to their doctor (Montejo et al., 2001). In most people the problem will not resolve spontaneously. While some people are not particularly concerned with this adverse effect, others may be particularly bothered by it and there is a risk of discontinuation of their antidepressant as a result.

Psychological factors such as depression, anxiety, performance anxiety, and relationship difficulties often cause ED (Perelman and Watter, 2016). Even where the cause of ED is physical, a psychological component is common with reduced confidence in their sexual performance, avoiding sex and sometimes avoiding affection, with negative impacts on the relationship. A partner may have doubts about their attractiveness or the man's fidelity. Couple's therapy is often recommended.

Diagnosis

Diagnosis is based on the man's report of his erectile difficulties, and considering potential causes discussed above such as medication, relationship issues, underlying disease, alcohol or drug misuse, or cigarette smoking (Shamloul and Ghanem, 2013; Hatzimouratidis et al., 2016; Bella et al., 2015). A medical and sexual history is required. ED can be confused by some men with other problems including premature ejaculation. Testosterone blood tests are indicated if there is evidence of hypogonadism (e.g., low energy, low libido, and cognitive impairment). Lower Urinary Tract Symptoms (LUTS) should be asked about. A physical examination check is recommended. Blood pressure, heart rate, lipids, and glucose should be measured. Questionnaires can be used, particularly to aid evaluation of the response to therapy. Sensitivity and privacy are important, as is understanding patient expectations of what is normal with respect to erectile function.

Men commonly take an extended period of time before discussing their ED with a health professional (Martín Morales et al., 2010), and some may never do it. Spanish men who had sought treatment for ED from a health professional took on average 26 months from their first symptoms of ED. This reluctance to discuss the concern with a doctor can result in men never seeking treatment or using the internet (Sugita and Miyakawa, 2010; Shaeer, 2013) to acquire treatment. Some groups are particularly reluctant, for example, only 6% of men with ED on opioid replacement are treated for ED, despite its association with reduced quality of life in this group (Lugoboni et al., 2017). Doctors often do not raise the topic of sexual disorders, and patients may be embarrassed or unsure as to the reaction of the doctor (Perelman and Watter, 2016).

Most men with diabetes who have ED have never discussed it with their doctor, despite its association with lower quality of life, a less satisfactory sexual life, and a higher level of depressive symptoms in men with type 2 diabetes, and doctors generally do not ask men with diabetes about it (De Berardis et al., 2002).

Quality of Life

Quality of life is affected by ED. It can affect the man's relationship with his partner and is associated with reduced self-esteem (Cappelleri et al., 2006; Paige et al., 2001; McCabe and Althof, 2014). Men with untreated ED have lower self-esteem and confidence

than men without (Cappelleri et al., 2006). Quality of life in diabetics (De Berardis et al., 2002) and in men on opioid replacement (Lugoboni et al., 2017) is also negatively affected by ED, particularly with increasing severity of ED. Treatment can help (see treatment below).

Management of Erectile Dysfunction

Lifestyle Measures

Modifiable risk factors should be addressed (Hatzimouratidis et al., 2016; NICE, 2017), e.g., quitting smoking, and weight loss, either before treatment or alongside treatment. Where ED may be associated with an underlying condition, e.g., hypertension or diabetes, control of the condition is important. For men doing long distance cycling (more than three hours per week), trialing a period without cycling is recommended.

Exercise increases nitric oxide release, both acute exercise (for 48 hours), and daily exercise (for longer), and men who exercise have a much lower risk of ED (Meldrum et al., 2011). Weight loss and increased physical activity can help ED (Hatzimouratidis et al., 2016; Meldrum et al., 2011). Meldrum et al. (2011) suggested that more frequent sexual intercourse may help prevent ED through the greater effect on the blood vessels of an erection compared with other exercise.

Pharmacological Treatment

Use of ED medicines is common, increasing with age, until peaking around 65–69 years (Bjerkeli et al., 2018). A Swedish study found 5.3% of men aged 45–64 years had filled a prescription with an ED medicine in 2016, and 9.2% of 65–79 year old men (Bjerkeli et al., 2018).

There is a high rate of discontinuation with ED medicines generally, and particularly for ethnic minorities (Perelman and Watter, 2016). In some cases this is likely to occur because of relationship changes, or inadequate consideration to psychological factors. Other reasons for failure of ED treatment include not waiting long enough for the medicine to work, that the onset of effect might have been delayed by food (**Table 1**), or their alcohol consumption might have affected their erectile function.

PDE5 Inhibitors

These medicines are regarded as first-line treatments by the European Association of Urology (Hatzimouratidis et al., 2016). They inhibit PDE5, stopping the breakdown of cyclic guanosine monophosphate. This causes smooth muscle relaxation and increased blood flow which compresses the veins with the outgoing blood, therefore trapping blood in the penis, and helping maintain the erection (Hatzimouratidis et al., 2016). This is only of use when the individual is sexually stimulated.

The first of these to be introduced was sildenafil, which remains very popular. It is used for on demand dosing, has a fairly short half-life, and its effect is slowed by food. With a long half-life, tadalafil provides longer cover than the others, and has a low once daily dose that can help LUTS also. However, tadalafil has a longer onset of action. Vardenafil is most affected by drug interactions, but its onset is reasonably quick and not particularly affected by food unless it is a high fat meal. Avanafil is the newest agent, and is very specific for PDE5, minimizing the frequency of side effects.

PDE5 inhibitors provide an erection sufficient for intercourse in most men with ED, having a success rate of 65% or more, depending on the dose (**Table 2**) (Shamloul and Ghanem, 2013). PDE5 inhibitor use in men with ED improves self-esteem, confidence, quality of life, their relationship with their partner, and their sex life (Cappelleri et al., 2006, 2008; McCabe and Althof, 2014; O'Leary et al., 2006; Leoni et al., 2013). Partner satisfaction is typically high for PDE5 inhibitors (Gil et al., 2001; Althof et al., 2006; Conaglen and Conaglen, 2012).

Table 1 Comparison of the PDE5 inhibitors (Pfizer, 2016; Lilly, 2017; Bayer, 2018; Menarini, 2018)

	Strength	*Dose*	*T_{max}*	*Half-life*	*Comments*
Sildenafil	25 mg, 50 mg, 100 mg	25–100 mg one hour before sexual activity, starting with 50 mg	Median 60 minutes	3–5 hours	T_{max} is delayed about one hour by food
Tadalafil	2.5 mg, 5 mg, 10 mg, 20 mg tablets	10–20 mg prior to sexual activity; or 2.5–5 mg once daily for continuous use	Median 2 hours	17.5 hours	No effect of food on the absorption
Vardenafil	5 mg, 10 mg, 20 mg	5–20 mg 25–60 minutes before sexual activity	Median 60 minutes	4 hours	A high fat meal delays absorption 1 hour
Avanafil	50 mg, 100 mg, 200 mg	50–200 mg 15–30 minutes before sexual activity, starting with 100 mg	Median 30–45 minutes	6–17 hours	A high fat meal delays the T_{max} 1.25 hours

Table 2 Percentage of a general ED population reporting improved erections after 12 (tadalafil and vardenafil) or 24 weeks' (sildenafil) treatment[a] (Hatzimouratidis et al., 2016)

	Sildenafil	*Tadalafil*	*Vardenafil*
Lowest dose	25 mg 56%		5 mg 66%
Moderate dose	50 mg 77%	10 mg 67%	10 mg 76%
High dose	100 mg 84%	20 mg 81%	20 mg 80%
Placebo-response as comparator	25%	35%	30%

[a]Not head-to-head studies.

The recommended doses typically start in the middle of the dose range, and increase or reduce as necessary, with a maximum of one dose per day. While there is a dose-response relationship, the middle dose is effective in nearly as many men as the upper dose is.

Failure of the PDE5 inhibitor can occur where the medicine is counterfeit (see below) and the drug is absent or subtherapeutic, or with insufficient dose, insufficient sexual stimulation, or taking the drug too close to the time of sexual activity (noting also the potential effect of food for some agents) (Hatzimouratidis et al., 2016). It is recommended that six attempts are made occurs before failure is decided. Up to 35% of men fail with PDE5 inhibitors, with failure more likely in men with diabetes mellitus, severe ED, history of pelvic surgery or severe neurological or vascular disease (Shamloul and Ghanem, 2013; Suetomi et al., 2008).

Adverse events are typically mild (Shamloul and Ghanem, 2013), and vary in incidence between the agents (Hatzimouratidis et al., 2016). The most common events are headache, flushing, dyspepsia, and nasal congestion. The European Association of Urology (EAU) Guidelines (Hatzimouratidis et al., 2016) report that avanafil is more highly selective for PDE5 inhibition versus other PDE subtypes, as compared to other PDE5 inhibitors. Frequencies of many of the side effects reported in clinical studies appear to be lower for avanafil than the rates reported for the other medicines, noting this data is not from comparative studies between the different agents. There is some other variation between the different PDE5 inhibitors, for example, the reported rates of dyspepsia (12%) appear higher for tadalafil than the reported rates for the other PDE5 inhibitors, and back pain (6.5%) and myalgia (5.7%) can occur with tadalafil but are not reported on for the others. Abnormal vision (differences in blue/green color discrimination) occurs particularly with sildenafil and vardenafil, but affects a small minority of men, at under 2%. Reports of some side effects for vardenafil seem more frequent than that reported for the other agents, for example, headache (16%), flushing (12%), and nasal congestion (10%).

Non-arteritic anterior ischemic optic neuropathy (NAION) has been identified as a possible side effect of PDE5 inhibitors, but the evidence is not clear (Aronson, 2016). The EAU Guidelines (Hatzimouratidis et al., 2016) report "no increase in myocardial infarction rates in patients receiving PDE5 inhibitors" in clinical trials. However, they have contraindications as noted in Panel 3.

Panel 3

Contraindications to PDE5 inhibitor use (Hatzimouratidis et al., 2016; Pfizer, 2016; Bayer, 2018; Lilly, 2017)[1]

- A myocardial infarction, stroke, or life-threatening arrhythmia in the last 3–6 months[1]
- Resting blood pressure <90/50 mmHg, or >170/100 mmHg or uncontrolled hypertension[1]
- Unstable angina, angina with sexual intercourse
- Severe cardiac failure[1]
- Loss of vision in one eye because of the risk of non-arteritic anterior ischemic optic neuropathy (NAION)
- Hereditary degenerative retinal disorders, e.g., retinitis pigmentosa
- Severe hepatic impairment (some agents)[1]
- Severe renal impairment (some agents)[1]
- Nitrate and alkyl nitrite usage
- Men with cardiac disease for whom sexual activity is inadvisable
- Men with uncontrolled arrhythmias[1]
- See also interactions

[1] Most contraindications are common to all PDE5 inhibitors, but see the summary of product characteristics for each medicine as there is some variation, e.g., with degree of cardiac failure and renal impairment.

Drug interactions vary a little between the agents. All PDE5 inhibitors are contraindicated with nitrates owing to the potential for an unpredictable, and potentially dangerous, drop in blood pressure. While being fairly selective, with a substantially greater effect on the penis than elsewhere, PDE5 inhibitors cause a fall in blood pressure of about 10 mmHg

(Preston, 2018). Stockley's Drug Interactions reports that as nitrates increase the cyclic guanosine monophosphate production, PDE5 inhibition causes cyclic guanosine monophosphate to increase and nitric oxide enters the circulation increasing vasodilation and reducing the blood pressure. The half-life of the agent is relevant, with a nitrate not given for 24 hours after sildenafil, versus 48 hours after tadalafil, and 12 hours after avanafil. Nicorandil and alkyl nitrites ("poppers") are also contraindicated with PDE5 inhibitors.

Cytochrome P450 3A4 is the major isoenzyme involved in metabolism of each of these PDE5 inhibitors (Pfizer, 2016; Lilly, 2017; Bayer, 2018; Menarini, 2018). Therefore, their clearance is reduced by CYP3A4 inhibitors and increased by CYP3A4 inducers to varying degrees discussed below. Grapefruit juice has a more modest effect than other CYP3A4 inhibitors, but some caution is advised (Preston, 2018).

For sildenafil, concomitant administration of the CYP3A4 inhibitor erythromycin results in nearly three times the exposure to sildenafil, and the manufacturer recommends a starting dose of 25 mg (Pfizer, 2016). However, for ritonavir, which is a highly potent CYP3A4 inhibitor, the fourfold increase in the C_{max}, and considerable prolongation of half-life and 11-fold increase in exposure (AUC), means this combination is not advised. CYP3A4 inducers can reduce the blood levels of sildenafil. Although CYP2C9 is a minor isoenzyme involved in sildenafil metabolism, CYP2C9 inhibitors seem to have no effect on sildenafil levels. Sildenafil's inhibition of some CYP isoenzymes appears to be too weak to affect other drugs.

While cytochrome P450 3A4 is also the major isoenzyme involved in tadalafil metabolism, the effect on C_{max} is minimal and the tadalafil exposure is not increased as much as for sildenafil, e.g., ritonavir increased the exposure to tadalafil by twofold (Lilly, 2017). The manufacturer advises caution. Rifampicin, a potent CYP3A4 inducer, reduces the AUC by 88%.

CYP3A4 is also the major isoenzyme for vardenafil metabolism (Bayer, 2018), and the effect on vardenafil pharmacokinetics is much greater than for sildenafil or tadalafil. Ritonavir caused a 13-fold increase in C_{max} and 49-fold increase in AUC for vardenafil 5 mg. Ketoconazole increased the AUC of vardenafil by 10-fold. Potent CYP3A4 inhibitors should be avoided with vardenafil.

A small QT prolongation has been reported for vardenafil (8 ms for 10 mg) (Preston, 2018). While the manufacturer states that the clinical impact of these changes is unknown, it suggests avoidance of vardenafil in patients with risk for prolonged QT, e.g., hypokalemia, concomitant use of Class IA antiarrhythmics (e.g., quinidine, procainamide) or Class III antiarrhythmics (e.g., sotalol, amiodarone) (Bayer, 2018). Some studies have reported 6 ms with 50 mg of sildenafil, but other studies have not (Preston, 2018), and the manufacturer provides no cautionary advice (Pfizer, 2016).

Alpha-blockers taken with PDE5 inhibitors can cause postural hypotension in some people. Caution is advised, it is recommended that the patient is stable on the alpha-blocker first, initiate with the lowest dose and the patient should be advised what to do if postural hypotensive symptoms develop (Pfizer, 2016; Bayer, 2018; Menarini, 2018) (lie down, raise the legs, and when feeling better get up slowly) (Preston, 2018). Dose separation is sometimes recommended, depending on the alpha blocker. The manufacturer recommends avoiding concomitant use with doxazosin owing to the significance and duration of the hypotensive effect (Lilly, 2017).

Riociguat is used for pulmonary arterial hypertension, and it is contraindicated with PDE5 inhibitors owing to hypotensive effects (Pfizer, 2016; Lilly, 2017; Bayer, 2018; Menarini, 2018).

Vacuum Erection Devices

These devices use negative pressure on the penis shaft, helping draw blood into the corpora cavernosa (Shamloul and Ghanem, 2013; Hatzimouratidis et al., 2016; Yuan et al., 2010). After achieving an erection, a constricting ring is placed at the base of the penis, preventing blood flow from the penis, and maintaining the erection. The erection can take half a minute to seven minutes to achieve. There is no additional arterial blood flow into the penis, and to prevent ischemia the constriction ring is removed within 30 minutes. With practice, over 90% of men will get an erection, and 85% of men with a spinal cord injury. Satisfaction rates have been variously reported as 35%–68%, possibly reflecting a need for more patient education in some studies. The erections feel cold and not natural, with numbness, and the devices can cause pain and delayed ejaculation. They are not recommended in men prone to priapism or with penile abnormalities. Vacuum devices can be used in conjunction with other ED therapies. Following radical prostatectomy, early use of vacuum devices aided early return of spontaneous erectile function, preservation of penile size (shrinkage is common after radical prostatectomy) and early return to sexual life.

Intercavernous Injections

Although intercavernous injections have a high success rate and work quickly, they are typically recommended only where oral drugs have failed (Shamloul and Ghanem, 2013; Hatzimouratidis et al., 2016). Men need to be taught how to use the injection in a clinic, and the summary of product characteristics provide recommended administration information for each injection, e.g., to vary the site of injection. The erection occurs about 10 minutes after the injection, with no need for sexual stimulation first. Satisfaction for the man and partner can be very high, but some men do not continue with these injections, with side effects, fear of needles, lack of spontaneity, inconvenience, poor response, and fear of complications common.

Medicines used include alprostadil (a form of prostaglandin E_1), papaverine, and phentolamine, sometimes in combination therapy. Alprostadil injections cause pain for about half of users, in about a tenth of their alprostadil injections, but is typically mild (Shamloul and Ghanem, 2013; Hatzimouratidis et al., 2016; Aronson, 2016). Systemic effects include hypotension and syncope.

More significant side effects include fibrosis (2%), which can require temporary or permanent cessation of this therapy, and priapism (1%). Priapism can cause damage to the penis and needs medical attention. Combination intercavernous injections have been used to aid effectiveness at lower doses.

Contraindications include conditions with a predisposition to priapism, e.g., sickle cell anemia, leukemia, multiple myeloma, or deformations of the penis (Pfizer Limited, 2017).

Other Therapies

Where testosterone measurements show low levels, testosterone replacement therapy can provide an improvement in ED (Shamloul and Ghanem, 2013).

Alprostadil used as intraurethral pellets has an advantage of the avoidance of needles and good safety, with no contraindications to use (Moisidis et al., 2016). The pellets have a success rate of 59%–78%, but have considerably higher doses than intracavernosal injections because of systemic uptake. They take about 5 minutes to achieve an erection. Sudden drops in systolic blood pressure occur in about 5% of men, sometimes with loss of consciousness, and there is commonly pain and a burning sensation on insertion.

Penile implant surgery is a third-line option, with high satisfaction of patients and partners (Shamloul and Ghanem, 2013). Possibilities include a semi-rigid implant, an inflatable implant or a hydraulic implant.

Herbals

While herbal medicines have been used historically for enhanced sexual performance (Shamloul, 2010), very few studies have been conducted to substantiate claims. Some herbals have been specifically studied for ED and include *Panax ginseng*, *Butea superba*, *Epimedium*, *Tribulus terrestris*, *Securidaca longipedunculata*, *Piper guineense*, and yohimbine (Ho and Tan, 2011). Three of these have been evaluated in human studies, *Panax ginseng*, *Butea superba*, and yohimbine, and while there is some evidence of benefit, the studies conducted were not robust enough to be considered definitive (Ho and Tan, 2011; Ernst et al., 2011). Yohimbine can cause hypertension, among other side effects (Aronson, 2016).

It is recognized that the use of herbal medicines for ED continues to grow worldwide, but concern has been raised about the negative impact of these medicines from a safety perspective (Bhagavathula et al., 2016). This is further complicated by the adulteration of these products with medicines (including PDE5 inhibitors, see "Counterfeit" section) (Skalicka-Woźniak et al., 2017).

Counterfeit Products and Undeclared Ingredients

PDE5 inhibitors are the most commonly counterfeited of all medicines, perhaps unsurprisingly given it is more profitable than supplying heroin (Jackson et al., 2010). In Japan, it was estimated that the counterfeit products supplied were over double that of the legitimate market (Sugita and Miyakawa, 2010). Counterfeit PDE5 inhibitors may contain different strengths to that stated on the label, for example, in Indonesia (Taher and Setiawati, 2013) 6% contained more than the labeled strength. Some may contain none of the ingredient on the label (Bate and Hess, 2010), although this appears less common. While counterfeiting is common with internet purchases, in some countries counterfeit products can be widespread. An Indonesian study (Taher and Setiawati, 2013) found all sildenafil purchased from street peddlers was counterfeit, while half of the drugstores supplied counterfeit tablets, and 7% of pharmacies provided counterfeit tablets. Packaging and package inserts were typically very similar to the original packaging. A man was hospitalized in Australia with hypoglycemia after he used a counterfeit medicine labeled Cialis purchased in Vietnam, which contained sildenafil and glibenclamide (Chaubey et al., 2010). Men were hospitalized and some died in Hong Kong after having sexual enhancement remedies containing sildenafil and glibenclamide, purchased from a variety of sources including pharmacies, friends, and peddlers (Poon et al., 2009).

Sourcing PDE5 inhibitors without health professional involvement is common, particularly in younger men (under 40 years), mostly through internet purchase (Jackson et al., 2010). Many of these men think they can get the same medicine from the internet as on prescription. Although most men with ED recognize ascertaining the legitimacy of an internet site for medicines is difficult (Young, 2013), and many men recognize safety limitations of internet-bought medicines (Jackson et al., 2010), over a third of men with ED would consider buying ED drugs from one (Young, 2013), and a minority of men with prescriptions get them that way (Jackson et al., 2010). There are multiple ways pharmacy can help address this. The first measure is to ensure a comfortable and positive experience for a man picking up this prescription, e.g., ensuring privacy and fast, friendly and helpful service, and consider offering delivery. Pharmacists can increase awareness, advising men getting a prescription for an ED product that getting them from any other sources, e.g., buying when travelling or buying from the internet has dangers such as inappropriate amounts of the medicine, no medicine, or other ingredients. Finally, encouraging authorities to allow pharmacists to supply PDE5 inhibitors without a prescription is likely to minimize the inconvenience of a prescription barrier.

A similar danger comes from complementary remedies with undeclared PDE5 inhibitors. This is a common situation with remedies for sexual enhancement available for sale in local stores and through the internet and highlighted by regulators or

researchers all over the world (Bonner, 2016; Medsafe, 2013; Haggan, 2018; Podder et al., 2014). One danger arises from the undeclared PDE5 inhibitors, sometimes in excessive strengths. A second danger is the inclusion of other pharmaceutical ingredients such as chloramphenicol, oxytetracycline, fluoxetine or sibutramine, and sometimes other contaminants. Pharmacists need to be wary of sexual enhancement supplements offered for supply through the pharmacy, and could usefully warn men to avoid their use, particularly men on nitrates.

Advice

The topic is sensitive. Pharmacists need to ensure any conversations about the products take place in a private area where the conversation cannot be overheard. The medicine should not be obvious to others in the pharmacy, i.e., should be in a bag before being taken out to the patient to avoid other people seeing it. Sometimes the medication will not be known to be used by a spouse or partner, and pharmacists need to respect patient confidentiality. There have been cases of a spouse picking up other repeat medicines for their male partner being asked if they want the sildenafil also, breaching confidentiality, and inadvertently raising questions about an extra-marital relationship.

Lifestyle advice is important, as discussed earlier, e.g., improved diet, weight loss if overweight, increasing exercise, stopping smoking, limiting alcohol or recreational drugs, and reducing stress. Having ED might be quite motivating to put some lifestyle changes in place.

Advice about avoiding use with interacting medicines is important, particularly nitrates and alkyl nitrites (recreational drugs also known as 'poppers'). It is also important to ensure men know about the risks of counterfeit products and complementary remedies with undeclared ingredients.

It is helpful to know about side effects, headache, flushing, and a potential effect on color vision, for example, with PDE5 inhibitors. Priapism with PDE5 inhibitors is extremely unlikely, but more likely with intercavernosal injections. These can cause long-term damage, and need medical attention.

For men taking a PDE5 inhibitor for the first time, advice about the potential for hypotension can be helpful.

Where the pharmacist can supply ED medication without prescription, it can be helpful to have the partner involved in the consultation also. It might benefit the relationship if the man mentions to his partner that he is using the medicine.

Where the man has come to the pharmacy to seek advice, remember that it may have taken considerable courage to raise the issue, and take care to be sensitive to this. For example, let him know that this is a very common problem and has effective solutions. Ideally the man should also mention his ED to his doctor as it provides important information to the doctor on cardiovascular risk. However, where a man does not wish to do this, a medical check-up is usually indicated to ascertain if he has elevated cardiovascular risk or diabetes, for example, that needs identifying and treating. The underlying cause should be considered, e.g., depression, anxiety, relationship issues, performance anxiety, medication, excessive alcohol consumption or recreational drugs.

Advise with a PDE5 inhibitor that sexual stimulation is still required to achieve an erection, and that it needs to be taken in advance of the need (see table 1 above). Food can sometimes delay the effect. A man can try it on their own first to get confidence that it will work. This will help reduce the potential for performance anxiety at the time which can be enough to stop the medication from being sufficiently effective. Typically the first dose used is in the middle of the dose range, with an increase recommended if the response is insufficient. Treatment failure is confirmed if it does not work on six different attempts, and referral to the doctor or for relationship counseling will be appropriate there, depending on the likely cause.

The Role of the Pharmacist in the Healthcare Team—Current and Future Roles in Pharmacotherapy and Management

Pharmacists have multiple roles with management of ED, advising patients about appropriate use of ED medicines, being aware that ED may cause compliance issues with other medicines, raising with patients at risk the possibility of ED, and, in some countries, providing ED medicines without a prescription.

ED might affect compliance, for example, in diabetes, depression, hypertension, and hyperlipidemia (McLaughlin et al., 2005). While pharmacists can mention to men that ED can happen with certain medicines, note the concerns with atenolol mentioned earlier (Silvestri et al., 2003). An open question about whether or not there are any side effects that are troubling them might be a useful start. Where non-compliance seems likely, further mention of the potential for ED, and that it can be managed if it does occur, might be useful. Addition of a PDE5 inhibitor might resolve the ED and allow them to continue their medication (McLaughlin et al., 2005). A US study from a healthcare claims database found initiation of sildenafil in men with poor adherence to antidepressants, antihypertensives, lipid-lowering agents, or oral hypoglycemics was associated with improved medication adherence (McLaughlin et al., 2005).

When dispensing medicines for ED, pharmacists should be ensuring the safety, being aware of potential interactions, and providing advice to maximize safe and effective use. This may include lifestyle advice, and reminding men to manage their other conditions or lifestyle factors that might have caused the problem. For example, with men who have diabetes and ED, lifestyle measures and PDE5 inhibitors are recommended, and better glycemic control might assist (Maiorino et al., 2014).

Non-Prescription Supplies

In some countries, pharmacists may be able to supply PDE5 inhibitors without a prescription.

In the UK, PDE5 inhibitors have been supplied by pharmacists through patient group directions in some pharmacies, starting with a pilot in three pharmacies with sildenafil in 2007 (Mayor, 2007). Under this model, pharmacists needed to have additional training and could supply only to men fulfilling certain criteria, with the criteria varying a little according to the patient group directive. Various PDE5 inhibitors have been available in a range of strengths through this mechanism.

In 2017, Pfizer reclassified sildenafil in the UK to a pharmacy-only medicine, allowing supply of up to eight tablets of 50 mg. This should broaden the number of pharmacies supplying it compared with the patient group direction. There is a non-compulsory screening tool with questions that consider medical conditions, interactions, and cardiovascular health.

In NZ, following a reclassification in 2014 initiated by a local generic company, Douglas Pharmaceuticals, pharmacists who have undergone additional training could supply sildenafil up to 100 mg to men who fit specific criteria, with the help of a screening tool. Pharmacists without the training and pharmacy assistants cannot supply the medicine without a prescription. Under the model the consultation at the initial non-prescription supply includes questions about medical history, and measuring of blood pressure and pulse, repeated annually. Most pharmacies charge for this consultation on top of the price of tablets (Braund et al., 2018). If the man goes to a different pharmacy the full initial consultation is needed again. Repeat sildenafil requests without a prescription by the same man at the same pharmacy include questions about changes in medical history and medication. Under this model, men typically return to the same pharmacy, providing continuity of care. Pharmacists inform the man's general practitioner unless he opts out of this.

In Poland, a reclassification also by a local generic company, Adamed, saw sildenafil 25 mg able to be supplied from pharmacies. The man is expected to only use it without a prescription if he meets certain criteria which he can use the screening tool to ascertain.

A Europe-wide attempt in 2008 to reclassify sildenafil was met with concern and withdrawn by the applicant, and attempts in Australia to reclassify vardenafil and sildenafil were rejected in 2017.

Where sildenafil is legally available without prescription, the models of supply, strengths available and criteria for supply differ. For example, men under 35 years old or over 70 years old cannot get the medicine in NZ, while the UK and Poland allow supply to men 18 years or above, with no upper age limit, in line with the age for the prescription product license. The strength available without prescription is 25 mg in Poland, 50 mg in the UK (or higher under patient group direction), and up to 100 mg in New Zealand. Screening tools have been found to increase the amount and consistency of patient assessment for other supplies by pharmacists (Schneider et al., 2013), so may also help here.

Availability from the pharmacist might help discourage purchase from the internet, and help address unmet need, where men do not access any treatment from the doctor but will access it from the pharmacy. Reduced internet supplies could benefit men through minimizing risk of counterfeit products, and enabling discussions with a health professional which could result in a medical referral where appropriate, reduce the risk of use in men with contraindications or precautions, and result in a more informed patient, given the opportunity for discussing appropriate use and lifestyle advice.

In some countries supply by pharmacists without a prescription is common, despite no official reclassification, for example, in Chile (Mennickent et al., 2005), Spain, and Greece (Martin Morales, 2013). In Spain men very commonly first discuss their ED with a pharmacist rather than a doctor (Martín Morales et al., 2010).

There is a small amount of literature on the role of pharmacists with ED.

An observational study in Spain (Martín Morales et al., 2010) compared men prescribed a PDE5 inhibitor with men requesting ED advice or treatment without a prescription. Men without a prescription were significantly younger and more likely to smoke than those getting it on prescription, but otherwise the groups did not differ statistically, for example in comorbidities, ED severity or how long they took to see a health professional for their ED. Smoking and comorbidities were very common in both groups.

In NZ post-reclassification, qualitative interviews with 35 pharmacists found that pharmacists providing the service were happy to undergo additional training, and were generally comfortable with the supply (Braund et al., 2018). Their experiences of supply indicate this service differs considerably from usual non-prescription supplies. The estimated consultation time was typically 15–20 minutes. Many pharmacists estimated that over 50% of initial consultations resulted in medical referral without supply, but asked questions first that most likely would cause referral. The acceptance of this new model with longer consultations, use of a screening tool and informing the doctor may reflect the fact that pharmacists are usually charging for their consultation. It may also reflect the ability to build rapport with the patient, and the opportunity some took for a longer discussion on cardiovascular risk and psychological factors. However, an audit of 90 pharmacies conducted by the Ministry of Health in 2017 (Medicines Control, 2017) indicated some failings with the service, with some pharmacists not keeping the expected records, and some supplies to men outside of the appropriate criteria. Some confusion on the supply criteria was seen in the qualitative research (Braund et al., 2018), which could be the cause of the audit failings. It shows the importance of having reminders from professional pharmacy organizations on pharmacists' responsibilities with a new service, and follow-up research to identify potential concerns or improvements.

In NZ, market growth post-reclassification (Gauld, 2017) suggested pharmacists were addressing unmet need, although that leveled off in time. Customs-intercepted sildenafil entering the country declined post-reclassification (**Fig. 1**), although it is unknown what effect reclassification had versus other factors.

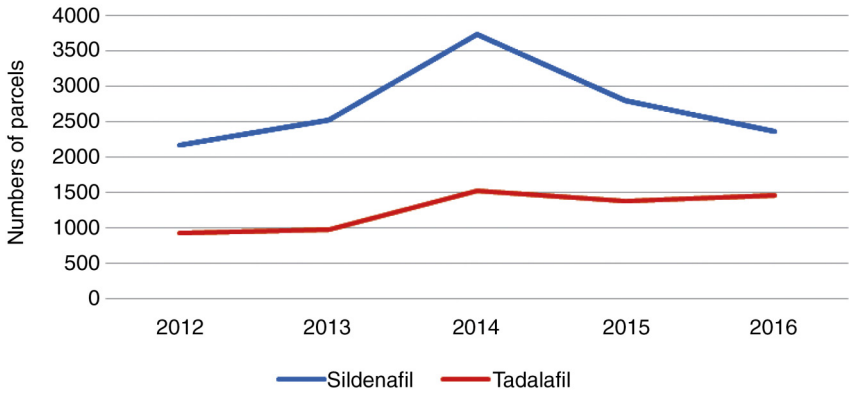

Figure 1 Customs interceptions of sildenafil and tadalafil in New Zealand before and after the reclassification (sildenafil tablets became available through pharmacists in October 2014). *Source: Medsafe, 2016.*

A conference abstract (Weber and Burch, 2006) from the US mentions the utilization of a pharmacist-run ED group clinic which reduced the wait time for the clinic from six months to less than 30 days, and reported high satisfaction in the clinic from patients. Another conference abstract (Orrico et al., 1998), used pharmacists to assist the doctor in determining the correct dose of sildenafil, reduce the risk of adverse effects, minimize the cost of therapy by titrating to the lowest dose and splitting tablets, and conduct an outcome review. Over 500 patients were seen by the pharmacist, many of whom responded to 50 mg of sildenafil.

Conclusion

ED is a common condition that men may not seek medical help on. While it has many potential causes, it is an important indicator of cardiovascular disease. Various treatments are available, with PDE5 inhibitors being used first-line, alongside lifestyle advice. Intracavernosal injections and penile implants are other options. Counterfeiting and complementary remedies with undeclared remedies are common problems with ED management, with deaths reported previously.

Pharmacists in some countries have played a greater role with supply of PDE5 inhibitors without a prescription under legitimate supply models. Such models vary from leaving assessment to the patient, through to requiring pharmacists to undergo extra training and adhere strictly to a screening tool. Research is needed to ascertain the safety of this model, and whether or not it reduces the likelihood of men acquiring the medicine from internet supply or other dubious routes.

Management of Urologic Disorders and the Pharmacist's Role in Urinary Incontinence

Rebekah Jane Moles, The University of Sydney, Sydney, Australia

Objectives

After reading this chapter, one should be able to:

- Understand the different types of urinary incontinence and recognize contributing factors.
- Identify drugs used to treat incontinence and understand their mechanisms of action.
- Give lifestyle advice to patients suffering from incontinence.
- Understand the role pharmacists can play in making medication management recommendations for patients suffering from incontinence.

Anatomy

The urinary tract is made of the following important structures that are necessary to understand when learning about and managing urinary incontinence (Fig. 1).

Physiology

Normal Urinary Functioning

Urine is a liquid by-product that is produced by animals after they have metabolized the foods and water and other compounds they have put into their bodies. Urine flows from the kidneys through the ureters to the bladder. As urine fills the bladder, its muscular walls will stretch. Thus, when the volume of urine inside the bladder reaches around 180–250 mL, the urge to urinate should be experienced through signaling via the nervous system. At 500 mL, a very strong urge to urinate should be experienced. When a person feels this urge to urinate, they will initially send signals to the bladder structures to hold the urine in, and when appropriate (i.e., they have reached the toilet), they will then allow the brain's signaling pathways to relax the urethral sphincter muscles and contract the detrusor or bladder muscle and push urine out. In addition to the above-mentioned structures involved in normal urine functioning,

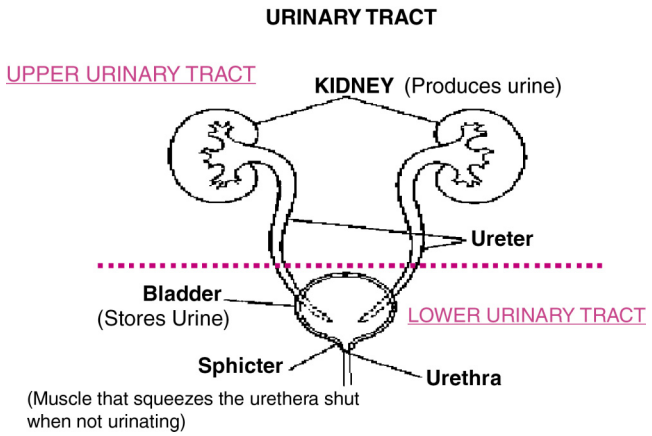

Figure 1 Urinary tract.

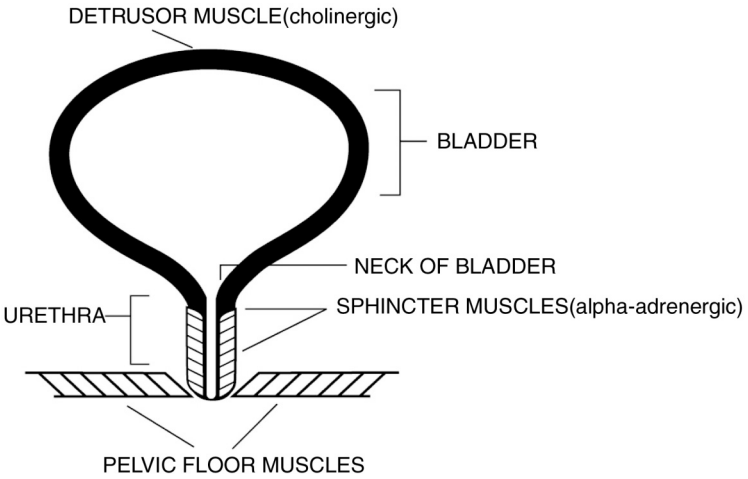

Figure 2 Important structures involved in urinary continence.

the pelvic floor muscles that support the urethra, rectum, and vagina in females are also an important to assist in supporting the urethra and maintaining adequate pressure to retain urine in the bladder, until the person voluntarily wants to empty their bladder/urinate (Campbell et al., 2002; Hickling et al., 2015) (Fig. 2).

Definition and Prevalence of Incontinence

Urinary incontinence refers to the involuntary loss of urine from the bladder. It is a condition where one has the inability to control the storage or release of urine (Moles, 2003a).

The prevalence of incontinence is markedly different between males and females. A review article published in Urology on prevalence (Nitti, 2001) reported that the prevalence of urinary incontinence among females is approximately 20%–30% in young female adults up to age 35 rising to 30%–50% in the elderly. Some studies, however, in specific populations showed prevalence rates of between 10% and 75% for stress incontinence, between 9% and 33% for urge incontinence, and between 14% and 61% for mixed urge and stress incontinence (Nitti, 2001). In contrast, the prevalence in men is markedly lower with rates quoted between 3% and 11% (Nitti, 2001).

Overall Principles on How Incontinence Occurs

Looking at the diagram presented in Fig. 2, incontinence occurs when the pressure inside the bladder exceeds the pressure at the urethral sphincter. One can think of the urethral sphincter like a tap. There are several ways that these pressure imbalances could

occur, and these will determine the type of incontinence that one is suffering from. For example, the pressure inside the bladder could exceed the pressure at the tap if the tap was weakened by medications that relax the sphincter muscles, or the sphincter muscles are not as well supported by the pelvic floor. In addition, the pressure inside the bladder may exceed the pressure at the tap if there is a downward force applied to the detrusor muscle. If there was a blockage at the tap, initially this would lead to urinary retention; however, as the bladder continues to fill with filtrate from the kidneys, eventually as it overfills, the pressure inside the bladder will exceed the pressure at the tap, again leading to incontinence (Moles, 2003a). Each of these underlying mechanisms of incontinence will be discussed in the next section of this chapter.

Types of Incontinence

There is a variety of different types of incontinence. It is important to understand the type of incontinence suffered, as it will assist in explaining the factors that are leading to or precipitating the incontinence and of course allow one to implement the correct nondrug and or drug interventions to treat the incontinence. The following types of incontinence, their symptoms, causes, and treatment will be discussed in this chapter: stress incontinence, urge incontinence, overflow incontinence, and nocturnal enuresis.

Stress Incontinence—Symptoms and Causes

Stress incontinence is a condition in which there is an involuntary loss of small amounts of urine when pressure within the abdomen increases suddenly. For example, when a female coughs, sneezes, laughs, jumps, or runs, she leaks a small amount of urine; this is stress incontinence (Yarnell et al., 1981).

Stress incontinence in women is often precipitated by pregnancy and childbirth. Pregnancy and childbirth often weakens the pelvic floor muscles as the baby pushes on these muscles. Once the pelvic floor muscles are weakened, the urethra is less supported allowing the pressure at the tap to be weakened. During activities that push down on the bladder such as coughing, sneezing, or jumping, the pressure inside the bladder may start to exceed the pressure at the tap leading to small involuntary losses of urine. In addition, estrogen helps to maintain the thickness of the urethra lining to keep the urethra sealed after passing urine; however, during menopause, estrogen is produced in lower quantities and as a result of this loss of estrogen, some women experience stress incontinence during menopause (Brunner, 2017).

Medications may also contribute to stress incontinence. As the urethral sphincter muscles are under alpha adrenergic control, alpha blocking medicines, which may be used for blood pressure, will relax the sphincter muscles and may precipitate stress incontinence (Moles, 2003a).

Urge Incontinence—Symptoms and Causes

Urge incontinence can be described as storage failure. It is due to uninhibited contractions of the bladder also known as detrusor instability (Arnold et al., 2012). This is the most common type of incontinence in the elderly (Thirugnanasothy, 2010). The patient suffering from urge incontinence feels a sudden and strong need to urinate but can often not make it to the toilet completely in time, hence having involuntary loss of urine. In a properly functioning bladder, the detrusor muscle remains relaxed as the bladder gradually fills up; however, if you have urge incontinence, then the bladder for some reason may feel fuller than it actually is, sending a strong signal to urinate, when in fact it may not be that full. This results in the bladder contracting too early when it is not very full, and not when one wants it to (Moles, 2003a).

The cause of urge incontinence is not fully understood; it is more common in females and gets worse as one ages (Thirugnanasothy, 2010). Symptoms may get worse at times of stress and may also be made worse by caffeine and alcohol, which both have diuretic effects. Urge incontinence may also occur as a result of constipation; an enlarged prostate gland in males is simply the result of a long history of poor bladder habits. In some cases, the cause of an overactive bladder is unknown. Medicines may also precipitate or aggravate urge incontinence. For example, medicines that lead to constipation may aggravate urge incontinence, and medicines that are diuretic in nature could aggravate urge incontinence (Moles, 2003a).

Mixed Incontinence—Symptoms and Causes

Mixed incontinence is more common in older females and is exactly as its name suggests, it is a mix of stress and urge incontinence. Patients suffering from mixed incontinence therefore have both of the conditions described above where they lose small amounts of urine when coughing and sneezing for example, and they also have an overactive detrusor muscle where a strong urge to urinate may be experienced and they are unable to make it to the toilet in time (Moles, 2003a).

Overflow Incontinence—Symptoms and Causes

Overflow incontinence is somewhat different from the other two types discussed (stress and urge), as it is caused by emptying failure due to an outlet obstruction (Dmochowski, 2005). This incontinence is therefore actually associated with chronic retention as the bladder is unable to empty properly. As the bladder continues to fill and fill, eventually the pressure inside the bladder will exceed the

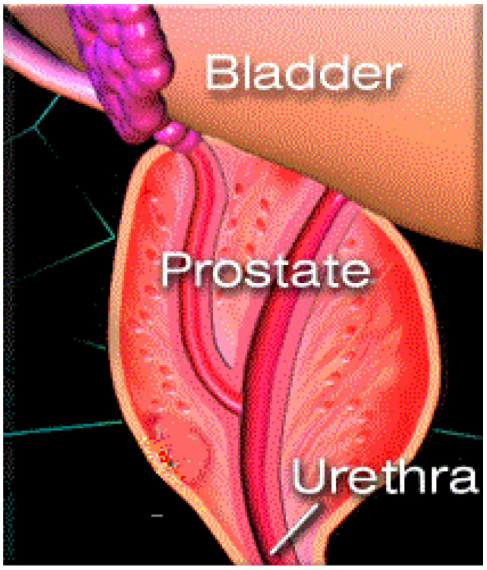

Figure 3 Prostate gland.

pressure at the tap and frequent leakage of small amounts of urine occurs as a result (Moles, 2003a). The main cause of outlet obstruction is an enlarged prostate (Arnold et al., 2012).

The prostate gland is typically the size of a walnut and it surrounds the urethra (**Fig. 3**).

Benign growth of the prostate tissue is not uncommon as males age. Benign prostatic hyperplasia (BPH) is thought to be due to changes in circulating male hormones and usually does not occur until males are above 40 years. Dihydroxytesterone, a metabolite of testosterone, causes the tissue to grow (Moles, 2003b).

As the prostate tissue that is surrounding the urethra grows, it begins to obstruct normal urine flow and eventually results in retention. Symptoms suggesting incomplete bladder emptying include: feeling the need to strain when passing urine, a weak or slow stream of urine, feeling that you are unable to completely empty your bladder, needing urinate frequently at night, dribbling more urine after going to the toilet.

Medications that relax the detrusor muscle may also exacerbate overflow incontinence. This is because the detrusor muscle is under cholinergic stimulation. If an anticholinergic medicine is taken, then this means that the detrusor muscle will not be able to contract with as much force, again leading to overfilling of the bladder. Again, when the bladder overfills, eventually, the pressure inside will exceed the pressure at the tap leading to involuntary loss in urine (Moles, 2003b).

Nocturnal Enuresis—Symptoms and Causes

Nocturnal enuresis is also known as bedwetting (O'Flynn, 2011). It involves involuntary urination while one is asleep. A person is said to have nocturnal enuresis when he or she continues to wet the bed at an age after bladder control usually occurs. For most girls, they will have achieved full bladder control by age six and for most boys, they will stay dry by age seven. By ten years of age, 95% of children are dry at night. The remaining 5% have nocturnal enuresis. Most commonly, bedwetting is from a developmental delay rather than a mental or physical illness (O'Flynn, 2011).

Primary nocturnal enuresis (PNE) is the most common form of bedwetting and would be defined by a child wetting the bed on an average of at least two nights a week with no long periods of dryness or to not sleep dry without being taken to the toilet by another person. In contrast, secondary nocturnal enuresis occurs after a person has had an extended period of dryness at night (usually six months or more) and then they revert to bedwetting. Secondary enuresis may be triggered by emotional stress, or a physical condition such as a urinary tract infection.

What causes a child to have nocturnal enuresis is not fully understood. However, there are some common principles that may be involved, including an overactive detrusor muscle, excessive urine volume, and a lack of arousal when the bladder is full. The later involves a neurological developmental delay and is thought to be due to a nervous system that is slow to process the feeling of a full bladder. An overproduction of urine could also be associated with insufficient production or response to antidiuretic hormone (ADH). ADH regulates urine production by increasing water reabsorption in the kidney. At night, ADH usually signals to the kidneys to make less urine, but in some bedwetters, they do not produce enough ADH or the ADH response is insufficient; hence, they end up with excessive urine production (Eggert and Kühn, 1995). Chronic constipation can also push on the bladder exacerbating nocturnal enuresis.

Management of Incontinence

Due to the different mechanisms involved in the different types of incontinence, there are a number of different treatments that are specific to a particular type of incontinence. In some instances, a medication treatment of one type of incontinence could exacerbate a different type of incontinence, so getting the medicines correct and understanding the underlying principles are essential.

Looking at Fig. 2, one can see that the detrusor muscle is predominately under cholinergic control. This means that giving a cholinergic medicine should contract the detrusor muscle, which could be of some help in overflow incontinence but would be detrimental for a patient with urge incontinence. On the other hand, an anticholinergic medicine would be helpful for urge incontinence but detrimental for overflow. Similarly, an alpha adrenergic stimulant could be theoretically of benefit for stress incontinence but detrimental for overflow and an alpha blocker could be helpful in overflow but exacerbate stress incontinence. These principles are useful when conducting comprehensive medication review services, as there may be a plethora of medicines that could help or hinder one's incontinence. The next sections will go through each type of incontinence and its preferred management.

Stress Incontinence—Management

The first-line treatment for stress incontinence is strengthening the pelvic floor through pelvic floor muscle training. If this fails, then surgery may be considered. As well as these treatments, lifestyle modifications are also recommended to decrease the pressure placed on the urethral closure mechanisms. This includes losing weight, avoiding constipation, and treating chronic cough.

Pelvic floor exercise can be performed by both men and women. The floor of the pelvis is made up of layers of muscle and other tissues. These layers stretch like a hammock from the tailbone at the back, to the pubic bone in front. Pelvic floor muscles support the bladder and bowel in both men and women, as well as support the uterus in women. The urine tube and the back passage all pass through the pelvic floor muscles as well as the vagina in females. Your pelvic floor muscles help you to control your bladder and bowel. They also help sexual function. It is vital to keep your pelvic floor muscles. Recommendations for conducting such exercises can vary between guidelines, but in general each person needs to follow steps similar to those outlined in the box below (Continence Foundation Australia, 2018a).

1. Identify your Pelvic Floor Muscles
   a. Sit or lie down with the muscles of your thighs, buttocks, and stomach relaxed.
   b. Squeeze the ring of muscle around the back passage as if you are trying to stop passing wind. Now relax this muscle. Squeeze and let go a couple of times until you are sure you have found the right muscles. Try not to squeeze your buttocks.
   c. When sitting on the toilet to empty your bladder, try to stop the stream of urine, then start it again. Do this to learn which muscles are the right ones to use—but only once a week. Your bladder may not empty the way it should if you stop and start your stream more often than that.
   d. If you do not feel a distinct "squeeze and lift" of your pelvic floor muscles, or if you cannot slow your stream of urine as talked about in point 3, ask for help from your doctor, physiotherapist, or continence nurse. They will help you to get your pelvic floor muscles working right. Women with very weak pelvic floor muscles can benefit from pelvic floor muscle training.
2. Begin Training
   a. Squeeze and draw in the muscles around your back passage and your vagina at the same time. Lift them UP inside. You should have a sense of "lift" each time you squeeze your pelvic floor muscles. Try to hold them strong and tight as you count to 8. Now, let them go and relax. You should have a distinct feeling of "letting go."
   b. Repeat "squeeze and lift" and let go. It is best to rest for about 8 s in between each lift up of the muscles. If you cannot hold for 8, just hold for as long as you can.
   c. Repeat this "squeeze and lift" as many times as you can, up to a limit of 8–12 squeezes.
   d. Try to do three sets of 8–12 squeezes each, with a rest in between.
   e. Do this whole training plan (three sets of 8–12 squeezes) each day while lying down, sitting, or standing.
   f. While doing pelvic floor muscle training:
      - keep breathing;
      - only squeeze and lift;
      - do NOT tighten your buttocks; and
      - keep your thighs relaxed.

Surgery involves the use of a synthetic mid-urethral sling or autologous fascial slings. If these fail, then implantation of an artificial urinary sphincter can also be tried (Kim et al., 2014).

With respect to medications to treat stress incontinence, several drugs have been trialed but there are none that are approved for the management of stress incontinence (Saks and Arya, 2009). The off-label use of alpha adrenergic agents such as pseudoephedrine or ephedrine is sometimes seen, as these agents theoretically contract the sphincter muscles, which are under adrenergic control (Saks and Arya, 2009). Duloxetine, a serotonin and noradrenalin reuptake inhibitor, indicated for depression, has more recently been trialed for its use in treating stress incontinence (Saks and Arya, 2009). Compared to placebo, Duloxetine has been shown to be favorable in decreasing stress incontinence episodes (Norton et al., 2002) and after prolonged use (30 months), it has been rated by women to be more effective than prior to starting treatment (Bump et al., 2008). However, many

women in the later trail discontinued treatment with Duloxetine; hence, long-term benefits of duloxetine as a treatment strategy for stress incontinence are yet to be proven, and the indications for this medicine are yet to be widened (Bump et al., 2008; Saks and Arya, 2009).

In females who are postmenopausal, the use of topical estrogen may be considered if the incontinence appears to be related to atrophic changes. In this case, it is recommended that topical estrogens are applied initially every night for the first 1–2 weeks and then once to twice weekly (Therapeutic Guideline, 2018).

Urge Incontinence—Management

As urge incontinence is caused by an overactive detrusor, the therapeutic treatments are twofold. First, a person may undergo bladder training to try to learn to hold onto urine longer before voiding. Second, medications are used to relax the detrusor muscle so that it is less likely to be overactive when signals are sent to the brain to indicate that the bladder is getting full.

With respect to bladder training, the aim is to help the patient gain better control and reduce frequency and withhold the need to void and increase the volume voided when one visits the toilet (Continence Foundation Australia, 2018b). Most bladder training is performed by a physiotherapist or a specialist continence advisor and may take up to 3 months of weekly appointments and the maintenance of a bladder diary to see improvements.

In addition to bladder training, medication treatment is often needed for patients with urge incontinence. Traditionally, medications with anticholinergic actions have provided the mainstay of treatment.

Anticholinergics reduce bladder contractility and increase the bladder capacity by relaxing the detrusor muscle. Benefits vary between individuals and in general have been reported to decrease incontinence episodes by one event per 48 h compared to placebo. Some of the anticholinergics used include: Oxybutynin, Solifenacin, Tolterodine, and Darifenacin. Propantheline is to be used but is no longer recommended. Medications with anticholinergic activity should be used with caution in the elderly as they are more prone to adverse effects including blurred vision, dry mouth, constipation, confusion, and urinary retention. Please note that while urinary retention in this case is the aim of therapy, patients need to ensure that they are still able to void (Arnold et al., 2012).

There is no evidence that any one anticholinergic is superior to another with respect to bladder control. Oxybutynin may cause the highest incidence of dry mouth, whereas Solifenacin has been reported to cause higher incidence of constipation. Solifenacin has been reported to increase the QT interval at high doses (Hesch, 2007).

Mirabegron is a newer agent that works in a similar way by relaxing the detrusor muscle and increases bladder capacity. Mirabegron, however, is a $Beta_3$-adrenarecptor agonist. Due to its action on Beta receptors, it is contraindicated in severe uncontrolled hypertension as blood pressure can increase after ingestion. It is also metabolized through the CYP3A4 pathway; hence, patients taking CYP3A4 inhibitors may be advised to take lower doses or avoid its use. Its use in renal impairment is also precautionary and lower starting doses maybe required (Warren et al., 2016). As this agent is relatively new at the time of writing, there is limited evidence as to what cut-off renal function should be used; hence, the manufacturer recommends avoiding its use in patients with an eGFR of less than 15 mL/min/1.73 m^2 (Australian Medicines Handbook, 2018). This new agent may be appropriate for patients who cannot tolerate the anticholinergic agents due to side effects or additive effects with concomitant medications.

One other medical intervention for urge incontinence is the use of Botulinum toxin. This may be used if other oral medications such as anticholinergics or Mirabegron are not tolerated or ineffective. As this may lead to a large reduction in bladder contractility, there is a risk of urinary retention, and hence this should only be used if a person is capable of self-insertion of a urinary catheter if required. Due to this reason, the use of Botulinum toxin in urge incontinence is limited (Orasanu and Mahajan, 2013).

Overflow Incontinence—Management

As overflow incontinence is caused via voiding dysfunction, usually due to outlet obstruction, such as benign prostatic hypertrophy, the treatment is centered around relaxing urethral smooth muscle, or decreasing prostate size, for urine flow to be less restricted.

The mainstay of drug treatment therefore includes alpha adrenergic receptor blockers that relax urethral and prostate smooth muscle and 5-alpha-reductase inhibitors, which inhibit the conversion of testosterone to dihydrotestosterone that has influence on benign prostate growth. If the overactive bladder syndrome is secondary to bladder outlet obstruction, then there may be a role for combinations of both the 5-alpha-reductase inhibitor and the alpha blockers (Moles, 2003b).

Prostate size is the most important factor influencing drug choice. Symptomatic relief, however, requires continuous treatment. Selective alpha-blockers can improve symptoms within 48 h (full effect in 4–6 weeks) and also improve urinary flow rates. They appear to be effective regardless of prostate size. The most commonly used alpha blockers include terazosin, doxazosin, tamsulosin, alfuzosin, silodosin, and prazosin. The most important side effects of alpha blockers are dizziness and low blood pressure after sitting or standing up. Some alpha blockers will interact with phosphodiesterase 5 (PDE5) inhibitors used to treat erectile dysfunction and may cause marked decreases in blood pressure. Tamsulosin and Alfuzosin are generally more acceptable to be prescribed to patients who use PDE5 inhibitors (Gillis and Wilde, 1997).

5-Alpha-reductase inhibitors are more likely to be prescribed when the prostate gland is greater than 30–40 cm^3. Treatment with these agents usually needs to be for greater than 6 months to observe a decrease in prostate size and may not exhibit full effects until after 12–18 months of treatment. The most commonly used 5-alpha-reductase inhibitors are Finasteride and Dutasteride.

Saw Palmetto (*Serenoa repens*) is a herbal product that is often marketed to assist men with symptoms of BPH. It should be noted, however, that a Cochran systematic review found that this product is no more effective than placebo in improving urinary symptoms (Tacklind et al., 2012).

Nocturnal Enuresis—Management

First-line treatment is usually non-drug in nature and involves ensuring a normal daily fluid intake, creating a typical toileting pattern and avoiding caffeine in drinks and chocolate, especially in the evening period. Enuresis alarms that are placed under the sheets that detect very small amounts of fluid are also often very successful.

With respect to medication management, Desmopressin, an analogue of antidiuretic hormone, is the first-line drug therapy in children above 6 years of age. Desmopressin comes in a variety of formulations; however, the oral tablet or sublingual form may be preferred over the nasal spray due to an increased risk in hyponatremia; however, all formulations are approved for use in children and the sublingual and tablet form can be harder for children to use appropriately. Usually, Desmopressin will be trialed for 1–3 months and then withdrawn to assess for relapse (O'Flynn, 2011).

If the above treatment measures fail, then imipramine may be used for its anticholinergic effects; however, this should be under specialist supervision due to its side-effect profile, which can be more predominant in small children.

Incontinence Appliances and Pads

Based on the above treatment options including medication and surgery for different types of incontinence, it should be noted that incontinence pads and pants are usually never the only option despite the fact they are less invasive. Incontinence pads are widely available; however, they should perhaps only be acceptable for patients who are not suitable for drug or surgical intervention (e.g., the frail elderly).

Role of the Pharmacist

The pharmacist has a key role to play in managing patients who suffer from all types of incontinence. As medications can both contribute to causing incontinence and assist in its management, a thorough understanding of medicines pharmacology and effects and adverse effects is required (Moles, 2003a, 2003b).

Often, an initial task in assisting a person with incontinence is to take a thorough medication history. As a pharmacist, you can easily ask a few questions related to bowel habits, urinary symptoms being suffered, a history of urinary tract infections, questions about your patient's lifestyle, as well as what medications they are taking, and a history of when the problem began. You can then try to relate some causal factors to the symptoms described.

Some example questions are listed in below Table.

1	How long have you had bladder problems?
2	When was it that it started to get worse?
3	Do you have any other problems when urinating? (pain or burning?)
4	What are your bowel habits usually like? Any constipation? How long has that been a problem?
5	Tell me a bit about your diet, what do you eat most days? And drink? Do you have coffee, tea, or alcohol? How often?
6	And what about your medications, how long have you been taking each one, and how have they been going?
7	Any other problems you wish to talk about, other medical conditions, or any other medications?
8	What are you doing currently to manage your issue?

After you have gathered the information about the patient, including their medication history, it is important to review their medications, alcohol and caffeine intake, and bowel habits to see if any of these factors can aggravate the issue.

You should be very particular about looking for medications/substances that increase volume such as diuretics, caffeine, and alcohol, cause constipation or sedation such as opioids and anticholinergic medicines, and those that have a direct effect on the function on the bladder (as listed above). Patients may need referral back to the GP and a comprehensive medication review should be performed.

Your role in medication review is to identify drugs/substances that may be aggravating incontinence. For example, medications with anticholinergic side effects would be a cause for concern in a patient with overflow incontinence, and alpha blockers would be a reason to consider alternative antihypertensive agents in a patient with stress or mixed incontinence. This intimate knowledge of the pharmacology of medicines provides the pharmacist a vital role in assisting physicians and patients manage their condition.

Furthermore, when dispensing medicines to treat incontinence, a large part of our role will be in providing advice about the new medicine. We have a role in discussing how the medicine will work, how to take the medication, and importantly the side effects that may be common. In addition to this usual advice, realistic expectations on what to expect should be delivered along with written information.

Pharmacist can also provide practical tips such as: Asking the patient to keep a bladder diary to help record the effectiveness of treatment or performing pelvic floor exercises to strengthen the urethral sphincter muscles. These are particularly useful for urge and stress incontinence, respectively. Other lifestyle factors should also be discussed such as: managing contributing factors to their bladder issues such as urinary tract infections, constipation, excessive fluid intake, unstable diabetes, obesity; or consumption of alcohol or caffeine-containing drinks.

Finally, providing protective pads may also be helpful in managing incontinence, especially in people with cognitive impairment or limited mobility, but as mentioned previously, these are rarely to be used as the patient's only solution to his or her problem (Moles, 2003a).

An Example Case Study of the Medication Review Process

Mrs. Reynolds is a 65-year-old customer who enters your pharmacy and comes to the counter with a packet of incontinence undergarments. She is an overweight lady with five children and four grandchildren who always comes to your pharmacy to collect her Prazosin prescription for hypertension, alongside her Hydrochlorothiazide and Amiloride prescription. She also takes Amitriptyline at night for depression and to aid her sleep. She explains that she has "lost some control over her waterworks" and this has been getting worse in the last few months. She says that sometimes she "all of a sudden needs to go to the toilet, but doesn't always make it in time," and often if she coughs or laughs, she leaks small amounts of urine. She appears a little embarrassed but comments that it is just part of getting older and there is nothing anyone can do about it.

Is this true? How can the Pharmacist Help?

As a pharmacist, we are able to provide Mrs. Reynolds with incontinence aids, but more importantly, we can organize and conduct a comprehensive medication review. In this case, some of the issues a pharmacist may consider include:

- Age itself is a factor that needs to be taken into consideration. Decreased elastin reduces bladder capacity, and sensations from the bladder may be delayed; therefore, an elderly person may have reduced reserve and increased vulnerability to incontinence, but it must be noted that it is not an inevitable part of normal ageing.
- Mobility may also impact on incontinence; if a patient's mobility is restricted, then the time taken to reach the toilet may be a factor.
- Certain medications may exacerbate incontinence and commonly those indicated include sedatives, diuretics, anticholinergic agents, caffeine, and alcohol.
- Urge incontinence may be caused by neurological conditions such as Parkinson's, multiple sclerosis, or Alzheimer's, and these should be medically assessed.
- Alternatively, symptoms may arise from increased sensory input from the bladder due to local causes, such as a urinary tract infection or constipation.
- Excessive fluid intake, alcohol, caffeine, and other diuretics can exacerbate urge incontinence.
- Stress incontinence is often associated with weak pelvic floor muscles caused by trauma during childbirth and atrophy of the pelvic floor after menopause as estrogen levels fall.
- In addition, constipation and obesity are predisposing factors to stress incontinence by contributing to an increase in pressure in the bladder.

It is likely that the alpha blocker prazosin is relaxing the urethral sphincter and exacerbating her stress incontinence. Furthermore, her diuretic is adding to the urine volume. In addition, while the amitriptyline may actually assist her urge incontinence, it may be causing constipation and its sedative effects can also be problematic. Providing an evidence-based recommendation of an angiotensin converting enzyme (ACE) inhibitor as a first-line antihypertensive agent to replace the current antihypertensive could be a good start to assisting Mrs. Reynolds.

As illustrated in this short case, the pharmacists' role in this area can be quite extensive and their unique knowledge of the pharmacology of medicines, alongside the physiology involved in incontinence, means they are well placed to assist patients with urinary incontinence.

Management of Rheumatology Disorders and the Pharmacist's Role: Gout and Related Conditions

Mohammad Ismail*, Hira Sajid*, Fahadullah Khan*, Mohamad Haniki Nik Mohamed†, *University of Peshawar, Peshawar, Pakistan; †Kulliyyah of Pharmacy, International Islamic University Malaysia, Kuantan, Malaysia

Learning Objectives

By the end of this chapter, the reader will be able to:

- Describe the main concept, etiopathogenesis, and typical clinical presentation of gout and other crystal-induced arthropathies.
- Discuss various pharmacological approaches and select a suitable therapy for acute gout and hyperuricemia.
- Design a patient-oriented care plan to ensure effective therapeutic outcomes.
- Educate patient regarding various aspects of gout and its therapy.
- Identify and manage adverse drug effects and drug interactions associated with pharmacotherapy of gout.

Introduction

Gout refers to a spectrum of diseases characterized by elevated serum uric acid (hyperuricemia) and deposition of monosodium urate (MSU) crystals in joints causing attacks of acute inflammatory arthritis. It might further advance to soft tissue deposits of urate crystals (tophi), interstitial renal disease, and uric acid nephrolithiasis (Khanna et al., 2012a). Acute attack typically affects a single joint (monoarticular) and often involves the first toe (podagra); however, other joints such as insteps, ankle, knee, fingers, wrist, and elbow can also be affected (Dalbeth et al., 2016).

Epidemiology

The global prevalence of gout ranges between 0.1% and 10% with an incidence rate of 0.3–6.0 cases per 1000 person-years (Kuo et al., 2015). Gout is more prevalent in developed countries (Kuo et al., 2015). In the United States, an estimated 3.9% of population had gout during 2007–08 (Zhu et al., 2011). The population-prevalence of gout is 1.1% in China (Liu et al., 2015). A

combined prevalence of 1.4% has been reported for gout in Germany and the United Kingdom (Annemans et al., 2008). Whereas, the prevalence of gout is 0.9% in France (Bardin et al., 2016).

Gout is more common in men, and its incidence increases with age (Burke et al., 2016). The cumulative incidence of gout among older adults (up to 65 years) is 8.6% in men and 2.5% in women, which increases up to 11.8% in men and 5% in women by the age of 75 years (Burke et al., 2016). Whereas, the prevalence in individuals above 80 years of age is around 10% in men and 6% in women (Ragab et al., 2017).

Etiology and Pathophysiology

Gout is associated with hyperuricemia, that is an abnormally elevated level of serum uric acid (>7 mg/dL). Uric acid is the end product of purine catabolism. Various enzymes are involved in the production of uric acid; however, xanthine oxidase plays a pivotal role (Schlee et al., 2018a). Uric acid is considered a waste product that has no known physiologic role in the body. Its major portion (2/3) is excreted in urine, whereas the remainder is eliminated through the gastrointestinal (GI) tract (Ragab et al., 2017; Richette and Bardin, 2010).

The main cause of hyperuricemia is reduced uric acid excretion by the kidney (>90% cases) that is genetically determined. Renal excretion of uric acid is also reduced by certain drugs such as thiazide or loop diuretics, cyclosporine, pyrazinamide, ethambutol, low-dose aspirin (<2 g/day), ethanol, levodopa, and cancer chemotherapy (Ben Salem et al., 2017).

Hyperuricemia may be caused by overproduction of uric acid. Some rare enzyme abnormalities such as deficiency of HGPRT (hypoxanthine-guanine phosphoribosyl transferase) and increased activity of PRPP (phosphoribosyl pyrophosphate synthetase) are associated with hyperuricemia. It may also occur in myeloproliferative and lymphoproliferative disorders due to increased breakdown of tissue nucleic acids. Cancer patients undergoing chemotherapy are also prone toward hyperuricemia because of lysis and breakdown of cellular matter (Ragab et al., 2017).

Under normal conditions, uric acid is present in the solubilized state. Upon exceeding 7 mg/dL, it achieves a saturated state and precipitates to form crystals (Schlee et al., 2018a). The deposition of MSU crystals in synovial fluid of various joints leads to a self-limiting pain and inflammation. The inflammatory response is initiated upon phagocytosis of MSU crystals by the synoviocytes which releases various pro-inflammatory mediators such as the cytokines, interleukin-1, interleukin-8, and tumor necrosis factor alpha. Chronic inflammation in the joint(s) may lead to loss of cartilage and erosion of the bone (Dalbeth et al., 2016; Ragab et al., 2017; Teng et al., 2006).

Clinical Features

In acute gout, the most frequent clinical presentation is "podagra" that refers to inflammation and pain in the first metatarsophalangeal joint (big toe) (Schlee et al., 2018b). Gout typically affects a single joint, but some patients may present with inflammation and pain involving multiple joints or periarticular soft tissue of the lower or upper extremities. The affected joint appears swollen, tender, warm, and dusky red. Gout attack involves severe pain that peaks at 2–6 h. It is rapid, intense, and localized to the affected joint. The attack usually occurs during night because water diffuses out of the synovial fluid when a person is in supine position leading to crystallization of MSU. Gout attack may be accompanied with fever, malaise, and even delirium when larger joints (knee) are affected (Schlee et al., 2018b). The frequency of gout recurrence varies considerably. Some patients may never experience a repeated attack of gout, while others may experience recurrent gout attacks within a year (Grassi and De Angelis, 2012).

Persistent hyperuricemia and frequent gout attacks lead to chronic gout. Patients with chronic gout may present with continuous joint pain and joint deformation that can cause functional impairment. In chronic cases, gout attack is less intense that can be precipitated by stress, trauma, alcohol ingestion, surgery, or uric acid lowering therapy (Grassi and De Angelis, 2012; Schlee et al., 2018b). Elderly patients may have an atypical presentation of gout involving multiple joints (polyarticular) which resembles that of rheumatoid arthritis (Schlee et al., 2018b).

Uncontrolled progressive gout may lead to the development of kidney stones, nephropathy, and tophi. Tophi often develops in hands, wrists, elbows, and knees that can lead to irreversible joint deformities and loss of functionality (Grassi and De Angelis, 2012; Ragab et al., 2017; Schlee et al., 2018b).

Diagnosis

Diagnosis is usually based on physical examination, presence of signs and symptoms, and response to therapy. Serum uric acid level provides crucial information about the risk or severity of gout, but it alone cannot predict the presence of gout as many patients with hyperuricemia do not develop gout. Arthrocentesis (joint aspiration) is the procedure of choice for the detection of MSU crystals in joint fluids in order to confirm the diagnosis of gout (Dalbeth et al., 2016; Schlee et al., 2018b).

Treatment

The primary goal of pharmacotherapy of acute gout is to resolve pain, preserve joint function, and improve the patient's quality of life. In chronic cases, the main goal is normalization of serum uric acid level (below 6 mg/dL) in order to prevent future episodes and complications.

The American College of Rheumatology (ACR) guidelines are widely used for the management of gout (Khanna et al., 2012a,b). However, other guidelines are also available and applicable to specific regions and situations (see Further Reading for detail).

Acute Gout

Management of acute gout mainly focuses on reduction of inflammation and pain (Fig. 1). Different anti-inflammatory drugs such as nonsteroidal anti-inflammatory drugs (NSAIDs), colchicine, or corticosteroids can be used to treat an acute attack (Khanna et al., 2012b; Richette et al., 2017). The selection of therapy depends on disease presentation (severity of the attack, duration since onset, and number of joints involved), previous drug use, and patient's factors. Typically, NSAIDs are the recommended first choice. If they are contraindicated, colchicine, or corticosteroids are alternative options (see Table 1 for drugs' doses and cautions). Usually monotherapy with one of the above drugs is used in most of the cases. However, combination-therapy or investigational drugs may be used in severe cases (Fig. 2). Moreover, an individualized approach is recommended for each patient in case of comorbidities such as chronic kidney disease, diabetes mellitus, hypertension, and heart diseases (Khanna et al., 2012b; Richette et al., 2017).

NSAIDs are effective in the treatment of acute gout. They are well-tolerated and have a good safety profile for short-term use. Although some NSAIDs (naproxen, indomethacin, and sulindac) are specifically approved by the US Food and Drug Administration (FDA) for the treatment of gout, others are similarly effective and can be used in full doses to treat an acute attack

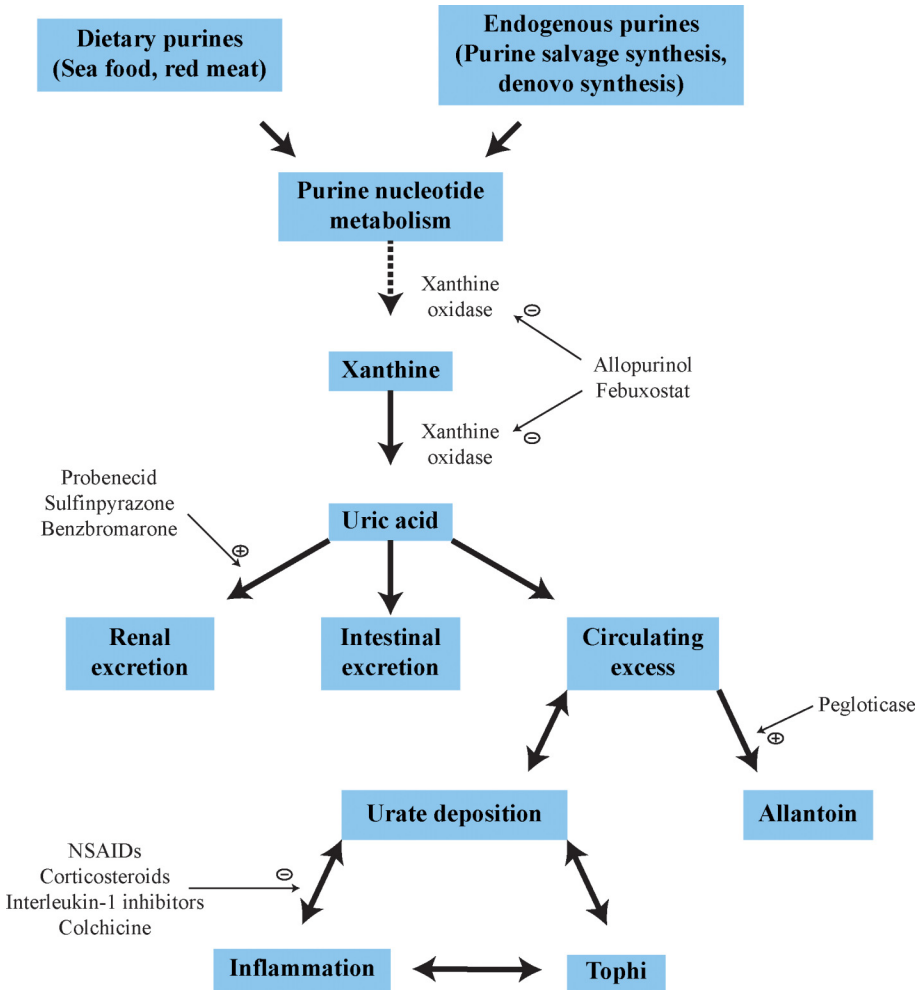

Figure 1 Drugs' site of action in the management of gout.

Table 1 Recommended doses, dose adjustment and cautions of drugs used for the treatment of acute gout

Drugs	*Adult dosage*	*Dose adjustments*	*Cautions*
Naproxen	750 mg oral followed by 250 mg thrice daily until attack has subsided	*Renal impairment:* Avoid if CrCl is <30 mL/min *Hepatic impairment and geriatrics*: Use lowest effective dose	Avoid in patients with peptic ulcer disease and active bleeding Use with caution in patients with CHF, dehydration and renal impairment Consider co-administration with a PPI when long-term treatment in individuals at high-risk for GI bleeding is necessary
Indomethacin	50 mg oral thrice daily until pain is tolerable; taper dose and discontinue based on pain response	*Renal impairment:* Not recommended unless benefits outweigh risks *Geriatrics:* Use lowest effective dose	
Diclofenac	50 mg oral thrice daily; or initial 100 mg oral thrice daily, followed by 50 mg oral thrice daily	*Hepatic impairment:* Initiate at lowest effective dose, discontinue if not efficacious; use not recommended in severe impairment *Geriatrics:* Use with caution and lowest effective dose *Renal impairment:* Use not recommended in severe impairment	
Ibuprofen	400–800 mg oral three or four times daily	*Renal impairment:* Use lowest effective dose	
Sulindac	200 mg oral twice daily for 7 days	*Renal and hepatic impairment*: Monitor patient closely and use lower dose	
Celecoxib	Initiate with 800 mg oral then 400 mg 12 h later followed by 400 mg twice daily for 7 days	*Renal and hepatic impairment:* Avoid in severe impairment *Hepatic impairment:* Reduce the dose by half in moderate hepatic impairment; in severe impairment, better to avoid *Geriatrics:* Use lowest effective dose *Slow cytochrome metabolizers:* Use alternate therapy	Increases risk of cardiovascular events such as myocardial infarction
Colchicine	1.2 mg oral at first sign of flare followed by 0.6 mg 1 h later (max 1.8 mg over 1 h)	*Renal impairment:* Severe (CrCl <30 mL/min), 0.3 mg/day orally initially; increase dose with adequate monitoring. Do not repeat course more than once every 2 weeks *Hepatic impairment:* Severe, consider dose reduction (in gout prophylaxis), do not repeat course more than once every 2 weeks (in gout flare) *Concomitant strong cytochrome and P-glycoprotein inhibitors*: Dose adjustment recommended	Intravenous use should be avoided because of increased toxicity
Prednisolone	0.5 mg/kg/day for 5–10 days followed by discontinuation or 0.5 mg/kg/day initially for 2–5 days, followed by tapering over 7–10 days	–	Use with caution in DM and CHF. Rebound flare may occur if prophylaxis not continued for 4–7 days
Triamcinolone	Initial, 2.5–15 mg as a single intra-articular injection, additional doses can be adjusted between 20 and 40 mg and administered as necessary	–	
Anakinra	100 mg subcutaneously daily for 3 consecutive days	*Renal impairment:* Administer every 48 h if CrCl is <30 mL/min	Opportunistic infections may occur. Avoid use with live vaccines
Canakinumab	Single dose of 150 mg subcutaneously	–	Opportunistic infections may occur. Avoid use with live vaccines

CHF, chronic heart failure; *CrCl*, creatinine clearance; *DM*, diabetes mellitus; *GI*, gastrointestinal; *PPI*, proton pump inhibitors.
Source: ASHP, 2018; Lexicomp, 2018; Micromedex Drugdex, 2018.

(Table 1). The therapy should be started within 24 h of the onset of an acute attack and continued until complete resolution. The usual duration of therapy is 5–10 days. Once the acute attack has resolved, the dose should be tapered down. Drug is discontinued after 2 days of complete resolution of symptoms. Aspirin is generally not recommended because in low doses it alters uric acid levels and increases the risk of gout attack. Cyclooxygenase-2 selective NSAIDs (e.g., celecoxib) are also effective and may be indicated in patients with a history of peptic ulcer disease or GI bleeding (Khanna et al., 2012b; Richette et al., 2017).

Colchicine can effectively reduce symptoms of an acute gout attack. It can be used if NSAIDs are contraindicated or fail to produce the desired response. According to the ACR guidelines, colchicine therapy must be initiated within 36 h of onset of an acute gout attack because of diminished success rates when delayed (Khanna et al., 2012b). Colchicine is orally administered at a loading dose of 1.2 mg followed by a maintenance dose of 0.6 mg every 1 h. The drug is discontinued if symptoms of acute attack resolve or

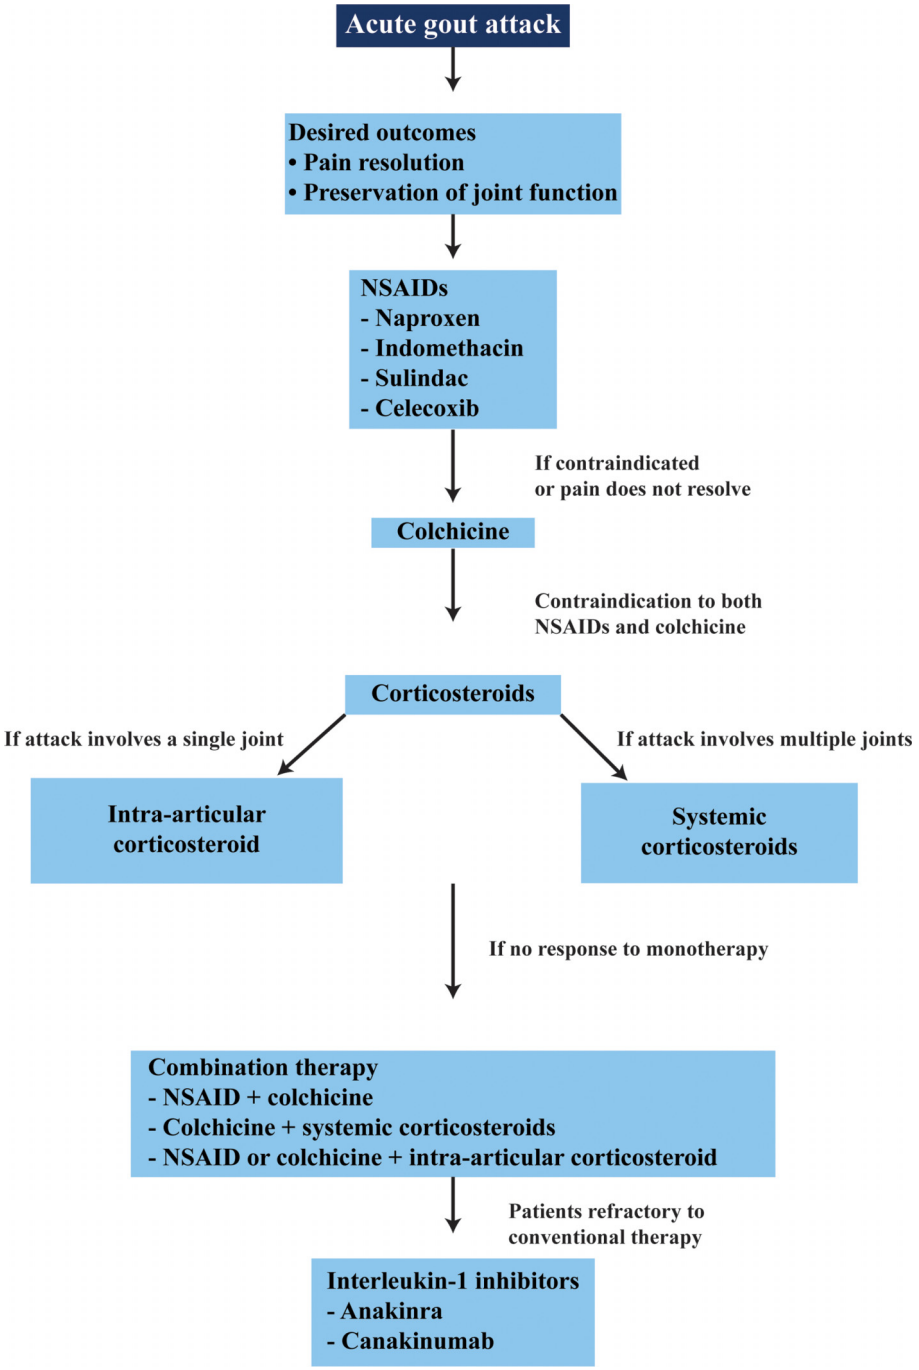

Figure 2 Algorithm for the treatment of acute gout.

GI adverse effects develop. Alternately, the ACR guidelines recommend oral colchicine at a loading dose of 1.2 mg followed by 0.6 mg every 12 h until the symptoms of an acute attack resolve. The dose of colchicine must be tailored in patients with hepatic or moderate renal impairment (Khanna et al., 2012b).

Corticosteroids are recommended in patients who are intolerant or do not respond to NSAIDs/colchicine therapy. The selection of corticosteroid treatment depends on the number and type of affected joints. Intra-articular therapy is recommended when one or two joints are affected, while systemic corticosteroid therapy is preferred in patients with multiple affected joints. For systemic corticosteroid therapy, oral prednisone or prednisolone at a daily dose of 0.5 mg/kg are used for 5–10 days. A full dose shall be prescribed initially (for 2–5 days) followed by down tapering of dose for the subsequent duration of therapy. Alternately, a single intramuscular injection of triamcinolone acetonide (60 mg) followed by oral prednisone or prednisolone therapy may be used (Khanna et al., 2012b).

Table 2 Recommended doses, dose adjustment and cautions of drugs used for the management of hyperuricemia

Drugs	*Adult dosage*	*Dose adjustments*	*Cautions*
Allopurinol	Mild gout: 200–300 mg oral once daily Moderately severe tophaceous gout: Oral 400–600 mg daily in divided doses Dose escalation in patients receiving allopurinol therapy for at least 1 month with serum urate ≥6 mg/dL: Increase by 100 mg daily every month until serum urate of ≤6 mg/dL is achieved	*Renal impairment and cancer patients:* Dose adjustment is necessary CrCl 10–20 mL/min: 200 mg orally daily CrCl 3–10 mL/min: Do not exceed 100 mg orally daily CrCl <3 mL/min: 100 mg orally at intervals Chronic kidney disease stage 4 or worse: Initial, 50 mg orally daily; titrate maintenance dose upward to target serum uric acid level every 2–5 weeks; may exceed 300 mg/day with adequate monitoring	Adjust dose based on target serum level
Febuxostat	40–80 mg oral once daily	*Cancer patients:* Dose adjustment is necessary *Renal impairment:* Limit dose to 40 mg once daily if CrCl is 15–29 mL/min	
Sulfinpyrazone	200–400 mg oral twice daily; increase dose gradually over a 1-week period titrating to desired urate blood levels to 400–800 mg/day	*Renal impairment*: Avoid in severe renal impairment	Avoid in acute gout attack
Probenecid	250 mg oral twice daily for 1 week followed by 500 mg twice daily, titrate dose every 4 weeks (maximum 2000 mg/day)		
Lesinurad	200 mg oral once daily in the morning with food and water (maximum 200 mg/day), give at the same time of the day with a xanthine oxidase inhibitor including allopurinol (at least 300 mg/day or 200 mg/day if CrCl is less than 60 mL/min) or febuxostat	*Renal impairment*: Avoid if CrCl is <30 mL/min *Hepatic impairment*: severe, do not use	
Pegloticase	8 mg intravenous infusion every 2 weeks	–	Infuse at slow rate

CrCl, creatinine clearance.
Source: ASHP 2018; Lexicomp 2018; Micromedex Drugdex, 2018.

Inadequate response to pharmacotherapy is defined as <20% improvement in pain score within 24 h of therapy or <50% improvement after 24 h of therapy (Khanna et al., 2012b). In patients with inadequate response to monotherapy, a combination therapy comprising any two drugs from the aforementioned classes (NSAIDs, colchicine, or corticosteroids), either in their full doses or one drug in its full dose and other at a lower dose, is recommended (Khanna et al., 2012b). Intravenous or intramuscular methyl prednisolone at a dose of 0.5–2 mg/kg may be considered in patients who cannot swallow oral corticosteroids (Khanna et al., 2012b). Patient refractory to the conventional therapy may be treated with interleukin-1 inhibitors such as anakinra and canakinumab (Khanna et al., 2012b).

Urate-Lowering Therapy

Urate-lowering therapy (ULT) is recommended to reduce serum uric acid level in individuals who experience two or more gout attacks per year. Additionally, patients having renal impairment (eGFR <60 mL/min), tophi, history of kidney stones, and elevated serum uric acid (>8 mg/dL) may be prescribed ULT (Hui et al., 2017; Richette et al., 2017). Appropriate ULT reduces the frequency of gout flares and recurrence and improves patient's quality of life (Richette et al., 2017). ULT comprises xanthine oxidase inhibitors (XOIs): allopurinol and febuxostat; and uricosuric agents: probenecid and sulfinpyrazone (Richette et al., 2017). They reduce uric acid level by different mechanisms (**Fig. 1**). Drugs doses and cautions of drugs used for the management of hyperuricemia are given in **Table 2**.

ULT is associated with acute gout flares due to dispersion or dissolution of urate crystals; therefore, preventive therapy is needed. For this purpose, colchicine or NSAID (e.g., naproxen) is recommended for a maximum duration of 3 (non-tophaceous gout) or 6 months (tophaceous gout). Low-dose corticosteroid (oral prednisolone or prednisone) may be considered as an alternate option (Hui et al., 2017; Khanna et al., 2012b).

ULT should be initiated at low doses and then titrated according to the desired serum uric acid level (<6 mg/dL) (Richette et al., 2017). Serum uric acid level should be monitored every 2–5 weeks during initial therapy when uric acid level is high. Once the desired serum uric acid level of <6 mg/dL or <5 mg/dL (in case of complicated gout) has been achieved, every 6 months monitoring is recommended.

Allopurinol is the recommended first-line therapy (**Fig. 3**), starting at a dose of 50–100 mg/day with an increment of 100 mg (50 mg in renal impairment) after every 4 weeks (maximum daily dose: 800–900 mg) till the desired serum uric acid level has been

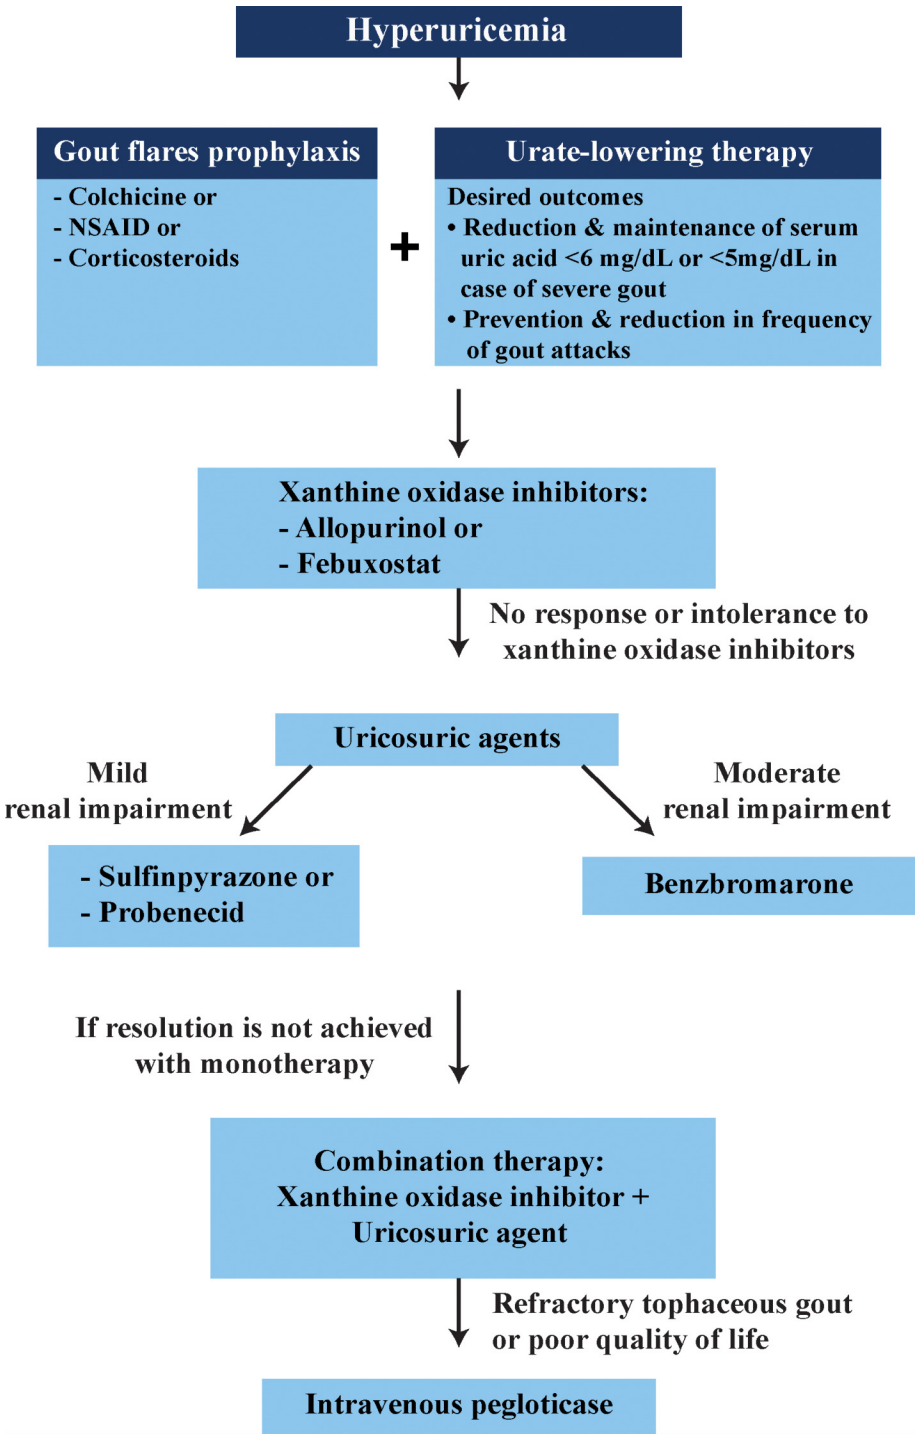

Figure 3 Algorithm for the management of hyperuricemia.

achieved (**Table 2**; Hui et al., 2017; Khanna et al., 2012a; Richette et al., 2017). Febuxostat is an alternate XOI, which is used at a dose of 80 mg/kg (may be titrated up to 120 mg/day after 4 weeks). Febuxostat is a preferred option in patients with mild to moderate renal impairment (Hui et al., 2017; Khanna et al., 2012a).

In case of inadequate response or intolerance to XOIs, uricosuric agents (probenecid and sulfinpyrazone) are recommended (**Fig. 3**). Sulfinpyrazone or probenecid might be used in patients with normal or mild renal impairment, whereas benzbromarone is suggested in patients with moderate renal impairment (Hui et al., 2017; Khanna et al., 2012a; Richette et al., 2017). However, they should be avoided in patients with history of kidney stones because they increase the risk of kidney stone

formation (Khanna et al., 2012a). Patients should be advised to increase fluid intake. Urine alkalinization with potassium citrate may also be considered in order to suppress reabsorption of uric acid (Khanna et al., 2012a). Combination therapy comprising a XOI and a uricosuric agent is recommended in patients who fail to respond to therapy with a single agent (Hui et al., 2017).

Lesinurad, a selective uric acid reabsorption inhibitor, may be used as an adjuvant with allopurinol or febuxostat. A combination of lesinurad and XOI is more efficacious with similar safety profile as compared with XOI alone (Dalbeth et al., 2017; Saag et al., 2017).

Refractory gout is characterized by severe tophaceous gout and poor quality of life with no response to maximal tolerated doses of a single or multiple drug therapy (Khanna et al., 2012a; Richette et al., 2017). In such situation, intravenous pegloticase in a dose of 8 mg every 2 weeks may be used. However, cost and higher rates of hypersensitivity reactions have greatly limited its use in practice (Shannon and Cole, 2012).

Several investigational drugs including canakinumab, rilonacept, and arhalofenate have been proven effective and safe in multiple clinical trials but none of them has been approved by the FDA for the treatment of gout.

Other Crystal-Induced Joint Disorders

Joint disorders may also be caused by intra-articular deposition of other crystals such as calcium pyrophosphate dihydrate (pseudogout), basic calcium phosphate, and calcium oxalate (Schumacher and Chen, 2018).

Calcium Pyrophosphate Dihydrate Crystal Deposition Disease

The calcium pyrophosphate dihydrate crystals deposition (CPPD) disease formerly known as pseudogout is a joint disorder caused by the deposition of CPPD in joints, articular cartilage, and hyaline cartilage. It may be asymptomatic (diagnosed after radiography) or symptomatic causing episodic pain. CPPD disease commonly affects joints of knees, wrists, and hips, but other joints may also be affected (Rosenthal and Ryan, 2016). This disease is common among elderly and is rare among individuals below 55 years of age (Richette et al., 2009). It has been postulated that increasing age and genetic predisposition increase breakdown of adenosine triphosphate thus producing large amount of pyrophosphate which binds with calcium and forms calcium pyrophosphate crystals (Coiffier and Albert, 2015; Rosenthal and Ryan, 2016).

CPPD disease is often asymptomatic and is only diagnosed incidentally following a radiography. Some patients may experience pain involving single or multiple joints that mimics gout. Uncontrolled CPPD disease may lead to synovitis and degenerative arthritis. Rarely, the affected joint may get infected and results in high fever. CPPD disease can be accurately diagnosed by characterizing CPPD crystals in synovial aspirate under a light microscope. Culture of the synovial fluid should be performed to rule out the possibility of any infection (Schlee et al., 2018b).

In an acute attack of CPPD disease, NSAIDs are preferred due to satisfactory efficacy and safety profile. Colchicine may be used for prophylaxis of acute pain. Whereas, intra-articular triamcinolone (10–40 mg) may be considered in patients who are intolerant or do not respond to NSAIDs or colchicine (Rosenthal and Ryan, 2016; Schumacher and Chen, 2018).

Basic Calcium Phosphate Deposition Disease

Basic calcium phosphate deposition disease develops as a result of deposition of hydroxyapatite, apatite, or other calcium phosphate salts in joints, tendons, ligaments, hyaline cartilage, skeletal muscles, and subcutaneous tissue. Various diseases such as calcific periarthritis, systemic sclerosis, Paget's disease, and ankylosing spondylitis impair mineral hemostasis, which leads to calcification of basic calcium phosphate in soft tissues. The dispersion or dissolution of these calcified masses provokes an inflammatory response that manifests as pain. NSAIDs and intra-articular corticosteroids are the recommended treatment options (Ea and Liote, 2014; Schumacher and Chen, 2018).

Calcium Oxalate Deposition Disease

Oxalosis is a rare metabolic condition characterized by deposition of calcium oxalate crystals in visceral tissues, blood vessels, bones, and cartilage. Oxalosis may be congenital (primary) or acquired (secondary). In primary oxalosis, increased levels of oxalates develop as a result of polymorphism in metabolic enzymes. Whereas, secondary oxalosis occurs as a result of impaired renal function which leads to reduced excretion of oxalates (Lorenz et al., 2013; Schumacher and Chen, 2018).

Calcium oxalate deposition disease has similar manifestations as other crystal deposition diseases and presents as pain in the affected area. The crystals of calcium oxalate appear bipyramidal when viewed under a microscope. NSAIDs, colchicine, and intra-articular corticosteroid are used for the symptomatic treatment of calcium oxalate deposition disease. Liver transplant in patients with primary oxalosis and frequent dialysis in patients with secondary oxalosis can help reduce crystals deposits (Lorenz et al., 2013; Schumacher and Chen, 2018).

Role of Pharmacists

Pharmacotherapy is an essential component of patient care that necessitates the specialized skills and knowledge of pharmacist in health-care team. Pharmacists can contribute significantly toward improving the appropriate, safe, and effective use of drugs and overall health of the patients. Many studies have addressed the role of pharmacist in the management of gout. Most notable role includes patient education about the importance of pharmacological and nonpharmacological treatment, and monitoring of medication adherence. Studies have evaluated community pharmacist's role in emphasizing lifestyle modifications and diet such as managing weight, limiting meat and seafood intake, and minimizing alcohol consumption (Cassagnol and Saad, 2013; Counsell et al., 2018).

The studies have also evaluated pharmacist-led patient's education about their medications, including appropriate dosing, duration of therapy, adverse effects, contraindications, drug interactions, colchicine use, and gout flares at the first 6 months of urate-lowering therapy (Counsell et al., 2018). Ambulatory care pharmacists and automated calling technology represent potentially important and underutilized resources for improving health outcomes in gout patients (Coburn et al., 2016b). Moreover, ambulatory care pharmacists also assist in implementing guidelines through developing evidence-based algorithms and processes, educating providers and staff, and participating in population management (Hawes and Tong, 2015). An interactive and patient-centered approach can enhance gout educational interventions (Fields and Batterman, 2018). A structured pharmacist-staffed program can effectively and safely lower and maintain uric acid levels in a high percentage of patients with recurrent gout in a primary care setting (Goldfien et al., 2014). Additionally, a simple ambulatory pharmacist-led intervention results in improvement of medication adherence and achievement of serum uric acid goal in gout patients using allopurinol (Mikuls et al., 2018). Pharmacist awareness of clinically significant interactions between colchicine and antibiotics that inhibit CYP3A4 can help ensure the efficacy of colchicine and minimize the risk of associated adverse events (Davis et al., 2013).

Pharmacists' Patient Care Process for Gout

Pharmacist as a member of the health-care team can optimize patients' medication therapy and contribute toward improving patients' health outcome. Pharmacists through effective communication with patients, their families, and other members of the health-care team collect, document, and recommend valuable information that promotes the appropriate, safe, and effective use of medicines and improve overall therapy outcome (ASHP, 2004; Shane and Abramowitz, 2015). The process of collecting, documenting, and recommending various aspects of patients' care has been improved and formalized following the development of Pharmacists' Patient Care Process by the Joint Commission of Pharmacy Practitioners (Gonyeau et al. 2018, JCPP, 2014). Pharmacists' patient-centered activities with special reference to gout are illustrated in **Fig. 4**.

Patient Education and Counseling

Patient education is of utmost importance in the management of gout. Patient education promotes therapy adherence and improves therapeutic outcome. Patients should be well-informed about the disease, its precipitating factors, and therapy. The patient needs to know about how to manage diet and acute attack and what to expect from pharmacological and nonpharmacological therapy. The patient must be involved in therapy selection process and all potential barriers to therapy adherence including doubts about the effectiveness of therapy, remission of gout symptomology, potential adverse effects, and cost of therapy should be addressed (Fields et al., 2017).

Patient must be informed about the curable nature of disease, its recurrence, role of hyperuricemia in disease progression, and the impact of lifestyle and dietary modifications. The need of lifestyle and dietary modifications must be stressed (Alvarez-Lario and Alonso-Valdivielso, 2014). Exercise should be encouraged in all patients because regular exercise reduces the incidence of gout flares. Overweight patients should be advised to lose weight; however, rapid weight loss should be avoided as it causes ketosis and increases uric acid level thus precipitating gout attack (Dessein et al., 2000). Diet comprising alcohol, seafood, red meat, sugar-sweetened beverages, and beer increases the risk of hyperuricemia; thus, they need to be avoided or taken in moderation. Intake of low-fat dairy products, such as coffee and fiber, must be encouraged as they reduce the risk of gout. Patient should be advised to drink water/fluid in sufficient amount in order to reduce kidney stone formation (Alvarez-Lario and Alonso-Valdivielso, 2014; Fields et al., 2017).

Adequate information about the benefits, potential harms, cost, and duration of pharmacotherapy should be provided to all patients. Patient must be educated about self-medication during an acute gout attack. Clear instruction about the dose, time, and duration of therapy must be communicated to each patient. The patient needs to understand the significance of ULT despite no symptoms of acute gout (Fields et al., 2017). Education about avoiding certain over-the-counter (OTC) medicines such as aspirin that may precipitate a gout attack is necessary. Regular monitoring of serum uric acid level must be encouraged in order to maintain the required serum uric acid level (Coburn et al., 2016a; Ramsubeik et al., 2018). Patient should be well-informed about the possible adverse effects of prescribed drugs and how to manage them (Aung et al., 2017; Fields et al., 2017).

Monitoring of Therapy Outcome

The primary outcome measure of therapy in acute gout is the resolution of pain and preservation of joint function. While, the outcome of ULT is assessed by measuring the reduction and maintenance of serum uric acid to the desired level, that is, <6 mg/dL in

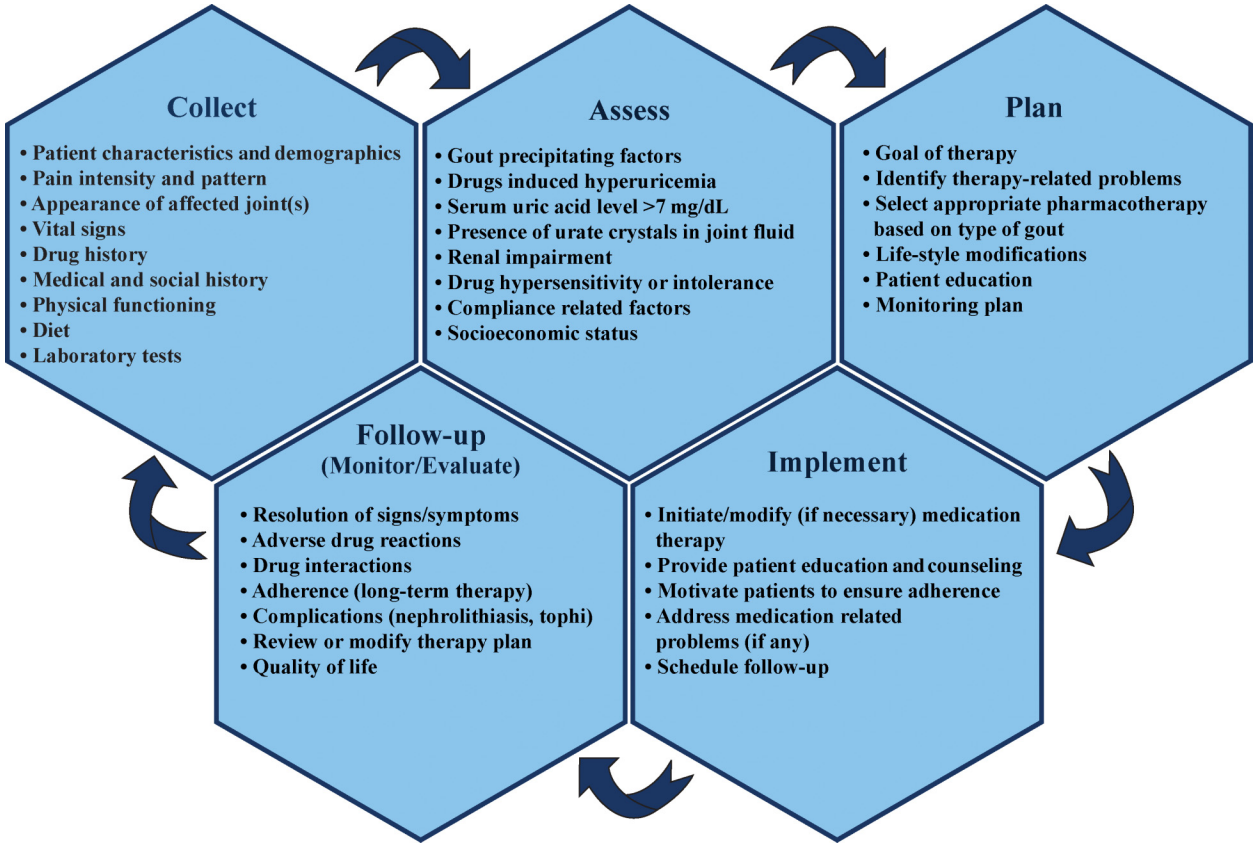

Figure 4 Pharmacists' patient care process for gout.

patients with noncomplicated gout and <5 mg/dL in patients with tophaceous gout (Khanna et al., 2012a). Regular monitoring of serum uric acid level is necessary in all patients. Serum uric acid tests should be performed every 2–5 weeks during initial phases of ULT (when the serum uric acid level is high) in order to titrate their dose to achieve the desired level. Once the desired serum uric acid level has been achieved, uric acid level should be assessed once every 6 months (Khanna et al., 2012a). Patients receiving ULT and prophylaxis therapy with colchicine or NSAIDs for gout flares should undergo laboratory tests including serum creatinine, blood urea nitrogen, and liver function tests in order to assess the status of renal or hepatic impairment and the need for dose adjustment (Perez-Ruiz et al., 2000). Patients with gout often have multiple comorbidities such as hypertension, diabetes, hyperlipidemia, and other cardiac diseases. Such patients should be regularly assessed, and appropriate therapy for these comorbidities should be selected considering their hyperuricemic effect, drug interactions, and adverse effects (Bardin and Richette, 2017).

Monitoring of Adverse Drug Reactions

Adverse drug reactions (ADRs) are inevitable consequences of pharmacotherapy of gout, thus monitoring of ADRs is necessary in all patients (Stamp, 2014). NSAID therapy may cause gastric bleeding, elevated blood pressure, and renal impairment; hence, they must be used with caution in patients predisposed to these conditions (Harirforoosh et al., 2013; Sostres et al., 2010). Corticosteroids are well-tolerated when used for a shorter duration of time, but their prolonged use may lead to hypothalamic pituitary adrenal axis suppression, hyperglycemia, osteoporosis, and impaired immunity. GI side effects such as vomiting and diarrhea are major limiting factors for colchicine therapy (Pelechas et al., 2019; Poetker and Reh, 2010). ULT precipitates gout flares and may cause other adverse effects, which can significantly affect patient's compliance (McHugh, 2018; Stamp, 2014). All ADRs should be monitored and timely managed. Patient should be educated regarding self-management of ADRs, their reporting, and situations when consultation with health-care professionals is needed. Moreover, many ADRs may be of minor nature that do not require any intervention. Patients need to be educated about the associated ADRs in order to improve patient satisfaction and compliance (Reach, 2011). **Table 3** enlists some of the common and serious ADRs associated with the drugs used for the management of gout.

Table 3 Adverse drug reactions associated with pharmacotherapy of gout

Drugs	*Cardiovascular*	*Dermatologic*	*Gastrointestinal*	*Renal*	*Hepatic*	*Neurologic*	*Respiratory*	*Others*
Naproxen	Edema, *fluid retention, vasculitis CHF, HTN, MI*	Pruritus, rash, *TEN, SJS*	Abdominal pain, constipation, heart burn, nausea, *GI hemorrhage, IBD*	*Acute renal failure, nephritis, nephrotic syndrome*	*Hepatitis, hepatotoxicity*	Dizziness, headache, *aseptic meningitis, stroke, seizure*	Dyspnea, *bronchospasm, pulmonary edema*	Ototoxicity, *hyperkalemia, agranulocytosis, anaphylaxis*
Sulindac	Edema, *MI*	Pruritus, rash, *erythema multiforms, SJS, TEN*	Abdominal pain, constipation, diarrhea, nausea and vomiting, *gastrointestinal ulceration, pancreatitis*	*Interstitial nephritis, nephrotic syndrome, papillary necrosis, renal failure*	*Cholestasis, hepatitis, hepatotoxicity, jaundice, liver failure*	Dizziness, headache, *stroke, seizure*	*Bronchospasm*	Tinnitus, *Agranulocytosis, neutropenia, thrombocytopenia, anaphylactoid reaction*
Indomethacin	*Dysrhythmia, thrombosis, CHF, HTN, MI*	*Erythroderma, SJS, TEN*	Abdominal pain, constipation, diarrhea, indigestion, nausea, *GI hemorrhage, GI ulceration, GI perforation*	Newborn renal dysfunction, *nephrotoxicity, renal failure*	Elevated liver enzymes, *hepatic necrosis, hepatitis, hepatotoxicity, jaundice, liver failure*	Dizziness, headache, vertigo, *stroke, seizure, ventricular hemorrhage*	*Persistent pulmonary hypertension of the newborn, pulmonary hemorrhage*	Hyponatremia, tinnitus, transitory neonatal hyperkalemia, *hearing loss, anemia, hemorrhage, neutropenia, anaphylaxis*
Celecoxib	HTN, *MI, TdP, ventricular hypertrophy*	*Erythema multiforms, SJS, TEN*	Diarrhea, nausea, *GI hemorrhage, GI perforation, GI ulceration*	*Acute renal failure, injury of kidney*	*Fulminant hepatitis, hepatotoxicity, rheumatoid arthritis, liver failure*	Headache, *stroke*	*Asthma, bronchospasm*	*Hyperkalemia, hemorrhage, thrombosis, anaphylactoid reaction*
Colchicine	–	–	Diarrhea, nausea, vomiting	–	–	–	–	*Myelosuppression*
Prednisolone	Fluid retention, HTN, *CHF*	Acne, ecchymosis, superinfection, *Kaposi's sarcoma*	Superinfection, *GI perforation, pancreatitis*	–	–	Headache, *pseudotumor cerebri, seizure*	*Pulmonary tuberculosis*	Hyperglycemia, muscle weakness, osteoporosis, cataract, glaucoma, superinfections, *diabetes mellitus with hyperosmolar coma, diabetic ketoacidosis, drug induced myopathy*
Triamcinolone	–	Injection site reaction	*GI perforation*	–	–	Headache, stroke, *infarction of spinal cord, seizure, paraplegia*	Pharyngitis, *perforation of nasal septum*	Cushing syndrome, influenza-like illness, *abnormal electrolytes, anaphylaxis, osteoporosis, cataract, glaucoma*
Anakinra	*Cardiorespiratory arrest*	Injection site reaction, *bacterial cellulitis, malignant melanoma*	–	–	–	–	*Bacterial pneumonia*	*Neutropenia, thrombocytopenia, anaphylaxis, infectious disease, breast cancer,*

Monitoring of Drug Interactions

Patients with gout often have comorbidities and require concomitant administration of multiple drugs, which increases the probability of drug–drug interactions and its associated adverse outcomes (Stamp, 2014; Stamp and Chapman, 2013). NSAIDs decrease the antihypertensive effect of angiotensin-converting enzyme inhibitors and angiotensin-II receptor blockers (Floor-Schreudering et al., 2015; Gualtierotti et al. 2013). They also increase the risk of bleeding when coadministered with anticoagulants and selective serotonin reuptake inhibitors (Choi et al., 2010; Masclee et al., 2014; Teklay et al., 2014). Colchicine is a substrate of CYP3A4 and P-glycoprotein; hence, caution is advised when it is used in combination with inhibitors or inducers of CYP3A4 and P-glycoprotein. Colchicine also interacts with statins leading to increased risk of rhabdomyolysis and myopathy (Davis et al., 2013; Kwon et al., 2017; Liuzzi et al., 2019; Terkeltaub et al., 2011). XOIs cause serious adverse effects when combined with azathioprine and mercaptopurine. They also increase the likelihood of bleeding with anticoagulants. Probenecid increases the plasma concentration of rifampin, lorazepam, and naproxen (Jordan and Gresser, 2018; Keith and Gilliland, 2007). **Table 4** enlists some important drug–drug interactions associated with pharmacotherapy of gout.

Table 4 Important drug–drug interactions

Interacting drugs	*Potential adverse outcome*	*Monitoring/management strategies*
Naproxen		
Amitriptyline; aspirin; betamethasone; budesonide; citalopram; clomipramine; clopidogrel; diclofenac; dexamethasone; duloxetine; enoxaparin; escitalopram; fluoxetine; gingko biloba; indomethacin; heparin; hydrocortisone; ibuprofen; ketorolac; nortriptyline; prednisolone; rivaroxaban; sulfasalazine; warfarin	Bleeding/gastrointestinal ulcer	Avoid combination; consider alternate therapy; monitor for PT, APTT, INR and signs of bleeding
Cyclosporine; tenofovir	Nephrotoxicity	Monitor electrolytes, RFTs and blood pressure; consider alternate therapy
Furosemide; hydrochlorothiazide; indapamide; spironolactone	Nephrotoxicity and reduced efficacy of diuretics	
Lithium	Lithium toxicity (diarrhea, tremors, abdominal pain, drowsiness)	Monitor for signs of lithium, digoxin or methotrexate toxicity
Digoxin	Digoxin toxicity (vomiting, diarrhea, abdominal pain, arrhythmias)	
Methotrexate	Methotrexate toxicity (leukopenia, thrombocytopenia, anemia, nephrotoxicity, mucosal ulcerations)	
Probenecid	Increased naproxen toxicity	Consider dose adjustment of naproxen if co-administered with probenecid and titrate to higher doses cautiously and in small increments
Bisoprolol; candesartan; captopril; carvedilol; lisinopril; losartan; propranolol; ramipril; valsartan	Renal dysfunction and/or increased blood pressure	Monitor antihypertensive efficacy, and RFTs, particularly in elderly patients, during treatment initiation, volume-depleted patients, or those with preexisting renal dysfunction
Indomethacin		
Amitriptyline; aspirin; betamethasone; budesonide; citalopram; clomipramine; clopidogrel; diclofenac; dexamethasone; duloxetine; enoxaparin; escitalopram; fluoxetine; gingko biloba; heparin; hydrocortisone; ibuprofen; ketorolac; naproxen; nortriptyline; prednisolone; rivaroxaban; sulfasalazine; warfarin	Bleeding/gastrointestinal ulcer	Avoid combination; consider alternate therapy; monitor for PT, APTT, INR and signs of bleeding
Cyclosporine; tenofovir	Nephrotoxicity	Monitor electrolytes, RFTs and blood pressure; consider alternate therapy
Furosemide; hydrochlorothiazide; indapamide; spironolactone	Nephrotoxicity and reduced efficacy of diuretics	
Lithium	Lithium toxicity (diarrhea, tremors, abdominal pain, drowsiness)	Monitor for signs of lithium, digoxin, methotrexate, gentamicin or amikacin toxicity
Digoxin	Digoxin toxicity (vomiting, diarrhea, abdominal pain, arrhythmias)	
Methotrexate	Methotrexate toxicity (leukopenia, thrombocytopenia, anemia, nephrotoxicity, mucosal ulcerations)	

(*Continued*)

Table 4 Important drug–drug interactions (*cont.*)

Interacting drugs	*Potential adverse outcome*	*Monitoring/management strategies*
Gentamicin (systemic); amikacin (systemic)	Gentamicin toxicity (renal dysfunction, ototoxicity)	
Probenecid	Increased indomethacin toxicity	Consider dose adjustment of indomethacin if co-administered with probenecid and titrate to higher doses cautiously and in small increments
Potassium (systemic)	Hyperkalemia	Discontinue potassium supplementation, decrease indomethacin dose, monitor serum potassium and ECG. Administration of intravenous sodium bicarbonate, glucose and insulin
Bisoprolol, candesartan; captopril; carvedilol; lisinopril; losartan; propranolol; ramipril; valsartan	Renal dysfunction and/or increased blood pressure	Monitor antihypertensive efficacy, and RFTs, particularly in elderly patients, during treatment initiation, volume-depleted patients, or those with preexisting renal dysfunction
Levofloxacin; ofloxacin	Seizures	Consider alternative therapy, particularly in patients predisposed to seizure activity
Diclofenac		
Amitriptyline; aspirin; betamethasone; budesonide; citalopram; clomipramine; clopidogrel; dexamethasone; duloxetine; enoxaparin; escitalopram; fluoxetine; gingko biloba; heparin; hydrocortisone; ibuprofen; indomethacin; ketorolac; naproxen; nortriptyline; prednisolone; rivaroxaban; sulfasalazine; warfarin	Bleeding/gastrointestinal ulcer	Avoid combination; consider alternate therapy; monitor for PT, APTT, INR and signs of bleeding
Cyclosporine; tenofovir	Nephrotoxicity	Monitor electrolytes, RFTs and blood pressure; consider alternate therapy
Furosemide; hydrochlorothiazide; indapamide; spironolactone	Nephrotoxicity and reduced efficacy of diuretics	
Lithium	Lithium toxicity (diarrhea, tremors, abdominal pain, drowsiness)	Monitor for signs of lithium, digoxin or methotrexate toxicity
Digoxin	Digoxin toxicity (vomiting, diarrhea, abdominal pain, arrhythmias)	
Methotrexate	Methotrexate toxicity (leukopenia, thrombocytopenia, anemia, nephrotoxicity, mucosal ulcerations)	
Ciprofloxacin	Increased ciprofloxacin plasma concentration	Monitoring for signs of ciprofloxacin-related adverse effects
Bisoprolol, candesartan; captopril; carvedilol; lisinopril; losartan; propranolol; ramipril; valsartan	Renal dysfunction and/or increased blood pressure	Monitor antihypertensive efficacy, and RFTs, particularly in elderly patients, during treatment initiation, volume-depleted patients, or those with preexisting renal dysfunction
Levofloxacin; ofloxacin	Seizures	Consider alternative therapy, particularly in patients predisposed to seizure activity
Miconazole; fluconazole; voriconazole	Increased diclofenac exposure	Do not exceed the lowest recommended diclofenac dose
Carbamazepine; phenobarbital; st john's wort; rifampin;	Reduced diclofenac exposure	Higher diclofenac dose may be required
Celecoxib		
Amitriptyline; aspirin; betamethasone; budesonide; citalopram; clomipramine; clopidogrel; dexamethasone; diclofenac; duloxetine; enoxaparin; escitalopram; fluoxetine; gingko biloba; heparin; hydrocortisone; ibuprofen; indomethacin; ketorolac; naproxen; nortriptyline; prednisolone; rivaroxaban; sulfasalazine; warfarin	Bleeding/gastrointestinal ulcer	Avoid combination; consider alternate therapy; monitor for PT, APTT, INR and signs of bleeding
Cyclosporine; tenofovir	Nephrotoxicity	Monitor electrolytes, RFTs and blood pressure; consider alternate therapy
Furosemide; hydrochlorothiazide; indapamide; spironolactone	Nephrotoxicity and reduced efficacy of diuretics	

Table 4 Important drug–drug interactions (*cont.*)

Interacting drugs	*Potential adverse outcome*	*Monitoring/management strategies*
Lithium	Lithium toxicity (diarrhea, tremors, abdominal pain, drowsiness)	Monitor for signs of lithium, digoxin or methotrexate toxicity
Digoxin	Digoxin toxicity (vomiting, diarrhea, abdominal pain, arrhythmias)	
Methotrexate	Methotrexate toxicity (leukopenia, thrombocytopenia, anemia, nephrotoxicity, mucosal ulcerations)	
Ciprofloxacin	Increased ciprofloxacin plasma concentration	Monitoring for signs of ciprofloxacin-related adverse effects
Bisoprolol, candesartan; captopril; carvedilol; lisinopril; losartan; propranolol; ramipril; valsartan	Renal dysfunction and/or increased blood pressure	Monitor antihypertensive efficacy, and RFTs, particularly in elderly patients, during treatment initiation, volume-depleted patients, or those with preexisting renal dysfunction
Levofloxacin; ofloxacin	Seizures	Consider alternative therapy, particularly in patients predisposed to seizure activity
Fluconazole; voriconazole	Increased celecoxib exposure	Do not exceed the lowest recommended celecoxib dose
Colchicine		
Clarithromycin; cyclosporine; diltiazem; erythromycin; fluconazole; indinavir; itraconazole; ketoconazole; lopinavir; quinidine; ritonavir; saquinavir; verapamil	Colchicine toxicity (diarrhea, abdominal pain, vomiting, seizures and hypotension)	Avoid combination
Atorvastatin; lovastatin; pravastatin; rosuvastatin; simvastatin	Rhabdomyolysis, myopathy	Use with caution. Monitor level of creatine kinase and sign/symptoms of rhabdomyolysis
Corticosteroids		
Rotavirus vaccine	Live vaccine induced infection	Avoid combination
Ciprofloxacin; levofloxacin; moxifloxacin; norfloxacin; ofloxacin;	Tendon rupture	Use with caution. Monitor for pain, inflammation and tendon rupture
Lopinavir; ritonavir	Cushing syndrome and reduced effectiveness of ritonavir/lopinavir	Monitor for signs of cushing syndrome
Aspirin; celecoxib; diclofenac; ibuprofen; indomethacin; ketorolac; mefenamic acid; naproxen	Gastrointestinal Bleeding	Monitor for PT, APTT, INR and signs of bleeding. Consider alternate therapy
Allopurinol		
Didanosine	Didanosine toxicity (diarrhea, vomiting, abdominal pain)	Avoid combination. Consider alternate therapy
Azathioprine	Azathioprine toxicity (vomiting, leukopenia, anemia)	Reduce the dose of azathioprine by 60%–75%. Monitor for signs of azathioprine toxicity
Mercaptopurine	Mercaptopurine toxicity (myelosuppression, vomiting)	Reduce the dose of azathioprine by 60%–75%. Monitor for signs of mercaptopurine toxicity
Warfarin	Bleeding	Monitor INR, PT, APTT and signs of bleeding
Captopril; enalapril	Hypersensitivity reactions	Monitor for signs of hypersensitivity reaction
Febuxostat		
Azathioprine	Azathioprine toxicity (vomiting, leukopenia, anemia)	Avoid combination. Consider alternate therapy
Mercaptopurine	Mercaptopurine toxicity (myelosuppression, vomiting)	Avoid combination. Consider alternate therapy
Probenecid		
Ketorolac	Ketorolac toxicity (gastric ulceration, edema, headache)	Avoid combination
Indomethacin	Indomethacin toxicity (gastric ulceration, bleeding and perforation)	Consider reducing the total daily dose of indomethacin. Monitor for signs of toxicity

(*Continued*)

Table 4 Important drug–drug interactions (*cont.*)

Interacting drugs	*Potential adverse outcome*	*Monitoring/management strategies*
Naproxen	Naproxen toxicity (diarrhea, drowsiness, headache and confusion)	Consider reducing the dose of Naproxen. Monitor for signs of toxicity
Methotrexate	Methotrexate toxicity (Leukopenia, thrombocytopenia, anemia, nephrotoxicity)	Avoid combination or monitor serum levels of methotrexate. Consider reducing the dose of methotrexate
Citalopram	QT interval prolongation	Limit the daily dose of citalopram to 20 mg. Monitor for changes in ECG and discontinue citalopram if QTc interval exceeds 500 ms.
Pegloticase	Anaphylaxis and infusion reactions	Avoid combination

APTT, activated prothrombin time; *ECG*, electrocardiogram; *INR*, international normalized ratio; *ms*, millisecond; *PT*, prothrombin time; *RFTs*, renal function tests.

Conclusions

Gout is a distressing life-long disease with a negative impact on patient's quality of life. It is often preceded by hyperuricemia and deposition of monosodium urate crystals in joints and soft tissues. The selection of appropriate pharmacotherapy relies on the presentation of disease, response to therapy, and patient's adherence. The specialized skills and knowledge of pharmacist for the development of an individualized care plan, provision of evidence-based therapy, and monitoring of adverse effects and drug interactions can improve the outcome of therapy and patient's quality of life.

Glossary

Hyperuricemia An abnormally increased level of uric acid (>7 mg/dL) in blood.
Monoarthritis Inflammation (arthritis) involving one joint at a time.
Nephrolithiasis Presence of calculi (crystalline stones) within the urinary system (kidneys and ureters).
Podagra Gout attack of foot especially affecting the big toe.
Polyarthritis Inflammation (arthritis) affecting more than one joint simultaneously.
Tophi A deposit of monosodium urate crystals that develop in and around joints, typically in patients with long-standing gout.
Urate-lowering therapy Drugs decreasing the serum uric acid level, such as xanthine oxidase inhibitors, uricosurics, and uricase.
Uricosuria Excessive amounts of uric acid in the urine.
Xanthine oxidase A form of xanthine oxidoreductase that catalyzes the oxidation of hypoxanthine to xanthine and xanthine to uric acid.

Management of Rheumatology Disorders and the Pharmacist's Role: Osteoporosis

Ott Laius[*], **Katre Maasalu**[†,‡], **Daisy Volmer**[§], [*]Estonian State Agency of Medicines, Tartu, Estonia; [†]University of Tartu, Tartu, Estonia; [‡]Tartu University Hospital, Tartu, Estonia; [§]University of Tartu, Institute of Pharmacy, Tartu, Estonia

Learning Objectives

Among other health-care professionals, pharmacists have been considered important contributors to osteoporosis risk assessment and prevention as well as monitoring of rationale, safe and adherent medication therapy.

The learning objectives of this chapter are as follows:

- to understand what is osteoporosis and what are the causes and risk factors of this disease and what risk scores to use for patient evaluation;
- to learn about osteoporosis symptoms and what are the consequences if this condition is not early diagnosed and treated;
- to know about what medicines are used for the treatment of osteoporosis;
- to understand the role of vitamin D and calcium supplements for osteoporosis;
- to learn about how pharmacist can contribute to the prevention and risk analysis of osteoporosis;
- to know about counseling aspects of medication use: administration details, adverse drug reactions, and drug–drug interactions;
- to understand the importance of medication adherence in osteoporosis treatment.

Take Home Messages

Osteoporosis is common; approximately one in two women and one in four men aged 50 and older will have fracture due to osteoporosis. Osteoporosis is asymptomatic until a fracture occurs, thus patients tend to underestimate the need for proper medication use.

There are several factors and diseases that can increase bone loss and the risk of developing osteoporosis, including age, sex, insufficient calcium, and vitamin D intake; low physical activity; increased alcohol consumption, low BMI; family history of fracture or osteoporosis; diabetes; several hormone-related conditions (hyperthyroidism, hyperparathyroidism, Cushing's disease); rheumatoid arthritis; malabsorption problems; long term use of high-dose glucocorticoids.

There are several risk-scores available online that can be used to assess the risk of a patient for developing osteoporosis.

The key elements for prevention of osteoporosis are sufficient exercise, vitamin D and calcium intake, and smoking cessation.

Bisphosphonates are the drugs of choice for treating osteoporosis to prevent fractures. Denosumab can be offered to patients who are intolerant of oral bisphosphonates or have trouble following the administration guidelines. Raloxifene, teriparatide, and strontium ranelate are less frequently used in certain patients and only if oral bisphosphonates are contraindicated and patients are closely monitored for potential adverse events.

Bisphosphonates should be taken after an overnight fast and an hour before the first food or drink of the day or any other oral medicinal products or supplementation (including calcium). The tablets must not be sucked or chewed. The patient should be sitting or standing in an upright position, while administration and the patient should not lie down for 1 h after taking bisphosphonates.

Patients should be instructed to discontinue the bisphosphonate and seek medical attention if they develop symptoms of esophageal irritation such as dysphagia, pain on swallowing or retrosternal pain, or new, or worsening heartburn.

During the treatment, patients should be advised to report any thigh, hip, or groin pain and any patient presenting with such symptoms should be evaluated for an incomplete femur fracture.

All patients should be encouraged to maintain good oral hygiene, receive routine dental checkups, and report any oral symptoms such as dental mobility, pain, or swelling.

Although there is a need to stress the favorable benefit–risk ratio of osteoporosis medicines among patients who need pharmacological therapy, quoting relevant statistics to patients is not usually sufficient to allay their concerns and improve adherence. Each patient's reasons for nonadherence tend to be different and depend on individual beliefs or circumstances. Thus, strategies to improve adherence to medicines should be individualized accordingly. Understanding patients' preferences and incorporating them in clinical decision-making could lead to improved care.

Counseling by pharmacists on aspects regarding administration, effectiveness, and possible side-effects and highlighting the importance of long-term continuous use at the first dispense of osteoporosis medicine has been shown to effectively improve adherence to medicines.

Introduction to Condition

Osteoporosis is a very common condition. Bone is a living tissue that is in a constant state of regeneration. The body removes old bone (called bone resorption) and replaces it with new bone (bone formation). Osteoporosis becomes more common with age. It is more common in women than in men. About 22 million women and 5.5 million men in the European Union (Hernlund et al., 2013) and 9 million women and 2.8 million men in the United States (Cawthon, 2011) had osteoporosis in 2010.

Osteoporosis is silent because there are no symptoms. Breaking a bone is a serious complication of osteoporosis though, especially for older patients. Osteoporotic fractures are most likely to occur in the hip, spine, or wrist, but other bones can break too. In addition to causing permanent pain, osteoporosis causes some patients to lose height and often leads to a stooped or hunched posture. Osteoporosis is responsible for two million broken bones and $19 billion in related costs every year. By 2025, experts predict that osteoporosis will be responsible for approximately three million fractures and $25.3 billion in costs annually (National Osteoporosis Foundation website, 2018).

Osteoporosis can present as an independent disease, but there are numerous rheumatic diseases, including rheumatoid arthritis, juvenile idiopathic arthritis, psoriatic arthritis, ankylosing spondylitis, systemic lupus erythematosus, systemic sclerosis, dermatomyositis/polymyositis, and vasculitis are characterized by osteoporosis and fragility fractures. Inflammatory cytokines, glucocorticoid treatment, immobilization, and reduced physical activity due to painful joints and muscle weakness are considered the main risk factors that cause low body mass density values in these diseases (Maruotti et al., 2014)

Osteoporosis in patients with rheumatic disease is of particular concern because bone loss may result from the disease process and from the medications used to control inflammation. Decreased bone mass, combined with an increased tendency of persons with musculoskeletal disease to fall, may also increase the risk of fractures.

Disease/Condition Information

Osteoporosis is characterized by reduced bone mineral density (BMD) and disruption of bone microarchitecture, resulting in increased bone fragility and increased fracture risk (Consensus development conference, 1993; Ström et al., 2008). Bone is a living tissue that is constantly being renewed (Assessment of fracture risk and its application to screening for postmenopausal osteoporosis. Report of a WHO Study Group, 1994). Under pathologic conditions, bone formation—resorption balance is disrupted. Continuous high osteoclast activity or low osteoblast activity leads to low bone mass (osteoporosis) (Zhong et al., 2014). Loss of bone mass per se and osteoporosis are usually asymptomatic until a fracture occurs (Silverman et al., 2011). The disease has clinical and public health importance only because of the fractures (Cummings and Melton, 2002), which cause pain, degrade people's quality of life, and are often disabling (Borgström et al., 2013). Clinically, osteoporosis is recognized by the occurrence of characteristic fractures after low-energy trauma; usually these are fractures of the hip, vertebrae, or distal forearm (Woolf and Pfleger, 2003).

Fracture incidence trends have been shown to differ in different parts of the world (Cooper et al., 2011). The potential drivers of negative changes to fracture rates are urbanization and a general aging of the population. Conversely, osteoporosis medication use, birth cohort effects such as maternal and offspring nutrition, an average increase in body mass index (BMI), and lifestyle interventions such as smoking cessation and fall prevention can result in a more positive trend (Ballane et al., 2014; Jürisson et al., 2015). Increasing and improving the consumption of osteoporosis medicines per a population has been shown to be one of the main factors that could positively influence fracture incidence trends (Alves et al., 2013; Støen et al., 2012).

Losing bone mass and quality is a normal part of the ageing process, but some people lose bone density at a higher than average rate and this can lead to the development of osteoporosis and fractures. Postmenopausal women are most affected by bone loss, due to changes in levels of reproductive hormones (Riggs, 2000; Sowers et al., 2006). Although men are less disposed to osteoporosis, they have been shown to be undertreated (Bor et al., 2015).

Osteoporosis develops slowly over several years. It is a chronic and progressive disease and is the most common metabolic bone disease. An understanding of bone metabolism and osteoporosis mechanisms is crucial in terms of effective disease prevention, diagnosis, and therapy. Osteoporosis diagnosis and fracture risk estimation are based mostly on bone densitometry (DXA) T-scores on BMD scale. T-score is the difference between a measured BMD and the average BMD in healthy young adults (Blake and Fogelman, 2007). Osteoporosis in postmenopausal women is defined as a T-score ≤2.5 SD (Kanis and Glüer, 2000); however, osteoporotic fractures might also occur among those at a moderate risk (Cefalu, 2004; Schuit et al., 2004; Siris et al., 2004). There are also several web-based osteoporosis risk tests and fracture risk calculators—tools to help doctors and health professionals estimate fracture risk.

Management of Condition

Treatment for osteoporosis is based on using medicines that strengthen bones. As a chronic and progressive bone disease, long-term treatment is needed to control bone metabolic disruption, and patients need to adhere to treatment if it is to be effective and cost-effective (McCombs et al., 2004; Rietbrock et al., 2009).

The efficacy of osteoporosis drugs ultimately depends on whether they reduce the risk of fractures (Diez-Perez et al., 2012). The medicines used to ameliorate osteoporosis are the bisphosphonates (ATC group M05BA), peptides of the parathyroid hormone family (ATC group H05AA), selective estrogen-receptor modulators (SERMs) (ATC group G03XC), and other drugs that affect bone structure and mineralization (strontium ranelate and denosumab) (ATC group M05BX) (Kanis et al., 2013).

The drugs used against osteoporosis have all been shown to reduce the risk of vertebral fractures, some have also been shown to reduce the risk of nonvertebral fractures and those of the hip (Body et al., 2010; Delmas, 2002). To date, no single agent has been shown to be significantly superior in preventing fractures (MacLean et al., 2008; Sanderson et al., 2016). The safety profile of the existing osteoporosis medicines has also been shown as favorable (Lewiecki, 2011).

The bisphosphonates group is the first-line osteoporosis treatment option in most countries, and the most used agents are orally administered alendronic acid, ibandronic acid, and risedronic acid and parenterally administered zolendronic acid. Bisphosphonates combination preparations consist of bisphosphonates with added calcium, colecalciferol, or both.

Structurally, bisphosphonates are chemically stable derivatives of inorganic pyrophosphate, a naturally occurring compound in which 2 phosphate groups are linked by esterification. Bisphosphonates have a very high affinity for bone mineral because they bind to hydroxyapatite crystals. Accordingly, bisphosphonate skeletal retention depends on availability of hydroxyapatite binding sites. Bisphosphonates are preferentially incorporated into sites of active bone remodeling, as commonly occurs in conditions characterized by accelerated skeletal turnover (Drake et al., 2008).

All bisphosphonates are associated with beneficial effects on reducing osteoporosis-induced fractures relative to placebo, with hazard ratios varying from 0.41 to 0.92, depending on treatment and fracture site. For vertebral fractures and percentage change in BMD, the treatment effects are also statistically significant. Pairwise comparisons between bisphosphonates indicate that no bisphosphonates is statistically significantly more effective than any other bisphosphonates for fracture outcomes (Davis et al., 2016).

Denosumab is a fully human monoclonal IgG2 antibody that specifically targets nuclear factor kappa B ligand (RANKL) that has been identified to be associated with osteoclast driven bone resorption and subsequent bone loss (von Keyserlingk et al., 2011). Denosumab is recommended for use in women who have known osteoporosis by the Committee of the American College of Physicians as a drug of choice beside the bisphosphonates (Qaseem et al., 2017) or it may also be restricted to patients for whom oral bisphosphonates are unsuitable due to contraindication, intolerance, or inability to comply with the special administration instructions due to cost-effectiveness or budget impact issues (Denosumab for the prevention of osteoporotic fractures in postmenopausal women, SMC advice on denosumab (Prolia), 2010).

SERMs are nonsteroidal agents that bind to the estrogen receptor and act as estrogen agonists or antagonists. Raloxifene is the most used SERM that is widely available for the prevention and treatment of postmenopausal osteoporosis. Raloxifene is recommended only as an alternative treatment option for the secondary prevention of osteoporotic fragility fractures in postmenopausal women who are unable to comply with the special instructions for the administration of bisphosphonates or have a contraindication to or are intolerant (Raloxifene and teriparatide for the secondary prevention of osteoporotic fragility fractures in postmenopausal women, NICE Guidance, 2008).

The intermittent administration of parathyroid hormones (PTHs) (e.g., with daily subcutaneous injections) results in an increase in the number and activity of osteoblasts, leading to an increase in bone mass and in an improvement in skeletal architecture at both cancellous and cortical skeletal sites. The 1-34 N terminal fragment (teriparatide) of PTH is therefore used for the management of osteoporosis. It has been shown to reduce significantly the risk of vertebral and nonvertebral fractures (Kanis et al., 2013). Similar to SERMs, teriparatide is recommended for the secondary prevention of osteoporotic fragility fractures in postmenopausal women who are unable to take bisphosphonates or have a contraindication to or are intolerant them (Raloxifene and teriparatide for the secondary prevention of osteoporotic fragility fractures in postmenopausal women, NICE Guidance, 2008).

Strontium ranelate is an orally administered drug that may dissociate bone formation and bone resorption by allowing continued production of bone while decreasing bone resorption. In clinical trials, strontium ranelate (2 g/d) has been shown to reduce the relative risk of new vertebral and nonvertebral fractures (Reginster et al., 2005). But its use is restricted in Europe because of its increased risk of serious heart problems to treatment of patients with severe osteoporosis and contraindicated for patients with

a current or past history of ischemic heart disease, peripheral arterial disease, or cerebrovascular disease, or with uncontrolled hypertension (Recommendation to restrict the use of Protelos/Osseor (strontium ranelate), European Medicines Agency, 2013), and it is not authorized in the Unites States.

A new agent that is currently being developed for osteoporosis treatment is romosozumab. It is a monoclonal antibody that binds to and inhibits sclerostin, increases bone formation, and decreases bone resorption. It has shown promising results compared to alendronate in reducing clinical fractures (Saag et al., 2017), but its potential place in clinical practice is yet to be determined in the future.

Regardless of the active ingredient, all the trials that ascertained the efficacy of an osteoporosis medicine to ameliorate the risk of vertebral fractures lasted mostly at least three years, and patients' medicine intake was monitored to assure sufficient adherence (Black et al., 2007; Chesnut et al., 2004; Cummings et al., 2009; Ettinger et al., 1999; Harris et al., 1999; Karpf et al., 1997; Meunier et al., 2004). These trials indicate that the optimal treatment duration using osteoporosis medicines is at least three years and sufficient adherence is necessary to obtain the results hoped for. Although there are some studies that have shown self-reported improvement in patients' quality of life after only 1 year of treatment with bisphosphonates (Kamatari et al., 2007).

The maximum required duration of treatment with bisphosphonates has recently been the subject of debate. Some authors recommend a drug holiday to prevent side effects from long-term use after 5–10 years of bisphosphonate treatment. Because bisphosphonates accumulate in bones and continue to provide some residual antifracture risk reduction, it does not pose a risk. The duration of treatment and length of the holiday should be based on individual fracture risk. Patients at a mild risk might stop treatment after 5 years and remain on holiday as long as their bone mineral density is stable and no fractures occur; higher risk patients should be treated for 10 years and have a holiday of no more than a year or 2 (Watts and Diab, 2010). Other research has shown that long-term bisphosphonate use does not influence bone material properties, but is associated with adverse effects (Hassler et al., 2015).

Monitoring the efficacy of antiosteoporotic drugs in a real-life setting is part of successful osteoporosis management, as it can help identify poor-adherent nonresponder patients (Bruyère and Reginster, 2014).

Role of Pharmacist in Health-care Team

A pharmacist is often the most accessible health-care specialist in many health-care settings and plays a key role as a drug expert. The pharmacist's role has shifted over the years with the focus on compounding during the early days, then focusing on drug dispensing in the end of the last century and to patient-centered pharmaceutical care nowadays (Hepler and Strand, 1990; Jones et al., 2005). There are a lot of interventions that can be carried out in a pharmacy that help improve patient's quality of care (patient counseling, education, medication management, etc.). The potential role for pharmacists in osteoporosis management is the improved identification of high-risk patients and high-quality patient counseling, which has been shown to increase central DXA testing and calcium and vitamin D intake among individuals at high risk for osteoporosis (Elias et al., 2011).

The main goal of counseling in a pharmacy is to make patients more knowledgeable about their disease and their medicines to improve their adherence to medicines. As osteoporosis consists of chronic and progressive metabolic bone failure that requires long-term treatment, the pharmacy provided counseling on aspects regarding administration, the benefits and risks of the medicine, and the long-term duration of osteoporosis treatment are very important (Heilmann et al., 2013).

Risk Factors

To alleviate the public and private burden of osteoporosis-related fractures, risk assessments and a reduction in individuals' risk of fractures are critical (Cauley, 2013). Key steps highlighted to tackle osteoporosis are awareness raising campaigns; preventive lifestyle strategies; evidence-based guidelines; fracture care; postfracture rehabilitation, and prevention of falls and available economic data (Compston, 2004).

The most important risk factors for postmenopausal osteoporosis that put patients in risk for osteoporosis-related fractures are as follows:

- Low bone mineral density
- Advancing age
- Personal history of fractures
- Maternal history of fractures
- Low body weight
- Low body mass index
- Use of certain medications (oral glucocorticoids, antiepileptics, aromatase inhibitors, excessive thyroid hormone)
- Estrogen deficiency (early menopause)
- Current smoking
- Certain medical conditions (inflammatory bowel disease, eating disorders that lead to malabsorption, lymphoma, leukemia, multiple myeloma, systemic mastocytosis)
- History of falls

One possibility to assess patients' risk factors is to use a web-based risk-score, such as the International Osteoporosis Foundation one-minute osteoporosis risk test (IOF One-minute osteoporosis risk test, 2018). Patients in risk of developing osteoporosis need extra attention in the pharmacy and should be counseled on the risks of osteoporosis (Levine, 2007).

Prevention/screening

The majority of women 60 years of age or older who attended a community pharmacy osteoporosis screening were at moderate or high risk for osteoporosis (Johnson et al., 2008). For patients who have been identified as being in the risk group for developing osteoporosis, the following recommendations on their lifestyle changes could be given:

Exercise—Regular physical activity and exercise is recognized as one of the most effective lifestyle strategies to maximize peak bone mass during growth and prevent bone loss during ageing. In frail and very elderly adults, resistance training and balance exercises in combination reduce falls and risk factors (Ebeling et al., 2013). As the physical exercise of choice, Nordic walking could be recommended for the elderly patients (Bieler et al., 2017);

Calcium—Most systematic reviews of scientific evidence favor supplementation of calcium plus vitamin D to reduce fracture risk. Dietary calcium is the preferred source of calcium, and calcium supplements should be limited to 500–600 mg/day;

Vitamin D—Vitamin D adequacy is important for bone and muscle function. Maintaining the recommended (Endocrine Society and the International Osteoporosis Foundation) serum level of 25(OH)D on the level of 75 nmol/L requires at least 1500–2000 IU (37.5–50 μg) per day of supplemental vitamin D. For the treatment of severe vitamin D deficiency, doses ≤ 10 000 IU (250 μg) per day have shown to be safe;

Smoking cessation—Cigarette smoking is an independent risk factor for osteoporosis and increases the risk of fractures (Kanis et al., 2005). Thus, patients in risk of osteoporosis should be counseled on cessation of smoking.

Education and counseling programs in pharmacies have shown to provide a significant increase in patients' daily calcium intake and duration of weekly exercise (Kalkım and Dağhan, 2017; Wong et al., 2004). An interdisciplinary, multifaceted intervention based on building knowledge has also been shown to improve the uptake of vitamin D and calcium in in long-term care facilities (Kennedy et al., 2015).

Patient satisfaction with the pharmacist interaction in identifying risk patients and with their role in improving awareness has been shown to be high among patients, and a large proportion of patients are highly motivated to follow the instructions by the pharmacist on their calcium intake, exercise, and/or consulting with their doctor (Law and Shapiro, 2005). A pharmacist-led intervention has proved efficacious in primary care clinics regarding the proportion of patients with the diagnosis of osteoporosis without contraindications to antiosteoporosis medicines who were prescribed an antiosteoporotic medicine (Tan et al., 2014). These data suggest pharmacists can play an important role in screening for osteoporosis patients and providing preventive counseling to high-risk patients.

Diagnosis

Pharmacists can provide osteoporosis screenings using questionnaires to detect high fracture risk patients and offer education. Sometimes peripheral devices for osteoporosis screening can be used, but for official diagnosis and treatment needs assessment DXA is required (MacLaughlin and Raehl, 2008).

BMD measurements, when used in conjunction with a fracture risk assessment tool (FRAT), help in determining the need for treatment. The Fracture Risk Assessment Tool (FRAX) is one such tool that helps clinicians determine a patient's risk for osteoporosis-related fracture (FRAX, 2018). The process can be time-consuming and may contribute to lower rates of screening in the primary care setting. Simpler instruments, such as the Osteoporosis Self-Assessment Screening Tool (OST), which relies on age and weight, have been developed to try and decrease the need for patient risk-factor data collection (Williams et al., 2017).

The FRAT and FRAX tools may also be used regardless of whether BMD information is available or not. They are helpful for areas of the country where BMD testing with DXA is not readily available (e.g., rural towns) (MacLaughlin, 2010).

Administration

Oral bisphosphonates are administered once a week (e.g., alendronate, risedronate) or once a month (e.g., ibandronate).

Bisphosphonates should be taken after an overnight fast (at least 6 h) and 1 h before the first food or drink (other than water) of the day or any other oral medicinal products or supplementation (including calcium). Tablets should be swallowed whole with a glass of water (approx. 200 mL) while the patient is sitting or standing in an upright position.

- Patients should not lie down for 1 h after taking bisphosphonates;
- Water is the only drink that should be taken with bisphosphonates;
- Patients should not chew or suck the tablet because of a potential for oropharyngeal ulceration

Patients should be instructed that if they miss a dose of the bisphosphonate, they should take one tablet on the morning after they remember. They should not take two tablets on the same day but should return to taking one tablet once a week, as originally scheduled on their chosen day (Bonviva SmPC, 2018; Fosavance SmPC, 2018).

The recommended dose of zoledronic acid is a single intravenous infusion administered once a year in hospital or other healthcare facility (Aclasta SmPC, 2018).

Denosumab is administered as a single subcutaneous injection once every 6 months into the thigh, abdomen, or upper arm (Prolia SmPC, 2018).

The absorption of strontium ranelate is reduced by food, milk, and derivative products and therefore should be administered in-between meals. Given also the slow absorption of strontium ranelate should be taken at bedtime, preferably at least 2 h after eating (Protelos SmPC, 2018).

Adverse Drug Reactions and Their Management

Upper gastrointestinal adverse reactions Bisphosphonates can cause local irritation of the upper gastrointestinal mucosa. Because there is a potential for worsening of the underlying disease, caution should be used when bisphosphonates are given to patients with active upper gastrointestinal problems, such as dysphagia, esophageal disease, gastritis, duodenitis, ulcers, or with a recent history of major gastrointestinal disease. Esophageal reactions (sometimes severe and requiring hospitalization), such as esophagitis, esophageal ulcers, and esophageal erosions, rarely followed by esophageal stricture, have been reported in patients receiving bisphosphonates. Therefore, patients should be instructed to discontinue the bisphosphonate and seek medical attention if they develop symptoms of esophageal irritation such as dysphagia, pain on swallowing, or retrosternal pain or new or worsening heartburn. The risk of severe esophageal adverse reactions appears to be greater in patients who do not administer bisphosphonates as they should, thus counseling on the correct administration is vital (Bonviva SmPC, 2018; Fosavance SmPC, 2018).

- Atypical fractures of the femur

Atypical subtrochanteric and diaphyseal femoral fractures have been reported with bisphosphonate and denosumab therapy, primarily in patients receiving long-term treatment for osteoporosis. These fractures occur after minimal or no trauma and some patients experience thigh or groin pain, often associated with imaging features of stress fractures, before presenting with a completed femoral fracture. During treatment, patients should be advised to report any thigh, hip, or groin pain and any patient presenting with such symptoms should be evaluated for an incomplete femur fracture (Aclasta SmPC, 2018; Bonviva SmPC, 2018; Fosavance SmPC, 2018; Prolia SmPC, 2018).

- Musculoskeletal pain

Bone, joint, and/or muscle pain has been reported in patients taking bisphosphonates. In postmarketing experience, these symptoms have rarely been severe and/or incapacitating. The time to onset of symptoms varied from 1 day to several months after starting treatment. Most patients had relief of symptoms after stopping treatment (Aclasta SmPC, 2018; Bonviva SmPC, 2018; Fosavance SmPC, 2018).

- Osteonecrosis of the jaw

Osteonecrosis of the jaw, generally associated with tooth extraction and/or a local infection, has been reported in patients with cancer who are receiving treatment regimens, including intravenously or orally administered bisphosphonates and denosumab. Many of these patients were also receiving chemotherapy and corticosteroids.

During osteoporotic treatment, all patients should be encouraged to maintain good oral hygiene, receive routine dental check-ups, and report any oral symptoms such as dental mobility, pain, or swelling (Aclasta SmPC, 2018; Bonviva SmPC, 2018; Fosavance SmPC, 2018; Prolia SmPC, 2018).

- Osteonecrosis of the external auditory canal

Osteonecrosis of the external auditory canal has been reported with bisphosphonates and denosumab, mainly in association with long-term therapy. Possible risk factors for osteonecrosis of the external auditory canal include steroid use and chemotherapy and/or local risk factors such as infection or trauma. The possibility of osteonecrosis of the external auditory canal should be considered in patients receiving bisphosphonates or denosumab who present with ear symptoms such as pain or discharge or chronic ear infections (Aclasta SmPC, 2018; Bonviva SmPC, 2018; Fosavance SmPC, 2018; Prolia SmPC, 2018).

- Skin infections

Patients receiving denosumab may develop skin infections (predominantly cellulitis) leading to hospitalization. Patients should be advised to seek prompt medical attention if they develop signs or symptoms of cellulitis (Prolia SmPC, 2018).

- Skin reactions

Life-threatening cutaneous reactions (Stevens-Johnson (SJS), toxic epidermal necrolysis (TEN) and drug rash with eosinophilia and systemic symptoms (DRESS)) have been reported with the use of strontium ranelate. Patients should be advised of the signs and symptoms and monitored closely for skin reactions (Protelos SmPC, 2018).

- Cardiac ischaemic events

In pooled randomized placebo-controlled studies of postmenopausal osteoporotic patients, a significant increase in myocardial infarction has been observed in patients treated with strontium ranelate. Patients with significant risk factors for cardiovascular events (e.g., hypertension, hyperlipidemia, diabetes mellitus, smoking) should only be treated with strontium ranelate after careful consideration. During treatment, these cardiovascular risks should be monitored on a regular basis generally every 6–12 months. Treatment should be stopped if the patient develops ischemic heart disease, peripheral arterial disease, cerebrovascular disease, or if hypertension is uncontrolled (Protelos SmPC, 2018).

- Venous thromboembolism

Raloxifene is associated with an increased risk for venous thromboembolic events that is similar to the reported risk associated with current use of hormone replacement therapy (Raloxifene hydrochloride SmPC, 2018).

- Orthostatic hypotension

Teriparatide might episodes of transient orthostatic hypotension. Typically, an event begins within 4 h of dosing and spontaneously resolves within a few minutes to a few hours. When transient orthostatic hypotension occurs, it happens within the first several doses. Patients should be placed in a reclining position. Treatment does not have to be discontinued (Teriparatide SmPC, 2018).

Drug–Drug Interactions

If taken at the same time, it is likely that food and beverages (including mineral water), calcium supplements, antacids, and some oral medicinal products will interfere with absorption of the bisphosphonates and strontium ranelate. Therefore, patients must wait at least 1–2 h after taking bisphosphonates before taking food/drink or any other oral medicinal product (Bonviva SmPC, 2018; Fosavance SmPC, 2018; Protelos SmPC, 2018).

Since Nonsteroidal Antiinflammatory Drug (NSAID) use is associated with gastrointestinal irritation, caution should be used during concomitant use with oral bisphosphonates.

No other clinically important interaction with osteoporotic medicines has been described.

Improving Adherence

Osteoporosis consists of chronic and progressive metabolic bone failure that requires long-term treatment. Previous research has shown that even a small decrease in the medication possession ratio (MPR) increases the risk of a hip fractures, and the relative risk reduction of a hip fracture can be up to 60% per persistent patients compared to nonpersistent ones (Jürisson et al., 2015; Rabenda et al., 2008). These results emphasize the importance of adherence to treatment to achieve optimal antifracture efficacy (Rabenda et al., 2009). The number of patients to receive treatment within a year after an osteoporosis-related fracture has been shown to be less than 20% (Elliot-Gibson et al., 2004), indicating there is a significant gap between the need for osteoporosis treatment and the actual prescribing of medicines (Haaland et al., 2009). About half of the patients who do receive treatment adhere to it sufficiently, and only 30%–35% persist with the treatment for at least a year (Clowes et al., 2004; Cramer et al., 2007; Laius et al., 2017). Although once weekly or monthly, rather than daily administered medicines are associated with improved adherence, uptake is still suboptimal (Cramer et al., 2006). The number of fractures prevented and the QALY gain obtained at real-world adherence levels are only 38% and 41%, respectively, of those expected with full adherence (Hiligsmann et al., 2010).

Improvement in adherence to osteoporosis medicines is imperative, as it would effectively prevent more fractures (Caro et al., 2004) and help save health-care resources from being spent on the treatment of bone fragility fractures (Sabaté, 2003). There are several factors that have been shown to affect patients' medication adherence, but most important seem to be the doctor–patient relationship, patient awareness about the medicine and the disease, and also the copayment of medicines (Cutler and Everett, 2010; Vermeire et al., 2001). The efficacy and safety of medicines are important determinants of patient preferences, and informed patient decision-making can have a beneficial impact on adherence to treatment of osteoporosis (Gold, 2011). Although there is a need to stress the favorable benefit–risk ratio of osteoporosis medicines among patients who need pharmacological therapy, quoting relevant statistics to patients is not usually sufficient to allay their concerns and improve adherence (Khosla et al., 2017). Each patient's reasons for nonadherence tend to be different and depend on individual beliefs or circumstances. Thus, strategies to improve adherence to medicines should be individualized accordingly (Elaine et al., 2008). Understanding patients' preferences and incorporating them in clinical decision-making could lead to improved care (Hiligsmann et al., 2015).

One of the interventions that has been shown to be effective in improving adherence is a proactive intervention by pharmacists. The intervention consisted of the pharmacy provided structured counseling on aspects regarding administration, effectiveness, and possible side-effects at the first dispense of osteoporosis medicine. The importance of continuous use was highlighted (Stuurman-Bieze et al., 2014).

In another study, pharmaceutical care intervention participants reported significantly higher medication adherence at 6 and 12 months compared with the control group. The intervention consisted of an explanation on osteoporosis, risk factors, lifestyle modifications, goals of osteoporosis therapy, side effects, and the importance of medication adherence. Verbal counseling was reinforced with an osteoporosis booklet (Lai et al., 2011).

Although patients should be warned of common adverse effects of medications and counseled on how to recognize them and how to react, but there is also a risk that such information might be misunderstood, leading to unjustifiable fear of adverse effects. As a result, the patient may refuse to take any medication (Lai et al., 2012). Thus, the pharmacist should take extra care in explaining the benefits and risks of osteoporosis medicines in a balanced manner. Side effects of medicines have been shown to be the critical element for therapy discontinuation (Bajger, 2018; Sewerynek et al., 2013). The patients who have a greater belief in the benefits of medication are more likely to initiate therapy, while those who reported a greater distrust of medications were less likely to do so (Barrett-Connor et al., 2012). Thus, recognition and management of side effects should have a distinct place in counseling.

Community pharmacies offer a good platform for monitoring and improving therapy adherence and for providing medication therapy management. If community pharmacies have the ability to monitor long-term dispensing data, it helps to identify non-adherent patients and approach them for intervention (van Boven et al., 2014).

Management of Rheumatoid Arthritis and the Pharmacist's Role

Khezar Hayat[*,†], **Hadar Zaman**[†], **Yu Fang**[*], **Muhammad Atif**[§], [*]Health Science Center, Department of Pharmacy Administration and Clinical Pharmacy, Xi'an Jiatong University, Xian, China; [†]Institute of Pharmaceutical Sciences, University of Veterinary and Animal Sciences, Lahore, Pakistan; [‡]University of Bradford, Bradford, United Kingdom; [§]Department of Pharmacy, The Islamia University of Bahawalpur, Bahawalpur, Pakistan

Learning Objectives

On completion of this chapter, the reader will know about:

1. Causes and risk factors for developing rheumatoid arthritis (RA).
2. Clinical presentations of RA.
3. Treatment goals and therapeutic plans for RA patients.
4. Pharmacological and nonpharmacological treatment offered to RA patients.
5. Pharmacist's role in managing RA.
6. Monitoring of drugs used for RA.

7. Important drug–drug interactions with antirheumatic drug therapy.
8. Pharmaceutical dosage forms of different antirheumatic drugs.

Take Home Messages

- RA is an autoimmune and chronic inflammatory disease of the joints that affects 1.3 million Americans and as much as 1% of the worldwide population.
- Genetic variations and exposure to external environmental factors are the main risk factors for RA.
- The American College of Rheumatology/European League Against Rheumatism has developed criteria for RA classification.
- Different diagnostic tests such as rheumatoid factor, C-reactive protein, erythrocyte sedimentation rate, X-rays, ultrasound, and magnetic resonance imaging are used for RA diagnosis.
- Drug treatment for RA comprises of nonsteroidal anti-inflammatory drugs, disease modifying antirheumatic agents, biologics, and corticosteroids.
- Close monitoring of antirheumatic drug therapy is recommended to prevent or minimize adverse effects such as gastrointestinal bleeding, risk of fractures, osteoporosis, hypertension, weight gain, and hepatotoxicity.
- Nondrug treatment for RA includes weight reduction, proper rest, and occupational therapy.
- Adherence to drug therapy can be significantly improved by patient counseling provided by pharmacists.

Introduction to Rheumatoid Arthritis

Rheumatic disorder, also known as rheumatism, is a cluster of a minimum of 200 different diseases that affect joints and/or connective tissues (Altorok et al., 2016). Rheumatoid arthritis (RA) is an autoimmune disorder that causes systemic inflammation by targeting the joints of the wrist and/or feet, making them painful, warm, and swollen. The term RA is of Greek origin, which means "inflamed and watery joints." It was first distinguished from rheumatic fever and gout in the mid-nineteenth century by Garrod (Paget et al., 2002). The deleterious effects of RA are not restricted to joints or connective tissues, but the heart, eyes, and lungs may also be affected (Alenghat, 2016; Prete et al., 2011). Patients may face joint degradation and premature death as a result of RA-induced systemic inflammation. A significant reduction in the health-related quality of life in RA patients has been observed because of fatigue, loss of bodily functions, and pain.

Epidemiology—Burden of Disease

Rheumatoid arthritis, shares a substantial burden not only for the individual, but society at large. It is estimated that between 1% and 2% of the world's population is affected by RA. It was estimated in 2015 that nearly 24.5 million people were suffering from RA worldwide (Vos et al., 2016). Rheumatoid arthritis diagnosis peaks between the ages of 20 and 40 years, but it can occur in any age group. It can be a debilitating condition, with approximately 50% of patients unable to continue their fulltime employment after 10 years post-onset. The prevalence of RA differs between sexes; it has been reported that in RA is slightly more common among women than men (3:1) (van Vollenhoven, 2009).

Regional variations in the prevalence of RA have also been reported; the rate of incidence was highest in Chippewa (6.8%) and Pima North American Indigenous Peoples (5.3%) and lowest in China and Japan (0.2%–0.3%) (Silman and Pearson, 2002). Nearly a 50% increase in premature deaths have been seen in RA patients (after adjusting for comorbid conditions), which causes a 3–10-year reduction in life expectancy (Myasoedova et al., 2010). There are also some suggestions that RA is a "new" disease, being reported only since the industrial revolution in Europe. It appears to be milder in less developed countries, raising the possibility of some new environmental agent that may be more common in industrialized nations (Kalla and Tikly, 2003).

Etiology

The exact cause of RA is unknown; however, it is a multifactorial disease associated with genetic and environmental factors. RA causes abnormal regulation of the immune system, with tissue damage and inflammation of the joints as the major outcomes (McInnes and Schett, 2017). The risk of RA is three to five times higher in patients with a positive family history of the disease indicating a genetic link. The expression of the disease is dependent on genetic predisposition and exposure to some undetermined environmental chemicals. Genetics is the major risk factor in 40%–65% of RA seropositive cases. Different genes known or suspected to affect the immune system have been studied as risk factors for RA. Human leukocyte antigen (HLA) genes, for example the HLA-DRB1 gene, are regarded as the key risk factor for RA. As a result of variations in HLA-DRB1, the body is unable to differentiate between the proteins produced by the host and intruders such as bacteria and viruses (Doherty et al., 2018). More recently, certain genetic variants of PTPN22 and other genes have been identified as a risk factor for RA (van der Helm-van Mil et al., 2007).

Table 1 The 2010 American College of Rheumatology/European League Against Rheumatism classification criteria for RA

Assessment criteria	*Score*
(1) At least 1 joint with definite inflammation of synovial membrane (clinical synovitis) (2) Synovitis not better described by any other abnormality This is a score-based algorithm and if the score of a patient is ≥6 (10 is the maximum score) after adding A–D categories then this patient is need to be classified as having definite rheumatoid arthritis[a]	
A. Joint involvement[b]	
1 large joint (elbows, knees, shoulders, ankles, and hips)	0
2−10 large joints	1
1−3 small joints (with or without involvement of large joints)[c]	2
4−10 small joints (with or without involvement of large joints)	3
>10 joints (at least 1 small joint, e.g., temporomandibular, acromioclavicular, sternoclavicular)	5
B. Serology (at least 1 test result is needed for classification)	
Negative RF and negative anti-CCP	0
Low-positive RF or low-positive anti-CCP	2
High-positive RF or high-positive anti-CCP	3
C. Acute-phase reactants (at least 1 test result is needed for classification)	
Normal CRP and normal ESR	0
Abnormal CRP or normal ESR	1
D. Duration of symptoms (depending upon the report of patient)	
<6 wks	0
≥6 wks	1

CRP, C-reactive protein; *anti-CCP*, anticitrullinated protein antibody; *ESR*, erythrocyte sedimentation rate; *RF*, rheumatoid factor; wks, weeks.

[a]Those patients whose score is less than 6 they can be reexamined as they may be able to meet RA standard criteria over time.

[b]First carpometacarpal joints, first metatarsophalangeal joints, and distal interphalangeal joints are not included.

[c]Small joints include proximal interphalangeal joints, metacarpophalangeal joints, 2nd–5th metatarsophalangeal joints, wrists and thumb interphalangeal joints.

Source: Aletaha, D., Neogi, T., Silman, A.J., et al., 2010. 2010 Rheumatoid arthritis classification criteria: an American College of Rheumatology/European League Against Rheumatism collaborative initiative. Annal. Rheum. Dis. 69, 1580–1588.

Diagnosis

There is no single set of globally confirmed criteria to diagnose RA. Patients often experience inflammation of joints, tenderness, and morning joint stiffness with abnormally elevated values of erythrocyte sedimentation rate (ESR) or C-reactive protein (CRP). There are a number of potential differential diagnoses that should be considered, such as osteoarthritis, septic arthritis (bacterial or viral), psoriatic arthritis, reactive arthritis, and autoimmune diseases including connective tissue disorder (Majithia and Geraci, 2007). The classification criteria of the American College of Rheumatology and European League Against Rheumatism for RA is presented in **Table 1**.

Various tests are used in the diagnosis and management of RA including X-rays, ultrasonography, rheumatoid factor (RF), anticyclic citrullinated peptide (Anti-CCP), complete blood count (CBC), white blood cell count (WBC), and magnetic resonance imaging (MRI).

Rheumatoid factor is positive in nearly 75% of patients with RA, although it is not etiologically linked to RA. High RF titers show a worst prognosis, as patients with higher RF levels are likely to have more severe disease and more intense treatment will be required. Anti-CCP detection is one of the most advance marker used to diagnose RA. It is found in 70% of RA patients and regarded as an important player in the progression of RA. It has sensitivity similar to rheumatoid factor (39%–94%) but has more specificity (81%–100%). Usually, these are detectable in the earlier phase of RA (Heidari et al., 2009). In order to determine the level of inflammation, ESR and C-reactive protein (CRP) are also advised but these levels may be normal in approximately 40% of RA patients so these readings need to be interpreted cautiously if done alone but when used in conjunction with other tests mentioned above are helpful in confirming diagnosis of RA.

Clinical Presentation—Signs and Symptoms

Some common signs and symptoms of RA are as follows:

- Warm, tender, and inflamed joints
- Weight loss

Figure 1 Patient with rheumatoid arthritis showing affected hand.

Figure 2 Patient with rheumatoid arthritis showing affected feet.

- Fever
- Fatigue
- Morning joint stiffness generally exceeding 30 min, which may persist for the whole day.

In the initial phase of RA, small joints of the hands and feet are affected as shown in **Figs. 1 and 2**. As the disease progresses, many other joints become affected, including ankles, knees, elbows, wrists, shoulders, and hips. It is important to note that the signs and symptoms of RA are not restricted to joints, but many nonjoint structures such as skin, lungs, heart, kidneys, nervous tissues, and bone marrow are also affected in up to 40% of RA patients (Shlotzhauer, 2014). Extra-articular features, such as rheumatoid nodules over the extensor surfaces of tendons or vasculitic skin involvement, may be seen but is less common.

Management of Rheumatoid Arthritis

If appropriate management of RA is not initiated early on in the disease diagnosis, it can lead to various short- and long-term complications such as joint destruction, deformity, osteoporosis, cardiac diseases, depression, and early death (Kiely and Nikiphorou, 2018; Nurmohamed, 2009; Wang, 2015). Treatments are targeted at reversing inflammation. The reduction in further damage or progression of the disease and improvement in physical function are possible if inflammation is reduced (Smolen et al., 2007). Therefore, a multifaceted and strategic approach is required to treat RA including pharmacologic and nonpharmacologic therapies (Smolen et al., 2016b).

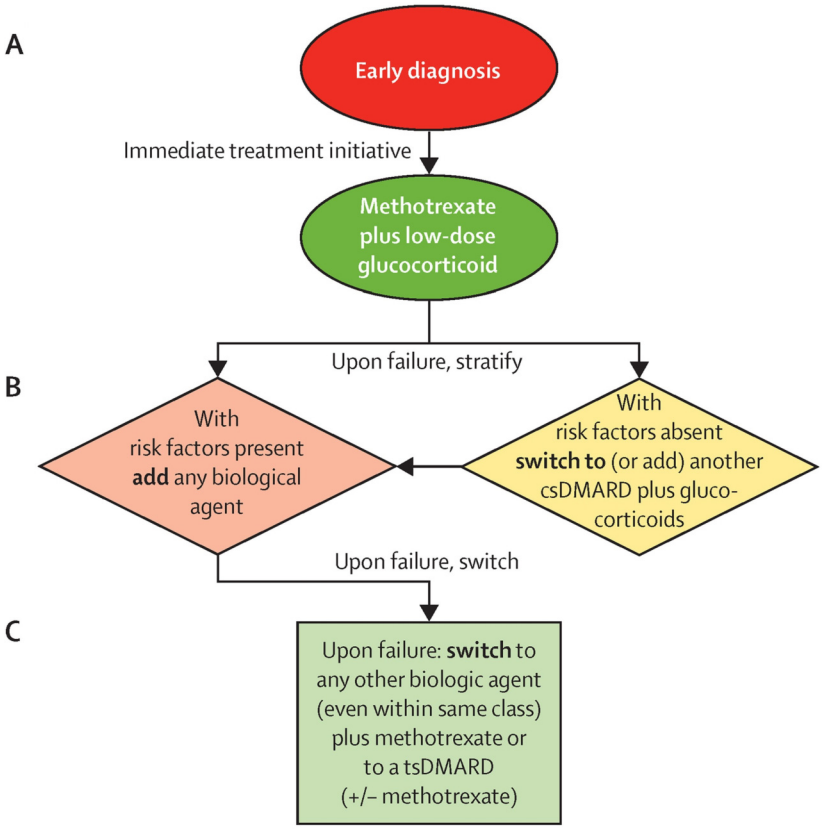

Figure 3 Therapeutic approaches to rheumatoid arthritis.

Pharmacological Management

Fortunately, the development and availability of newer drugs such as biologicals to treat RA in the last few years have significantly improved therapeutic outcomes including quality of life (Davies and Hyrich, 2018). The specific components of the immune system, such as T cells, antigen presenting cells (APCs), cytokines, and B cells, are all potential targets for drugs. The major therapeutic classes of drugs that are currently used in RA include nonsteroidal anti-inflammatory drugs (NSAIDs), corticosteroids, immunosuppressants, biologic and nonbiologic disease-modifying antirheumatic drugs (DMARDs) (Kiely and Nikiphorou, 2018). As per European League against Rheumatism (EULAR) recommendations, the treatment of RA should be initiated with a combination of methotrexate (conventional synthetic DMARD) with a low-dose glucocorticoid (Smolen et al., 2016a). **Fig. 3** shows an algorithm and different therapeutic approaches used for the treatment of RA.

NSAIDs and Analgesics

These agents are primarily used on a temporary basis to treat an acute flare up of RA because they possess mild to moderate analgesic as well as anti-inflammatory properties. However, they do not have any role in slowing the progression of RA (Crofford, 2013b). Therefore, these drugs are usually given in combination with other drugs such as DMARDs and corticosteroids (Gøtzsche, 1989). Acetaminophen is the most commonly prescribed analgesic drug because of its limited side effects.

The selection of NSAIDs for a specific patient is based on efficacy, patient risk factors, potential toxicities related to concomitant drugs, and cost. Acetaminophen should be prescribed in older patients or patients with renal or hepatic diseases (Crofford, 2013a). The COX-2 inhibitors, or coxibs, such as celecoxib and meloxicam, are also effective and possess fewer gastrointestinal side effects than the older medicines.

NSAIDs work best when given in low doses to RA patients with mild inflammation, but higher doses are required in other forms of arthritis, such as inflammatory arthritis. The effectiveness of NSAIDs should be determined over a 4-week period and if the patient is unable to tolerate the medication or does not get any significant benefit, then another type of NSAID should be tried.

Corticosteroids

Corticosteroids are not only able to restrict the inflammatory cascade but can also suppress the functions of the immune system (i.e., they are immunomodulatory agents) (Coutinho and Chapman, 2011). Different corticosteroids, such as prednisone and methyl

prednisolone, are used for short periods in RA patients to limit disease progression and acute flare ups (Haraoui et al., 2015). The clinical effectiveness of the therapy increases if corticosteroids are given as adjuvant therapy to DMARDs. Therefore, monotherapy with DMARDs is not as effective as combination therapy with corticosteroids in suppressing the progression of RA (Landewé et al., 2002).

These agents can be administered orally (prednisone 5–10 mg daily) or parenterally (methyl prednisolone 40 or 80 mg/mL) with the lowest possible dose to minimize side effects. It is difficult to discontinue the therapy once started even with the low dose due to the risk of withdrawal effects. So, clinicians do not stop corticosteroids therapy suddenly but taper off gradually over a period of weeks (Goekoop-Ruiterman et al., 2005).

Facial flushing is a common side effect that most patients develop after the first few days of parenteral (intermuscular or intra-articular) corticosteroid therapy (Berthelot et al., 2013). Other side effects with chronic use of corticosteroids include Cushingoid appearance, gastrointestinal bleeding, risk of fractures, osteoporosis, hypertension, weight gain, diabetes mellitus (DM), peptic ulcer disease (PUD), cataracts, and infections (Courtney and Doherty, 2005).

Disease-Modifying Antirheumatic Drugs

Disease-modifying antirheumatic drugs (DMARDs) reduce the progression of active RA disease by improving radiographic outcomes (Kumar et al., 2009). The improvement with DMARDs is slower and may take weeks to months, which contrasts with the rapid effect of NSAIDs and corticosteroids. The use of DMARDs as an early treatment option is usually preferred because they provide numerous beneficial effects including a reduction in mortality rates (Yeganeh et al., 2018). DMARDs are classified as either biologic or nonbiologic. The most frequently used nonbiologics are methotrexate (MTX), leflunomide, hydroxychloroquine (HCQ), and sulfasalazine (SSZ) (Soriano et al., 2014). The common side effects associated with nonbiologics are nausea, vomiting, diarrhea bone marrow suppression, abdominal pain, and hepatitis.

Biologic DMARDs, such as infliximab, rituximab, abatacept, tocilizumab, and anakinra, are used in RA patients when non-biologic DMARDs fail to produce desired therapeutic goals.

Biologic Disease-Modifying Antirheumatic Drugs

Biologic DMARDs (bDMARDs) are newer and the most effective therapeutic agents for treating RA; however, they are costly (Keystone et al., 2012; Singh et al., 2016). The use of different bDMARDs in RA depends on efficacy, dose, cost, side effects, route of administration, and clinical practice guidelines. These agents are very selective in their mode of action and are involved in (1) interference with cytokine function or production, (2) inhibition of "second signal" required for T-cell activation, and (3) depletion of B-cells or inhibiting factors that active B-cells (rituximab and belimumab). According to the guidelines given by the American College of Rheumatology (ACR), nonbiologic DMARDs (monotherapy) should be considered as the first choice of treatment for early low, moderate, or severe forms of RA because of their lower cost and higher safety. However, if a patient does not respond to traditional DMARDs, then a combination of different nonbiologic DMARDs or a tissue necrosis factor (TNF) inhibitor, with or without methotrexate, can be recommended (Bongartz et al., 2006; Singh et al., 2016).

There is a standard nomenclature in practice for these bDMARDs; for example, if a drug's name ends with "inib" it is small kinase inhibitor and if it ends with "cept," "mab," "zumab," or "mumab," it is a receptor, chimeric monoclonal antibody, humanized monoclonal antibody, or fully human monoclonal antibody, respectively.

Anti-TNF bDMARDs

Tissue necrosis factor (TNF) is found in abundant quantity in the synovial fluid and serum of patients suffering from RA and plays an integral role in the disease pathogenesis by causing systemic inflammation. The efficacy of anti-TNF bDMARDs can be reduced due to the production of autoantibodies against them. All anti-TNF bDMARDs show promising results when given in combination with methotrexate (Breedveld et al., 2006; Edwards et al., 2004; Keystone et al., 2004, 2008, 2009; Klareskog et al., 2004; Maini et al., 1999, 2004). Examples of anti-TNF bDMARDs are infliximab, etanercept, adalimumab, certolizumab, and golimumab.

The most common side effects associated with anti-TNF DMARDs are diarrhea, abdominal pain, vomiting, headache, itching, bleeding, reactions at the injection site, bruising, and respiratory tract infections. Patients with tuberculosis (TB) should be treated first with anti-TB drugs before starting therapy with bMARDs to avoid the risk of reactivating latent TB (Bongartz et al., 2006; Thalayasingam and Isaacs, 2011).

These agents are contraindicated in conditions of active infection, heart failure and in patients with a history of demyelination. Caution should be exercised in patients with previous malignancy and pregnancy (Verstappen et al., 2011).

Anti-B Cell Therapy

B cells, which are part of the immune system, increase the severity of RA when activated. Rituximab is the only approved anti-B cell therapy. It removes nearly all the peripheral B cells after binding with them (CD20). It stimulates the complement system and antibodies to cause cellular toxicity. It is approved by the US Food and Drug Administration (FDA) and is the preferred therapeutic approach for treating RA in patients who have had a poor response to anti-TNFs or methotrexate. The effectiveness of combination therapy with rituximab and methotrexate has been highlighted in different randomized clinical trials in patients who have inadequate response to methotrexate alone or methotrexate plus anti-TNFs (Cohen et al., 2006; Edwards et al., 2004; Lopez-Olivo et al., 2015).

Table 2 Summary of clinical monitoring of antirheumatic drug therapy

Drug	*Toxicities requiring monitoring*	*Symptoms to inquire about*
NSAIDs and salicylates	Renal impairment, GIT ulcer and bleeding	Hematochezia, melena, dyspepsia, nausea/vomiting, weakness, dizziness, abdominal pain, edema, weight gain, and SOB
Corticosteroids	Hyperglycemia, hypertension, and osteoporosis[a]	Blood pressure if available, polydipsia, polyuria, edema, SOB, visual changes, weight gain, headaches, and bone pain
Azathioprine	Hepatotoxicity, myelosuppression, and lymphoproliferative disorders	Symptoms of myelosuppression (fatigue, bleeding or bruising, infection), jaundice
Hydroxychloroquine	Macular injury, diarrhea, and rash	Visual changes (reduction in night or peripheral vision), rash, diarrhea
Methotrexate	Myelosuppression, hepatic fibrosis, cirrhosis, fibrosis, stomatitis, and rash	Symptoms of myelosuppression, SOB, nausea/vomiting, lymph node swelling, jaundice, coughing, mouth sores, and diarrhea
Leflunomide	Hepatitis, GIT distress, and alopecia	Gastritis, nausea/vomiting, diarrhea, hair loss, and jaundice
Sulfasalazine	Melosuppression, rash	Symptoms of myelosuppression, photosensitivity, rash, and nausea/vomiting
Etanercept, Adalimumab, and Anakinra	Local injection-site reactions, infection	Symptoms of infection
Infliximab, Rituximab, and Abatacept	Post infusion reactions, Immune reactions, and infection	Symptoms of infection

GIT, Gastrointestinal tract; *NSAIDs*, nonsteroidal anti-inflammatory drugs; *SOB*, shortness of breath.

[a]Osteoporosis usually does not occur at the beginning of the treatment; however, patients should take precautionary measures to avoid bone loss.

Source: American College of Rheumatology Ad Hoc Committee on Clinical Guidelines, 1996. Guidelines for monitoring drug therapy in rheumatoid arthritis. Arthritis Rheum. 39, 723–731.

Rituximab is administered parentally at a dose of 1 g over 2 weeks, in addition to premedication with methylprednisolone (100 mg) and an antihistamine to prevent the risk of infusion-related side effects.

T-lymphocyte Co-Stimulation Blocker

Abatacept is the only approved T-cell activation inhibitor. It binds to CD80/CD86 receptors and prevents the interaction between T-cells and antigen presenting cells (APCs). Thus, T-cells are unable to become active, and the inflammatory cascade produced by T-cells is blocked. Patients who do not clinically benefit from TNF inhibitors can benefit from abatacept (Genovese et al., 2005; Maxwell and Singh, 2010; Rubbert-Roth and Finckh, 2009).

Abatacept can be given via intravenous (IV) and subcutaneous (SC) routes, but the dose is based on the body weight of patients when given as an IV preparation. For example, 500 mg is given if the patient's weight is less than 60 kg, 750 mg is given to patients whose weight is in between 60 and 100 kg, and patients who are over 100 kg receive 1000 mg. Following the initial intravenous administration, an intravenous infusion should be given at 2 and 4 weeks after the first infusion and every 4 weeks subsequently.

Abatacept causes nasopharyngitis, dizziness, cough, headache, nausea, back pain, dyspepsia, and urinary tract infections (UTIs). However, despite these side effects, it is well tolerated by RA patients (Schiff et al., 2008). The summary of major clinical monitoring parameters of anti-rheumatic drug therapy is indicated in **Table 2**.

Interleukin Inhibitors

Interleukins such as interleukin-1 (IL-1) and interleukin-6 (IL-6) are inflammatory mediators that cause joint destruction in RA patients by driving inflammation and multiplication of synovial cells. Tocilizumab (an IL-6 inhibitor) and anakinra (an IL-1 inhibitor) are the only approved drugs in this class to treat RA (Cohen et al., 2002; Smolen et al., 2008). Headache, arthralgia, upper respiratory tract infection, and nasopharyngitis are most frequent side effects with the use of interleukin inhibitors.

Protein Kinase Inhibitors

Janus kinase (JAK) is a type of tyrosine kinase that helps in signaling cytokines and factors important for the growth of the immune system and hematopoiesis. Tofacitinib is the only FDA-approved bDMARD that can be taken orally at a dose of 10 mg/day in moderate to severe RA patients who have had an inadequate response or are intolerant to methotrexate (Lee et al., 2014; van Vollenhoven et al., 2012). The side effects of Tofacitinib are headache, nasopharyngitis, upper respiratory tract infection, diarrhea, and elevated cholesterol levels.

Nonpharmacological Management

The management of RA is not limited to drugs, but nonpharmacological interventions also play a vital role. These interventions include physical activity, appropriate rest, weight reduction, occupational therapy, and surgery (Vlieland and van den Ende, 2011).

Physical Activity

Many of the RA patients are not physically active because of disease complications, including cachexia (accelerated loss of muscles). Thus, quality of life is reduced. Hence, the comprehensive management of RA also includes physical activity that helps in regaining the muscle strength to do daily activities (de Jong and Vlieland, 2005). Numerous studies advocate the advantages of exercise in RA patients without affecting their joints (Metsios et al., 2007; Plasqui, 2008; Veldhuijzen van Zanten et al., 2015). Patients should be encouraged to perform aerobic and moderate exercise as a part of their therapy (Cooney et al., 2011; Stenström and Minor, 2003). Effectiveness of physiotherapy and exercise (aerobic, joint flexibility, and muscle strength) in RA improves fitness, enhances psychological status, reduces pain and fatigue, and has a positive effect on functional capacity, without exacerbating RA or accelerating joint damage.

Occupational Therapy

Occupational therapy (OT) helps RA patients by providing them with the necessary training and counseling about joint protection to overcome disease associated barriers. It further offers assistive devices, such as walkers, canes and splints, to encourage patients to maintain or improve their mobility (Steultjens et al., 2002). There is good evidence that psychological interventions (e.g., relaxation, stress management, and cognitive coping skills) have a beneficial impact on pain and functional ability, and that stress reduction techniques and cognitive behavioral therapy could improve some aspects of psychological status.

Weight Reduction and Surgery

The stress of inflamed joints reduces with the reduction in weight in RA patients. However, healthy weight reduction strategies could be used under the supervision of a qualified health-care professional to get maximum clinical benefits (Sparks et al., 2017). Surgeries such as synovectomy and joint replacement are only done in patients suffering from the severe forms of RA (Ali and Khalid, 2016).

Dosage Forms

Antirheumatic drugs are available in different dosage forms with different strengths. Detailed information about dosage forms, strength, and route of administration is shown in **Table 3**.

Dose Tapering

The sustained remission in RA is possible by using conventional and DMARD therapy. Dose tapering has become a thought-provoking concept in patients who have controlled RA completely by antirheumatic drug therapy because of higher risk of adverse effects that outweigh the benefits. A tailored approach is needed in patients to provide the optimal management of RA (Schett et al., 2016). However, this process demands great caution as the disease may flare up at any time. Thus, continuous monitoring is recommended to resume DMARD therapy if required (O'Mahony et al., 2010). There are no approved criteria to deescalate or withdraw antirheumatic drugs in RA patients. Gradual dose tapering over a period of 6 months is recommended by the American College of Rheumatology.

Role of the Pharmacist in the Management of Rheumatoid Arthritis

To manage RA, pharmacists are engaged primarily in compounding, screening of diseases, improving patient safety, counseling, and encouraging adherence to drug therapy. A community pharmacist is the only health-care professional who could be accessed easily by RA patients to refill their prescriptions and to get answers to some of their medical queries.

In hospital settings, pharmacists are involved in dispensing drugs, discharge counseling, medication reconciliation, and providing suggestions or treatment options for RA patients during ward rounds with physicians.

Role in Medication Management

A pharmacist can have a significant role in medication management for RA patients, including (Carissa Flick, 2013):

- Designing drug-use policies
- Developing pharmaceutical care services for RA patients
- Providing drug information
- Developing treatment guidelines and protocols for managing RA
- Monitoring patients and reporting side effects

Role in Pharmaceutical Care Services

The role of pharmacists in providing pharmaceutical services to RA patients is (Carissa Flick, 2013) as follows:

- Establishing a trusting relationship with patients
- Obtaining the history of patients

Table 3 Information about selected antirheumatic preparations

Generic	*Brand*	*Dosage form and strength*	*Route of administration*
NSAIDs			
Aspirin/acetylsalicylic acid	Easprin	Regular, enteric-coated, buffered 81, 165, 325, 500, 650, 800 mg tablets; 81, 650, and 800 mg timed- or extended-release tablets	Oral
		120, 200, 300, 600 mg suppositories	Rectal
Celecoxib	Celebrex	100, 200 mg capsules	Oral
Diclofenac	Cataflam, Voltaren	50 mg tablets; 25, 50, and 75 mg delayed-release tablets; 100 mg extended-release tablets	Oral
Diflunisal	Dolobid	250, 500 mg tablets	Oral
Fenoprofen	Nalfon	200, 300 mg capsules; 600 mg tablets	Oral
Flurbiprofen	Ansaid	50, 100 mg tablets	
Ibuprofen	Motrin	100, 200, 400, 600, 800 mg tablets; 50, 100 mg chewable tablets; 200 mg capsules; 100 mg/2.5 mL suspension, 100 mg/5 mL suspension	Oral
Indomethacin	Indocin	25, 50 mg capsules; 75 mg sustained-release capsules; 25 mg/5 mL suspension	Oral
		50 mg suppositories	Rectal
Meloxicam	Mobic	7.5, 15 mg tablets; 7.5 mg/5 mL suspension	Oral
Nabumetone	Relafen	500, 750 mg tablets	Oral
Piroxicam	Feldene	10, 20 mg capsules	Oral
Naproxen	Naprosyn	200, 220, 250, 375, 500 mg tablets; 375, 550 mg controlled-release tablets; 375, 500 mg delayed-release tablets; 125 mg/5 mL suspension	Oral
DMARDs			
Abatacept	Orencia	250 mg/vial lyophilized, for reconstitution for IV injection	Parenteral (IV)
Adalimumab	Humira	40 mg/0.8 mL for SC injection	Parenteral (SC)
Anakinra	Kineret	100 mg solution for SC injection	Parenteral (SC)
Auranofin	Ridaura	3 mg capsules	Oral
Etanercept	Enbrel	50 mg/mL, 25 mg powder for SC injection	Parenteral (SC)
Hydroxychloroquine	Plaquenil	200 mg tablets	Oral
Infliximab	Remicade	100 mg powder for IV infusion	Parenteral (IV)
Leflunomide	Arava	10, 20, 100 mg tablets	Oral
Methotrexate	Rheumatrex	2.5 mg tablet dose packs, 5, 7.5, 10, 15 mg tablets	Oral
Penicillamine	Cuprimine, Depen	125, 250 mg capsules; 250 mg tablets	Oral
Rituximab	Rituxan	10 mg/mL for IV infusion	Parenteral (IV)
Sulfasalazine	Azulfidine	500 mg tablets; 500 mg delayed-release tablets	Oral
Corticosteroids			
Methylprednisolone	Medrol	2, 4, 8, 16, 24, 32 mg tablets	Oral
Prednisone	Meticorten	1, 2.5, 5, 10, 20, 50 mg tablets; 1, 5 mg/mL solution and syrup	Oral

IV, Intravenous; *SC*, subcutaneous.

RA Medication Assessment Tool

Pharmacists can make a substantial contribution by developing medication assessment tools when working with a RA team to improve the standards of care provided. Medication assessment tool helps ensure that doctors comply with guidelines for prescribing drugs (Whitman et al., 2018). Such tools are of great importance to determine issues related to pharmaceutical care and gaps in the official guidelines. This can only be done through efforts of a multidisciplinary team that includes pharmacists. RA medication assessment tool (RhMAT) is one example where the pharmacist can collaborate with other health-care professionals to help and improve the pharmaceutical care of RA patients (Grech et al., 2015). There are 11 sections with 54 criteria for RhMAT. The 11 sections are as follows:

1. Diagnosis of RA
2. Use of analgesics and nonsteroidal anti-inflammatory drugs

3. Use of methotrexate
4. Use of sulfasalazine
5. Use of hydroxychloroquine
6. Use of leflunomide
7. Use of sodium aurothiomalate parenteral preparation
8. General screening for biological therapies
9. Use of biological therapies
10. Use of glucocorticoids
11. Handling remission cases

Clinicians can select any response from four choices starting from not applicable (N/A), adherence (yes), nonadherence (no), and inadequate data to select any criterion. This tool is very useful for pharmacists to rationalize the pharmacotherapy offered to RA patients by identifying gaps in treatment strategies, thereby improving the quality of life of RA patients (Grech et al., 2015).

Role in Decision Making

Pharmacists play an important role in the decision-making process to start DMARD therapy to treat RA patients. The monitoring of drug therapy becomes crucial before and during therapy if patients do not have any prior information. There is a need for baseline information about complete blood count, liver enzymes, and serum creatinine before starting RA treatment (Francart, 2013).

Community pharmacists provide a free service called Medicine Use Review (MUR) for RA patients in the United Kingdom, where patients can discuss any concerns they have about their medication. The purpose behind a MUR is to improve patient adherence and understanding of their medications. Where clinically appropriate pharmacists may suggest a few changes in drug therapy to get the optimal benefit from the medication, which may be discussed with the patient's GP.

Role in Patient Counseling

There is a need to design customized counseling guidelines for RA patients so pharmacists can provide rational and risk-free delivery of medication. Pharmacists working in different health-care settings can provide education and counseling to enable RA patients to comply with their dosage regimen appropriately. Different interventions based on counseling and education, including oral and written information for patients with diabetes, AIDS, asthma, and cardiac diseases, have shown a positive impact on their health (Mitchell et al., 2011; Penn et al., 2011; Saini et al., 2011; van Geffen et al., 2011). Designing similar interventions for RA patients has the potential to improve their quality of life.

The most important purpose of patient counseling is to enhance patient's compliance with drug therapy. Medication adherence is often a critical challenge in patients suffering from chronic diseases such as RA. More than half (55%) of the patients with osteoporosis stop taking medication after the first year, and similarly low medication adherence (as low as 38%) has also been detected in RA patients. Different factors that affect medication adherence are age, marital status, patient beliefs, socioeconomic status, and presence of comorbidities (Chua et al., 2018; Suh et al., 2018).

Pharmacists are the integral part of a multidisciplinary team (MDT) that comprises physicians, nurses, and pharmacists to treat RA. The major fears of patients about drug therapy are related to safety, cost, and indication for use. By using motivational messages during counseling to RA patients about the adverse effects of antirheumatic medication, how to take the drugs, dietary modifications, and justification for their use can improve adherence to their pharmacotherapy regimen (Kreps et al., 2011).

Pharmacists are expert in interpretation and analysis of the literature. By using this skill, they can arrange face-to-face educational sessions with RA patients to improve the understanding of the patient's drug therapy. Different studies have highlighted that health-care professionals are unable to provide detailed information about the side effects of drugs (Auyeung et al., 2011; Saini et al., 2011; Schmitt et al., 2011). Pharmacist can fill this gap by focusing more on providing side effects related information to RA patients.

Role in the Interprofessional Team

Pharmacists are the most neglected and under-used member of the health-care professional team despite their accessibility (Giberson et al., 2011). Most patients assume that the role of pharmacists is restricted to dispensing medication, but pharmacists also provide direct patient care related services in different hospital settings. A teamwork approach adopted by all health-care professionals to optimize the health benefits is already in use (Florentinus et al., 2006). There is a need for active collaboration among all members of a well-defined health-care team to treat and manage RA. Pharmacists through their education have the skills and abilities to prevent and solve drug-related problems that RA patients encounter. The partnership of the pharmaceutical care practitioner with all stakeholders will maximize the benefits of RA patients (Dupotey and De Oliveira, 2009; Dupotey Varela et al., 2011).

Different multidisciplinary and interprofessional models of care have shown positive outcomes in the management of numerous chronic disease such as diabetes, psychiatric disorders, infectious, and cardiac diseases (Archer et al., 2012; Holland et al., 2005; Sherer et al., 2002; Stellefson et al., 2013). The management of RA is difficult as it targets more than one system, affects different age

Table 4 Important drug–drug interactions of antirheumatic drugs.

Antirheumatic drug	*Interacting drug*	*Manifestations*	*Level of severity*
Glucocorticoids (GC)	Warfarin	↑ INR	Severe
	Fluoroquinolones	Tendon rupture	Moderate
	Azole antifungals	↑ GC adverse effects	Moderate
Methotrexate (MTX)	Co-trimoxazole	MTX toxicity	Severe
	PPIs	MTX toxicity	Severe
	Hepatotoxic drugs	Hepatotoxicity	Severe
	Nephrotoxic drugs	Nephrotoxicity	Severe
Leflunomide (LEF)	Warfarin	↑ INR	Severe
	Cholestyramine,	↓ Efficacy of LEF	Severe
Azathioprine (AZA)	Allopurinol	AZA toxicity	Severe
	Warfarin	↓ INR	Severe
Ciclosporin	CYP3A4 inhibitors	↑ Ciclosporin toxicity	Moderate to very severe
	Statins	Statin toxicity	very severe
Cyclophosphamide	Allopurinol	Myelosuppression	Moderate

csDMARDs, Conventional synthetic DMARDs such as methotrexate and hydroxychloroquine; *DMARD*, disease-modifying antirheumatic drug; *INR*, international normalized ratio; ↑, increases; ↓, decreases; *tsDMARDs*, targeted synthetic DMARD such as adalimumab and abatecept.

(A) Early treatment phase. (B) Treatment approach if methotrexate (plus glucocorticoid) does not achieve the treatment target. (C) Treatment approach after a first biologic has failed.

Moderate level: Significant changes in pharmacokinetic parameters (C-max increased by 25%–99%, C-max reduced by 20%–49%, AUC increased by 25%–199%, AUC reduced by 25%–59%).

Severe level: Excessive changes in pharmacokinetic parameters (above the ranges given for moderate interactions) requiring one/both drug dosage adjustment in most patients to prevent adverse events or toxicity.

Very severe level: Excessive changes in pharmacokinetic parameters associated with adverse events, toxicity and hospitalization and/or death or considered as contraindication.

groups, and requires specialized education for drug administration. The presence of an interprofessional team, including a pharmacist, is an ideal way to cope with such problems because pharmacists are expert in medication therapy management. This type of pharmacist-based care is already in practice in different rheumatology clinics in many countries (Dennis et al., 2008; Rowley et al., 2007; Wilbur and Kur, 2015). For example, in the United Kingdom, pharmacists work in collaboration with consultant rheumatologists and in the capacity as independent prescribers. They are involved in medication reviews, to screen for contra-indications, to agree a clinical management plan (CMP) with the patient and the clinic consultant, and to optimize currently prescribed treatment. A number of follow-up appointments are offered to new patients at which pharmacists evaluate the effectiveness of any pharmaceutical intervention and either add new medicines or dose titrate existing medicines according to the CMP (Thomas, 2005).

Important Drug–Drug Interactions

The chronic nature of RA with multiple drugs of different combinations used to prevent the progression of disease most RA patients are older adults with comorbidities, so these factors amplify the risk of adverse effects and drug–drug interactions. It is better to avoid or manage such interactions by providing appropriate awareness. The most common drug–drug interactions are highlighted in **Table 4**.

Role of Primary and Secondary Care

Early diagnosis and treatment of RA can help in achieving optimal therapeutic outcomes. A large set of studies advocate the commencement of antirheumatic drug therapy within 3 months of disease onset (Hochberg, 1999; Quinn et al., 2001). There is a need to provide sufficient resources to meet this timely delivery of DMARDs in primary and secondary care. Primary care is usually offered by a general physician (GP) or family physician, and secondary care is provided in referral cases because of disease complications. It is possible to manage RA patients in primary care effectively by a MDT approach. Different hospitals have established a primary care-based rheumatology service to prevent unnecessary referral of RA patients. This not only improves patient care but also reduces wasted time (Critchley and Ball, 2007). Continuous educational programs for GPs can further help in managing RA in primary and secondary care (Wise and Isaacs, 2005).

Conclusion

The major therapeutic target in RA is the reversal of inflammation because it is the apex of all the clinical events. Thus, a multifaceted and strategic approach is required to treat RA, including nonpharmacologic (physical activity, appropriate rest, weight reduction,

and occupational therapy) and pharmacologic therapies (nonsteroidal anti-inflammatories (NSAIDs), analgesics, corticosteroids, biologics, and nonbiologic DMARDs). In managing RA, pharmacists are working in a community or hospital setting involved in dispensing of drugs, screening of diseases, improving patient safety, counseling, and ensuring adherence to drug therapy.

Management of Eye and Ear Disorders and the Pharmacist's Role: Glaucoma

Jonathan Hsi-Dar Penm*, Ivan Goldberg*,†,‡, *The University of Sydney, NSW, Australia; †Sydney Eye Hospital, Sydney, NSW, Australia; ‡Eye Associates, Sydney, NSW, Australia

Glaucoma

Glaucoma is the leading cause of irreversible *preventable* blindness around the world and second to cataracts for causing blindness around the world (World Health Organization, 2012). The World Health Organization has estimated that in 2010 glaucoma accounted for 8% of global blindness and 2% of visual impairment (World Health Organization, 2012). Glaucoma refers to a group of conditions that are defined as "progressive optic neuropathy with characteristic structural damage to the optic nerve and characteristic visual field defects" (Gupta and Weinreb, 1997). Although raised intraocular pressure (IOP) is recognized as an important risk factor, it is not a defining characteristic of glaucoma (Gupta and Weinreb, 1997). Hence, patients may have a raised IOP without having glaucoma, known as ocular hypertension, or may have glaucoma without having a raised IOP, known as "normal-pressure" glaucoma (Tezel et al., 1996).

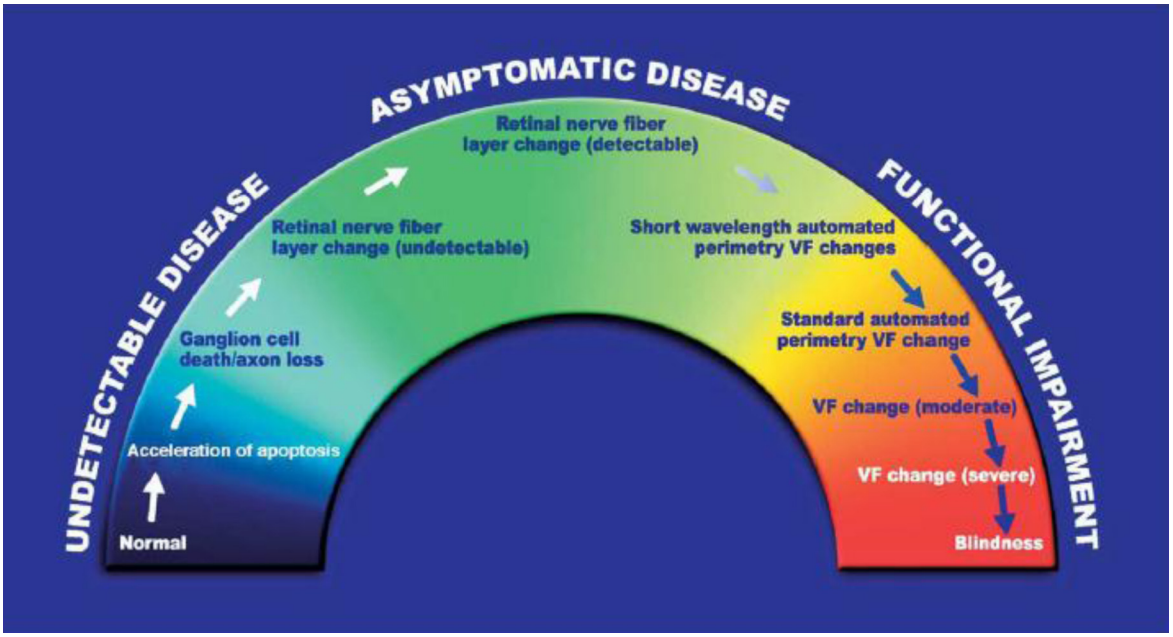

Figure 1 The glaucoma continuum. *Source: Reproduced from Weinreb, R.N., Friedman, D.S., Fechtner, R.D., et al. Risk assessment in the management of patients with ocular hypertension. Am. J. Ophthalmol. 138 (3) (2004) 458–467 (Weinreb et al., 2004).*

Structural damage associated with glaucoma is detected by examining the optic disk and surrounding retinal nerve fiber layer, whereas functional loss is detected by automated visual field testing. Initial structural damage to the optic nerve and retina are asymptomatic and often undetectable with current diagnostics (Weinreb et al., 2004). Glaucoma is considered a continuum (**Fig. 1**) where undetectable disease progresses to asymptomatic disease with optic nerve and visual field (VF) changes, then progresses on to visual impairment and eventually the risk of blindness. Visual impairment from glaucoma is usually observed as "tunnel vision" from preferential loss of mid-peripheral vision (Taylor et al., 2008). Once functional visual impairment from glaucoma is present, the disease is already at an advanced stage on the continuum with more than 30% of retinal ganglion cell axons damaged or dead (Broadway, 2012). Screening and treatment of patients in the asymptomatic disease state is important to arrest, delay, or limit progression of early optic nerve damage to significant visual impairment.

The glaucomas are classified in part on the anatomical configuration of the drainage pathways at the iridocorneal angle (King et al., 2013). Normally, aqueous humor is produced by the ciliary body and leaves the anterior chamber via the trabecular meshwork and Schlemm's canal (conventional outflow) or via the ciliary muscle, through the sclera and into the orbit (uveoscleral or unconventional outflow) (**Fig. 2**A) (Grehn and Stamper, 2009a). Normally, 90% of the aqueous is drained through the trabecular outflow, the remaining 10% through the uveosclearal outflow route (Olver and Cassidy, 2005). In open angle glaucoma, the aqueous outflow via the trabecular meshwork is generally restricted, increasing IOP (**Fig. 2**B) (King et al., 2013). Primary open angle glaucoma (POAG) is the most common type of glaucoma and has been estimated to account for 70% of cases (King et al., 2013).

In primary angle-closure glaucoma (PACG), the iridocorneal angle is narrow (between the iris and cornea). When these structures are close together, even intermittent contact may affect trabecular function, later adhesions may form between them; drainage of the aqueous is affected (**Fig. 2**C) (King et al., 2013). This obstruction of draining pathways by the iris increases IOP and results in glaucoma.

Glaucoma can also be classified as "primary" (no identifiable cause) or secondary. Secondary glaucomas can result from comorbidities such as uveitis, rubeosis associated with ocular ischemia from vascular occlusion or diabetes, exfoliation syndrome, or after ophthalmic surgery (e.g., retinal detachment surgery) (King et al., 2013).

Epidemiology

In 2013, the total number of people (aged 40–80 years) estimated to have glaucoma globally was 64.3 million (3.5% of the population) (Tham et al., 2014). Based on the United Nations' classification of macro-geographic continental regions (Asia, Africa, Europe, North America, Latin America and the Caribbean, and Oceania), Asia had over 60% of the world's glaucoma cases: 53% of global POAG persons and 77% of global PACG sufferers. Africa had the second highest number of glaucoma cases with 8.3 million (13% of the world's total glaucoma cases).

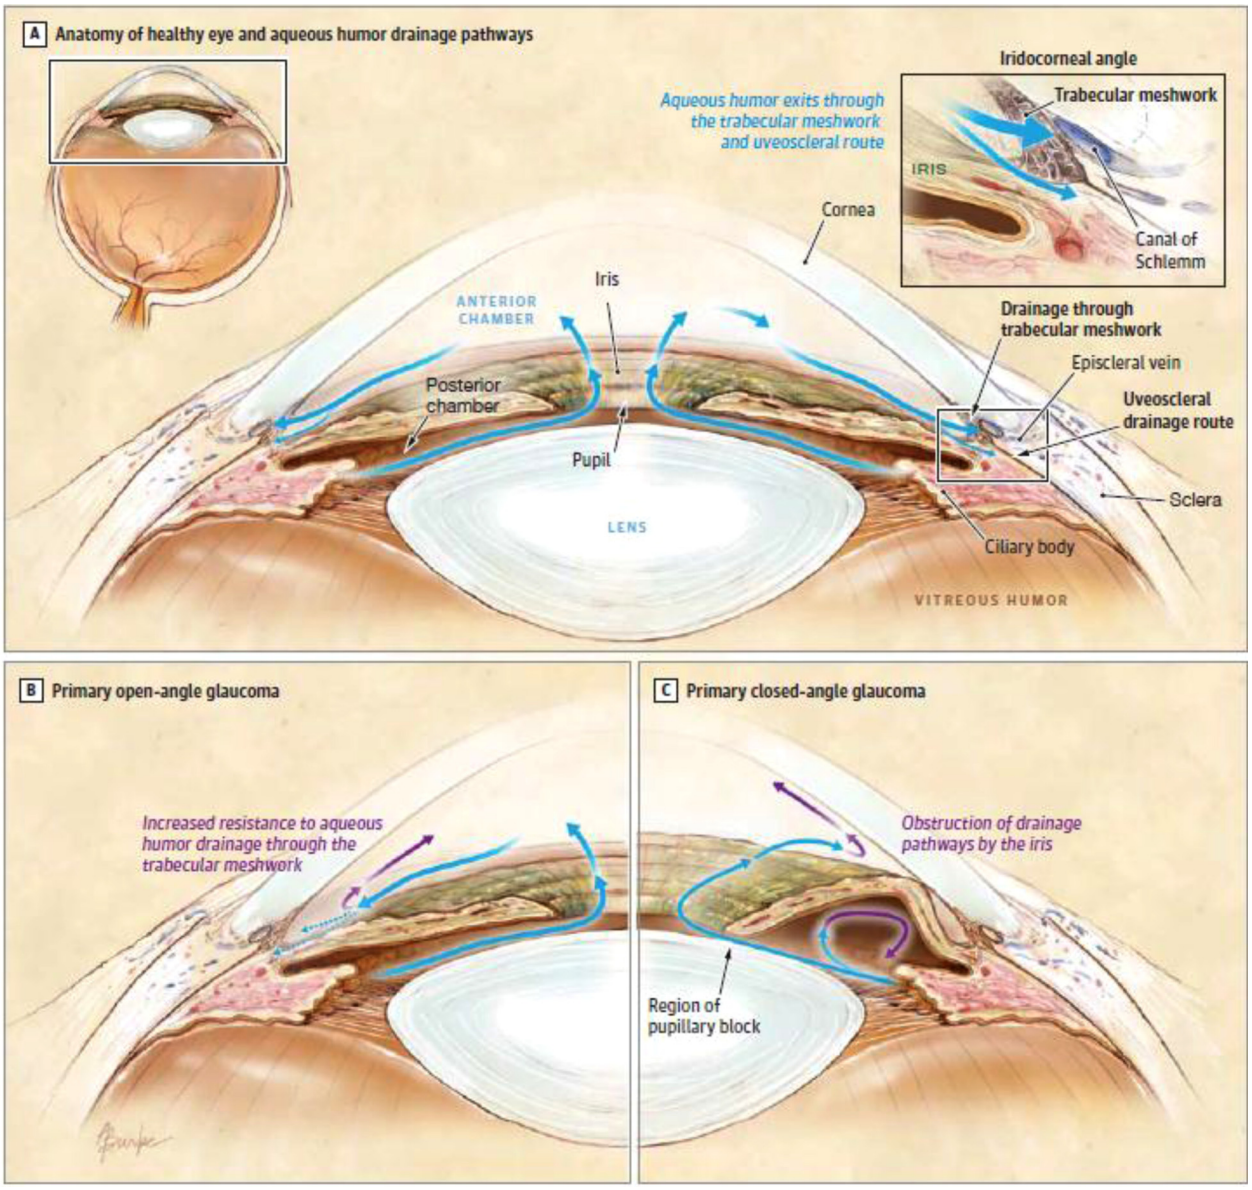

Figure 2 Aqueous humor drainage pathways. *Source: Reproduced from Weinreb, R.N., Aung, T., Medeiros, F.A. The pathophysiology and treatment of glaucoma: a review. JAMA 311 (18) (2014) 1901–1911. (Weinreb et al., 2014).*

By 2020, the number of people (aged 40–80 years) with glaucoma worldwide has been predicted to increase by 18.3% to 76 million and to 111.8 million by 2040. Many of these increases are attributable to Asian and African communities.

Pathophysiology

While the pathophysiology of glaucoma is not well understood, there is a strong association between IOP levels and retinal ganglion cell death (Weinreb et al., 2014). IOP can cause mechanical stress on the posterior structures of the eye, notably the lamina cribrosa and adjacent tissues (**Fig. 3**) (Quigley et al., 1981), provoking structural damage at the lamina, the weakest site in the wall of the pressurized eye, where retinal ganglion cell axons exit. Hence, increased IOP may compress, deform, and remodel the lamina cribrosa, thereby damaging retinal ganglion cell axons. By possibly disrupting axonal transport, IOP may interrupt retrograde delivery of essential trophic factors to retinal ganglion cells from their brain target regions (Fechtner and Weinreb, 1994).

Neurodegenerative changes associated with glaucomatous optic neuropathy also occur in individuals with IOP within the normal range. This may be caused or exacerbated by low cerebrospinal fluid pressure in the optic nerve subarachnoid space. This

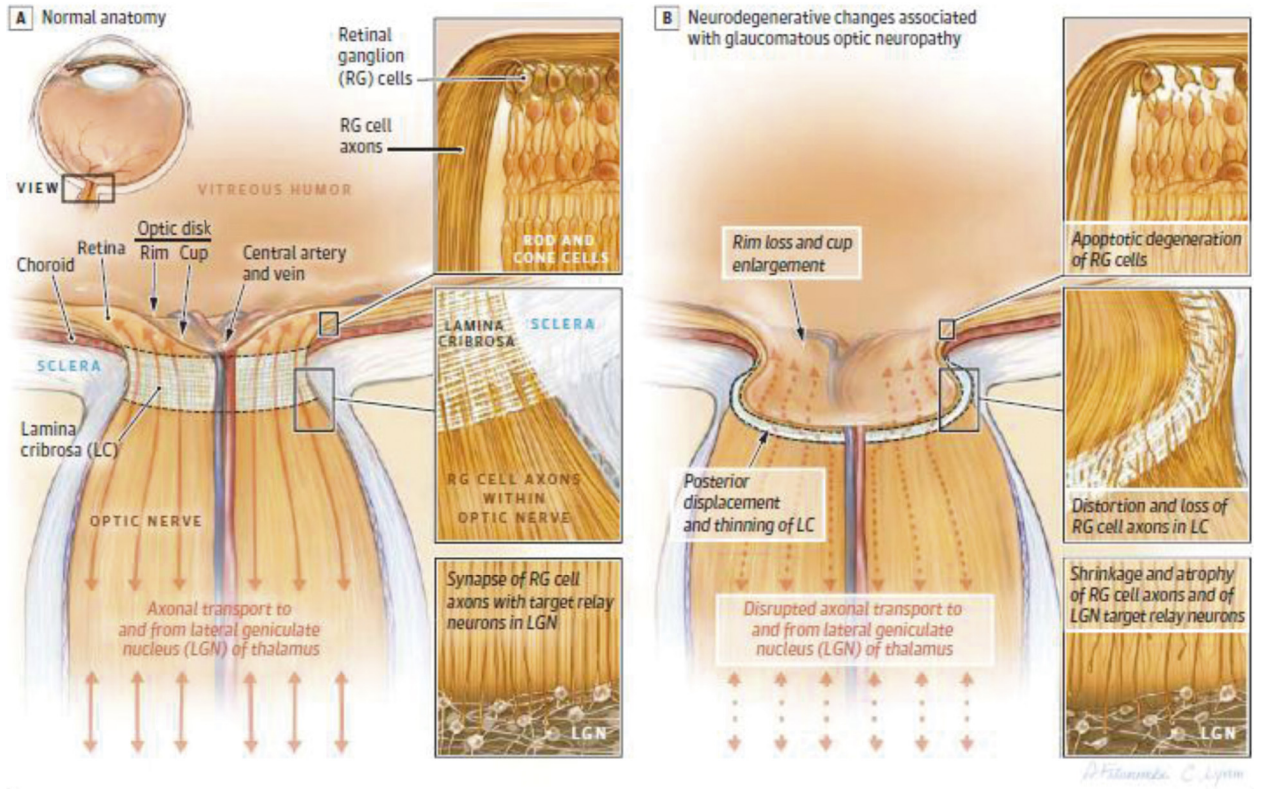

Figure 3 Normal anatomy and neurodegenerative changes associated with glaucomatous optic neuropathy *Source: Reproduced from Weinreb, R.N., Aung, T., Medeiros, F.A. The pathophysiology and treatment of glaucoma: a review. JAMA 311 (18) (2014) 1901–1911. (Weinreb et al., 2014).*

results in an abnormally large pressure gradient across the lamina (Wang et al., 2012). Impaired microcirculation, altered immunity, excitotoxicity, and oxidative stress may also contribute to glaucoma (Weinreb et al., 2014).

Risk Factors for Glaucoma

Risk factors for glaucoma are identified through a comprehensive patient history and a full ocular examination by suitably trained health-care providers. For the purposes of this chapter, only risk factors that can be identified with a patient history will be presented. Ocular signs identified by a full ocular examination will be discussed under "Diagnosis" as they identify definite or highly likely glaucoma.

Age

Advancing age is a major risk factor for glaucoma. In the Melbourne Visual Impairment Project, participants aged 50 years and older were more likely to have glaucoma (odds ratio range: 2.6–17.6) than those aged 40–49 (Weih et al., 2001a). In particular, those aged 80 years and older were 17 times more likely to have glaucoma than participants aged less than 50 years (Weih et al., 2001a).

Family History

A family history for glaucoma is another major risk factor for glaucoma. It has been estimated that individuals with first-degree relatives diagnosed with glaucoma have ten times the risk of developing glaucoma compared with the general population, adjusting for age and other risk factors (Mitchell et al., 2002; Tielsch et al., 1994; Weih et al., 2001b; Wolfs et al., 1998). A criticism of most of these studies is that they rely on self-reported family history of glaucoma rather than clinical examination of relatives, which may result in recall bias. However, Wolfs et al. confirmed a positive family history by examining first-degree relatives and also showed this association (Wolfs et al., 1998).

Ethnic Origin

People of African descent were reported to have four times the risk of developing glaucoma compared with Caucasians, adjusting for age (Tielsch et al., 1991). Optic nerve glaucoma damage is reported at least a decade earlier in people of African descent rather than Caucasian ancestry (Leske et al., 1994; Mason et al., 1989).

Prevalence of PACG has been reported to be highest among those of Chinese, Mongolian, Vietnamese, Pakistani, or Inuit descent, with rates in these populations reported to be over three times that of other ethnic groups (Bourne et al., 2001; Stein et al., 2011).

Diabetes Mellitus

A recent meta-analysis of 47 studies showed that the pooled relative risk of having POAG in patients with diabetes mellitus compared with those without diabetes was 1.48 (95% CI, 1.29–1.71) (Zhao et al., 2015). In this meta-analysis, the risk of POAG increased by 5% for each year since diabetes mellitus was diagnosed (Zhao et al., 2015). Hence, both the presence of diabetes and its duration appear to be associated with a significantly increased risk of glaucoma.

Myopia

Pooled relative risk from four studies of POAG among participants with myopia compared with nonmyopic studies was estimated to be 1.88 (95% CI, 1.53–2.31) (Burr et al., 2007). More recently, the Los Angeles Latino Eye Study also showed an independent relationship between longer axial length (axial myopia) and OAG (Kuzin et al., 2010). Perhaps individuals with axial myopia have weaker scleral support at the optic nerve head, placing them at greater risk of glaucomatous damage (Kuzin et al., 2010).

Smoking

A systematic review and meta-analysis of six studies found that people that smoked cigarettes had an odds ratio of 1.37 (95% CI, 1.00–1.87) for having glaucoma compared with nonsmokers (Bonovas et al., 2004). Past smokers had no increased risk (OR = 1.03, 95% CI, 0.77–1.38) (Bonovas et al., 2004).

Other Factors—Long-term Steroid Users, Migraine and Peripheral Vasospasm, Hypertension

Several factors have been associated with glaucoma, but the strength of those associations has not been established. From a pharmaceutical perspective, corticosteroids are the main cause of drug-induced glaucoma, which is a secondary glaucoma (Adis International, 2004). Steroids administered via multiple routes (oral, inhaled, topical ophthalmic, and topical skin) may increase IOP (Kersey and Broadway, 2006). Case–control and retrospective data of prolonged nasal and inhaled corticosteroid appear to be associated with developing glaucoma (Kersey and Broadway, 2006); however, the cumulative dosage that poses a risk has not been ascertained (Leone et al., 2003).

Migraine and peripheral vasospasm (Raynaud's) are risk factors for glaucomatous optic nerve damage (Budenz et al., 2006; Mitchell et al., 1996). These conditions may decrease autoregulation of optic nerve head blood flow causing an increased risk of optic nerve damage (Park et al., 2014).

Systemic arterial hypertension and its treatment appear to be significant risk factors for glaucoma. Although numerous studies have presented conflicting data, this may stem from the extent potential confounders were or were not adjusted for (Bonomi et al., 2000; Leske et al., 1995; Quigley et al., 2001; Tielsch et al., 1995). For instance, Newman Casey et al. (2011) found that when adjusting for diabetes and hyperlipidemia, patients with systemic arterial hypertension had a 17% increased risk of developing OAG (95% CI, 13–22%) (Newman-Casey et al., 2011). Systemic arterial hypertension may increase glaucoma due to increased perfusion of the ciliary body, resulting in increased aqueous production and higher IOP (Bulpitt et al., 1975), decreased perfusion to the optic disk from damaged and sclerotic arterioles (Wolf et al., 1993), or treatment of systemic arterial hypertension with antihypertensives causing systemic hypotension and a reduction in perfusion of the optic nerve (Graham and Drance, 1999).

Angle Closure Glaucoma

The American Academy of Ophthalmology (2016) states that risk factors for developing angle closure glaucoma are family history of angle closure (AC); advancing age; female gender; Chinese, Vietnamese, Pakistani, or Inuit descent; hyperopia; short axial length; and shallow anterior chamber (American Academy of Ophthalmology, 2016). However, there is limited quantification of the risk (**Table 1**).

Diagnosis

Glaucoma can present in many ways, rarely as a medical emergency. A diagnosis of glaucoma is made based on the presenting history, a search for relevant risk factors, and an ocular examination to assess the structure and function of the eye. A comprehensive clinical examination usually includes slit lamp examination, tonometry, fundus and optic nerve head examination, gonioscopy, and corneal thickness measurement. Additional investigations may also be conducted to document the extent of structural damage to the optic nerve head and the retinal nerve fiber layer, using optic nerve and retinal nerve fiber layer analysis and/or disk photography, computer-assisted visual field (VF) analysis. Optic disk structural review is particularly important, as commonly a loss in disk neuroretinal rim and/or retinal nerve fiber loss is detected prior to VF loss.

Open Angle Glaucoma

Open angle glaucoma is generally symptomless in its early stages. It is not until significant neuronal damage has occurred that characteristic visual loss is observed. Ocular examination for open angle glaucoma should include an assessment of the (1) pupil, (2)

Table 1 Summary of risk factors from patient history for glaucoma

Risk	*Risk factor from patient history*[a]
Extremely high	IOP > 21 mmHg
(≥12×)	Age >80 years
High	Age > 50 years
(≥3×)	Family history
	Ethnic origin:
	• African (POAG)
	• Chinese, Vietnamese, Pakistani or Inuit descent (PACG)
Moderate	Diabetes
(≥1.5×)	Myopia (POAG)
Lower	Smoking
(>1×)	Steroid use[b]
	Migraine[b]
	Eye injury[b]
	High blood pressure[b]

IOP, Intraocular pressure; *POAG*, primary open angle glaucoma; *PACG*, primary angle-closure glaucoma.
[a]No statistic has been provided for this risk factor.
[b]The presence of ocular signs indicating possible glaucoma immediately raises risk.
Adapted from the National Health and Medical Research Council Guidelines for the Screening, Prognosis, Diagnosis, Management and Prevention of Glaucoma (NHMRC, 2010).

anterior segment, (3) IOP, (4) central corneal thickness (CCT), (5) gonioscopy (to evaluate the anterior chamber angle to exclude AC or other causes), (6) optic nerve head and retinal nerve fiber layer evaluation, and (7) VF sensitivities.

Angle Closure

AC can present in either primary or secondary forms, in acute or chronic situations. Patients may also present with acute attacks superimposed on a chronic condition. When optic disk damage occurs, the eye is deemed to have progressed from primary angle closure (PAC) to PACG (American Academy of Ophthalmology, 2016).

Chronic PACG presents similarly to POAG. However, acute angle closure crisis (AACC) is associated with significant and distressing symptoms, and if left untreated, may cause permanent vision loss or blindness (American Academy of Ophthalmology, 2016). Symptoms of AACC include blurred vision, colored rings around lights, pain, frontal headache, palpitations and abdominal pain, and nausea and vomiting (American Academy of Ophthalmology, 2016). Although some cases of acute angle-closure crisis may be self-limited, any patient experiencing symptoms like these should be referred immediately.

Examination of Eye Structure

Glaucoma describes a group of eye diseases in which there is progressive damage to the optic nerve. This is characterized by specific structural abnormalities of optic nerve head and associated patterns of VF loss (Burr et al., 2004). Examination of the optic nerve head is conducted by assessing the optic disk and the retinal nerve fiber layer. Changes that occur in glaucoma include increasing excavation of the optic nerve head (also referred to as cupping), progressive loss of neuroretinal rim, and possibly optic disk margin hemorrhages.

Optic Disk

Retinal ganglion cell axons exit the eye through the posterior scleral foramen, which forms a truncated cone with a narrower neck internally and a broader base externally (Varma and Spaeth, 1993). The narrow internal neck of this cone is clinically visualized as the optic disk (Fig. 4) (Schacknow and Samples, 2010). The optic disk may be examined using a direct ophthalmoscope, with the patient's pupils dilated and the room darkened. A cup to disk ratio of approximately 0.3 is seen in a healthy optic nerve head (Fig. 4). However, an increased cup to disk ratio may indicate glaucoma. Direct ophthalmoscopy displays a magnified view of the optic disk with an appreciation of depth only possible with clues and experience. Indirect ophthalmoscopy performed on a slit lamp offers a magnified stereoscopic view of the optic disk and retinal nerve fiber layer, usually best with a dilated pupil.

A wide variety of digital and non-digital cameras are available to provide color images of the optic disk. Photography has an advantage over ophthalmoscopy as it provides a permanent baseline image of the optic disk that serves as a baseline for future comparisons.

Retinal Nerve Fiber Layer

The retinal nerve fiber layer can be highlighted or quantified in various ways. In nerve fiber photography enhanced with red-free illumination, the fiber bundles are seen as silver striations, radiating from the superior and inferior poles of the optic disk. In early

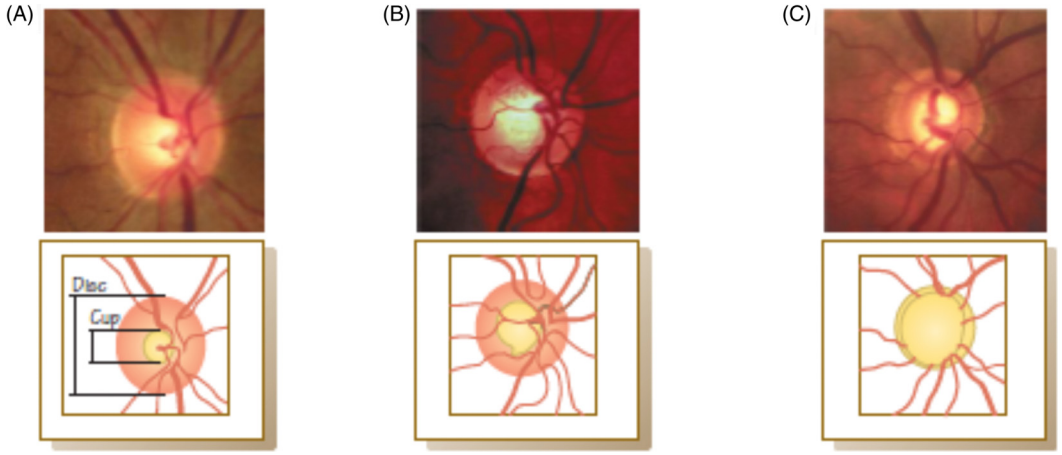

Figure 4 Normal and cupped optic nerve heads. (A) Normal disc (cup-disc ratio 0.3), (B) glaucoma: focal notch and (C) glaucoma: diffuse cup enlargement (cup-disc ratio 0.8) *Source: Reproduced from Olver, J., Cassidy, L., Jutley, G., Crawley, L., 2014. Ophthalmology at a Glance, second ed. Wiley Blackwell, Oxford, UK.*

glaucoma, estimation of structural abnormalities from serial nerve fiber layer photographs may be more sensitive than assessment of the optic nerve head itself (NHMRC, 2010).

Other methods include scanning laser ophthalmoscopy (Heidelberg Retinal Tomography), optical coherence tomography, and scanning laser polarimetry (GDx). Scanning laser ophthalmoscopy can provide objective, quantitative measures of the optic disk topography (Miglior et al., 2003), optical coherence tomography measures the thickness of the retinal nerve fiber layer before the axons reach the optic nerve head (high-resolution, cross-sectional, in vivo imaging of the human retina in a fashion analogous to B-scan ultrasonography, using near infrared (840 nm) light instead of sound) (Johnson et al., 2007), while scanning laser polarimetry provides an objective, quantitative measure of the retinal nerve fiber layer thickness by using the retardation of a reflected 780 nm polarized laser light source. No single test (or group of tests) appears to be more accurate than any other for diagnosing glaucoma (Burr et al., 2007).

Assessment of the Anterior Chamber

Assessment of the anterior chamber is essential to identify the risk of AC (supplemented by gonioscopy) and to identify other causes of glaucoma. These include sectoral iris atophy, glaukomflecken, posterior synechiae, and peripheral anterior synechiae. Signs of secondary glaucoma can also be identified such as uveitis, pigment dispersion (iris transillumination and pigment deposits on the corneal endothelium), exfoliation syndrome, and iris rubeosis (neovascular causes). In addition, on follow-up, signs of corneal epithelial toxicity, conjunctival hyperemia, and papillae can indicate adverse drug reactions (NHMRC, 2010). Gonioscopy allows observation of the angle of the anterior chamber including the angle anatomy and detection of appositional or synechial closure. It also determines the extent of any peripheral anterior synechiae (NHMRC, 2010). Gonioscopy of both eyes should be included in any glaucoma examination.

Examination of Eye Function

Optic nerve damage in glaucoma is characterized by specific structural abnormalities of the nerve fiber layer, optic nerve head, and patterns of VF loss (Burr et al., 2004). Glaucoma tends to produce localized areas of VF loss, while other conditions (e.g., cataracts) produce diffuse VF loss. Repeated and consistent VF measurements are required to diagnose glaucoma. As there are concerns about the reliability of VF testing, which is a subjective psychophysical test, a consistent examination approach that can be repeated over time is important.

Visual Field Testing

Standard automated perimetry (SAP) is the reference standard in VF examination of glaucomatous patients (NHMRC, 2010). It estimates the threshold sensitivity within the VF: target locations remain constant while the brightness is modified to determine sensitivity thresholds. SAP quantifies the reliability of a test and compares measured thresholds with an age-matched normal database. Examination of the visual fields in glaucoma is usually limited to the central 24–30° since almost all clinically relevant defects fall within this area (NHMRC, 2010). This test takes around 5–18 min to complete for both eyes, although newer software algorithms just released promise to reduce this by 50% (Burr et al., 2007).

Frequency doubling technology perimetry (FDT) is offered in a portable, relatively inexpensive instrument designed for fast and effective screening for VF loss. FDT is simpler to administer, reasonably tolerated by most patients, not greatly affected by refractive error and cataract, has high test-retest reproducibility, offers rapid screening tests, and has full threshold programs (NHMRC, 2010). In screening mode, it usually takes less than a minute to conduct in patients with a normal VF.

Oculokinetic perimetry (OKP) with the Damato chart is simple and inexpensive. Twenty numbers are located on a flat, white card within the central 30° of VF (Burr et al., 2007). The subject refixates from number to number, sequentially reporting whether the central 1.5-mm black spot remains visible or disappears. There is a 40-cm hinged arm that maintains the test distance and occludes the non-tested eye. Any points missed, other than the physiological blind spot area, are confirmed, before considered truly missed (Burr et al., 2004). It also has potential as a screening tool.

Intraocular Pressure Measurement

Glaucoma can be present in eyes with normal or raised IOP. However, IOP measurement remains core to diagnosis and management of glaucoma: it is the major modifiable risk factor for development and progression of glaucoma. With a "usual range" in most communities between 10 and 20 mm Hg, IOP is a continuous variable, with fluctuations.

Several instruments measure IOP, having either contact or no contact with the cornea. Applanation tonometry (e.g. Goldmann Applanation Tonometry, GAT) infers the IOP from the force required to flatten a constant area of the cornea (NHMRC, 2010). Noncontact tonometry uses rapid air pulses (air puffs) to flatten the cornea. IOP is estimated by detecting the force of the air jet at the instant of flattening (NHMRC, 2010).

Timing of Intraocular Pressure Measurements

As IOP varies throughout the day and night, IOP should be measured at different times (NHMRC, 2010). From 690 diurnal curves, a large proportion displayed an increased IOP in the morning with most peaks observed before noon (David et al., 1992). The usual diurnal variation is 3–6 mmHg (NHMRC, 2010). Although there is a decrease in aqueous production at night by about 50–60%, this does not account for the diurnal variation in IOP observed (Grehn and Stamper, 2009b). IOP measurements can also be affected by alcohol and marijuana (decrease IOP), rapid fluid intake (increases IOP), and posture (horizontal or head down position increases IOP) (NHMRC, 2010).

Central Corneal Thickness

The Goldmann Applanation Tonometer assumes an average CCT of 520 μm. A meta-analysis of values reported in the literature indicates that "normal" individuals have a significant variation in CCT (535 ± 31 μm) (Burr et al., 2007). This influences the accuracy of this IOP measurement. In thinner corneas, tonometers will read lower-than-true IOP values, while thicker corneas produce falsely high IOP values. There is no valid correction formula applicable to all individuals across the spectrum of measured IOP. A general approach is to correct by 1–3 mmHg per 40 μm deviation from 525 μm (NHMRC, 2010).

In contact tonometry, there is direct physical contact between the measuring instrument and the surface of the eye (Whitacre et al., 1993), raising concerns about transmissible disease. All equipment should undergo chemical disinfection after use to reduce the risk of cross infection (Whitacre et al., 1993). Salvi et al. (2005) recommend using disposable prisms for Goldmann and Perkins tonometry, or disposable covers for the Tono-Pen tip (Salvi et al., 2005). Disposable prism tonometry is potentially a reliable alternative to Goldmann Applanation Tonometry (Salvi et al., 2005).

In applanation tonometry, a specially calibrated disinfected probe attached to a slit lamp biomicroscope is used to flatten the central cornea by a fixed amount. As the probe makes contact with the cornea, a topical anesthetic eye drop is instilled. A yellow fluorescein dye is used in conjunction with a cobalt blue filter to highlight the circumference of flattened (applanated) cornea with a clearly defined end point. Insufficient fluorescein in the tear film falsely lowers readings, while excessive fluorescein falsely raises readings. Falsely elevated readings may also result from globe pressure from the eyelids (e.g., blepharospasm), digital pressure if the lids have to be held apart, obesity, a patient straining to reach the head/chin rest, patient breath holding, neck-constricting clothing, hair lying across cornea, or lens-corneal apposition (NHMRC, 2010).

Air puff (noncontact) tonometry is noncontact using a rapid air pulse to applanate the cornea. Applanation is detected via an electro-optical system. IOP is estimated by detecting the force of the air jet at the moment of applanation. Noncontact tonometry has the advantage of not requiring topical or general anesthesia and may be useful for patients uncooperative during applanation tonometry, or patients with corneal disease in whom contact tonometer cannot be accurately performed (NHMRC, 2010). Despite this, the puff of air may frighten some young children and make it difficult to get an accurate IOP reading (Lambert et al., 2013).

Rebound tonometry has shown to be useful in young children as it is better tolerated than noncontact tonometry (Lambert et al., 2013). Rebound tonometry uses a light probe that is propelled by an electrical-pulse generator that creates a magnetic field. After the probe strikes the cornea, it rebounds back into the instrument, causing a voltage change that is detected by a solenoid inside the tonometer. The IOP is calculated by the length of time the probe comes in contact with the cornea and the time it takes to rebound back into the tonometer. Due to its design, rebound tonometer is potentially less intimidating to young children (Lambert et al., 2013). In an observational study of 180 children, aged 6 months to 15 years, rebound tonometry successfully measured IOP in 89% of children compared with only 72% with noncontact tonometry (Kageyama et al., 2011). Also, as rebound tonometry is easy to perform with a handheld instrument, it has been used successfully by parents to monitor the IOP of their children in their homes, known as home tonometry (Flemmons et al., 2011).

Table 2 Intraocular pressure targets for primary open angle glaucoma

POAG stage	*Risk status*	*↓ IOP*	*Specified level*
Suspect	Low		No treatment
	Moderate	20%	
	High	20%	≤24 mmHg
Early	Unspecified		≤19 mmHg
Established	Moderate	20%	≤16 mmHg
	High	30%	Close to episcleral venous pressure
Advanced	Unspecified	30-50%	≤14 mmHg

Adapted from the National Health and Medical Research Council Guidelines for the Screening, Prognosis, Diagnosis, Management, and Prevention of Glaucoma (NHMRC, 2010).

Target Intraocular Pressure

A target IOP should be nominated at diagnosis, depending upon the glaucoma severity, presenting IOP, familial, and other risk factors. Usual recommendations suggest at least 25% reduction from baseline at diagnosis (Heijl et al., 2002; Leskea et al., 2004) with further 20% reductions if further progression occurs (Canadian Glaucoma Study Group, 2006). A lower IOP is set when glaucoma is more severe (Dally et al., 2003; Ederer et al., 2000). Target IOPs for POAG are outlined in **Table 2** and based on a 5-year prediction risk of POAG categorized as low (<5%), moderate (5–15%), and high (>15%). In normal tension glaucoma, a 30% IOP reduction or a target close to the episcleral venous pressure (8–11 mmHg) is recommended (NHMRC, 2010). Although IOP control is useful in PACG, these cases generally require an iridotomy using either a thermal (e.g., Argon) or neodymium yttrium-aluminum-garnet (Nd:YAG) laser (American Academy of Ophthalmology, 2016).

Treatment

Early treatment is recommended to reduce the number of patients with glaucoma who develop visual disability. The progression of visual defects from acute or poorly controlled glaucoma may lead to rapid damage with permanent loss of vision. This can have devastating consequences. Medication is generally the first management choice for most patients with glaucoma, even in patients with AAC as they are prepared for laser therapy or surgery. Medications to treat glaucoma aim to reduce IOP by enhancing aqueous outflow and/or by reducing aqueous production.

Glaucoma management often starts with topical eye drops. Hyperosmotic medications, such as intravenous mannitol or oral glycerol 50%, may be used to lower IOP in emergency situations. When initiating glaucoma medications, many factors should be considered including IOP-lowering potency, additive effects, interaction with concomitant systemic medications and disease states, side effects, and ease of administration (NHMRC, 2010). Persistence with and adherence to medication regimens is vital in the management of any chronic disease. In situations where patients are unable to administer eye drops safely or effectively, or where reduction in IOP is less than desired, oral acetazolamide or laser or surgical interventions may be required (NHMRC, 2010).

Initial treatment may start with one medication (monotherapy), traditionally in one eye only (monocular trial) (NHMRC, 2010). A monocular trail allows clinicians to use the untreated eye as a "control" to account for diurnal variations in IOP and monitor the efficacy of the medication. However, this is no longer recommended as each eye may respond to the medication differently and asymmetric spontaneous fluctuations in IOP have been reported (Realini et al., 2004). Instead, it is now recommended that the efficacy of the medication be assessed by comparing multiple measurements in the treated eye(s) (Realini et al., 2004).

Patients are generally followed up 3 to 6 weeks after initiation of a new medication. This is because medications such as prostaglandin analogs having a maximum IOP-lowering effect after 3 to 5 weeks (European Glaucoma Society, 2014). However, if a patient's IOP is not controlled by a single medication then either another medication is added or switched for the initial medication. The initial medication could be continued if its partial effect was beneficial, but otherwise should be ceased. If the initial medication is being switched, a washout period is generally required followed by a trial of the new medication. Wash out periods are necessary as medications may still have an effect on IOP even after they have been ceased (NHMRC, 2010). Effects of various topical medications on IOP and their washout periods are shown in **Table 3**.

Five main classes of medication are used in glaucoma: (1) prostaglandin analogs (PGA), (2) β-blockers (BB), (3) carbonic anhydrase inhibitors (CAIs), (4) α_2-agonists (AAs), and (5) cholinergics. PGAs and BBs are considered first choice/line agents due to their efficacy, once daily dose frequency and favorable side-effect profile (NHMRC, 2010). Topical CAIs and AAs are considered second choice/line agents. Many of these agents are also available commercially as combination therapy with BBs as well as one fixed combination of a CAI and AA to improve convenience and thereby to enhance adherence (NHMRC, 2010). Third choice/line agents include cholinergics and a systemic CAI. However, their unfavorable side-effect profile poses challenge and has resulted in them being used less commonly, with surgical or laser interventions preferred (NHMRC, 2010).

Table 3 Effect of topical medications on intraocular pressure

Drug	*Peak IOP*[a,b]	*Trough IOP*[a]	*Dose frequency*	*Washout period*[c]
Prostaglandin analogs				
Bimatoprost	−33%	−28%	Once a day	4–6 weeks
Latanoprost	−31%	−28%	Once a day	4–6 weeks
Travoprost	−31%	−29%	Once a day	4–6 weeks
Tafluprost	−30%	−26%	Once a day	4–6 weeks
β-Blockers				
Betaxolol	−23%	−20%	2 times a day	2–5 weeks
Timolol	−27%	−26%	1 to 2 times a day	2–5 weeks
Carbonic anhydrase inhibitors				
Brinzolamide	−17%	−17%	2 to 3 times a day	1 week
Dorzolamide	−22%	−17%	2 to 3 times a day	1 week
α_2-Agonists				
Brimonidine	−25%	−18%	2 to 3 times a day	1–3 weeks

[a]Data are based on a meta-analysis of 28 randomized clinical trials (van der Valk et al., 2005).
[b]Data for tafluprost based on (Konstas et al., 2013).
[c]National Health and Medical Research Council Guidelines for the Screening, Prognosis, Diagnosis, Management and Prevention of Glaucoma (NHMRC, 2010).

Systemic Effects of Topical Ophthalmic Medications

Despite the relative safety of topical ophthalmic medications, they should all be considered as potentially potent systemically. Pharmacokinetics make topical ophthalmic medications more similar to intravenous than to oral administration as they may be absorbed by the highly vascular nasal mucosa, avoiding first-pass hepatic metabolism (Diggory and Franks, 1996; Korte et al., 2002). One drop of timolol 0.5% in each eye has similar effects to a 10 mg oral dose, used to treat hypertension or angina (Diggory and Franks, 1996). Combined use of topical and systemic β-blockers have been linked with adverse respiratory and cardiovascular events, as well as reduced topical ocular hypotensive efficacy (Schuman, 2000). Clinicians may not be aware of these systemic effects as many of them go unreported by patients or misdiagnosed (Goldberg et al., 2008). This is further complicated as many patients do not consider eye drops as "real" medications when asked about their drug history (Goldberg et al., 2008).

Prostaglandin Analogs

PGAs (bimatoprost, latanoprost, travoprost, and tafluprost) are considered first choice/line medications, and their use has increased over BBs as they are more effective at lowering IOP, have fewer systemic side effects, and also only require once a day administration (European Glaucoma Society, 2014). Their primary mechanism of action is to increase uveoscleral outflow, reducing IOP by up to 33% (van der Valk et al., 2005). Their effect is seen within 2–4 h of administration, with a peak effect at 8–12 h, and a maximum effect at 3–5 weeks (European Glaucoma Society, 2014). Evening administration of prostaglandin analogs has been shown to provide a better circadian IOP profile when measuring IOP over 24 h (Alm and Stjernschantz, 1995; Konstas et al., 2002; Konstas et al., 1999). A meta-analysis by Stewart et al. (2010) also showed that PGAs had the greatest effect on reducing IOP fluctuations compared with other topical agents (Stewart et al., 2010).

About 10% of patients do not respond to PGAs, with less than 10 or 15% reduction in IOP from baseline (Ikeda et al., 2006; Rossetti et al., 2006). As the PGAs are structurally different from one another, it may be appropriate to try a different prostaglandin analog if response has been poor to one (Bartlett and Jaanus, 2008; Rossi, 2018). Switching may be preferred as it keeps administration to once a day. As bimatoprost has provoked the greatest hyperemia, it is often prescribed after other prostaglandin analogs have been trialled (Bartlett and Jaanus, 2008; Honrubia et al., 2009). Prior exposure to another PGA may reduce the hyperemic effects of bimatoprost (Bartlett and Jaanus, 2008). When switching between PGAs, patients need to be sure to cease the first one, as the concomitant use of 2 PGAs diminishes their IOP lowering effect (Rossi, 2018).

The most common side effect of PGAs is conjunctival hyperemia. However, this side effect often diminishes over a few months. Eyelash growth and increased pigmentation of the iris and periorbital tissue have also been reported (Bartlett and Jaanus, 2008). This pigmentary change of the iris is irreversible and particularly noticeable in hazel-colored irides; it occurs over months of treatment. The change in pigmentary change of the iris or periorbital tissue can become quite noticeable when patients are treated monocularly. The increased eyelash growth may be popular with some patients and bimatoprost is now also marketed to promote eyelash growth under the brand name Latisse® (Allergan Inc., Irvine, CA) (Jones, 2011). Other side effects are displayed in **Table 4**.

Table 4 Contraindication, precautions, side effects, and interactions of common topical ophthalmic medications for glaucoma

Class	*Contraindications*	*Precautions*	*Ocular side effects*	*Systemic side effects*	*Interactions*
Prostaglandin Analogs	Active intraocular inflammation (uveitis) Active herpetic keratitis	Intraocular inflammation (iritis, uveitis) Aphakia, pseudophakia, torn posterior capsule, known risk factors for macular edema	Blurred vision Burning Stinging Conjunctival hyperemia Foreign-body sensation Itching Increased pigmentation of the iris/ periorbital skin Longer-darker, and thicker lashes Reversible macular edema Reactivation of herpetic infection Iritis/uveitis	Unlikely, but possible.	NSAIDs (eye drops)— reduce efficacy of prostaglandin analogs
β-Blockers	Reversible airways disease, e.g. asthma. Betaxolol, may be safer, used with care. Brady arrhythmia Heart block	Diabetes Hyperthyroidism Cardiac Failure COPD—betaxolol preferred Depression Elderly — May cause falls Children— May cause bradycardia, bronchospasm and mask warning symptoms of hypoglycemia	Burning Stinging Photophobia Itching Tearing Decreased corneal sensitivity Hyperaemia Punctate keratitis Diplopia	Bronchospasm Hypotension Bradycardia Heart block Mask hypoglycemia Adversely affects lipid profile Impotence Fatigue Depression Reduced exercise tolerance Syncope Confusion Alopecia	Systemic beta blockers—potential additive effects Catecholaminedepleting medications Medications that reduce BP, cardiac contractility and conduction— potential additive effects Verapamil— only use under specialist supervision
α_2 Agonists	Monoamine oxidase inhibitors therapy Children younger than two years—use with caution in children younger than seven years	Severe cardiovascular disease Depression	Ocular allergic reaction Burning Stinging Blurring Foreign-body sensation Itching Hyperaemia Lid retraction Conjunctival blanching Photophobia Mydriasis (Apraclonidine)	Central nervous system depression Oral dryness Headache Fatigue Drowsiness Bradycardia Systemic hypotension Hypothermia Apnoea Taste disturbance Syncope	CNS depressant: Alcohol Barbiturates Opiates Sedatives Anesthetics Tricyclic antidepressants Hypotensive agents—potential additive effect
Carbonic Anhydrase Inhibitors (topical)	Corneal grafts, endothelial dystrophy. Allergy to sulfonamides.	Severe hepatic/renal impairment	Burning Stinging Itching Punctate epithelial keratopathy Blepharoconjunctivitis Corneal endothelial cell-decompensation	Bitter taste Headache Nausea Fatigue Dry mouth Dizziness Anaphylaxis	None reported, but potential exists for similar interactions as for systemic carbonic anhydrase inhibitors

Adapted from the NHMRC Guidelines for the Screening, Prognosis, Diagnosis, Management and Prevention of Glaucoma (NHMRC, 2010) Hyperosmotics

Figure 5 Prostaglandin-associated periorbitopathy in the left eye. *Source: Reproduced from Berke, S.J., A previously underrecognized but important side effect. Adv. Ocular Care (2011) 23–24 (Berke, 2011).*

Another previously under-recognized but important side effect is prostaglandin-associated periorbitopathy (PAP) (Berke, 2011; Shah et al., 2013). PAP had previously been referred to as Deep Superior Sulcus Syndrome or Deepening of Upper Eyelid Sulcus, but PAP appears to encompass all of the eyelid and orbital changes. PAP can include upper lid ptosis, deepening of the upper lid sulcus, involution of dermatochalasis, periorbital fat atrophy, mild enophthalmos, inferior scleral exposure, increased prominence of lid vessels, and tight eyelids (Berke, 2011). Aside from the cosmetic effects, PAP makes it difficult to perform applanation tonometry, surgery in the superior fornix, laser suture lysis, bleb needling, or argon/selective laser trabeculoplasty (Berke, 2011) (**Fig. 5**).

Due to prostaglandins' mechanism of action, they should be used cautiously in patients with intraocular inflammation. This includes a history of uveitis: they are relatively contraindicated in the presence of active intraocular inflammation (NHMRC, 2010). In addition, these medications should be used cautiously in patients with a history of herpetic keratitis, as it may reactivate the infection. They are contraindicated if herpetic keratitis is active (NHMRC, 2010), and in patients with aphakia, pseudophakia, or history of ruptured posterior capsule during cataract surgery, which are known risk factors for macular edema (NHMRC, 2010). Pharmacologically, nonsteroid anti-inflammatory drugs (NSAIDs) used topically with PGAs may reduce their IOP lowering effect (NHMRC, 2010).

β-Blockers

The BBs (timolol and betaxolol) are also first choice/line medications. These medications reduce aqueous humor production and can be potent ocular hypotensives (van der Valk et al., 2005). Timolol is a nonselective β-blockers, while betaxolol is β_1 selective. Side effects may include eye irritation, burning, tearing, and foreign body sensation. However, these effects are unusual and mostly short term. Longer term side effects include dry eye and tachyphylaxis, as some patients demonstrate less IOP lowering effects after years of use (Bartlett and Jaanus, 2008). Switching between BBs or different formulations does not overcome tachyphylaxis; if this occurs, a new medication class is usually required.

Systemic side effects of topical BBs are potentially serious. They may cause cardiovascular, respiratory, and/or nervous system effects. Even the β_1 selective/cardioselective betaxolol should be used with caution in patients with known respiratory dysfunction (Goldberg and Goldberg, 1995). Contraindications to topical BBs include sinus bradycardia, second- or third-degree heart block, cardiogenic shock, uncompensated overt cardiac failure, bronchial asthma, or chronic obstructive pulmonary disease. Owing to potential drug interactions, clinicians should be cautious when coprescribing topical β-blockers with adrenergic psychotropic, catecholamine-depleting, calcium channel blockers, or digitalis. Combined use of systemic with topical BBs should be minimized as this combination has been linked with adverse respiratory and cardiovascular events, as well as reduced topical ocular hypotensive efficacy (Schuman, 2000). Other contraindications, precautions, side effects, and interactions are displayed in **Table 4**.

Topical BBs are prescribed either once or twice a day. Once daily dosing may provide adequate therapeutic effect for most patients and will minimize their risk of side effects. Topical BBs once or twice a day reduce IOP by 20–25% (Soll, 1980). If once a day dosing is used, it is optimal to instil in the morning, because BBs reduce the production of aqueous humor and 50% more aqueous humor is produced in waking hours (Grehn and Stamper, 2009b).

Carbonic Anhydrase Inhibitors

Carbonic anhydrase inhibitors (CAIs) suppress aqueous humor production and are considered second or third choice/line medications. Topical CAIs include brinzolamide and dorzolamide. Oral CAIs include acetazolamide. Topical CAIs are not as effective as PGAs/BBs and require administration 2–3 times a day. It is not uncommon for these medications to cause surface discomfort and a bitter metallic taste, more commonly with dorzolamide than brinzolamide (Bartlett and Jaanus, 2008).

Topical CAIs have been reported to contribute to corneal edema and may precipitate corneal decompensation in patients with pre-existing endothelial compromise (e.g., Fuchs' endothelial dystrophy) (Bartlett and Jaanus, 2008). Hence, they are often avoided

in patients with corneal grafts or endothelial dystrophy (NHMRC, 2010). Other contraindications, precautions, side-effects and interactions are displayed in **Table 4**.

Oral CAIs (acetazolamide) are generally limited to the management of AAC or in cases where other medications have been proven to be inadequate or contraindicated and as a temporizing measure while awaiting surgery. Despite its effectiveness in these scenarios, up to 50% of patients treated with acetazolamide do not tolerate it (Bartlett and Jaanus, 2008). Topical and oral CAIs act synergistically; there is little advantage to using both together except as a low-dose systemic supplement to topical instillation.

CAIs are also sulfonamide related and should not be used in patients with a history of severe sulfonamide allergy/reactions. Severe reactions to sulfonamides include aplastic anemia, Stevens-Johnson syndrome, and fulminant hepatic necrosis. As such, CAIs should be discontinued if any signs or symptoms of these reactions occur (Bartlett and Jaanus, 2008).

α_2-Agonists

The α_2-agonists (AAs) suppress aqueous humor production and facilitate uveoscleral outflow. They are considered second choice/line medications. Although two AAs are available (apraclonidine, brimonidine) on the market, brimonidine is mainly used in the longer term. Apraclonidine is not used long term as about a third of patients only have a modest treatment effect (3–5 mmHg) lasting for only 3–6 months (Bartlett and Jaanus, 2008). Hence, apraclonidine is most commonly used as a pretreatment medication to prevent spikes in IOP after glaucoma laser procedures (Bartlett and Jaanus, 2008).

A major concern with brimonidine is that a significant percentage of patients developed a delayed hypersensitivity reaction to the 0.2% formulation. As a result, the concentration was been reduced to 0.15 and 0.1% in newer formulations (using a different preservative) (Bartlett and Jaanus, 2008). These lower concentrations appear to reduce the incidence of delayed hypersensitivity reactions while also preserving similar IOP lowering effects (Bartlett and Jaanus, 2008).

Due to their mode of action, these medications may also cause a variety of systemic side-effects. In particular, brimonidine has also been shown to cause dry mouth and nose, fatigue, headache, drowsiness, dizziness, central nervous system depression, palpitations, and hypotension (Rossi, 2018). Patients should be warned especially about possible drowsiness or dizziness, as people generally do not associate these problems with their eye drops (Rossi, 2018). These medications are also not used in infants or young children owing to increased risks of lethargy, respiratory arrest, and somnolence. Other contraindications, precautions, side-effects, and interactions are displayed in **Table 4**.

Cholinergic Agonists

The cholinergic agonists decrease IOP by improving aqueous outflow through the trabecular meshwork through the contraction of the ciliary muscle. As they also stimulate the iris sphincter, they cause miosis. Although pilocarpine has been used widely to treat glaucoma in the past, its use has been superseded by the other topical ophthalmic medications discussed (NHMRC, 2010). Particular challenges with pilocarpine include an optimal administration frequency of 3–4 times a day and miosis-induced reduction in retinal illuminance that diminishes a patient's functional ability and negatively impact visual field testing (Bartlett and Jaanus, 2008). In addition, chronic use may result in the loss of the ability to dilate the pupil, making any subsequent cataract surgery more difficult (Bartlett and Jaanus, 2008).

Currently, this medication is primarily used in the management of AAC, once the pressure has been reduced to around 30 mmHg (Bartlett and Jaanus, 2008). Pilocarpine may be beneficial in these instances as pupillary miosis and mechanical deformation of the scleral spur decrease appositional iris-trabecular closure, allow aqueous access to the meshwork for drainage, decrease IOP, and stretch the iris, which facilitates laser peripheral iridotomy (Bartlett and Jaanus, 2008). However, if the AACC lasts for more than 1–2 h or if the IOP is greater than 50 mmHg then the iris sphincter muscle may be ischemic and unlikely to respond to pilocarpine. Another indication that pilocarpine may be useful is in the treatment of pigmentary glaucoma, as moving the iris away from the lens zonules might be beneficial (Bartlett and Jaanus, 2008).

Hyperosmotics are used in the treatment of AACC to lower IOP quickly, reduce pain, and to clear corneal edema. However, this is primarily to prepare the patient for laser iridotomy and possible laser iridoplasty. Hyperosmotics cause increased blood serum osmolarity, which pulls water from tissues into the bloodstream. By increasing the osmotic gradient between plasma and the eye, vitreal dehydration occurs, which results in reduced ocular volume and lowering the IOP. The results are relatively rapid (15 min to 2 h) and short in duration (6–8 h).

Hyperosmotics used include intravenous mannitol and oral glycerol 50%. Although mannitol has been recommended to be given as 1–2 g/kg iv over 30–45 min, most authors preferred the lower 1–1.5 g/kg dose due its safer side effect profile (Hill, 1964; Singh, 2005). Both of these drugs can cause electrolyte disturbances and should be used with caution in frail or elderly people (Schacknow and Samples, 2010). They are contraindicated in patients with kidney failure or who are on dialysis (Schacknow and Samples, 2010). The induced fluid shifts may cause congestive heart failure from expansion of blood volume (Schacknow and Samples, 2010). Due to their mode of action, other contraindications include acute pulmonary edema, anuria, severe dehydration, active intracranial bleeding (Bartlett and Jaanus, 2008). Patients with acutely high intraocular pressures may be nauseated. Imbibing oral glycerol 50% over ice helps palatability (Schacknow and Samples, 2010). Oral glycerol should be ingested over about 30 min, taking several sips at a time (Schacknow and Samples, 2010).

Laser Therapy and Surgery

The primary purpose of laser therapy and surgery is to reduce IOP when medications prove ineffective and/or intolerable. Outcome measures include a lowered IOP, reduction of antiglaucoma medication usage, maintenance of visual acuity, and minimization of VF loss (NHMRC, 2010). For the purposes of this chapter, laser therapy and surgery will not be discussed in depth.

Laser therapy includes iridotomy, iridoplasty, trabculoplasty, and cyclodestructive procedures. Laser iridotomy is used to treat AC by creating a hole in the iris in order to break pupil block. It is most frequently undertaken by Nd:YAG laser iridotomy (NHMRC, 2010). Laser iridoplasty is used in AC following iridotomy when the angle remains appositionally closed or occludable (NHMRC, 2010). Contraction burns are applied to the peripheral iris to pull it away from the trabecular meshwork. Laser trabculoplasty is used in OAG and uses a laser focussed on the trabecular meshwork to increase aqueous outflow (NHMRC, 2010). Cyclodestructive procedures can also be used for OAG by using a laser to damage the ciliary body, reducing aqueous humor production (NHMRC, 2010). However, as the effects of cyclodestruction are unpredictable, and visual loss is possible, it is usually reserved for uncontrollable IOPs in eyes with poor vision already.

Surgery for glaucoma typically includes trabeculectomy, iridectomy, and glaucoma drainage devices. A trabeculectomy includes surgically creating a drainage channel between the anterior chamber and subconjunctival space. Standard trabeculectomy 5-year survival is reported to be 80% (Dally et al., 2003). Trabeculectomy may be undertaken as a primary procedure, or when laser and medical therapies do not successfully lower IOP. Since excessive scarring in the operative area will lead to failure of filtering surgery, antifibrotic medications such as 5-fluorouracil and/or mitomycin C are often applied locally to retard healing. A serious drawback with antimetabolites is that some of the complications associated with filtering blebs are increased, such as a higher rate of bleb leaks and late-onset infections (Ederer et al., 2000; Dally et al., 2003).

An iridectomy is the surgical removal of part of the iris. This procedure is most frequently performed in the treatment of AC glaucoma but has been largely superseded by Nd:YAG laser iridotomy (NHMRC, 2010). Iridectomy is most commonly used as part of a trabeculectomy to prevent iris occlusion of the channel. It can also be performed when corneal clarity or lack of equipment precludes a laser iridotomy (NHMRC, 2010).

Glaucoma drainage devices (implants and shunts) are generally employed in secondary glaucomas or where trabeculectomy has failed (Minckler et al., 2006). Tube shunts work by allowing aqueous to flow along a plastic tube and delivered onto a plate surface, which creates a conduit and reservoir that cannot be obliterated by local fibrosis to reduce IOP. Although a 5-year IOP control success rate is between 50% and 100% (Molteno et al., 2001), a meta-analysis suggests approximately 10% failure rate per year for the first 3 years (Hong et al., 2005).

Recently, a number of so-called minimally invasive glaucoma surgeries (MIGS) have become available, including the iStent (Glaukos Corp. Laguna Hills, CA), Hydrus Microstent (Ivantis, Irvine, CA, USA), Trabectome (NeoMedix, Tustin, USA), the Xen Implant (Aliso Viejo, CA, USA), and the InnFocus Microshunt (InnFocus, Miami, FL, USA) (Nardi et al., 2015). Which devices work best for which patients, with or without simultaneous cataract surgery, is being determined by a series of clinical trials.

The Role of the Pharmacist

Like other chronic diseases, pharmacists have an important role to improve glaucoma management outcomes. In particular, they can assist patients to obtain optimal effects from their medications and to minimize the risk of adverse effects by addressing adherence, instillation techniques, timing, and choice of medications. Also, as pharmacists are one of the most accessible health-care professionals in many communities, they can impact public health strongly by improving screening rates for glaucoma in high-risk patients.

Ensuring Optimal Effect of Medications, Adherence, and Persistence

Adherence and persistence are major problems in glaucoma as it is asymptomatic and consequences are not immediately apparent when a medication is missed (European Glaucoma Society, 2014). Nonadherence in patients with glaucoma is reported to range from 24% to 59% (Gurwitz et al., 1993; Patel and Spaeth, 1995; Rotchford and Murphy, 1998). Adherence is reduced by increased frequency of instillations, increased side effects (especially those unexpected or alarming), and increased cost (NHMRC, 2010). Individualized strategies should be used to overcome specific issues identified that align with the patient's life style. Strategies to minimize side effects will be discussed later.

Due the asymptomatic nature of glaucoma, patient education about the disease process may aid adherence by highlighting the risk of VF loss that may results from nonadherence. Informed participation in treatment decisions has also been shown to improve adherence and treatment outcomes (Osterberg and Blaschke, 2005). Self-management strategies that engage patients in their own care have been shown to improve treatment outcomes compared with the traditionally "paternalistic" care offered by health-care professionals (Nys, 2008). To assist patients to manage their glaucoma and other health issues, pharmacies can provide a medicines profile, listing all the patient's prescriptions, over-the-counter and complementary medicines. These profiles can also be used as an effective communication tool when the patients see other health professionals. Patient-centered approaches appear to offer the most effective long-term strategies for glaucoma management.

For patients who have difficulty adhering to their medications, often despite best intentions and understanding of their disease(s), simplifying the medication regimen may help greatly. A once-daily medication can improve adherence compared with more frequent administrations. This can be facilitated by the use of combination eye drops instead of separate agents used sequentially (Stewart et al., 2004). Once daily medications such as PGAs and BBs could be used morning or evening, depending on the individual patient's preference and likelihood to remember.

Adherence may fail from physical obstacles such as tremors (e.g., Parkinson's) or poor hand/arm/finger control or power (e.g., arthritis). Physical barrier nonadherence is known as dyscompliance (NHMRC, 2010). Medication aids may help and may be purchased from local pharmacies, patient support associations, or some technology outlets. Ophthalmic medication manufacturers also have devices that are designed for their specific eye drop bottles to assist patients experiencing these issues. Local glaucoma associations may also be a valuable resource for patients to access assistive technologies. In Australia, Glaucoma Australia (www.glaucoma.org.au; 1800 500 880), is able to assist patients without cost.

Administration Timing of Medications

Administration timing is also important when patients are on multiple ophthalmic medications. On average, the total tear film volume is around 7 μL, and the rate of tear film turnover is approximately 15% (±1 μL) per minute but can double after application of a topical eye drop (each eye drop may have a volume of 30–50 μL) (European Glaucoma Society, 2014). Although the conjunctival cul-de-sac tear film compartment can expand, it cannot accommodate the whole volume of an eye drop; less than 5% enters the eye (European Glaucoma Society, 2014). The remaining medication will either run down the cheek, be absorbed through the conjunctival tissues, or be drained to the nose via the nasolacrimal duct. Once an eye drop is instilled into the conjunctival sac, spontaneous tear flow will wash it out completely within 5 min (European Glaucoma Society, 2014). If multiple eye drops are used in succession, for optimal efficacy, they should be separated by at least 5 min. When two ophthalmic medications are instilled only 30 s apart, almost 50% of the first drug will be washed out (European Glaucoma Society, 2014).

Ophthalmic medication formulation affects their recommended administration. Eye drop solutions should be applied first, followed by any eye drop suspensions (cloudy liquids, e.g., brinzolamide), followed in turn by any eye gels or ointments. Applying medications in this order allows the medications in solution to be absorbed through the cornea and sclera, preventing possible hindrance by insoluble or oily substances present in suspensions, gels, and ointments. Ophthalmic suspension requires to be shaken before use. If patients do not shake the bottle, they may instil only vehicle to the eye, rather than the active ingredient (European Glaucoma Society, 2014).

Minimizing and Addressing Side Effects

Administration technique for ophthalmic topical medications is important to maximize efficacy, to minimize risk of eye infection and systemic side effects. Patients should be advised to wash their hands before instillation and to ensure that the tip of the eye dropper or tube does not touch the eye, eyelid, or lashes to prevent infections. Many ophthalmic products should be discarded after 28–30 days after opening, unless stated otherwise (Rossi, 2018). Hospitals may have their own discard policy due to the increased risk of infection.

Pharmacokinetics make topical ophthalmic medications mimic intravenous rather than oral administration—they avoid first-pass hepatic metabolism via transconjunctival absorption and transnasal mucosal absorption (Diggory and Franks, 1996; Korte et al., 2002). See comments on timolol above The "double DOT" procedure is recommended as it reduces systemic absorption by 70% (Goldberg et al., 2008). The "double DOT" includes (1) Don't Open the eyelids Technique (DOT) and (2) Digital Occlusion of the Tear duct (DOT) for 1 to 2 min (Goldberg et al., 2008). Keeping the eyes closed and applying digital pressure over the lacrimal sac for 1–2 min after drop administration will significantly reduce systemic absorption of most agents. Two medications from the same class should not be coprescribed as this can increase the risk of side effects with no beneficial effects on IOP (Goldberg et al., 2008) (**Fig. 6**).

Preservative Toxicity and Effects on the Eye

Preservatives are used in ophthalmic medications to inhibit or destroy micro-organism growth and to maintain sterility. However, preservatives can also provoke local reactions or lead to preservative toxicity, especially when used frequently and in the longer term. Chronic use of antiglaucoma eye drops can cause eye burning and stinging, dry eyes, and reflex tearing (Baudouin, 2008). The majority of multidose eye drops contain benzalkonium chloride, a quaternary ammonium-based preservative. Adverse effects from preservatives may be diminished if benzalkonium chloride is substituted with a less toxic preservative or a nonpreserved drop is used. In particular, Purite (Alphagan P; Allergan Optical, Irvine, CA, USA), polyquaternium-1 (PolyQuad in Travatan; Alcon Laboratories, Inc, Fort Worth, TX, USA), and sofZia (Travatan Z; Alcon Laboratories, Inc, Fort Worth, TX, USA) are alternative ophthalmic preservatives designed to eliminate the toxic side effects of benzalkonium chloride (Yee, 2007). Tafluprost, bimatoprost, and timolol are available in preservative-free, single-dose units. Particularly if a patient is using four or more drops a day, products with less toxic preservatives or preservative-free should be considered (Rossi, 2018).

Screening

Community pharmacy holds a number of benefits as a setting for public health activities. With extended opening hours and no appointment needed for advice, community pharmacy can be more accessible than other settings. A systematic review of pharmacists and consumers showed that both groups believed community pharmacists should have a public health role. Glaucoma is a public health concern as it can cause irreversible blindness and half of all patients with glaucoma are undiagnosed and thus untreated—and glaucoma is a progressive disease causing irreversible visual damage (Mitchell et al., 1996; Quigley and Jampel, 2003; Tielsch et al., 1991). Those who are diagnosed are often diagnosed late sometimes with significant VF loss already present (Martus et al., 2005). Improved screening of high-risk groups would allow earlier diagnosis of glaucoma at a stage of less visual damage and enhance treatment outcomes. The highest risk group are first-degree relatives of diagnosed patients: such persons have a 23% lifetime risk for glaucoma (NHMRC, 2010). Pharmacist should repeatedly recommend to glaucoma patients filling prescriptions to ensure their relatives are aware of this and are being assessed regularly for both IOP levels and an optic nerve check.

Management of Eye Disorders and the Pharmacist's Role: Eye Infections

Vicky S.K Chen*, Jonathan Hsi-Dar Penm†, *Sydney Hospital and Sydney Eye Hospital, Sydney, NSW, Australia; †The University of Sydney School of Pharmacy, Camperdown, NSW, Australia

Introduction to Eye Infections

Eye infections are a common medical presentation and can vary from being self-limiting to sight threatening. Although most eye infections that present to a pharmacy are self-limiting, some may cause corneal scarring and/or permanent blindness. As such, it is important that pharmacists refer these patients appropriately.

Eye infections often manifest when the eye has been exposed to pathogens that are not part of the normal flora of the ophthalmic chamber. This usually occurs when the integrity of the eye is compromised, or there is damage to the eye due to trauma or surgery.

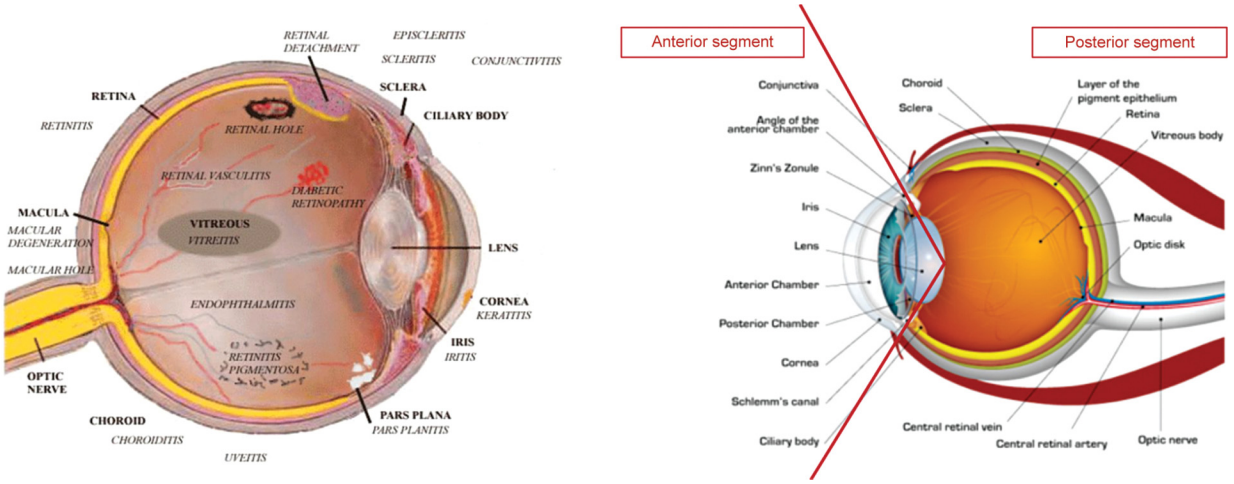

Figure 1 (A) Ocular infections categorized by location of eye. (B) Ocular infections affect both the anterior and posterior segments of the eye (Vision Best Eye Care Centre, 2019).

Infections are also more common in people who wear contact lenses or are immunosuppressed where normal microbial flora may become opportunistic (Thielen et al., 2000).

Eye infections are categorized by their etiology and anatomical location of the infection. Eye infections can occur around the eye, on the eyelid, or in the anterior or posterior segments of the eye (Fig. 1A). Eye infections are classified by the location of the infection (Fig. 1B). For instance, an infection may cause keratitis if it affects the cornea or retinitis if it affects the retina. Causative organisms for ophthalmic infections can be bacteria, viruses, fungi, or protozoa.

Common eye infections and their pathogens can usually be determined by assessing patient's history, symptoms, and clinical presentations. To confirm diagnosis, diagnostic techniques such use of fluorescein and examination through a slit lamp or microbiology testing of corneal scrapings or the vitreous may be employed. Identifying the location of the infection and the causative organism are critical in selecting a pharmacotherapeutic agent as absorption, penetration and the bioavailability of the drug will affect treatment decisions (Gerstenblith and Rabinowitz, 2012).

Epidemiology

The epidemiology and the availability of data for each eye infection vary significantly. The overall burden and the epidemiology of eye infections have not been well described, as most of the data regarding infections such as keratitis, endophthalmitis, and trachoma have been from individual studies and publications. The patterns and circumstances associated with the incidence of eye infections vary between populations and geographical locations. The factors causing the variations are based on climate and economic development (Channa et al., 2016). In less developed countries, large scale vision loss may be due to deficiency of resources and endemic infections. Trachoma, an eye infection caused by *Chlamydia trachomatis*, is more common in lower socioeconomic countries where infection spreads due to poor hygiene and high population density. It has been estimated that trachoma accounts for approximately 3% of the world's blindness with about 8 million people permanantly impaired by trachoma (World Health Organization, 2019).

In community pharmacies, red eye is the most common presentation of an eye infection. A small study in the United Kingdom showed that community pharmacies on average saw two cases of red eye per week (Rutter, 2017). Most red eye presentations are caused by conjunctivitis. Allergic conjunctivitis is the most frequent cause of conjunctivitis, affecting 15%–40% of the population (Bielory et al., 2012) and is observed more frequently in spring and summer (Høvding, 2008). Viral conjunctivitis is the most common cause of infectious conjunctivitis both overall and in the adult population (Fitch et al., 1989; Harding et al., 1987; Hørven, 1993; Rönnerstam et al., 1985; Stenson et al., 1982; Uchio et al., 2000; Woodland et al., 1992). Some studies have shown that up to 80% of conjunctivitis cases are caused by viruses, which do not require treatment with antibiotics and are usually self-limiting (Azari and Barney, 2013). Bacterial conjunctivitis is the second most common cause (Fitch et al., 1989; Hørven, 1993; Rönnerstam et al., 1985; Stenson et al., 1982; Woodland et al., 1992) and is responsible for the majority (50%–75%) of cases in children (Høvding, 2008).

Another common cause of red eye is due to an infection of the cornea, known as keratitis. Keratitis is a serious infection of the eye as it is one of the most common causes of corneal blindness and visual impairment around the world (McLeod et al., 1995). The epidemiology of keratitis varies significantly between the western and developing countries due to the fact that less industrialized countries have significantly lower number of contact lens users; hence, fewer contact lenses related infections (Al-Mujaini et al., 2009). In the United States, about 30,000 cases of microbial keratitis are reported annually (Sharma and Taniguchi, 2017). Bacterial keratitis is the most common form of microbial keratitis in temperate climates, such as United

States, accounting for 89%–96% of cases of microbial keratitis (Estopinal and Ewald, 2016; Varaprasathan et al., 2004). However, in sub-Saharan Africa, filamentous fungi has accounted for 42% of cases of microbial keratitis (Leck et al., 2002).

One of the most serious eye infections is an infection inside the eye, known as endophthalmitis. The incidence of endophthalmitis varies between studies, as the presentation of the eye infection is usually secondary to ophthalmic surgery or procedures, or is a consequence of ocular trauma. Endophthalmitis can be classified as exogenous or endogenous. Exogenous endophthalmitis refers to a cause external to the globe, such as surgery or trauma, while endogenous endophthalmitis is due to hematogenous spread. Overall, the incidence of exogenous endophthalmitis postcataract surgery appears to be decreasing. Studies from the United States show that the incidence has reduced from 0.08% over 1984–1994 to 0.025% over 2002–2009 (Ramakrishnan et al., 2009). Endogenous endophthalmitis is generally less common than exogenous endophthalmitis, with studies reporting ranges from 2% to 41% of all cases of endophthalmitis being endogenous, again varying due to geographical location and patient history (Chee and Jap, 2001).

Diagnosis

Rapid identification of eye infections is crucial as treatment regimens and visual prognosis are dependent on accurate and timely diagnosis between noninfectious, mild, and severe infections. Precise diagnosis requires a combination of analyzing clinical features that are characteristic of the infection, as well as microbiological investigation. At initial presentation, a preliminary diagnosis and empirical treatment is determined based on specific clinical features, and laboratory data enables the confirmation of a suspected diagnosis. In determining the pathogen both in vivo and in vitro, diagnostic methods are available, which include a range of conventional (such as blood testing) and molecular techniques (Sharma, 2012).

Fluorescein and Slit Lamp Biomicroscopy

The use of slit lamp biomicroscopy is the most common method to explore the cornea for eye examinations. It allows the ophthalmologist to gain a detailed assessment of the anterior and posterior segments of the eye (Martin, 2018). Fluorescein is an orange dye used during the slit lamp biomicroscopy examinations. Fluorescein is administered topically via a dropper or a strip (Gerstenblith and Rabinowitz, 2012). The action of blinking spreads the dye over the surface of the cornea, staining the eye and allowing the visualization of ocular surface disorders such as corneal ulcers, abrasions, or other epithelial defects (Martin, 2018).

Conventional Pathology and Microbiology Testing

Conventional testing requires clinical samples to be collected from the site of infection to confirm the causative pathogen. **Table 1** summarizes the type of samples required from the infected eye in order to diagnose the infection (Sharma, 2012). These samples are then processed for culture of bacteria, fungi, or parasites.

Blood samples are only required where an endogenous infection might be suspected. However, it is important to note that a negative peripheral blood results does not exclude the possibility of infection (Sharma, 2012). If a positive culture is obtained, antimicrobial susceptibility is also identified to assist clinicians in identifying an appropriate antimicrobial agent (Sehu, 2009).

Molecular Testing: Polymerase Chain Reaction

Molecular diagnosis has added sensitivity, specificity, and speed compared to the conventional techniques of microscopy and culture (Bowling, 2015; Sharma, 2012). Polymerase chain reaction (PCR) is a laboratory method to detect and measure specific genes, such as those from pathogens. PCR is the most common molecular diagnostic method used in eye infection investigations. In

Table 1 Type of sample and recommended procedure for sample collection in various eye infection

Type of infection	*Type of sample*
Conjunctivitis	Fluid/discharge from lower conjunctival sac
Blepharitis	Scales/discharge from lid margin
Dacryocystitis	Fluid/discharge from lower conjunctival sac
Keratitis	Corneal scraping
Uveitis	Anterior chamber fluid
Endophthalmitis	Anterior chamber fluid vitreous aspirate vitreous biopsy
Deep seated stromal infiltrate in keratitis	Corneal biopsy
Contact lens-associated keratitis	Contact lenses, lens cases, and lens solution
Postoperative endophthalmitis postintraocular lens implantation	Intraocular lens

Source: Modified from Sharma (2012).

cases of bacterial and fungal infections, culture is still preferred over molecular methods; however, there is increased utilization of the PCR technique in the diagnosis of bacterial and fungal endophthalmitis (Bowling, 2015; Sharma, 2012). PCR testing is also useful in the detection of organisms that are difficult to culture such as *Microsporidia*, *Propionibacterium acnes*, and *Toxoplasma gondii*, or for organisms that take a long time to grow, such as *Mycobacterium tuberculosis* (Sharma, 2012).

For many viral infections, PCR analysis has superseded less sensitive culture and pathology techniques. For instance, it is now common for conjunctivitis or keratoconjunctivitis caused by adenoviruses, herpes simplex virus, *Chlamydia*, or microsporidia to be confirmed by PCR-based techniques in the clinical setting (Bowling, 2015; Chan et al., 2005; Sharma, 2012). In fungal infections, PCR techniques are superior in improving diagnosis compared to conventional method, particularly in the diagnosis of fungal endophthalmitis (Chan et al., 2005; Sharma, 2012). Furthermore, the ability to sequence genomic fragments has assisted in the detection of organisms that are difficult to identify and can isolate new organisms associated with ocular disease.

Concepts in Ocular Pharmacotherapy

The challenge in commencing appropriate management is that there is not one therapy or regimen that can treat all the types of eye infections. Varying infections require different treatments, ranging from nonpharmacological eye care to antimicrobials and surgery. Appropriate choice of pharmacotherapy will be based on factors such as causative organism, absorption, penetration, and bioavailability of the drug and whether the infection is in the anterior or posterior segment of the eye.

Mode of Drug Delivery

Ocular drug delivery has been a major challenge due to the unique anatomy and physiology of the eye. The structure of the eye includes different layers of cornea, sclera, and retina including blood aqueous and blood–retinal barriers (Bowling, 2015; Cohen, 2009; Gaudana et al., 2010). Structural variation of each layer of ocular tissue can present a significant barrier following drug administration by any route. In theory, topical application of drugs is suitable for management of the anterior segment, and intravitreal injections or systemic medications are generally used for posterior infections. **Table 2** summarizes the types of ocular drug delivery and their associated benefits and challenges (Gaudana et al., 2010).

Antimicrobials

Eye infections can be caused by a range of microorganisms such as bacteria, viruses, fungi, or protozoa. As such, a range or antibacterial, antiviral, antifungal, and antiprotozoal agents may be used to treat eye infections. However, liberal use of antimicrobials has resulted in a rise in antimicrobial resistance rates in numerous microorganisms around the world, limiting the usefulness of antimicrobials (Grzybowski et al., 2017). For instance, patients receiving prophylactic antimicrobial eye drops prior to intravitreal injection administration for chronic retinal disease showed increased ophthalmic microbial flora resistance rates (Kim and Toma, 2011). In these patients, resistance rates to moxifloxacin rose from 26% to 65% over only one year (Kim and Toma, 2011). Clinicians should be familiar with local antimicrobial resistance patterns to ensure appropriate antimicrobials are used. Also, to prevent further rise in resistance rates, antimicrobials should be restricted to clinical cases that have been shown to provide benefit.

Table 2 Routes of delivery, benefits, and challenges in ocular delivery

Route	*Eye infections treated*	*Benefits*	*Challenges*
Topical	Keratitis, uveitis, conjunctivitis, scleritis, episcleritis, blepharitis	High patient compliance, self-administrable, and noninvasive	Higher tear dilution of drug and turnover rate Corneal barrier
Oral/Systemic	Scleritis, episcleritis, cytomegalovirus retinitis	Patient compliance, and noninvasive route of administration	Blood–Aqueous Barrier Blood–Retinal Barrier Systemic dosing with associated adverse effects and toxicity
Intravitreal	Cytomegalovirus retinitis, acute retinal necrosis, endophthalmitis	Direct delivery to vitreous and retina, sustains drug levels, evades blood—retinal barrier	Retinal detachment Possible hemorrhage Risk of cataract and endophthalmitis
Intracameral	Prevention and treatment of endophthalmitis with antibiotic delivery	Provides higher drug levels in the anterior chamber, eliminates usage of topical drops, reduces corneal and systemic side effects seen with topical steroid therapy	Toxic anterior segment syndrome Toxic endothelial cell destruction syndrome

Source: Modified from Gaudana et al. (2010).

Adjuvant Therapy

Corticosteroids

Corticosteroids are used as adjuvant therapy in the management of eye infections and aid in decreasing inflammation of the eye. The most commonly used corticosteroids are dexamethasone, prednisolone acetate, and triamcinolone. The use of corticosteroid therapy in active infection is debatable, since it can delay healing of the cornea as well as amplify the risk of opportunistic infection (Cohen, 2009). However, the benefits of both topical and systemic corticosteroid treatment in reducing the severity of corneal stromal melt, neovascularization, and subsequent scarring have been proposed (Williams and Paterson, 1987). Furthermore, corticosteroids may improve patient compliance with other eye drops by decreasing pain and discomfort from the infection (Renfro and Snow, 1992).

Anticholinergics

Topical anticholinergic eye drops include atropine, cyclopentolate, and tropicamide. They are often used for their cycloplegic effects in the management of eye infections (Rossi, 2018). Their cycloplegic effects are due to blockade of the muscarinic receptor, causing paralysis of the ciliary muscle. Immobilizing the eye can decrease the pain associated with severe eye infections (Bowling, 2015). However, clinicians should be cautious of systemic absorption of anticholinergic agents as they may cause adverse reactions such as dry mouth, headache, dizziness, hypertension, and tachycardia (Rossi, 2018). Regular review and a short duration of treatment are advised (Rossi, 2018).

Treatment of Eye Lid and Conjunctiva Infections

Blepharitis

Blepharitis is the inflammation of the margins of the eyelids, with or without the presence of ulceration. Blepharitis can be classified as either anterior blepharitis or posterior blepharitis. Anterior blepharitis affects the region of the eyelashes, with often a collarette visible at the eyelashes roots. Anterior blepharitis is usually associated with either staphylococcal or seborrheic contamination of the eye lid margin and lashes, presenting with crusting around the eyelids (Guillon et al., 2012; McCulley and Dougherty, 1985). Posterior blepharitis affects the cutaneous mucosal junction, where the meibomian glands are located and often present with sticky discharge (McCulley et al., 1982).

Anterior Blepharitis or Staphylococcal Blepharitis

Anterior (Staphylococcal) blepharitis is an infection that involves inflammation of the eyelid and hair follicles. It is characterized by crusting on the eyelid edges. Patients may present with painful, burning eyes, with ulceration or abscesses and the feeling of a foreign body in the eye or grittiness (Bowling, 2015; Therapeutic Guidelines, 2014). The most common causative pathogen is *Staphylococcus*. Other pathogens include *Pneumococcus* and *Haemophilus*.

In most cases, appropriate lid hygiene is sufficient as the condition is self-limiting and does not require topical antibiotic treatment (Therapeutic Guidelines, 2014). Lid hygiene involves applying warm compresses for 2–5 minutes to soften the crusts followed by gentle scrubbing of the eye lashes (Therapeutic Guidelines, 2014). Commercially available lid solutions can be used, alternatively patients may use a dilute sodium bicarbonate solution (1 teaspoon in 500 mL cooled boiled water) or diluted baby shampoo solution (5 drops in 100 mL cooled boiled water) (Therapeutic Guidelines, 2014). If the infection is unresolved after one to two weeks, treatment with a topical antibiotic ointment, such as chloramphenicol, may be considered (Bowling, 2015; Therapeutic Guidelines, 2014).

Posterior Blepharitis or Seborrheic Blepharitis

Posterior (seborrheic) or nonulcerative blepharitis is the most common form of blepharitis. It is characterized by burning and itchy eyes, with discharge, especially in the morning upon waking. Red and inflamed eyelids are also typical of posterior blepharitis, and in some cases, patients may also present with a secondary chalazion infection (Bowling, 2015).

Risk factors include exposure to allergen, dust, smoke, irritating chemicals, or association with seborrhea of the scalp, eyebrows, and ears (Bowling, 2015; Therapeutic Guidelines, 2014). It can occur due to irregular oil secretion from the sebaceous (meibomian) glands on the eyelid edges allowing an environment for bacterial growth. It is also associated with other dermatological conditions such as rosacea, psoriasis, and dermatitis around the scalp and forehead (Bowling, 2015).

Similar to anterior blepharitis, lid hygiene is the mainstay for treating posterior blepharitis (Therapeutic Guidelines, 2014). In patients that are unresponsive to lid hygiene alone, long-term (minimum of eight weeks) systemic antibiotics such as low-dose doxycycline or erythromycin are prescribed. In this case, these antibiotics are used for their anti-inflammatory effect rather than their antibacterial effects (Therapeutic Guidelines, 2014).

Ophthalmic Cellulitis

Ophthalmic cellulitis is an acute infection of the subcutaneous tissue around the eye and is categorized as periorbital (preseptal) or orbital (postseptal).

Periorbital Cellulitis

Periorbital cellulitis typically affects the soft tissue of the eyelid. It is usually secondary to an existing infection either originating from the orbital septum, which is the main fibrous section of the eyelid, or from the sinus region (Duane et al., 2013). The causative organisms are usually staphylococcal, *Streptococcus pyogenes* or *Streptococcus pneumoniae*. *Haemophilus Influenza type B* (Hib) can also be a source of infection in children who have not been vaccinated. Patients with a history of trauma, wound, or existing stye, dacryocystitis, or impetigo are at higher risk of developing periorbital cellulitis (Bowling, 2015; Duane et al., 2013; Moorfields Eye Hospital, 2006; Sehu, 2009).

Symptoms are usually unilateral, with swelling, pain, tenderness of the eyelid, and redness of the eyelid and adjacent soft tissue (e.g., forehead). Visual disturbances are not common for periorbital cellulitis (Bowling, 2015; Duane et al., 2013).

Treatment of periorbital cellulitis should target the most likely and common causative organisms, *Staphylococcus* and *Streptococcus* (Renfro and Snow, 1992; Rossi, 2018). Systemic antibiotics such as flucloxacillin and cefalexin are recommended. Periorbital cellulitis associated with *H. influenza type b* requires treatment with amoxicillin/clavulanic acid, cefuroxime or clindamycin (Gerstenblith and Rabinowitz, 2012; Therapeutic Guidelines, 2014). In cases where periorbital cellulitis remains unresolved after full course of antibiotic treatment or in severe infection, a systemic source of infection may be suspected and sampling of blood cultures should be considered.

Orbital Cellulitis

Orbital cellulitis is an infection of the tissue that surrounds the orbital septum. The infection may extend to ocular muscles and nerves including the optic nerve and is considered an ophthalmic emergency. Rapid diagnosis is essential for timely management of orbital cellulitis, as intracranial spread of the infection may be life threatening (Bowling, 2015; Rossi, 2018). Increased pressure of the eye and surrounding regions can result in blindness and other life-threatening manifestations (Duane et al., 2013). Orbital cellulitis usually occurs with preceding or concurrent infection of the sinus region, dental infections, or other endogenous source of bacteremia. A history of upper respiratory infection is also a determinant factor. Unlike preorbital cellulitis, it is more common in adults than children (Channa et al., 2016).

The most common causative organisms include *Staphylococcus aureus*, *Streptococcus pneumoniae*, *Streptococcus pyogenes*, and other anaerobes. *H. influenzae* can also be present in unvaccinated patients. Taking blood cultures and swabs from the sinus regions is important to determine the primary infective organism. In the immunocompromised patient, the source of infection may also be fungal (Channa et al., 2016)

Orbital cellulitis requires intravenous broad-spectrum antibiotic therapy to prevent intracranial spread of the infection. A reasonable choice in therapy may include both ceftriaxone, a third-generation cephalosporin with broad activity against Gram-positive and Gram-negative organisms, in conjunction with flucloxacillin (Gerstenblith and Rabinowitz, 2012; Therapeutic Guidelines, 2014). To ensure full resolution of orbital cellulitis, antimicrobial therapy should be continued for 10 days (Bowling, 2015; Gerstenblith and Rabinowitz, 2012; Therapeutic Guidelines, 2014). In some cases, surgery may be required to drain the patients' sinuses or abscesses in the orbital or intracranial space (Bowling, 2015; Therapeutic Guidelines, 2014).

Bacterial Conjunctivitis

Conjunctivitis is the inflammation of the conjunctiva and is the most common presenting ophthalmic infection in community pharmacies. Acute conjunctivitis is classified into infectious, which includes bacterial and viral conjunctivitis, or noninfectious, which includes allergic and nonallergic conjunctivitis. Bacterial conjunctivitis is more prevalent in children than adults. The most common causative pathogens include *Streptococcus pneumoniae*, *Streptococcus pyogenes*, and *Staphylococcus aureus* (Fitch et al., 1989; Therapeutic Guidelines, 2014).

Although patients with contact lenses are at a higher risk of developing bacterial conjunctivitis, a referral to a physician is generally required to exclude a diagnosis of keratitis. Patients with contact lenses are more predisposed to keratitis because the space between the contact lens and cornea can act as an incubator for bacteria and enhance mechanical abrasion (Rutter, 2017).

Bacterial conjunctivitis is characterized by purulent discharge, with a "sticky" eye and crusting on the eyelid upon waking. The discharge can continue throughout the day and is described as green, yellow, and globular. Symptoms initially occur unilaterally but may be transmitted to the adjacent eye after one or two days if proper hygiene is not observed (Bowling, 2015).

Bacterial conjunctivitis can resolve spontaneously within five days without treatment in 65% of cases (Rutter, 2017). However, it is highly contagious and can be spread by contamination of ophthalmic discharge on surfaces and sharing of objects. As such, patients are encouraged to wash their hands often with soap and warm water and avoid touching or rubbing their eyes. It is also recommended that patients wash their pillowcases, sheets, and towels often in hot water and detergent (National Center for Immunization and Respiratory Diseases (NCIRD) Division of Viral Diseases, 2019).

In some cases, symptoms of bacterial conjunctivitis can last for up to 14 days. If symptoms remain after five days, topical antibiotic (chloramphenicol or framycetin) may be used to hasten the recovery (Sheikh et al., 2012).

Chlamydial Conjunctivitis

Chlamydia trachomatis conjunctivitis, or also known as inclusion conjunctivitis, occurs in neonates and patients with sexually transmitted infections. In adults, it has also been documented to be a chronic and latent infection. Concurrent, asymptomatic, urogenital infection, or urethritis may also be present in mothers of neonates (Fitch et al., 1989). Clinical features of chlamydial

conjunctivitis are usually unilateral and similar or the same as bacterial or viral conjunctivitis. PCR testing can confirm diagnosis, particularly if symptoms persist for more than 14 days. Systemic antimicrobial treatment is recommended for chlamydial conjunctivitis (Nakagawa, 1997; Therapeutic Guidelines, 2014). Azithromycin, administered as a single 1g dose, may be used for its long half-life and high ocular penetration (Bowling, 2015; Nakagawa, 1997).

Trachoma is another form of chlamydial conjunctivitis, but differentiated by recurrent and severe infection resulting in extensive inflammation and scarring of the eyelid. If left untreated, the scarring can thicken causing inward turning eyelashes (trichiasis). The constant abrasion from the eyelashes can cause irreversible corneal opacity and blindness (Bowling, 2015).

The prevalence of this type of conjunctivitis is low in developed countries and occurs mainly in areas with poor hygiene and high population density (Nakagawa, 1997; Therapeutic Guidelines, 2014). Trachoma infection can initially be asymptomatic or cause mild redness or discharge which occurs 5–15 days after contact with an infected person. Trachoma diagnosis is made by clinical examination, which shows pale round spots (follicles) or further changes on the inner surface of the upper eyelid (Bowling, 2015; Nakagawa, 1997; Therapeutic Guidelines, 2014). Pharmacological treatment is the same as chlamydial conjunctivitis with a single dose of azithromycin (Bowling, 2015). Transmission prevention is an effective strategy to reduce the prevalence of trachoma.

Gonococcal Conjunctivitis

Gonococcal conjunctivitis is caused by the Neisseria species, particularly *N. gonorrhoeae*, and can be sight threatening. The organism is usually transmitted from the genitalia to the hands and then eyes. Concurrent, asymptomatic, urogenital infection, urethritis, or chlamydial infection is common (McAnena et al., 2015; Therapeutic Guidelines, 2014). Worldwide, the epidemiology of gonococcal infection in developed countries is less than 1% due to screening and treatment availability (McAnena et al., 2015). In neonates, gonococcal infection usually occurs in the first 5 days of life, and is an ophthalmic emergency as it can lead to corneal perforation of the globe and blindness (Zikic et al., 2018).

Gonococcal conjunctivitis is characterized by sudden onset of profuse and purulent discharge presenting within 12 h of acquiring the infection. Eyelids will be red, inflamed, swollen, and edematous, with the presence of corneal ulceration and perforation. Unlike other types of conjunctivitis, patients may present with systemic symptoms (Bowling, 2015; McAnena et al., 2015; Therapeutic Guidelines, 2014; Zikic et al., 2018). For the treatment of gonococcal conjunctivitis, regular irrigation of the eye with saline throughout the day is recommended until discharge decreases. Gonococcal conjunctivitis is highly contagious and eye hygiene should be observed (Cohen, 2009). Systemic antibiotic therapy, such as a third-generation cephalosporin, is recommended (Bowling, 2015). The presence of gonococcal conjunctivitis is commonly complicated by genitourinary and epipharyngeal chlamydial infections, and therefore, topical antimicrobial treatment is inadequate and is not indicated (Nakagawa, 1997; Zikic et al., 2018). In cases where there is coinfection of chlamydia, treatment with a single dose of azithromycin described in the previous section is recommended (see chlamydial conjunctivitis) (Bowling, 2015; McAnena et al., 2015; Therapeutic Guidelines, 2014).

Viral Conjunctivitis

Viral conjunctivitis is typically caused by adenovirus associated with a recent viral upper respiratory tract infection. On occasion, the conjunctivitis may be a prodromal symptom of a viral infection, which is followed by fever, pharyngitis, and upper respiratory tract infection (Azari and Barney, 2013; O'Brien et al., 2009). Symptoms of viral conjunctivitis occur unilaterally and are characterized by watery or mucous discharge, with a sensation of burning or sand in the eye (Azari and Barney, 2013). It is less contagious than bacterial conjunctivitis, but transmission to the adjacent eye can also occur after two to three days (Azari and Barney, 2013; O'Brien et al., 2009). Viral conjunctivitis can be distinguished from bacterial infection by a more watery discharge. However, patients may still experience initial morning crusting of the eye lids two weeks after the initial symptoms despite resolution of other symptoms (Azari and Barney, 2013; O'Brien et al., 2009).

Viral conjunctivitis is usually self-limiting and does not require topical or systemic antiviral therapy (Bowling, 2015; Therapeutic Guidelines, 2014). Symptoms frequently worsen for the first three to five days, with a very gradual resolution over three weeks (Azari and Barney, 2013; O'Brien et al., 2009). Viral conjunctivitis is contagious, and appropriate eye hygiene is encouraged. For the treatment of viral conjunctivitis, there is no specific effective pharmacotherapy. Antivirals and topical antibiotics are not indicated for this infection, as they have limited effect. Symptomatic management can alleviate clinical symptoms of viral conjunctivitis, and cold compresses are used for vasoconstriction to minimize watery discharge from the eye. Alternatively, topical vasoconstrictors and antihistamines may also be used. Lubricant eye drops are recommended for comfort and relief of burning, gritty sensation. In cases where pain and fever are present, paracetamol or NSAIDs can be used for analgesic and antipyretic effect (Azari and Barney, 2013; Bowling, 2015; O'Brien et al., 2009; Therapeutic Guidelines, 2014). Topical corticosteroids are not indicated as initial treatment, particularly if HSV infection is suspected (Azari and Barney, 2013; O'Brien et al., 2009). If topical corticosteroids are required, dexamethasone or prednisone eye drops can be used up to six times a day but should be ceased if symptoms do not resolve after two to three weeks (Bowling, 2015; Therapeutic Guidelines, 2014).

Treatment of Corneal Infections

Keratitis describes the inflammation of the cornea caused by microbial infection. Keratitis is associated with decreased visual acuity and, if untreated, may result in blindness. Microbial keratitis is characterized by a subacute onset of pain and redness. It is usually

manifested unilaterally but may be present in both eyes. Patients may also describe a sensation of feeling a foreign body in the eye, worsening photophobia (Bowling, 2015; Therapeutic Guidelines, 2014). Conjunctival injection (blood shot eyes), and corneal ulceration, which may result in impaired vision, may also be present. Clinical signs do not reliably distinguish between different causative organisms, and priority should be given to taking scrapings to identify pathogens as soon as possible and directing therapy accordingly (Tabbara et al., 2000).

Bacterial Keratitis

Bacterial keratitis mostly occurs among patients who wear contact lenses or with a history of ocular injury. As described in previous sections, the incidence of keratitis varies significantly between countries who have higher number of contact lens users, due to hygiene considerations (Al-Mujaini et al., 2009; Tabbara et al., 2000). The distinguishing clinical feature for bacterial keratitis is the presence of a white spot on the surface of the eye, often seen even without a slit-lamp examination (Tabbara et al., 2000; Thomas and Kaliamurthy, 2013). The most common causative organism for bacterial keratitis is *Staphylococci*, *Streptococci*, and Gram-negative *Bacilli* such as *Pseudomonas* (Austin et al., 2017; Tabbara et al., 2000; Thomas and Kaliamurthy, 2013). **Figs. 2–4** show common presentations of bacterial keratitis.

Corneal scrapings should be performed immediately before the commencement of treatment. Systemic antimicrobial treatment is generally not indicated in bacterial keratitis, but may be considered if there is suspected risk of developing endophthalmitis or bacterial scleritis (Austin et al., 2017; Bowling, 2015; Thomas and Kaliamurthy, 2013). Initial treatment should be commenced as soon as possible with a broad-spectrum antibiotic to cover both Gram-positive and Gram-negative pathogens (Austin et al., 2017).

Antibiotic management is prescribed according to the severity of the infection and the level of risk for visual loss or blindness (Austin et al., 2017; Gerstenblith and Rabinowitz, 2012; Thomas and Kaliamurthy, 2013). Mild bacterial keratitis has a lower risk of visual loss and is characterized by minimal anterior chamber involvement and no discharge. As such, the treatment of mild bacterial keratitis usually includes topical fluoroquinolones eye drops, such as ofloxacin or ciprofloxacin. Hourly treatment is essential

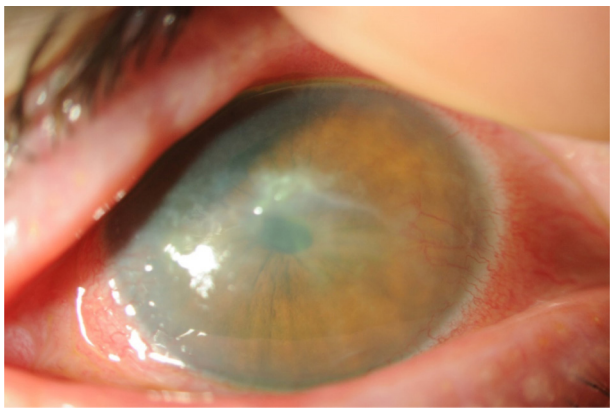

Figure 2 Bacterial keratitis characterized by a purulent opaque layer with a typical white spot on the surface of the cornea, which can be seen even without a slit lamp.

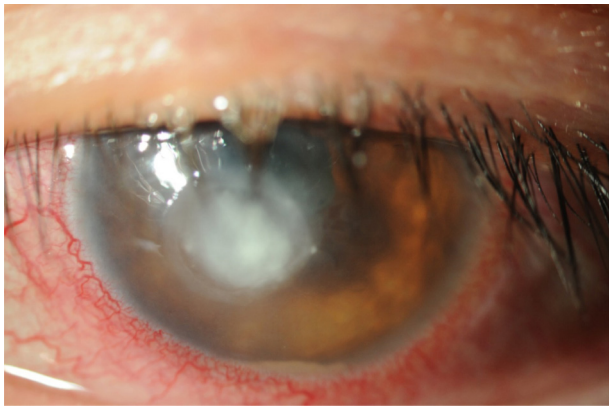

Figure 3 Bacterial keratitis with a more prominent white infiltrate on the cornea. Redness of the eye is reflective of the inflammation and pain caused by the microbial infection. White spot can also be indicative of a corneal ulcer.

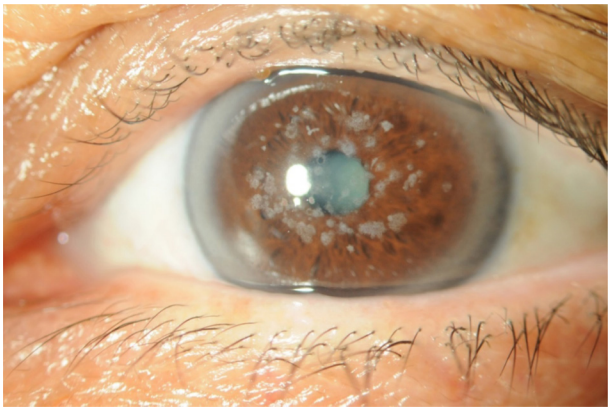

Figure 4 Typical crystalline Streptococcal bacterial keratitis, characterized by surface growth on the cornea. Hyperinflammation usually occurs at the induction of treatment before infection resolves with ongoing topical bacterial treatment.

during the first few days to ensure adequate therapeutic tissue concentrations and control of the infection. For patients who are contact lens wearers (Gokhale, 2008; Sueke et al., 2010), the addition of a topical antibiotic ointment (for example, tobramycin) at night may be beneficial for sustained effect. In cases where risk of visual loss is borderline, distinguished by epithelial and anterior chamber involvement, topical fluoroquinolones, administered hourly, are the treatment of choice (Sueke et al., 2010). Although ciprofloxacin has a better inhibitory effect against *Pseudomonas aeruginosa* and *Serratia*, moxifloxacin should be considered for superior Gram-negative cover (Hindman et al., 2009; Sueke et al., 2010).

Severe keratitis is vision threatening and is indicated with presence of large ulcers >1–2 cm, or when the infection is unresponsive to initial treatment. Fortified aminoglycoside plus cefalotin/cefazolin (5% w/v) eye drops are the recommended therapies (Ly et al., 2006; Therapeutic Guidelines, 2014; Wong et al., 2003). The aminoglycoside antibiotics used in fortified drops are gentamicin (0.9% w/v) and tobramycin (1.4% w/v) and have an excellent Gram-negative coverage (Ly et al., 2006; Wong et al., 2003). Topical treatment should be commenced every hour, and administered throughout a 24-h period.

The practice patterns in using fortified antibiotic eye drops for the treatment of bacterial keratitis has changed as antimicrobial resistance emerged. A recent international study recorded that clinicians prefer fortified antibiotics versus fluoroquinolone monotherapy, particularly in the United States where there is a greater concern with resistant organisms (Tuft and Burton, 2013). However, it is important to note that fortified preservative-free gentamicin/tobramycin and cefalotin/cefazolin ophthalmic drops are not available commercially and require manufacturing from specialized units in hospitals or pharmacies. Loading doses of topical treatment have been suggested for more severe infections, commencing at a frequency of one drop every five minutes for the first five doses or thirty minutes, and then every half hourly for the first 24 h (Bowling, 2015; Cohen, 2009; Sueke et al., 2010; Tuft and Burton, 2013). Prolonged use of topical aminoglycosides such as gentamicin may cause epithelial toxicity or necrosis and delayed recovery. In these cases, topical therapy may be replaced by topical fluoroquinolone drops, and subsequently be modified according to the results of bacterial sensitivity.

Cycloplegic agents are important adjuvant therapies in the management of microbial keratitis and are indicated when there is substantial anterior chamber inflammation. They are administered twice to three times daily, to decrease pain as well as synechia formation in bacterial keratitis. Topical corticosteroids are not usually part of the initial treatment regimen, and the place of adjuvant corticosteroids in the treatment of bacterial keratitis has been debated (Chung et al., 1998). The use of corticosteroids may be beneficial to improve outcomes by decreasing inflammation, thereby reducing scarring. However, corticosteroids may delay epithelial healing in keratitis and may even worsen infection (Chung et al., 1998; Schein, 2016). In some practices, topical corticosteroids are commenced after 24 h of topical antibiotics. Preservative-free formulations should be used where available to reduce epithelial toxicity.

In patients at risk of corneal perforation, antimetalloproteinases may be useful as they have proven anticollagenolytic activity to prevent progression of corneal necrosis and tissue breakdown (McElvanney, 2003). Tetracyclines, such as doxycycline, have been shown to display antimetalloproteinase properties and can achieve therapeutic levels in the anterior segment of the eye (McElvanney, 2003). Oral doxycycline 100 mg twice daily maybe be useful in these patients (Gerstenblith and Rabinowitz, 2012). In eyes with corneal thinning, a shield should be used to protect the ocular surface (Gerstenblith and Rabinowitz, 2012).

Fungal Keratitis

Fungal keratitis is a slower progressing form of keratitis, found more commonly in tropical climates. It is diagnosed primarily through PCR tests or cultures collected from corneal scrapings. The most common pathogens for fungal keratitis are usually *Aspergillus*, *Fusarium*, or *Candida* species (Austin et al., 2017; Therapeutic Guidelines, 2014). Compared to bacterial keratitis, the incidence of fungal infection is much lower but can have a high risk of causing loss of vision (Medoff and Kobayashi, 1980). In tropical areas, fungal infections have been documented to be responsible for 50% of corneal ulcers, and they carry a worse prognosis

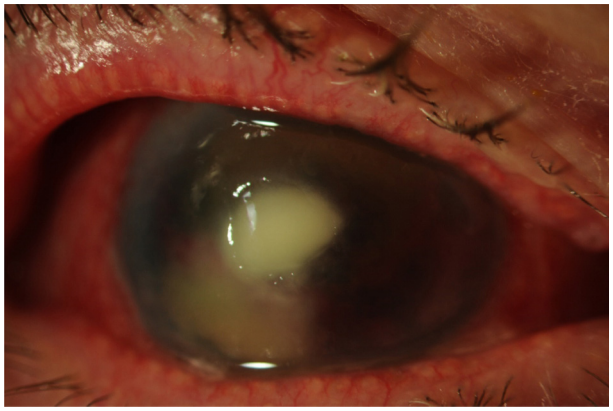

Figure 5 Slit-lamp image of fungal keratitis, typically with white spot with filamentous or "fluffy" edges. Identification of fungal keratitis, without a slit lamp, can be made with characteristic remarkable opaque infiltrate on one section of the cornea.

compared with bacterial keratitis as they are associated with higher rates of corneal perforations (Austin et al., 2017; Medoff and Kobayashi, 1980). Common presentation of fungal keratitis is shown in **Fig. 5**.

Studies have described the empirical and preferred treatment for fungal keratitis is topical natamycin, as it is active against *Fusarium* and *Aspergillus* (Xie et al., 2001). Natamycin works by binding to fungal plasma membrane and causes disruptions by altering membrane permeability and is commercially available in eye drop formulation (Xie et al., 2001). In cases of suspected fungal keratitis, and for established filamentary fungal infection, natamycin is generally administered every 1–2 h throughout the day and reduced according to clinical response (Ansari et al., 2013; Xie et al., 2001). Topical chlorhexidine 0.02% with the addition of topical voriconazole can be used as an alternative if natamycin is unavailable (FlorCruz and Evans, 2015). Topical amphotericin 0.15% every 1–2 h is the recommended treatment if *Candida* species has been isolated (Ansari et al., 2013; Yu et al., 2004).

Systemic (oral) and topical voriconazole may be beneficial in treating patients with *Fusarium* species for the treatment of deep corneal ulcers or suspected fungal endophthalmitis (Medoff and Kobayashi, 1980; Prajna et al., 2016). Therapeutic drug monitoring of voriconazole is recommended as it has a narrow therapeutic range, nonlinear pharmacokinetics and is primarily metabolized by CYP2C19 in the liver (Li et al., 2016). A meta-analysis has shown that CYP2C19 displays polymorphism with poor metabolizers exhibiting higher voriconazole trough concentrations than intermediate of extensive metabolizers (Li et al., 2016). Furthermore, the meta-analysis showed that extensive metabolizers had poorer treatment success rates than poor metabolizers, as they may not have achieved adequate levels of voriconazole (Li et al., 2016). Although limited evidence exists on the appropriate levels required in ophthalmology, it has been recommended that trough concentrations of between 1 mg/L and 4–6 mg/L are effective without causing toxicity (Rossi, 2018). To achieve therapeutic levels in a timely manner, loading doses are recommended commencing at 400 mg twice daily and reducing to 200 mg twice daily thereafter (Bowling, 2015; Therapeutic Guidelines, 2014; Yu et al., 2004).

Cycloplegic agents can be used in the management of pain associated with keratitis. Topical or oral corticosteroids are not recommended in fungal keratitis. Existing corticosteroid therapy for other comorbidities should be tapered rapidly and discontinued (Sueke et al., 2010).

Acanthamoeba Keratitis

Acanthamoeba keratitis is a rare protozoal infection of the eye, with recent increased incidence (Yu et al., 2004). The infection is commonly misdiagnosed for noninfectious or bacterial, fungal, or viral keratitis. Acanthamoeba keratitis is often caused by poor contact lens hygiene (such as swimming, showering, and face washing whilst wearing contact lenses) or corneal trauma involving soil or contaminated water.

Clinical features of acanthamoeba keratitis are not useful as a diagnostic tool, as presentation of the infection varies greatly. Patients may present with manifestations indicative of other less sight-threatening eye infections, so rapid differential diagnosis is essential by assessing clinical signs, as well as patient history (Lorenzo-Morales et al., 2015; Simitzis-Le et al., 1989; Yu et al., 2004). Symptoms of acanthamoeba keratitis include severe eye pain and sensation of foreign body. Photophobia and visual disturbances, such as deceased visual acuity, are also commonly described. Epiphora, or increased tearing of the eyes, and redness are also present. Infection presents unilaterally, but cases of bilateral infection have been reported. Immediate cultures and swabs of the eye should be taken, and therapy should be directed appropriately (Lorenzo-Morales et al., 2015; Simitzis-Le et al., 1989). **Figs. 6 and 7** show common presentations of acanthamoeba keratitis.

The aim of topical treatment is to eliminate amoebic cysts (Lorenzo-Morales et al., 2015; Simitzis-Le et al., 1989). Topical polyhexanide (also referred to as polyhexamethylene biguanide, PMHB) and chlorhexidine, administered every hour, are the recommended treatments for acanthamoeba keratitis. The two agents can be used interchangeably as there is absence of documented evidence that one is superior to the other. However, it has been suggested that polyhexanide may be superior due to its cysticidal effects (Simitzis-Le et al., 1989). In some practice settings, dual therapy of topical polyhexanide and chlorhexidine are

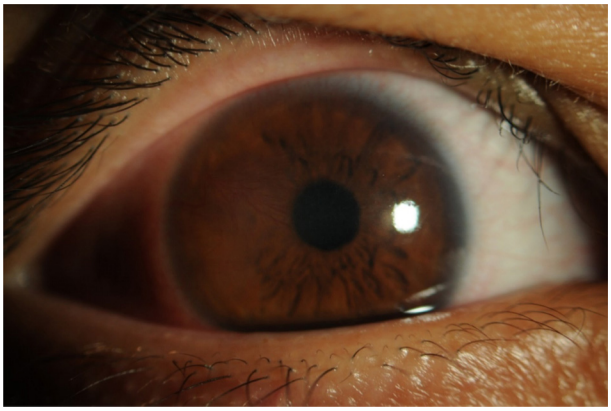

Figure 6 Acanthamoeba keratitis is difficult to differentially diagnose. At times, the typical white infiltrate may be present but in the initial stage of infection, the eye has less opacity, but with a distinct 360° stromal ring surrounding the iris.

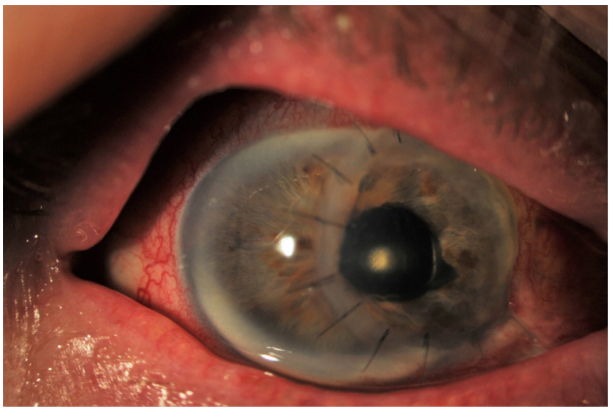

Figure 7 Enhanced slit-lamp image of Acanthamoeba keratitis with distinct stromal ring around the iris.

commonly used (Ferrari et al., 2011; Lorenzo-Morales et al., 2015; Simitzis-Le et al., 1989). In addition, the use of double biguanide therapy has been described for additional and superior treatment outcomes. Hexamidine eye drops can be prescribed in conjunction with both PMHB and/or chlorhexidine (Ferrari et al., 2011). In countries where hexamidine is not available, propamidine isethionate 0.1% eye drops may be a suitable alternative (Chu and Hu, 2013; Gerstenblith and Rabinowitz, 2012).

Corticosteroid therapy is not recommended during the initial treatment of acanthamoeba keratitis as it may affect the immune response thought to be important in elimination of acanthamoeba infection. Subsequently, this may delay recovery and adversely affect outcome (Gokhale, 2008).

Atypical Keratitis

The incidence of atypical keratitis is very rare. It is usually caused by mycobacteria or Gram-positive nocardia, which can be found in soil, dust, or water. Mycobacterium keratitis is difficult to identify, often incorrectly misdiagnosed as other forms of keratitis, and subsequently results in significant delays in treatment. Atypical keratitis can be treated with topical antimicrobials or in combination with systemic treatment. Most infections require the use of more than two types of antibiotics, such as a macrolides, fluoroquinolones, and amikacin (Gerstenblith and Rabinowitz, 2012; Kampougeris et al., 2005; Tabbara, 2007). Topical moxifloxacin is the fluoroquinolone of choice with higher ocular penetration and is used in *mycobacterium* infection (García-Sáenz et al., 2001; Tabbara, 2007). Amikacin eye drops are effective if *Nocardia* species is suspected. Initially, hourly topical therapy should be commenced, with gradual tapering of treatment according to clinical response (Grigg et al., 1992; Tabbara, 2007). If systemic antimicrobials are required, oral moxifloxacin or clarithromycin has been described as an additional therapy (Bowling, 2015; Chu and Hu, 2013).

Herpes Simplex Keratitis

Herpes simplex keratitis is caused by the herpes simplex virus (HSV) or the reactivation of latent herpes simplex virus infection. Herpes simplex keratitis (also known as HSV keratitis) may be further classified as epithelial keratitis or stromal keratitis

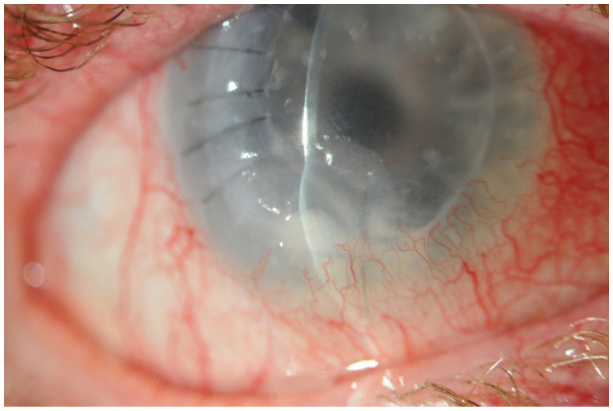

Figure 8 Typical purulent opaque layer of microbial keratitis. Herpetic infection is generally characterized by conjunctival injection (or blood shot) eyes.

(Bowling, 2015; Farooq and Shukla, 2012; Therapeutic Guidelines, 2014). Epithelial keratitis generally resolves within one to two weeks, and may not require treatment while stromal keratitis may include corneal scarring, that can lead to pain and loss of vision. Confirmation of HSV keratitis usually occurs through fluorescein corneal staining or PCR testing in conjunction with slit lamp examination (Bowling, 2015). Patients with HSV keratitis may present with similar symptoms of other ocular inflammation such as blepharitis, dacryocystitis, retinitis, or iritis (**Fig. 8**). Unilateral infection is common, though both eyes may be affected in immunocompromised patients. Other symptoms may include extensive ulceration of the cornea and associated severe pain, sensation of a foreign body in the eye, photophobia, and epiphora (Bowling, 2015).

Both oral and topical antiviral treatment is recommended in the treatment of HSV keratitis (Catron and Hern, 2008; Farooq and Shukla, 2012; Tsatsos et al., 2016). Topical aciclovir 3% ointment is commonly used, applied five times a day for 14 days. Ganciclovir 0.15% eye gel is generally reserved for refractory or severe herpes simplex keratitis not responding to other treatment (Bowling, 2015). Systemic antivirals can also be used monotherapy or in combination with a topical antiviral. Oral aciclovir (400–800 mg), valaciclovir (1 g), or famciclovir (250–500 mg) are usually given three to five times a day for 7–10 days (Bowling, 2015; Therapeutic Guidelines, 2014; Tsatsos et al., 2016).′ Oral therapy has been implicated as the preferred treatment choice in stromal keratitis as topical treatment can lead to scarring and possible nasolacrimal duct obstruction. It is also documented that oral therapy may have superior effects compared to topical therapy due to greater ocular penetration (Tsatsos et al., 2016).

Topical or oral corticosteroids are contraindicated in active and epithelial herpetic infection but may be effective to control severe inflammation and assist with pain when used with an antiviral to manage later-stage stromal involvement or uveitis. Again, topical cycloplegic adjuvant therapy can assist relieve photophobia and reduce pain (Bowling, 2015; Tsatsos et al., 2016).

Herpes Zoster Ophthalmicus

Herpes zoster ophthalmicus (HZO) describes shingles involving the dermatome supplied by the ophthalmic division of the fifth cranial (trigeminal) nerve (Bowling, 2015). Varicella-zoster virus (VZV) causes both chicken-pox (varicella) and shingles (herpes zoster). Reactivation of VZV is the most common cause of viral ophthalmicus (Bowling, 2015). The difference between herpes simplex keratitis and HZO is the noticeable and recognizable dermatological presentation in the latter disorder. Patients with HZO usually present with skin and mucosal involvement typical of standard zoster infection. Reactivation of the infection involves the trigeminal nerve in 15% of patients, and subsequently the eye (Therapeutic Guidelines, 2014). Initial manifestations and symptoms can be similar to other infective eye disorders and may be difficult to differentially diagnose. Confirmation of HZO can be confirmed by other VZV characteristics on the skin and past history of infection (Tsatsos et al., 2016). For the treatment of HZO, systemic antiviral therapy is recommended and commenced within 72 h of onset of symptoms. Initial treatment is the same as for herpes simplex keratitis, including systemic use of aciclovir, valaciclovir, and famciclovir (Bowling, 2015). Topical aciclovir ointment can also be used in addition in severe cases of HZO.

Treatment of Posterior Eye Infections

Posterior eye infections include those of the sclera, retina, vitreous humor, and possibly the optic nerve.

Endophthalmitis

Endophthalmitis is usually caused by infection leading to an inflammatory condition of the intraocular cavity (Bowling, 2015; Ciulla et al., 1997; Therapeutic Guidelines, 2014). Inflammation affects one or more layers of the eye and an adjacent cavity (anterior, posterior chamber) or vitreous cavity. Onset of endophthalmitis is usually acute and characterized by impaired vision,

Table 3 Most common organisms in endophthalmitis

Bacterial:
Gram-positive bacteria (75%–85%)
Staphylococcus epidermidis 43%
Streptococcus spp. 20%
Staphylococcus aureus 15%
Propionibacterium acnes 30 reports
Bacillus cereus 1%
Gram-negative bacteria (10%–15%)
Pseudomonas 8%
Proteus 5%
Haemophilus influenzae 0%–1%
Klebsiella 0%–1%
Coliform spp. 0%–1%
Fungal (rare)
Candida parapsilosis
Aspergillus
Cephalosporium

Source: Modified from Sunaric and Pournaras (1997).

edema in the eyelid, congested eye, and redness. Pain, which was initially considered essential in diagnosis, can be absent in approximately 25% of cases (Ciulla et al., 1997).

Studies have reported that the infecting organism profile is very similar to periocular microbes, which may suggest endophthalmitis is caused by the patient's own flora. **Table 3** shows the most common causative pathogens in endophthalmitis (Sunaric and Pournaras, 1997).

Bacterial Endophthalmitis

Endophthalmitis is a serious condition that can lead to vision loss. Due to the vision threatening nature of endophthalmitis, empirical treatment of intravitreal antimicrobials is given immediately, while investigations are undertaken to determine the causative organisms. A 10-year review of bacterial endophthalmitis isolates in the United States observed that no single agent provided effective treatment for all isolated microbes (Schimel et al., 2013). As such, empirical treatment includes the combination of (Therapeutic Guidelines, 2014) intravitreal vancomycin (1.0–2.0 mg in 0.1 mL) and a broad-spectrum cephalosporin, such as ceftazidime (2–2.25 mg in 0.1 mL) (Schwartz and Flynn, 2014). Vancomycin covers Gram-positive organisms, including methicillin-resistant Staphylococcus aureus (MRSA), while broad-spectrum cephalosporins and quinolones cover Gram-negative organisms (Schimel et al., 2013). Intravitreal amikacin is generally not recommended due to the possibility of retinal toxicity (Bhagat et al., 2011), although its use has been described in the Endophthalmitis Vitrectomy Study (Doft and Barza, 2004; Han et al., 1996). Intravitreal treatment can be repeated after 48–72 h if there is no improvement (Bowling, 2015). Acute-onset postoperative endophthalmitis with multidrug-resistant organisms occurs rarely (Khera et al., 2013). Alternative intravitreal agents, such as moxifloxacin, have been reported useful in these situations (Bowling, 2015).

As an adjunct, systemic fluoroquinolones have been shown to have adequate ocular penetration to achieve therapeutic levels (Pathengay et al., 2006). Ciprofloxacin is the fluoroquinolone of choice, but recently studies have suggested that moxifloxacin has superior effect with more rapid resolution of inflammation in the interior chamber and superior ocular effects compared to other quinolones. However, moxifloxacin is not active against *Pseudomonas* infection and should not be used if it is suspected.

The use of corticosteroids is controversial. Although corticosteroids have a theoretical role in reducing inflammation-related ocular damage associated with endophthalmitis, limited evidence supports its use. One pilot series of five patients showed that (Pathengay et al., 2006) the use of intravitreal triamcinolone acetonide 48–72 h after initial treatment with antibiotics was associated with favorable clinical outcomes (Pathengay et al., 2006). However, additional studies are required before recommending its routine use. If corticosteroids are used, intravitreal dexamethasone or triamcinolone (0.4 mg in 0.1 mL) or topical dexamethasone 0.5% or prednisolone acetate 1% may be suitable (Bowling, 2015; Riddell et al., 2011). Oral corticosteroid may be commenced 24 h after intravitreal injection if corticosteroid therapy is not contraindicated by patient factors or suspected fungal infection (Pathengay et al., 2006). Preservative free eye drops are recommended as high frequency treatment is required and intraocular toxicity from preservatives can occur, particularly if open globe injuries are suspected (Bowling, 2015).

Fungal Endophthalmitis

Fungal endophthalmitis is rare but occurs more frequently as a complication of candidemia compared to invasive aspergillosis (**Fig. 9**). Penetration of systemically administered antifungal agents is highly variable, as absorption of these drugs into the posterior segment of the eye is difficult. Riddell et al. (2011) documents that amphotericin B achieves very poor concentrations (Riddell et al., 2011). However, the study showed that voriconazole achieved high concentrations in the vitreous, where therapeutic concentrations were most significant for the treatment of *Candida* and *Aspergillus* (Riddell et al., 2011). Recently, intravitreal

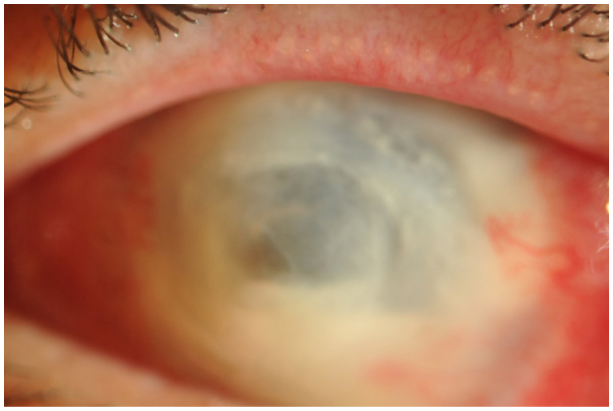

Figure 9 Severe Fungal Endophthalmitis characterized by a matt-like opacity due to infiltrate of fungal filaments.

administration has become more common, where amphotericin is administered into the vitreous space at a dose of 5–10 μg in 0.1 mL and voriconazole at 0.05 mg in 0.1 mL (Bowling, 2015; Riddell et al., 2011). Oral voriconazole may also be used for 5–6 weeks due to slow clinical response and resolution of fungal infections. Once fungal species have been confirmed, therapy can be altered to fluconazole for candida or itraconazole for aspergillus (Bowling, 2015; Gerstenblith and Rabinowitz, 2012).

Viral Retinitis

Viral retinitis can be caused by cytomegalovirus, herpes simplex virus, or varicella-zoster virus in immune compromised patient. All types of viral retinitis have a high risk of vision loss and require immediate referral.

Cytomegalovirus Retinitis

Cytomegalovirus retinitis is the most common type of viral retinitis and is predominantly described in patients with human immunodeficiency virus (HIV) infection. HIV markers are useful in diagnosing CMV retinitis as approximately 15%–40% of HIV patients are affected by the disease (Bowling, 2015). If CMV retinitis is suspected, clinicians should order a CD4 count screen, CD8+ T-lymphocyte count, CMV DNA capture PCR test, DNA PCR (from ocular fluids), viral load, and complete blood count (Bowling, 2015). Typically, patients with CMVR present with a painless, red, and inflamed eyes. Although it is painless, patients may feel some discomfort in their eye, such as a feeling of foreign objects or have specks in their visual field. CMV retinitis is often described as having a "cottage cheese with tomato sauce" appearance due to perivascular hemorrhage (Fig. 10).

Drugs used for the treatment of CMVR retinitis are virostatic and therefore do not eliminate the infection or prevent recurrence of the infection. Treatment is directed by the cause of immunosuppression. In addition, intravitreal foscarnet (2.4 mg in 0.1 mL) may be used with oral antiviral therapy. Oral valganciclovir is generally the treatment of choice and commenced at 900 mg twice daily for

Figure 10 Cytomegalovirus retinitis slit-lamp image displaying typical opacity with red vasculature, often described as "cottage cheese with tomato sauce."

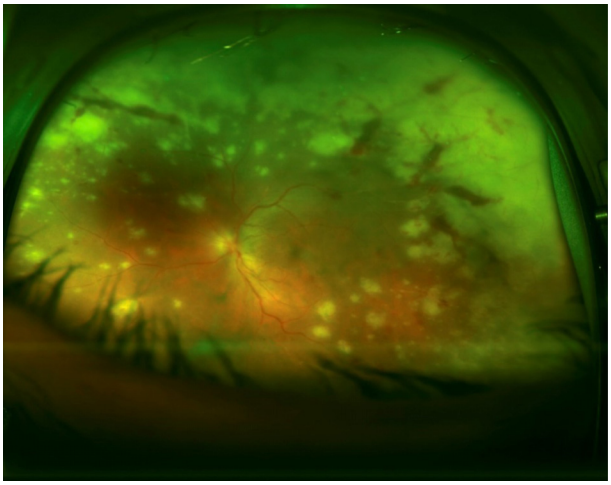

Figure 11 Acute retinal necrosis cannot be differentially diagnosed without slit-lamp imagine and PCR testing of microbial strains. Image shows characteristic opaque patches and thickening of the retina.

two to three weeks, and then reduced to 900 mg daily (Bowling, 2015; Gerstenblith and Rabinowitz, 2012). In refractory disease, intravenous cidofovir is used concomitantly with oral probenecid as a nephroprotectant (Wolf et al., 2003).

Systemic corticosteroids are not recommended in the management of CMV retinitis. The use of intravitreal, dexamethasone (unpreserved) 4 mg per 0.1 mL administered with intravitreal antivirals, topical preservative-free corticosteroid, or oral corticosteroid have also been described in literature to manage ocular inflammation (Gerstenblith and Rabinowitz, 2012).

Acute Retinal Necrosis

Acute retinal necrosis (ARN) generally presents as necrotizing retinitis caused by a viral infection of the retina, typically VZV or HSV. ARN can occur in healthy individuals but is twice as common in males than in females and is often presents with a history of immunosuppression. ARN is mostly due to HSV in younger patients, and VZV in the older population. ARN caused by cytomegalovirus, syphilis, or toxoplasmosis is rare (Bowling, 2015). ARN is characterized by acute pain and photophobia. Patients may also describe vision disturbances, decreased vision, and presence of floaters. Diagnosis of ARN is through an eye examination, which will show multiple white opaque patches and thinning of the retina is typical of the disease (**Fig. 11**). Severe inflammation may result in difficulty to differentially diagnose between ARN and other ocular disease. Confirmation of disease is via cultures obtained through a vitreous procedure and PCR results. Confirmation of sensitivities may direct therapy (Bowling, 2015; Shantha et al., 2015; Therapeutic Guidelines, 2014).

ARN should be treated immediately and aggressively with systemic and intravitreal antiviral therapy. Advancements in pharmacotherapy and experience with intravitreal injections have resulted in intravitreal foscarnet (2.4 mg in 0.1 mL) being the preferred initial treatment. A single injection can be easily administered, and then repeated once ARN is confirmed (Bowling, 2015; Kawaguchi et al., 2008; Shantha et al., 2015). Systemic therapy is also recommended with the aim to inhibit viral replication and halt disease progression in the affected eye and prevent involvement of the unaffected eye (Shantha et al., 2015). Systemic therapy for ARN includes aciclovir, valaciclovir, famciclovir, valganciclovir, foscarnet, and ganciclovir (Bowling, 2015; Kawaguchi et al., 2008; Shantha et al., 2015). Oral maintenance treatment with valaciclovir (1 g 3 times a day) or aciclovir, may be used up to 14 weeks from the onset of infection depending on clinical response.

Cycloplegic agents and anticholinergic treatments can be used as adjuvant therapies in the management of acute retinal necrosis. If inflammation is present in the anterior segment of the eye, topical corticosteroids may be used.

Studies show that vascular occlusion and ischemia of the retina are also involved in ARN. As such, aspirin 100 mg daily and oral corticosteroid treatment have a place in treatment to prevent platelet aggregation (Gerstenblith and Rabinowitz, 2012). Heparin and warfarin have also been reviewed, but currently there is no robust evidence for anticoagulation in ARN treatment (Shantha et al., 2015). Systemic corticosteroids are considered when optic nerve involvement is suspected. Delaying corticosteroid therapy is advised and should only be commenced at least 24 h after the initiation of antiviral therapy (Bowling, 2015; Kawaguchi et al., 2008; Shantha et al., 2015).

Ocular Toxoplasmosis

Ocular toxoplasmosis is a progressive and recurring necrotizing retinitis, with vision-threatening complications. Ocular toxoplasmosis can be congenital or acquired, and worldwide, toxoplasmosis is the most common cause of posterior uveitis (Bowling, 2015; Duane et al., 2013). Ocular toxoplasmosis is caused by *Toxoplasma gondii*, a single cell intracellular protozoan opportunistic organism. Primary infection can occur with exposure to high-risk environments, such as tropical, warm, and wet areas, compared

to areas that have low humidity. The most common host for *Toxoplasma gondii* is felines, but humans, reptiles, and avian hosts are also possible (Hovakimyan and Cunningham, 2002).

Toxoplasmosis is characterized by blurred vision and floaters. Infection can cause inflammation of the iris which results in eye pain and redness. Diagnosis is through PCR, and testing both the aqueous and vitreous humor for positive cultures of *Toxoplasma gondii* immunoglobulin (Duane et al., 2013; Hovakimyan and Cunningham, 2002).

Mild and non sight-threatening disease does not require medical management as it is generally self-limiting in immunocompetent patients. Pharmacological treatment is only required when major vessels, or the infection, extend beyond the peripheral section of the eye. If medications are required, a combination drug regimen is generally recommended and includes the use of pyrimethamine, folinic acid, sulfadiazine, clindamycin, and corticosteroids (Bowling, 2015; Duane et al., 2013; Stanford et al., 2003). Pyrimethamine is probably the most effective single drug as it interferes with parasite replication by inhibiting the folate production pathway. It is therefore coadministered with folinic acid (15 mg) to protect against bone marrow suppression in the host. Clindamycin interferes with protein synthesis and can be used as a single drug or in combination with corticosteroids. Clindamycin may also be given as an intravitreal injection as initial empirical treatment (Kishore et al., 2001; Stanford et al., 2003).

The Role of the Pharmacist

In acute eye infections, pharmacists have an important role to ensure resolution of infection and to improve patient outcomes. Eye hygiene is the cornerstone for most treatment to prevent the spread and worsening of the infection. These principles compliment pharmacists' role in antimicrobial stewardship to reduce antimicrobial use and resistance. As primary health-care professionals, pharmacists should also be able to recognize severe infection and ensure early referral. Pharmacists have the responsibility of ensuring patients can remain adherent to their medication regimen, which can be complicated by the use of compounded eye drops that are often used for eye infections.

Hygiene and Antimicrobial Stewardship

Nearly all eye infections require patients to maintain eye hygiene to prevent the spread and progression of the infection. Cross infection may occur through contaminated instruments, hands, communal towels, droplets, and the eye drop bottles. In addition, patients with dry eye or inadequate lid closure are more susceptible to cross infection. Pharmacists should encourage patients to wash their hands often with soap and warm water and avoid touching or rubbing their eyes. It is also recommended that patients wash their pillowcases, sheets, and towels often in hot water and detergent (National Center for Immunization and Respiratory Diseases (NCIRD) Division of Viral Diseases, 2019). Patients should also avoid sharing pillows and towels (Rutter, 2017). If possible, clear any discharge from the eye with sterile sodium chloride 0.9% before using other ocular medications (Rossi, 2018). If patients use tissues to wipe discharge from the eye, the tissue should be thrown away immediately (Rutter, 2017). Patients that wear contact lenses should also be advised not to wear them until 24 h after the infection has resolved (Rossi, 2018).

Pharmacists should also be guided by antimicrobial stewardship principles to prevent the growing rise of antimicrobial resistance. Historically, overuse of antimicrobials has been the primary driver for the rise of antimicrobial resistance. Limiting the use of antimicrobials to only clinical cases that will benefit from their use is recommended. An example of this is the treatment of conjunctivitis in the pharmacy. As up to 80% of infective conjunctivitis are caused by viruses and are self-limiting, antibiotics should not be recommended and instead pharmacists should focus on eye hygiene counseling for these patients (Azari and Barney, 2013; Rutter, 2017). However, if the patient's symptoms persist for more than 5 days, they should be reassessed and antibiotics considered (Rutter, 2017).

When antimicrobials are used, pharmacists can ensure that appropriate empirical therapy is used based on clinical symptoms. Once the causative organisms and its sensitivities are confirmed, pharmacists may recommend switching to a narrow-spectrum antimicrobial to preserve broad-spectrum antimicrobials for more difficult cases.

Pharmacists should ensure that there is an estimated length of time of drug administration for all antimicrobials used. Excessive use of antimicrobials can cause hypersensitivity or toxicity reactions. In addition, using antimicrobials longer than necessary may facilitate the development of resistant strains of bacteria. The excessive use of multiple antimicrobials increases the risk of superinfection.

Referral

Community pharmacists are often presented with vague red eye symptoms from patients, and a thorough history and examination are required to determine a diagnosis. Minor ailments such as allergic and viral conjunctivitis can be managed within the pharmacy setting without referral (Azari and Barney, 2013). For bacterial conjunctivitis, some countries allow pharmacists to supply topical chloramphenicol eye drops or ointments to patients without a prescription (Robaei et al., 2015). However, any patients presenting with severe conjunctivitis with marked redness throughout the eye are best referred (Rutter, 2017). Furthermore, patients with contact lenses should be referred as they are more predisposed to keratitis because the space between the contact lens and cornea can act as an incubator for bacteria and enhance mechanical abrasion (Rutter, 2017).

Pharmacists should also be aware that a painful red eye should generally be referred. Although it is common for conjunctivitis to present with discomfort from ocular irritation, described as gritty, true pain would indicate a more serious condition, such as scleritis, uveitis, or keratitis (Rutter, 2017). Furthermore, a patient that presents with photophobia or distortion of vision should also be referred as these are symptoms not commonly presented with conjunctivitis (Rutter, 2017; Sehu, 2009). Pharmacists should also exclude the risk of a foreign body (e.g., metal, glass, wood, plastic, sand) or infection inside the eye before recommending any treatments. Patients who have recently had eye surgery or a history or welding/woodworking should also be referred (Rutter, 2017; Sehu, 2009).

Adherence

Treatment adherence and compliance is high in eye infection due to pain and discomfort of the disease, and administration of therapy has immediate and apparent outcomes (Dolz-Marco et al., 2015). However, in severe eye infections, low adherence of treatment may be due to high frequency of eye drops, particularly in the treatment of bacterial keratitis, which requires patients to administer eye drops every 5–30 min. Low adherece may also be due to difficulty in obtaining compounded antimicrobial eye drops. Subsequently, compounded eye drops have a very short shelf-life and may require special storage conditions, such as refrigeration. All these factors may lead to poor adherence in those requiring long-term treatments. Clear communication is crucial so patients are aware of their medication regimen, supply options, and appropriate storage requirements (Dolz-Marco et al., 2015).

Epilepsy: Management of Neurological Disorder and the Pharmacist's Role

Huma Rasheed, Hafiz Awais Nawaz, Syed Muhammad Muneeb Anjum, Muhammad Usman, Institute of Pharmaceutical Sciences, University of Veterinary and Animal Sciences, Lahore, Pakistan

Learning Objectives

- To understand etiology and diagnosis of epilepsy
- To understand the therapies, as well as monitoring of efficacy and toxicity of medicines
- To understand the pharmacist role of in the management of epilepsy

Take Home Messages

1. Choice of a therapy is related to seizure type and patient demographics.
2. Most of the antiepileptic drugs AEDs are narrow therapeutic index medicines requiring counseling on adverse drug reactions ADRs and therapeutic drug monitoring.
3. AEDs have a higher degree of drug interaction and therefore need additional counseling and use of written information on medicines.
4. Knowledge of emergency treatment of seizures is important for pharmacist working in community setting as it may help avoid further complication of disease.
5. Resistant epilepsies require special dosing management both for initiation and tapering.
6. Pharmacists can play an important role in managing disease and therapy in special patient groups, women and patients with psychiatric conditions.

Introduction to Epilepsy

Seizures and Epilepsy

Epilepsy is a brain disorder typically manifested by sudden brief periods of altered and diminished consciousness, involuntary movements, or convulsions due to abnormal electrical activity in the brain (Merriam-Webster, 2018; World Health Organization, 2018). Globally, epilepsy is one of the most common and significant diseases of the central nervous system (Löscher et al., 2013), affecting approximately 50–70 million people (Ngugi et al., 2010; World Health Organization, 2018). Approximately 4.6 million people develop epilepsy every year (Fiest et al., 2017). According to the International League Against Epilepsy (ILAE), someone is presumed epileptic when he or she has an epileptic seizure and "demonstrates a pathologic and enduring tendency to have recurrent seizures" (Fisher et al., 2014). Conceptually, an epileptic seizure is "a brief occurrence of signs and/or symptoms due to abnormal excessive or synchronous neuronal activity in the brain" (Fisher et al., 2005).

The imbalance between excitatory and inhibitory neuronal activity, overshooting and synchronous electrical discharges by groups of neurons in the brain, gives rise to epileptic seizures (Wu et al., 2015). The abnormal neuronal activity in neural pathways involved in seizure development, known as epileptic networks, may lead to inter-ictal and ictal epileptic activity (Luo et al., 2014; McCormick and Contreras, 2001). Although, the hallmark for epilepsy is the presence of epileptic seizures, it is important that seizures and epilepsies are considered and understood separately (Fisher et al., 2014; World Health Organization, 2018).

Diagnosis of Epilepsy

According to the ILAEs "new operational definition," epilepsy is diagnosed clinically, when someone has (1) at least two unprovoked or reflex seizures >24 h apart (2) one unprovoked or reflex seizure and the risk of at least 60% to have another within the following 10 years or (3) an epilepsy syndrome (Fisher, 2015; Fisher et al., 2014). A person does not necessarily become epileptic after one seizure, as at least 10% of people worldwide encounter one seizure during their lifetime (World Health Organization, 2018). However, epilepsy can be diagnosed after a single unprovoked seizure if sufficient supporting evidence such as inter-ictal EEG or brain imaging is available (Beretta et al., 2017).

Here unprovoked seizures also referred as spontaneous recurrent seizures (SRS), need to be distinguished from early or provoked or symptomatic seizures and their underlying diseases, which are therisk factors for the development of epilepsy (Löscher and Brandt, 2010; Pitkanen et al., 2016). Early seizures are caused by transient factors, for example, acute nervous system insults such as a stroke, trauma, toxicity, or infections (Beghi et al., 2010; Rizvi et al., 2017), high grade fever, concussions, or alcohol withdrawal (Scheffer et al., 2016), and are not a symptom of epilepsy, as they temporarily lower the seizure threshold of an otherwise normal brain (Fisher et al., 2014).

The burden of comorbidities in epileptic patients is often high (Keezer et al., 2016; Löscher et al., 2013; Tellez-Zenteno et al., 2007), as epilepsies are often associated with psychological, neurobiological, and cognitive disorders with social impact affecting the quality of life (Fisher et al., 2005; Jacoby et al., 2009; Rudzinski and Meador, 2013). A bilateral relationship between psychiatric disorders and epilepsy is also documented (Mula, 2017). Mood and anxiety disorders are pre-dominant in adults whereas intellectual disabilities, autism, and other developmental issues are common occurrence in pediatric patients (Mula, 2017).

Classification of Seizures

Epilepsies can be classified based upon the type of seizures and their underlying causes (Falco-Walter et al., 2018). Recently there have been revisions and updates in the classification of seizure types (Fisher et al., 2017a,b) and etiology of epilepsy (Scheffer et al., 2017). These classifications serve as an important tool for evaluating individuals presented with spontaneous seizures. It is also important to select therapy based on the seizures types (Scheffer et al., 2017) (**Fig. 1**).

Based on their key signs and symptoms, seizures can be of known (focal or generalized) or unknown origin (Fisher et al., 2017b; Scheffer et al., 2017) or considered unknown or unclassifiable (Fisher et al., 2017a), as detailed in **Table 1**.

This classification applies to seizures in adults as well as children; there is a separate classification for neonatal seizures (Falco-Walter et al., 2018). The frequency of seizure occurrence is highly unpredictable and ranges from many seizures per day to once in a year or even longer (World Health Organization, 2018) with variable severities ranging from brief losses of attention, muscle twitching, and sensory malfunctions to prolonged life-threatening seizures (Scheffer et al., 2016). The results of neuroimaging studies, electroencephalography and additional investigations exploring underlying causes of epilepsy are taken into account to classify both seizure and epilepsy type (Scheffer et al., 2017).

Classification of Epilepsies

The classification of epilepsies is broader in scope than classifying seizures. However, the seizure type provides a starting point for this classification (Scheffer et al., 2017). Additionally, the overall clinical picture, hereditary tendencies, diagnostic test outcomes and comorbidities are taken into account. Epilepsies can be classified into (1) focal, (2) generalized, (3) combined generalized and focal, and (4) unknown (Falco-Walter et al., 2018; Scheffer et al., 2017).

The patient's age, family history, types of existing sensory and motor seizures, EEG findings, and information collected from clinical observations aid in diagnosing patients with a specific epilepsy type (Falco-Walter et al., 2018). The inter-ictal EEG analysis

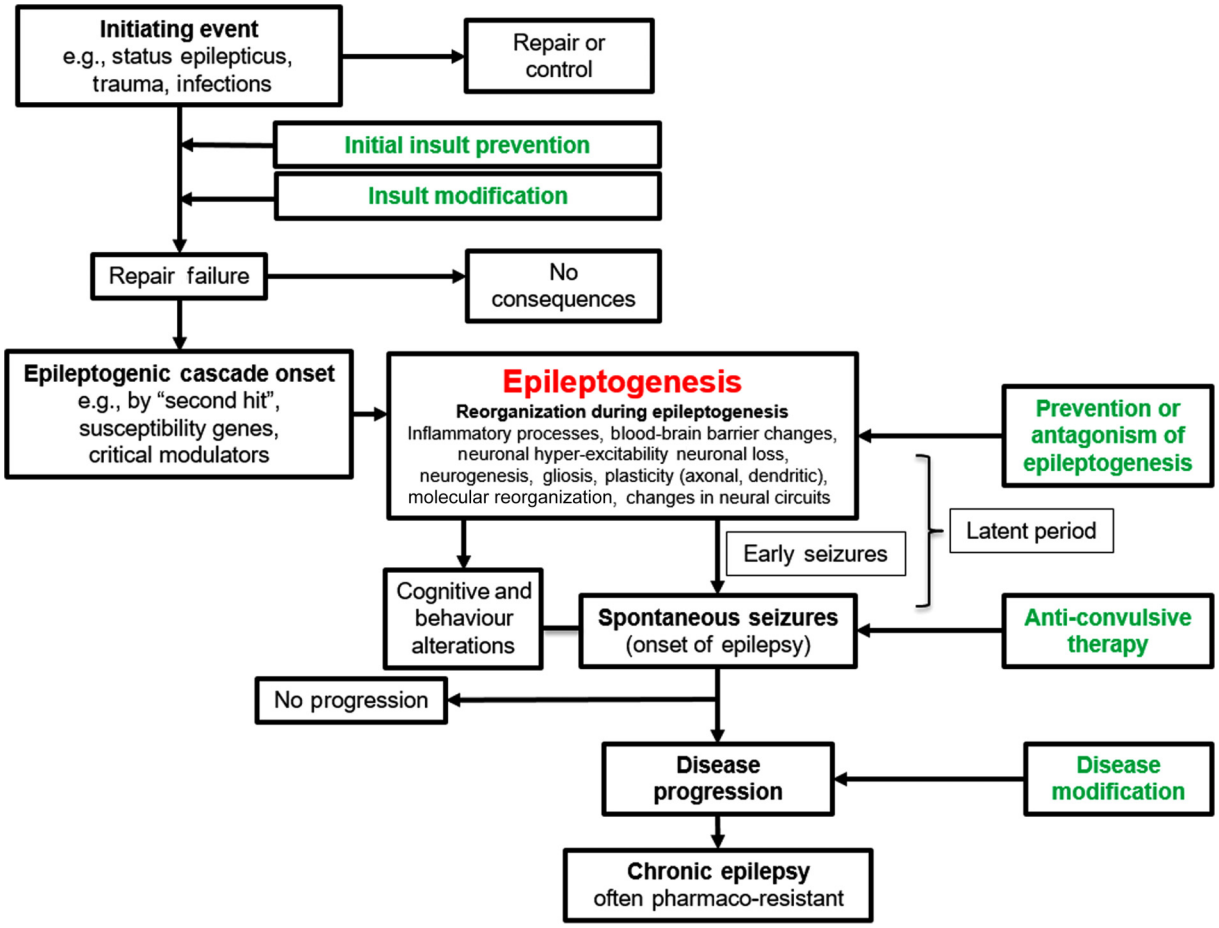

Figure 1 Steps of the development and progression of temporal lobe epilepsy and possible therapeutic interventions. *Source: Modified from Löscher and Brandt (2010)*

generally shows the presence of typical generalized spike-wave activity (generalized epilepsy), focal epileptiform discharges (focal epilepsies), and generalized spike-wave and focal epileptiform discharges (combined generalized and focal epilepsies) at the time of diagnosis. In cases when a clinician is sure of a patient having epilepsy, but neither has enough clinical evidence to support the decision nor a normal EEG, epilepsy of unknown cause is identified (Scheffer et al., 2017).

Etiology of Epilepsy

Finding the underlying cause of epilepsies on primary patient contact is desired for appropriate treatment options (Falco-Walter et al., 2018). The ILEA's recent updates has divided epileptic seizures into the following types for better clinical application and comprehension of disease (Falco-Walter et al., 2018; Scheffer et al., 2017):

1. Structural etiology including acquired (by trauma, stroke, and infection) or innate (e.g., cortical malformation) abnormalities in brain structure. Presence of hippocampal sclerosis associated with mesial temporal lobe epilepsy is one common finding (Scheffer et al., 2017).
2. Genetic etiology is linked to acquired de-novo mutations, e.g. SCN1A (sodium channel gene) mutations (Claes et al., 2001), or hereditary autosomal dominant disorders, for example, benign familial neonatal epilepsy (Grinton et al., 2015), though involvement of the environmental factors cannot be ruled out (Scheffer et al., 2017).
3. Infectious etiology is common worldwide (Vezzani et al., 2016) including infectious pathogens such as viruses (e.g., herpes viruses, West Nile viruses), parasites (e.g., Plasmodium falciparum), bacteria (e.g., mycobacteria), and fungi (e.g. *Cryptococcus* and *Candida albicans*) can cause epilepsies (Vezzani et al., 2016). The acute seizures caused by insults such as meningitis or encephalitis do not represent the disease, which is characterized by the presence of late seizures (Scheffer et al., 2017).
4. Metabolic etiology includes porphyria, uremia, and aminoacidopathies associated with seizures. They also most likely have genetic bases, but could be acquired such as cerebral folate deficiency (Scheffer et al., 2017).

Table 1 Types of seizures according to ILAE 2017 operational classification (Fisher et al., 2017a)

Seizure origin	Known							Unknown	
Confidence level	>80%							<80%	
Seizure type	Focal seizures				Generalized seizures		Focal to generalized tonic clonic seizures	Unknown onset seizures	
Hemisphere involved	One cerebral hemisphere				Both cerebral hemispheres		Focal in origin and then propagates from one to both cerebral hemispheres	–	
Awareness	Retained		Impaired		Generally impaired		Generally impaired	–	
Brain network involved	Motor	Non-motor	Motor	Non-motor (Absence)	Motor	Non-motor	–	Motor	Non-motor
Specific sub-classification based on 1st sign and symptoms	Atonic *	Autonomic	Clonic	Typical	-	-	-	Tonic-clonic epileptic spasms	Behavior arrests

5. Immunological etiology refers to illnesses of the immune system with seizures as a primary symptom (Scheffer et al., 2017). Autoimmune mediated CNS inflammation may provide an indication of immune system mediated epilepsies (Vezzani et al., 2016).
6. Unknown groups include epilepsies that have limited clinical information currently to classify to any set of etiology (Scheffer et al., 2017).

Epileptogenesis

The phenomenon of developing epilepsy is called "epileptogenesis", which is a combination of the two ancient Greek words epilēpsis = attack, invasion and genesis = genesis (Löscher and Brandt, 2010). About 40% of all epilepsies have an identifiable cause, that is, they develop after an initial brain insult (Banerjee et al., 2009; Löscher and Brandt, 2010). These initial brain assaults, for example, trauma, stroke, brain tumors, status epilepticus or infections, often accompanied by early seizures, play a role in transforming an otherwise healthy brain into an epileptic brain (Löscher and Brandt, 2010; Ravizza et al., 2011). After an initial brain insult, the failure of intrinsic repair mechanisms followed by a second hit, gene sensitivity, or comorbidities provides a favoring milieu to develop late seizures (Löscher and Brandt, 2010).

Various underlying mechanisms (**Fig. 1**) such as inflammation, changes in blood brain barrier, neurodegeneration, gliosis, neuronal hyper-excitability, alterations of receptor and ion channel expression are involved in this transformation (Löscher and Brandt, 2010; Vezzani et al., 2016). The seizure free period, also known as "latency" or "latent period," between the initial insult and the occurrence of the 1st unprovoked epileptic seizure, ranges from months to years in humans and results in the manifestation of chronic epilepsy (Jozwiak et al., 2017; White and Loscher, 2014). A schematic representation of epileptogenesis and potential intervention strategies is given in **Fig. 1**

Pharmacotherapy, Pharmacoresistance, and Epilepsy Prevention

There are currently more than 20 therapeutic agents available for the management of epilepsy (Löscher et al., 2013; Pitkanen et al., 2016). Fifteen of these are 3rd generation agents, added in the past 3 decadesthat have provided clinicians more chances of attaining successful therapeutic goals (Löscher and Schmidt, 2011). Although these drugs are primarily known as "anti-epileptic drugs" (AEDs) they do not cure epilepsy itself, but rather provide symptomatic relief from seizures and are thus more appropriately called "anti-seizure or anticonvulsant" drugs (Kaminski et al., 2014). However, only 70%–80% of new onset epilepsy patients become seizure free when treated with current AEDs, while 20%–30% of patients fail to respond to these treatments (Brodie et al., 2012; Löscher et al., 2013; Sillanpaa and Schmidt, 2006).

Patients, who do not remain adequately seizure free for a prolonged period of time or do not respond to any of two or more well tolerated AEDs, are said to be pharmacoresistant (Kwan et al., 2010). The underlying mechanism of this pharmacoresistance have not been understood completely (Kwan and Brodie, 2006). Hence, the quality of life of these patients is compromised with psychological and social consequences (Weaver and Pohlmann-Eden, 2013). Currently, there are many new drugs in clinical trials or are under development that have novel mechanisms of action for pharmacoresistant epilepsy (Younus and Reddy, 2018). However if the therapy does not work then the final option for these patients is surgical resection of brain regions involved in seizure formation (Schmidt et al., 2004). However, the risks and adverse effects of these neurosurgical procedures limit the usefulness of such measures. Only 50% of such patients achieve long-term from seizure and many patients still receive the drug therapy after surgery to achieve seizure control (Loscher and Schmidt, 2006).

Choice of Therapy According to Seizure Type

The ultimate objective of epilepsy treatment is prevention of seizures. It can be achieved by maintaining a suitable dose of one or more AEDs. It is recommended to start with lowest possible dose and slowly achieve the dose where seizures stop or adverse effects appear. Dosing frequency is based on the half-life of AEDs whereas selection of AED depends on the type of seizures diagnosed. Other factors that contribute to the selection of AED are age, sex, co-medication, and co-morbidity. Important AEDs that are recommended in treating different types of seizures are listed in **Table 2**.

Status Epilepticus

The recently proposed conceptual definition by ILEA states that "SE is a condition resulting either from the failure of the mechanisms responsible for seizure termination or from the initiation of mechanisms which lead to abnormally prolonged seizures (after time point t1). It is a condition that can have long-term consequences (after time point t2), including neuronal death, neuronal injury, and alteration of neuronal networks, depending on the type and duration of seizures" (Trinka et al., 2015). This definition is further explained in **Table 3** (Trinka et al., 2015).

Various treatment options are used for management of convulsive status epilepticus in community settings such as schools (described as outside emergency room), few are mentioned in **Table 4** as well, which gives a brief overview of emergency

Table 2 Type of seizures and recommended AEDs (National Institute of Health and Care Excellence, 2018; Royal Pharmaceutical Society, 2018)

Seizure type	*1st line therapy*	*Adjunctive treatment*	*By tertiary epilepsy specialist*	*Not recommended*
Focal seizures	Carbamazepine and lamotrigine. If not tolerated use oxcarbazepine, sodium valproate and levetiracetam	Carbamazepine, clobazam, gabapentin, lamotrigine, levetiracetam, oxcarbazepine, sodium valproate, or topiramate	Eslicarbazepine acetate, lacosamide, phenobarbital, phenytoin, pregabalin, tiagabine, vigabatrin and zonisamide	
Generalized seizures				
Tonic	Sodium valproate (except in premenopausal women)	Lamotrigine	Rufinamide or topiramate	Carbamazepine, gabapentin, oxcarbazepine, pregabalin, tiagabine or vigabatrin
Tonic-clonic or generalized tonic-clonic (GTC)	Sodium valproate (except in premenopausal women)	Lamotrigine, carbamazepine and oxcarbazepine (may exacerbate myoclonic seizures)	Clobazam, lamotrigine, levetiracetam, sodium valproate or topiramate	Myoclonic seizures
Myoclonic	Sodium valproate. If unsuitable give topiramate or levetiracetam (except in premenopausal women)	Combination of these mentioned drugs	Clobazam, clonazepam, zonisamide or piracetam	Carbamazepine, gabapentin, oxcarbazepine, phenytoin, pregabalin, tiagabine and vigabatrin
Atonic	Sodium valproate (except in premenopausal women)	Lamotrigine	Rufinamide or topiramate	Carbamazepine, gabapentin, oxcarbazepine, pregabalin, tiagabine or vigabatrin
Absence	Ethosuximide Sodium valproate or lamotrigine (except in premenopausal women)	Combination of any of these two	Clobazam, clonazepam, levetiracetam, topiramate or zonisamide	Carbamazepine, gabapentin, oxcarbazepine, phenytoin, pregabalin, tiagabine and vigabatrin

Table 3 Operational dimensions with t1 indicating the time that emergency treatment of SE should be started and t2 indicating the time at which long-term consequences may be expected (Trinka et al., 2015)

Type of SE	**Operational dimension 1** Time (t1); when a seizure is likely to be prolonged leading to continuous seizure activity	**Operational dimension 2** Time (t2); when a seizure may cause long term consequences (including neuronal injury, neuronal death, alteration of neuronal networks and functional deficits)
Tonic–clonic SE	5 min	30 min
Focal SE with impaired consciousness	10 min	>60 min
Absence status epilepticus	10–15 min	Unknown

Table 4 Doses of AEDs and anticonvulsant medications in convulsive status epilepticus

Drug	*Route of administration*	*Dose*				*Instructions for administration*
		Initial	*Increment*	*Usual dose*	*Up to*	
Lorazepam	Slow IV injection	4 mg/dose	4 mg/dose if required after 10min			Administer in large vein
Diazepam	IV	10 mg	10 mg if required after 10min			Administer at a rate of 5 mg/min
	Rectal	10–20 mg	10–20 mg if required after 10–15 min			
Phenytoin	Slow IV injection	20 mg/kg		100 mg every 6–8 h	2 g/dose	100 mg of phenytoin sodium is therapeutically equivalent to 92 mg of phenytoin base,
Midazolam	Buccal	10 mg	10 mg if required after 10min			
Fosphenytoin sodium	IV infusion	20 mg/kg		4–5 mg/kg in 1–2 divided doses		Administer at a rate of 100–150 mg/min (initial dose) and 50–100 mg/min (usual dose), 1 mg of phenytoin sodium = 1.5 mg of fosphenytoin sodium
Phenobarbital sodium	IV			10 mg/kg	1 g/dose	Rate of administration should not be more than 100 mg/min, dilute 1 in 10 with WFI

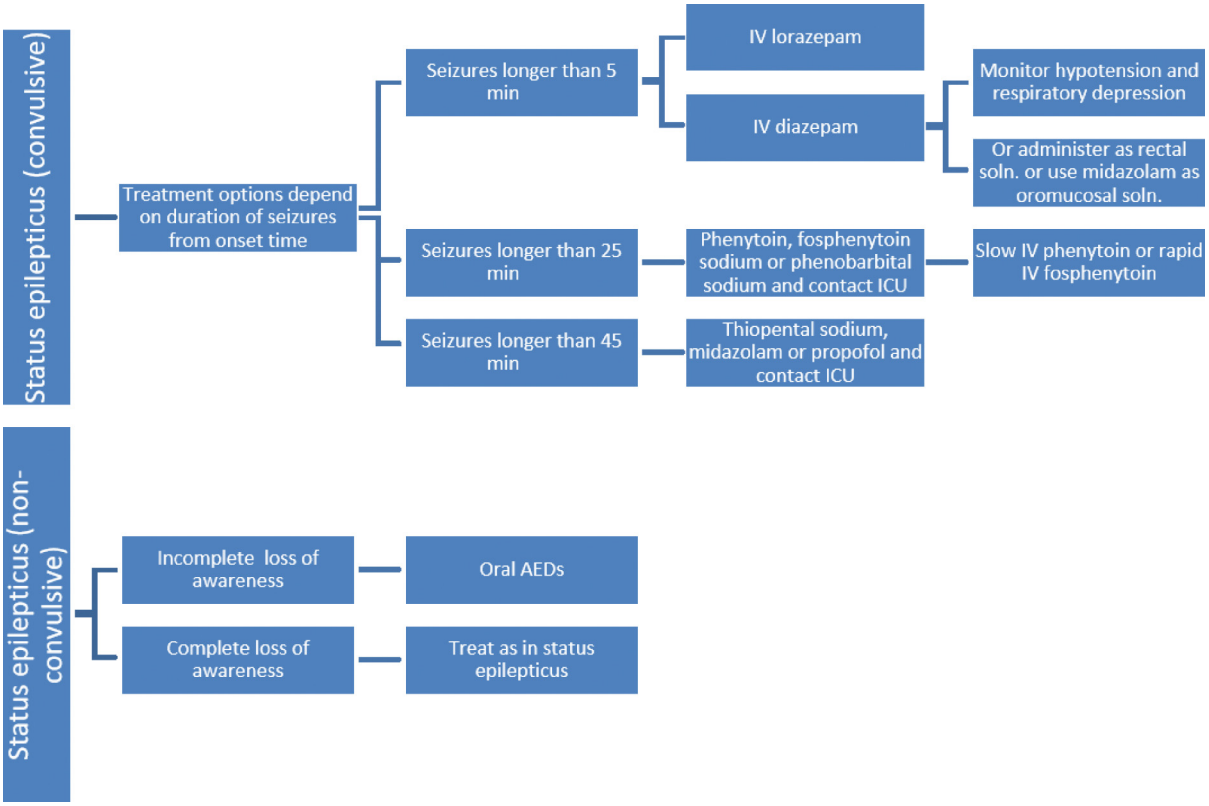

Figure 2 Decision flow in treatment of status epilepticus (Royal Pharmaceutical Society, 2018).

management. Buccal and intranasal midazolam and diazepam anema/suppository are more acceptable treatment options when trained health professional and intravenous lines are not available (Fig. 2).

Treatment of Febrile Convulsions

Febrile convulsions are common emergency conditions experienced in pediatric patients. Management of these patients includes general pharmacologic (paracetamol) and non-pharmacologic measures (sponging with tepid water) to lower body temperature. In case the duration of seizures exceed 10–15 min control of seizures must be carried out using the dosing described under convulsive status epilepticus. In-time-control-of seizures is essential in preventing brain damage associated with the prolonged seizures.

Pharmacokinetic Properties of AEDs

AEDs mostly include narrow therapeutic index drugs and the pharmacokinetics of the drugs is affected by age-related factors. Specifically, the neonates present a large volume of distribution, with a low protein binding and so a different half-life from adults. Table 5 provides an overview of the basic pharmacokinetic parameters of AEDs in adults and children.

Posology of AEDs

AEDs are given in specialized dosage regimens depending upon the age and indication (Royal Pharmaceutical Society, 2018; van Dijkman et al., 2018). Therapy is initiated with an initial dose which is build up to a usual or a routine dose using defined increments at specified intervals (Table 6). Doses can be increased up to a maximum limit depending upon the success in control of symptoms and tolerance of adverse events.

Therapeutic Drug Monitoring of AED's

TDM is a well-established tool for safe administration of AEDs because it allows the selection of individualized dosage regimen in patients with specific nature of epilepsy with variability in pharmacokinetics of AEDs. Although, the quantification of AEDs is mostly performed in plasma, however, many AEDs can be readily monitored in dried blood spot (DBS) or saliva (Patsalos et al., 2018). For AEDs with high protein-bound capacity (phenytoin, carbamazepine, and phenobarbital), saliva has proved to

A, adult; P, pediatric

be the most appropriate matrix with the advantage non-invasive sampling and reflecting the free, pharmacologically active, drug concentration in plasma (Carvalho et al., 2018). The DBS can be used alternatively to plasma sampling, which has simplified the effective TDM for AEDs (Linder et al., 2017). For almost all AEDs, the reference ranges have been defined that are to be considered for maintaining the plasma levels of AEDs in order to achieve safe and effective therapy. However, the drug levels outside the reference range are required for some patients due to individual variation in type and severity of seizure. The monitoring of individual therapeutic drug concentration of AEDs has advantage of administering specific dose to an individual for whom optimum seizure control with minimal adverse effects is achieved. The principal indications for TDM of AEDs are listed as follows (Patsalos et al., 2018):

- After initialization of treatment for dose adjustment
- On achievement of desired therapeutic response
- When toxicity is difficult to differentiate or assess clinically
- To regulate the extent of dose change
- When seizures persist despite of adequate dose administration
- When variability in pharmacokinetics is expected
- When formulation is changed
- When clinical response is changed, unexpectedly
- When poor compliance from the patient is suspected.

In addition to mentioned conditions, monitoring of plasma levels is also recommended during pregnancy to maintain the therapeutic levels necessary for seizure control (Royal Pharmaceutical Society, 2018). TDM is also helpful in monitoring the time-scale of drug interaction. In routine, stabilized patients are advised to undergo TDM 1–2 times a year and before initiation of the adjuvant AED it is advisable to carry out baseline level of the first AED (Whittlesea and Walker, 2011).

Population Pharmacokinetic Modeling

As the pharmacokinetics of AEDs vary among individuals due to inter-individual variability, the TDM of AEDs based only on the quantification of drugs in plasma is becoming ineffective, even for AEDs with very precisely defined therapeutic ranges. The adaptive control of dosage using computer software is effectively increased for dose tailoring (Patsalos et al., 2018) and population pharmacokinetic (popPK) modeling has been used as a valuable tool to identify sources of variability among the individuals and incorporation of these sources as covariate factors in the model. These models are then used for simulation of dosage regimens in order to design the tailored dosage regimens for individual patients (van Dijkman et al., 2018).

Contraindications and Use of AEDs in Pregnancy and Lactation

The major contraindication brought forward in the recent time includes the restriction of the sodium valproate in women of reproductive age and during pregnancy due to serious teratogenic effects (**Table 7**). If needed, it should be given in very low doses and in combination with lamotrigine for synergistic effect (Iapadre et al., 2018).

Table 6 Indications, dose regime and routes of administration for AEDs in adults (Royal Pharmaceutical Society, 2018)

		Dose				
Drug	*Indications*	*Initial*	*Increment*	*Usual dose*	*Up to*	*Route of administration*
Brivaracetam	partial-onset seizures	25–50 mg BD		25–100 mg BD		Oral or IV injection or IV infusion
Carbamazepine	Focal and secondary generalized tonic-clonic seizures: Primary generalized tonic-clonic seizures	100–200 mg 1–2 OD or BD	100–200 mg every 2 weeks	0.8–1.2 g daily in divided doses	1.6–2 g daily in divided doses 1 g daily in 4 divided doses for up to 7 days	Oral By rectum
Ethosuximide	1st line treatment for Absence seizures	500 mg daily in 2 divided doses	250 mg every 5–7 days;	1–1.5 g daily in 2 divided doses	2 g daily	Oral
Gabapentin	Adjunctive treatment of focal seizures with or without secondary generalization	300 mg OD on day 1	300 mg BD on day 2, then 300 mg TDS on day 3	0.9–3.6 g daily in 3 divided doses	1.6 g TDS	Oral
	Monotherapy for focal seizures with or without secondary generalization	300 mg OD on day 1	300 mg BD on day 2, then 300 mg TDS on day 3	0.9–3.6 g daily in 3 divided doses	1.6 g TDS	Oral
Lamotrigine	Monotherapy of focal seizures ǀ Monotherapy of primary and secondary generalized tonic-clonic seizures ǀ Monotherapy of seizures associated with Lennox-Gastaut syndrome	25 mg OD for 14 days,	50 mg OD for further 14 days, then increased in steps of up to 100 mg every 7–14 days	100–200 mg daily in 1–2 divided doses	500 mg daily	Oral
	Adjunctive therapy of focal seizures with valproate ǀ Adjunctive therapy of primary and secondary generalized tonic-clonic seizures with valproate ǀ Adjunctive therapy of seizures associated with Lennox-Gastaut syndrome with valproate	25 mg OD alternate days for 14 days,	25 mg OD for further 14 days, then increased in steps of up to 50 mg every 7–14 days	100–200 mg daily in 1–2 divided doses		
	Adjunctive therapy of focal seizures (with enzyme inducing drugs) without valproate ǀ Adjunctive therapy of primary and secondary generalized tonic-clonic seizures (with enzyme inducing drugs) without valproate ǀ Adjunctive therapy of seizures associated with Lennox- Gastaut syndromes (with enzyme inducing drugs) without valproate	50 mg OD for 14 days	50 mg BD for further 14 days, then increased in steps of up to 100 mg every 7–14 days	200–400 mg daily in 2 divided doses,	700 mg daily	
	Adjunctive therapy of focal seizures (without enzyme inducing drugs) without valproate ǀ Adjunctive therapy of primary and secondary generalised tonic-clonic seizures (without enzyme inducing drugs) without valproate. Adjunctive therapy of seizures associated with Lennox–Gastaut syndromes (without enzyme inducing drugs) without valproate	25 mg OD for 14 days	50 mg OD for further 14 days, then increased in steps of up to 100 mg every 7–14 days	100–200 mg daily in 1–2 divided doses		
	Monotherapy or adjunctive therapy of bipolar disorder (without enzyme inducing drugs) without valproate	25 mg once daily for 14 days	50 mg daily in 1–2 divided doses for further 14 days, then 100 mg daily in 1–2 divided doses for further 7 days	200 mg daily in 1–2 divided doses	400 mg per day	

Levetiracetam	Monotherapy of focal seizures with or without secondary generalization	250 mg OD for 1–2 weeks	250 mg BD, then increased in steps of 250 mg BD, dose to be increased every 2 weeks		1.5 g BD	O or IV infusion
	Adjunctive therapy of focal seizures with or without secondary generalization	250 mg BD,	500 mg BD, dose to be increased every 2–4 weeks		1.5 g BD	Oral
	Adjunctive therapy of myoclonic seizures and tonic-clonic seizures					Oral or IV infusion
Phenytoin	Tonic-clonic seizures Focal seizures: Prevention and treatment of seizures during or following neurosurgery or severe head injury	3–4 mg/kg daily		200–500 mg daily,		Oral
Phenobarbital	All forms of epilepsy except typical absence seizures			60–180 mg OD		Oral
Rufinamide	Adjunctive treatment of seizures in Lennox-Gastaut syndrome	200 mg BD	Increase in steps of 200 mg BD		900 mg BD (body weight 30–49 kg), 1.2 g BD ((body-weight 50–69 kg), 1.6 g BD ((body-weight 70 kg and above)	Oral
Topiramate	Monotherapy of generalized tonic-clonic seizures or focal seizures with or without secondary generalization	25 mg OD for 1 week	Increase as 25–50 mg every 1–2 weeks, in two divided doses		500 mg per day	Oral
	Adjunctive treatment of generalized tonic-clonic seizures or focal seizures with or without secondary generalization | Adjunctive treatment for seizures associated with Lennox-Gastaut syndrome	25–50 mg OD for 1 week	Increase as 25–50 mg every 1–2 weeks, dose to be taken in 2 divided doses	200–400 mg daily in 2 divided doses	400 mg per day	Oral
Valproate sodium	All forms of epilepsy	600 mg daily in 1–2 divided doses	Increase as 150–300 mg every 3 days	1–2 g daily	2.5 g per day	
Zonisamide	Monotherapy for treatment of focal seizures with or without secondary generalization in adults with newly diagnosed epilepsy	100 mg OD for 2 weeks	Increase as 100 mg every 2 weeks	300 mg OD	500 mg per day	
	Adjunctive treatment for refractory focal seizures with or without secondary generalization	50 mg daily in 2 divided doses for 7 days	Increase as 100 mg daily in 2 divided doses, then increased in steps of 100 mg every 7 days	300–500 mg daily in 1–2 divided doses		

Table 7 Use of AEDs in pregnancy, lactation, hepatic and renal impairment

Drug	*Use in pregnancy*	*Breast feeding*	*Contra-indications*	*Hepatic impairment*	*Renal impairment*
Brivaracetam	Avoid unless potential benefit outweighs risk—limited information available.	Should avoid, present in milk in animal studies.		Require dose adjustment, starting dose of 25 mg BD in chronic liver disease; max. maintenance dose 75 mg BD in all stages of impairment.	
Carbamazepine	Monitor plasma drug concentration and adjust the dose	Amount probably too small to be harmful. Monitor infant for possible adverse reactions.	Acute porphyria. AV conduction abnormalities (unless paced). History of bone marrow depression	Withdraw immediately in cases of aggravated liver dysfunction or acute liver disease and leucopenia. Metabolism impaired in advanced liver disease.	Use with caution
Ethosuximide	Monitor during pregnancy and after birth, and adjustment on clinical basis.	Present in milk. Hyperexcitability and sedation reported.		Use with caution	Use with caution
Gabapentin	Monitor during pregnancy and after birth, and adjustment on clinical basis.	Present in milk—manufacturer advises use only if potential benefit outweighs risk.			Reduce the dose depending upon the values of eGFR
Lamotrigine	Monitor plasma drug concentration and adjust the dose	Present in milk, but limited data suggest no harmful effect on infant.	Myoclonic seizures, Parkinson's disease	Halve dose in moderate impairment. Quarter dose in severe impairment.	Caution in renal failure; metabolite may accumulate. Dose adjustments required.
Levetiracetam	Monitor plasma drug concentration and adjust the dose, also monitor fetal growth	Present in milk—manufacturer advises avoid.		In adults Halve dose in severe hepatic impairment if eGFR less than 60 mL/min/1.73m^2.	In adults Maximum 2 g daily if eGFR 50–80 mL/min/1.73m^2. Maximum 1.5 g daily if eGFR 30–50 mL/min/1.73m^2. Maximum 1 g daily if eGFR less than 30 mL/min/1.73m^2.
Phenytoin	Monitor plasma drug concentration and adjust the dose	Small amounts present in milk, but not known to be harmful	Acute porphyrias	Adjust the dose, reduce dose to avoid toxicity.	
Phenobarbital	Monitor the dose and adjust on clinical basis.	Avoid if possible; drowsiness may occur.		May precipitate coma. Avoid in severe impairment.	Use with caution.
Rufinamide	Monitor the dose and adjust on clinical basis.	Manufacturer advises avoid.		Avoid in severe impairment. Adjust the dose.	
Topiramate	Increased risk of major congenital malformations following exposure during the first trimester.	Manufacturer advises avoid—present in milk.	Avoid in active liver disease.	Use with caution in moderate to severe impairment—clearance may be reduced.	Use with caution and adjust the dose
Valproate	must not be used unless there is no suitable alternative treatment;	Present in milk—risk of haematological disorders in breast-fed newborns and infants.	In women and girls of childbearing potential unless conditions of pregnancy prevention programme are met. Acute porphyrias	Avoid if possible—hepatotoxicity and hepatic failure may occasionally occur (usually in first 6 months).	Reduce dose.
Zonisamide	Use only if clearly necessary and the potential benefit outweighs risk	Manufacturer advises avoid for 4 weeks after last dose.		Avoid in severe impairment. Dose adjustments Initially increase dose at 2-week intervals if mild or moderate impairment.	Initially increase dose at 2-week intervals; discontinue if renal function deteriorates.

Table 8 Chronic side effects with use of major AEDs

Drug	*Chronic side effects*	*Drug*	*Chronic side effects*
Carbamazepine	Antiepileptic hyper-sensitivity syndrome, Hyponatremia	**Phenobarbital**	Behavior changes, connective tissue disorders, intellectual blunting, metabolic disease, mood change, sedation
Ethosuximide	Behavior changes, headache	**Topiramate**	Kidney stones, weight loss
Gabapentin	Weight gain	**Valproate**	Polycystic-ovary like syndrome, weight gain, hyperammonemia, menstrual cycle irregularities
Phenytoin	Behavior changes, Cerebellar syndrome, connective tissue changes, skin thickening, folate deficiency, gingival hyperplasia, Hirsutism, coarsening of facial features, acne, cognitive impairment, metabolic bone disease, sedation	**Zonisamide**	Kidney stones, weight loss

Carbamazapine and gabapentin are not recommended in tonic, atonic, myoclonic or absence seizures, whereas lamotrigine and phenytoin are contraindicated in myoclonic or absence seizures. Some genetic variants in population are more prone to the cutaneous adverse effects of antiepileptic agents such as carbamazepine, oxycarbamazepine, phenytoin and lamotrigine. FDA recommends screening of the South Asian population for the HLA*B 1502 allele for preventing the serious ADRs like Steven–Johnson syndrome (SJS)and toxic epidermal necrolysis(TENS).

Side Effects of AEDs

AEDs are narrow therapeutic index medicines with many CNS and other side effects. Table 8 shows some examples of chronic side effects of commonly used AEDs.

Chronic side effects

Hypersensitivity and other serious cutaneous adverse drug reactions

SJS and TENS are the serious cutaneous ADRs associated with the AEDs carbamazepine and phenytoin. These ADRs show substantial morbidity and mortality (40%–50%). In a recent study on 480 validated cases of SJS/TENS reported in the UK on use of AEDS, highest risks were found with phenytoin (45.86 cases/100,000 exposed), lamotrigine (44.17cases/100,000 exposed), and carbamazepine (20.38 cases/100,000 exposed). No cases were observed for levetiracetam, clonazepam or topiramate whereas valproate, gabapentin, pregabalin and clobazam had a high odds ratio but no causal relationship identified using drug casualty for epidermal necrolysis (ALDEN) score used in the study (Frey et al., 2017).

Pharmacogenetic investigations for identifying the etiology of these reactions have shown that the HLA allele, HLA*-B* 1502 is associated with the increased risk of skin reactions for carbamazepine, phenytoin, oxcarbamazepine, and lamotrigine. The Population of Southeast Asia (China, Thailand, Malaysia, Indonesia, the Philippines, and Taiwan) are found to be more prone to these reactions than India and Japan. Owing to this relationship, FDA has introduced screening for HLA-B*1502 commencing the carbamazepine and phenytoin therapy in Southeast Asian Population (Whittlesea and Walker, 2011).

Drug Interactions of Antiepileptic Drugs

AEDs are used as long-term monotherapy, in combination or as adjunctive therapy and mostly consist of drugs that are likely to exhibit drug interactions. (van Dijkman et al., 2018) The classical AEDs cause inhibition (valproate) or induction (carbamazepine, phenobarbital, phenytoin, primidone) and affect the plasma concentration of other AEDs. It also affects other drug classes including anti-depressants, anti-psychotics, anti-microbial drugs and many more. These drug interactions could be classified depending upon the severity of clinical complications. Level 1 enlists serious clinical complications that develop due to AED interactions and should be avoided. Level 2 include drug interactions that usually require dose adjustments and co-administration of these drugs is possible. The interactions where dose adjustment is not necessarily required are categorized under Level 3. Updated information on the possibility and severity of drug interactions may help to treat the seizure more effectively. AED interactions with other co-administered AEDs (Table 9) and other drugs (Table 10) are described later.

Table 9 Drug interactions of AEDs with co-administered AEDs

Brivaracetam	**Brivaracetam**													
Carbamazepine	2, m, St	**Carbamazepine**												
Ethosuximide			**Ethosuximide**											
Fosphenytoin	2, m, St	2, s, St, Ad		**Fosphenytoin**										
Gabapentin					**Gabapentin**									
Lamotrigine		2, m, St, Ad		2, m, St, Ad		**Lamotrigine**								
Levetiracetam							**Levetiracetam**							
oxcarbazepine		1, m, St, Ad		2, m, St, Ad		2, m, St, Ad		**Oxcarbazepine**						
Phenobarbital		2, m, St, Ad		2, m, St					**Phenobarbital**					
Phenytoin	2, m, St	2, s, St, Ad		2, m, St				2, m, St, Ad	2, m, St	**Phenytoin**				
pregabalin											**Pregabalin**			
Rufinamide												**Rufinamide**		
Topiramate		3, m, St		2, m, St, Ad					2, m, St	2, m, St, Ad			**Topiramate**	
Valproate				2, s, St		1, s, St, Ad			2, m, St, Ad	2, s, St		1, m, St, Ad	3, s, St	**Valproate**
Zonisamide		2, m, St, Ad		2, m, St, Ad					2, m, St, Ad	2, m, St, Ad			3, s, Th	

Key: 1. Affects the efficacy or exposure of drugs, 2. Affects the concentration of drugs, 3. Produces toxic effects Ad, adjust; An, anecdotal; Av, avoid; m, moderate; Mo, monitor; s, severe; St, study; Th, theoretical; U, unknown.

Table 10 Drug interactions of AEDs with co-administered drugs.

Drug	*Interaction with*	*Effect*	*Method*	*Severity*	*Advice*
Brivaracetam	Enzalutamide (1, Th, m), rifampicin (1, St, m, Ad), St John's Wort (1, Th, m)				
	Neuromuscular blocking drugs, non-depolarising (atracurium, cisatracurium, pancuronium, rocuronium, vecuronium).	AED decrease the effects of (but acute use increases the effects of drug)	Study	Moderate	
	Suxamethonium	Co-administration increases the risk of prolonged neuromuscular blockade	Study	Moderate	
	Theophylline	Potentially increase the clearance of theophylline	Anecdotal	Moderate	
Carbamazepine	Thyroid hormones	Increase the risk of hypothyroidism	Study	Moderate	
	Oral cladribine	increase the risk of haematological toxicity	Theoretical	Moderate	
	Clozapine	Increase the risk of myelosuppression	Anecdotal	Study	Avoid
	Coumarins	AED decrease the anticoagulant effect	Study	Severe	Monitor and adjust the dose
	Procarbazine	Combine administration may increase the risk of hypersensitivity reaction.	Anecdotal	Severe	
	afatinib (1, Th, m), aliskiren (1, Th, m), antifungals, azoles (miconazole, fluconazole, posaconazole) (3, An, s, Ad), antimalarials (quinine) (3, St, u), Calcium channel blockers (diltiazem, verapamil) (2, Th, m, Av or Mo, Ad), caspofungin (1, Th, m, Ad), dabigatran (1, St, s, Av), Danazol (2, St, s, Mo, Ad), edoxaban (1, St, m), efavirenz (1, St, s), Grapefruit juice (1, St, m, Mo, Ad), H_2 receptor antagonists (cimetidine) (2, St, s, Mo, Ad), HIV-protease inhibitors (1, Th, s, Mo, Ad), ketoconazole (2, Th, m, Av, or Mo, Ad), ledipasvir (1, Th, s, Av), Macrolides (clarithromycin and erythromycin) (2, St, s, Mo, Ad), mianserin (1, St, m, Ad), modafinil (1, Th, m), monoamine-oxidase A and B inhibitors, irreversible (3, Th, s, Av), monoclonal antibodies (brentuximab vedotin) (1, Th, s), nintedanib (1, St, m), olanzapine (1, St, m, Mo, Ad), ombitasvir (1, Th, s, Av), opioids (tramadol) (2, St, s, Ad), raltegravir (1, Th, m), selexipag (1, St, m, Ad), sofosbuvir (1, St, s, Av), St John's Wort (2, Th, m, Mo, Ad), statins (atorvastatin) (1, Th, m, Mo, Ad), statins (simvastatin) (1, St, s, Mo, Ad), trazodone (2, An, m, Ad), tricyclic antidepressants (1, St, m, Ad), vitamin D substances (1, St, m), zolpidem (1, St, m),				
	Isoniazid	Increases the risk of hepatotoxicity administered together	Study	Severe	Monitor and adjust the dose
	Lithium	Increases the risk of neurotoxicity administered together	Anecdotal	Severe	
Ethosuximide	Not available				
Fosphenytoin	Antifungals, azoles (miconazole, fluconazole, posaconazole, voriconazole) (3, An, s, Av), Sulfonamides (sulfadiazine) (1, St, m, Mo, Ad),				
Gabapentin	Antacids	Antacid decrease the absorption of gabapentin		Take AED 2 h after taking antiacids	

(*Continued*)

Table 10 Drug interactions of AEDs with co-administered drugs. (*cont.*)

Drug	*Interaction with*	*Effect*	*Method*	*Severity*	*Advice*
Lamotrigine	Desmopressin	Increase the risk of hyponatraemia when given together	Theoretical	Severe	Adjust the dose
	Rifampicin	The drug increases the clearance of AED	Study	Moderate	Adjust the AED dose
	Combined hormonal contraceptives (1, St, m, Ad), Desogestrel (1, St, m), HIV-protease inhibitors (ritonavir) (1, St, s), Hormone replacement therapy (1, Th, m)				
Levetiracetam	Methotrexate	AED decreases the clearance of drug	Anecdotal	Severe	
oxcarbazepine	ciclosporin (2, An, s), cobicistat (2, Th, s), combined hormonal contraceptives (1, St, s), daclatasvir (1, St, s), dolutegravir (1, Th, s, Av), etonogestrel (1, Th, s), glecaprevir (1, Th, s, Av), guanfacine (1, Th, m, Mo, Ad), hormone replacement therapy (1, An, m), imatinib (1, St, m, Av), levonorgestrel (1, Th, s), pibrentasvir (1, Th, s, Av), rilpivirine (2, Th, s, Av), simeprevir (1, Th, s, Av), ulipristal (1, An, s), velpatasvir (1, Th, s, Av), voxilaprevir (2, Th, s, Av)				
	Lithium	Increases the risk of neurotoxicity administered together	Anecdotal	Severe	
Phenobarbital	Antifungals, azoles (itraconazole, ketoconazole, voriconazole) (1, St, m, Av), beta blockers, non-selective (carvedilol, labetalol, propranolol, acebutolol, bisoprolol, metoprolol, nebivolol) (1, St, m), calcium channel blockers (diltiazem, verapamil) (1, St, m, Mo, Ad), chenodeoxycholic acid (1, Th, m, Mo, Av), chloramphenicol (2, St, m), cholic acid (1, St, m, Av), clozapine (1, An, m), efavirenz (1, Th, s), Folates (2, St, s, Ad), griseofulvin (1, St, m), HIV-protease inhibitors (1, Th, s), metronidazole (1, St, m), metyrapone (1, St, m, Av), mianserin (1, St, m), modafinil (1, Th, m), monoamine-oxidase A and B inhibitors, irreversible (1, Th, s), norethisterone (1, An, s), Phenothiazines (chlorpromazine) (2, St, m), raltegravir (1, Th, m, Av), rifampicin (1, St, m, Ad), St John's Wort (2, Th, s, Av), thyroid hormones (1, Th, m), tricyclic antidepressants (1, St, m), vitamin D substances (1, Th, m)	Decreases the exposure	Study	Moderate	Avoid and for 14 days after stopping fosphenytoin
	Volatile halogenated anesthetics (methoxyflurane)	Co-administration increases the risk of nephrotoxicity	Theoretical	Severe	Avoid
	Procarbazine	Combine administration may increase the risk of hypersensitivity reaction.	Anecdotal	Severe	
	Coumarins	AED decrease the anticoagulant effect	Study	Moderate	Monitor INR and adjust the dose
	Dapsone	Given together can increase the risk of methemoglobinemia	Theoretical	Severe	
Phenytoin	Antifungals, azoles (miconazole, fluconazole, posaconazole, voriconazole) (3, An, s, Ad), antifungals, azoles (itraconazole) (1, St, m, Av), .anaesthetics, local (ropivacaine) (1, Th, m), melatonin (1, Th, m), duloxetine (1, Th, m), olanzapine (1, St, m, Mo, Ad), Sulfonamides (sulfadiazine) (2, St, m, Mo, Ad)				
	Antimalarials (pyrimethamine)	Increase the risk of haematological toxicity	Study	Severe	
	Enteral feeds	Drug decrease the absorption of AED	Study	Severe	
Pregabalin	Not available				
Rufinamide	combined hormonal contraceptives (1, St, s), etonogestrel (1, Th, s), hormone replacement therapy (1, An, m), levonorgestrel (1, Th,s), norethisterone (1, An, s), ulipristal (1, An, s)	AED decrease the efficacy of other drug	Study	Severe	
Topiramate	Combined hormonal contraceptives (1, St, s), etonogestrel (1, Th, s), hormone replacement therapy (1, An, m), levonorgestrel (1, Th,s), norethisterone (1, An, s), ulipristal (1, An, s)	AED decrease the efficacy of other drug	Study	Severe	

Valproate	Bupropion (1, St, s), Carbapenems (2, An, s, Av), glycerol phenylbutyrate (1, Th, m), guanfacine (2, St, m, Mo, Ad), HIV-protease inhibitors (ritonavir) (2, An, s), paliperidone (1, St, m, Ad), propofol (2, Th, s, Ad), selexipag (1, Th, u), sodium oxybate (1, St, m, Ad), sodium phenylbutyrate (1, An, m), zidovudine (1, St, m),				
	Penicillins (pivmecillinam).	Increase the risks of side effects when given together	Anecdotal	Severe	Avoid
	Quetiapine	Combined administration may increase the risk of neutropenia	Study	Moderate	
Zonisamide	Antihistamines, sedating (hydroxyzine), Haloperidol, Oxybutynin, Tricyclic antidepressants (clomipramine, imipramine)	Potentially increase the risk of overheating and dehydration	Theoretical	Severe	Avoid in children
Carbamazepine, fosphenytoin, phenobarbital, phenytoin, primidone	Abacavir (1, Th, m), Abiraterone (1, Th, s, Av), Albendazole (2, St, m), aldosterone antagonists (eplerenone) (1, Th, m, Av), alprazolam (1, Th, m, Ad),antiarrhythmics (disopyramide, dronedarone, propafenone)(1, St, s, Av), anticholinesterases, centrally acting (donepezil) (1, St, m), antifungals, azoles (isavuconazole) (1, St, s, Av), antimalarials (artemether, piperaquine) (1, St, s, Av), apixaban (1, St, s, Av), premilast (1, St, s, Av), aprepitant (1, St, s, Av), aripiprazole (1, St, s, Av), axitinib (1, St, s, Av), bazedoxifene (1, St, s, Av), bedaquiline (1, St, s, Av), bortezomib (1, St, s, Av), bosentan (1, St, s, Av), bosutinib (1, St, s, Av), bupropion (1, St, s, Av), buspirone (1, St, s, Av), cabozantinib (1, St, s, Av), calcium channel blockers (amlodipine, felodipine, lacidipine, lercanidipine, nicardipine, nifedipine, nimodipine) (1, St, m, Ad), cannabis extract (1, St, s), ceritinib (1, St, s, Av), ciclosporin (2, St, s), cilostazol (1, Th, m), cinacalcet (1, St, m, Mo, Ad), clomethiazole (1, St, m, Mo, Ad), cobicistat (1, Th, s, Av), cobimetinib (1, Th, s, Av), combined hormonal contraceptives (1, St, s), corticosteroids (budesonide, deflazacort, dexamethasone, fludrocortisone, hydrocortisone, methylprednisolone, prednisolone, prednisone, triamcinolone) (1, St, m, Mo, Ad), corticosteroids (fluticasone) (1, Th, u), crizotinib (1, St, s, Av), dasabuvir (1, Th, s, Av), dabrafenib (1, Th, m, Av), daclatasvir (1, St, s, Av), dasatinib (1, St, s, Av), darifenacin (1, Th, m), delamanid (1, St, m, Av), desogestrel (1, Th, s), dolutegravir (1, St, s, Ad), elbasvir (1, St, s, Av), elvitegravir (2, Th, s, Av), ergotamine (1, Th, m), erlotinib (1, St, s, Av), etonogestrel (1, Th, s), etoposide (1, St, m), etravirine (1, Th, s, Av), everolimus (2, St, s, Ad), exemestane (1, St, m), fesoterodine (1, St, m, Av), fosaprepitant (1, Th, m, Av), gefitinib (1, St, s, Av), glecaprevir (1, St, s, Av), grazoprevir (1, St, s, Av), guanfacine (1, St, m, Ad), haloperidol (2, St, m, Ad), hormone replacement therapy (1, An, m), ibrutinib (1, St, s, Av or Ad), idelalisib (1, St, s, Av), imatinib (1, St, m, Av), irinotecan (1, St, s, Av), iron chelators (deferasirox) (1, Th, m, Mo, Ad), ivabradine (1, Th, m, Ad), ivacaftor (1, St, s, Av), ixazomib (1, St, s, Av), lapatinib (1, St, s, Av), levonorgestrel (1, Th,s). linagliptin (1, St, m), lomitapide (1, Th, m, Mo, Ad), Lumacaftor (1, Th, s, Av), lurasidone (1, St, m, Av), macitentan (1, St, s, Av), maraviroc (1, St, s, Ad), midazolam (1, St, m, Mo, Ad), midostaurin (1, St, s, Av), mirtazapine (1, St, s, Ad), montelukast (1, St, m), naloxegol (1, St, m, Av), nateglinide (1, St, m), netupitant (1, St, s, Av), Nevirapine (2, St, s), nilotinib (1, St, s, Av), nitisinone (1, Th, m, Ad), norethisterone (1, An, s), olaparib (1, Th, m, Av), ondansetron (1, St, m), opioids (alfentanil, fentanyl) (1, St, m), opioids (buprenorphine) (1, Th, m, Mo, Ad), opioids (methadone) (1, St, s, Mo, Ad), opioids (oxycodone) (1, St, m, Mo, Ad), osimertinib (1, St, m, Av), palbociclib (1, St, s, Av), paliperidone (1, St, s, Mo, Ad), panobinostat (1, Th, m, Av), paracetamol (1, St, m), paritaprevir (with ritonavir and ombitasvir) (1, St, s, Av), pazopanib (1, Th, s, Av), phosphodiesterase type-5 inhibitors (avanafil, tadalafil) (1, St, s, Av), phosphodiesterase type-5 inhibitors (sildenafil, vardenafil) (1, Th, m), pibrentasvir (1, St, s, Av), pitolisant (1, St, m), ponatinib (1, Th, m, Av), praziquantel (1, St, m, Av), quetiapine (1, St, m), ranolazine (1, St, s, Av), reboxetine (1, An, m), regorafenib (1, St, m, Av), repaglinide (1, St, m, Mo (blood glucose), Ad), ribociclib (1, St, s, Av), rilpivirine (1, St, s, Av), risperidone (1, St, m, Ad), rivaroxaban (1, St, s, Av), roflumilast (1, St, m, Av), rolapitant (1, St, s, Av), ruxolitinib (1, St, m, Mo, Ad), saxagliptin (1, St, m), simeprevir (1, St, s, Av), sirolimus (2, St, s, Av), sofosbuvir (1, Th, s, Av),				

(*Continued*)

Table 10 Drug interactions of AEDs with co-administered drugs. (*cont.*)

Drug	*Interaction with*	*Effect*	*Method*	*Severity*	*Advice*
	solifenacin (1, Th, m), sorafenib (1, Th, m), sunitinib (1, St, m, Ad or Av), tacrolimus (2, St, s, Mo, Ad), taxanes (cabazitaxel, paclitaxel) (1, St, s, Av), taxanes (docetaxel) (1, Th, s), temsirolimus (2, St, s, Av), tenofovir alafenamide (1, Th, m, Av), tetracyclines (doxycycline) (1, St, m, Mo, Ad), ticagrelor (1, St, s, Av), tivozanib (1, St, s), tofacitinib (1, St, s, Av), tolvaptan (1, St, s, Av), toremifene (1, St, m, Ad), trabectedin (1, Th, s, Av), ulipristal (1, An, s), vandetanib (1, St, m, Av), velpatasvir (1, St, s, Av), vemurafenib (1, Th, s, Av), venetoclax (1, St, s, Av), vinca alkaloids (vinblastine, vincristine, vindesine) (1, Th, s), vinca alkaloids (vinflunine and vinorelbine) (1, th, s, Av), vismodegib (1, Th, m, Av), vortioxetine (1, St, m, Mo, Ad), voxilaprevir (2, St, s, Av), zopiclone (1, St, Mo, Ad)				
Fosphenytoin, phenytoin	agomelatine (1, Th, m), Aminophylline (1, St, m, Ad), antiarrhythmics (lidocaine) (1, An, s), Antiarrhythmics (amiodarone) (2, St, s, Mo, Ad), antifungals, azoles (itraconazole) (1, St, m, Mo, Av)	AED decreases the effect of other drug			
	calcium channel blockers (diltiazem, verapamil) (1, St, s), Capecitabine (2, An, s), caspofungin (1, Th, m, Ad), Intravenous chloramphenicol (2, St, s, Mo, Ad), Chlordiazepoxide (2, St, s), Clobazam (2, An, s), Clonazepam (2, An, s), clozapine (1, An, m), Disulfiram (2, St, s, Mo, Ad), Diazepam (2, St, s, Mo, Ad), Diazoxide (2, An, m), Digoxin (2, St, s), efavirenz (1, Th, s), Fluorouracil (2, An, s, Ad), Folates (2, St, s, Ad). H_2 receptor antagonists (cimetidine) (2, St, s, Mo, Ad), HIV-protease inhibitors (1, Th, s), Isoniazid (2, St, m), levodopa (1, St, m), loop diuretics (furosemide) (1, St, m), metyrapone (1, St, m, Av), modafinil (2, Th, m, Mo, Ad), Monoclonal antibodies (tocilizumab)(1, Th, m, Mo, Ad), pirfenidone (1, Th, m), Quinolones (ciprofloxacin) (2, St, s, Mo, Ad), raltegravir (1, Th, m, Av), rifampicin (2, St, m, Ad), selexipag (1, St, m, Ad), SSRIs (fluoxetine, fluvoxamine) (2, An, s, Mo, Ad), SSRIs (sertraline) (3, An, s, Mo, Ad), SSRIs (paroxetine) (2, St, m), St John's Wort (2, Th, s, Av), statins (atorvastatin, simvastatin) (1, An, m), Sulfinpyrazone (2, St, m), suxamethonium (1, St, m), Tegafur (2, An, s, Mo, Ad), theophylline (1, St, m, Ad), tizanidine (1, St, m), Trimethoprim (2, St, m), vitamin D substances (1, St, m)	Increase the concentration of antiepileptics	Study	Severe	Monitor and adjust dose
	Caffeine citrate	moderately increase the clearance of caffeine citrate.	Study	Moderate	Monitor and adjust dose
	Coumarins	AED alters the anticoagulant effect	Anecdotal	Moderate	
	Dapsone	Given together can increase the risk of methemoglobinemia	Theoretical	Severe	
	Procarbazine	Combine administration may increase the risk of hypersensitivity reaction.	Anecdotal	Severe	
	Neuromuscular blocking drugs, non-depolarising (atracurium, cisatracurium, pancuronium, rocuronium, vecuronium).	AED decrease the effects of (but acute use increases the effects of drug)	Study	Moderate	
	Thyroid hormones	Increase the risk of hypothyroidism	Study	Moderate	
	Topotecan	AED increase the clearance of drug	Study	Moderate	
	Topical anaesthetics, local (prilocaine),	Combine administration may increase the risk of methemoglobinemia	Theoretical	Severe	Avoid or use with caution

Ad, adjust; *An*, anecdotal; *Av*, avoid; *m*, moderate; *Mo*, monitor; *s*, severe; *St*, study; *Th*, theoretical; *U*, unknown

Role of Pharmacists in Management of Patients with Epilepsy

Epilepsy being a chronic disease requires years long duration of treatment and in many cases life-long management at outpatient basis. Hence, it stands as a strong candidate for pharmacists to contribute especially in community settings including:

1. Empowering patient on disease management
2. Medication adherence and compliance aids/approaches
   Non-compliance or failure to medication adherence is long been identified as a major challenge in the epilepsy management (Leppik, 1988) with the consequence of increasing treatment cost and increased rate of hospitalization due to episodes of uncontrolled seizures. A properly planned counseling session that empowers patient on the management of side effects and information on the consequences of deviation from the treatment plan, as well as constant follow up and reiteration of the message play key role in medication adherence. Provision of adequate information on the use of medication should remain the prime focus of the pharmacy personnel with the use of written information where necessary. Use of simple dosage regimens and less frequent dose administrations like sustained release preparations should also be encouraged.
   Assessment of adherence is a complicated area where direct assessment using invasive approach is not always and frequently applicable. Indirect methods involve use of medication adverse events monitoring system (MEMS) by using MEMS devices and dosage unit counts. The former method is expensive whereas the latter one is not a confirmatory approach due to errors and incomplete information at many instances.
   Use of self-reported medication adherence using questionnaires like medication adherence reporting scale (MARS) is a practical approach with its limitations involving underestimation of adherence. A short study with limited number of participants accessed on telephone showed significant increase in the number of patients perfectly adherent to their AED prescriptions assessed suing MARS after the pharmacist led epilepsy consultation (Fogg et al., 2012). Especially showing improvement in quality of life by decreasing seizure worry, coping with physical effects of AEDs, and emotional well-being. Participants reported to be more aware on the information on medicines and their working, how they interfere with other medicines and side effects after the consultation by pharmacist.
3. Monitoring of efficacy (recording seizure control/seizure diary)
4. Monitoring of toxicity (information on symptoms of toxicity)
5. Drug interactions
6. TDM
7. Adverse drug reaction monitoring and management of side effects
8. Specialized dosing protocols (low starting dose and slow tapering)
9. Management of status epilepticus and prevention of development of refractory seizures/importance of emergency management in epilepsy
10. Counseling on the decision for stopping the treatment
    Upto 40% of patients who are seizure free for more than 2 years may have a risk of relapse. The longer the patient remains seizure free the lesser the chances of relapse. Relapse of seizures may have serious social consequences as well as the complication that the seizures might not be controllable by the initial drugs and dosage regime. Hence, it is important to inform and involve the patient of the possible risks and benefits of the termination of AED therapy in before making the decision. In any case, the withdrawal should be carried out very slowly with tapering of one drug at a time (Whittlesea and Walker, 2011).
11. Management of withdrawal symptoms
12. Management of poisoning and over dose
13. To inform what to do when the dose is missed
14. Generic substitution and use of therapeutic equivalence for AEDs
    Prescribing generic AEDs is challenging because of these being narrow therapeutic index drugs as well as due to the associated apprehensions and actual events of loss of seizure control, chances of pharmacoresistance, and withdrawal symptoms that force the practitioners and patients to weigh down the expected cost savings of generic substitution (Gidal, 2009). Certain patients show more vulnerability to the variations in blood levels associated with the formulation changes (Gidal, 2009). Difficulty in generic substitution also makes the AEDs a complex area regarding the access issues especially affordability of medicines. In a study on lamotrigine, it was estimated that the increased hospital visits and more chances of emergency services and hospitalization due to generic substitutions may in some instances prove to be more expensive when total per annum projected costs were considered (LeLorier et al., 2008). Care should be taken for drugs like phenytoin where drug dose–serum level relationship does not behave linearly. The publications and reports on potential harms of switching the branded AED with generic drug has been reviewed by Commission Human Medicine (CHM) and concluded that the loss of seizure control could be chance associations and could not be related to switching therapy. AEDs have been sub-divided into three categories depending upon brand substitution advice (**Table 11**).
15. Quality of life assessment
    Use of self-administered questionnaires for assessing health related quality of life in epilepsy inventory (QOLIE-32) or general health questionnaire (GHQ-12) can help pharmacist in assessing the patient's well being and identifying the need for change in prescription or information to patient on managing ADRs and drug interactions

Table 11 Medicines and Healthcare Regulatory Authority (MHRA)/Commission on Human Medicine (CHM) advice on brand substitution of AEDs (Royal Pharmaceutical Society, 2018)

Category	*AEDs*	*Advice*
1	Phenytoin, carbamazepine, phenobarbital, primidone	Patient should be maintained on a particular manufacturer's product
2	Valproate, lamotrigine, perampanel, rufinamide, clobazam, clonazepam, oxcarbazepine, eslicarbazepine acetate, zonisamide, topiramate	Need of particular manufacturer's product is based on clinical judgment and consultation with the physician and patient
3	Levetiracetam, lacosamide, tiagabine, gabapentin, pregabalin, ethosuximide, vigabatrin	Unnecessary to maintain the patient on a particular manufacturer's product, unless risk of patient confusion, dosing error or patient anxiety is expected.

Apart from the earlier mentioned generalized role of pharmacists for patients with epilepsy, some patient groups may exhibit additional needs for which pharmacists can provide more diverse range of services in helping the patient achieve the treatment objectives.

1. Role of pharmacists for patients with psychiatric comorbidities
   Epilepsy and psychiatric disorders have bidirectional relationship. Mula enlists a checklist for patients with epilepsy and psychiatric comorbidities which comprises three prime components closely related to the medication use presenting potential roles of the pharmacists in the care of epileptic patients. It states that the potential treatment-emergent psychiatric problems of AED's must be discussed with the patient, low starting dose and slow titration of AEDs must be ensured, and potential side effects and drug interaction should be discussed with the patients (Mula, 2017).
   Patients with aggressive behavior receiving topiramate are at 4 times higher risk of developing depression when started with AEDs. A study on epileptic patients shows that the use of rapid titration schedule increases the risk of depression with topiramate to 23 times and 12.7 times higher in patients with history of depression and febrile seizures, respectively (Mula et al., 2009).
   Attention deficit hyperactivity disorder (ADHD) has been identified as an important comorbidity which adversely affects the quality of life of patients with epilepsy in children and adolescents. Contrary to the reluctance of clinicians on co-prescription of AEDs and methylphenidate, RCTs have shown a positive response rate from 60% to 70% in this respect. However, due to inhibitory effect of methylphenidate on hepatic isoenzymes a low starting dose, slow titration rate and clinical monitoring are advised during therapy.
   In case of psychiatric comorbidities, there are higher degree of chances of pharmacokinetic interactions of psychotropic drugs with inducers drugs carbamazepine, barbiturates and phenytoin. Increased risk of seizures (especially with clozapine), weight gain, higher risk of sedation and sexual dysfunction are some of the complications that arise in the concomitant therapy with AEDs and antiepileptic medicines (Mula, 2017)
2. Role of pharmacists for women with epilepsy
   Gender is an important consideration for designing the counseling and pharmaceutical care services for the patients receiving AEDs. Adverse effects such as hormonal disturbances, weight gain, menstrual irregularities as well as the hormonal phases (menstruation, contraception and menopause), reproductive phases (fertility, pregnancy and lactation) require special counseling and interventions to prevent decline in the patient's quality of life, a problem that is documented for women with epilepsy. Girls taking enzyme-inducing AEDs are advised to avoid concomitant use of progestogen pill and implants (National Institute of Health and Care Excellence, 2018). Difficulty in control of number of seizures, need of multiple AEDs and depression are the challenges faced in clinical care of these patients. **Table 7** provides the key information on the use of AEDs during pregnancy and lactation along with the recommended actions to be taken. Losada-Camacho et al. (2014) have studied provision of pharmacy services in women with epilpesy. **Table 12** describes various pharmacist-led interventions and varous assesment methods used to performs these services.
3. Role of pharmacists in dealing with pediatric patients and their caregivers

Table 12 Few examples of pharmacy services provided in epilepsy management for women with epilepsy and their assessment methods (Losada-Camacho et al., 2014)

	Pharmacy service/ pharmacist-led intervention	*Assessment methods*
1.	Medication review	Dader's method
2.	Group education session	
3.	Adherence	Haynes–Sackett test and Moriski-Green test
4.	Adverse drug reaction	Liverpool adverse event profile (Liverpool AEP)
5.	Depression	Questionnaire of the center for epidemiologic studies depression scale (CES-D),
6.	Seizure frequency record	Using seizure diary
7.	Health related quality of life (HRQOL)	Quality of life in epilepsy inventory-31 (QOLIE-31

Epilepsy Management and Importance of Multidisciplinary Clinical Team

Multidisciplinary clinical team approaches are encouraged for the management of epilepsy. The need of constant evaluation of efficacy and toxicity of the therapy has led to involvement of many non-prescribers to deliver this role including nurses and pharmacists. Pharmacist-led epilepsy consultation provide more information on medication adherence, addressing the queries of the patient regarding therapy, advise in time, changes in the prescription due to reported ADRs and the changes needed to suite the patient preferences and life style.

Management of Neurological Disorders and Pharmacist's Role: Multiple Sclerosis

Shazia Q. Jamshed[*], Angham Ibrahim[†], Ahmed Awaisu[‡], Adeel Aslam[*], Mohammad J. Siddiqui[§], Madeeha Malik[‖], Azhar Hussain[‖], [*]Department of Pharmacy Practice, Kulliyyah of Pharmacy, International Islamic University Malaysia, Kuantan, Pahang, Malaysia; [†]College of Pharmacy, Qatar University, Doha, Qatar; [‡]College of Pharmacy, Qatar University, Doha, Qatar; [§]Department of Pharmaceutical Chemistry, Kulliyyah of Pharmacy, International Islamic University Malaysia, Kuantan, Pahang, Malaysia; [‖]Hamdard University, Islamabad, Pakistan

Learning Objectives

At the end of this chapter, the reader should be able to:

- Describe the epidemiology, etiology, pathophysiology, clinical manifestations, and diagnosis of multiple sclerosis (MS).
- Discuss the course of illness and complications associated with MS.
- Identify the pharmacological and nonpharmacological approaches used in the management of the different forms of the disease.
- Identify the current and future role of pharmacists in the management of MS.

Take-Home Message

MS is an autoimmune chronic inflammatory condition that affects the central nervous system (CNS) and is associated with an unpredictable clinical course. Although MS has no cure, different therapeutic modalities hold a great promise for the treatment of MS at different stages. The challenging safety profiles and trajectory of prices of the different therapeutic agents call for the need of emphasizing the pharmacist's role in the management of MS. Pharmacists contribute to the management of MS through serving as patients advocates and collaborating with other health care professionals to generate better health outcomes.

Introduction

MS is an autoimmune disease, characterized by chronic inflammation that affects the CNS (i.e., the brain, spinal cord, and optic nerves) (Goldenberg, 2012). MS causes an immune-mediated axonal damage and demyelination of the protective myelin sheaths covering the nerve cells. Inflammation and absence of myelin interrupt the transmission and affect numerous elements of the

human body. This can result in various reversible and irreversible consequences, including potential disability (Goldenberg, 2012). However, due to the unpredictability of the disease course, some patients may present with a worsening disease associated with major disability over time, while others may experience a milder course with little to no disability. Although one cannot anticipate how the disease may progress with each individual patient, most patients often experience short periods of symptoms or acute exacerbations followed by longer periods of partial or full recovery (Leray et al., 2016). Recently, several environmental and genetic factors have been associated with the development of MS; however, the etiology of the disease remains unclear (Ascherio and Munger, 2016; Reich et al., 2018).

Moreover, depending on the severity and course of disease progression, MS could be classified into four different disease forms with variable responses to therapy: (1) relapsing remitting MS (RRMS), (2) primary progressive MS (PPMS), (3) secondary progressive MS (SPMS), and (4) progressive relapsing MS (PRMS) (Ascherio and Munger, 2016; Reich et al., 2018). Consequently, patients with MS may experience a variable range of clinical signs and symptoms. Most common among these are acuity and visual disturbances, walking difficulties, helplessness, and clumsiness in attitude and emotions, changes in pain perception, and peculiar sensation like tingling (Swann, 2008). In addition, while there is currently no cure for MS, a number of pharmacologic and nonpharmacologic approaches are available for the management of MS, including injectable and oral disease-modifying therapies (DMTs) (Ascherio and Munger, 2016; Reich et al., 2018). Furthermore, newer challenges have surfaced with the emergence of novel MS treatments. Thus, research is still ongoing in this area in order to improve the overall quality of care of MS patients. MS is associated with a significant economic burden globally (Schafer et al., 2010). Pharmacotherapy as well as MS-related hospitalizations, physical/occupational therapy, and polypharmacy are among the major contributors to MS cost burden (Asche et al., 2010; Schafer et al., 2010).

Epidemiology of Multiple Sclerosis

MS is the most common neurologic disorder worldwide. Its prevalence has been steadily increasing globally; according to the Atlas of MS, the number of MS patients increased from 2.1 million in 2008 to approximately 2.3 million in 2013 worldwide. Nonetheless, the likelihood of underestimation cannot be ruled out owing to limited data from India and China (Browne et al., 2014). In addition, with an uneven global distribution, the prevalence of MS is highest in North America (140/100,000 population) and Europe (108 per 100,000 population) and lowest in East Asia and Sub-Saharan Africa (Browne et al., 2014). Although the prevalence of MS is highest in Europe and North America (Heydarpour et al., 2015; Leray et al., 2016), a shift toward a moderate-to-high prevalence of MS has been evident in several gulf countries, including Qatar (Deleu et al., 2013), Kuwait, and Iran (Ascherio and Munger, 2016; Leray et al., 2016; Reich et al., 2018).

Generally, there is a 2:1 ratio of women-to-men with MS, indicating an increasing incidence of MS in women worldwide. In America, the incidence of MS in women is more than twice that in men with a ratio of 2.6. The reason pertaining to the higher difference of MS risk in women as compared with men has not been fully established; however, it is believed to be related to different social and environmental aspects, including genetic differences (Browne et al., 2014). Moreover, MS is often diagnosed between the ages of 15–45 years, with an average age of MS onset is 30 years (Awad and Stüve, 2010; Leray et al., 2016).

Pathophysiology of Multiple Sclerosis

There are several suggestions pertaining to the involvement of the immune system in the pathogenesis of MS. Although still debatable, the autoimmunity theory of MS has been well established to be the underlying mechanism that guides the understanding of the pathogenesis of MS (Korn, 2008). Briefly, according to several lines of evidence, in MS myelin antigen-specific CD4+ T helper cells are activated in the peripheral immune compartments. The activated T cells then cross the blood–brain barrier into the CNS, resulting in further differentiation of autoreactive T cells and production of effector cytokines. This, in turn, contributes toward dissemination of immune cells (e.g., macrophages) into the CNS parenchyma. Consequently, the immune cells mediate the inflammation and demyelination of the myelin sheaths resulting in axonal damage and secretion of toxic oxygen species. With time, the immune-mediated CNS destruction and axonal damage may become irreversible causing severe disability in MS patients. In addition, chronic inflammation and continued neurodegeneration may promote secondary progressive forms of the disease (Korn, 2008; Wu and Alvarez, 2011). While the actual trigger for the activation of this autoimmune inflammatory activity in MS patients remains elusive, evidence suggests that certain infectious agents (e.g., Epstein–Barr virus) may be responsible for initiating this peripheral immune activation (Korn, 2008; Wu and Alvarez, 2011).

Etiology of Multiple Sclerosis

As mentioned previously, the etiology of MS, like other autoimmune disorders, is still unclear. However, several modifiable and nonmodifiable environmental, hereditary, and epigenetic risk factors have been identified as possible contributors to the overall risk of developing MS. Such factors include genetic variations, female gender, smoking, and low vitamin D levels. While an increased risk is inevitable with MS-associated genetic factors, some environmental and lifestyle-related risk factors can be modified to minimize interactions with genetic events, thus serving as possible preventative mechanisms for MS (Olsson et al., 2017).

Genetic Susceptibility of Multiple Sclerosis

The strongest known genetic element attributed to MS susceptibility may be the HLA-DRB1*1501 haplotype (Patsopoulos et al., 2013). However, it is not fundamental for the development of MS because it only escalates the risk by two to fourfolds and exists in about 20%–30% of healthy individuals. In contrast, there is a strong association between hereditary elements and the development of MS, whereby an up to 40-fold increase in the risk of disease development is evident in first-degree relatives of patients with MS. In addition, the risk is increased by up to 30% in monozygotic twin (Zwibel and Smrtka, 2011).

Environmental Factors Associated With Multiple Sclerosis

Environmental factors, such as vitamin D levels, viral infections, sunlight exposure, geographic latitude, and place of birth, play a key role in determining the risk of developing MS. One proposed explanation for the potential association of MS with latitude is that contact with sunlight could be protective, either due to the impact of ultraviolet radiation or due to that of vitamin D (Ascherio and Munger, 2007). Moreover, research highlights a relationship between sunlight exposure, ultraviolet radiation, serum vitamin D levels, and the risk of MS (van der Mei et al., 2003; Munger et al., 2004); such that some of these factors are thought to be inversely correlated with MS disease activity in established MS cases (Mowry et al., 2012; Ascherio et al., 2014).

In view of the evidence, the distribution of MS is higher in areas away from the equator. Caucasians and residents of Northern European descents are at a significantly higher risk of developing MS as compared with other ethnicities. In addition, although the chance of developing MS is higher in individuals residing in areas of Northern Europe, the degree of disease risk may differ with respect to their place of residence in early life. According to a research conducted by Dean and Kurtzke (1971), migration from low to high-risk zones in childhood does not increase the risk or chance of developing MS. However, the complete cutoff is relatively indeterminate, considering that Hispanic Americans and Black Americans encounter more rapid disease development than White Americans (Ventura et al., 2017). Moreover, environmental triggers unrelated to geography are also possible risk factors for the development of MS. Such triggers include tobacco smoking, obesity, contraception, and late childbirth (Franklin and Nelson, 2003; Koch-Henriksen and Sørensen, 2010). Interestingly, the risk of MS relapse is significantly reduced during pregnancy, but increases again postpartum (Lee and O'Brien, 2008).

Clinical Presentation—Signs and Symptoms of Multiple Sclerosis

Clinical signs and symptoms are widely variable among different MS patients. Similarly, symptoms severity and degree of disease progression may also vary extensively within the same individual over time (Schapiro, 2005). Initially, patients commonly present with sensory deficits like tingling or numbness, optic neuritis manifested as blurry or doubled vision, muscle pain or weakness, and problems in gait or bladder control. At a later stage, symptoms such as cognitive impairment, mood swings, and physical fatigue may become more prominent. Accordingly, complications secondary to primary disease symptoms may arise over time, such as urinary tract infections secondary to MS-related urinary retention (Schapiro, 2005). Eventually, patients may develop symptoms that affect their daily life activities and overall quality of life (Schapiro, 2005).

As mentioned earlier, the clinical course of MS has four clinical classifications (Lublin et al., 2014). First is the RRMS phase in which 85% of patients present with exacerbations that last for at least 24 h, following a clinically isolated syndrome (CIS). These new symptoms, also known as relapses, correspond with magnetic resonance imaging (MRI) findings and are subsequently followed by clearly defined periods of complete or partial disease remission. Due to the unpredictable nature of the disease, the occurrence of MS attacks cannot be anticipated (Lublin et al., 2014). However, certain circumstances have been associated with symptoms or exacerbations such as heat, stress, infections, and malnutrition. Subsequently, most RRMS patients enter a progressive phase, referred to as SPMS, which is characterized by evidence of significant disability with undistinguishable periods of relapses and remissions (Lublin et al., 2014). On the contrary, around 10%–15% of patients begin with a progressive form of MS at disease onset, a phase referred to as PPMS (Lublin et al., 2014). PPMS is equally common in men and women and is characterized by a worsening disability which is diagnosed at a later age (Tremlett et al., 2005). Finally, at onset, fewer patients (~5%) present with a mixture of both a progressive and a relapsing form of MS known as PRMS (Lublin et al., 2014). Notably, although the life expectancy of MS patients is not directly affected by the condition, several factors may be associated with a better disease prognosis, such as the female gender, or a less favorable one, such as an age of disease onset later than 40 years.

Diagnosis of Multiple Sclerosis

The diagnosis of MS is challenging because it shares common features with other neurological disorders. A complete neurological examination and collecting a comprehensive medical history are essential for excluding other causes and confirming a correct MS diagnosis (Ghasemi et al., 2017). Despite the lack of a specific diagnostic test for MS, a set of criteria, known as "McDonald Criteria," were established by an international panel of MS experts in association with the National MS Society of America for the purpose of achieving a prompt diagnosis to allow for a sooner initiation of MS treatment (McDonald et al., 2001). Briefly, according to the McDonald Criteria, a diagnosis of MS is established upon the identification of two different neurological attacks that have occurred

at two different time points and are in at least two distinct locations in the CNS (brain, spinal cords, or optics nerves) (McDonald et al., 2001; Polman et al., 2005). The attacks could be identified through the patient's clinical history, MRI examination, or both, given that other possible causes for such events are ruled out. The first attack is referred to as CIS, for which several medications are approved for use at this stage to prevent progression to a clinically definite MS diagnosis (Swanton et al., 2007). On the contrary, patients may initially present with a radiologically isolated syndrome (RIS), which may progress to a CIS and eventually to a clinically definite MS over time (Lebrun et al., 2009). RIS is a newly identified concept whereby asymptomatic patients present with incidental MRI findings suggestive of MS; however, unlike CIS, the initiation of MS treatment at this stage is still elusive (Lebrun et al., 2009; Gerber et al., 2017).

In addition to the typical clinical symptoms, data from MRI are generally considered in order to support the diagnosis of the condition, given the characteristic CNS lesions associated with MS, also known as plaques or sclerosis (Ghasemi et al., 2017). On the contrary, cerebrospinal fluid (CSF) evaluation, blood analysis, and neurophysiological testing could provide major evidence toward a more accurate diagnosis. Moreover, characteristic biomarkers in MS are objectively measured and evaluated as indicators of normal biological processes, disease activity, disease progression, and pharmacological response to therapeutic interventions (Lesko and Atkinson, 2001; Paul et al., 2018). The most established biomarkers in MS are linked to MRI of the brain, which permits the identification and quantification of MS lesions of progressive nature (Martin et al., 2006). Although the biological biomarkers in MS have already been identified in various bodily fluids, such as urine, blood, tears, and CSF, each kind of specimen has its own merits and demerits. In addition, as MS lesions are hardly ever biopsied, the CSF evaluation remains the optimal indictor of the disease pathology and could better reflect on relevant inflammatory mechanisms (Sospedra et al., 2010). Furthermore, the use of optical coherence tomography for the evaluation of the retina is also noteworthy because the ganglion-cell axon loss in the retina corresponds to changes in the brain MRI and can predict the development of disability in MS patients (Saidha et al., 2015).

Management of Multiple Sclerosis

Pharmacological Therapy

The pharmacotherapy of MS is grouped into three different classifications: (1) treatment of acute MS exacerbations; (2) management of the underlying disease course; and (3) management of MS-related symptoms. These three treatment categories are aimed at minimizing the duration and severity of attacks, halting the disease progression, and optimizing patients' quality -of -life, respectively. Moreover, slowing the progression of disability over time and maintaining the quality -of -life in patients with MS mandate an early detection of the disease followed by an immediate initiation of drug therapy (Polman et al., 2005). Although international MS guidelines and relevant professional associations have proposed several treatment algorithms, a universally accepted algorithm is yet to be established. Hence, due to the complexity of MS and the heterogeneity of symptoms among different patients, a treatment algorithm is often tailored as per each individual patient case, while constantly weighing for the benefit-to-risk ratio. One example of a simple treatment algorithm adopted from a clinical review published in the *British Medical Journal* is demonstrated in **Fig. 1** (Wingerchuk and Weinshenker, 2016).

In addition, owing to the demanding monitoring schedules, the need for comprehensive educational sessions, and the introduction of new pharmacological agents, the management of MS could become challenging for health care practitioners, patients, and patients' caregivers (Förster et al., 2019). However, different evidence-based therapeutic categories, both pharmacological and nonpharmacological, have been proven efficacious in treating the relapsing-remitting stages, slowing the disease progression, and reducing the treatment burden.

Treatment of Acute Attacks

The goal of the acute management of MS is to reduce the duration and severity of initial or recurrent attacks (Kaufman et al., 2000; Ontaneda and Rae-Grant, 2009; Rae-Grant et al., 2018). MS exacerbations could be defined by a number of findings that must solely be attributed to the natural course of the disease: (1) new or enhancing MRI lesions of the brain, spinal cord, or optic nerves; (2) a new MS-related symptom or one that is worsening over a period of 2 weeks; and (3) clear functional limitations. Findings secondary to other causes, such as heat, stress, or infections, are referred to as "pseudo-exacerbations" and should be carefully ruled out before administering an acute therapy or modifying a current disease-modifying therapy (DMT).

According to the European Committee of Treatment of Research in Multiple Sclerosis and European Academy of Neurology (ECTRIMS/EAN), American Academy of Neurology (AAN), and the NICE guidelines, a high-dose intravenous (i.v.) corticosteroid (500–1000 mg i.v. methylprednisolone) should be administered for 3–5 days as first-line therapy in patients with acute MS attacks (Kaufman et al., 2000; Perry et al., 2014; Montalban et al., 2018). Although the mechanism of action of corticosteroids in MS remains unclear, they presumably speed up recovery by exerting an anti-inflammatory effect in the CNS (Ontaneda and Rae-Grant, 2009). Moreover, i.v. methylprednisolone has also been shown to delay subsequent MS attacks by 1–2 years (Kaufman et al., 2000), although this did not directly affect MS progression (Zivadinov et al., 2001). On the contrary, guidelines recommend the use of plasma exchange or i.v. immunoglobulin as second-line treatments if an exacerbation fails to respond to i.v. corticosteroid or if a patient initially presents with a severe attack (e.g., paraplegia).

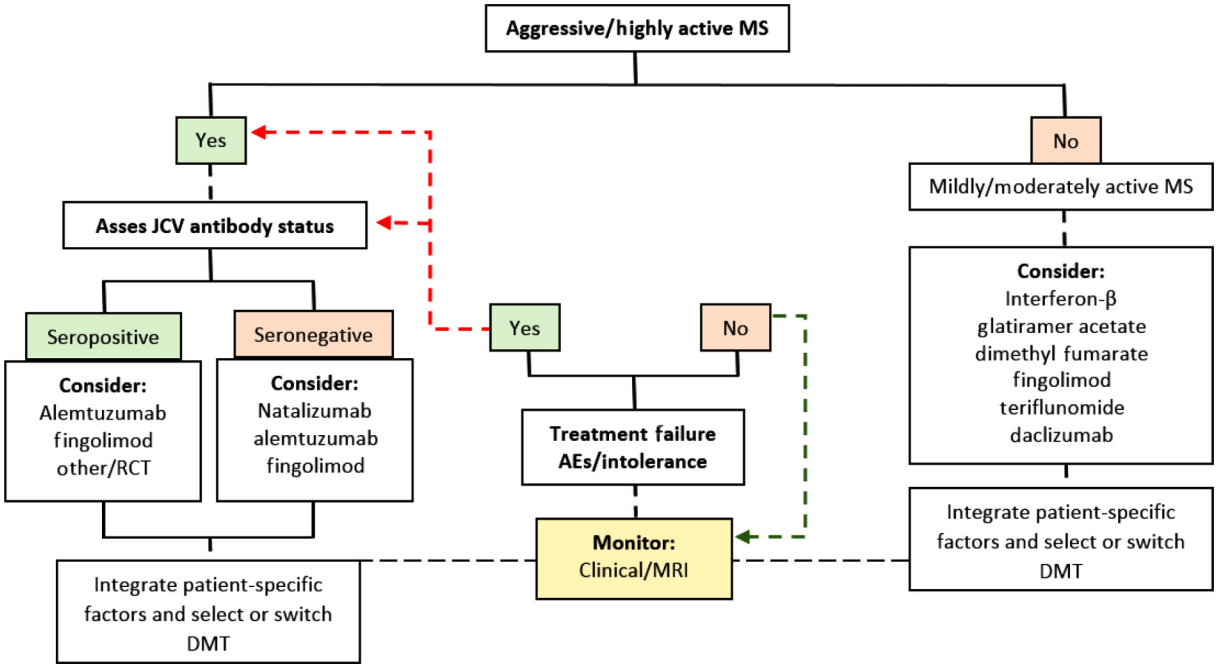

Figure 1 A proposed algorithm for the treatment of multiple sclerosis.

Disease-Modifying Therapy

While some clinicians may choose to defer the use of DMT until the nature of the disease course is clearly identified, current evidence recommends conducting a more comprehensive diagnostic work-up to allow for a sooner initiation of therapy (McDonald et al., 2001; Polman et al., 2005). On that note, the available DMTs do not cure MS; however, they can alter the immune system either through immunomodulation or through immunosuppression. Although both therapies target the inflammatory activity of MS (Katsavos and Anagnostouli, 2013), immunosuppressant drugs tend to cause direct cytotoxic activity and bone marrow suppression, while immunomodulatory agents do not. With this in mind, selecting a DMT is generally based on determining the severity of the initial disease presentation, availability of treatment options, safety profiles of the medications, and patients' preferences and expectations (Montalban et al., 2018).

Moreover, patients are usually assigned either to an induction or an escalation treatment algorithm depending on the intensity of their initial clinical presentation. In the escalation approach, FDA-approved self-injected medications, that are associated with better safety profiles yet partial effectiveness, are considered first-line treatments (four interferon-β [IFN- β] formulations and glatiramer acetate) (Kasarełło et al., 2017). However, upon evidence of ongoing treatment failure, patients are consequently switched to second-line DMTs (natalizumab, ocrelizumab, mitoxantrone, fingolimod, teriflunomide, dimethyl fumarate, and alemtuzumab) owing to their higher effectiveness (Kasarełło et al., 2017). On the contrary, the induction strategy involves using second-line DMTs as initial therapies in the earlier phases of the disease, followed by long-term maintenance treatment. Despite their high therapeutic effectiveness, second-generation DMTs are also associated with higher risk of more serious side effects (De Jong et al., 2017). Therefore, the induction treatment approach is generally reserved for patients with poor prognosis or highly active disease at onset. On the contrary, DMTs can be subclassified into three other categories based on the premises of safety (e.g., INF-β and galtiramer acetate), convenience (e.g., oral DMTs: fingolimod, teriflunomide, and dimethyl fumarate), and effectiveness (e.g., natalizumab, ocrelizumab, and alemtuzumab). Lastly, an investigational or non-FDA-approved drug, such as rituximab, is recommended in the case that both the first- and second-generation DMTs fail to improve the disease progression, that a patient initially presents with aggressive forms of MS, or that a patient is unable to tolerate the initial therapy (Montalban et al., 2018).

The common DMTs used in the treatment of MS are summarized in **Table 1** (Comi et al., 2017).

Additionally, it is important to recognize that DMTs do not improve symptoms secondary to MS. Several pharmacological agents such as methylphenidate, gabapentin, baclofen, and propantheline are recommended for the treatment of MS-related fatigue, sensory complaints, spasticity, and abnormal bladder control, respectively (Schapiro, 2005).

Summary of Recommendations from Clinical Practice Guidelines

According to most recent evidence-based clinical practice guidelines in Europe, the United Kingdom, the United States, and Australia/New Zealand, all patients with recent evidence of active RRMS should be started on a DMT (Ontaneda and Rae-Grant, 2009; Broadley et al., 2014; Montalban et al., 2018; Rae-Grant et al., 2018). However, the guidelines recommend individualizing the choice of a specific DMT as per the patient's clinical presentation, personal values, expected goals, medical comorbidities, and medications tolerability. The ECTRIMS/EAN guidelines also recommend the initiation of a low-risk DMT, either INF-β or

Table 1 Disease-modifying therapies used in the treatment of multiple sclerosis

Medication	*Trade name*	*Indication*	*Dose and route of administration*	*Side effects*	*Comments*
First-generation DMTs (safety -preference)					
Interferon-β1a	Avonex	CIS; RRMS. SPMS	30 μg IM every week	Injection-site reactions, elevated liver enzymes, depression	Self-injectable
Interferon-β1a	Rebif	CIS; RRMS. SPMS	44 μg SQ three times a week	Injection-site reactions, elevated liver enzymes, depression	Self-injectable
Interferon-β1b	Betaferon/ Extavia	CIS; RRMS. SPMS	250 μg SQ every other day	Injection-site reactions, elevated liver enzymes, depression	Self-injectable
Pegylated interferon-β1a	Plegridy	RRMS	6.3 μg SQ day 1, then 94 μg SQ on day 15, then 125 μg SQ on day 29, then 125 μg SQ every 14 days	Injection-site reactions, elevated liver enzymes, depression	Self-injectable
Glatiramer acetate	Copaxone	CIS; RRMS	20 mg SQ once daily	Injection-site reactions, flu-like symptoms, lipoatrophy	Self-injectable; pregnancy category B
Second-generation DMTs (convenience -preference)					
Fingolimod	Gilenya	RRMS	0.5 mg orally once daily	Bradycardia, infections	Risk of PML
Teriflunomide	Aubagio	RRMS	14 mg orally once daily	Diarrhea, hair thinning	Teratogenic (pregnancy category X)
Dimethyl fumarate	Tecfidera	RRMS	240 mg orally twice a day	Flushing, gastrointestinal symptoms	Risk of PML
Second-generation DMTs (effectiveness -preference)					
Natalizumab	Tysabri	RRMS	300 mg i.v. every 4 weeks	Infusion reactions; infections	i.v. infusion; risk of PML
Ocrelizumab	Ocrevus	RRMS; SPMS; PPMS	300 mg i.v. once, and 300 mg i.v. once after 2 weeks, then 600 mg i.v. once every 6 months	Infusion reactions; infections	i.v. infusion; contraindicated in active hepatitis B virus infection
Alemtuzumab	Lemtrada	RRMS	12 mg i.v. once a day for 5 consecutive days and, after 12 months, 12 mg i.v. once a day for 3 days	Infusion reactions; infections	i.v. infusion

CIS, Clinically isolated syndrome; *DMTs*, disease-modifying therapies; *IM*, intramuscular; i.v., intravenous; *PPMS*, primary progressive multiple sclerosis; *RRMS*, relapsing-remitting multiple sclerosis; *SPMS*, secondary-progressive multiple sclerosis; *SQ*, subcutaneous.

galtiramer acetate, for patients with a CIS and characteristic radiological finding who do not fulfill the criteria of definite MS diagnosis (Montalban et al., 2018).

Upon the progression of RRMS to SPMS, it is recommended that patients be started on, or switched to, an INF-β1a/1b formulation. Ocrelizumab and mitoxantrone have also demonstrated efficacy in reducing relapse rates in patients with SPMS (Montalban et al., 2018). Moreover, a randomized clinical trial showed that mitoxantrone reduced the progression of disability in patients with PRMS (Hartung et al., 2002). However, owing to its high -risk of serious adverse events, mitoxantrone should only be offered to MS patients if the benefits significantly outweigh the risks. In addition, according to the AAN and ECTRIMS/EAN guidelines, ocrelizumab should be offered to patients with PPMS following a careful evaluation of its benefit-to-risk ratio. Generally, given that patients are adherent to current therapy, clinicians should consider switching to another DMT upon evidence of frequent disease activity over a period of 1 year, a long enough duration to determine the full efficacy of a DMT.

Finally, all guidelines recommend that DMTs should be stopped and should not be initiated during pregnancy, unless the risk of MS during pregnancy outweighs the risk of DMT use during pregnancy. Women of childbearing age are strongly advised to follow strict contraceptive methods and discuss pregnancy planning with their health care providers. According to the ECTRIMS/EAN guidelines, women who plan to become pregnant despite pervious recommendations should be offered either INF-β or glatiramer

acetate until pregnancy is confirmed. In the event that women becomes pregnant, the use of glatiramer acetate, natalizumab, or alemtuzumab throughout pregnancy may be considered.

Non-pharmacological Treatment

Nonpharmacologic approaches are interventions offered either by health care practitioners or by caregivers to alleviate the sufferings and symptoms of patients with MS for the purpose of minimizing disease-related morbidity. As MS is associated with a wide range of symptoms, several nonpharmacological approaches are recommended to minimize MS-related pain, fatigue, spasticity, and mood disorders. Such approaches include transcutaneous electrical nerve stimulation, psychotherapy, moderate physical exercise, transcranial random noise stimulation, transcranial direct stimulation, hydrotherapy, reflexology, neuromuscular electrical stimulation, modified Paleolithic diet, stress management, meditation, and massages. In addition, lifestyle modifications can improve MS symptoms and reduce symptoms or exacerbations (Bowling, 2014). Therefore, MS patients are also advised to adhere to self-management activities such as drinking plenty of fluids, reporting signs of infections or disease relapse, avoiding extreme temperatures, and avoiding excessive exercise (Bowling, 2014).

Moreover, incorporation of physical exercise in the clinical care of MS can positively affect patients' wellness, quality -of -life, and participation in daily life activities (Motl et al., 2017). A large body of evidence demonstrated mixed findings with regard to the effect of physical exercise on the disease progression in patients with MS (Roehrs and Karst, 2004; Ratchford et al., 2010; Pilutti et al., 2011; Straudi et al., 2013; Fornusek and Hoang, 2014; Pilutti et al., 2016). However, results showed improvements in thigh circumference, endurance and severe spasticity, walking rate, gait, fatigue, and quality -of -life (Roehrs and Karst, 2004; Ratchford et al., 2010; Pilutti et al., 2011; Straudi et al., 2013; Fornusek and Hoang, 2014; Pilutti et al., 2016).

Monitoring Therapy in Multiple Sclerosis

MRI is the most commonly recommended tool for the quantification of lesions in MS patients. It is used for estimating disease progression and identifying response to therapy. MS is characterized by a buildup of plaques in white matter and gray matter, which are presented as quantifiable volumes of deviant magnetic properties in conventional MRI (i.e., in T2-weighted imaging data T2 lesions). New or enhancing T2 lesions that appear during therapy are reliable indicators of subclinical disease evolution and inflammatory activity. In addition, the most widely used means of measuring the progression of MS over time is the clinical rating scale called the "Expanded Disability Status Scale" (EDSS) (Kurtzke, 1983). The EDSS is used to evaluate the change in patients' neurological and daily functioning (Kurtzke, 1983).

MS is associated with a complex array of symptoms and possible risk of disability issues. Therefore, monitoring of physical, social, and cognitive parameters is important to ascertain adequate counseling and treatment measures (Köhler et al., 2018). Likewise, one cannot underestimate the concept of self-monitoring, which not only benefits the patients but also provides health care professionals with more relevant information about the patient's condition. The International Organization of Multiple Sclerosis Nurses (IOMSN) highlighted the need of a self-assessment scale that enables close monitoring of MS patients for the goal of achieving better care outcomes.

"Monitoring My Multiple Sclerosis", a web-based monitoring algorithm which incorporates various patient outcome measures, along with computerized cognitive batteries (such as the CogState Brief Battery), wearable biosensors, and a recently developed application (MS Sherpa) is used in examining disability, functional mobility, and cognitive impairment in MS patients. Although periodic assessments in clinical settings remain imperative for the evaluation of MS progression, active and passive smartphone-based self-monitoring strategies are more explicit in nature. Despite being user-friendly and convenient, those monitoring devices could be subject to several limitations including potential measurements' inaccuracy, non-adherence by users, and the issues with data management.

Prevention

With more than 2 million people afflicted globally and the burden of disease being substantial both on individuals and society, modifiable risk factors need to be identified to prevent morbidity and mortality. Given that vitamin D is one of the key regulators of the immune and nervous function, low vitamin D can increase the chances of developing MS. Studies suggestive of reduced relapse rate with increased vitamin D levels demonstrate the positive role of vitamin D in preventing the development of MS. In the present era of vaccine being marketed for every disease, it is imperative to remember that no single microorganism is implicated in MS and therefore developing a vaccine to prevent MS cannot be of substantive significance, although BCG vaccine was reported to decrease the number of active brain lesions in MRI scan of MS patients. Furthermore, maintaining a healthy lifestyle with normal BMI, abstinence from smoking and alcohol, and gearing up with dietary modifications such as omega-3 oils are expected to keep MS at bay.

The Role of Pharmacist in the Management of Multiple Sclerosis

The idea behind medication therapy management (MTM) is to assess patients from a holistic viewpoint, identify and resolve all patients' drug-related problems, promote concordance and adherence to drug and nondrug therapy, and create customized care plan

with emphasis on regular follow-ups for better health care outcome (Anderson and Philbrick, 2014). Pharmacists can be viewed as educators and counselors for MS patients and assist them in setting realistic goals for their therapy and lifestyle modifications, and prior inform the patients regarding the barriers related to adherence (Anderson and Philbrick, 2014). In the context of MS, therapeutic agents have challenging safety profiles and may require regular laboratory monitoring with close follow-up for undesirable effects. For instance, consistent laboratory monitoring is essential for many medications and therefore, in patients prescribed with dimethyl fumarate (Tecfidera [Biogen Idec]), lymphocyte counts need to be assessed every 6 months.

The presence of a skillful clinical pharmacist is expected to minimize the chances of medication errors and treatment delays and promotes improved adherence, culminating into better clinical outcomes for the patients (Schultz et al., 2016). A pharmacist can be an active member in an MS multidisciplinary team who can improve the treatment outcome by carefully reviewing individual patient's therapeutic plan. In the backdrop of initiating new line of treatment, the pharmacist collaborates with other team members and patients to comprehensively appraise the different aspects of medication use followed by response to queries from the patients or other health care professionals.

Studies have been conducted on the effect of MTM and MS with regard to patients administrating their own injections. In a behavioral study, it was observed that patients who self-inject compared with those who rely on other caregivers were found to be more likely adherent to their drug therapy (Mohr et al., 2001). The impact of patient adherence to interferon beta-1b SQ (MS relapse) on prices and health care resource usage was studied among individuals with RRMS over an interval of 3 years. The outcomes reported that medication taking behavior is the key to minimizing direct or indirect expenses of disease exacerbation and enhanced adherence (Steinberg et al., 2010). Pharmacists need to be aligned with the MS patient's health care team and can make efforts in shifting the mindset toward "getting the drug therapy right for each patient." Hanson et al. (2014) cited a few of the known reasons for patient's poor adherence in MS: the misperception of DMT benefits, needle phobia, lack of social support, and insufficient understanding regarding their disease condition. Because of the complexity of the condition, care coordination among different health -care providers is necessary for long-term benefits.

There are numerous reasons why persons living with MS might neglect to stick to their valuable therapy. Factors like adverse drug reactions, inconvenient usage, cost of therapy, mood, and education need to be improved through effective communication. According to Taddei-Allen et al. (2017), pharmacist-led effective communication is divided into two levels for MS patients. During this first level of communication, once a new individual is identified with MS, a clinical pharmacist contacts her or him to establish a therapeutic relationship and perform a preliminary screening. This is followed by establishing a baseline on the patient's condition, evaluating their regular MS symptoms and recording the prior medical history, evaluating risk elements, and measuring the patient's knowledge and understanding of medications (Taddei-Allen et al., 2017).

The second level of communications involves patients who either discontinue their treatment or no longer respond to the pharmacy's outreach efforts. The findings showed that communication is also substantially associated with adherence and thus better communication is advocated between a health care provider, office staff, and patient to increase adherence (Patty Taddei-Allen, 2017)

Attention-Deficit Hyperactivity Disorder Management and the Role of the Pharmacist

Muhammad Umair Khan, Parisa Aslani, The University of Sydney School of Pharmacy, Faculty of Medicine and Health, The University of Sydney, Camperdown, NSW, Australia

General Overview of Attention-Deficit Hyperactivity Disorder

History

Attention-deficit hyperactivity disorder (ADHD) is a common childhood neurobehavioral disorder that often persists into adolescence and adulthood (Gintner and Mooney, 2015). The history of ADHD dates back to the early 20th century when a British pediatrician, Sir George Still found that some children lacked the ability to control their behaviors compared to other children. He described this condition as "an abnormal defect of moral control in children" (Conners, 2000). Later in 1915, after the epidemic of encephalitis, it was noted that children who survived the infection developed behavioral problems such as hyperactivity and impulsivity. This condition was initially termed as "brain-injured child syndrome," which was later changed to "minimal brain damage" and then to "minimal brain dysfunction" (Lange, 2017).

In 1952, the American Psychiatric Association issued the first Diagnostic and Statistical Manual of Mental disorders (DSM) in which all mental disorders were recognized except ADHD. However, in 1968, the disorder was introduced for the first time in DSM-II by the name of "hyperkinetic reaction of childhood" (Barkley, 2014). The 1970s saw changes in ADHD research as scholars began to emphasize the issues of impulse control and lack of attention in addition to hyperactivity (Lange, 2017). In 1980, DSM-III incorporated those changes and the disorder was named as "attention-deficit disorder" (ADD) (Barkley, 2014). However, in 1987, the disorder was renamed as "attention-deficit hyperactivity disorder" (ADHD) in the revised version of DSM-III (DSM-III-R) (Conners, 2000). During the 1990s, it was recognized that ADHD is not exclusively a childhood disorder, but it may persist into

adolescence and adulthood (Barkley, 2014). Hence, the DSM-IV included examples of occupational difficulties in the diagnosis of ADHD. Moreover, DSM-IV also introduced the three specific subtypes of ADHD identified as predominantly inattentive, predominantly hyperactive/impulsive, and combined (Barkley, 2014). The recent publication of DSM-V named the disorder as ADHD and placed it under the umbrella of neurodevelopmental disorders. The revisions included the elaboration of diagnostic criteria with specific examples, change of terminology from ADHD "types" to "presentations," and the use of modifiers (mild, moderate, severe) to specify the severity of the disorder (Rosales et al., 2015).

In contrast, the International Classification of Diseases, Tenth Revision (ICD-10), published by the World Health Organization (WHO) in 1992, classifies ADHD as hyperkinetic disorders (HKD) (F90) (Doernberg and Hollander, 2016). This group of disorders is classified under "behavioral and emotional disorders with onset usually occurring in childhood and adolescence" (F90-F98), in a section of Chapter 5: "Mental and behavioral disorders" (F00-F99) (Doernberg and Hollander, 2016). HKD are further classified into disturbance of activity and attention (F90.0), hyperkinetic conduct disorder (F90.1), other kinetic disorders (F90.8), hyperkinetic disorder, and unspecified (F90.9). Hyperactive disorders are characterized by an early onset (within the first 5 years of birth) in which a child with excess activity moves from one activity to another without completion (Santosh et al., 2005).

Epidemiology

ADHD is a childhood disorder but often persists into adolescence and adulthood. The prevalence of ADHD varies among children, adolescents, and adults (Polanczyk et al., 2007). Although there is no global consensus on the prevalence of ADHD, a meta-analysis of 175 studies worldwide reported a pooled estimate of 7.2% in children under 18 years of age (Thomas et al., 2015). Approximately, 129 million children in the age group 5–19 years worldwide have ADHD (Thomas et al., 2015). The prevalence in adults varies from 1.2% to 7.3% globally (Fayyad et al., 2007). The variation in the prevalence of ADHD in different parts of the world is mainly due to behavioral and environmental changes, use of different diagnostic criteria, and methodological differences between studies (Polanczyk et al., 2007).

A study published in January 2018 reported that 5.4 million children (8.4%) in the United States (US) have a current diagnosis of ADHD (Danielson et al., 2018). Of these, 2.9 million are adolescents aged 12–17 years, 2.2 million are school-aged children aged 6–11 years, and 0.3 million are young children aged 2–5 years (Danielson et al., 2018). In Europe, the prevalence varies from 1.2% in Spain to 7.3% in France (Fayyad et al., 2007). In Brazil, a study reported a prevalence of 6.7% (Ponde and Freire, 2007). In Australia, ADHD is regarded as the most common mental disorder among children and adolescents with a prevalence of 7.4% (Australia Institute of Health and Welfare et al., 2018).

In the United States, ADHD results in an extra burden of $143 billion to $266 billion annually (Doshi et al., 2012). In the United Kingdom, the cost associated with the management of ADHD is reported as £670 million (Telford et al., 2013). The higher costs associated with ADHD invite efforts for early diagnosis and better management of the disorder.

Etiology

ADHD has a multifactorial etiology due to its complex nature. Researchers have proposed four factors that are likely to be responsible for the development of ADHD, pregnancy and birth complications, psychosocial adversity, exposure to toxins, and genetics (Willcutt et al., 2010). Although the exact cause is unknown, a large portion of the published literature strongly suggests that ADHD develops due to the interplay between environmental and genetic factors (Faraone and Buitelaar, 2010).

Diagnosis

The use of DSM-V to diagnose ADHD is common in different parts of the world including the United States and Australia. For children, DSM-V requires the presence of at least six symptoms of inattention and/or six symptoms of hyperactivity/impulsivity to be persistent for at least 6 months in a way that is not consistent with development and adversely affects social and academic/occupational functioning (American Psychiatric Association, 2013). For adolescent and adults (aged 17 years and over), at least five symptoms are required. According to DSM-V, patients should have experienced most symptoms before the age of 12, and in at least two different settings (DSM-V, 2013). It must be clear that the symptoms are interfering with social and academic/occupational activities. Moreover, symptoms should not occur during the course of any other psychiatric disorder (e.g., schizophrenia, personality disorder, mood disorder, substance abuse, and anxiety disorder) (DSM-V, 2013).

Clinical Presentation

Inattention, hyperactivity, and impulsivity are the three hallmark symptoms of ADHD. Symptoms of inattention include the inability to pay attention to details, self-focused behavior, increased frequency of careless mistakes at school or workplace, difficulties in following directions, reduced alertness, and difficulties in maintaining focus (Milich et al., 2001). For example, a child may lose concentration while reading or writing or may make careless mistakes and then have to start over with the task. Symptoms of hyperactivity include the inability to sit still, excessive talking, being highly energetic, excessive fidgeting, problems with playing quietly, difficulties in settling down, and roaming around the classroom (Wilens et al., 2009). Symptoms of

impulsivity include interrupting others at school or workplace, intrusion in other's space, trouble waiting for their turns, initiating tasks without listening to instructions, problems with finishing the task, and starting new projects or assignments that catch their interest before finishing previous ones (Wilens et al., 2009). It is important to note that the symptoms are only considered clinically relevant if they start to interrupt daily functioning and occur in multiple settings (American Psychiatric Association, 2013).

The Management of ADHD

Successful management of ADHD requires careful history taking and observation of the child. This process involves both parents and teachers of the child, as a child may behave differently at home and at school, considering the different environments, tasks, and demands. This, however, is conducted in two phases (Burcham and DeMers, 1995). The first phase involves the clinician's and parent's assessment of ADHD symptoms followed by a physical and neurological examination.

The second phase involves a detailed teacher's report of the child's behavior at school. A range of standardized rating scales for clinicians, parents, and teachers are available that can be used in this process (Pappas, 2006). After detailed analyses of all collected information, the clinician makes informed recommendations tailored to the needs of the child. As there is no cure for ADHD, management strategies aim to minimize the symptoms and improve functioning (Abikoff et al., 2004). Management strategies include the use of pharmacotherapy and behavioral therapy. The short-term effectiveness of both strategies has been supported by a number of scientific publications (Connor et al., 2002; Emilsson et al., 2011; Jadad et al., 1999). However, given the limitations of the strategies, the literature supports the use of a multimodal approach to achieve optimal outcomes (Murphy, 2005; Pelham and Gnagy, 1999).

International Guidelines for the Management of ADHD

The National Institute for Health and Care Excellence (NICE), a widely referred to public body in Europe, supports the use of nonpharmacological management as first-line management in children with ADHD (NICE, 2018). If symptoms persist, medication, preferably methylphenidate, is recommended to be commenced in children aged 5 years and above. A course of cognitive behavioral therapy (CBT) is also recommended to be considered for people who have shown some improvements in symptoms after medication use but are still experiencing problems with social skills, peer interactions, self-control, and controlling emotions (NICE, 2018). The NICE recommends the same strategy for adults with the added flexibility that nonpharmacological interventions, such as CBT, may follow environmental modifications if the patient makes an informed decision to not take ADHD medications. In contrast, the American Academy of Pediatrics (AAP) recommends a combination of FDA approved ADHD medications, preferably stimulants, and parent- or teacher-administered behavior therapy as first-line management in patients aged 6–18 years (ADHD, 2011). The National Health and Medical Research Council (NHMRC) in Australia recommends the use of psychosocial strategies and/or behavioral interventions as first-line management. If those strategies fail, pharmacotherapy stimulants are indicated (NHMRC, 2018; Tonge, 2013). Health professionals should refer to the latest version of the above-mentioned guidelines for detailed guidance.

Pharmacological Management

Pharmacological management is one of the well-established approaches to the management of ADHD (Dopheide, 2009). With growing evidence, the use of pharmacotherapy has increased significantly in the past two decades. Specifically, the use of pharmacotherapy has increased by 75% in children and 18% in adults (Dopheide, 2009). An Australian study reported an increase of 101.8% from 2007 to 2015 (Brett et al., 2017). Medications are highly effective in reducing the symptoms of ADHD and improving the academic, occupational, and social functioning of people with ADHD. It is important to note that the use of ADHD medications requires extensive monitoring by health professionals to maximize the effectiveness of the medications and at the same time minimize the side effects which could be experienced.

Psychostimulants

Methylphenidate and dextroamphetamine are the two most commonly used psychostimulants. The use of psychostimulants is supported by numerous clinical trials, which have demonstrated improvements in core symptoms of ADHD (Jensen, 1999; Pelham et al., 2014). Evidence from the literature has also suggested that these agents have greater effectiveness in improving the social, behavioral, and academic functioning in 50%–95% of people with ADHD (Barkley, 2014).

Psychostimulants are the first-line pharmacological agents for the management of ADHD (Banaschewski et al., 2004). These medications are indicated in patients who are hyperactive, impulsive, and inattentive. It has been suggested that psychostimulants are also effective in comorbid disorders associated with ADHD (Jensen et al., 2001; Scheffer et al., 2005). Although psychostimulants may be indicated in patients with any subtype of ADHD, patients with combination-type ADHD are more likely to respond to psychostimulants (Millichap, 2010).

Psychostimulants do not cure ADHD (Advokat, 2009). Their use is limited to symptomatic management (Advokat, 2009). The benefits of psychostimulants usually prevail as long as the therapy is continued, but once the therapy stops, symptoms start to

reappear. Furthermore, the long-term beneficial effects of psychostimulants are still debatable because of limited evidence. The increased frequency of side effects also limits the use of psychostimulants. According to research, more than 50% of children taking psychostimulants experience at least one side-effect (Kos et al., 2006).

Nonstimulants

Nonstimulants are usually the second choice of agents and are only reserved for people who do not respond to or cannot tolerate the side effects of psychostimulants. It has been estimated that approximately 10%–30% of children and adults with ADHD who take medications are on nonstimulants (Banaschewski et al., 2004). Like psychostimulants, nonstimulants provide symptomatic management in patients with ADHD. Currently, three nonstimulant medications (atomoxetine, guanfacine, clonidine) are approved by the Food and Drug Authority (FDA) for use in people with ADHD. Atomoxetine and guanfacine are the two nonstimulants approved by the European Medicines Agency for use in ADHD in the European Union, while atomoxetine is the only Therapeutic Goods Administration approved nonstimulant in Australia.

Atomoxetine

Atomoxetine (ATMX) is the most commonly used nonstimulant in the management of ADHD. It is the first nonstimulant to receive approval for use in ADHD by the FDA in 2002 (Hammerness et al., 2009). ATMX is an effective nonstimulant and is generally well-tolerated. A number of randomized control trials have provided evidence of ATMX efficacy and safety in patients with ADHD (Kelsey et al., 2004; Michelson et al., 2001; Michelson et al., 2003; Weiss et al., 2005).

Studies have reported the significant benefits of atomoxetine in improving the core symptoms of ADHD; inattention, hyperactivity, and impulsivity (Banaschewski et al., 2004; Bushe and Savill, 2014). Atomoxetine is more effective than stimulants in patients with comorbid disorders such as tics, sleeping disorder, and Tourette disorder (Garnock-Jones and Keating, 2009). Atomoxetine has demonstrated improved ADHD outcomes in both children and adults (Upadhyaya et al., 2013). Furthermore, atomoxetine is also effective in patients with substance abuse due to its reduced ability to be misused (Upadhyaya et al., 2013). Some patients respond to ATMX at an early stage, but it may take up to 10 weeks to get the full benefits of ATMX (Lorberg and Prince, 2010). The unique advantage of ATMX is its usefulness in people with ADHD who also have anxiety and mood disorder (Adler et al., 2009).

One limitation of atomoxetine is that it takes approximately 4 weeks of continuous use to reach full effectiveness (Garnock-Jones and Keating, 2009). ATMX may not be the best choice for people with ADHD who only use the medication when needed to gain focus and attention.

Other nonstimulants

Other nonstimulant medications such as clonidine and guanfacine have also shown some effectiveness in symptomatic improvements in patients with ADHD (Arnsten et al., 2007). Other medications such as antidepressants and bupropion, although not approved, have been shown to be moderately effective in improving ADHD symptoms (Biederman and Spencer, 1999).

Clonidine and guanfacine have been shown to be useful in improving the three core symptoms of ADHD. However, these medications are mainly reserved for patients with ADHD who have a history of Tourette syndrome or tics (Rizzo et al., 2013). The use of extended-release guanfacine in the clinical management of ADHD increased after it received FDA approval in 2009. Since FDA approval, alpha 2 agonists are mainly used as stimulant extenders, soporifics (sleep aid), or stimulant enhancers. As stimulant extenders, these agents limit the dose of stimulants and extend the duration of therapeutic action (Palumbo et al., 2008). People with ADHD are prone to sleep disturbances, and if they are on a stimulant, it can further aggravate the problem. Alpha 2 agonists, as soporifics, are well suited for such situations because of their profound sedative effects. As stimulant enhancers, alpha 2 agonists are combined with a stimulant to enhance their effect. This use is mainly occasioned by the presence of a comorbid disorder such as Tourette disorder, oppositional defiant disorder, or aggressive/impulsive behavior.

With the advent of an extended-release formulation of stimulants, the use of alpha 2 agonists in ADHD has been limited to complex and comorbid ADHD (Scahill et al., 2001). Even in those complex cases, the evidence for the efficacy of alpha 2 agonists as monotherapy is sparse, and their use is limited to adjunct therapy along with stimulants (Pliszka, 2007).

Novel Pharmacotherapy for ADHD

In the past few decades, many pharmacological agents have been evaluated for their effects in people with ADHD. Nicotinic agents, such as donepezil, galantamine, metadoxine, are some of the medications that have been studied for the treatment of ADHD (Prince et al., 2015). Though these medications show some efficacy in small-scale trials, their role in the management of ADHD remains investigational (Prince et al., 2015).

Most of the recently approved medications for ADHD and the medications under trial are the modified forms of already established methylphenidate, amphetamine, and guanfacine and other approved salts (De Sousa and Kalra, 2012). For example, in 2017, FDA approved a new medication for ADHD aiming to control all-day symptoms in patients older than 13 years (Wigal et al., 2018). This triple-bead, mixed amphetamine salt (MAS) is a long-acting medication planned for once-daily use (Wigal et al., 2018). This formulation employs a unique triple-bead technology to extend its duration of action. It contains three beads of MAS; an immediate-release bead, a pulse-delayed bead, and an extended-release bead. Similarly, another formulation of guanfacine was approved in 2017 for use in children between the ages of 6 and 17 years (Childress, 2017). This medication offers a time-release

pharmacokinetics compared to the original guanfacine formulation, resulting in a once-daily dose and reduced side effects (Li et al., 2018).

Preliminary data have suggested that metadoxine, a novel nonstimulant therapy, may improve attention in people with ADHD (Manor et al., 2014); however, the medication failed to reach its primary endpoint in a phase III trial in 2017 (Alcobra, 2015). On the other hand, dasotraline, a serotonin-norepinephrine-dopamine reuptake inhibitor, which showed promising results in a phase II trial (Koblan et al., 2015), is now under review by the FDA. Mazindol, a stimulant, also showed positive results in phase II trials, resulting in both a reduction in symptoms and gain in function (Konofal et al., 2014; Wigal et al., 2018).

Certainly, there are gaps in the optimal pharmacotherapy of ADHD that need to be filled by newer medications. Specifically, there is a need for newer compounds with improved efficacy and tolerability to address the limitations of existing medications.

Psychoeducation

Psychoeducation refers to providing didactic psychotherapeutic intervention to enhance patients' and their families' knowledge of mental health illness and its treatment and empowering them to cope with their condition in an optimal manner (Lyman et al., 2014). It is considered an important part of ADHD management. Its use is well supported by several studies (Ferrin et al., 2014, 2016; Montoya et al., 2011) and is recommended by The National Institute of Health and Care Excellence (NICE) guidelines to be used as first-line management of ADHD (NICE, 2018; Taylor et al., 2004). It provides patients and their families/carers with essential and comprehensive information about their disease and its management, as well as possible difficulties they can face at school, workplace, or at home, and the skills to create environments that foster success (Montoya et al., 2011). Psychoeducation can be delivered in many ways such as providing affected people and their families with an expert's view on the disorder, didactic discussions, and providing materials and online resources (Knouse et al., 2008). It is important to note that effectiveness of psychoeducation programs only remains valid as long as the process is active and ongoing (Ferrin and Taylor, 2011). It is also highly important that these programs should not only be limited to the affected people and their families but also to a broader environment including teachers and carers (Ferrin and Taylor, 2011).

Behavioral Management

Behavioral therapy is an important component of nonpharmacological management that can help patients with ADHD manage their symptoms. The characteristic symptoms of ADHD often put a lot of pressure on affected families and teachers. These therapies do not aim to target the symptoms of ADHD but teach affected people and their families the skills needed to control them. Research supports the use of behavioral therapies in the management of ADHD (Emilsson et al., 2011). Behavioral therapies can be further classified as parent-led, classroom-based, and cognitive behavioral therapy.

Parent-Led Behavioral Therapy

Evidence suggests that involving parents in the process of disease management can improve health outcomes (Chronis-Tuscano et al., 2016). Various strategies can be employed in this process. One such strategy could be using a daily report card in which a child is given a plan to improve behavior, and the child is awarded upon the execution of the set plans (Horn et al., 1991). Another strategy could be the use of proactive antecedent actions to prevent misbehavior by deploying rules and providing instructions and awarding the child based on compliance (Fabiano, 2007).

Classroom-Based Behavioral Therapy

Evidence from the literature suggests that effective classroom interventions can enhance the learning of children with ADHD (DuPaul et al., 2011). These interventions if delivered in an actual classroom will result in marked improvements in social skills, anger management, and self-control in children (DuPaul and Stoner, 2014). These interventions are mainly delivered by trained teachers at school. The important consideration for the teachers is to identify and address the unique needs of students and the demands of the environment. Nonverbal support, such as verbal tone, gestures, and facial expression, rewarding children, and time management are some of the examples of preventive strategies that could be implemented in classroom settings to help students becoming academically and behaviorally successful.

Cognitive Behavioral Therapy

Cognitive behavioral therapy (CBT) is a fusion of behavioral therapy and cognitive therapy that identifies and then subsequently negates the person's negative feelings and behavior through discussion and home exercises (Toplak et al., 2008). CBT has been well-established over the years for the management of anxiety, depression, obsessive–compulsive disorder, and other related conditions (Hofmann et al., 2012). A review of studies evaluating CBT has shown mixed results in children with ADHD (Mongia and Hechtman, 2016). However, another review has shown no additional benefits of using CBT in children (Sonuga-Barke et al., 2013), while some have suggested that CBT can help in improving core ADHD symptoms, academic performance, and social adjustments (Froelich et al., 2002; Pelham et al., 1998). In contrast, CBT can be more helpful in adults with ADHD (Safren et al., 2005). CBT can help adults to deal with their problems associated with time management, organizing short-term and long-term plans, stress management, and emotional self-regulation (Solanto et al., 2008).

Prevention

To date, medical science has not been able to find ways to prevent ADHD. The major emphasis in clinical practice is on managing symptoms and maximizing the functional behavior of people with ADHD. Evidence suggests that early interventions may alter the trajectory of ADHD and thus prevent the long-term impact of the disorder (Halperin et al., 2012). Research has demonstrated that a number of factors increase the likelihood of ADHD, and therefore strategies to minimize these factors can help to decrease the likelihood of ADHD (Halperin et al., 2012).

Antenatal and Postnatal Care

Poor diet, alcohol use, drug addiction, and smoking during pregnancy increase the likelihood of ADHD in a child (Hausknecht et al., 2005; Kim and Chang, 2011; Thapar et al., 2013). A mother's exposure to lead during pregnancy may put her child at risk of developing ADHD (Rodriguez and Bohlin, 2005). Premature birth and low birth weight have also been associated with ADHD (Mick et al., 2002). Moreover, a study found breastfeeding newborns for at least 3 months could have a protective effect from developing ADHD later in life (Mimouni-Bloch et al., 2013).

Balanced Diet

Although not universally accepted, some researchers believe that processed sugar and carbohydrates play an important role in the development of ADHD (Millichap and Yee, 2012). Artificial colors, flavoring agents, and preservatives should be avoided or minimized to improve a child's behavior. These ingredients are believed to contribute to hyperactivity in children by producing an adrenalin rush (Breakey, 1997). Excessive consumption of food additives, sugar, and salt may negatively affect a child's behavior (Tomlinson et al., 2009). It is important to use a balanced approach while deciding on a balanced diet.

Preschool Strategies

Effective behavioral modifications in preschool children aged 3–6 years may help in reducing the likelihood of ADHD symptoms (Young and Myanthi Amarasinghe, 2010). These strategies focus on the start and stop techniques such as encouraging children to participate in activities and stopping them from running around and being disruptive. These techniques can be easily taught and are applicable to different school settings. They can positively influence ADHD-related symptoms while not harming children without such symptoms (Egger and Angold, 2006).

Parenting Quality

Although the quality of parenting is not the primary cause of ADHD, it is one of the important risk factors that may influence the severity and/or impairment of the disorder (Halperin et al., 2012). A randomized control trial showed that parenting quality plays an important role in improving ADHD-related symptoms in school-aged children (Thompson et al., 2009). This evidence suggests that the quality of parenting can have a profound effect on ADHD. It is also suggested that improving parenting quality may help to prevent the worsening of ADHD-related symptoms (Modesto-Lowe et al., 2008). A study suggested that parents' higher involvement with a child, consistent discipline, and supervision can play a role in the child's expression of symptoms (Ellis and Nigg, 2009). The current evidence therefore suggests the need to target parents to optimize the quality of their parenting, which support the focus of intervention programs being on parents, as the key strategy to improve a child's behavior.

Role of Pharmacists in the Management of ADHD

The role of general physicians, pediatricians, and psychiatrists in the identification, assessment, and management of ADHD has been well-defined in the literature; however, there is a huge gap in the literature about the role of pharmacists in the management of ADHD. Given that approximately 129 million people are affected by ADHD worldwide, and medications remain a major source of treatment, pharmacists are well-positioned to play an important role in reducing the burden associated with ADHD and deliver effective pharmaceutical services to the patients and their parents or carers.

Evidence for the Role of the Pharmacist

The potential contributions of pharmacists in the management of ADHD have not been well explored. Although previous researchers have highlighted the roles pharmacists can play to increase quality use of medicines (Kehoe, 2001; Levin, 1995), no attempt has been made to examine the effectiveness of these roles on a larger scale. An extensive search of the literature yielded only a couple of pilot/small-scale studies that established the role of pharmacists (Reutzel et al., 2008; Tobaiqy et al., 2010). There is a need for further studies to validate the existing findings and strengthen the body of evidence.

Educational Programs for School Personnel

Ruetzel et al. demonstrated that pharmacists can effectively deliver educational programs to school staff in collaboration with a mental health therapist to enhance their understanding of ADHD and medication use (Ruetzel, 2008). The school environment can be challenging for children with ADHD. It was demonstrated that providing education to teachers and other school personnel about

ADHD can improve their knowledge of the medications used in ADHD and give them the confidence to recognize the symptoms of ADHD. Ruetzel et al. stated that increased knowledge and confidence levels in school personnel should reduce the occurrence of medication errors and improve the overall effectiveness and safety of the therapy (Ruetzel, 2008). Moreover, it would enable them to be aware of important issues relating to managing children with ADHD at school.

Pharmacist-Led ADR Monitoring

Tobaiqy et al. reported that community pharmacists can be very effective in monitoring adverse drug reactions (ADRs) in people taking medications for ADHD (Tobaiqy et al., 2010). The use of long-term ADHD medications may result in ADRs; however, in most cases, these ADRs do not pose a serious threat to a patient. Nonetheless, it is important to continue monitoring for ADRs throughout the course of treatment. Pharmacists with their comprehensive knowledge of medications can play a crucial role by detecting and subsequently reporting ADRs to their respective national ADR reporting authority.

Expanding the Role of Pharmacists

The role of pharmacists in the identification, support, and management of ADHD has not been recognized universally. Limited effort has been made in the past to examine the role of pharmacists in managing patients with ADHD. Therefore, the published evidence that supports the role of pharmacists in ADHD is presently very limited. However, the role of pharmacists has evolved considerably in other mental health diseases, such as depression, in the last decade (Rubio-Valera et al., 2014). Pharmacists with their unique set of skills and knowledge are well placed to expand these roles to patients with ADHD. This section will discuss a range of services that pharmacist could provide to optimize ADHD management.

Medication Optimization

The role of pharmacists is well established in optimizing medication use in patients with chronic diseases such as hypertension, diabetes, asthma, arthritis, and depression. Given the increase in the use of medications in people with ADHD, the opportunity exists for pharmacists to contribute to the management of ADHD by ensuring optimum use of medications. Pharmacists can promote medication optimization through patient engagement and risk communication, medication reviews, health-care interface pharmacist services, and improving medication adherence.

Patient engagement and risk communication

In recent years, the health-care model has shifted from disease-focused to patient-centered care. The new model involves consideration of patient's values, goals, and concerns about the effectiveness and risk of therapy. This model encourages health professionals to make clinical decisions in consultation with a patient. Research has demonstrated the positive effects of shared decision making (SDM) between parents/carers of children with ADHD and pediatricians (Brinkman et al., 2013). There remains an opportunity to replicate a similar model in people with ADHD with their pharmacist. Pharmacists should enhance their understanding of this approach to engage patients, build relationships, and play their part in promoting the optimum use of medications.

Another advantage of patient engagement is risk communication. Risk communication is an important process through which health professionals use a scientific approach to communicate with patients about the benefits and harms of the medication and enable them to make an informed decision about their treatment. This is a very important concept in the management of ADHD as it is often seen that parents/carers do not start or adhere to their child's medication regimen due to the fear of side effects or lack of effectiveness. Therefore, it is essential for pharmacists to embrace effective patient communication and positively influence patient's decision making about the use of medications.

Regular medication reviews

People receiving ADHD medications, such as stimulants, are required to attend regular medication reviews to ensure the safety and effectiveness of their medications (Swanson et al., 1993). Furthermore, stimulant medications are associated with drug misuse (Volkow and Swanson, 2003). Drug diversion is another issue that is gaining the attention of many researchers (Wilens et al., 2008). Adolescents with ADHD are more susceptible to being involved in drug diversion (Wilens et al., 2006). Drug diversion has been defined as a transfer of prescribed medication from one person (whom it was prescribed for) to another person (whom it was not prescribed for) for illicit use (Cooper et al., 1992). Pharmacist-led medication reviews can be very helpful in examining these issues. As medication experts, pharmacists are well aware of such possibilities and can use a holistic approach in reviewing ADHD medications.

Health-care interface pharmacy services

The diagnosis of ADHD is usually carried out by a psychiatrist, pediatrician, or health professionals with specialized training in ADHD or relevant psychiatric conditions. The specialist then takes the decision to put the person with ADHD on medication. Once the therapy starts, the information/plan about medication use is passed on to a primary care provider who is responsible to ensure the effectiveness and safety of the medication. Studies have shown that the chances of medication errors increase as a patient moves between primary and secondary care (Kvamme et al., 2001; Preston et al., 1999). For example, general practitioners may not receive clear explanation about the future course of medication use so continue to prescribe medication, which may not

be effective. Pharmacists can team up with general practitioners (GPs) and specialists to facilitate medication management across the interface.

Furthermore, other professionals, such as psychologists, behavioral therapists, social workers, teachers, school nurses, and educational therapists, are also involved in caring for children with ADHD. Hence, a leadership opportunity exists for pharmacists to work at multiple interfaces and ensure that good communication is maintained, and all efforts are aligned toward quality use of medications and improved health outcomes of the person with ADHD.

Improving medication adherence

The first step in understanding the issue of medication adherence is to assess patient or carer understanding about ADHD and its treatment options. Pharmacists are required to communicate effectively to determine what a patient or carer thinks about a medication or what they expect from a medication. Most patients/carers may not realize that medications do not cure ADHD rather they help improve the academic, social, and behavioral outcomes of the person with ADHD. Similarly, there may be a lack of awareness among patients and/or carers about the expected side effects of medications. Pharmacists are encouraged to take initiatives to speak to patients/cares about medication-related issues and establish rapport with patients/carers to ensure that they express their concerns about the use of a medication. This will help to identify knowledge gaps and patients'/cares' beliefs toward ADHD and its medication.

The second step is to assess adherence and identify the factors influencing medication adherence. This is an important step, and pharmacists need to be aware of the methodological and practical issues associated with the measurement of adherence. It has been suggested to measure medication adherence and assess factors influencing medication adherence at three phases, namely, initiation, implementation, and discontinuation (Khan et al., 2018; Vrijens et al., 2012). It is important to first look at the factors that influence patients' or their parent's/carer's decision to start medication. Second, it is important to examine if they continue to take medication as prescribed on a daily basis, and finally, assess the reasons for early discontinuation of medication. It is imperative that a distinction is made between the three phases as the factors influencing one phase may differ from the other phases. Moreover, consideration should be given to the person with ADHD to see if they are children, adolescents, or adults, as factors influencing medication adherence in one group may differ from the other groups. In the case of children and to some extent, adolescents, the role of parents in decision making about medication use is important. Hence, it is also important to examine the parental factors that may affect adherence to medications.

The last step is to deliver tailored interventions to promote adherence at the appropriate phase of adherence. Pharmacists can play an active role in this step as their involvement would increase the likelihood of positive outcomes (Dopheide, 2009). Pharmacist-led interventions have successfully improved medication adherence in patients with other disease states, for example, in psychiatric conditions, such as depression (Rubio-Valera et al., 2014).

Pharmacist-Led ADHD Screening Services

Early detection of ADHD-related symptoms is important to start early management and therefore reducing the long-term impact of the disorder (Sonuga-Barke et al., 2006). Pharmacists, as the first point of contact for parents and carers of children, can provide ADHD screening services in community settings. There is considerable evidence of pharmacists providing cost-effective screening services in other psychiatric conditions such as depression (Rubio-Valera et al., 2014). There is therefore a great opportunity for pharmacists and researchers to take this initiative to build an evidence-based role for pharmacists in this area. It is possible that not all pharmacists will feel confident in providing such services. Therefore, to establish their role in ADHD screening, pharmacists are required to have a thorough understanding of ADHD screening procedures and available tools. Specialized mental health education or training in assessment and screening of ADHD can help pharmacists reach their true potential in providing such services. Pharmacy practice regulatory authorities may consider regulating such services by allowing pharmacists to deliver the services only after successful completion of relevant training.

Given the shortages of medical doctors and other health-care facilities in rural areas, there is an opportunity for pharmacists to take a lead role in increasing awareness of ADHD among rural communities, particularly in developed countries, and provide screening services to children or adults who are suspected of having ADHD. Rural pharmacists can influence people (Nissen and Tett, 2005). Previous research has established the role of pharmacists in providing mental health counseling to rural communities (Scott et al., 2016). It is therefore a timely opportunity for appropriately trained and accredited pharmacists to expand their role in public health by delivering ADHD screening services in rural communities.

Reducing Stigma

Studies suggest that pharmacists can be very effective in providing education to people about mental health in a proactive and individualized manner (Crump et al., 2011; Finley et al., 2003). Pharmacists-led ADHD awareness campaigns may help to spread the correct information about the condition and the role of medicines taking. The campaigns could target people with ADHD, parents/carers, teachers, health professionals, and the community in general. Effective strategies need to be designed to customize information as per the needs of each group being targeted. For example, parents can be provided with comprehensive information about ADHD and its treatment options.

Anxiety Disorders

Hadar Zaman*, Joanne C. Lin†, Amy Chan†, Frederick Sundram‡, *Bradford School of Pharmacy & Medical Sciences, University of Bradford, Bradford, United Kingdom; †School of Pharmacy, University of Auckland, Auckland, New Zealand; ‡Department of Psychological Medicine, University of Auckland, Auckland, New Zealand

Learning Objectives

- Describe the prevalence, epidemiology, and etiology of anxiety disorders and list the four most common conditions.
- Explain the pharmacological and nonpharmacological management options for GAD, panic disorder, PTSD, OCD, and describe which treatment option would be used and in what situations.
- List the most common side effects and interactions associated with SSRIs, SNRIs, pregabalin, and benzodiazepines, and describe how to manage these.
- Describe the role of the pharmacist in managing anxiety disorders and give examples where pharmacists can contribute to the pharmaceutical care of anxiety disorders.

Take Home Messages

- Anxiety disorders are the most prevalent psychiatric disorder.
- There are different types of disorders, which fall under the wider category of anxiety disorders, each with their own preferred treatment options.
- Treatment should be tailored to the individual—taking account of his or her comorbidities, treatment preferences, adverse effects, and prior experience with pharmacotherapy.
- SSRIs and SNRIs remain the mainstay of anxiety treatment, though efficacy varies depending on the exact anxiety condition being managed.
- Benzodiazepines should be used at the lowest effective dose for the shortest period of time (maximum 4 weeks) and should only be used while waiting for medium- to long-term treatments to take effect.
- The pharmacist plays a key role in anxiety management as individuals may first come to the attention of health services through primary care, and long-term management responsibility will mainly reside in the community, making the pharmacist well placed to the treatment of anxiety.
- Opportunities to optimize medicines use in anxiety include side effect management, managing interactions, and benzodiazepine withdrawals.

Introduction to Condition

Anxiety is common and can occur as an isolated, short-lived, and self-limiting symptom. From an evolutionary perspective, anxiety is known to occur in the context of an adaptive response to environmental threats and prepare the person for the "fight or flight" response (Cannon, 1915). However, when persistent or disabling, it can lead to impaired functioning and be part of an umbrella of clinical disorders termed anxiety disorders. Anxiety disorders are the most prevalent of psychiatric disorders and often show comorbidity with other anxiety or depressive disorders (Kessler et al., 2005b; Thibaut, 2017).

There are numerous anxiety disorders with each having its own set of etiology, epidemiology, physiology, and prognosis. In this chapter, there will be an exploration of overlaps between anxiety disorders as a group and then selective focus on certain subtypes. It is beyond the scope of this chapter to explore the various anxiety disorders in significant detail. This chapter will focus on generalized anxiety disorder (GAD), panic disorder, post-traumatic stress disorder (PTSD), and obsessive-compulsive disorder (OCD) (see **Table 1** for key features). While there is much overlap in symptomatology between various anxiety disorders, at the core of these disorders are a set of physical, behavioral, and cognitive attributes that show variation between them and are therefore classified as discrete conditions. There are numerous treatment options available, which can involve monotherapy or combinations of pharmacotherapy, psychotherapy, and social interventions.

Brief History of Anxiety Disorders

Though the description of anxiety disorders is often thought to be a recent development (since the 19th century), historical records suggest that they have been recognized since antiquity (Crocq, 2015). Situations such as going to battle/facing one's own mortality, a loved one dying, public speaking and romantic courtship, among others, were recognized as possible triggers for states of anxiety and potentially influenced by the Greek or Roman Gods.

Consistent with the theory of body humors by Hippocrates, anxiety was thought to arise from an imbalance in humor levels. This theory persisted till the Renaissance; subsequently, till roughly the 19th century, anxiety was grouped together with depression as contributing to states of melancholy and not recognized as a condition of its own. However, since then, the classification of anxiety has moved toward a medical model and recognition as a separate disorder (Stone, 2009). Medically, there was conceptualization of anxiety being driven by weaknesses of the nervous system, which was termed *neurosis* by the Scottish physician William Cullen. However, while neuroses contained a wide number of possible neurological, psychiatric, psychological, and other disorders, it also captured situations when behaviors were not socially acceptable (Bienvenu et al., 2010). The neurologist Jean Marie Charcot and his

Table 1 Summary of key features in various anxiety disorders

Disorder	*Key features*
Generalized anxiety disorder (GAD)	• Excessive, difficult to control anxiety and worry (apprehensive expectation) about multiple events or activities (e.g., school/work difficulties) • Accompanied by symptoms such as restlessness/feeling on edge or muscle tension
Panic disorder	• Recurrent unexpected panic attacks, in the absence of triggers • Persistent concern about additional panic attacks and/or maladaptive change in behavior related to the attacks
Posttraumatic stress disorder (PTSD)	• Exposure to actual or threatened death, serious injury, or sexual violation • Intrusion symptoms (e.g., distressing memories or dreams, flashbacks, intense distress) and avoidance of stimuli associated with the event • Negative alterations in cognitions and mood (e.g., negative beliefs and emotions, detachment), as well as marked alterations in arousal and reactivity (e.g., irritable behavior, hypervigilance)
Obsessive–compulsive disorder (OCD)	• Obsessions: recurrent and persistent thoughts, urges, or images that are experienced as intrusive and unwanted and that cause marked anxiety or distress • Compulsions: repetitive behaviors (e.g., hand washing) or mental acts (e.g., counting) that the individual feels driven to perform to reduce the anxiety generated by the obsessions

Source: Adapted from (American Psychiatric Association, 2013; Katzman et al., 2014b)

protégé, Sigmund Freud (who started his career as a neurologist) encountered several cases of what appeared to be medically driven neurosis but were able to clarify possible psychological contributors for states such as *anxiety neurosis*, *hysteria,* and *neurasthenia*, and applied psychoanalysis as a modality to understand and treat these conditions (Bogousslavsky and Dieguez, 2014; Perez-Rincon, 2011).

Following World War I, there were several documented cases of "shell-shock," a precursor to what is now known as PTSD. After World War II, psychopharmacology and biological treatments for anxiety became much more developed including the emergence of benzodiazepines and tricyclic antidepressants. Later in the 20th century, discussions around "state" versus "trait" representations of anxiety emerged (Cattell and Scheier, 1960) but it was not until the third edition of the Diagnostic and Statistical Manual of Mental Disorders (DSM-III) that there was delineation of the various types of anxiety disorders under an anxiety disorders chapter. Therefore, while concepts of anxiety were historically in the domains of astrology, theology, and philosophy, in more modern times, it has moved toward being recognized as discrete disorders under psychiatry and psychology (Berrios, 1996).

Condition Information

Definition/Classification of Anxiety Disorder and Diagnosis

Transient anxiety is recognized as a normal symptom or an experience that can occur in the context of a response to a stimulus. However, when it is disruptive to normal functioning, excessive or persistent, it is regarded as a disorder. For example, it can be secondary to a medical disorder (e.g., in association with hyperthyroidism or pheochromocytoma) or be part of discrete clinical psychiatric disorders e.g., GAD, panic disorder, or specific phobias. Physical symptoms associated with anxiety disorders include sweating, dizziness, shortness of breath, muscle tension, or a racing heart.

While anxiety disorders demonstrate core features involving excessive levels of anxiety and fear, they have associated cognitive features, which can contribute to behavioral disturbances (American Psychiatric Association, 2013). Cognitive symptoms include a sense of impending doom or a fear of dying/embarrassment/humiliation. It is thought that anxiety corresponds to future threat and is associated with vigilance and preparing for a threat; in contrast, fear relates to a real or perceived threat and is associated with autonomic arousal. However, there is often overlap between anxiety and fear within the rubric of anxiety disorders and they are differentiated by the context where symptoms arise, associated cognitions, and behaviors such as avoidance.

Looking across the lifespan, the anxiety disorders as described by DSM-V include specific phobias, selective mutism, separation anxiety disorder, social anxiety disorder, GAD, panic disorder, and agoraphobia. Additional anxiety disorders include substance-induced or medication-induced, other specified and unspecified anxiety disorders and due to other medical conditions. PTSD and OCD used to be historically included under the anxiety disorders chapter but since DSM-V, these have been moved to adjacent chapters (obsessive-compulsive and related disorders and trauma- and stressor-related disorders) (American Psychiatric Association, 2013).

Usually, the diagnosis of an anxiety disorder is based on clinical criteria such as the DSM or the International Statistical Classification of Diseases and Related Health Problems (ICD) (American Psychiatric Association, 2013; World Health Organization, 1992). Prior to diagnosis, it is necessary to assess and consider other differential diagnoses such as mental health, medical, physiological, or medication/substance-induced conditions. Anxiety disorders are frequently underdiagnosed or diagnosed as another mental health disorder such as depression (Ormel et al., 1991; Wittchen et al., 2002). There are several tools that can be used to help diagnosis and are relatively straight forward to use and can be completed quickly. Such screening tools for anxiety

disorders include the Generalized Anxiety Disorder 7, which is a 7-item rating scale (GAD-7) (Spitzer et al., 2006), hospital and anxiety depression scale (HADS) (Zigmond and Snaith, 1983), PHQ-4 (Kroenke et al., 2009), Beck's Anxiety Inventory (BAI) (Beck and Steer, 1993), as well as ones for anxiety states (Rose and Devine, 2014). A recent systematic review done by Herr and colleagues reviewed the use of tools to help in the diagnosis of anxiety. They found that the GAD-7 and the PHQ-4 screening tool were most effective (Herr et al., 2014). These screening tools are used for case-finding purposes and not for diagnosis. As such, these can be used by pharmacists when screening for "at-risk" patients, who can then be referred for further work-up and diagnosis (see Role of the Pharmacist section for further details). Although these screening instruments are useful and may be used as part of the initial diagnostic evaluation, a criterion-based diagnosis should be established through further evaluation by a primary care physician or by a mental health professional to whom the patient is referred. Such confirmation will also help rule out psychiatric disorders with related symptoms (e.g., PTSD, depression) and medical causes of symptoms suggestive of anxiety (Kroenke et al., 2007).

Epidemiology

As a group of psychiatric disorders, anxiety disorders are the most prevalent (Narrow et al., 2002) with lifetime prevalence estimates as high as 31% (Kessler et al., 2005a, 2007). Prevalence rates appear higher in high-income relative to low-income countries (Lewis-Fernandez et al., 2010). They are underdiagnosed in primary care (Sartorius et al., 1996; Vermani et al., 2011) and other settings and are overall undertreated (Martin-Merino et al., 2010; Weisberg et al., 2007; Wittchen et al., 2002). There are a variety of reasons for this including people feeling uncomfortable discussing their emotions or general practitioners not routinely screening for these or a lack of training in diagnosis.

There is a gender imbalance with women demonstrating higher rates of anxiety disorder across all age bands, with lifetime rates approximately 1.5–2 times higher than men, and being generally more disabling (McLean et al., 2011). There are often higher rates of quality of life impairments, disability, health-care utilization, and wider impacts to society, for example, through lost productivity (Barrera and Norton, 2009; Wittchen, 2002; Wittchen et al., 2011). With the move of PTSD and OCD from the anxiety disorders chapter in DSM-V to their own separate chapters, it is possible that prevalence estimates of anxiety disorders will fall (American Psychiatric Association, 2013).

Anxiety disorders are often associated with comorbidities such as other anxiety disorders and depression (Wittchen et al., 2000). Moreover, alcohol and substance use and gambling are overrepresented in populations with anxiety disorder (el-Guebaly et al., 2006; Petry et al., 2005). Although anxiety disorders are associated with increased risk of suicide and self-harm attempts, when comorbid with other mental health disorders such as depression, these risks are further enhanced by odds ratios between 1.5 and 4 (Sareen et al., 2005).

Etiology

The etiology of anxiety disorders is complex and often multifactorial involving biological, psychological, social, environmental, cultural, cognitive, and behavioral mechanisms (Gross and Hen, 2004; Humble, 1987; Lau et al., 2007). It can also be helpful to consider factors that contribute to stress causation versus stress continuation (Uliaszek et al., 2012). Possible contributors to anxiety include exposure to threat and can be an adaptive response and there have been theories suggesting an evolutionary basis to fear/anxiety states but classical Pavlovian conditioning as a longer term maintenance factor for anxiety disorder (Gross and Canteras, 2012; LeDoux, 2000; Mineka, 2002). Fear and threat neural system circuits have also been suggested to contribute (LeDoux and Pine, 2016).

Endogenous production of catecholamines such as adrenaline prepares the individual for the fight or flight response in the context of fear but can be chronically overactivated in an anxiety disorder. The sympathetic nervous system contributes to physical symptoms of anxiety e.g., sweating, tachycardia, hypertension, dyspnea, nausea, and light-headedness.

Exogenous substances including nonprescribed agents such as caffeine and stimulants (e.g., cocaine, amphetamine) as well as prescribed methyldopa, theophylline, salbutamol, and corticosteroids can contribute to states of anxiety. Additionally, when someone develops dependence to substances such as benzodiazepines or alcohol, when withdrawing from the substance, this is likely to precipitate anxiety symptoms and autonomic arousal. Neurodegenerative, endocrine, and other physical disorders can also contribute to secondary anxiety states e.g., dementia, asthma, cardiac failure, and epilepsy (Craske et al., 2017).

Place of Pharmacotherapy in Context of Treatment Options

Treatment options for anxiety and related disorders include psychological and pharmacological treatments. The choice of treatment depends on factors such as patient preference and motivation, ability of the patient to engage in treatment, severity of illness, clinician skills and experience, availability of psychological treatments, patient's prior response to treatment, and the presence of comorbid medical or psychiatric disorders (Katzman et al., 2014a).

Psychotherapy and pharmacotherapy generally demonstrate about equivalent efficacy for the treatment of most anxiety and related disorders (Bandelow et al., 2007; Roshanaei-Moghaddam et al., 2011). The choice between psychotherapy and pharmacotherapy as first-line treatment can depend on the severity of anxiety, patient preference (e.g., beliefs associated with the treatments, medication side effects, and the time needed for psychotherapy), and treatment availability. Those with milder symptoms that do

Table 2 Summary of pharmacotherapy options for anxiety disorders

	First-line drug treatment	*Second-line drug treatments*	*Other (PRN) treatment*
Generalized Anxiety Disorder	SSRIs or SNRIs • May initially exacerbate symptoms • A lower starting dose often required Pregabalin • Not approved for GAD in the US	Some TCAs • Imipramine, clomipramine Buspirone • Delayed onset of action Second-generation antipsychotics	Benzodiazepines • Normally for short-term use only (maximum 2–4 weeks) • Usually as an adjunct to antidepressant therapy
Panic Disorder	SSRIs or SNRIs • Therapeutic effect can be delayed • Patients can experience an initial exacerbation of panic symptoms	Some TCAs • Imipramine, clomipramine	Benzodiazepines • Panic symptoms can return quickly if the drug is withdrawn • NICE does not recommend benzodiazepines
Posttraumatic Stress Disorder	Drug treatment should not be used as a routine first-line treatment • SSRIs may be recommended where there is minimal/incomplete response to psychological therapy		α-Blockers may be useful for trauma-content nightmares Benzodiazepines not usually appropriate
Obsessive-Compulsive Disorder	SSRIs • Citalopram is not approved or authorized for this indication • Doses licensed for OCD are higher than those for depression	Clomipramine	Benzodiazepines not usually appropriate

not interfere significantly with functioning may be managed with psychotherapy based on cognitive behavioral therapy (CBT). However, when patients do not benefit from CBT or have a limited response, the addition of pharmacotherapy may be advisable. See Table 2 for a summary.

Benzodiazepines

All guidelines and consensus states recommend that benzodiazepines should be used only to treat anxiety that is severe, disabling, or subjecting the individual to extreme distress. Due to their potential to cause physical dependence, sedation, cognitive impairment, and withdrawal symptoms, benzodiazepines should be used at the lowest effective dose for the shortest period of time (maximum 4 weeks) while medium- to long-term treatment strategies are implemented. They should also be used with caution in patients with a history of substance misuse. However, a small number of patients with severely disabling anxiety may benefit from long-term treatment with a benzodiazepine; this should be done in consultation with a specialist.

GAD

Benzodiazepines have been shown to be beneficial in the treatment of GAD as they work quickly and generally lead to a reduction of emotional and somatic symptoms within minutes to hours, depending on the specific medication (Davidson, 2004; Offidani et al., 2013). While benzodiazepines should be used with caution, their use need not be entirely avoided. They may be used for acute, maintenance, or long-term treatment of GAD, either as monotherapy or, more commonly, as an adjunct to antidepressant treatment. They are most commonly used for acute management of anxiety and worry during the period before serotonergic reuptake inhibitors (SSRIs/SNRIs—described later) take effect. They can counteract the initial activation caused by serotonergic reuptake inhibitors. Once the patient responds to the SSRI/SNRI, the benzodiazepine can be tapered off gradually.

Panic Disorder

Benzodiazepines are the least preferred monotherapy for patients with panic disorder and co-occurring depression or substance use disorder. They may be useful adjunctively with antidepressants to treat residual anxiety symptoms, or in patients with very distressing or impairing symptoms in whom rapid symptom control is critical (American Psychiatric Association, 2009).

PTSD

Although the efficacy of benzodiazepines in treating the core symptoms of PTSD has not been established, they are frequently used to treat symptoms of anxiety and hyperarousal. However, clinical observations include the possibility of dependence (there is high prevalence of comorbid substance abuse in patients with PTSD), increased incidence of PTSD after early treatment with benzodiazepines, or worsening of PTSD symptoms after withdrawal of these medications. Thus, benzodiazepines are not recommended as monotherapy in PTSD; however, they can be useful as an adjunct to other long-term treatments (see below) (American Psychiatric Association, 2004).

OCD

There is limited evidence for efficacy of benzodiazepines in the treatment of OCD; therefore, they cannot be recommended for monotherapy (American Psychiatric Association, 2007). They may be used cautiously for short periods to counteract the early activation effects of SSRIs (National Institute for Health and Care Excellence, 2005a).

Serotonergic Reuptake Inhibitors

Selective serotonin reuptake inhibitors (SSRIs) have "broad spectrum" efficacy in both short- and long-term treatment of anxiety, and are generally well tolerated. These are widely considered the first-line pharmacological approach for patients with anxiety disorders and OCD. SSRIs have potentially troublesome adverse effects, including initial increased nervousness, insomnia, nausea, and sexual dysfunction (Gartlehner et al., 2011; Serretti and Chiesa, 2009; Sinclair et al., 2009). There may be an increased risk of gastrointestinal bleeding; therefore, gastroprotective drugs may be appropriate for some patients e.g., those taking nonsteroidal anti-inflammatory drugs (Laporte et al., 2017; Paton and Ferrier, 2005). SSRIs may also cause activation—a distinct constellation of behavioral side effects including agitation, restlessness, anxiety symptoms, insomnia, or akathisia. It may occur any time during the treatment, but is most common during the first few weeks (Warden et al., 2010). When stopped abruptly, and even when tapered slowly, SSRIs can produce a discontinuation syndrome characterized by dizziness, insomnia, and flu-like symptoms (Baldwin et al., 2007); this appears more likely with shorter half-life SSRIS, e.g., paroxetine (Tint et al., 2008).

Serotonin-norepinephrine reuptake inhibitors (SNRIs), duloxetine and venlafaxine, have proven efficacy for the short- and long-term treatment of GAD (Baldwin et al., 2011), and placebo-controlled trials have shown that venlafaxine is efficacious in the acute treatment and prevention of relapse in panic disorder (see Panic Disorder section) (Batelaan et al., 2012). Although the tolerability profiles of SSRIs and SNRIs in patients with anxiety disorders are not established fully, systematic reviews of studies in depressed patients suggest that duloxetine and venlafaxine may be less well tolerated than the SSRIs (Cipriani et al., 2012; Schueler et al., 2011). The most common side effects include nausea, constipation, dizziness, insomnia, sedation, and changes in sexual function. Venlafaxine may also cause elevated blood pressure and increased risk for gastrointestinal bleeding. Both agents have been associated with discontinuation symptoms after withdrawal due their short half-lives (Baldwin et al., 2007).

GAD

SSRIs and SNRIs are generally considered to be first-line pharmacotherapies for GAD, with response rates in the range of 30%–50% (Reinhold and Rickels, 2015). There is a lack of data available directly comparing the different serotonergic reuptake inhibitors (including SSRIs vs SNRIs) (Bielski et al., 2005; Hidalgo et al., 2007). Trials have generally shown that all serotonergic reuptake inhibitors have similar degrees of efficacy so the choice of agent should be customized to the patient based on patient treatment history/preference or response, side effect profile, drug interactions (see Drug Interactions section), and/or cost.

SSRIS should initially be prescribed at half the normal starting dose for the treatment of depression, and the dose titrated upward into the normal antidepressant dose range as tolerated—though doses higher than typical antidepressant doses may be required for complete response. These serotonergic drugs are often activating (with increased anxiety, agitation, and sleep problems) and difficult to tolerate in early dosing. To avoid overstimulation and insomnia, doses may be given in the morning or at midday, except in patients reporting daytime sedation (Bandelow et al., 2008).

Time to onset of clinically meaningful action varies by patient, but response is usually seen within 6 weeks (Ballenger, 2004). The initial therapeutic dose should be continued for 4–6 weeks, and increased in 1- to 2-week increments until sufficient improvement is seen or the maximum recommended/highest tolerated doses is reached (Bystritsky, 2018). However, if there is no response (less than 25% reduction in symptoms from baseline), the patient may be switched to a different class of treatment (Davidson et al., 2010).

Panic Disorder

SSRIs are considered the first-line pharmacotherapy for panic disorder. SSRIs reduce the frequency of panic attacks, severity of anticipatory anxiety, and degree of phobic avoidance. There is no evidence of superior efficacy for some SSRIs over others (American Psychiatric Association, 2009); choice of agent is guided by the side effect profile, propensity for medication interactions, half-life, and/or availability of generic preparations.

As patients with panic disorder are unusually sensitive to overstimulating effects with antidepressants (Cowley et al., 1997), treatment should be started at low doses and gradually titrated 3–7 days after initiation and up to a therapeutic dose over 2–6 weeks. The dose can be increased if no clinical improvement is seen; however, increases should occur no faster than at 1- to 2-week intervals to minimize the risk of side effects. Higher doses of all drugs may be effective when standard doses have failed (National Institute for Health and Care Excellence, 2011).

Double-blind, placebo-controlled trials have found extended-release venlafaxine to be an efficacious treatment for patients with panic disorder (Bradwejn et al., 2005; Pollack et al., 2007). Like SSRIs, venlafaxine should be started at low doses (approximately half the starting dose given in depression). The immediate-release version of venlafaxine should not be used for panic disorder as it has a greater side effect burden and patient with panic disorder can have difficulty tolerating internal bodily sensations and somatic side effects (Bystritsky, 2018).

PTSD

Drug treatments for PTSD should not be used as a routine first-line treatment for adults in preference to trauma-focused psychological therapy. Where pharmacological treatment is required, such as when the individual has shown minimal or incomplete response to psychological therapy, SSRIs may be recommended as first-line pharmacotherapy for PTSD as they ameliorate all three PTSD symptom clusters (i.e., reexperiencing, avoidance/numbing, and hyperarousal). SSRIs are typically started at the low end of their therapeutic range and titrated up gradually until response. Although there is no clear evidence of a dose–response relationship for SSRIs in PTSD, it is not uncommon to push the dose to the very high end of the therapeutic range, as tolerated by the patient. A therapeutic trial of an SSRI should be a minimum of 6–8 weeks before concluding that a medication has failed (Stein, 2017). Paroxetine is the only drug that is approved for PTSD in the UK (National Institute for Health and Care Excellence, 2005b), while sertraline and paroxetine are approved for PTSD by the FDA (Jeffreys, 2017). No SSRIs are specifically approved for the treatment of PTSD in Australia and New Zealand (National Health Committee, 1998).

OCD

SSRIs are recommended as first-line treatment for OCD as there is greater support from randomized trials for SSRIs than for venlafaxine, and they have a superior side effect profile compared to TCAs (American Psychiatric Association, 2007). All SSRIs except citalopram have approval/authorization for use in OCD in the United States or United Kingdom (American Psychiatric Association, 2007; National Institute for Health and Care Excellence, 2005a). Neither venlafaxine nor duloxetine has been FDA-approved specifically for the treatment of OCD.

Most trials of serotonergic antidepressants in OCD suggest that higher doses are associated with greater response rates and/or greater mean rates of improvement, so the doses licensed in the treatment of OCD are higher than those licensed for the treatment of depression (Simpson, 2017). However, lower (standard antidepressant) doses may be effective, particularly for maintenance treatment. The initial response is usually slower to emerge than in depression (it can be up to 10–12 weeks), and guidelines suggest that patients who respond to an adequate trial of a serotonergic antidepressant should stay on that medication for at least 1 to 2 years (Simpson, 2017; Taylor et al., 2012).

Tricyclic Antidepressants

The efficacy of tricyclic antidepressants (TCAs) is predominantly related to the reuptake inhibition of serotonin. Imipramine and clomipramine have shown greater potency at SERT; therefore, they have proven efficacy in some anxiety disorders. Imipramine and clomipramine have been used in the treatment of panic disorder; imipramine has shown efficacy in GAD, and some studies suggest that clomipramine may have greater efficacy than SSRIs in OCD. However, SSRIs and SNRIs are generally preferred because they have a more favorable safety profile, particularly in terms of risk of Q_{Tc} prolongation and safety in overdose, as TCAs are highly toxic in overdose (Bystritsky, 2018; Roy-Byrne, 2017). Side effects of tricyclic antidepressant include anticholinergic effects e.g., dry mouth, blurred vision, urinary retention, antihistaminic effects, e.g., sedation and weight gain, and α_1-adrenergic blockade effects, e.g., postural hypotension. TCAs also interact with several medications—particularly those that inhibit CYP2D6 (Baldwin et al., 2014b).

Buspirone

Buspirone has well-established efficacy in GAD and anxiety symptoms in depression, but is ineffective for other anxiety disorders. It has similar efficacy to benzodiazepines but lacks addictive potential and is safe in overdose. However, when compared to benzodiazepines in GAD, the onset of anxiolytic effects is slower (more similar to that of antidepressants, on the order of 4–6 weeks) and appears to have a weaker anxiolytic effect (Bystritsky, 2018). Buspirone also has a relatively short half-life, which necessitates dosing two to three times per day, which can adversely affect adherence to treatment. These factors have limited its use in practice largely to augmentation of SSRIs in GAD, though it can be used as a monotherapy (in the absence of comorbid major depression). Buspirone is generally well tolerated; main side effects include dizziness, insomnia, agitation, and nausea on treatment initiation. These may be minimized by slow dose titration (Nutt, 2005).

Pregabalin

Pregabalin acts as a presynaptic modulator of several excitatory neurotransmitters and may also increase GABA synthesis (Pollack, 2009). Pregabalin should not be stopped abruptly as it may precipitate seizures.

Several large randomized controlled trials have demonstrated its efficacy and tolerability, with comparable speed of onset to benzodiazepines (Montgomery et al., 2006; Rickels et al., 2005). It is approved for the treatment of GAD in Europe; however, it is not approved for this indication by the US FDA.

Antipsychotic Medications

Given their efficacy in the treatment of mood disorders, the use of second-generation antipsychotics (SGAs) in the treatment of GAD has increased, particularly for patients who have not responded to other first-line treatments. However, use of SGAs in the treatment of GAD is currently considered off-label in the United States and Europe (Hershenberg et al., 2014).

There is some conflicting evidence as studies suggest that SGAs—quetiapine, aripiprazole, olanzapine, and risperidone—are effective in reducing symptoms of anxiety among individuals with primary diagnoses of GAD (Hershenberg et al., 2014). More specifically, the most evidence exists for the use of quetiapine in relatively low doses (150 mg/day XR) (Gao et al., 2011). Side effects associated with SGAs include sedation, extrapyramidal symptoms, tardive dyskinesia, weight gain, and elevation of glucose and lipid levels. Because of this, SGAs should only be considered for treatment-resistant GAD after better tolerated alternatives have been exhausted (Bystritsky, 2018).

β-Blockers

Beta-blockers were used historically because they reduce the peripheral physical symptoms of anxiety (palpitations, tachycardia) within 30–60 min; however, evidence from randomized controlled trials is lacking. They do have a role in performance anxiety where tremor is a problem (e.g., musicians) but they do not affect the cognitive and emotional symptoms of anxiety.

They are also associated with significant side effects e.g., negative chronotropic effects, increased airway resistance (so cannot be used in people with asthma), facilitation of hypoglycemia, hyperkalemia, and fatigue, and are toxic in overdose; therefore, they are not generally used in practice.

α-Blockers

There is some evidence for the efficacy of centrally acting α_1-adrenergic antagonist —prazosin—in PTSD (Miller, 2008; Raskind et al., 2003, 2007)—particularly to manage nightmares. Prazosin may counteract some of the excesses noradrenergic brain activity that contributes to PTSD-related trauma-content nightmares, and can decrease the occurrence of trauma-content nightmares in both combat veterans and patients with noncombat-related PTSD (Miller, 2008).

What is Coming Up in Pharmacological Management

There is much drug development focused on improving the efficacy and tolerability of existing anxiety medications; however, there are also efforts to identify novel molecular targets (Miller, 2010).

Novel Pharmacological Targets

Neuropeptides are short-chain amino acid neurotransmitters and neuromodulators implicated in anxiety, pain, and stress regulation (Belzung et al., 2006). Their activity is more discretely localized than antidepressants, suggesting a more favorable side effect profile (Madaan and Wilson, 2009).

Neuropeptide targets under investigation include substance P, neuropeptide Y, and vasopressin. However, trials have failed to show consistent evidence for efficacy and safety (Farach et al., 2012).

Other molecular targets, including agents that block the effects of glutamate or promote compensatory neurogenesis, are being actively pursued (Snyder et al., 2011). Blocking glutamate activity and stimulating N-methyl-D-aspartate (NMDA) receptors may reduce stress and anxiety, possibly by restoring neurogenesis. Preliminary studies with riluzole and ketamine—NMDA receptor antagonists—have been shown to reduce symptoms in patients with anxiety disorders (Pittenger et al., 2008; Rodriguez et al., 2011).

Psychedelic Drugs

Although most psychedelic drugs have been illegal or heavily regulated for several decades, some research has suggested that psychedelic drugs may be able to augment exposure-based treatment for anxiety disorders.

Among the psychedelic drugs, 3,4-methylenedioxymethamphetamine (MDMA, or "ecstasy") is thought to be the best candidate for exposure augmentation as traditional psychedelics (e.g., lysergic acid diethylamide, psilocybin) can impair cognitive functioning, visual perception, and emotional control. MDMA can support and enhance psychotherapy by increasing a patient's access to emotionally upsetting material, modulating the associated level of arousal, and strengthening the therapeutic alliance (Mithoefer et al., 2013). Placebo-controlled pilot studies have yielded promising results in PTSD; in one study, 85% of patients in the MDMA group (compared with 15% of patients in the placebo group) no longer met criteria for PTSD after three sessions of MDMA-assisted psychotherapy (Mithoefer et al., 2011). These results were sustained at over 3-year follow-up, with no further MDMA required and many patients stopping their regular psychiatric medications (Mithoefer et al., 2013). A subsequent study demonstrated substantial improvement in PTSD symptoms in patients with resistant, chronic PTSD (Chabrol, 2013). In late 2017, the US FDA granted Breakthrough Therapy Designation to MDMA for the treatment of PTSD, and also reached an agreement for the design of Phase 3 clinical trials for MDMA-assisted psychotherapy for patients with severe PTSD. This will allow further research to fully assess the potential of MDMA in PTSD.

In recent years, cannabidiol (CBD), a phytocannabinoid constituent of *Cannabis sativa* that lacks the psychoactive effects of Δ9-tetrahydrocannabinol (THC), has drawn increasing interest as a treatment for a range of neuropsychiatric disorders. Preclinical evidence supports CBD as a treatment for GAD, panic disorder, OCD, and PTSD when administered acutely; however, few studies

have investigated chronic dosing (Blessing et al., 2015). Similarly, evidence supports an anxiolytic role for CBD, but studies are limited to acute dosing, uncontrolled studies/case reports, and few have been carried out in clinical populations (Greer et al., 2014; Passie et al., 2012). Further study is needed to understand the chronic and therapeutic effects of CBD in relevant clinical populations.

Digital Health Interventions

There has been a huge increase in the use of mobile health to target mental health through the use of "apps." It is estimated around 6% of the total number of apps available target people with mental health conditions. Advantages of apps include the improvement of treatment accessibility, real-time symptom and activity monitoring, tracking of treatment progress through ecological momentary assessment (EMA) and provision of personalized feedback and motivational support. However, there are disadvantages around the identification and timely management of crises, and risk of harm when integrating smartphone technology into health care (Donker et al., 2013).

Mobile health technologies will likely provide opportunities to deliver interventions to patients in their natural settings, and treatments such as CBT will become more affordable and accessible (Pramana et al., 2014).

Non-Pharmacological Management

There is good evidence to support the efficacy of some psychological interventions in anxiety disorders (Roberts et al., 2010). Occasionally, initial pharmacological therapy may be required to help the patient become more receptive to psychological input. Some studies suggest that optimal outcome is achieved by combining psychological and pharmacological therapies (National Institute for Health and Care Excellence, 2011); however, this is not always the case (Marcus et al., 2007; van Apeldoorn et al., 2008). For many patients, psychological therapies are an appropriate first-line treatment (National Institute for Health and Care Excellence, 2011).

Cognitive Behavioral Therapy

CBT is conceptualized as a short-term, skills-focused treatment aimed at altering maladaptive emotional responses by changing the patient's thoughts, behaviors, or both. Many diverse protocols have been created for providing CBT to patients with GAD, panic disorder, PTSD, OCD, as well as other anxiety conditions.

GAD

In CBT for GAD, patients are taught to become personal observers of their anxiety and worry. They learn to implement skills of cognitive restructuring to replace catastrophic appraisals with more evidence-based and coping oriented appraisals, and techniques of relaxation training to control excessive tension. Patients are encouraged to apply the cognitive and relaxation skills during exposures to images of feared negative events, and to anxiety-provoking situations, as they prevent themselves from engaging in overt and subtle avoidance behaviors.

Panic Disorder

In CBT for panic disorder, patients are taught to become personal observers of their panic, anxiety, and avoidance. They implement skills of cognitive restructuring to replace catastrophic appraisals with more evidence-based and coping oriented appraisals, and skills of breathing retraining or relaxation to control dysregulated physiology. Patients are encouraged to apply the cognitive and somatic skills during exposure to feared bodily sensations and situations. Through repeated exposure, patients learn that panic-related sensations are not harmful, that panic and anxiety can be managed or tolerated, and that they are able to accomplish tasks that were previously avoided.

PTSD

In CBT for PTSD, patients are assisted in thinking about the traumatic event and themselves more realistically. Socratic questioning is used to elicit information and challenge the patient's maladaptive beliefs. Exposure therapy assists patients in confronting their feared memories and situations in a therapeutic manner. Reexperiencing the trauma through exposure allows it to be emotionally processed so that it can become less painful.

Eye movement desensitization and reprocessing (EMDR) is a form of CBT that incorporates saccadic eye movements during exposure (Shapiro and Solomon, 1995). The technique involves the patient imagining a scene from the trauma, focusing on the accompanying cognition and arousal, while the therapist moves two fingers across the patient's visual field and instructs the patient to track the fingers. The sequence is repeated until anxiety decreases, at which point the patient is instructed to generate a more adaptive thought.

OCD

The most essential component of CBT for OCD is therapist-guided repeated and prolonged exposure to situations that provoke obsessional fear along with abstinence from compulsive behaviors (response prevention). This might occur in the form of

repeated actual confrontation with feared low-risk situations (i.e., in vivo exposure), or imaginal confrontation with the feared disastrous consequences of confronting the low-risk situations (imaginal exposure). Response prevention is a critical component because the performance of rituals to reduce obsessional anxiety would prematurely curtail exposure and rob the patient of learning that the obsessional situation is not truly dangerous, and that the anxiety would naturally subside. Effective exposure and response prevention requires that the patient remain in the exposure situation until the obsessional distress decreases spontaneously, without attempting to reduce the distress by withdrawing from the situation or by performing compulsive rituals or neutralizing strategies.

Psychodynamic Therapy

Psychodynamic therapy is based on the theories and principles of psychoanalysis, but is less focused on the patient–therapist relationship, as it is equally focused on the patient's relationship with his or her external world. In GAD, treatment focuses on core conflictual relationship themes, and emphasis is placed on a positive therapeutic alliance to provide a corrective emotional experience to offset insecure attachment. However, trials have found CBT to be more effective than psychodynamic therapy in GAD (Durham et al., 1999; Leichsenring et al., 2009). There is an absence of evidence for psychodynamic therapy in panic disorder, PTSD, and OCD (Fonagy, 2015).

Mindfulness and Acceptance and Commitment Therapy

Mindfulness involves the nonjudgmental observation of moment to moment experiences, while Acceptance and Commitment Therapy (ACT) combines mindfulness with acceptance of internal states and orientation of actions toward valued goals. Although there are some similarities between ACT and CBT (Arch and Craske, 2008), ACT does not involve any form of cognitive restructuring (i.e., identifying, challenging, and replacing negative thinking with more realistic thinking) or any attempt to change or correct somatic dysregulation (e.g., relaxation training). One meta-analysis suggested that mindfulness-based treatments are moderately effective in GAD (Hofmann et al., 2010); however, these approaches are less supported in other conditions e.g., panic disorder and PTSD.

Self-Help Techniques

The management of anxiety through self-help techniques undertaken individually or in groups has increased, partly driven by patient dissatisfaction with pharmacological treatment, and suboptimal effects of psychotropic and psychological interventions. The evidence behind these self-help interventions is limited but patients and their carers report considerable benefit. With the limited evidence base, one systematic review found that guided self-help had similar effectiveness compared to face-to-face psychotherapy (Cuijpers et al., 2010). Another systematic review concluded that Internet-based interventions have overall positive benefit in the management of anxiety but further investigations are required to determine the factors associated with beneficial outcomes (Griffiths et al., 2010). Self-help approaches such as the use of Internet-based educational resources have potential benefits in managing mild anxiety symptoms, but in some cases, patients may not benefit so keeping these patients under review is crucial so that alternative treatments can be initiated when warranted.

Role of the Pharmacist in Managing and Prescribing in Anxiety Disorders

Pharmacists are an integral part of the multidisciplinary team who can add value to the care of patients with anxiety disorders beyond medicines management and pharmaceutical care. The pharmacist can be involved in screening for anxiety disorders in primary care and identifying high-risk patients eligible for referral, optimizing treatment, and providing advice on complementary therapies where patients seek this approach. Pharmacists are well placed to support patients in making informed choices, thus in some ways, acting in a patient advocacy role.

Optimizing Treatment

Pharmacists can play a key role in optimizing pharmaceutical care—key aspects that are particularly relevant for anxiety are management of medication adverse effects, drug interactions, and benzodiazepine withdrawal.

Managing Adverse Effects of Pharmacological Treatment

Adverse effects with psychotropic medications can be distressing and can lead to patients stopping their medications. Adverse effects vary depending on the class of psychotropic; for example, SSRIs are commonly associated with sexual dysfunction, SNRIs with excessive perspiration, pregabalin and benzodiazepines with drowsiness, and antipsychotics with weight gain (see Pharmacological Management section). However, it is not only the adverse effect that may affect adherence but also the fear of developing tolerance or becoming dependent on medications contributes toward nonadherence. The pharmacist can play a key role in educating and providing information to patients, and correcting any misconceptions the patient has about their

Table 3 Groups of psychotropics used to manage anxiety disorders and most commonly reported adverse effects.

	SSRI	*SNRI*	*Pregabalin*	*Benzodiazepines*	*Antipsychotics*
Adverse effects	Sexual dysfunction, gastrointestinal (dose-related), increased risk of bleeding, dizziness, drowsiness	Hypertension, nausea, dry mouth, sexual dysfunction, increased risk of bleeding, drowsiness, insomnia	Increased appetite and weight gain, sexual dysfunction, gastrointestinal effects, euphoria, irritability, dizziness, somnolence	Drowsiness, decreased concentration, headaches, decreased libido, erectile dysfunction, paradoxical effects (talkativeness, excitement), tolerance and dependence	Extrapyramidal symptoms, weight gain, hyperprolactinemia, sedation, postural hypotension, dyslipidemia, impaired glucose tolerance, QT prolongation, anticholinergic effects

treatment. Pharmacists need to explore patient attitudes and concerns at the start of treatment, and periodically thereafter, allowing any issues to be addressed early on.

When starting antidepressant treatment, anxiety symptoms can worsen. Patients should be monitored closely for this and other adverse effects, as well as discontinuation symptoms (see Monitoring section) (**Table 3**).

Managing Drug Interactions

SSRIs

Some SSRIs are potent inhibitors of individual or multiple hepatic cytochrome P450 (CYP) pathways and the magnitude of these effects is dose related. For example, fluvoxamine is a potent inhibitor of CYP1A2, and fluoxetine and paroxetine are both potent inhibitors of CYP2D6. Care should be taken when prescribing escitalopram and citalopram alongside drugs that prolong the QT interval, due to the increased risk of torsade de pointes. The maximum daily doses have been restricted to escitalopram 20 mg and citalopram 40 mg daily in adults and in patients over the age of 65 years to escitalopram 10 mg and citalopram 20 mg daily, respectively.

Benzodiazepines

Benzodiazepines do not induce microsomal enzymes and so do not frequently precipitate pharmacokinetic interactions with other drugs. Most benzodiazepines are metabolized by CYP3A4 enzymes. Concomitant use of P450 inhibitors in a patient taking diazepam can result in increased serum levels of diazepam leading to increased effect; conversely, drugs that induce cytochrome P450 enzyme can accelerate hepatic elimination of diazepam and decrease its action. In practice, pharmacodynamic interactions (usually increased sedation) are common, for example, when benzodiazepines are administered alongside methadone, which can result in cardiopulmonary depression. The severity and impact of these interactions on patient safety need to be monitored for, and the pharmacist has an essential role in communicating these with the prescriber to manage their effects.

Management of Benzodiazepine Withdrawal

For most people in primary care, even minimal intervention, such as an information sheet or a single brief consultation, can be effective in reducing or stopping benzodiazepine use without adverse effects (Bashir et al., 1994). Although good quality evidence for this is lacking, withdrawing benzodiazepines gradually is recommended to allow a smooth, gradual fall in drug levels, thus minimizing withdrawal symptoms (Lader et al., 2009). Abrupt withdrawal can produce confusion, toxic psychosis, convulsions, or a condition resembling delirium tremens. This is more likely in people taking high doses, although seizures or psychosis may occur when other predisposing factors are present. The optimal speed or duration of dose reduction is unknown; drug withdrawal should be guided by individual choice and severity of withdrawal symptoms (Ashton, 2002). More detailed information on benzodiazepine withdrawal is outside the scope of this chapter, please refer to local specialist resources for further guidance.

Special Populations

Children and Adolescents

The evidence base for prescribing for the management of anxiety disorders of children and adolescents is relatively poor compared to adults (18–65 years old) with only a few randomized controlled studies (Ipser et al., 2010). It is recommended, where possible, to manage anxiety disorders in children and adolescents through the use of psychological interventions. Psychotropic treatment such as SSRIs should only be initiated where there has been no response to psychological interventions. If the decision has been made to initiate psychotropic treatment, then the same range of treatments for adults such as SSRIs should be considered, but done so very cautiously.

Women of Childbearing Age

Anxiety disorders are common in pregnancy and in the postpartum period, and in some cases, the symptoms may remit during these phases. As the evidence base for the use of psychotropics during pregnancy and breastfeeding is still growing, pharmacists have an important role in providing advice on a case-by-case basis. Key considerations include weighing up the risks of discontinuation when

stopping treatment, safety of the drug in pregnancy/breastfeeding, in addition to its effectiveness, tolerability, and adverse effects. When providing advice in relation to the appropriateness of a pharmacological agent during pregnancy, pharmacists should seek specialist advice from medicines information services. The decision to use any drug during pregnancy and breastfeeding should be done in collaboration with the patient who should be fully informed of all risks associated with taking or not taking a particular medication (Freeland and Shealy, 2013).

Older-aged Patients

Similar to the evidence base in children and adolescents, there are few randomized studies investigating the effectiveness and acceptability of psychotropics in the elderly population (>65 years old). Anxiety disorders in patients aged over 65 years are less common compared to the younger population (Oakley Browne et al., 2006). In elderly patients, the rate of clearance of drugs through the liver and/or kidneys is slower than adults, thus necessitating lower doses. The management of anxiety in elderly patients is not dissimilar compared to younger patients but the patient's full medical history (conditions) and any currently prescribed medications need to be carefully considered to mitigate possible drug interactions.

Monitoring Patients with Anxiety

Pharmacists have a key role in monitoring symptoms and treatment response and/or tolerance (Locke and Kamo, 2016). Patients who have started on an SSRI or SNRI should be seen every 2–4 weeks for the first 3 months, and if under the age of 30 years, should be reviewed within 1 week of initiation as these classes of drugs are associated with an increased risk of suicidal thinking and self-harm (Medicines and Healthcare Products Regulatory Agency, 2014).

Treatment should be continued for at least 12 months in patients diagnosed with OCD and PTSD, 6 months for social anxiety and panic disorder, and 18 months for GAD, to prevent relapse (Baldwin et al., 2014a). Patients should be monitored through this period to ensure continued benefit with treatment. The following should be reviewed:

- Monitor progress, considering factors including severity, duration of symptoms, degree of distress, and functional impairment. Consider using anxiety screening questionnaires such as GAD-7 to compare with previous scores.
- Check treatment adherence (either pharmacological or psychological interventions) and inquire about adverse effects.
    - If necessary, advise dose adjustment or a switch to a different drug, based on adverse effects and progress.
    - If a drug is effective, advise to continue taking it for at least a year as the likelihood of relapse is high if stopped earlier.
    - If there is no response to pharmacological treatment, offer an alternative medication (from the same or alternative medication class), or psychological intervention.
    - If there is no response to psychological intervention, consider offering a pharmacological treatment, if not previously on psychotropics.
- Assess for suicidal ideation and suicide risk, especially if the person has comorbid depression.

If the decision has been made to stop treatment, this should be done gradually over a minimum period of 3 months to avoid rebound symptoms and discontinuation symptoms, which may occur with abrupt cessation of treatment or missed doses. The drugs most implicated in causing discontinuation symptoms are the short half-life drugs such as venlafaxine or paroxetine (see Pharmacological Management section). Symptoms can be offset by switching to modified-release preparations to prolong drug release.

Bipolar Affective Disorder

Joanne C. Lin*, Amy Chan*, Hadar Zaman†, Frederick Sundram†,‡, *School of Pharmacy, University of Auckland, Auckland, New Zealand; †Bradford School of Pharmacy and Medical Sciences, University of Bradford, Bradford, United Kingdom; ‡Department of Psychological Medicine, University of Auckland, Auckland, New Zealand

Learning Objectives

- Describe the epidemiology and etiology of bipolar affective disorder (BPAD), including the different presentations and BPAD Types 1 and 2
- Briefly outline the signs and symptoms underlying different diagnostic criteria for BPAD
- Explain the pharmacological and nonpharmacological management options for BPAD
- Describe the first- and second-line treatment option for BPAD and what options can be considered when usual first-line treatments fail
- List the most common side effects and interactions associated with mood stabilizers, lithium, and antipsychotics
- Describe novel treatment options coming up in the management of BPAD
- Describe the role of the pharmacist in managing BPAD and where pharmacists can contribute to the pharmaceutical care

Take Home Messages

- Bipolar affective disorder (BPAD) is a serious mental health illness that can cause significant disruption to individuals, their families and carers, workplace, and society during an episode of mood disorder
- The presentation of BPAD can be heterogeneous with a variety of different symptoms and durations of onset
- Treatment varies depending on whether the presentation is primarily depression or mania during the acute stage, but should always include consideration of a mood stabilizer in the long term
- Lithium is generally considered the mainstay of treatment in terms of both acute and long-term maintenance treatment
- Second-generation antipsychotics or mood stabilizers can be considered for monotherapy management of the depressive phase of BPAD
- The use of antidepressants in people with BPAD remains contentious and its long-term efficacy unclear. Caution is advised due to risk of switching to mania
- Pharmacists are an integral part of the multidisciplinary team for BPAD management, partly due to the "neutral" position of pharmacists in terms of medication supervision and administration, thus may take on a patient advocacy role for optimization of treatment plans
- Key opportunities to optimize pharmaceutical care for patients include improving adherence through psychoeducation and maximizing efficacy or minimizing adverse effects of treatment

Introduction to Condition

Bipolar disorder, also known as manic depressive disorder or bipolar affective disorder (BPAD), is a serious mental illness. It is classified as a mood disorder, whereby mood disturbance is usually represented by episodes of depression or mania. Between acute episodes, patients may be in full remission, but in some cases, there can be residual symptoms between episodes. It usually presents in early adulthood with much heterogeneity as well as comorbidity, leading to poor mental and physical health and reduced quality of life (Gutierrez-Rojas et al., 2008). BPAD can cause significant disruption to individuals, their families, workplace, and society. Treatments not only involve medication but also psychoeducation to improve insight and support for the individual and family. When making a diagnosis, it is important to exclude potential physical disorders that could contribute to an altered mood state, e.g., thyroid disease, medications (e.g., steroids), or illicit drugs.

Brief History of BPAD

BPAD symptoms have been recognized for approximately 2000 years, and the condition has been known by other terms such as melancholia and manic depression. Melancholia is a term from ancient Greece that was used to describe someone in pre-Hippocratic times with depression. This is because their mood was thought to be related to the brain being affected by black bile, which was consistent with the theory of bodily humors at the time.

With regard to mania and depression being considered part of the spectrum of the same disease, the Greek physician Aretaeus of Cappadocia was the first to do so in the first century AD (Marneros, 2001). In the 1800s, BPAD was termed folie circulaire and folie à double forme by Jean-Pierre Falret and Jules Baillarger, respectively. Later, it was described by Emil Kraepelin in the early 1900s as "manic depressive psychosis" and subsequently as bipolar disorder by Karl Leonhard and colleagues.

Condition Information

Definition/Classification of BPAD

Mood can be conceptualized as a spectrum with major depressive disorder (MDD) at one end and mania at the opposite end.

Bipolar disorder I (BD I) is used to describe a clinical diagnosis of bipolar disorder with manic episodes, whereas bipolar II (BD II) is used to categorize bipolar disorder with hypomanic episodes in the absence of manic episodes (American Psychiatric Association, 2013). The ICD-10 diagnostic criteria do not include BD II as a separate diagnostic category (World Health Organization, 1992).

Cyclothymic disorder is a chronic mood disorder characterized by depressive or hypomanic symptoms, whereby these do not meet the threshold for a manic or depressive episode (American Psychiatric Association, 2013). The symptom duration is usually 2 years in adults, whereas the time criteria for adolescents are shorter at 1 year. Symptoms include mood swings and subthreshold low mood, and it is regarded as a milder form of BPAD.

Rapid cycling bipolar disorder is a term used to describe 4 or more discrete mood episodes (mania, hypomania, depression, or mixed) in an annual timeframe (Lee et al., 2010).

Depending on the diagnostic classification system used, for a diagnosis of BPAD to be made, an episode of mania is required (American Psychiatric Association, 2013), or two mood episodes whereby at least one is mania, see later in chapter for full diagnostic criteria (World Health Organization, 1992). With ICD-10, BPAD is classified as a mood disorder and can be found together with other mood disorders such as recurrent depressive disorder or persistent mood disorders (World Health Organization, 1992).

Epidemiology

The bipolar spectrum (which includes BD I, BD II, and subthreshold BPAD) has a lifetime prevalence of approximately 2.4% (Merikangas et al., 2011) and affects both genders equally (Leibenluft, 1996). The mean age of diagnosis is in the third decade although depressive symptoms or discrete episodes of depression occur earlier in life, typically in adolescence or early adulthood (Leboyer and Kupfer, 2010; Phillips and Kupfer, 2013), and there are often several episodes of depression before developing manic episodes (Leverich et al., 2007). The ratio of manic to depressive episodes is estimated to be 1:3 (Judd et al., 2003), and there are a number of associated comorbidities including anxiety, addiction, and other psychiatric disorders.

According to the Aesop study undertaken in the United Kingdom, BPAD was reported to be higher in Black and other minority ethnic groups compared to the White population (Lloyd et al., 2005). Studies have also shown that people of Afro-Caribbean background were more likely than White people to be hospitalized with BPAD, have a higher rate of attempted suicide, and more frequent psychotic episodes, which were more likely to be associated with substance or alcohol misuse (Bani-Fatemi et al., 2013; Snowden et al., 2009). Approximately 10% of people with BPAD have the rapid cycling form, which can cause significant functional and social disturbance and often associated with a poorer prognosis. Up to a quarter of those with BPAD have a lifetime history of self-harm, while rates of suicide are estimated to be 15 times higher than the general population (Angst et al., 2005; Goetz et al., 2007).

The quality of life impairments associated with BPAD are significant due to its chronic course, early onset and the loss of disability-adjusted life years (DALYs) which is more than all forms of cancer or major neurological conditions (Merikangas et al., 2011; World Health Organization, 2002). People with BPAD have an increased risk of cardiovascular disease and approximately 38% of people die from this, which is twice the expected mortality rate for the general population (18%) (Westman et al., 2013). People with BPAD also have an increased risk of chronic kidney disease, respiratory disease (such as chronic obstructive pulmonary disease (COPD)), and diabetes (Hsu et al., 2017; Smith et al., 2013).

Postpartum psychoses can occur in women with BPAD with the onset of symptoms following childbirth (Jones et al., 2014), and these are referred to as episodes with peripartum onset (American Psychiatric Association, 2013). Usually these episodes have a mood component (typically hypomanic or manic) but can be associated with depressive symptoms too. The symptoms often develop within 2 weeks after delivery and can include delusions, hallucinations, mood disorder symptoms, confusion, and perplexity (Jones et al.)

Etiology

BPAD is thought to have a strong genetic component and increased familial aggregation based on twin, adoption, and family studies (Cowen et al., 2012). A recent estimate of the heritability of bipolar disorder was quoted as 85%, and the lifetime risk for bipolar disorders in first-degree relatives is estimated to be about 10%. There also appears to be overlap of susceptibility between BPAD and schizophrenia with polygenic contribution from several individual risk alleles of small effect (Baum et al., 2008; Craddock and Sklar, 2013; Lichtenstein et al., 2009). As with many psychiatric disorders, there is an interplay between genetics, epigenetics, and environment.

For example, early childhood adversity has been suggested to contribute to the evolution of BPAD (Sugaya et al., 2012). Furthermore, rapid cycling and mixed affective episodes are more common in the context of substance use (Krishnan, 2005). There is recognition of substance- or medication-induced bipolar symptoms, which is termed bipolar and related disorder (American Psychiatric Association, 2013). It is not just illicit substances that can induce BPAD symptoms, but prescribed medication such as corticosteroid medication used for reducing inflammation has been associated with BPAD symptoms. Manic or hypomanic symptoms can additionally arise with other prescribed treatments such as levodopa, methylphenidate, and stimulants such as caffeine (Kiselev et al., 2015), cocaine, and amphetamines. However, should someone experience a hypomanic/manic state following the commencement of an antidepressant or course of electroconvulsive therapy, this is regarded as BPAD rather than a medication-induced bipolar and related disorder (Licht et al., 2008).

Bipolar and related disorder may also arise due to an underlying medical condition, which include endocrine disorders such as Cushing's disease and thyroid disorder. Dysfunction of the hypothalamic–pituitary–adrenal axis with abnormal secretion of cortisol has been implicated in depression and may contribute to BPAD (Daban et al., 2005; Fries et al., 2014). Neurodegenerative disorders such as multiple sclerosis, frontal lobe dementia, and HIV dementia can further contribute to BPAD presentations.

Diagnosis

Signs and Symptoms

People with BPAD usually present with episodes of depression earlier in their life, often in adolescence followed by manic episodes in adulthood. Sometimes the mood episodes, when severe, can be associated with psychotic symptoms. Up to half of the people diagnosed with BPAD experience psychotic symptoms such as hallucinations and delusions, which are regarded as distortions in reality (Vandeleur et al., 2014). When someone experiences mania and psychosis, the symptoms can be congruent with the mood state such as thinking they are famous or rich and can result in sexual indiscretions or overspending. Conversely, when depressed, they may have the belief that they are destitute and that there is no point living any longer.

BPAD has high comorbidity with other mental health disorders, personality disorders, and addictions. For example, conditions that are highly comorbid with BPAD include anxiety disorder, alcohol and substance misuse, gambling, and attention-deficit hyperactive disorder (ADHD) (Di Nicola et al., 2014; Malhi et al., 2015). There are increased rates of associated risks including self-harm and suicide, violent/nonviolent crime, and metabolic syndrome (Malhi et al., 2012; Schaffer et al., 2015a; Schaffer et al., 2015b).

Criteria for episodes of mania and hypomania are summarized in **Table 1**. Although manic episodes can occur acutely for the first time in adulthood, there are often warning signs for months and sometimes years prior to such episodes (Faedda et al., 2015). Symptoms can include irritability, lability, mood shifts, hyperactivity, and anxiety, and these symptoms may extend as far back as childhood or adolescence (Egeland et al., 2000; Merikangas et al., 2007; Shankman et al., 2009). The prodromal state may involve dysregulation of mood and energy; however, these symptoms are nonspecific and do not necessarily predict future development of BPAD (Skjelstad et al., 2010).

Treatment Considerations in BPAD

When managing BPAD, there should be consideration of not only the prevailing mood (e.g., depression or mania) but also the treatment phase, which would include mood prophylaxis/maintenance phase versus treatments that occur during an acute phase.

Indeed, when considering the best environment for BPAD to be managed, the severity and comorbidity of episodes affect the decision of managing someone as an inpatient or outpatient. With psychotic symptoms, suicidality, homicidality, catatonia, severe psychosocial disruption, vulnerability, impaired judgement/impulsivity, or substance addiction, inpatient management is preferred (Malhi et al., 2015). Apart from considering the most appropriate environment to manage BPAD, pharmacotherapy and non-pharmacotherapy are other important considerations; both should be used where appropriate.

Nonpharmacological Management

Optimum management of BPAD needs integration of pharmacotherapy with targeted psychotherapy. Common overall objectives of psychosocial interventions for BPAD include building a therapeutic alliance and education of patients (British Psychological Society, 2010), and where possible, caregivers, about strategies for the management of stress, the identification and intervention of early signs of recurrence, and how to maintain a regular lifestyle (e.g., sleep and exercise) habits (Miklowitz and Scott, 2009) and optimal metabolic control (Goodwin et al., 2016; Malhi et al., 2015).

Adjunctive Psychotherapy in the Acute Phase

There is a strong clinical consensus about the benefits of engaging with people even in acute mania, making all reasonable efforts to work in a genuinely collaborative and normalizing way. Unstructured supportive psychotherapy is likely to be useful for the patient and their family during acute mania. Acute settings also provide an opportunity to engage individuals for future psychological therapy.

Adjunctive Psychotherapy in the Maintenance Phase

Group and individual psychoeducation, detecting early warning signs, and family therapy can be used as adjunctive psychotherapies. These therapies are time limited, structured, and typically administered to euthymic patients during maintenance. Psychoeducation is a core element of adjunctive cognitive behavioral therapy, family therapy, and interpersonal and social rhythm therapy.

Table 1 Diagnostic criteria for BPAD with particular focus on features of manic and hypomanic episodes (American Psychiatric Association, 2013)

Diagnostic Criteria

For a diagnosis of bipolar I disorder, it is necessary to meet the following criteria for a manic episode. The manic episode may have been preceded by and may be followed by hypomanic or major depressive episodes.

Manic Episode

A. A distinct period of abnormally and persistently elevated, expansive, or irritable mood and abnormally and persistently increased activity or energy, lasting at least 1 week and present most of the day, nearly every day (or any duration if hospitalization is necessary).
B. During the period of mood disturbance and increased energy or activity, three (or more) of the following symptoms (four if the mood is only irritable) are present to a significant degree and represent a noticeable change from usual behavior:
   1. Inflated self-esteem or grandiosity.
   2. Decreased need for sleep (e.g., feels rested after only 3 h of sleep).
   3. More talkative than usual or pressure to keep talking.
   4. Flight of ideas or subjective experience that thoughts are racing.
   5. Distractibility (e.g., attention too easily drawn to unimportant or irrelevant external stimuli), as reported or observed.
   6. Increase in goal-directed activity (either socially, at work or school, or sexually) or psychomotor agitation (e.g., purposeless nongoal-directed activity).
   7. Excessive involvement in activities that have a high potential for painful consequences (e.g., engaging in unrestrained buying sprees, sexual indiscretions, or foolish business investments).
C. The mood disturbance is sufficiently severe to cause marked impairment in social or occupational functioning or to necessitate hospitalization to prevent harm to self or others, or there are psychotic features.
D. The episode is not attributable to the physiological effects of a substance (e.g., a drug of abuse, a medication, other treatment) or another medical condition.
   - **Note:** A full manic episode that emerges during antidepressant treatment (e.g., medication, electroconvulsive therapy) but persists at a fully syndromal level beyond the physiological effect of that treatment is sufficient evidence for a manic episode and, therefore, a bipolar I diagnosis.

Note: Criteria A–D constitute a manic episode. At least one lifetime manic episode is required for the diagnosis of bipolar I disorder.

Hypomanic Episode

A. A distinct period of abnormally and persistently elevated, expansive, or irritable mood and abnormally and persistently increased activity or energy, lasting at least 4 consecutive days and present most of the day, nearly every day.
B. During the period of mood disturbance and increased energy and activity, three (or more) of the following symptoms (four if the mood is only irritable) have persisted, represent a noticeable change from usual behavior, and have been present to a significant degree:
   1. Inflated self-esteem or grandiosity.
   2. Decreased need for sleep (e.g., feels rested after only 3 h of sleep).
   3. More talkative than usual or pressure to keep talking.
   4. Flight of ideas or subjective experience that thoughts are racing.
   5. Distractibility (e.g., attention too easily drawn to unimportant or irrelevant external stimuli), as reported or observed.
   6. Increase in goal-directed activity (either socially, at work or school, or sexually) or psychomotor agitation.
   7. Excessive involvement in activities that have a high potential for painful consequences (e.g., engaging in unrestrained buying sprees, sexual indiscretions, or foolish business investments).
C. The episode is associated with an unequivocal change in functioning that is uncharacteristic of the individual when not symptomatic.
D. The disturbance in mood and the change in functioning are observable by others.
E. The episode is not severe enough to cause marked impairment in social or occupational functioning or to necessitate hospitalization. If there are psychotic features, the episode is, by definition, manic.
F. The episode is not attributable to the physiological effects of a substance (e.g., a drug of abuse, a medication, other treatment) or another medical condition.
   - **Note:** A full hypomanic episode that emerges during antidepressant treatment (e.g., medication, electroconvulsive therapy) but persists at a fully syndromal level beyond the physiological effect of that treatment is sufficient evidence for a hypomanic episode diagnosis. However, caution is indicated so that one or two symptoms (particularly increased irritability, edginess, or agitation following antidepressant use) are not taken as sufficient for diagnosis of a hypomanic episode, or necessarily indicative of a bipolar diathesis.

Note: Criteria A–F constitute a hypomanic episode. Hypomanic episodes are common in bipolar I disorder but are not required for the diagnosis of bipolar I disorder.

Some topics covered in psychoeducation include illness awareness, medication options and adherence, identifying prodromal signs of recurrent episodes, and regulating habits. Other topics may include triggers, avoiding substance abuse, pregnancy and heritability, and stress management (Geddes and Miklowitz, 2013).

Pharmacotherapy Treatment Options

Pharmacotherapy can be used for all stages of BPAD, with the aim of reducing morbidity and mortality (Harrison et al., 2016). The desired outcome of treatment is to prevent acute manic, hypomanic, or depressive episodes, resulting in improved functioning to premorbid level, and reducing further episodes of mania and depression (American Psychiatric Association, 2002). Treatment of

BPAD must be individualized depending on the clinical presentation, severity, and frequency of episodes. Once the acute presentation has been managed, maintenance pharmacotherapy is recommended with observational studies demonstrating that initiation of maintenance early in the course of illness is associated with better long-term outcomes (Kessing et al., 2014).

Acute Mania and Hypomania

Despite clinical differences between acute manic and hypomanic episodes, for the purposes of treatment, they are considered to be similar and thus treated with the same medication (Grunze et al., 2009; Wong, 2011; Yatham et al., 2013). The goal of treatment is remission, defined as "resolution of mood symptoms or improvement to the point that only one or two symptoms of mild intensity persist. If psychotic features (delusions or hallucinations) are also present, resolution of the psychosis is required for remission" (Grunze et al., 2009).

Based on randomized trials, the medication classes commonly used to treat acute mania or hypomania include lithium, anticonvulsants, and antipsychotics used in combination or as monotherapy, depending on severity of symptoms. Benzodiazepines are primarily used as adjunctive treatment for insomnia, agitation, or anxiety.

Lithium

Lithium monotherapy is effective in the treatment of moderate to severe mania, depression, and mixed episodes. The main indication for lithium is the prophylaxis of BPAD, where it reduces both the number and severity of relapses (Tondo et al., 2010); however, lithium is more effective at preventing manic than depressive relapses. The National Institute for Health and Care Excellence (NICE) in the United Kingdom supports the use of lithium as a first-line mood stabilizer (National Institute for Health and Care Excellence, 2014a).

Before initiating lithium, renal, thyroid, and cardiac function should be checked. Thyroid dysfunction should be corrected before treatment is commenced. An electrocardiogram (ECG) is recommended in patients with risk factors for, or existing, cardiovascular disease. A baseline weight is also appropriate.

Lithium dosing depends on the patient's age and weight, tolerance to adverse effects, and the acuity of the illness. Plasma levels should be measured 12 h postdose, 1 week after starting lithium, and 1 week after every dose change, and weekly until the levels are stable (National Institute for Health and Care Excellence, 2014a). Standardized 12-h lithium (trough) levels have become the accepted mode of monitoring. A systematic review of the relationship between plasma levels and response determined that the optimal range is 0.6–0.75 mmol/L (Severus et al., 2008).

Once the desired therapeutic reference range for lithium levels has been achieved, levels should be measured every 3 months. More frequent tests may be necessary in those who are prescribed interacting medications such as anti-inflammatory or angiotensin-converting enzyme drugs, and in elderly, people at risk of impaired renal or thyroid function, or people who have poor symptom control or adherence. Body weight (or body mass index) and tests for urea, electrolytes, estimated glomerular filtration rate (eGFR), and thyroid function should be measured every 6 months (National Institute for Health and Care Excellence, 2014a).

Most side effects associated with lithium treatment are dose related and, therefore, plasma level related. These include mild gastrointestinal upset, fine tremor, polyuria, and polydipsia (Taylor et al., 2015). Long-term use increases the risk of hypothyroidism (Frye et al., 2009), which can be managed with thyroxine. Thyroid levels can also normalize with lithium cessation; however, this is often not practical if lithium is pivotal to a treatment. There is also increased risk of hyperparathyroidism; calcium levels should be monitored every 6 months, or more often if there is impaired renal function. For a review of the toxicity profile of lithium, see McKnight et al. (2012).

Toxic effects of lithium occur at levels >1.5 mmol/L but also have known to occur at normal plasma levels and usually consist of gastrointestinal effects (anorexia, nausea, and diarrhea) and central nervous system effects (muscle weakness, drowsiness, ataxia, coarse tremor, and muscle twitching). At levels above 2.0 mmol/L, increased disorientation and seizures occur, which can progress to coma, and ultimately death. When lithium treatment is initiated, patients should always be given information relating to the symptoms of toxicity and common risk factors (Gerrett et al., 2010). When lithium toxicity is suspected, an urgent lithium level should be done and, because there is no antidote to lithium, supportive measures should be put in place and lithium levels checked every 6–12 h to ensure they are falling. When considering stopping lithium, abrupt discontinuation should be avoided as this is associated with increased risk of relapse to mania. When discontinuing long-term treatment, doses should be gradually tapered over at least 4 weeks and preferably over 3 months. Patients should be monitored for signs of relapse, emerging symptoms, mood, and mental state while discontinuing treatment, and for up to 2 years after treatment has stopped.

Valproate

Valproate is often prescribed as a mood-stabilizing agent and commonly used in the maintenance phase of treatment. It's mechanism of action is not fully understood. Valproate is available in three formulations: valproic acid (widely used for BPAD in the United States, but only licensed for the treatment epilepsy in the United Kingdom), sodium valproate, and semi-sodium valproate. Both sodium valproate and semi-sodium valproate formulations are metabolized to valproic acid, which is responsible for the pharmacological activity. Doses of sodium valproate and semi-sodium valproate are not equivalent; a slightly higher dose (approximately 10%) is required to allow for extra sodium content when sodium valproate is used (Fisher and Broderick, 2003).

Randomized controlled trials have shown valproate to be effective in the treatment of mania, with a response rate of 50% (Nasrallah et al., 2006). It may be considered a first-line option for acute episodes and for prophylaxis. It can also be used in

combination with antidepressants for acute episodes of depression (National Institute for Health and Care Excellence, 2014a). Valproate may also be preferred over lithium for mixed episodes (American Psychiatric Association, 2002).

Before initiating valproate therapy, baseline full blood count, liver function tests, and weight or BMI should be measured. Full blood counts, weight/BMI, and liver tests should be repeated after 6 months and annually thereafter.

Common dose-related side effects include gastrointestinal distress, hyperammonemia, sedation, and hair loss with curly regrowth (Segura-Bruna et al., 2006). Rare, idiosyncratic, but potentially fatal adverse events include irreversible hepatic dysfunction, hemorrhagic pancreatitis, and agranulocytosis (American Psychiatric Association, 2002). Lethargy and confusion can occasionally occur with starting doses above 750 mg/day; therefore, treatment should start with low divided doses to minimize side effects, then titrated accordingly. Weight gain can be significant and up to a quarter of patients may develop postural tremor (Zadikoff et al., 2007), which is reversible upon valproate cessation. If stopping valproate, the dose should be slowly reduced over at least 4 weeks to minimize the risk of relapse (National Institute for Health and Care Excellence, 2014a). Valproate is associated with an increased prevalence of polycystic ovary syndrome (Bilo and Meo, 2008); it should not be offered to female children/adolescents, women of childbearing potential, or pregnant women without specialist advice (National Institute for Health and Care Excellence, 2014a).

Carbamazepine

Randomized studies have suggested that carbamazepine monotherapy is effective in bipolar depression (Dilsaver et al., 1996); however, it is generally thought to be less effective than lithium in the prophylaxis of mania (Nasrallah et al., 2006), and is considered to be a third-line agent for this purpose (National Institute for Health and Care Excellence, 2014a).

Before initiating carbamazepine, baseline full blood count, liver function tests, and renal function tests should be done. Serum electrolytes can also be obtained, especially in the elderly, who may be at higher risk of hyponatremia. A baseline measure of weight is also desirable (American Psychiatric Association, 2002; National Institute for Health and Care Excellence, 2014a).

The main side effects associated with carbamazepine are dizziness, diplopia, drowsiness, ataxia, and headaches. This can sometimes be avoided by starting with a low dose and increasing slowly. Carbamazepine commonly causes chronic low white blood cell count and treatment should be discontinued if the patient develops leucopenia that is severe, progressive, or accompanied by clinical manifestations, e.g., fever or sore throat. Rare, idiosyncratic, but serious side effects include agranulocytosis, aplastic anemia, hepatic failure, exfoliative dermatitis (e.g., Stevens–Johnson syndrome), and pancreatitis. Carbamazepine is a hepatic enzyme inducer that induces its own metabolism as well as that of other drugs. It is, therefore, advisable to check plasma levels to ensure levels are within the therapeutic range or if noncompliance is suspected. Plasma levels should be checked 2–4 weeks after dosage increases to ensure that desired levels (of at least 7 mg/L) are still being obtained to ensure efficacy of treatment (Taylor et al., 2015).

Antipsychotics

Individual antipsychotics possess sedative, anxiolytic, anti-manic, mood-stabilizing, and antidepressant properties; some (quetiapine and olanzapine) show all of these.

First-generation antipsychotics (FGAs) have long been used in that treatment of mania; however, until recently, there was a paucity of published evidence on their role in the treatment of mania. Recent studies have demonstrated clear efficacy of haloperidol for this indication (Smulevich et al., 2005). However, the long-term use of FGAs is limited by the increased risk of extrapyramidal side effects and tardive dyskinesia (Tohen and Vieta, 2009). The efficacy of second-generation antipsychotics (SGAs) aripiprazole, clozapine, olanzapine, quetiapine, and risperidone has been more robustly evaluated. Comparison among different SGAs is difficult as there are no conclusive head-to-head studies; the choice often depends upon the difference in side effects. In the United Kingdom, NICE recommends a therapeutic trial of either haloperidol, olanzapine, quetiapine, or risperidone in the management of the acute phase of mania and, if the first antipsychotic is not effective or tolerated, a second antipsychotic from the four options is offered. Metabolic problems such as weight gain, glucose intolerance, and hyperlipidemia are most likely to occur with olanzapine, followed by quetiapine and risperidone.

Asenapine is newly approved in the United States and the United Kingdom for the acute treatment of manic or mixed episodes with or without psychotic features. Trials have demonstrated that it is well-tolerated and may be less likely than olanzapine to cause clinically significant weight gain (McIntyre et al., 2009, 2010).

Before starting antipsychotic medication, weight or BMI, pulse, fasting blood glucose, and blood lipid profile should be measured. Pulse and blood pressure should be monitored after each dose change, weight/BMI should be monitored weekly for the first 6 weeks and then at 12 weeks, and blood glucose and lipid profile should be measured at 12 weeks. ECG should be done before initiation of an antipsychotic, especially if using haloperidol, and subsequently after dose changes. Prolactin levels should be measured 6 months after starting treatment, and liver function tests completed every 12 months. Response to treatment, adherence, and side effects should also be monitored regularly throughout treatment (National Institute for Health and Care Excellence, 2014a).

Electroconvulsive Therapy

Electroconvulsive therapy (ECT) may be considered for patients with severe or treatment-resistant mania. In addition, ECT is a potential treatment for patients experiencing mixed episodes or for patients experiencing severe mania during pregnancy (American Psychiatric Association, 2002).

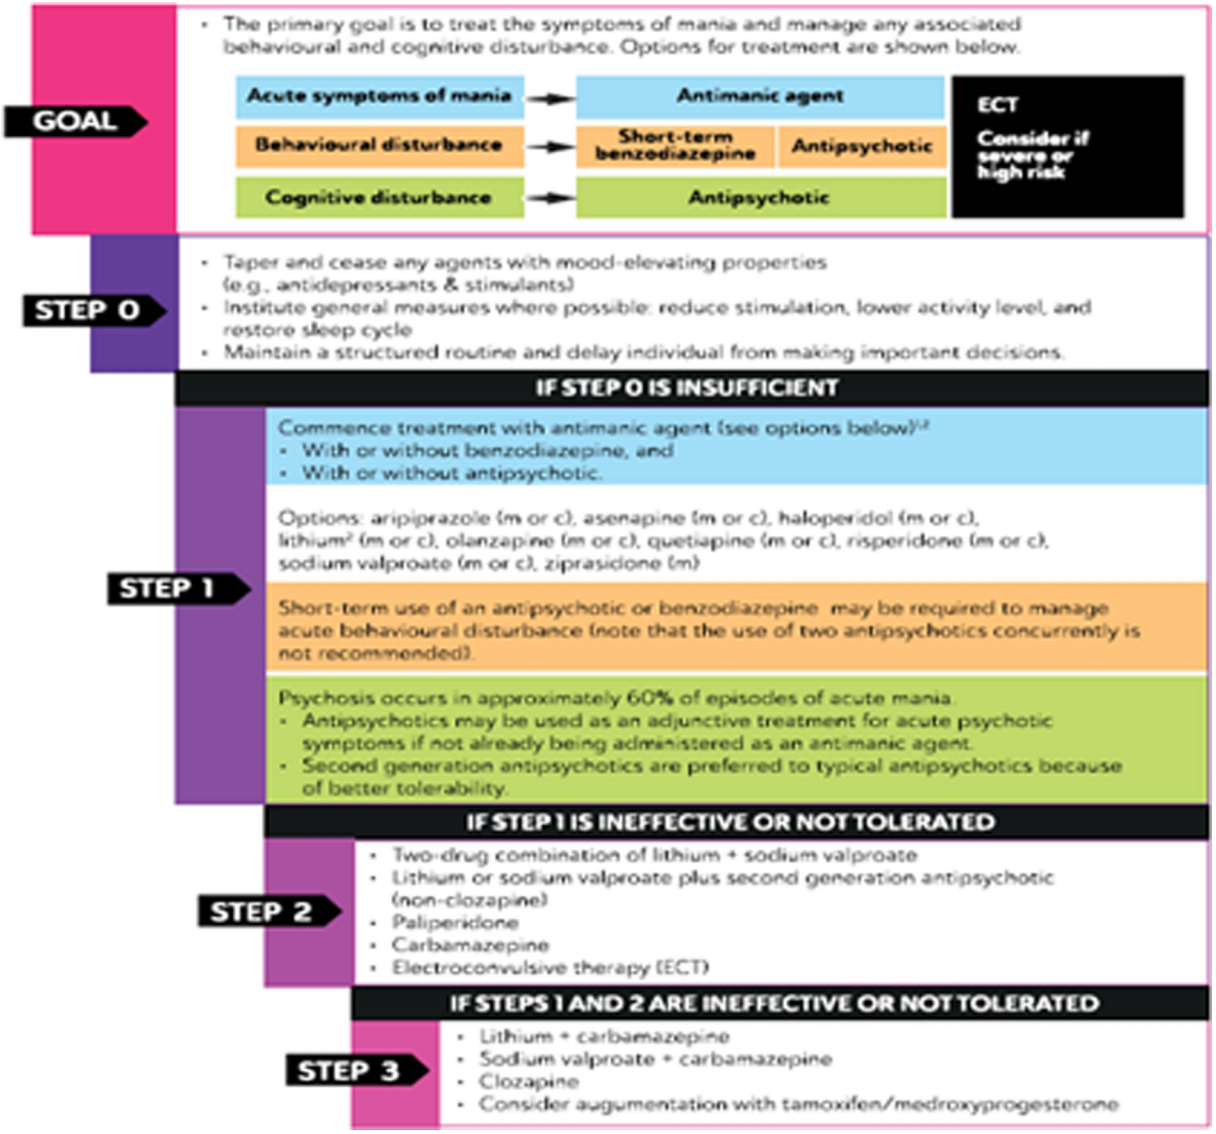

Figure 1 The management of mania is illustrated as a series of steps. The primary targets of treatment are "ABC": Acute symptoms of mania, behaviour disturbance, and cognitive disturbance. Taken from the Australian and New Zealand College of Psychiatrists clinical practice guidelines. m, monotherapy; c, combination.

Fig. 1 nicely illustrates a step-wise approach in managing patients with mania, which is used in Australia and New Zealand. However, it is important to note the pharmacological approach used to manage patients with mania may be different depending on the country and clinical guidelines used.

Acute Depression

Bipolar depression is the predominant and most disabling component of BPAD (Judd et al., 2003). Patients can present with either de novo or breakthrough episodes while on maintenance therapy (Malhi et al., 2015).

Monotherapy

Monotherapy has demonstrated efficacy in bipolar depression and comprises two groups of medications SGAs and mood-stabilizing agents. The use of adjunctive antidepressants remains contentious, and the long-term efficacy is unclear. There is a growing consensus that antidepressant monotherapy should be avoided if possible due to the risk of switching to mania.

SGAs include quetiapine (at doses of 300–600 mg), lurasidone, and olanzapine; the latter being least favored as it has the greatest likelihood of causing metabolic syndrome. Mood-stabilizing agents such a lithium, lamotrigine, and valproate can also be prescribed (Malhi et al., 2015).

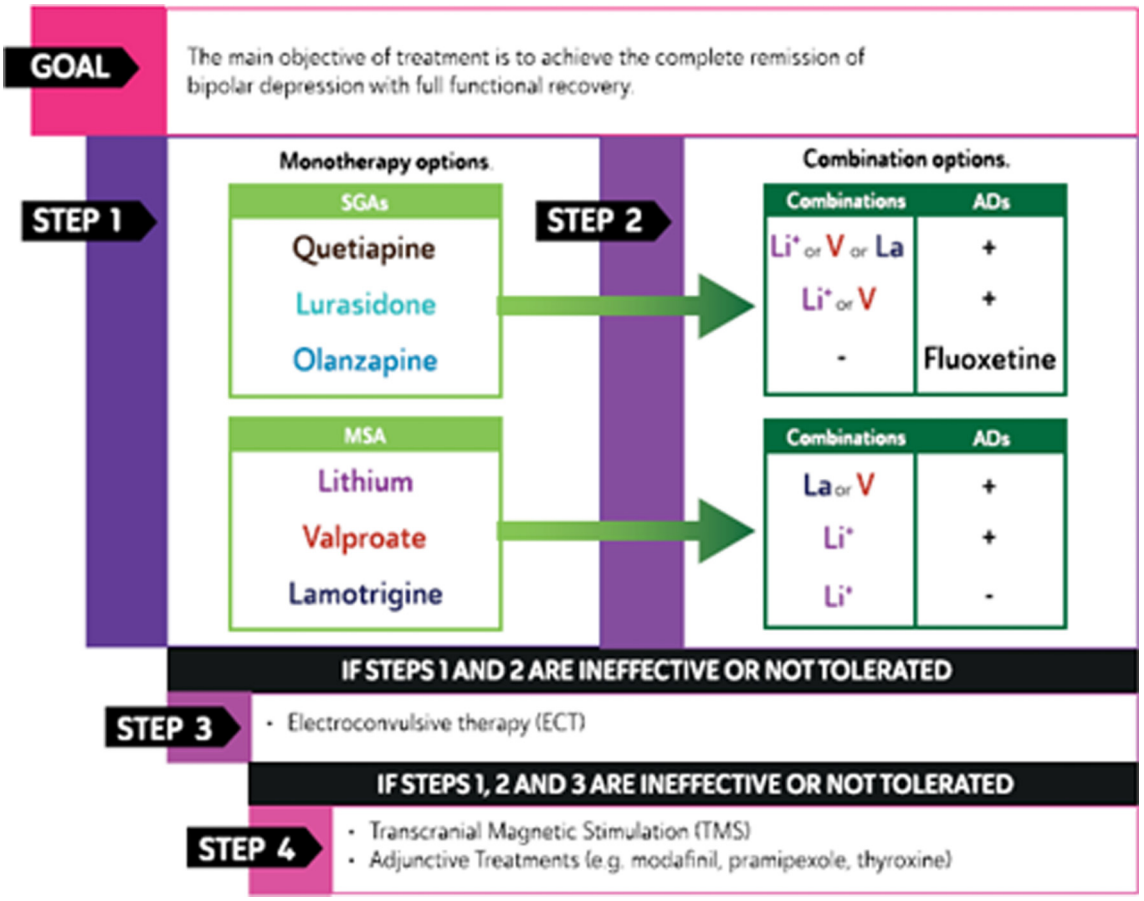

Figure 2 Treatment pathway illustrating the step-wise pharmacological management of bipolar depression. Taken from the Australian and New Zealand College of Psychiatrists clinical practice guidelines.

Combination Therapy

While monotherapy is ideal, patients frequently require combinations of medicines. The SGAs can be added to either mood-stabilizing agents or antidepressants. Lithium and valproate can be combined with all other monotherapy options. However, caution is advised when valproate is combined with lamotrigine, as valproate inhibits the clearance of lamotrigine by 30%–50% (Kanner, 2004). Therefore, lower dose of lamotrigine should be used to reduce the risk of the interaction and avoid side effects. Lamotrigine is associated with causing hypersensitivity reactions and rare life-threatening skin rashes and requires slow dosage titration (American Psychiatric Association, 2002). Antidepressants can be added to all effective monotherapy options, with the exception of lamotrigine, but the benefits of this strategy remain unclear (Malhi et al., 2015). However, there is specific clinical trial evidence for the combination of olanzapine and fluoxetine (Selle et al., 2014). It is important to note here that management of bipolar depression may vary from country to country with certain drug choices being considered first line and combination of drugs favored over others. Fig. 2 is an example of managing a patient with bipolar depression in Australia and New Zealand.

The diagram illustrates the potential binary combinations between second-generation antipsychotics (SGAs), mood-stabilizing agents (MSAs), and antidepressants (ADs) when considered appropriate. Lithium (Li+) and ADs can be added to all agents, but each has one exception: olanzapine and lamotrigine (La), respectively. The combination of SGAs with each other has no confirmed benefits in efficacy, but MSAs may usefully be combined, provided one is lithium. The combination of lithium and lamotrigine carries the complication of increased blood levels of both medications, making close monitoring critically important. "+" means that agent can be added, "−" means that it should not be added.

Switching

The occurrence of mania and hypomania in people receiving antidepressant therapy may be an adverse effect of treatment with tricyclic antidepressants and dual-action agents, e.g., venlafaxine, which carry a greater risk than single-action drugs (Gijsman et al., 2004; Tondo et al., 2010). Risk is higher with tricyclic antidepressants compared to SSRIs.

Choosing Maintenance

Following remission of an episode, patients generally require maintenance treatment to delay or prevent another episode. Successful long-term management requires both pharmacological and psychological interventions. In long-term treatment, the first decision point occurs at the transition from acute to continuation treatment (up to 6 months after). Antidepressants should also only be used in the short term and continued if the risk of severe depressive relapse is high. In the long-term management of BD I antidepressants should be combined with a mood stabilizer.

The second decision point occurs at the transition from continuation to maintenance treatment. At this point, efficacy of treatment should be assessed. The gold standard of maintenance is monotherapy; however, this is often an elusive goal. Most individuals require more than one medication long-term to maintain mood stability. Generally, maintenance pharmacotherapy consists of the same regimen that successfully treated the acute episode (National Institute for Health and Care Excellence, 2014a; Yatham et al., 2013). Options for maintenance therapy include lithium, valproate, olanzapine, quetiapine, lamotrigine, risperidone, and aripiprazole.

What's Coming Up in Pharmacological Management

Overall, advances in drug treatment for BPAD remain quite modest. Advances in pharmacological treatment have come mainly from the repurposing of drugs used in other neuropsychiatric disorders and do not target the mood instability that characterizes the disorder.

Cariprazine is a potent D_3 and D_2 receptor partial agonist with preferential binding to D_3 receptors. Cariprazine appears promising for the treatment of acute mania—it is approved in Europe for schizophrenia and has demonstrated efficacy in manic and mixed/manic states in BPAD I in Phase III clinical trials (Sachs et al., 2015) but has not yet been approved by Canadian or US regulatory agencies. It is also being evaluated in Phase II trials for bipolar depression (Durgam et al., 2016).

Novel or Experimental Agents

Preliminary data are available to support novel treatments not previously investigated in patients with bipolar depression, including ketamine and armodafinil. Patients receiving a single ketamine infusion experience rapid reduction of depressive symptoms and suicidal ideation (within 40 min), with the improvement remaining significant through day 3 (Diazgranados et al., 2010; Zarate et al., 2012). Adjunctive armodafinil— the longer-lasting R-enantiomer of modafinil – has been associated with an improvement in depressive symptoms according to some, but not all, measures (Calabrese et al., 2010). While ketamine is more widely accepted as a rapid antidepressant treatment, armodafinil is still regarded as experimental and both agents require further study in the context of BPAD.

Monitoring and Measuring

Regular contact with health professionals is essential for appropriate management, but the frequency of visits can vary considerably, and rapid access for additional consultations when early warning signs are emerging, should be allowed for. The frequency of contact is usually not less than biannual visits once long-term stability is achieved. Follow-up is more frequent depending upon the history of the illness and time since the last mood episode.

People with bipolar disorder are at increased risk of morbidity and mortality because of mental health complications (such as increased suicide risk) as well as physical complications such as type 2 diabetes, obesity, and cardiovascular disease. It is also important to monitor the adverse effects of antipsychotics and antidepressant medication as these can lead to the person stopping medication and relapsing. More frequent reviews are recommended if the person has sleep disturbance or following stressful life events on the basis that both may trigger an acute episode, and sleep disturbance is an early symptom of a depressive or hypomanic/manic episode.

Treatment Nonresponse

It is important to assess the patient's symptoms through self-report, observation, and corroboration from family in order to understand the patient's entire disease process. Observation by health professionals is an essential source, and an overall pattern of subtle core manic signs and symptoms may only be apparent when assessed continuously over hours or days and even weeks. Furthermore, the nature of nonresponse might extend beyond the persistence of core manic symptoms to comorbidity, such as substance abuse and lack of compliance with treatment.

Routine investigations should be repeated, e.g., full blood count, electrolyte levels, renal, liver, and thyroid function tests along with (if indicated) neuroimaging and urine screen for substances to determine whether there are rare organic reasons for nonresponse.

Strategies to address nonresponse may include (Malhi et al., 2015) the following:

- Addressing adherence: medication administration and blood levels should be checked when available (this is covered more in the "Role of the Pharmacist" section).

- Changing medication: switching to a different anti-manic or SGA can be effective. However, prior to switching, doses of existing agents should be maximized in case of "pharmacokinetic" treatment resistance and should not be abruptly stopped but tapered down over a period of 4 weeks.
- Combination therapy: combining an SGA with lithium or valproate is a common strategy. Conventional treatments have also been combined with hormonal therapies, e.g., tamoxifen, hormone-replacement therapies, in the treatment of mania.
- ECT: can be highly effective in refractory mania and can be useful in the management of treatment-resistant mania where there is direct threat to the person's life.

Ongoing subsyndromal depressive symptoms are common in BPAD, as is a high rate of treatment nonresponse. Data suggest that the absence of early improvement (2–3 weeks) may be a reliable predictor of eventual nonresponse, suggesting that these patients may benefit from a change in therapy (Kemp et al., 2011).

Role of the Pharmacist in Managing and Prescribing in BPAD

Pharmacists are an integral part of the multidisciplinary team who can add value to patient care beyond medicines management and pharmaceutical care. Many patients seek the views of a pharmacist for an unbiased "neutral" opinion of medication since the pharmacist is not involved in direct medication supervision and administration of medicines. Pharmacists are well-placed to support patients in making informed choices about their treatment, thus in some ways, acting in a patient advocacy role.

The Pharmacist in the Multidisciplinary Team

Pharmacists are considered experts in medicines and bring a unique skill set that complements those in the multidisciplinary team (Rubio-Valera et al., 2014). While there are differences in the role of a pharmacist depending on the health-care setting; in general, pharmacists provide (Harms et al., 2017; McMillan et al., 2017) pharmaceutical input broadly in two key areas:

- Improving adherence and facilitating informed consent (through *education* and addressing barriers to *adherence*)
- Optimizing pharmaceutical care (through *maximizing efficacy* and *reducing or managing adverse effects* of treatment and ensuring medication safety)

These aspects will be discussed in further detail below.

In a hospital setting, pharmacists are routinely involved in reconciling medicines on admission, confirming previous treatments trialed and ensuring the most appropriate treatment for managing the acute presentation. This may include optimizing treatments to achieve control of mania and depression, managing any acute behavioral disturbance, and advice around the use of parenteral medication to manage the acute presentation. In the short- to medium-term, the pharmaceutical goals will shift toward stabilization of the patients' medication(s) before discharge. Key points for pharmacists to consider include optimizing medication formulation and regimen to encourage adherence, therapeutic drug monitoring, reviewing funding and supply of medication on discharge, discharge medicines reconciliation, psychoeducation, and liaison with the community care team (including the pharmacy team in community) to ensure continuity of care.

Improving Adherence and Facilitating Informed Consent

Education—Shared care/decision-making

Receiving and understanding information about the medicines prescribed is an essential part where the pharmacist can add value. Despite the availability of various medication information, patients often report not receiving sufficient information and express a desire for more (Bowskill et al., 2007); one study found patients with BPAD were significantly less satisfied with information about their medication than people prescribed medication for HIV (Bowskill et al., 2007).

In order to achieve treatment goals, patients should be involved in shared decision making, which can increase patient satisfaction, adherence, and improve therapeutic relationships (Younas et al., 2016). Purely educational interventions have been shown to be ineffective in changing patient behavior and modifying adherence (Dolder et al., 2003). A shared decision-making approach is recommended by international treatment guidelines in BPAD, which state that patients should have the opportunity to make informed decisions about their care and treatment in partnership with their health-care professionals (Hasan et al., 2013; Malhi et al., 2015; National Institute for Health and Care Excellence, 2014a, 2014b).

Medication education delivered by pharmacists is in collaboration with psychiatrists, in an outpatient setting, can have a significant impact on improving adherence and quality of life (Mishra et al., 2017). Education should deliver information about their medication and BPAD and give personalized advice on adherence that is tailored to the patient's reasons for nonadherence.

One example of an education model that has demonstrated effectiveness for improving adherence, symptom-management, and risk of relapse are medication education or psychotherapy groups (Swartz and Swanson, 2014) (see **Box 1**).

Box 1 Medication education groups in mental health

Medication education or psychotherapy groups have been run in community and inpatient settings by pharmacists. A format for these groups have been proposed by the United Kingdom Psychiatric Pharmacy Group (UKPPG) guidelines—the education sessions involve discussion of the neuropharmacological basis of various mental health conditions and how psychotropics (including antipsychotics, antidepressants, mood stabilizers, and benzodiazepines) are thought to work (explanation of neurotransmitters and associated imbalances), the how and why of side effects, the need for long-term treatment adherence, and issues of dependence and tolerance. A recent pilot study investigating the effectiveness of these groups found a positive impact on patient understanding of the purpose and side effects of their medication, and their perceptions of involvement in decisions about their medicines (White et al., 2017). The positive effects demonstrated support the implementation of these pharmacist-led education groups as part of pharmaceutical care of patients.

Improving Adherence

Medication nonadherence is a major issue in patients with BPAD (Bates et al., 2010) with over a third of patients missing at least one dose of medication in a 10-day period (Baldessarini et al., 2008). While there have been many studies that have considered factors predicting nonadherence in BPAD, such as gender or ethnicity, no single sociodemographic factor or group of factors have been consistently shown to be predictive of nonadherence (Bates et al., 2010). Medication nonadherence is driven by patient-centered experiences such as their satisfaction with treatment (Bates et al., 2010), experiences of side effects (Johnson et al., 2007), and their beliefs about the treatment (Clatworthy et al., 2007), as well as practical adherence barriers (White et al., 2017). Effective pharmacist adherence interventions and education should target both practical and perceptual adherence barriers (White et al., 2017).

Addressing Practical Barriers

Pharmacists have expert knowledge of different formulations and dosing, which can be a key in simplifying dosing regimens and facilitating informed choice to improve adherence. An example is lithium or antipsychotics; rather than prescribing as twice daily they can be prescribed once daily (Malhi and Tanious, 2011).

Building a routine around medication taking can be helpful—for example, linking medication taking to particular habits such as placing the morning medication near the toothbrush. "Interpersonal and social rhythm therapy," which focuses on maintaining regular daily rhythms in activities such as sleeping, waking, eating, and exercise, can also have positive impacts on quality of life, symptoms and adherence, suggesting that having a structured routine may be helpful (Frank et al., 2005).

External reminders such as alarms and medication organizers can increase the ease of medication taking and improve adherence by reducing some of the cognitive effort of needing to take a medication regularly (Depp et al., 2008).

Addressing Perceptual Barriers

Many patients with BPAD have elements of both unintentional and intentional nonadherence (Clatworthy et al., 2007). In unintentional nonadherence, the patient inadvertently does not take medication as prescribed. In intentional nonadherence, the patient deliberately does not adhere; this could be due to lack of insight about their condition and views about treatment (treatment beliefs), perception of the illness, and attitude toward medication (side effect burden) (Clifford et al., 2008).

Pharmacists should consider these beliefs when addressing adherence (Lingam and Scott, 2002; Petrie and Weinman, 2012; Scott and Pope, 2002). These beliefs may be influenced by social networks (Sajatovic et al., 2011); establishing an effective therapeutic alliance may combat some of the negative effects of such social networks and help foster more positive beliefs and perceptions (Chakrabarti, 2016; Lingam and Scott, 2002; Strauss and Johnson, 2006).

Optimizing Pharmaceutical Care

Optimizing Treatment Efficacy

Beyond education and improving adherence, pharmacists can optimize patient treatment efficacy through addressing stigma, or minimizing system-related factors that prevent access to optimal treatment (Chakrabarti, 2016).

Pharmacists can help ensure continuity of care by acting as a point of liaison between primary care, hospital, and psychiatrists around medication-related issues. This can include handing over treatment and monitoring plans, sharing decisions made by the previous treating team around medication choices to prevent duplication of any ineffective treatment trials and/or poorly tolerated treatments, and ensuring adequate supply of medication that may be difficult to source or afford.

Over adherence, where patients take more medication than prescribed, can occur in BPAD, particularly in those patients at risk of substance abuse or addiction (Weiss et al., 1998). Benzodiazepines, neuroleptics, such as quetiapine, and tricyclic antidepressants are considered high-risk medicines. Facilitating communication between the different health-care professionals involved in the patient's care can minimize this risk.

Deprescribing and addressing polypharmacy in BPAD or more broadly mental health patients (Gupta and Cahill, 2016) is also key. Many medications are started in the acute setting to achieve remission and manage acute behavioral disturbance. These medications are at risk of being continued beyond the required period of treatment, partly due to the reluctance of community and primary care teams changing what appears to be a stable regime. Pharmacists can facilitate liaison between primary care and hospital teams, providing education and advice around safe deprescribing of unnecessary medication. Deprescribing within

Table 2 Deprescribing psychotropic medications

Step 1: Choose the right time
Step 2: Compile a list of all the patient's medications (medication reconciliation)
Step 3: Initiate the discussion with the patient
Step 4: Introduce deprescribing to the patient
Step 5: Identify which medication would be most appropriate for a taper
Step 6: Develop a plan
Step 7: Monitor and adapt, if necessary

Source: Adapted from Gupta and Cahill (2016)

psychiatry itself is a relatively new area, and Gupta et al. have proposed some guidelines, which describe steps to deprescribing (**Table 2**).

Patients on multiple medications have increased risk of medication interactions, which can be particularly problematic in BPAD as many BPAD treatments are considered high risk for interactions, partly because of the narrow therapeutic index. Checking for interactions whenever a new medication is started, and deprescribing, can minimize harm.

Side Effect Management

Managing side effects is a key to ensuring ongoing adherence, relapse prevention, patient satisfaction, and quality of life. Patients are more likely to be dissatisfied with treatments that cause weight gain, extrapyramidal side effects, sexual dysfunction, and cognitive side effects (Johnson et al., 2007; Zarate, 2000), but are more likely to take medication, which can help reduce the severity of depressive episodes (Johnson et al., 2007). The pharmacist is well-placed to advise on side effect profiles and may often be the first person to see side effects or be aware that a patient's presentation is related to medication use. The pharmacist can help with discussing treatment options with the patient, facilitating informed choice, and negotiating treatment options with the clinical team to ensure the best treatment options, which ensure both clinical efficacy, and patient satisfaction and long-term adherence to treatment.

Special Populations

Children and Adolescents

Due to limited studies in youth, most of the treatment recommendations for BPAD are derived from the adult literature. Evidence supporting the efficacy of these medications is increasing; however, significant gaps remain.

The mainstay of treatment of BPAD in children and adolescents is pharmacotherapy. Aripiprazole is first-line treatment because it is licensed in adolescents (over 13 years) with BPAD. There is some research that other SGAs, valproate, and lithium are efficacious in adolescents (Goodwin et al., 2016). Although patients may respond to monotherapy, combination pharmacotherapy is necessary for some patients (McClellan et al., 2007). When offering treatment to young people, their cognitive ability, emotional maturity, developmental level, their capacity to consent to treatment, the severity of their bipolar disorder, and risk of suicide or self-harm or any other risk must be taken into account (National Institute for Health and Care Excellence, 2014a).

Adjunctive psychotherapy is generally regarded as essential to provide families with an understanding of symptoms, course, and treatment, teach youth and parents methods for coping with symptoms, and prevent relapse (Fristad and MacPherson, 2014).

Women of Childbearing Age

For women planning to conceive, an integrated care plan should be developed. Where possible, this should involve the individual, their partner/family/carer, primary and secondary care teams (obstetrics, psychiatry), pharmacists, and midwives and outline the care and treatment during pregnancy and the postnatal period (National Institute for Health and Care Excellence, 2017).

Valproate and carbamazepine have established teratogenic effects in humans—known as fetal valproate syndrome or fetal carbamazepine syndrome, respectively. Valproate should not be offered to women of childbearing potential, or pregnant women without specialist advice (National Institute for Health and Care Excellence, 2014a). If valproate treatment cannot be avoided, adequate contraception should be ensured. The patient should be fully informed of the risks for the unborn child if she becomes pregnant during treatment with valproate and carbamazepine, and prophylactic folic acid should be prescribed to reduce the incidence of neural tube defects (Drug Safety Update, 2015).

Approximately 20%−−50% of women with BPAD relapse postpartum; therefore, prophylactic treatment is recommended immediately postpartum to decrease the risk of relapse (Viguera et al., 2002). Prophylactic medications such as lithium or valproate can prevent postpartum episodes in women with BPAD (American Psychiatric Association, 2002). When lithium is used during pregnancy, it should be tapered to the lowest effective dose necessary to decrease the risk of relapse.

If the woman would like to breastfeed and is taking medications to treat BPAD, specialist's help and advice should be sought. Lithium is present in significant amounts in breast milk; most experts therefore recommend against lithium use in breastfeeding (American Academy of Pediatrics Committee on Drugs, 2000; American Psychiatric Association, 2002; Ernst and Goldberg, 2002).

Valproate has been used widely in mothers who breastfeed; reports of toxicity in infants from ingestion of valproate in breast milk are rare (Dodd and Berk, 2004). Evidence suggests that the exposure of infants to valproate by breastfeeding is low (Tsuru

et al., 1988), and that, in most cases, the benefits of breastfeeding outweigh the risks; however, vigilance against hematological adverse events in the infant is required.

Carbamazepine and its active metabolite are poorly excreted into breastmilk, partly due to plasma protein binding. The serum level in infants is usually low, and it is considered compatible with breastfeeding (American Academy of Pediatrics Committee on Drugs, 2001).

Older-aged Patients

General principles for managing mania in older patients are similar to those for younger patients. Older patients will generally require lower doses, since aging is associated with reduced renal clearance and volumes of distribution (Sproule et al., 2000). Concomitant medications and other medical conditions may also alter the pharmacokinetics (Young and Klerman, 1992); older patients may also be more sensitive to side effects. Many elderly patients may respond to low serum levels of lithium (0.4–0.6 mmol/L) (Van Gerpen et al., 1999).

Older patients may be more likely to develop cognitive impairment with medications such as lithium and benzodiazepines (Van Gerpen et al., 1999). They may also have difficulty tolerating antipsychotic medications and are more prone to extrapyramidal side effects and tardive dyskinesia than younger patients (Caligiuri et al., 2000). Furthermore, due to age-related changes in pharmacokinetics and pharmacodynamics, there is an increased risk of cardiovascular and cerebrovascular accidents (Gareri et al., 2014).

Summary

The medicines expertise of pharmacists is invaluable in optimizing patient pharmaceutical care and improving quality of life. The importance of the pharmacist in managing BPAD is clear from the literature. Benefits are seen throughout all aspects of the patient's treatment journey, from the acute presentation to longer-term care. The pharmacist is a key part of the patient's multidisciplinary team and can add value to the therapeutic alliance by providing impartial medicines information to support informed consent and choice.

Major Depressive Disorder

Louise E. Curley*, Joanne C. Lin*, Timothy F. Chen†, *The University of Auckland, Auckland New Zealand; †The University of Sydney, Sydney, Australia

Learning Objectives

- Describe the incidence, prevalence, epidemiology, and etiology of major depressive disorder (MDD).
- Briefly outline the signs and symptoms of MDD.
- Explain the pharmacological and nonpharmacological management options for MDD.
- Describe the first- and second-line treatment options for MDD and what options can be considered when usual first-line treatments fail.
- List the most common side effects and interactions associated with antidepressants and how to manage these.
- Describe the role of the pharmacist in managing MDD and give examples where pharmacists can contribute to the pharmaceutical care.

Take-Home Messages

- Major depressive disorder (MDD) is a common mental health disorder, which can cause significant disruption to individuals, their families and carers, workplace, and society.
- The use of antidepressant medicines in people with MDD remains the mainstay of therapy, alongside behavioral therapy.
- Pharmacists play an integral role in the multidisciplinary team for MDD management.

- Key opportunities to optimize pharmaceutical care for patients include improving medication adherence, and advice on switching, tapering, and discontinuation of medicines.
- In the future, pharmacists may be routinely involved in targeted screening services for depression in primary care; however, this would need to be coupled with training, the use of validated screening tools and resources, including private areas to conduct this screening, time, and up-to-date information. More research needs to be conducted on this avenue.

Introduction to the Condition

Major depressive disorder (MDD) is one of the most prevalent mental health disorders. According to the World Health Organization, it is the leading cause of ill health and disability (World Health Organization, 2017a, 2018). The proportion of the global population living with depression is estimated to be 322 million people—4.4% of the world's population (World Health Organization, 2017b). The number of people living with depression has increased by 18.4% between 2005 and 2015, and depressive disorders were the single largest contributor to nonfatal health loss globally in 2015. At its worst, depression can lead to suicide. Close to 800,000 people die due to suicide every year (World Health Organization, 2012).

MDD is characterized by: "a depressed mood, loss of interest or pleasure, feelings of guilt or low self-worth, disturbed sleep or appetite, low energy, and poor concentration" (World Health Organization, 2012). Symptoms should be present for at least 2 weeks and at sufficient severity for most of every day. MDD has an enormous impact on the individual and their family. Emotional and physical well-being can be affected, in addition to social functioning and the economic burden caused by the condition. The economic impact of MDD on patients and society has been reported to be 4.2 times higher than a nondepressed patient (Simon et al., 2001; World Health Organization, 2003). The overall economic burden (medical costs, suicide-related mortality costs, and workplace costs) was estimated to be $US 83 billion in the United States in 2000. This cost was comprised of direct medical costs, suicide-related mortality costs, and workplace costs (Greenberg et al., 2003).

Despite the huge impact that depression has on every aspect of the person and society, many people do not seek help. It is reported that men are less likely to ask for help than women, and only 25% of men who suffer from anxiety or depression actually access treatment (Beyond Blue, 2008).

This chapter will provide an overview of the current thinking around treatment on MDD for pharmacists, beginning with an overview of diagnosis and presentation of the condition, followed by a discussion of treatment options and the role of pharmacists and how they can contribute to the management MDD.

Epidemiology of MDD

MDD is highly prevalent through the world and the prevalence has increased over time (Andrade et al., 2003). A survey of epidemiological data in 14 countries in the World Health Organization (WHO) World Mental Health Survey Initiative estimated the lifetime prevalence of major depression and persistent depressive disorder (dysthymia) in adults to be 12% (Kessler et al., 2011).

The prevalence of MDD is approximately two times greater in females compared with males (Pedersen et al., 2014), and higher in high-income versus low/middle-income countries (Kessler and Bromet, 2013). Prevalence rates also vary by age, peaking in older adulthood (above 7.5% in females aged 55–74 years, and above 5.5% in males aged 55–74 years). Depression also occurs in children and adolescents below the age of 15, but at a lower level than older age groups (World Health Organization, 2017b).

Etiology of MDD

Despite advances in the understanding of the neurobiology of MDD, currently no established mechanism can explain all aspects of the disorder; it is multifactorial and complex. There is thought to be an interaction between individual vulnerability and environmental stressors (New Zealand Guidelines Group, 2008). This may explain the wide variation in clinical presentation and response to treatment.

Various mechanisms, theories, and hypotheses have been proposed to help explain the pathophysiological basis of depression, including (Jesulola et al., 2018; Otte et al., 2016):

- The biogenic amine hypothesis: monoaminergic systems (noradrenergic, serotonergic, and dopaminergic) are instrumental to many behavioral symptoms of depression, such as low mood, reduced motivation, fatigue, and psychomotor agitation or retardation. They are responsible for many fundamental brain functions and the "monoamine hypothesis" proposes that the reduced availability of these neurotransmitters may contribute to MDD.
- Neuroendocrine dysfunction: several endocrine system abnormalities have been identified as possible contributors to the etiology of MDD. These include altered growth hormone levels, thyroid abnormalities, and hypothalamus-pituitary-adrenal axis dysfunction.
- Environmental and genetic factors: heritability for MDD has been quantified as approximately 35%. Other relevant genetic variants can also confer risk or protection; a "stress vulnerability" model has been described whereby stressful situations may

trigger depression in vulnerable or susceptible individuals, but not in others who display protective traits. These situations, or life events, may include, for example, work stress, loss of employment, relationship loss, or grief.

There are many other contributors including neurogenesis, neuroinflammation, elevated levels of corticotrophin-releasing factor, and abnormalities of second messenger systems. Full discussion of these factors—and the combinations and linkages between them—is beyond the scope of this chapter; for a comprehensive review, please see Jesulola et al. (2018).

Diagnosis of MDD

The essential features of depression are depressed mood (dysphoria) and/or loss of pleasure in most activities (anhedonia). Severity of the disorder is determined by the number and severity of symptoms, as well as the extent of functional impairment.

Definition/Classification of MDD

Depression is a heterogeneous disorder in which a number of underlying presentations may share a common phenomenology. A number of classification systems/subgroupings have been used; two frequently used classification systems are the International Classification of Diseases (ICD) 10th edition and Diagnostic and Statistical Manual for Mental Disorders (DSM) 5th edition. The ICD and DSM are both operational diagnostic systems that classify behavioral and psychological disorders (American Psychiatric Association, 2013; World Health Organization, 1992).

The ICD has been endorsed by the WHO as a standard diagnostic tool for epidemiology, health management, and clinical purposes of all diseases and other health problems. It classifies "mood disorders" as part of "mental and behavioral disorders." Within the cluster of mood disorders, depression is mentioned as a "depressive episode" or a "recurrent depressive disorder," defined as (Cesar and Chavoushi, 2013):

- *Depressive episode:* In typical mild, moderate, or severe depressive episodes, the patient suffers from lowering of mood, reduction of energy, and decrease in activity. Capacity for enjoyment, interest, and concentration is reduced, and marked tiredness after even minimum effort is common. Sleep is usually disturbed and appetite diminished. Self-esteem and self-confidence are almost always reduced and, even in the mild form, some ideas of guilt or worthlessness are often present. The lowered mood varies little from day-to-day, is unresponsive to circumstances, and may be accompanied by so-called somatic symptoms, such as loss of interest and pleasurable feelings, waking in the morning several hours before the usual time, depression worst in the morning, marked psychomotor retardation, agitation, loss of appetite, weight loss, and loss of libido. Depending upon the number and severity of the symptoms, a depressive episode may be specified as mild, moderate, or severe.
- *Recurrent depressive disorder:* A disorder characterized by repeated episodes of depression as described for depressive episode (see above), without any history of independent episodes of mood elevation and increased energy (mania). There may, however, be brief episodes of mild mood elevation and over-activity (hypomania) immediately after a depressive episode, sometimes precipitated by antidepressant treatment. The more severe forms of recurrent depressive disorder have much in common with earlier concepts such as manic-depressive depression, melancholia, vital depression, and endogenous depression. The first episode may occur at any age from childhood to old age, the onset may be either acute or insidious, and the duration varies from a few weeks to many months. The risk that a patient with recurrent depressive disorder will have an episode of mania never disappears completely; however, many depressive episodes have been experienced. If such an episode does occur, the diagnosis should be changed to bipolar affective disorder.

Unlike the ICD, the DSM only classifies mental disorders. Within the cluster of "mood disorders," depressive disorders are further specified as a "single major depressive disorder," "recurrent major depressive disorder," "dysthymia," or as a "depressive disorder not otherwise specified" (Cesar and Chavoushi, 2013).

Signs and Symptoms

A formal diagnosis using the ICD-10 classification system requires at least 4 out of 10 depressive symptoms, whereas the DSM-V system requires at least five out of nine (**Table 1**). Symptoms should be present for at least 2 weeks, and each symptom should be present at sufficient severity for most of every day. Both diagnostic systems require at least one (DSM) or two (ICD) key symptoms to be present: low mood/loss of interest or pleasure (both ICD and DSM) and loss of energy (ICD only).

It is being increasingly recognized that depressive symptoms below the DSM and ICD threshold criteria can be distressing and disabling if persistent. Therefore, the National Institute for Health and Care Excellence (NICE) (National Institute for Health and Care Excellence, 2016) guidelines cover "subthreshold depressive symptoms," and are defined as at least one key symptom of depression but with insufficient other symptoms and/or functional impairment to meet the criteria for full diagnosis.

Treatment of MDD

In the management of MDD, there are two main initial treatment options: psychotherapy and pharmacotherapy. The goal of treatment in those diagnosed with depression is to achieve remission of symptoms and prevent relapse. Interventions for MDD comprise a range of therapies, including exercise and self-management, psychological therapies, pharmacological treatments, and

Table 1 Definition of MDD according to DSM-5

- An individual will show five (or more) of the following symptoms, which should be present during the same 2-week period nearly every day and should represent a change from previous functioning:
  - Depressed mood[a]
  - Markedly diminished interest or pleasure in all, or almost all, activities[a]
  - Considerable weight loss when not dieting, weight gain, or decrease or increase in appetite
  - Insomnia or hypersomnia
  - Psychomotor agitation or retardation
  - Fatigue or loss of energy
  - Feelings of worthlessness, or excessive or inappropriate guilt, which might be delusional; that is, not merely self-reproach or guilt about being sick
  - Diminished ability to concentrate, or indecisiveness
  - Recurrent thoughts of death (not just fear of dying), recurrent suicidal ideation without a specific plan; the individual has made a suicide attempt or a specific plan for committing suicide
- The symptoms cause clinically significant distress or impairment in social, occupational or other important areas of functioning
- The episode is not attributable to the physiological effects of a substance or to another medical condition
- The occurrence of the episode is not better explained by schizoaffective disorder, schizophrenia, schizophreniform disorder, delusional disorder, or other psychotic disorders
- The individual has never had a manic episode or hypomanic episode

[a]Depressed mood and/or diminished interest or pleasure must be evidence for a diagnosis.

Table 2 The stepped-care model

Focus of the intervention	*Nature of the intervention*
Step 1 All known and suspected presentations of depression	Assessment, support, psychoeducation, active monitoring, and referral for further assessment and interventions
Step 2 Persistent subthreshold depressive symptoms; mild-to-moderate depression	Low-intensity psychological interventions, psychological interventions, medication, and referral for further assessment and interventions
Step 3 Persistent subthreshold depressive symptoms or mild-to-moderate depression with inadequate response to initial interventions; moderate and severe depression	Medication, high-intensity psychological interventions, combined treatments, collaborative care, and referral for further assessment and interventions
Step 4 Severe and complex depression; risk to life; severe self-neglect	Medication, high-intensity psychological interventions, electroconvulsive therapy, crisis service, combined treatments, multiprofessional, and inpatient care

Source: Adapted from National Institute for Health and Care Excellence, 2016. Depression in adults: recognition and management

intensive interdisciplinary interventions (New Zealand Guidelines Group, 2008). The consensus among different guidelines is that individuals with moderate-to-severe MDD should be treated with medication or with a combination of medication and psychotherapy (National Institute for Health and Care Excellence, 2016; Cleare et al., 2015; Gelenberg, 2010). In contrast, a mild depressive episode may be treated with psychotherapy alone (Otte et al., 2016). However, when deciding on the clinical management, individual preferences and prior treatment history should be taken into consideration.

Stepped Care

The stepped care model provides a framework in which to organize the provision of interventions. Under this model, the least intrusive, most effective intervention is provided first; if a person does not benefit from, or declines, the initial intervention, he or she is offered an alternative intervention from the next step (**Table 2**).

Pharmacological Treatment

Although trial data support some differences in the efficacy and tolerability between antidepressant medicines, their effectiveness is generally considered comparable between and within classes of medications, although individual response may vary markedly (Cipriani et al., 2018). Therefore, the choice of antidepressant will largely be based on:

- Individual preference
- Nature of prior response to medications
- Safety, tolerability, and anticipated side effects

- Concomitant psychiatric or general medical conditions
- Pharmacological properties of the medication, for example, half-life, actions on cytochrome P450 enzymes, other drug interactions
- Cost and availability of formulations

First-Line Therapy

Selective serotonin reuptake inhibitors

For most indications, selective serotonin reuptake inhibitors (SSRIs) are considered first-line, as they are generally well tolerated and have a wider safety margin than other classes of antidepressant medicines. However, SSRIs do have some potentially troublesome side effects, including initial nervousness, insomnia, nausea, sexual dysfunction, and weight gain (Gartlehner et al., 2011; Serretti and Chiesa, 2009; Sinclair et al., 2009). These are particularly troublesome when first starting treatment but tolerance to these effects usually occurs after 4–6 weeks of treatment.

The principal agents within the SSRI class have the same major pharmacologic feature: selective and potent inhibition of the serotonin transporter (SERT). However, each SSRI has secondary pharmacologic actions other than SERT blockade, and no two SSRIs have identical secondary characteristics (Stahl, 2013):

- Fluoxetine has additional $5HT_{2C}$ antagonist actions, which disinhibits the release of noradrenaline and dopamine. This may contribute not only to its therapeutic action but also to its tolerability profile.
- Sertraline has dopamine reuptake inhibition and sigma-1 receptor binding properties. Its sigma-1 binding properties may contribute to its anxiolytic actions. The clinical relevance of dopamine reuptake inhibition to anxiolytic effects is unknown; however, it is possible that dopaminergic action is associated with lower risk of sexual side effects and hyperprolactinemia, compared to other SSRIs (Park, 2017).
- Paroxetine has muscarinic anticholinergic properties as well as noradrenaline reuptake inhibition. This SSRI is preferred by many clinicians for patients with anxiety symptoms; it tends to be more calming early in treatment compared to fluoxetine and sertraline. However, of the SSRIs, paroxetine is most associated with serotonin syndrome and discontinuation syndrome due to its very short half-life.
- Fluvoxamine binds to sigma-1 receptors but its action is more potent compared to sertraline, which may contribute additional anxiolytic effects. Of the SSRIs, it is one of the weakest inhibitors of dopamine and norepinephrine reuptake (Ordacgi et al., 2009). However, it is associated with higher incidence of adverse effects than other SSRIs, particularly gastrointestinal effects, and has the potential for P450-mediated drug interactions (Irons, 2005).
- Citalopram is comprised of two enantiomers, *R* and *S*, one of which is the mirror image of the other. The racemic mixture has mild antihistaminic properties attributed to the *R*-enantiomer. This may be responsible for some of its sedating properties. It is generally one of the better-tolerated SSRIs; however, there is potential for Q_{Tc} prolongation at high doses. Removing the *R*-enantiomer from the mixture leaves the pure active *S*-enantiomer, known as escitalopram. Escitalopram lacks antihistaminic properties and, while the risk of Q_{Tc} prolongation appears to be similar to citalopram, the magnitude of this side effect in practice is less than citalopram. See drug interactions section for additional detail about this effect.

Some improvement is usually evident within 2 weeks of treatment with an antidepressant medicine at a therapeutic dose. If there is a partial response after 3–4 weeks of treatment, the dose of medication can be increased (Trangle et al., 2016). If the individual does not respond to treatment, that is, report a significant level of improvement by 4–6 weeks, the treatment plan should be reviewed with the individual. Options include increasing the dose, changing the medicine, changing to a psychological therapy, or adding a psychological therapy (Irish College of General Practitioners, 2006; National Institute for Health and Care Excellence, 2016; New Zealand Guidelines Group, 2008).

If the individual opts to change to a different antidepressant medicine, either a second SSRI, another class of serotonergic reuptake inhibitor or a tricyclic antidepressant (TCA) is suitable as a second-line option.

Second-Line Therapies

Serotonin–noradrenaline reuptake inhibitor

Serotonin–noradrenaline reuptake inhibitors (SNRIs) primarily act upon serotonergic and noradrenergic neurons and are often referred to as "dual action agents." SNRIs differ in their affinity for the serotonin and noradrenergic transporter. Venlafaxine and duloxetine are more potent inhibitors of serotonin reuptake than noradrenaline; however, this can depend on the dose administered. For example, venlafaxine is essentially an SSRI at 75 mg/day (Spina et al., 2012) but at higher doses, such as >150 mg/day, it has significant effects on the noradrenaline transporter (Debonnel et al., 2007). SNRIs have little or no effect on α_1-adrenergic, cholinergic, dopaminergic, or histaminergic receptors (Spina et al., 2012).

TCAs

SSRIs have generally replaced TCAs as first-line agents, not because of established differences in efficacy, but rather due to a generally more favorable side effect and safety profile. The TCAs are "broad spectrum" in that they interact with many neurotransmitter systems, which is the basis for their efficacy as well as side effects (Hirsch and Birnbaum, 2018a). TCAs block muscarinic M1,

histamine H1, and α_1-adrenergic receptors and can cause cardiac effects, anticholinergic effects, antihistaminic effects, decreased seizure threshold, sexual dysfunction, diaphoresis, and tremor. TCAs are extremely dangerous in overdose; unlike SSRIs, TCAs can be fatal in doses as little as 10 times the daily dose (Schatzberg and Nemeroff, 2017). They are also cardiotoxic and should be avoided in susceptible individuals with heart disease. These factors generally make TCAs less tolerable compared with SSRIs and other newer antidepressants (Anderson et al., 2008). Nevertheless, many individuals use TCAs safely and effectively.

Other Treatments

Mirtazapine

Mirtazapine, an "atypical antidepressant," can be used as a second-line therapy when there is an inadequate response or an intolerable side effect with first-line medications. Mirtazapine is not a reuptake inhibitor; instead, it antagonizes presynaptic α_2-adrenergic receptors and postsynaptic $5HT_2$ and $5HT_3$ receptors, thereby increasing release of noradrenaline and serotonin. Additionally, mirtazapine also has high affinity for histamine H1 receptors (which may account for its sedative properties), and low affinity for cholinergic, α_1-adrenergic, and dopaminergic receptors (Hirsch and Birnbaum, 2018b). Mirtazapine can also be an appropriate choice for an individual with anxiety-predominant depression, and in elderly patients who have low body weight as it can help promote weight gain (Alam et al., 2013).

Bupropion

Bupropion is classified as a dopamine–noradrenaline reuptake inhibitor and is structurally related to amphetamine (Labbate et al., 2010). It inhibits presynaptic reuptake of dopamine and noradrenaline (with a greater effect upon dopamine). The drug has little effect upon other neurotransmitters, and little to no affinity for postsynaptic receptors. Bupropion appears to be associated with less risk of weight gain and sexual dysfunction compared to SSRIs, and can be mildly stimulating in some individuals (Hirsch and Birnbaum, 2018b).

Monoamine oxidase inhibitors

Monoamine oxidase inhibitors (MAOIs) are now rarely used because of their relatively extensive side-effect profile, drug–drug interactions leading to severe adverse effects such as hypertensive crisis and serotonin syndrome. These potential side effects necessitate dietary restrictions and caution regarding drug–drug interactions. Many of the traditional "MAOI diets," which remain standard at numerous hospitals, are unnecessarily restrictive (Sullivan and Shulman, 1984), and many of the foods once thought to be dangerous for individuals taking MAOIs are now considered to be safe. However, foods containing high amounts of tyramine should be restricted, for example, aged cheeses and meats, sauerkraut, soybean products (including soy sauce), and tap beer. Health care professionals should monitor and advise on any recommended dietary restrictions (Sweet et al., 1995).

MAOIs have potent hypotensive effects, which is particularly important when treating elderly patients as they may be more sensitive to hypotensive effects and more likely to fall and sustain fractures (Hirsch and Birnbaum, 2018c).

Several compounds with selective MAO-a and MAO-b inhibiting properties have been developed, as well as reversible MAOIs, for example, moclobemide. These agents have less potential for interaction than irreversible agents such as phenelzine and tranylcypromine; however, MAOIs should only be initiated by psychiatrists familiar with their use (Hirsch and Birnbaum, 2018c).

Other antidepressant medicines

Some antidepressant medicines are distant from the other classes mentioned previously; they are often used in individuals who have inadequate responses or intolerable side effects to first-line treatments. Although there is some evidence for their use, additional comparative studies are need to better compare efficacy and safety with traditional agents and determine the best place in practice.

- Agomelatine is a synthetic analogue of melatonin and antagonizes $5HT_{2C}$ receptors; its effects appear to be marginally better than placebo is contraindicated in individuals with liver disease (Hirsch and Birnbaum, 2018b).
- Reboxetine was the first selective noradrenaline reuptake inhibitor used in the treatment of MDD; however, in a meta-analysis of active controlled trials, reboxetine was significantly less effective than other newer antidepressant medicines and had the highest dropout rates (Cipriani et al., 2018). A further meta-analysis showed that reboxetine showed no benefit over placebo and was inferior to other SSRIs for remission and response rates (Eyding et al., 2010).
- Vortioxetine is a serotonin modulator that acts as an antagonist at several subtypes postsynaptic serotonin receptors to inhibit the reuptake of serotonin (Hirsch and Birnbaum, 2018d). The downstream pharmacodynamic effects include increased levels of serotonin, acetylcholine, dopamine, and norepinephrine in specific areas of the brain (Sanchez et al., 2015). The safety and efficacy of vortioxetine have only been assessed in three published trials (D'Agostino et al., 2015); therefore, additional studies are needed to better compare with more traditional therapies.

Complementary and alternative medicine (CAM) therapies

There is increasing interest in the use of complementary and alternative medicine (CAM) therapies to treat depression. A recent study found that 40% of adults with depressed mood used CAM therapies, and most did not tell their physicians (Freeman, 2009). It is becoming more important for health professionals to proactively ask patients about use of CAM therapies.

St John's wort is an extract of *Hypericum perforatum* and it has been commonly used to treat depression since the 1980s. Its exact mechanism of action is unclear; however, it appears to inhibit serotonin reuptake and alter levels of dopamine, norepinephrine, and other neurotransmitters (Shelton, 2009). The efficacy and safety of St John's wort have been well established; short-term use of St John's wort is as effective as antidepressant medicines for mild to moderate depression (Linde et al., 2008). However, it is not recommended as a first-line treatment due to drug–drug interactions and varying levels of potency across different preparations (Cleare et al., 2015). St John's wort should not be combined with other antidepressant medicines, such as SSRIs, TCAs, or MAOIs, as this will increase the risk of drug-induced side effects such as serotonin toxicity. It also induces cytochrome P450 3A4 enzymes and intestinal P glycoprotein, and, therefore, interacts with many other medicines, including cyclosporine, warfarin, and HIV treatments (Izzo, 2004).

Limited evidence exists to support the use of other CAM therapies in depression, including omega-3 fatty acids, S-adenosyl methionine, folate, or L-methylfolate; therefore, they are not recommended as monotherapy treatment for MDD (Cleare et al., 2015; Nahas and Sheikh, 2011).

Antidepressant Prophylaxis

A single episode of depression should be treated for at least 6–9 months following full remission of symptoms (Anderson et al., 2008). If antidepressant therapy is stopped immediately on recovery, approximately 50% of individuals experience a return of their depressive symptoms within 3–6 months (Anderson et al., 2008; Reimherr et al., 1998). Of the individuals who have one episode of major depression, 50%–85% will go on to have a second episode, and 80%–90%, of those who have a second episode, will go on to have a third (Bauer et al., 2017). Therefore, NICE recommends that individuals who have had two or more episodes of depressions in the recent past, and who have experienced significant functional impairment during those episodes, should be advised to continue antidepressants for at least 2 years (National Institute for Health and Care Excellence, 2016). Doses for prophylaxis are the same as used for acute treatment (Anderson et al., 2008).

Refractory Depression

Refractory, or treatment-resistant, depression is difficult to treat successfully and outcomes are poor (Dunner et al., 2006). However, the evidence base has been substantially improved by the publication of the Sequenced Treatment Alternatives to Relieve Depression (STAR-D) program. STAR-D was a pragmatic effectiveness study in which participants received first citalopram; participants who failed to remit were then entered into the continued study of sequential treatments (Fava et al., 2006; McGrath et al., 2006; Nierenberg et al., 2006; Rush et al., 2006; Trivedi et al., 2006). The results of STAR-D showed that treatment of refractory depression requires a flexible approach and that response to a particular treatment is not readily predicted by pharmacology or previous treatments. The program established bupropion and buspirone augmentation as worthwhile options, as well as T_3 augmentation and the use of nortriptyline.

Augmentation of antidepressant treatment with low-dose antipsychotics is also well supported by published literature. For example, quetiapine (300–600 mg/day) added to SSRI/SNRI (Anderson et al., 2009; Sagud et al., 2006), risperidone (0.5–2 mg/day) added to antidepressant (Mahmoud et al., 2007; Rapaport et al., 2006; Yoshimura et al., 2008), or aripiprazole (5–20 mg/day) added to antidepressant (Hellerstein et al., 2008; Marcus et al., 2008).

Switching Antidepressants

There are a number of strategies for switching between antidepressants (Jefferson, 2008; Luft, 2013; Taylor and Kapur, 2015). Close clinical observation and caution is required with all approaches, and individual patient factors and illness factors may require modification of a switching strategy.

- Conservative switch: the first antidepressant is gradually reduced and stopped. It is followed by a drug-free washout interval of five half-lives of the first drug before the new antidepressant is started according to its dose regimen. This strategy is most appropriate for primary care; the risk of drug–drug interactions is very low; however, there is a high risk of relapse as there is a prolonged period where the individual is without medication. Therefore, this method is not appropriate for high-risk individuals, and close monitoring is required.
- Moderate switch: the first antidepressant is gradually reduced and stopped. It is followed by a drug-free washout interval of 2–4 days before the new antidepressant is started at a low dose. This strategy may also be used in general practice; the risk of drug interactions is reduced, depending on the half-life of the first antidepressant.
- Direct switch: the first antidepressant is stopped and the second antidepressant is started the next day at the usual therapeutic dose. This strategy is quick; however, discontinuation symptoms may occur, depending on the pharmacological profile of the first antidepressant medicine. Moreover, there is a high risk of pharmacodynamic interactions, as both antidepressant medicines may affect similar neurotransmitter systems. This method requires clinical expertise and is only feasible in certain circumstances, for example, switching from one short half-life SSRI to another or in acute hospital settings where more intensive monitoring is possible.
- Cross-taper switch: the first antidepressant is gradually reduced and stopped while the second antidepressant is introduced at a low dose at some stage during the reduction of the first. The patient will be taking both antidepressants simultaneously; the dose of the second antidepressant is increased to the therapeutic dose when the first antidepressant has been stopped. This strategy is frequently used in patients with high risk of illness relapse; however, there is risk of drug–drug interactions and increased adverse effects from both medicines.

Withdrawing Antidepressants

Antidepressants should normally be withdrawn gradually over a 4-week period, although some individuals may require a longer period, particularly with drugs with shorter half-lives (e.g., paroxetine and venlafaxine). This is generally not required with fluoxetine because of its long half-life. Patients should be warned that they may experience withdrawal symptoms; however, these are usually mild and self-limiting. Common withdrawal symptoms for SSRIs are flu-like symptoms, "shock-like" sensations, dizziness, excessive dreaming, insomnia, and tearfulness. Withdrawal of TCAs can cause flu-like symptoms and insomnia. If discontinuation symptoms are severe, the patient may need to resume taking the original antidepressant medicine and taper the dose more gradually while monitoring symptoms (National Institute for Health and Care Excellence, 2016; New Zealand Guidelines Group, 2008).

Nonpharmacological Treatment

Electroconvulsive Therapy

Electroconvulsive therapy (ECT) may be considered when all other treatments have failed or in life-threatening situations. ECT should only be considered a first-line treatment in MDD for urgent and emergency situations such as catatonia, high risk of suicide, or extreme levels of distress (Cleare et al., 2015; Otte et al., 2016). It requires hospitalization needs to be administered by specialists and usually requires hospital attendance. Although ECT is considered a safe treatment, it is associated with side effects, including effects on cognition, especially anterograde and retrograde amnesia, and heart rhythm disturbances.

Psychotherapy

There are many different forms of psychotherapy for MDD; each paradigm relies on different conceptual models and prescribed techniques that vary in their focus and methods. The most common forms include cognitive behavioral therapy (CBT), behavioral activation therapy, psychodynamic therapy, problem-solving therapy, interpersonal psychotherapy, and mindfulness therapy. In severe depression, there often needs to be pharmacological treatment to help an individual to a stage where he or she is able to engage with psychotherapy.

Emerging Treatments in MDD

There are numerous new approaches to the treatment of MDD including –

- Transcranial magnetic stimulation (TMS): a method of delivering brain stimulation using an electromagnetic coil. It is thought to activate regions of the brain that have decreased activity in MDD. A recent review of studies of standard repetitive TMS (rTMS) concluded that, for patients with MDD that failed treatment with at least two antidepressant medicines, rTMS is a reasonable and effective consideration (Gaynes et al., 2014). Although is it not associated with seizures and other risks and side effects of ECT, it is inferior with regard to efficacy (Ren et al., 2014). In contrast to rTMS, deep TMS (dTMS) modulates neuronal activity in deeper regions of the brain. One review concluded that, in patients with treatment-resistant depression, dTMS is effective as a monotherapy and as adjunctive treatment to other pharmacotherapy (Bersani et al., 2013).
- Glutamatergic drugs: a novel pharmacologic approach involves parenteral or intranasal delivery of ketamine or esketamine, which are *N*-methyl-D-aspartate (NMDA) receptor antagonists. A meta-analysis of 21 studies showed that a single intravenous infusion of ketamine can elicit a significant antidepressant effect from 4 h to 7 days in patients with MDD (Coyle and Laws, 2015). Another study using esketamine, which has a threefold to fourfold higher affinity of NMDA receptors, reported similar rapid onset of antidepressant effects (Singh et al., 2016). However, this treatment remains experimental as more adequately controlled studies are necessary.

Role of the Pharmacist

The goals of treatment in those diagnosed with depression are to achieve remission of symptoms and prevent relapse (Best Practice Advocacy Centre New Zealand, 2009a). Antidepressant medicines are often prescribed to individuals with moderate to severe depression (Best Practice Advocacy Centre New Zealand, 2009a, 2009b). Many patients are nonadherent to antidepressant medicines. Studies have reported that one-third of individuals discontinue their antidepressant treatment in the first month (Lin et al., 1995) and 50%–75% discontinue within 6 months of treatment initiation (Chong et al., 2011). Whilst this poor adherence may be due to the efficacy of the antidepressants, or the stigma that surrounds mental health, it also may be due to side effect and concerns that individuals have about treatment. Hu et al. (2004) studied a group of 401 patients who were prescribed an SSRI. They reported that 86% of patients experienced a side effect and over half of patients found at least one of their side effects bothersome (Hu et al., 2004).

Pharmacists, across different practice settings (e.g., community pharmacy, hospitals), are in the ideal position to discuss and provide support to patients, especially those who are initiating antidepressant therapy, swapping, or discontinuing medicines (Anderson, 2014; Rubio-Valera et al., 2014). Furthermore, it has been suggested by Boudreau, Capoccia (Boudreau et al., 2002) that effective drug management in patients with depression includes the provision of a group of services that can be effectively supplied

by a pharmacist; these services include: "patient education, medication selection, and appropriate dosing, enhancing medication compliance, monitoring treatment effectiveness, and identifying and managing of adverse effects" (Boudreau et al., 2002). Two randomized controlled trials focused on pharmaceutical care interventions in depression. Clinical outcomes measuring clinical severity in the intervention groups led to mixed results. One study found a significant difference in clinical measures (Marques et al., 2013), whereas the other did not (Rubio-Valera et al., 2013). The latter study, however, led to significant changes in quality of life, but not clinical severity.

In addition, evidence has indicated that the behavior of health-care professionals, including pharmacists, has the potential to have a substantial impact on antidepressant adherence (Chong et al., 2011). The majority of the studies have focused on the impact on adherence. Bultman and Svarstad (2002) interviewed individuals with depression regarding their interactions with pharmacists. While 75% reported that the pharmacist had asked if they had questions, only 54% said the pharmacist listened to their concerns. There is scope for pharmacists to advise individuals about potential side effects and what action to take and to advise clinicians about when antidepressants need to be tapered and switched; however, studies that have evaluated the effect of the pharmacist in these roles are scant.

Adherence

Nonadherence to medicines can be further divided into two categories: discontinuation or inconsistent administration (Chong et al., 2011). In regard to the latter, treatment with antidepressants requires consistent daily dosing, and some patients do not take their medication regularly. Nonadherence is a significant barrier to the success of the treatment (Chong et al., 2011).

Pharmacist involvement in patient education has resulted in improvements in patient satisfaction, adherence, and clinical outcomes. A systematic review, conducted by Chong and Aslani (Chong et al., 2011), evaluated pharmacist adherence interventions specific to individuals with depression. The interventions that were identified in the review were classified as educational, behavioral, and multifaceted interventions (i.e., that employed combinations of educational, behavioral, affective, and provider-targeted strategies). Forty-three percent of the interventions were successful at significantly improving outcomes, and these interventions were mostly multifaceted and involved mental health care specialists (Chong et al., 2011). The authors suggest that these findings highlight the need to target all dimensions affecting medication adherence problems—the patient, the healthcare provider, and the health care system to show benefit to patients (Chong et al., 2011). In another systematic review, Srimongkon et al. have reported on the psychometric properties of tools used to evaluate medication adherence in consumers with depression, using the ABC adherence framework, which conceptualizes adherence into initiation, implementation, and discontinuation phases. Specifically, this review points to the use of specific tools to measure adherence depending on the phase of adherence (Srimongkon et al., 2019).

Management of Side Effects

Antidepressant effect can be slow to onset; while some patients may feel some treatment response in the first 2 weeks, others may take up to 4–6 weeks to have an effect (Best Practice Advocacy Centre New Zealand, 2009b), and therefore many patients may experience side effects before treatment response. As mentioned, side effects can have a negative impact on individuals and cause a significant burden (Kelly et al., 2008). Talking to patients about expectations surrounding treatment response/effect is of utmost importance, since the occurrence of side effects can have a large impact on adherence (particularly leading to early discontinuation), quality of life, and treatment response. Each patient may view side effects differently, with some assigning greater importance to some side effects than others (Kelly et al., 2008). In addition, patients may have preconceived ideas about what side effects are, how they relate to treatment response (Uzun and Kozumplik, 2009), and the relationship between the side effects and medication efficacy. It is important therefore to understand the patient's thoughts and beliefs around side effects and offer reassurance about any preconceived notions. Factored in to suitability of an antidepressant is the treatment response that the patient is experiencing, as both response to treatment and side effects can differ between individuals (Best Practice Advocacy Centre New Zealand, 2009a, 2009b).

The type, frequency, and likelihood of when a side effect could emerge should be discussed. It is also important to discuss which side effects require prompt action versus those which are more than likely self-limiting. Written advice tends to be beneficial so that patients have something to refer to if side effects do occur. Discussion of potential side effects has not been associated with higher discontinuation rates (Hu et al., 2004); a study by Bull et al. (2002) reported that discussing adverse effects with patients is associated with less or equal rates of premature discontinuation and a higher rate of switching of medicines, which can be considered a favorable outcome if use of a different medication is associated with greater treatment continuation and symptom improvement (Bull et al., 2002; Kelly et al., 2008).

Pharmacists must be aware of an individual's ability to tolerate side effects; if a patient considers a side effect intolerable, they may discontinue treatment or reduce their dose of their own accord (Hu et al., 2004; Uzun and Kozumplik, 2009). *Patients must be advised not to do either of these without their health professional's advice*; symptoms of depression may return and withdrawal-like side effects may also occur (Kelly et al., 2008). It is imperative to ensure that patients are aware of potential side effects (both common and more rare but serious), and how to manage these, including when to seek help from their doctor (Kelly et al., 2008; Uzun and Kozumplik, 2009).

For specific antidepressant side effects, please consult individual drug monographs and the data sheets for prevalence. All recommendations concerning medications should be discussed with the patient's prescriber.

Nausea may occur with any antidepressant but it is most often associated with venlafaxine and SSRIs (Sienaert, 2014). Taking the medication with food can help alleviate nausea (MayoClinic, 2016; NPS MedicineWise, 2012; Sienaert, 2014). Other ways to reduce nausea include eater smaller meals more often, drinking plenty of fluids, sucking on sugar-free sweets (MayoClinic, 2016), and consuming ginger-containing food or beverages (Kelly et al., 2008).

Some antidepressants may cause fatigue and drowsiness, especially at the start of treatment, or longer in some individuals (Hu et al., 2004; Kelly et al., 2008). Discussion with the prescriber regarding drowsiness is advised; careful management of dosing and monitoring of sleep patterns is important. For example, timing dose administration at bedtime for some medications may help (Best Practice Advocacy Centre New Zealand, 2009b; Kelly et al., 2008; Bostwick, 2010). Sleep hygiene is important; encourage the patient to take part in physical exercise and avoiding napping during the day (Kelly et al., 2008; MayoClinic, 2016). If a patient is drowsy or is fatigued, it is important to ensure that he or she understands not to drive or operate machinery (MayoClinic, 2016; NPS MedicineWise, 2012).

Furthermore, individuals with depression can have altered sleeping patterns, including difficulty getting to sleep or staying asleep (Bostwick, 2010). This can be due to the depression itself, or may be a side effect of the antidepressants (Bostwick, 2010; Ferguson, 2001; Kelly et al., 2008). For some antidepressants, ways to reduce insomnia include avoiding caffeinated foods and drinks, engaging in regular exercise, or recommendations on sleep hygiene measures (Kelly et al., 2008).

Weight loss can occur during the initial period of antidepressant use; however, this is often regained and then increased with long-term use (Ferguson, 2001; Sienaert, 2014). The majority of antidepressants cause only slight weight gain, except for mirtazapine, amitriptyline, and paroxetine (Sienaert, 2014). To limit weight gain, patients can be advised to make healthy choices with eating—reducing the consumption of sugary foods and beverages and increasing fruit and vegetables, keeping a food diary and partaking in regular physical activity (Kelly et al., 2008).

Depression itself can cause sexual dysfunction, and sexual side effects can also be due to some antidepressants. Paroxetine has been reported to be the antidepressant most likely to cause sexual dysfunction (Kelly et al., 2008). Dysfunction can include reduced sexual drive and difficulty reaching orgasm (Ferguson, 2001; Kelly et al., 2008). If the medication is being taken only once daily, patients could try to time sexual activity prior to dosing; if this is not successful, the patient should be advised to discuss further with his or her health professional (Kelly et al., 2008). There is a clear role for the pharmacist in managing side effects discussing with their doctor and/or care team. Other courses of action may include additional medication to be prescribed, if appropriate, or may consider lowering the antidepressant dose or switching antidepressant depending on the individual (Kelly et al., 2008; MayoClinic, 2016; NPS MedicineWise, 2012).

SSRIs have been associated with suicide and suicidal thoughts (US Food and Drug Administration, 2016). Suicidal thoughts and behaviors are more prevalent in children and young adults (US Food and Drug Administration, 2016). If any of these symptoms emerge, then patients should be advised to seek assistance straight away. Information on after hour's crisis services is something that could also be given to all patients.

Advice to Prescribers

As many individuals will may have to try more than one antidepressant medicine before finding the one that is most appropriate for them (Best Practice Advocacy Centre New Zealand, 2009b), the pharmacist has an integral role in advising on tapering and switching of antidepressants to clinicians. More specifically, the pharmacist is in an ideal position to advise when switching medications on the need for washout periods, cross-tapering, potential drug interactions and their management, and the management of discontinuation syndrome (Best Practice Advocacy Centre New Zealand, 2009a; Shepherd and Parker, 2017). Factors that will need to be considered include the individual pharmacokinetics of the medications and the existence of active metabolites (Best Practice Advocacy Centre New Zealand, 2009b).

Advice on the potential for serotonin toxicity is also particularly important. Serotonin toxicity, although rare, is an extremely serious and potentially life-threatening condition that can occur if a medication that affects serotonin is given in high doses or if it is coadministered with other medicines with serotonergic activity (Medsafe, 2015). The pharmacist should be checking interactions with prescribed antidepressant medicines (including natural and complementary medications, such as St John's wort) and advising the prescriber accordingly while bearing in mind the washout periods for the medications (Medsafe, 2015).

Self-Management and Promotion of Support Networks

As discussed earlier, self-management is something that can be encouraged and promoted as part of the overall management of people with depression. In addition, giving clear information about the appropriate online resources that the patients can use, and which local groups are available for the support of people with depression (Shepherd and Parker, 2017).

Challenges

There are challenges that need to be surmounted by pharmacists to cement their role in the ongoing care of patients with depression. These include time, privacy, lack of pharmacist training, remuneration for the service, and lack of liaison between the pharmacist and other health-care professionals (Liekens et al., 2013).

Appropriate education of pharmacists in this area is paramount. A lack of education in mental health has been described as the main barrier to successful pharmaceutical care for people with depression (Scheerder et al., 2008). A study by Crockett and Taylor (2009) conducted an intervention study with rural pharmacists. Pharmacists allocated to the intervention group were given training in depression and asked to dispense medication with extra advice and support. By the conclusion of the study, pharmacists were more likely to initiate conversation, discuss medication and its side effects, point out the importance of remaining on the medication, provide ongoing follow-up, and encourage patients to talk with their GPs and pharmacists (Crockett and Taylor, 2009). In addition, the pharmacists who were in the intervention group were more likely to initiate conversation on dispensing a repeat prescription and to discuss extended support. A key element highlighted by the pharmacists in this study was that a major barrier to care was the "fear of saying the wrong thing." This is echoed by other studies, such as Liekens et al. (2012) and Scheerder et al. (2008), where a lack of education in mental health was perceived as a barrier to depression care. Specialized training for pharmacists in this field could potentially lead to more confidence in initiating conversations with patients with depression. To support this notion, Liekens et al. (2014) assessed the impact of an educational training day on pharmacists in a cluster randomized controlled trial. Mystery shopper interactions were assessed to measure outcomes, evaluating pharmacists' communication with individuals starting a new antidepressant therapy. The authors reported that pharmacist training can positively affect the quality of care in patients with depression (Liekens et al., 2014).

Understanding roles of other healthcare professions in the holistic approach to mental health care is also an important challenge. This was also identified by Crockett and Taylor (2009), with the suggestion that this training should be implemented during undergraduate training of all medical and health professionals. Subsequently, this should lead to improved understanding of the various roles of health professionals in mental health and facilitate interprofessional teamwork (Crockett and Taylor, 2009).

These barriers are not isolated to the community setting. Desplenter et al. (2011) described the perceptions and challenges of counseling patients at discharge from hospital in Belgium. Whilst pharmacists were perceived as a reliable healthcare professional and a key person in the team, the authors reported barriers to care included the acceptance of the broadening role and new competencies of the pharmacist in the team, interdisciplinary communication, timing of discharge, and lack of medical information (Desplenter et al., 2011).

Future Potential Roles

In many countries worldwide, the role of the pharmacist is continuing to evolve (Liekens et al., 2013). Collaborative care models have been proposed between clinic-based pharmacists and clinicians to support the management of patients with major depression (Kehoe, 2002). In an ongoing study by Boudreau et al. (2002), a pragmatic randomized control trial, was conducted. Patients were randomized to receive either standard care or enhanced care. Enhanced care included the role of the pharmacist in the team, and there was ongoing follow-up with the patient from the pharmacist or PharmD resident. At each follow-up contact, depression score was assessed. If no significant improvement in symptoms were seen after 8–10 weeks, then the pharmacist referred the patient back to the psychiatrist. The authors report that this study, albeit ongoing, demonstrated that pharmacists working as members of teams could "positively affect patient outcomes, satisfaction with face to face contact, quality of prescribing and the delivery of care."

This result was also reflected in a separate study by Finley et al. (2002). Patient satisfaction, outcomes, medication adherence, and visits to their primary care providers were all improved in those patients in the intervention group (Finley et al., 2002). A further randomized control trial using the same collaborative care model found improvements in adherence and patient satisfaction; clinical improvement was seen in both groups, but difference was not statistically significant (Finley et al., 2003).

Depression screening has the potential to increase early identification of signs and symptoms and allow for referral to the most appropriate medical professional. Pharmacists are in a unique position, being the most accessible health-care professional in the community setting (O'Reilly et al., 2015) and held in high regard by the public (Roy Morgan News Poll, 2014). Screening services within community pharmacies have evaluated by several studies and have the potential to be a beneficial. A feasibility study in Australia evaluated the potential of community pharmacists to provide screening services for depression (O'Reilly et al., 2015). Results showed that pharmacists were capable of providing this service and making the appropriate referrals when necessary. In addition, in a separate study by Rosser et al. (2013), a screening service was developed and implemented over 32 locations, which also demonstrated that pharmacists had the ability to effectively screen patients using a validated tool, and follow-up showed that these patients had initiated or modified treatment. Through this screening, individuals at risk of suicide were also identified and referred, highlighting the value of the pharmacist in this role and unmet need of patients (Rosser et al., 2013). However, if pharmacists are to engage in this type of screening service, it is imperative to have appropriate training in depression and using a recognized and validated tool to conduct this service, with resources available to refer patients to the most appropriate health care professional.

Management of Mental Health Disorders and the Pharmacist's Role: Schizophrenia

Carolyn B. McNabb*, **Emma R. Smith**†, **Bruce R. Russell**†, *University of Reading, Reading, United Kingdom; †University of Otago, Dunedin, New Zealand

Introduction

Schizophrenia is a serious mental health condition, characterized by relapsing episodes of delusions, hallucinations and diminished emotional expression, persistent cognitive dysfunction, and a number of other disruptive symptoms. The disorder most commonly emerges during adolescents or early adulthood and is a leading cause of disability in individuals aged between 15 and 44 years (Rössler et al., 2005, 2013). Pharmacological intervention is the most effective means for controlling the positive symptoms associated with schizophrenia and is effective in many cases (Matheson et al., 2014); however, there remains a small proportion of individuals whose symptoms persist despite best practice.

The current definition of schizophrenia, as set out in the Diagnostic and Statistical Manual of mental disorders (DSM-5) (American Psychiatric Association, 2013) and International Classification of Diseases (ICD-10) (WHO, 2016), is a culmination of several influential theories described over the past century. Many noteworthy developments have occurred in the history of the disorder but particular importance should be placed on:

1. Emil Kraepelin's popularization of the term "dementia praecox" (premature dementia or precocious madness) to describe the chronic, deteriorating nature of this psychotic illness,
2. Eugen Bleuler's emphasis of the splitting of psychic functioning and renaming of the disorder to "schizophrenia,"
3. Karl Jasper's elegant description of the symptoms of schizophrenia in philosophical and psychological terms in this book Allgemeine psychopathologie (General Psycholopathology, 1913),
4. The discovery of chlorpromazine for the treatment of schizophrenia in the early 1950s.

A complete history of schizophrenia is outside the remit of this encyclopedia; however, many excellent resources are available should readers wish to learn more about the subject.

Schizophrenia within the International Criteria for Diagnosis-10 (ICD-10) and the proposed changes for ICD-11

Within the framework of the ICD-10 (WHO, 2016), schizophrenia is grouped with schizotypal and delusional disorders as well as a larger group of acute and transient psychotic disorders. The Diagnostics and Statistics Manual-5 (DSM-5) (American Psychiatric Association, 2013) adopts a similar arrangement, grouping schizophrenia spectrum and other psychotic disorders together. Both diagnostic tools demand that a diagnosis of schizophrenia be made only in the absence of extensive depressive or manic symptoms, unless schizophrenic symptoms antedate the affective disturbance. Likewise, a diagnosis of schizophrenia should not be made in the presence of overt brain disease or during states of intoxication or withdrawal.

Although the ICD-10 (and DSM-IV) (American Psychiatric Association, 1994) categorizes schizophrenia based on clinical features (simple, hebephrenic, catatonic, paranoid, undifferentiated, schizoaffective, childhood, and chronic), low stability, poor inter-rater reliability, minimal clinical utility, and limited validity of these subtypes have resulted in their proposed exclusion from ICD-11 (not yet released). These changes have already been implemented in the DSM-5 (American Psychiatric Association, 2013). Suggested replacements to the traditional subtyping include using ratings of individual symptom domains (Keeley and Gaebel, 2017), clinical staging (McGorry et al., 2006), and response to treatment (Farooq et al., 2013). Each strategy possesses

its own strengths and weaknesses, some providing benefits surrounding a diagnosis (symptom ratings or clinical staging) and others surrounding treatment (response subtyping).

Estimates suggest that from as few as 5% to as many as 60% of the population affected with schizophrenia are resistant to first-line treatment (Brenner et al., 1990; Elkis, 2007; Essock et al., 1996; Juarez-Reyes et al., 1995; Kane, 1995; Lehman et al., 2004). Treatment-resistance accounts for some of the highest rates of hospitalization and impaired functioning in mental health (Iasevoli et al., 2016; Lieberman and Murray, 2012). The atypical antipsychotic, clozapine is effective for treating between 30% and 70% of individuals who are deemed treatment resistant because it provides relief for their most debilitating symptoms (Elkis, 2007; Essali et al., 2009; Kane and Correll, 2016; Kane et al., 1988b; Meltzer, 2010). However, the serious and potentially life-threatening side effects associated with clozapine limit its use so it is reserved for treatment-resistant patients only. Unfortunately, a significant number of patients do not respond to clozapine either (Howes et al., 2016).

Epidemiology/Burden of Disease

During 2013, the Global Burden of Disease Study estimated that 23 million people, worldwide, were living with schizophrenia (Vos et al., 2015). This disorder accounts for between 0.01% and 0.7% of the total population but is a leading cause of years lived with disability and accounts for 3.7% of the global burden of disease (McGrath et al., 2008; Vos et al., 2015). Individuals with schizophrenia experience a standardized mortality ratio 2.6 times that of the general population (McGrath et al., 2008). The incidence of suicide in those with schizophrenia is also particularly high (12.9 times that of the general population) (McGrath et al., 2008). A high incidence of premature cardiovascular disease has also been reported. The annual national cost of schizophrenia is estimated to range between US$ 92 million and US$ 102 billion, with indirect costs making up between 50% and 85% of this amount (Chong et al., 2016). Resistance to first-line antipsychotic therapy is estimated to require US$ 34 billion per annum in direct health-care costs in the United States alone (Kennedy et al., 2014).

Etiology of Schizophrenia

Evidence supports both genetic and environmental influences in the etiology of schizophrenia, as well as purported gene–-environment interactions.

The estimated heritability of schizophrenia from a recent study was ~80% (Hilker et al., 2018), which emphasizes a substantial genetic risk for those with affected parents and siblings. The genetic risk is conferred by a large number of alleles, with over 100 loci associated with the disorder (Schizophrenia Working Group of the Psychiatric Genomics, 2014). Of major interest are polymorphisms associated with the dopamine (D2) receptor gene DRD2 and the genes involved in glutamatergic neurotransmission (Schizophrenia Working Group of the Psychiatric Genomics, 2014). Despite high heritability, however, concordance rates from monozygotic and dizygotic twins are only 33% and 7%, respectively, implying that vulnerability is not solely attributable to genetic factors (Hilker et al., 2018).

Substantial evidence also implicates environmental factors such as urban upbringing (Krabbendam and van Os, 2005), childhood adversity (Longden and Read, 2016), cannabis use (Arseneault et al., 2002), and maternal influenza infection (Adams et al., 1993) in the development of schizophrenia. These factors in combination with genetic influences are thought to increase the risk of developing schizophrenia via gene–environment interactions, whereby the effect of an individual's genotype depends on environmental exposure and vice versa (European Network of National Networks studying Gene-Environment Interactions in et al., 2014).

In neurochemical terms, schizophrenia has been linked to disrupted striatal and prefrontal dopamine regulation (Howes and Kapur, 2009), which is possibly the result of underlying disturbances in N-methyl-D-aspartate (NMDA) receptor modulation (Stephan et al., 2009). All currently licenced antipsychotic drugs block dopamine D2 receptors (whether via antagonism, inverse agonism, or partial agonism) (Howes et al., 2015), which reinforces the hypothesis that dopamine plays a critical role in the manifestation of the symptoms associated with schizophrenia. Variability in the responsiveness of individual patients to these drugs (Agid et al., 2011), however, indicates that in some cases, the disorder is at least partly attributable to other neurochemical mechanisms.

Clinical Presentation of the Positive, Negative, and Cognitive Symptoms

Three main types of symptom contribute to the overall diagnosis of schizophrenia, i.e., the positive, negative, and cognitive symptoms.

Bleuler described positive symptoms as features of schizophrenia supplementary to a healthy psyche. They consist of delusions and hallucinations among other excessive functions (Stahl, 2013); positive symptoms are listed in **Table 1**.

Karl Jaspers defined delusions as "*pathologically falsified judgements*" of reality, describing them as transformations in one's total awareness of, and impairment in one's ability to judge, reality (Jaspers et al., 1997). This is in accordance with modern interpretations which describe delusions as "*involving a misinterpretation of perceptions or experiences*" (Stahl, 2013). Delusions themselves can take on many forms; Jaspers expressed that it is not the content of the delusion that is important, however, but the original experience

Table 1 Positive symptoms of schizophrenia

Positive symptoms
Delusions
Hallucinations
Distortions or exaggerations in language and communication
Disorganized speech
Disorganized behavior
Catatonic behavior
Agitation

Table 2 Negative symptoms and their descriptions

Negative symptoms of schizophrenia	
Avolition	A reduction in desire, motivation, or persistence, restricting the initiation of goal-directed behavior. May reduce one's ability to undertake or complete everyday tasks, including personal hygiene.
Blunted affect	Restriction in the range or intensity of emotional perception, experience, and expression. A person may report feeling "numb" or "empty inside."
Asociality	Reduced social drive and interaction—diminished sexual interest, few friends, or little interest in spending time with friends. May be a consequence of limited social interactions or an association of avolition.
Anhedonia	A reduction in the ability to experience pleasure or recount pleasurable experiences. Previous hobbies or interests may become less pleasurable.
Alogia	Restriction in the fluency and productivity of thought and speech—Conversation is stunted; an affected individual will offer few words and fail to elaborate without prompting.

that leads to this content (Jaspers et al., 1997). This experience, arising as a sensation, feeling, mood, or altered awareness, signals to the individual that there has been some subtle change in the environment (Jaspers et al., 1997). Kapur suggested that these impressions of altered atmosphere stem from an increase in aberrant salience that causes misattribution of significance to normally nonsalient stimuli (Kapur, 2003). Individuals reporting their experiences during the prodromal phase of schizophrenia recount that they *"became fascinated by the little insignificant things around [them]"* (Bowers and Freedman, 1966) that something in the world around them is changing, leaving them confused and looking for explanations (Kapur, 2003). Though Jaspers purported that these delusional ideas develop through essentially normal cognitive processes (Stanghellini et al., 2013), others suggest that a defect in probabilistic reasoning (i.e., jumping to conclusions) may be involved (Maj, 2013; Menon et al., 2008).

Like delusions, hallucinations may also be attributed to abnormal salience, this time of the mental impressions of sensory experiences and memories (Kapur, 2003). Auditory and visual hallucinations are most common, although tactile and gustatory hallucinations can also occur.

Disorganized thinking refers to substantially impaired communication resulting from frequent derailment of or incoherent speech (2013). Speech may become so disorganized as to resemble receptive aphasia, restricting an individual's ability to express him/herself meaningfully through language and resulting in complete incoherence or "word salad" (2013). Distortions or exaggerations in language and communication may also occur (Stahl, 2013).

In some cases, motor behavior may be affected in schizophrenia, hindering goal-directed behavior and activities of daily living (2013). "Child-like silliness" and unpredictable agitation are hallmarks of this disorganized or abnormal motor behavior (2013). In more severe cases, a marked decrease in reactivity to the environment, known as catatonia, may occur (2013). Catatonic behavior may manifest in a number of different ways, some of which are presented in **Table 2**.

Negative symptoms contribute substantially to the morbidity associated with schizophrenia and are strong determinants of poor social functioning and outcome (2013, Rabinowitz et al., 2012). They generally represent deteriorations in normal function and though less dramatic than positive symptoms, their presence is often associated with long periods of hospitalization, trouble maintaining stable social relationships and employment, and a decreased ability to live independently (Stahl, 2013).

The most prominent negative symptoms of schizophrenia are avolition and blunted affect, described, along with the remaining negative symptoms, in **Table 2**.

The cognitive symptoms of schizophrenia present early in the course of the disorder and are largely resistant to current antipsychotic drug therapy. They may appear prior to the development of psychosis in some individuals and are more highly correlated with measurable brain dysfunction that other aspects of the disorder (Keefe and Fenton, 2007). Cognitive symptoms affect mental processes necessary for day-to-day function and future planning and include deficits in attention, working memory, explicit memory, problem solving, and executive function. Social cognitive deficits may also be present. These include deficits in the ability to infer the intentions of others (theory of mind) and may lead to the generation of explanatory delusions.

Although recognized as an associated feature of schizophrenia in the DSM-5, cognitive symptoms are not explicitly included in the diagnostic criteria for the disorder. Instead, guidelines emphasize the importance of cognitive assessment for making critical distinctions between the various schizophrenia spectrum and other psychotic disorders.

Diagnosis of Schizophrenia

The DSM-5 requires that a diagnosis of schizophrenia be made if an individual presents with delusions, hallucinations, or disorganized speech, either in combination with each other or with grossly disorganized or catatonic behavior, diminished emotional expression, or avolition. The DSM-5 diagnostic criteria for schizophrenia (American Psychiatric Association, 2013) are summarized below.

1. Two (or more) of the following, each present for a significant portion of time during a 1-month period (or less if successfully treated). At least one of these must be (a), (b), or (c):
    a. Delusions.
    b. Hallucinations.
    c. Disorganized speech (e.g., frequent derailment or incoherence).
    d. Grossly disorganized or catatonic behavior.
    e. Negative symptoms (i.e., diminished emotional expression or avolition).
2. For a significant portion of the time since the onset of the disturbance, level of functioning in one or more major areas, such as work, interpersonal relations, or self-care, is markedly below the level achieved prior to the onset (or when the onset is in childhood or adolescence, there is failure to achieve expected level of interpersonal, academic, or occupational functioning).
3. Continuous signs of the disturbance persist for at least 6 months. This 6-month period must include at least 1 month of symptoms (or less if successfully treated) that meet Criterion A (i.e., active-phase symptoms) and may include periods of prodromal or residual symptoms. During these prodromal or residual periods, the signs of the disturbance may be manifested by only negative symptoms or by two or more symptoms listed in Criterion A present in an attenuated form (e.g., odd beliefs, unusual perceptual experiences).
4. Schizoaffective disorder and depressive or bipolar disorder with psychotic features have been ruled out because either (1) no major depressive or manic episodes have occurred concurrently with the active-phase symptoms or (2) if mood episodes have occurred during active-phase symptoms, they have been present for a minority of the total duration of the active and residual periods of the illness.
5. The disturbance is not attributable to the physiological effects of a substance (e.g., a drug of abuse, a medication) or another medical condition.
6. If there is a history of autism spectrum disorder or a communication disorder of childhood onset, the additional diagnosis of schizophrenia is made only if prominent delusions or hallucinations, in addition to the other required symptoms of schizophrenia, are also present for at least 1 month (or less if successfully treated).

Treatment Options

Early treatment options included bloodletting and emesis that was thought to remove poisons from the body, or for example spinning the patient until they lost consciousness, which was believed to rearrange the content of the brain. Insulin coma therapy was also used and very popular in the 1930s, but it was not until the serendipitous discovery of chlorpromazine (which was being tested as a sedative antihistamine) during the early 1950s that an effective treatment for schizophrenia was developed.

Treatment options now include oral or intramuscular injections of antipsychotic medication in conjunction with psychological interventions (family intervention and individual Cognitive Behavioural Therapy). Generally, there are two and some argue three classes of oral antipsychotic available. These include the first-generation antipsychotics (FGA) like chlorpromazine, first synthesized in 1950 by Paul Charpentier. During the subsequent two decades, increasingly selective D2 antagonists such as haloperidol were synthesized and tested with the aim of improving their efficacy. Ultimately this approach was unsuccessful, but a range of drugs became available with varying degrees of adverse effects such as sedation. For example, chlorpromazine and levomepromazine are very sedative and haloperidol is far less so. The primary pharmacological effect of the FGA is attributed to their antagonism of dopamine receptors (D2). The ability to block D2 receptors in the mesolimbic pathway is largely responsible for reducing the positive symptoms of schizophrenia and also unfortunately inducing Parkinsonian-like or extrapyramidal side-effects (EPSEs), which they are so well known for (Stahl, 2013).

The second-generation antipsychotics (SGA) include risperidone, olanzapine, quetiapine, and amisulpride. The defining pharmacological property that separates SGAs from FGAs is their antagonism of serotonin ($5HT_{2A}$) receptors, in addition to D2 receptor antagonism (Sykes et al., 2017). The decreased incidence of EPSEs during a patient's first exposure to a SGA in contrast to the FGA's has led to their recommendation as drugs of choice within clinical treatment guidelines for antipsychotic use. The side effect profile is also different from that of the FGAs. The more common side effects induced by this group include weight gain and symptoms associated with the metabolic syndrome, i.e., high cholesterol, diabetes, and cardiovascular disease. Like the FGAs some are also very sedative and some are not.

Third-generation antipsychotics currently include aripiprazole and brexpiprazole (Fleischhacker et al., 2017; Forbes et al., 2018; Shirley and Perry, 2014). Both drugs differ from the other antipsychotics in that they are partial agonists of D_2 and 5-HT_{1A} receptors rather than antagonists. They also act as antagonists of serotonin 5-HT2A and noradrenaline α1B/2C receptors. They are not

generally sedative and not associated with increasing prolactin levels or weight gain so they are becoming more widely used. However, akathisia can be a problematic side effect.

For the purposes of this encyclopedia, we will refer to only two classes of antipsychotic, i.e., FGA and SGAs including aripiprazole and brexpiprazole.

Clozapine appeared in Vienna in 1966 and for most of the last three decades remains the drug of choice for treatment-resistant schizophrenia. It is considered a SGA and the only drug shown to reduce the rate of suicide and hospitalization in those with schizophrenia (Meltzer, 2010; Modestin et al., 2005; Tiihonen et al., 2009).

All antipsychotics have their own specific properties and are effectively used in the acute and long-term treatment of schizophrenia. Tandon et al. (2008) state that there is no convincing evidence to support the preferential use of SGAs over FGAs especially if the EPSEs can be minimized (Tandon et al., 2008). With the exception of clozapine, a number of Cochrane reviews across heterogeneous populations have not provided any evidence that any particular antipsychotic is more effective than another (Asenjo Lobos et al., 2010; Asmal et al., 2013; Khanna et al., 2014; Komossa et al., 2009; Komossa et al., 2010a; Komossa et al., 2010b; Komossa et al., 2011; Leucht et al., 2012a). However, there is clear evidence of differing adverse effects of clinical significance between specific antipsychotics (Bazire, 2016). For example, although both olanzapine and amisulpride are SGAs, their side effect profiles are quite different. In practice, olanzapine causes marked sedation and weight gain, likely due to its antagonist effects at histamine (H1), muscarinic (M1), and adrenergic (α1) receptors (Leucht et al., 2013). In contrast, amisulpride can cause a marked elevation in prolactin leading to amenorrhea, galactorrhea, sexual dysfunction, and possibly over time osteoporosis (Bazire, 2016). However, amisulpride is not very sedative and less likely to induce weight gain when compared to olanzapine.

Interestingly, a meta-analysis conducted by Leucht et al. (2013) showed there may be small advantages in symptom resolution when using olanzapine, amisulpride, and risperidone in contrast to other antipsychotics with the exception of clozapine (Leucht et al., 2013). Aripiprazole may be somewhat less effective than olanzapine, but more tolerable because it has a lower incidence of adverse metabolic effects and is less sedative. Aripiprazole is also less likely to induce EPSE's than risperidone or the majority of FGA's (Leucht et al., 2013).

Of particular importance, a report published by the World Health Organization during 2003 stated that adherence rates in developed countries average only about 50% (World Health Organisation, 2003) for all drugs. Consequently, ensuring long-term adherence is fundamental to treating people who suffer from schizophrenia (Kovacs et al., 2018). The desired outcomes of treatment are to prevent acute psychotic episodes, reduce hospital admissions, minimize drug-induced adverse effects, and maintain a reasonable quality of life for the patient.

For those with a diagnosis of schizophrenia, long-term use of an antipsychotic is crucial in conjunction with psychological and psychosocial interventions (Leucht et al., 2012a). To increase adherence, prescriber's might also utilize depot antipsychotics, which guarantee medication delivery and in turn help to improve treatment outcomes. Antipsychotics taken regularly, protect against the short-, medium-, and long-term risk of relapse (Leucht et al., 2012b). By preventing relapse, the risk of developing treatment-resistance is also decreased (Kane, 2013).

A number of country-specific guidelines such as the National Institute for Clinical Excellence (NICE) from the United Kingdom (UK) and the Royal Australian and New Zealand College of Psychiatrists recommend that after 4–6 weeks of treatment at an optimal antipsychotic dose, a change in antipsychotic should be considered (McGorry, 2005; NICE, 2009). These guidelines also recommend that where there is partial response, the patient should be reassessed after 8 weeks unless there are significant adverse effects. If a patient does not respond to treatment with two different antipsychotics (one of which should be a SGA), then treatment with clozapine is recommended (McGorry, 2005; NICE, 2009).

Importantly, treatment of schizophrenia must be individualized and tailored to the clinical presentation, comorbidities, concurrent medication, the use of recreational drugs, severity and frequency of episodes, and should include both pharmacological and nonpharmacological strategies (McGorry, 2005; NICE, 2009).

Pharmacological and Nonpharmacological Management

The choice of antipsychotic should be well informed and discussed with the patient and include where possible support from family members or carers. A multidisciplinary team (MDT) caring for a patient will typically include some of the following:

- Responsible clinician, i.e., consultant psychiatrist
- Registrar
- House or senior house officer
- Nurse looking after the patient
- Pharmacist
- Social worker
- Psychologist
- Occupational therapist

The pharmacist needs to be actively involved in facilitating an open, impartial, considered decision about which antipsychotic is the most appropriate for an individual. There are many useful reputable sources of information available to both health-care professionals and service users, for example, the Psychotropic Drug Directory (Bazire, 2016), which provides

considerable detail about the condition and treatment options. Pharmacists need to provide an appropriate level of information and be prepared to discuss the benefits and possible adverse effects of each drug with members of the MDT and patient or carer. Adverse effects may include:

- Metabolic disturbances (including weight gain and diabetes)
- Extrapyramidal side effects (including akathisia, dyskinesia, and dystonia)
- Cardiovascular side effects (including QT prolongation)
- Hormonal (including increasing plasma prolactin)
- Others such as sedation, constipation, dry mouth, and dry eyes

Pharmacological options include a choice of first- or second-generation antipsychotics. Some examples of FGAs include chlorpromazine, flupentixol, haloperidol, zuclopenthixol, and fluphenazine. Examples of the SGAs include olanzapine, amisulpride, quetiapine, risperidone, paliperidone, and ziprasidone. As mentioned previously, with the exception of clozapine, the difference between the two classes is essentially due to differing side effects. Clozapine has superior efficacy in those experiencing resistant symptoms but its serious adverse effects profile means it is reserved for those who are treatment resistant (Kane et al., 1988a; Leucht et al., 2013).

Treatment guidelines typically follow the same algorithm for first-episode psychosis, please see Fig. 1. Choice should be based on the potential of the drugs offered to induce metabolic and extrapyramidal side effects. On first exposure to an antipsychotic, the likelihood of EPSEs occurring is also greater than subsequent exposures, depending on the drug chosen. Metabolic side effects are not immediate, but careful monitoring of body weight, blood glucose, and lipid profiles is important in the short term, i.e., weeks and over longer time periods. If the patient has a history of cardiac disease or the drug is likely to induce QT-prolongation, an ECG should also be carried out both before and after beginning treatment.

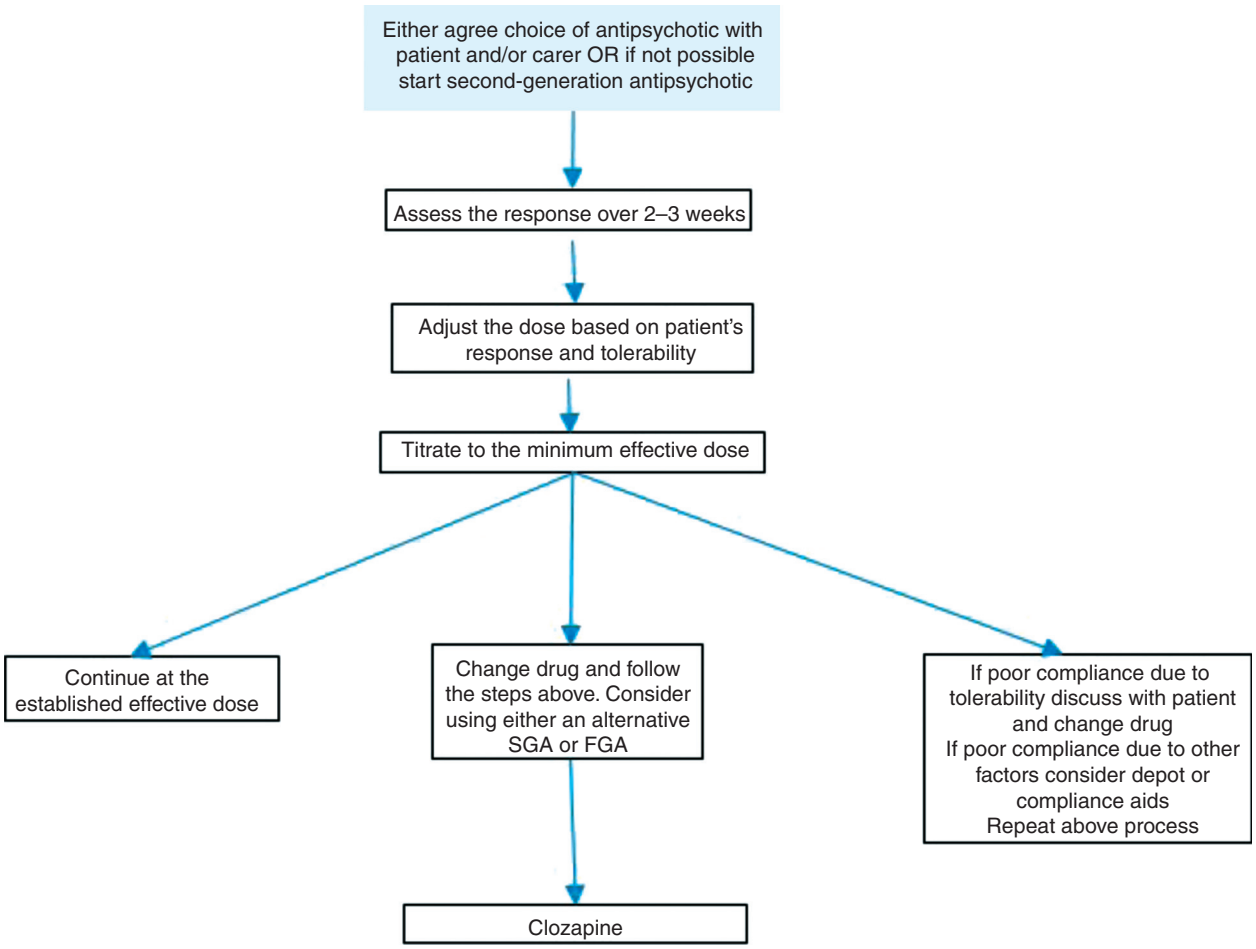

Figure 1 Treatment of first-episode psychosis. Improvements subsequent to beginning an antipsychotic are usually apparent within 2–3 weeks of reaching an effective dose, although a full response can often take 6 weeks or longer. Generally, if there is no improvement at all within the first few weeks of treatment it is unlikely there be a response. If there are no improvements within this period, consider changing the drug/dose.

Whether or not SGAs have an advantage over the FGAs for the treatment of schizophrenia remains uncertain (Naber and Lambert, 2009). During the last two decades, there have been two significant trials undertaken to determine whether there any significant advantages associated with the use of SGAs in contrast to FGAs. The Clinical Antipsychotic Trials of Intervention Effectiveness (CATIE) and Cost Utility of the Latest Antipsychotic drugs in Schizophrenia Study (CUtLASS) trials have proven to be landmark, independent, pragmatic clinical trials with no industry sponsorship. Both trials used broad inclusion criteria and a long follow-up period to mimic routine practice. The CATIE trial recruited 1493 patients and observed them for 18-months as a double-blind trial comparing the SGAs olanzapine, quetiapine, risperidone, and ziprasidone with the FGA perphenazine (Stroup et al., 2003; Swartz et al., 2003). The CUtLASS trial (n = 277) was an open label, multisite, randomized controlled trial of FGA (chlorpromazine, flupenthixol, haloperidol, loxapine, methotrimeprazine, sulpiride, trifluoperazine, zuclopenthixol, and the depots fluphenazine decanoate, flupentixol decanoate, haloperidol decanoate, pipothiazine palmitate, and zuclopenthixol decanoate), and SGAs (risperidone, olanzapine, amisulpride, zotepine, and quetiapine) with blind assessments at 12, 26, and 56 weeks using an intention-to-treat analysis (Jones et al., 2006). In both studies, there was no clear separation in the quality of life or patient responses between FGA and SGA. Consequently, there is no single antipsychotic that is best for each patient because individual responses differ considerably. For successfully individualized treatment, a multitude of antipsychotic options are needed (Leucht et al., 2013).

A more recent study (n = 69 taking FGA and n = 80 taking SGA for 24 weeks) suggested that patient-reported quality of life is significantly higher in those given SGAs in contrast to those given FGAs when treatment selection was individualized (Grunder et al., 2016). However, their advantage still needs to be weighed against the potential metabolic adverse effects of some SGAs, which do not always become apparent within that time frame.

The British Association for Psychopharmacology (BAP) guidelines recommend identification and treatment of schizophrenia spectrum disorders as early as possible to prevent the development of negative symptoms (Barnes and Schizophrenia Consensus Group of British Association for, 2011).

Maintenance pharmacotherapy is generally recommended for every patient; however, there has been debate about the use of long-term prophylactic antipsychotics in those who have had an acute psychotic episode, especially if they are diagnosed with schizophrenia (Murray et al., 2016). As with all medical practices, there are advantages and disadvantages to treating or not treating. There is also concern over the cumulative effects of antipsychotics on physical health and brain structure (Murray et al., 2016). The pharmacist should regularly review the benefits of continuing prophylactic antipsychotics against the risks associated with side-effects for each patient. Psychiatrists should also work with their patients to slowly reduce the antipsychotic to the lowest practical dose that prevents the return of distressing symptoms. While there is uncertainty about how long to continue antipsychotics, it is also well known that there is an approximately 80% rate of relapse into psychosis during the 1st year following the discontinuation of antipsychotics, which increases to >90% before the end of second year (Leucht et al., 2012a).

Combining antipsychotics should be avoided, as there is little evidence to support this practice and ample evidence to support the potential for harm (Porcelli et al., 2011). However, there is also some evidence to support the addition of a second antipsychotic as an adjunct to treatment with clozapine to provide relief from residual symptoms. In practice, the most commonly prescribed drugs used as adjunctive treatments are amisulpride (Barnes et al., 2017) and aripiprazole (Muscatello et al., 2011).

Some antiepileptic drugs have also been used as adjuncts (Zheng et al., 2017). In particular, lamotrigine, a drug which inhibits glutamate release, has been utilized as an adjunctive treatment for schizophrenia but with mixed results (Ohnuma et al., 2013; Vayisoglu et al., 2013).

Psychological and psychosocial interventions also increase the chance of staying well and avoiding a relapse (NICE, 2009). The NICE guidelines suggest individual cognitive behavioral therapy (CBT) with or without family intervention. CBT should be delivered on a one-to-one basis over at least 16 planned sessions (McGorry, 2005; NICE, 2009).

Where practical, family interventions should include the person with psychosis or schizophrenia and be carried out for between 3 months and 1 year, including at least 10 planned sessions. These sessions should take account of the relationship between the main carer and the person with psychosis or schizophrenia and have a specific supportive, educational or treatment function including negotiated problem solving or crisis management (McGorry, 2005; NICE, 2009).

A care plan should also be developed that includes activities that promote physical health and social inclusion, especially education, but also employment, volunteering, and other occupations such as leisure activities. Provide support to help the person and their family or carers realize the plan and agree on a suitable time to review it (McGorry, 2005; NICE, 2009).

For children and young people with first episode psychosis who are unable to attend mainstream school or college, facilitate alternative educational input in line with their capacity to engage with educational activities and according to their individual needs, with an ultimate goal of returning to mainstream education, training, or employment (McGorry, 2005; NICE, 2009).

New Developments

The current focus remains on improving the use of the dopamine antagonists currently prescribed with an emphasis on reducing their adverse effects, rather than developing entirely new classes of drugs (Taylor et al., 2015).

However, there are also efforts being made to develop new treatments, which target specific symptoms such as thought blocking and cognitive decline. For example, blonanserin that acts as a mixed 5HT2A and D2 receptor antagonist but unfortunately has yet to exhibit any significant advantages over existing antipsychotics (Kishi et al., 2018).

New methods of drug delivery are also being developed, for example, inhaled loxapine, a new 3-monthly paliperidone depot injection and the 2-monthly aripiprazole depot (Frampton, 2017).

Depot injections are useful preparations because they help to ensure adherence by supporting ongoing contact with services without significantly disrupting day to day living. The arrival of a clozapine IM injection is also being followed with great interest by acute service providers. The aim of using an IM injection of clozapine is as a short-term intervention to initiate patients who refuse medication, with a view to convert to oral clozapine as soon as possible (Trust, 2017).

The evidence for abnormalities in glutamatergic neuronal function in schizophrenia has also been increasing and provides support for the development of novel antipsychotic agents which target this system (Howes et al., 2015). These drugs have a completely different side-effect profile to D2 antagonists and to date have no propensity to extrapyramidal side effects, prolactinaemia, or weight gain. It has been hypothesized that glutamatergic drugs may be of benefit to the 20%–30% of individuals with schizophrenia who fail to show any response to dopaminergic agents and may be particularly useful in the early stages of the illness, where they may be disease-modifying. A number of glutamatergic compounds have been reported as having promising results in phase II drug trials. If these reach the clinic, they will represent the first truly novel approach to pharmacotherapy in schizophrenia for more than 50 years (Stansley and Conn, 2018).

The antibiotic minocycline has somewhat unexpectedly been shown to inhibit the effects of NMDA receptor antagonism and appears to be an effective adjunctive treatment option for schizophrenia. Moreover, minocycline has an acceptable safety and tolerability profile (Solmi et al., 2017; Xiang et al., 2017). However, more methodologically sound and larger RCTs remain necessary to confirm and extend these results (Solmi et al., 2017).

Monitoring and Measuring—How do we Know That Treatment is Working?

It is vital that patients, carers, and key workers are aware of the early signs of relapse and how to access help (Bazire, 2016; Taylor et al., 2015).

Treatment with antipsychotic medication should be considered an explicit individual therapeutic trial and continued at optimum dosage for a specified period of time. If during treatment, the service user continues to have symptoms, impaired functioning, or is distressed, then consider increasing the dose of the drug (if possible) or changing to another antipsychotic by cross-titrating.

However, there is some variation within treatment guidelines about the minimum length of time required before deciding whether a patient has shown a satisfactory response to the first antipsychotic selected. For example, the Maudsley Guidelines suggest the first antipsychotic need only be used for 2–3 weeks before considering a change in the absence of a significant response. This would be followed by a 6-week period for the second antipsychotic selected before considering any further changes or the use of clozapine (Taylor et al., 2015). In contrast, the American Psychiatric Association guidelines suggest that the first antipsychotic selected should be used for ≥6 weeks before deciding whether there has been a satisfactory response. If not, a second antipsychotic could be trialled for at least another 6 weeks.

A recent publication in the American Journal of Psychiatry by experts within the field from around the world has a convenient summary of treatment guidelines and made practical suggestions about the diagnosis of treatment-resistant schizophrenia (Howes et al., 2016).

The Psychotropic Drug Directory by Stephen Bazire also has clear, practical advice about how to switch treatment from one antipsychotic to another using a variety of methods (Bazire, 2016). These include drug-free intervals (safest), no intervals (generally preferred), abrupt switching (risks discontinuation symptoms), partial overlap (usually acceptable), overlap (risks—neuroleptic malignant syndrome, serotonin syndrome, and combined adverse drug reactions), and full overlap (as with overlap).

Adherence must also be considered as a possible reason for treatment failure. There are a variety of methods to check/aid adherence, which include monitoring plasma concentrations and side-effects, speaking to family members or carers, and simply changing from oral medication to a depot formulation. Clear documentation of any action taken and the rationale for change in dose/drug must be recorded in the medical notes; this is incredibly useful if the patient needs a medication history to consider future treatment options. The frequency and duration of monitoring should be determined by the severity and frequency of symptoms/behavior (using a validated assessment tool), level of impairment and/or distress, and the degree of family disruption or concern (NICE, 2009).

Schizophrenia is thought to be caused by a combination of biological, psychological, and environmental factors, which may be impossible to avoid. So preventing the development of the illness appears unlikely. Heavy cannabis use has been associated with onset of psychotic illness (Colizzi and Murray, 2018); however, it is not clear whether risk of psychosis increases with use of cannabis or those at high risk are more likely to use the drug. A definitive cause has yet to be discovered (Nielsen et al., 2017).

Patients may be at an increased risk of relapse or developing psychosis for a variety of reasons. The NICE guidelines suggest that early identification and referral are helpful if a person is distressed, has a decline in social function, and exhibits transient or attenuated psychotic symptoms, or other experiences or behavior suggestive of possible psychosis or a first-degree relative with psychosis or schizophrenia.

Role of a Mental Health Pharmacist

The role of a pharmacist in the MDT is contextual in nature and can differ in focus and scope between primary and secondary care and between specialisms (Quinlan and Robertson, 2010). In general, hospital pharmacists' participate in regular MDT meetings.

Their role is often clearly defined, where they work directly with other health-care professionals (HCPs) focusing on a specialist clinical area. By way of a general example, every morning the psychiatric intensive care unit would have a MDT meeting, but the eating disorders unit might only have weekly MDT meetings. In community settings, pharmacists often work in isolation or remotely from other clinical colleagues and may not always have a specific team to contact (Quinlan and Robertson, 2010).

Pharmacists have been involved in MDT meetings for many years (time frame of involvement varies from country-to-country and region-to-region). Their position in the clinical team is integral. A key determinant of a successful MDT meeting includes good quality, unambiguous communication, which allows full involvement of all team members. Mutual recognition of clinical experience and influence, collegial respect, knowledge of differing MDT skills, and an ability to build rapport are important components of building and sustaining trust between colleagues in the MDT and patients. Quinlan and Robertson (2010) suggested understanding the role and responsibility of other team members increases efficiency and productivity by reducing repetition and allowing experts in their field to state their views. Not only that, having clear team objectives, shared goals and roles clearly defined (in other words, who does what and when) help to ensure a more effective team.

The MDT meeting is recognized as a platform for pharmacists to demonstrate a variety of their specialist skills, including but not limited to:

Interventions. Identification of drug/drug interactions. For example, clozapine and carbamazepine; or altering drug doses/formulations (i.e., a switch from oral to depot or from tablets to liquid). Pharmacists can also offer advice on rapid tranquilization, if required.

Request monitoring and follow-up. For example, monitoring weight gain with olanzapine or blood pressure with quetiapine. Follow-up—ensuring that the drug is working as intended, whereby symptoms are well controlled and any associated side effects are not problematic for the patient. It is very important that the Pharmacist documents baseline measurements as a benchmark, which can include weight and height; waist and hip circumference; pulse and blood pressure; blood tests such as liver function tests (LFTs), thyroid function tests (TFTs), urea and electrolytes (U&Es), full blood count (FBC), HbA1c, lipid profiles, creatine kinase (CK), and prolactin levels; and assessment of movement disorders.

Aid adherence—service users who are identified as needing advice are referred. Pharmacists provide counseling about drug-induced adverse effects and try to engage those who are struggling with for example: sedation while prescribed clozapine, galactorrhea while prescribed risperidone, or muscle stiffness while taking haloperidol. Pharmacists can also provide general lifestyle advice, such as improvements to diet and/or exercise regimes, smoking cessation, alcohol-related issues, and/or illicit substance cessation.

Monitoring outcomes is a key component of a Pharmacist's role. *Is the drug prescribed actually doing what we want it to do*? More generally, being able to engage with service users is a vital skill.

Discuss future recommendations—if the current drug is not seen as efficacious or the side effects are intolerable, a Pharmacist will form a view about the next reasonable step(s) to pursue.

Aiding a smooth transition from secondary to primary care—Ensuring clear, concise communication of medication that a service user has ceased, commenced, or altered during their admission, which is done in order to try to prevent errors and potential readmission as a result.

Education—Pharmacists have a role in educating the MDT about any new drugs available, safety alerts, new or changes in policies and procedures that require adherence, and performing or giving feedback on audits undertaken in their service/practice.

When a Pharmacist participates in the review of a service user, they will critically analyze the need for each individual medication and from experience and evidenced-based medicine form a clinical view about whether or not the medication is working as intended and/or is superfluous to requirements. A Pharmacist will also listen to feedback from MDT members or patients and critically assess whether there has been a reasonable reduction in a patient's symptoms. Confirming any troublesome adverse effects experienced by patients—and discussing how to resolve any problems identified—is an important element of a Pharmacists role. Often two or more antipsychotics can be prescribed in an acute setting (both regularly and "as required"), which can continue long term if not highlighted and reviewed within the MDT meeting by the pharmacist. A Pharmacist will help ensure service users are counseled about their medication at discharge to alleviate any concerns they have and aid adherence. They also monitor blood results to ensure that the drug is not affecting the liver, kidneys, thyroid, prolactin, cholesterol, glucose levels, or ability to fight infection for example. If any of these results are concerning, suggestions for mitigating their effects will be offered to the team. Pharmacists also play an important role in assisting nursing staff with pragmatic solutions to problems as they arise—for example, issues with drug formulation where the patient has swallowing difficulties may be required. Funding issues, crisis planning, and seamless discharge planning fall under the umbrella of the Pharmacist's remit and are also addressed in the MDT meeting.

Independent Prescribing for the Pharmacist

Doctors will continue to be responsible for the diagnosis of psychotic illnesses, but pharmacists are ideally placed to undertake the prescribing and monitoring of medication for that particular condition (within their scope of expertise). Pharmacists are capable of managing the prescribing of high-risk medications—for example, clozapine, including continual monitoring clinical performance and any adverse effects induced by the medicine. Not only that, pharmacists can interpret plasma levels, alter doses to optimize a drug's safe and effective use (pharmacovigilance), and advising patients about lifestyle changes to achieve maximum benefit and increase adherence. Treating and monitoring patients with long-term conditions (LTCs) require a good working rapport and clear communication with other health-care professionals. Pharmacists will need to continue to actively engage and collaboratively work with General Practitioners to add value to current services.

In their current role, pharmacists can play a critical, positive role in helping to minimize the risk of prescribing errors reaching patients (Baqir et al., 2015).

Case Studies

The following examples illustrate differing degrees of complexity.

1. A 20-year-old female with a family history of schizophrenia has become socially withdrawn while studying at university. She is paranoid and believes that her housemates can read her mind and that the television is talking to her.
   She has no allergies or comorbidities and does not drink or smoke.
   This person is exhibiting prodromal negative symptoms associated with schizophrenia (social withdrawal). She is also showing some positive symptoms, which include paranoia, thought broadcasting, and ideas of reference (thinks the TV is talking to her).
   Treatment choice involving the patient will ultimately aid adherence. In practice, a Pharmacist might consider a website such as "choice and medication" http://www.choiceandmedication.org/ (Limited, 2018) to assist decision making. The NICE guidelines emphasize the importance of patient choice, especially for first-line treatment (NICE, 2009). Generally all treatment guidelines suggest that a SGA is used first line.
   Fortunately antipsychotics are effective in both the acute and maintenance treatment of schizophrenia and other psychotic disorders. They all differ in their pharmacodynamics, pharmacokinetics, overall efficacy/effectiveness, and tolerability, but perhaps more importantly, response and tolerability differ between patients. Unfortunately, the variability of individual response suggests that there is no clear first-line antipsychotic suitable for all (Taylor et al., 2015).
   This person may choose any of the antipsychotics available, either typical or atypical. In practice, the choice is usually based on the likelihood of inducing minimal acceptable side-effects. Arguably young women do not tend to choose drugs that cause marked increase in weight such as olanzapine or quetiapine. The patient will generally choose to continue using a drug that has already been prescribed while acutely unwell if it is efficacious and tolerable.
2. A 51-year-old male with a family history of schizophrenia is recalled to hospital again for shouting at traffic on the side of a busy motorway. At times he experiences marked positive and negative symptoms. He has taken both typical and atypical antipsychotics in the past.
   As recommended by the SIGN and NICE guidelines, this person is a candidate for clozapine because he has had more than two antipsychotics, one of them has been an atypical (NICE, 2009; Taylor et al., 2015). It is important to start treatment at a low dose, increase the dose slowly to minimize adverse effects, and increase it to the lowest effective dose (Taylor et al., 2015). The pharmacists' role in the MDT for this person would include:
   Ensuring registration with the appropriate monitoring service, checking whether the MDT is aware of the requirements for monitoring FBC when prescribing clozapine. These requirements vary in different parts of the world. For example, in the United Kingdom, the requirements are a weekly FBC for the first 18 weeks that clozapine is taken then bi-weekly for up to 1 year and then 4-weekly FBCs.
   Counsel the patient and family/carer if possible about clozapine—ensuring that the patient has some insight or capacity to understand, i.e., not while floridly psychotic. In practice, this is not always possible. The key to the potential success of clozapine is to ensure adherence, which is often the greatest challenge.
   Discuss any nonprescribed therapies the patient might wish to use (including complementary therapies) with the patient and carer if appropriate (NICE, 2009).
   Managing a switch from the current prescribed antipsychotic to clozapine, this can be more difficult if the previous antipsychotic was a depot formulation.
   Listening to the patient once established on clozapine and attempting to resolve any issues with adverse effects. For example, hypersalivation can be successfully treated with 300 μg hyoscine hydrobromide (Kwells) taken up to three times daily with monitoring and follow-up to ensure effectiveness. Desmopressin nasal spray (10–20 μg nocte) is also an effective way to treat nocturnal enuresis if lifestyle changes are ineffective. Nocturnal enuresis can occur at any time while taking clozapine and is very distressing, which can affect adherence. There are strict rules about monitoring FBCs to prevent agranulocytosis. There are now more deaths from gastrointestinal stenosis and obstruction than from clozapine-induced dyscrasias (Shirazi et al., 2016). Ensuring that a patient is not constipated can be difficult because many people do not like discussing their bowel habit or may be unaware they are constipated. The Porirua protocol is now widely considered to be a useful guideline and was introduced in New Zealand following a fatality during 2017 (Every-Palmer et al., 2017).

   Checking there are no drug/drug interactions.
   Chemotherapy—due the neutropenia caused secondary to bone marrow suppression.
   Care needs to be taken with concurrently prescribed medications that prolong the QTc interval.
   When relevant smoking status should be discussed because the effects of cigarette smoke can alter clozapine levels by up to 70% (Lowe and Ackman, 2010).
   Illicit drug use—cannabis cessation can cause clozapine intoxication by stopping the induction of CYP1A2 (Zullino et al., 2002).

Consider future potential comorbidities, e.g., family history of myocardial infarction, diabetes mellitus—may need baseline ECG or HbA1c, respectively.

Education about the differences between FBC and clozapine plasma levels. Requesting the latter should be undertaken if poor adherence is suspected, change in smoking status, constipation, or other side effects that have changed significantly. Once clozapine and norclozapine levels are received, the MDT might need support when interpreting the results and then alter the clozapine dose accordingly if required.

Ensuring that the GP and community pharmacy are kept up-to-date with medication prescribed in the hospital (especially clozapine).

Organizing the smooth transfer of clozapine prescribing from an inpatient setting to a community setting or vice versa.

Conclusion

The aims of the chapter are to give an overview of schizophrenia, its treatments (including side effects), and how pharmacists play an essential role within the multidisciplinary team, using case study examples. Schizophrenia is a long-term, serious mental health condition caused by a combination of genetic and environmental factors.

The condition most commonly emerges during adolescence or early adulthood and is a leading cause of disability in individuals aged between 15 and 44 years (Rössler et al., 2005, 2013). Three main types of symptom contribute to the diagnosis of schizophrenia, i.e., positive, negative, and cognitive symptoms.

Numerous antipsychotics have been developed, each with their own side effects. However, FGAs tend to cause EPSEs on first exposure, whereas SGAs are more often associated with weight gain and diabetes. Tandon et al. (2008) state that there is no convincing evidence to support the preferential use of SGAs over FGAs, especially if the EPSEs can be minimized. In both the CATIE and CUtLASS trials, there was no clear separation in the quality of life or patient responses between FGA and SGA.

Clozapine is the gold standard antipsychotic used for treatment-resistant schizophrenia and is the only medicine shown to reduce the rate of suicide and hospitalization (Meltzer, 2010; Modestin et al., 2005; Tiihonen et al., 2009).

Pharmacists are actively involved in facilitating open, impartial, considered decision-making about which antipsychotic is the most appropriate for an individual. Choice of antipsychotic should be well informed and discussed with the patient and include where possible support from family members or carers, which will in turn aid adherence.

Pharmacists have been involved in MDTs for many years and demonstrate a variety of specialist skills, including but not limited to, making interventions; monitoring outcomes and follow-up, aiding adherence; discussing future recommendations; aiding a smooth transition from secondary to primary care; and educating staff, patients, and families/carers.

Acne Vulgaris

Paul Jarrett, Middlemore Hospital, Auckland, New Zealand; The University of Auckland, Auckland, New Zealand

Learning Objectives

To Understand in Acne vulgaris:

- Pathophysiology
- Psychosocial burden
- Indications for acne treatment
- Topical and systemic treatments
- Common adverse effects of acne treatments
- Pharmacists role in the multidisciplinary care of patients with acne vulgaris

Key Points

- A global disease.
- Not confined only to adolescence but also seen in children and especially post adolescence (>25 years old) age groups.
- Psychosocial burden is significant and does not always correlate with the severity of the disease.
- Patients need reassurance that effective treatments exist for acne vulgaris.
- Treatments need to be targeted to specific patient circumstances.
- Do not use topical or systemic antibiotics as monotherapy.
- With effective early intervention permanent acne scarring can be minimised.
- Pharmacists can treat mild, non-scarring, predominantly comedonal acne.

- Pharmacists should not treat extensive inflammatory acne, scarring acne or acne with a significant psychosocial component.
- Pharmacists can reinforce key messages about acne treatments as part of the healthcare team.

Epidemiology

Acne vulgaris (henceforth referred to as acne) is a common disorder ranking 8th in the most prevalent global diseases (Hay et al., 2014). It is a common and possibly universal disease of adolescence and early adulthood with an 85% prevalence rate recorded in 12–24 year olds in North America (White, 1998). In other locations prevalence rates recorded in students and institutions are: Far East (9.8%–91.3%), Europe (0.10%–82%), Australasia (14%–91%), Africa (0.2%–36%), Middle East (13%–93.2%), and South America (3%–42%) (Tan and Bhate, 2015).

Although acne is commonly considered a disease of adolescence and early adulthood, it can affect a wide age range including young and older patients. Neonatal acne may be inflammatory due to maternal hormones (Henderson et al., 2000) with 20% having an acneiform eruption commonly settling by 3 months (Mancini et al., 2011) as the maternal hormonal influence wanes, infants may develop non-inflammatory comedonal acne. In males, acne prevalence and severity correlates with advancing pubertal maturation with acne lesions identified in 9 year olds (Lucky et al., 1991). In females acne lesions can also be identified in 9 year olds with early development of comedones associated with more severe disease (Lucky et al., 1997). Acne prevalence in an older European population was reported at 64% in 20–29 year olds, 43.5% in 30–39 year old, 24.3% in 40–49 years old 9.1% in 50–59 years old and 12.7% in those greater than 59 years (Schafer et al., 2001).

Adult acne becomes more prevalent with age in females compared to men both in Europe and Asia (Goulden et al., 1999; Shen et al., 2012). Three types of female acne are identified; "Continuous" where acne never settles from teenage years to adulthood, "Late Start" occurring after the age of 25 years and "Relapse" having had the disease in adolescent years which settles but only to recur in adulthood (Preneau and Dreno, 2012).

There are many different scoring systems for the grade of acne, which makes the epidemiology of the severity of the disease difficult. Generally, acne improves with increasing age (Goulden et al., 1999; Perkins et al., 2012). The risk for acne increases after 11 years of age to a prevalence of 12.1% at 17 years of age in a North American population, more prevalent in boys aged 16–17 years and higher socio-economic groups (Silverberg and Silverberg, 2014). Using objective grading, adult female acne usually is less severe (Goulden et al., 1999; Perkins et al., 2012).

Information on the differences in the epidemiology of acne between ethnicities is limited. In North American acne was found in Asian, African-American, Caucasian and Hispanic women and this study also found acne in women from the UK (Caucasian and Indian), Italy (Caucasian) and Japan (Asian) (Perkins et al., 2011). Severe acne was more prevalent in those of white skin compared with African–American/black, Asian and multiracial groups (Silverberg and Silverberg, 2014). In Peru, Peruvian Indians have significantly less acne than Peruvian whites or Mestizos (Freyre et al., 1998). Interestingly, no cases of active acne were observed on the Kitavan Islanders of Papua New Guinea or the Aché hunter gatherers of eastern Paraguay (Cordain et al., 2002).

Pathophysiology

The pathogenesis of acne is not completely understood, particularly the correct sequence of events leading to comedo formation and then rupture. The clinically diagnostic hall mark lesion of acne is the macrocomedo (>1 mm in diameter) which can be open ("blackhead") or closed ("whitehead") (**Figs. 1** and **2**). The development of a comedo is a complex interaction between occlusion of

Figure 1 Open comedones "Blackheads" (examples indicated by *arrows*). *Source: Courtesy of DermNet New Zealand.*

Figure 2 Closed comedones "Whiteheads" (Examples indicated by *arrows*). *Source: Courtesy of DermNet New Zealand.*

Figure 3 Inflammatory papules and pustules (examples indicated by *arrows*). *Source: Courtesy of DermNet New Zealand.*

the pilosebaceous duct due to cornification, increased sebum production and the bacterium *Propionibacterium acnes*. An inflammatory response centered around the comedo produces the clinical papule or pustule (Fig. 3) which may resolve by fibrosis causing scarring (Figs. 4–6).

The sebaceous gland is a lobular structure with a duct communicating with a hair follicle. The duct is lined by stratified squamous epithelium. Ductal hyperproliferation in acne has been confirmed by immunohistochemistry (Knaggs et al., 1994). Hyperproliferation causes ductal hypercornification with subsequent retention of ductal corneocytes and blockage of the duct lumen. This process forms the basis of microcomedo formation but with sebum and keratinocyte debris accumulating until the larger clinically visible macrocomedo is formed (Gollnick, 2015).

Sebum production is derived from the sebaceous gland, which is under the control of androgens. Testosterone and 5α dihydrotestosterone stimulate the proliferation of facial sebocytes in a dose dependent manner (Akamatsu et al., 1992). Sebocyte activity is also controlled by a number of other factors including growth hormone, insulin-like growth factor and melanocortins (Schneider and Paus, 2010).

P. acnes is an oxygen tolerant, anaerobic bacterium which colonises the pilosebaceous duct (Gollnick, 2015). The exact role of this organism in the pathogenesis of acne is uncertain. *P. acnes* is associated with inflammation through a variety of mechanisms including secreted inflammatory mediators and both the innate and cellular immunity pathways (Beylot et al., 2014). Acne affected follicles show a higher prevalence of *P. acnes* colonisation (Jahns et al., 2012). Although *P. acnes* is found in both affected and unaffected skin, an examination of the skin microbiome reveals that different strains are implicated in acne patients (Fitz-Gibbon et al., 2013).

The inflammatory response is complex and occurs at the early stages of the comedone formation with expression of interleukin 1 (Dreno et al., 2015a; Jeremy et al., 2003). Interleukin 1α has been shown in vitro to promote infundibular cornification (Guy and Kealey, 1998) and interleukin 1β has been demonstrated to drive inflammatory responses to *P. acnes* (Kistowska et al., 2014).

Figure 5 Extensive acne scarring on the back. *Source: Courtesy of DermNet New Zealand.*

Figure 6 Hypertrophic and keloid acne scarring. *Source: Courtesy of DermNet New Zealand.*

CD4+ T cells are present in early acne lesions (Jeremy et al., 2003) and in vitro *P. acnes* can promote T helper (Th) 17/Th1 responses by inducing interleukin 17, which is a proinflammatory cytokine and interferon γ from CD4+ T cells (Kistowska et al., 2015).

Psychosocial Factors

The psychosocial effects of acne even of mild disease should not be underestimated. The impact of acne is significant. It ranks second in the list of skin diseases measured by the Global Burden of Disease Study 2013 with a disability-adjusted life year score of 0.29% (Karimkhani et al., 2017). There are a number of validated skin specific questionnaires to assess quality of life in skin disease (Gieler et al., 2015). Patients with severe acne report levels of social, psychological and emotional problems as great as those with chronic disabling asthma, epilepsy, diabetes, back pain or arthritis (Mallon et al., 1999). The patient's assessment of their acne frequently differs from that of the health care professional which is a phenomenon not only confined to acne (Mallon et al., 1999; Jones-Caballero et al., 2007; Chen et al., 2015).

The largest group of acne patients with whom pharmacists will interact are adolescents and young adults as they have the greatest prevalence of the disease (see Epidemiology). Adolescence is a time of great change for the individual sometimes combined with egocentrism and preoccupation with self (Revol et al., 2015). Psychological distress and psychological vulnerability can be a particular feature of this period of life (Misery, 2011). Among adolescents with a lot, compared to those with little acne, suicidal ideation is reported three times as frequently by boys (22.6% vs. 6.3%) and twice as frequently by girls (25.5% vs. 11.9%) and those with substantial acne also report low attachment to friends, not thriving at school, never having had a romantic relationship and never having sexual intercourse (Halvorsen et al., 2011). 21st century adolescents have unprecedented access to communication and information which may help or hinder appropriate interventions for their acne. The pharmacist needs to be mindful of these special issues when advising this age group.

Adult female acne also requires particular attention to psychosocial issues. Women over 25 years of age with localised acne are more likely to report higher stress levels and having a psychologically stressful job (Dreno et al., 2015b). Facial acne in adult women also reduces quality of life, is associated with anxiety and depression, impacts self-confidence and impairs ability to concentrate on work or school (Callender et al., 2014; Tanghetti et al., 2014). Although acne tends to improve with age in women (Perkins et al., 2012) it has a significant psychosocial burden.

Diagnosis

The diagnosis of uncomplicated acne is clinical and involves taking a history and examining the patient. There are no specific investigations required unless there is suspicion of other co-morbidities. Acne can be associated with endocrine disorders such as polycystic ovarian syndrome and rarely with other disorders including: cushing syndrome, congenital adrenal hyperplasia, andogen secreting tumours and acromegaly. Rare non endocrine associations include: Apert syndome, Synovitis Acne Pustulosis Hyperostosis Osteitis Syndrome (SAPHO), Beçhet syndrome and PAPA syndrome (pyogenic arthritis, pyoderma gangrenosum and acne. Medication can induce acne and "acneiform" eruptions including corticosteroids, anabolic steroids, progesterones, lithium, isoniazid, phenytoin, halogen exposure, epidermal growth factor receptor inhibitors and B vitamins including riboflavin (B2), pyridoxine (B6) and cyanocobalamin (B12) (Lolis et al., 2009). Pomade acne, first described in African–American men, is due to the application of occlusive cosmetic oils and creams to the skin (Plewig et al., 1970).

Severe acne in adolescents has recently been found to be associated with other comorbidities including sinopulmonary disease; sinus infection, non-streptococcal sore throat, asthma, non-asthmatic lung disease and gastrointestinal disease including; reflux/heartburn, abdominal pain, nausea and vomiting and food/digestive allergy but the significance of these associations is uncertain (Silverberg and Silverberg, 2014).

History and Examination

In the setting of a busy pharmacy practice a quiet and private space or room should be set aside for the history and examination. Patients are unlikely to volunteer sensitive information in a public setting.

A complete history should be taken. Important elements of the history are the duration, previous treatments and psychosocial effect of the disease. Other components of the history are relevant previous illness, current medication and previous recorded drug allergy or intolerance. A positive family history of acne is often obtained. A detailed social history should include an occupational history, cosmetic usage, contraception and family planning.

Be prudent in the need to ask for a chaperone. The examination should be carried out in a well-lit area and if needed with the aid of magnification. All components of acne should be assessed including comedone, papule, pustule, nodule and scarring. Examine the face and the trunk both front and back. A papule is defined as an elevated, solid, palpable lesion $\leq$1 cm in diameter, a nodule as an elevated, solid palpable lesion $>$1 cm in diameter located primarily in the dermis and/or subcutis and a pustule as a circumscribed lesion containing pus (Nast et al., 2016b). Comedones can be difficult to see and may require gentle stretching of the skin and observation at a shallow angle (**Figs. 1** and **2**). Failure to identify significant comedonal disease can result in suboptimal therapy and significant flaring especially when patients are treated initially with isotretinoin (See Systemic Treatment) (Cunliffe et al., 2000).

Severe inflammatory, nodular acne as well as superficial inflammatory lesions, all have the potential to scar and affect both sexes equally in up to 95% of patients. Different patterns of scarring are described including ice-pick, macular atrophic, follicular macular atrophic, hypertrophic and keloid (Layton et al., 1994) (see **Figs. 4–6**).

Differential Diagnosis

Usually the diagnosis of acne is self-evident when the cardinal features of the disease are identified. Acne may co-exist with other diseases of the face and trunk. However, there are a number of common papular and inflammatory conditions on the face and truck that can potentially mimic acne. Non-inflammatory lesions mimicking comedones include milia, which are small white dome shaped keratinous cysts approximately 1–2 mm in diameter (**Fig. 7**) and adnexal tumours such as syringomata, which are 1–2 mm skin colored papules often around the eyes and derived from sweat glands (**Fig. 8**). Inflammatory conditions include rosacea (**Fig. 9**) and periorificial dermatitis (**Fig. 10**). Rosacea is an inflammatory condition causing flushing, erythema, papules and pustules on the face. The absence of comedones in the presence of these symptoms and signs is a useful diagnostic clue. Periorificial dermatitis describes erythema, papules and pustules around the eyes or mouth. It may be idiopathic or induced by creams including topical steroids and cosmetics.

Pharmacological Management of Acne Vulgaris

The choice of treatment will depend on many factors including the severity of the acne, psychosocial impact, patient choice and previous treatments (**Fig. 11**). The specific treatment options available vary between countries and will be governed by different legislation. Topical agents are usually appropriate for mild, facial acne and short term use ($<$12 months). They are difficult to use on

Figure 10 Perioral dermatitis. *Source: Courtesy of DermNet New Zealand.*

the trunk. Systemic treatment, with or without topical treatment, is indicated for failed topical treatment, extensive involvement including face and trunk or severe acne at any site. Women who are attempting to conceive or who are pregnant and children need special consideration. There is increasing concern about the development of antimicrobial resistance with prolonged use of topical and systemic antibiotics in the management of acne. In addition to their antimicrobial action antibiotics may have an anti-inflammatory effect in acne (Walsh et al., 2016).

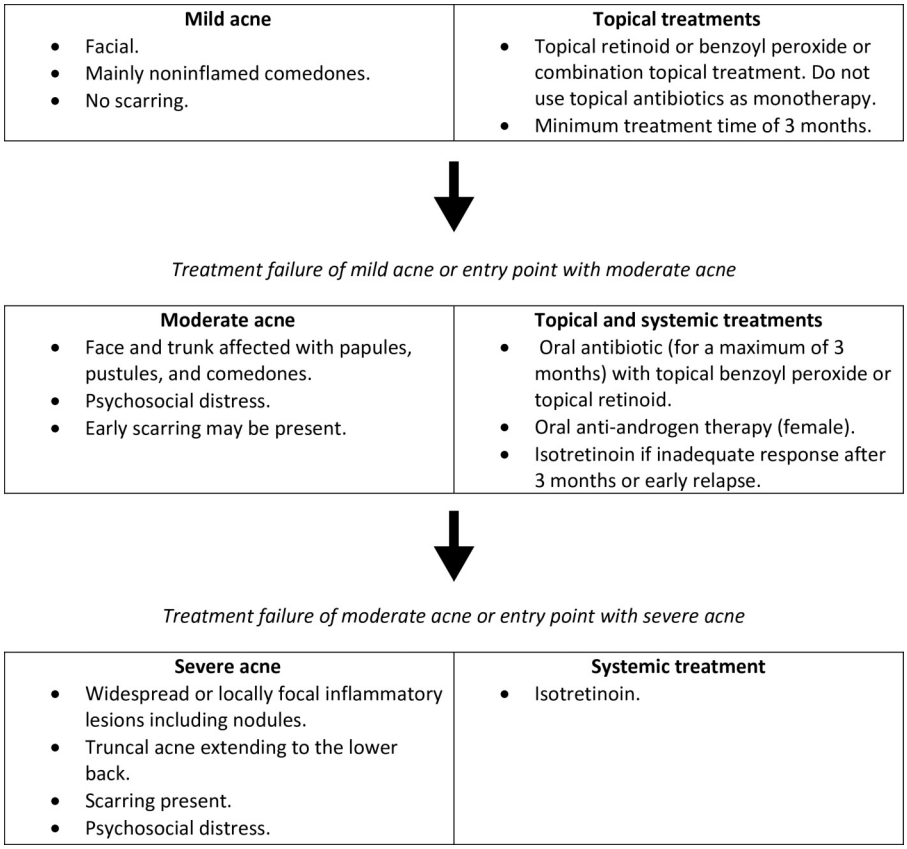

Figure 11 Pharmacological management of acne vulgaris.

Pharmacological interventions for acne should be re-evaluated after 8 weeks for mainly comedonal or mild inflammatory acne or 12 weeks for severe disease (Gollnick et al., 2016).

Topical Agents

Topical agents include salicylic acid, benzoyl peroxide, retinoids, azelaic acid, sulphones, and antibiotics. There are also combination topical treatments.

Salicylic Acid

Salicylic acid is a common over the counter preparation for acne and it is also combined with other topical agents such as clindamycin and benzoyl peroxide to treat acne (Akarsu et al., 2012). Salicylic acid can be used to treat acne because it has keratolytic and comedolytic effects (Akarsu et al., 2012; Degitz and Ochsendorf, 2008).

Benzoyl Peroxide

Benzoyl peroxide is widely available and usually accessible as an over the counter medicine in pharmacies. The exact mechanism of action is uncertain but it has both antimicrobial effect against to *P. acnes* and keratolytic activity (Lamel et al., 2015; Mohd Nor and Aziz, 2013). When benzoyl peroxide is encapsulated in nanoparticles the antimicrobial effect is mediated by direct cell wall damage (Friedman et al., 2013), which may be the reason why resistance by *P. acnes* is not described (Mohd Nor and Aziz, 2013; Lamel et al., 2015).

Benzoyl peroxide is available in differing concentrations including 2.5%, 5%, 10% and formulations including lotion, cream or a gel. A systemic review of randomised vehicle-controlled trials of different preparations and strengths of benzoyl peroxide demonstrated a statistically significant average overall reduction in non-inflammatory lesions of 41.5% and inflammatory lesions of 52.1% (Lamel et al., 2015).

Treatment should be initiated with the lower strength preparations and application is usually twice daily depending on the tolerance of the patient. Side effects include bleaching fabric and hair, irritant contact dermatitis and rarely severe hypersensitivity reactions including angioedema, periorbital oedema, bronchospasm, and syncope (Administration, 2014).

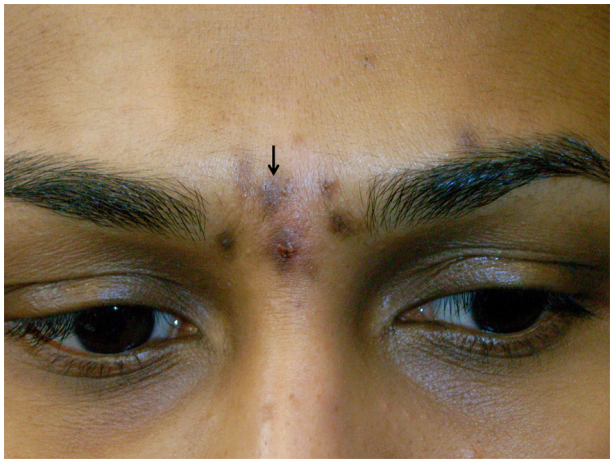

Figure 12 Post-inflammatory hyperpigmentation due to acne (example indicated by *arrow*). *Source: Courtesy of DermNet New Zealand.*

Retinoids

Topical retinoids are important agents in the treatment of acne particularly for their comedolytic effect and in combination with other agents for the treatment of all types of acne (Zaenglein et al., 2016). Consensus guidelines for the management of predominantly comedonal facial acne recommend topical retinoids as the first line approach (Gollnick et al., 2016). Multiple randomised controlled studies have verified the effectiveness of these agents for the management of acne (Vera et al., 2017). Topical retinoids include; isotretinoin, tretinoin, adapalene and tazarotene available in different formulations including cream, gel and foam. There is a role for topical retinoids in maintenance treatment after discontinuing oral therapy (Zaenglein et al., 2016). Common side effects are dryness, peeling erythema and irritation and photosensitivity. Topical retinoids are contra-indicated in pregnancy and women of childbearing age must not become pregnant while using these drugs, as retinoids are highly teratogenic.

Azeleic Acid

Azaleic acid has antibacterial, anti-keratinizing and anti-inflammatory effects (Vera et al., 2017; Zaenglein et al., 2016). Azaleic acid has an additional benefit of having reversible inhibitor tyrosinase activity, which is a key enzyme for melanogenesis (Nazzaro-Porro, 1987), which may reduce the problem of post inflammatory hyperpigmentation associated with acne, especially in those patients with skin of colour (**Fig. 12**). Local skin irritation may be experienced as a side effect.

Sulphones

Topical dapsone is available as a treatment for acne. The mechanism of action is not fully understood but it may work as an anti-inflammatory and anti-bacterial agent (Vera et al., 2017; Zaenglein et al., 2016; Aslam et al., 2015). Women may derive more benefit compared to men using topical dapsone (Tanghetti et al., 2012).

Antibiotics

Monotherapy with topical antibiotics for the treatment of acne is no longer recommended because of the development of antibiotic resistance (see section "Systemic Antibiotics") (Vera et al., 2017; Zaenglein et al., 2016; Sandoval et al., 2014). If a topical antibiotic is to be used then it should be used in combination with a non-antibiotic agent such as benzoyl peroxide to minimise the risk of resistance. Clindamycin and erythromycin are commonly used.

Systemic

Oral drugs used to treat acne are antibiotics, hormonal agents, and isotretinoin.

Antibiotics

Systemic antibiotics have been used in the treatment of acne for many years. However, the routine use of these agents as monotherapy in the management of acne is being increasingly questioned in the light of the development of resistance and the need for antibiotic stewardship (Dreno, 2016; Adler et al., 2017; Walsh et al., 2016). The use of oral antibiotics as the only treatment for acne is not recommended and guidelines suggest the addition of a non-antibiotic topical agent such as a topical retinoid, benzoyl peroxide or azaleic acid in addition to the oral antibiotic (Dreno, 2016; Adler et al., 2017). Limiting the duration of treatment with oral antibiotics ideally for 3 months, may limit resistance development (Nast et al., 2016a; Zaenglein et al., 2016). Resistant strains of *P. acnes* can result in lack of response to treatment of acne and serious infection such as endocarditis, prosthetic joint infection and

breast implant infections can occur (Walsh et al., 2016). Furthermore, the use of antibiotics for acne exerts selection pressure on other bacteria of the microbiome, which can develop resistance and this is of concern particularly for *Staphylococci* (Walsh et al., 2016).

A large number of different types of antibiotics have been used including tetracyclines (e.g., doxycycline, minocycline), macrolides (e.g., erythromycin, azithromycin), trimethoprim and trimethoprim/sulphamethoxazole (Zaenglein et al., 2016). Each group has a number of different potential side effects and these include gastrointestinal upset, drug eruptions, photosensitivity and hypersensitivity reactions of varying severity. Tetracyclines should not be prescribed to children under 12 years of age to prevent enamel staining in secondary teeth. Minocycline can induce a lupus-like syndrome in females with a rate of 52.8 cases per 100,000 prescriptions compared to 17.2 cases per 100,000 prescriptions for oxytetracycline (McHugh, 1999).

Hormonal Agents

These agents are combined oral contraceptives, cyproterone acetate and spironolactone. Combined oral contraceptives contain oestrogen and synthetic progesterone and are effective in reducing inflammatory and non-inflammatory acne (Arowojolu et al., 2012). They reduce the effect of androgens by reducing ovarian androgen production and by a secondary effect of increasing steroid hormone binding globulin, which lowers circulating testosterone levels (Shaw, 2002). Cyproterone acetate is an androgen receptor blocker and synthetic progesterone. It can be used alone and in combined oral contraceptives although it is often added at a low dose so it is uncertain if it acts through its androgen blocking role or its combined effect on cycle regulation (Shaw, 2002). The use of these medications requires considerable oversight and attention to suitable eligibility including age, smoking history, breast cancer history, hypertension, diabetes, pulmonary or deep vein thromboembolism, cardiovascular disease, weight, headache, hepatic disease and dyslipidaemia (Zaenglein et al., 2016).

Spironolactone is an androgen receptor antagonist (Garthwaite and McMahon, 2004). The use of this drug in acne is "off label". It can inhibit 5α-dihydrotestosterone in human sebaceous glands and in vitro has been demonstrated to androgen-induced human sebocyte proliferation (Akamatsu et al., 1993). A systematic review of randomised controlled trials concluded that there was limited quality evidence to use spironolactone in usual doses (≤100 mg/day) in adult females (Layton et al., 2017). Electrolyte disturbance can occur with the use of spironolactone particularly hyperkalaemia.

Isotretinoin

Isotretinoin is a derivative of retinoic acid and is an effective treatment for patients with acne. It decreases the size of sebaceous glands, the production of sebum and normalises follicular hyperkeratinisation (Zaenglein et al., 2016; Peck et al., 1979; Torma, 2001). The indications for the use of isotretinoin are: for severe nodular acne, treatment resistant acne or acne that is causing significant physical or psychosocial distress (Zaenglein et al., 2016). Depending on the severity, dose and patient tolerance of isotretinoin, treatment duration may be many months. Isotretinoin is commonly started at a low dose, which is increased. Using a lower dose of isotretinoin over a longer time period may be just as effective as a higher dose used for shorter periods but associated with significantly fewer adverse side-effects (Rademaker, 2013).

There are a number of potentially significant side effects with the use of isotretinoin. Mucocutaneous dryness is almost universal with dry skin, dry eyes and a propensity for nose bleeds. These can be mitigated by reducing or temporarily stopping the drug and with the use of appropriate emollients. It is common to experience a flare of acne when starting isotretinoin at higher doses and special care is needed initiating treatment in extremely severe cases when additional therapy such as systemic steroids or oral antibiotics may be required to reduce the risk. Isotretinoin is highly teratogenic and women must not fall pregnant whilst taking the drug. Women who are sexually active must practice effective contraception and for this to be established before isotretinoin is started. Isotretinoin causes skin fragility therefore patients should avoid hair waxing. Isotretinoin is a common photosensitising drug so care needs to be taken with sun protection where needed.

Isotretinoin can rarely cause abnormalities of lipids and liver function therefore some patients will have these monitored prior to and during therapy. A full blood count may also be monitored. Pregnancy testing prior to starting isotretinoin is essential with periodic monitoring during the treatment course.

Patients who have been treated with isotretinoin may wish to have further treatment for acne scarring. Although there are reports of adverse outcomes following treatment whilst on isotretinoin (Zachariae, 1988; Rubenstein et al., 1986) leading to the recommendation to defer such treatments for 6–12 months after stopping isotretinoin, more recent evidence suggests this restriction may not be needed (Prather et al., 2017; Zaenglein et al., 2016).

An important drug–drug interaction of isotretinoin is with tetracyclines. Tetracyclines are often used to treat acne and if they are unsuccessful it is common for a switch to be made to isotretinoin. The development of severe headache due to benign intracranial hypertension is a potential side effect of both of these drugs and more likely if they are inadvertently taken concurrently. Additionally, if patients are using a topical agent to treat their acne this should be discontinued as excessive dryness can be problematic. Patients who take vitamin supplements should avoid vitamin A. Isotretinoin is a derivative of this vitamin and side effects could be compounded if they are taken together.

The role of isotretinoin in mood change, depression and suicidal ideation is uncertain and not proven. A meta-analysis of 31 studies concluded that isotretinoin did not appear to be associated with an increased risk of depression and that the treatment of acne appeared to ameliorate depressive symptoms (Huang and Cheng, 2017). Treating patients who are depressed because of their acne is beneficial. Similarly, at present, evidence is insufficient to prove either an association or causal relationship between isotretinoin and inflammatory bowel disease (Zaenglein et al., 2016).

Non-Pharmacological Treatment

The evidence around the non-pharmacological interventions for the management of active acne and acne scarring is limited.

Light Therapy

Various light devices have been used to treat acne including intense pulsed light, narrowband blue, narrowband red, combined blue–red light and lasers but there are limited studies (Handler et al., 2016; Zaenglein et al., 2016). These devices may be more beneficial for inflammatory rather than non-inflammatory acne (Handler et al., 2016). Their mechanism of action is not fully understood but may include activating natural porphyrins produced by *P. acnes*, reducing keratinocyte inflammation and destroying *P. acnes* (Handler et al., 2016). Photodynamic therapy involves applying a photosensitizing agent to the skin such as aminolaevulinic acid, which is preferentially absorbed by the pilosebaceous units. A light emitting device is used to activate the agent damaging the pilosebaceous unit and reducing *P. acne* (Ozog et al., 2016; Zaenglein et al., 2016). Of the light therapies, most evidence exists for the use of photodynamic therapy (Zaenglein et al., 2016).

Chemical Peels

Chemical peels may improve acne and a wide variety of agents have been used including glycolic acid and salicylic acid to induce a partial-thickness skin injury by reducing keratinocyte adhesion and plugging (Kessler et al., 2008). These two agents may have a role for the management of non-inflammatory acne but repeated treatments are needed and high quality evidence is lacking (Zaenglein et al., 2016; Abdel Hay et al., 2016).

Diet

The role of diet in acne is unclear and no specific dietary changes are recommended (Zaenglein et al., 2016; Fiedler et al., 2017). There is some evidence to support an association with high glycaemic diets (Fiedler et al., 2017; Kwon et al., 2012; Smith et al., 2007).

Scarring Treatment

Scarring is the consequence of inflammatory acne. With effective treatment options, especially isotretinoin, all options should be explored to prevent scarring however it is inevitable that some patients will scar. Different types of acne scar are formed including keloid, hypertrophic and atrophic (**Figs. 4–6**). There are a wide variety of modalities to treat scars depending on the subtype including lasers, dermabrasion, chemical peels, needling, subcision, punch excision, radiofrequency, stem cell therapy, fat transplantation, platelet rich plasma and fillers (Zaleski-Larsen et al., 2016; Sanchez Viera, 2015). However, a Cochrane review noted the lack of high-quality evidence about the effects of different interventions for acne scars (Abdel Hay et al., 2016). Silicone gel sheets are available for purchase and have been used for hypertrophic and keloid scars. However, another Cochrane review reported weak evidence of benefit for the use of silicone gel sheeting (O'Brien and Jones, 2013).

Role of the Pharmacist in the Management of Acne Vulgaris

Pharmacists may be the first health care professional with whom a patient with acne contacts and this presents an opportunity to offer cost effective advice. Take a careful history with particular attention to psychosocial issues and examine the patient in a well-lit room including the chest and back. A comprehensive assessment will guide appropriate management. The pharmacist will have access to a range of topical treatments available for general sale or pharmacist only sale depending on the regulatory environment.

General advice is useful. It is important to reassure the patient that effective treatment options exist and that a therapeutic "ladder" can be followed utilising topical agents, topical and systemic agents then isotretinoin if needed, with some requiring a prescription. It is important to place the patient on the appropriate initial rung of the ladder after a thorough assessment (**Fig. 11**). Picking or squeezing comedones, papules and pustules is not recommended as if done with vigour this may contribute to the inflammatory response and subsequent scarring. A variant of acne called acne excoriée exists which can form part of a compulsive skin picking disorder, which is frequently associated with scarring. Avoiding occlusive make up and the use of non comedogenic products will help. Cigarette smoking has been associated with post-adolescent acne (Capitanio et al., 2009). Some patients perceive acne as a dirty disease and wash excessively. This should be discouraged as excessive washing will lead to irritancy and compound the effects of retinoids. Encourage the patient to wash normally using gentle soaps and washes. There is a lack of evidence for the use of complementary therapies in the treatment of acne including herbal medicine, acupuncture or wet cupping and low quality evidence from single trials for the use of tea tree oil, bee venom and low glycaemic load diet (Cao et al., 2015).

Pharmacists are well placed to manage mild, non-scarring predominantly comedonal acne of the face. Having decided on a therapy, clear and simple instructions are needed. Patients should be told that they may need to wait up to 8–12 weeks before they see any benefit. Some patients only apply topical agents to the spots that they can see on their face so it is important to clearly state

that the preparation should be applied to all of the skin of the face. The finger- tip unit is a useful concept (Long and Finlay, 1991). One finger–tip unit is the amount of cream expressed from the distal skin-crease to the tip of the index finger and approximately 2½ finger-tip units are required to treat the face and neck so approximately 1 or 2 finger-tip units would be required to treat a face. The patient should be reviewed at 8–12 weeks and if clear improvement is noted then continue with the therapy. However, if there is no improvement or deterioration despite compliant use of the preparation the patient should be referred to their primary care physician or a dermatologist. It is useful to ask the patient to bring the tube of cream so that consumption and therefore compliance can be estimated from the quantity used.

Pharmacists have a choice of the type of preparation to recommend to patients with acne, either as active treatment or an emollient to mitigate dryness due to treatment effect. Preparations may include lotions, gels, foams, creams and ointments. In many countries benzoyl peroxide is available as an over the counter medication and, provided there are no contra-indications, is a good starting point for pharmacists. Patient preference partly will drive choice as well as the need for therapeutic efficacy. Treatments will fail if the patient does not use them because they are too irritant or look unappealing when applied. Creams because of their effect of occlusion and hydration of the epidermis enhancing penetration of the product, are more efficacious than gels or lotions but less cosmetically appealing. A useful therapeutic manoeuvre is to recommend that the active treatment, if it is occlusive and cosmetically visible, is applied at night and removed in the morning. If needed a lighter and more cosmetically appealing product can be used during the day.

Patients with extensive acne, significant inflammatory acne at risk of scarring or with established scarring and those with significant psychosocial concern regardless of the extent of acne should not be managed by pharmacists but be referred to their primary care physician or dermatologist.

Pharmacists are ideally placed to work with the primary care physician or dermatologist when patients attend to have their script dispensed. A good working relationship between the health care professionals involved is important so that seamless multidisciplinary advice is offered to the patient. Pharmacists are likely to have oversight of all the patient's medications and have knowledge of their over the counter purchases so can check for potential drug–drug interactions for example the potential loss of efficacy of the oral contraceptive when starting oral antibiotics for acne if the antibiotic induces vomiting or diarrhoea and appropriate management should be advised.

Pharmacists can play a pivotal role in the management of a patient on isotretinoin. The point of dispensing offers an opportunity to reinforce the important issues around this medication. A degree of skin dryness is universal with this medication and which may also affect the lips and mucous membranes. Patients who use contact lenses can find them too irritating to use whilst on isotretinoin because of ocular dryness. It is important to give suitable advice about emollients for the skin, dry eyes and lips. Isotretinoin commonly photosensitises patients and sun protection needs to be encouraged with suitable clothing, sun protection behaviour and adequate use of sunscreens. There is confusion around sunscreens and they are often under used by patients so this is another opportunity to offer an additional health care message (Chao et al., 2017; Petersen and Wulf, 2014). Some sunscreens are combined with a moisturiser and there are lip slaves that contain sunblock, which should also be advised.

In a recent study, using a case vignette technique, pharmacists were able to confidently and appropriately recommend antibiotics when presented with a limited range of diseases, including moderate acne (Ung et al., 2016). There is the potential for expanding the pharmacist's role in the management of acne in the future. However, more research would need to be conducted to evaluate whether this would be able to be appropriately managed in the community setting given the pressing need for antibiotic stewardship, the probability of antibiotics being used less and non-antibiotic therapies being used more frequently for the management of acne in the future.

Central to good care is effective, and if needed robust, communication between the patient, pharmacist and doctor. There is a danger of fragmentation of care when individual practitioners do not communicate with the potential for adverse outcomes. Good communication ensures that all three participants in the therapeutic triad know what the other is doing.

Learning Objectives

After reading this chapter, the reader should be able to:

- understand the epidemiology, etiologies, clinical presentations, and diagnoses of some common skin disorders.
- discuss the management of the common skin disorders including nonpharmacological and pharmacological interventions.
- discuss the current and future role of pharmacist in the management of the common skin disorders.

Key Points

- Despite the high prevalence of some common skin disorders and high utilization of self-care, the role of the pharmacist in the management of skin disorders has not been widely explored.
- Considering patients' limited access to dermatology consultation clinics for common skin disorders, community pharmacists have the potential to provide safe and effective advice to patients on pharmacologic and nonpharmacologic interventions including personal hygiene and lifestyle modifications.
- It is also evident that pharmacist interventions for common skin disorders can be cost-effective for both consumers and health care system. In an interprofessional team of health care providers, pharmacists are considered as "initial screeners" and the "final checkers."

- Community pharmacists have the opportunity to identify drug-related problems and to develop suitable pharmaceutical care plan to follow-up with patients for an optimal skin disease management.

Introduction to Common Skin Disorders

Skin is the largest organ constituting 17% of a person's body weight. The major function of skin is to serve as a barrier and to protect human body from moisture, humidity, variation in temperature as well as a protection against the invasion of pathogenic microorganisms (McGrath et al., 2004). Skin conditions are known to bring a significant change in patient's health-related quality of life (HRQoL), affecting daily life, and causing physical discomfort and psychological problems. In this chapter, we will describe the prevalence, etiologies, signs and symptoms, diagnosis, and pharmacotherapy of common skin disorders, particularly acne vulgaris, psoriasis, atopic dermatitis (AD), and fungal infections. The chapter discusses the pharmacist's role in the management of these skin disorders.

Prevalence of Common Skin Disorders

The Global Burden of Disease (GBD) 2010 estimates for 1990–2010 from 187 countries reported skin conditions as the 4th leading cause of nonfatal disease globally affecting 985 million people after dental caries, tension-type headache, and migraine (Hay et al., 2014). Fungal infections, subcutaneous skin diseases, and acne are the most commonly occurring skin diseases globally. Taking into account the disability adjusted life years (DALYs), skin remains the 18th leading cause of health burden globally (Hay et al., 2014). Several factors such as environment, access to proper health care, socioeconomic status, and cultural practices could contribute toward the high prevalence of certain skin disorders such as acne vulgaris (Lynn et al., 2016).

Acne vulgaris is a universal teenage problem which affects people between the ages of 15 and 17 years (Bhate and Williams, 2013). As per Global Burden of Disease (GBD) study, acne vulgaris affects nearly 85% of young adults aged from 12 to 25 years (Celgene, 2014). Regardless of sex and socioeconomic status, the production of androgens during puberty explains the prominence of acne among young adults (Lynn et al., 2016). Although genetic influence of acne remains uncertain, a study conduct among Chinese undergraduates found acne to have a 78% heritability in first-degree relatives (Wei et al., 2010). Atopic dermatitis (AD) is commonly seen in the early stages of life affecting up to 20% of children and up to 3% of adults, where it is evident that its prevalence is still increasing, especially in low-income countries (Nutten, 2015). On the other hand, the reported prevalence of psoriasis ranges between 0.09% and 11.4%, causing great emotional, physiological, and psychological burden which may occur at any age (Celgene, 2014; World Health Organization, 2016).

Etiology of Common Skin Disorders

In general, three important factors explain the etiology of skin disorders (i.e., hygiene, climate, and overcrowding) (Hay et al., 2014). Specific to skin conditions such as acne, a number of hormonal, genetic, dietary, and environmental factors are associated with its progression (Wells et al., 2000). During puberty, a prevalent cause is hyperplasia of sebaceous glands. Overproduction of androgen stimulates the production of sebum which is associated with acne (Gollnick et al., 1991). Bacterial colonization and release of proinflammatory mediators and lipases are also linked with acne (Leyden et al., 1975). Mechanical trauma, cosmetics, and steroids are some of the external factors which may attribute to acne. Psoriasis, on the other hand, is associated with genetic predisposition and an abnormal immune response. In genetically susceptible individuals, it is assumed that T cells and dendritic cells (DCs) cause inflammatory cytokines to create an environment in the skin that stimulates proliferation of endothelial cells causing psoriasis (Liu et al., 2007). AD often referred to as eczema, is linked with environmental and genetic factors. It is observed that patients with AD have positive family history (Al-Shobaili et al., 2016) and is influenced by genes with general effects on dermal inflammation and immunity (Cookson et al., 2001). Environmental factors such as food allergens particularly eggs, milk, peanuts, and soya may contribute to AD (Leung et al., 2004). Besides that, fungal infections can be acquired both endogenously and exogenously. The endogenous fungal infections of skin and mucosa are commonly seen among patients with compromised immune system. Furthermore, malnutrition and diabetes mellitus also contributes to fungal infections (Alldredge et al., 2013). Similarly, ecological factors such as excessive heat and humidity contribute to fungal skin infections (De Pauw, 2011).

Clinical Presentations of Common Skin Disorders

Acne lesions are most commonly located on face, neck, back, and chest area. In severe cases, they may extend to the buttocks. Acne vulgaris could be inflammatory and noninflammatory. The noninflammatory acne is often characterized by open and closed comedones. The closed comedones are smaller in size (1–2 mm) which are visible as whiteheads on a stretched skin. However, the open comedones, also called blackheads are relatively larger in size (2–5 mm) and are dark in color (Gollnick, 2003). The inflammatory acne is characterized by pustules, which appear as white lesion filled with pus and are approximately 5 mm in

diameter (Gollnick, 2003). These lesions may be itchy and can be painful upon eruption. Nodular lesions are the most severe type of inflammatory acne, having warm lesions often 5 mm or greater in diameter.

The main clinical feature of AD is intense itch with dry skin. AD is commonly associated with inflammation and exudation. Because of its chronic nature, it can cause physical and emotional distress especially in adult patients. The symptoms of AD usually appear during the first 8–12 months of childhood, while in severe cases it may continue until adulthood (Ring et al., 2012). The child may have dry and scaly patches on the skin of the forehead, face, cheek, and scalp. During acute phases of the disease, red itchy skin with sometimes blisters is commonly seen (Ellis et al., 2003).

Psoriasis, most commonly involves the skin and nails causing great physical and emotional burden (Fortune et al., 2002). Skin lesions are localized or generalized causing itching, stinging, and pain. The lesions are well demarcated, mostly sharp red papules usually covered with white or silver scales which sometimes crack and bleeds (World Health Organization, 2016).

Superficial fungal infections may vary in their presentation. *Tinea pedis*, particularly affects the web of the toe and the planter surface of the foot. *Tinea capitis* can cause hair loss with broken hairs at the surface. On the other hand, *Tinea unguium* (onychomycosis) causes separation of the nail from the nail bed. The four major types of onychomycosis are: distal subungual, proximal subungual, superficial, and total dystrophic onychomycosis (Faergemann and Baran, 2003). *Tinea corporis* may have vesicles and pustules typically appearing on exposed skin of leg, arms, and trunk. *Tinea manuum*, usually affect one hand with prominent redness and scaling (Patient.info, 2015).

Diagnosis of Common Skin Disorders

In order to diagnose skin infections, it is critical to consider patient assessment, including signs and symptoms, genetic history as well as dietary and lifestyle habits. Furthermore, psychological issues and drug-induced skin disorders need consideration for an accurate diagnosis.

The diagnosis of acne vulgaris generally depends on clinical history and physical findings. Although a misdiagnosis is rare, it is critical to differentiate between acne rosacea, which is similar in presentation in adults (Wang and Zane, 2008). A variety of drugs provoke acne, including steroids, anti-epileptics, antituberculosis drugs, and lithium (Kazandjieva and Tsankov, 2017). The diagnosis may include a detailed history of drug consumption as well as ruling out other clinical factors known to trigger acne. Similarly, the diagnosis of AD is based on clinical presentation of the skin and no objective test is available for confirmation. Several criteria are suggestive of the accurate clinical diagnosis such as age dependent eczematous skin lesions, early onset, pruritus, stigmata of atopy, personal and family history of atopy, and IgE mediated sensitization (Leung, 2013).

Diagnosis of psoriasis is usually made based on clinical presentation rather than laboratory data. The disease is generally classified into mild, moderate, and severe. Disease assessment often includes severity of symptoms, body surface area involved and the effects on patient's HRQoL (Dipiro et al., 2016). The diagnosis of fungal infection remains a challenge for most clinicians. Due to nonspecific clinical presentation and difficult colonization in case of invasive disease, blood culture reports are usually negative (Stevens, 2002). Several tests on body fluid may be useful for an accurate diagnosis.

Management of Common Skin Disorders

Nonpharmacological Treatment

Acne Vulgaris

In accordance with recent dermatological guidelines (Zaenglein et al., 2016), drugs such as antibiotics, retinoid, benzoyl peroxide, and hormonal agents are first line treatment for acne. However, these drugs have associated risks such as antibiotic resistance and side effects. Although data on safety and efficacy of nonpharmacological therapies are scarce, these therapies are often used by health care professionals. The most common types of nonpharmacological therapies used are laser and light-based therapies, chemical peels, and fractional micro-needling radiofrequency (De Vries et al., 2018). Cleansing with warm water and mild facial cleanser twice daily is recommended. The patient must not squeeze or prick at the acne lesions. This will prevent the scarring and recurrence. Oil free moisturizers may improve the penetration of anti-acne medicines into the skin. Although limited evidence on surgical comedones extraction is available, comedones removal is often helpful in the management of comedones that are resistant to other therapies (Zaenglein et al., 2016). Chemical peels such as glycolic acid and salicylic acid chemical peels may end in slight improvement in comedonal acne (Grover and Reddu, 2003). A number of laser and light devices have been investigated for acne. However, among all, the most evidences exist for photodynamic therapy (PDT) (Pollock et al., 2004; Zaenglein et al., 2016).

Atopic Dermatitis (AD)

Nonpharmacological therapies in the management of AD aim to complement the conventional therapies, but not a substitute. These therapies are to reduce the episodic symptoms of AD and to improve patient's HRQoL (Criton and Gangadharan, 2017). Dry skin is one of the characteristic of AD. Gentle cleansing and bathing (only 5 minute duration) is suggested to get rid of crust and contaminants in case of bacterial infection (Wollenberg et al., 2018). Adding antiseptics such as sodium hypochlorite in the bathing

water may also benefit AD patients (Wollenberg et al., 2018). To avoid dehydration of the skin, use of bath oil or mild emollients may help to keep the skin soft and hydrated (Wollenberg et al., 2016). Use of wet-wrap therapy with or without a topical corticosteroid can be recommended for patients with moderate to severe AD to decrease disease severity and water loss during flares (Criton and Gangadharan, 2017; Eichenfield et al., 2014). Food sensitization happens in approximately 50% of children with severe AD. Thus, AD patients should be evaluated for any food allergies (Wollenberg et al., 2016). Probiotics such as lactobacillus mixtures have been shown to have beneficial effects in preventing the development of AD (Grüber, 2012; Isolauri et al., 2000).

Psoriasis

Nonpharmacological treatment is recommended in all stages of psoriasis (Menter et al., 2009). This mainly includes stress-reduction strategies, moisturizers, and sunscreens. Stress-reduction approaches such as mindfulness-based stress reduction (MBSR) intervention have shown some positive effects among psoriasis patients. In a randomized clinical trial, psoriasis patients undergoing photochemotherapy were introduced to MBSR intervention delivered by audiotape, which showed that MBSR can increase the rate of resolution of psoriatic lesions (Kabat-Zinn et al., 1998). Use of moisturizers can help to retain moisture on the skin by forming a thin layer. A randomized placebo-controlled trial of *aloe vera* gel for the treatment of mild to moderate psoriasis reported beneficial moisturizing effects (Syed et al., 1996).

Fungal Infections

Although most of the superficial fungal skin infections require pharmacological therapies however, home remedies have been used traditionally since ages. These include use of baking soda, apple cider vinegar, coconut oil, garlic, etc. Coconut oil can help to kill the species of yeast due to the presences of medium chain fatty acids which act as a fungicide (DebMandal and Mandal, 2011). Applying crushed garlic is useful to treat some fungal infections under the nail-bed (Ledezma et al., 1996).

Pharmacological Treatment

Acne Vulgaris

Topical therapies, systemic antibiotics, hormonal agents, and isotretinoin are the mainstay of treatment of acne vulgaris. As per recent acne vulgaris guidelines, the treatment plan in **Table 1** can be applicable for patients with mild, moderate, and severe acne (Zaenglein et al., 2016).

Therapy choice may be influenced by the age of the patient, site of involvement, severity of acne, and patient preferences. Topical therapy benefits treatment in mild-moderate acne. In severe acne, systemic therapy is recommended together with topical therapies. Topical therapy should start with caution and should be compatible for patients as initial irritation may lead to nonadherence to therapy. Once control is achieved, simplify the regimen according to the response. For moderate to severe cases, systemic antibiotics must be used in combination with a topical retinoid and benzyl peroxide. Tetracycline antibiotics are recommended; however, caution should be taken for pregnant women, children <8 years of age and known history of tetracycline allergy. Doxycycline 20 mg twice daily to 40 mg daily has shown efficacy in patients with moderate inflammatory acne (Toossi et al., 2008). Topical retinoid Vitamin A derivatives are recommended as a first line therapy. They are marketed as tretinoin (0.025%–0.1% in cream, gel, or microsphere gel vehicles), adapalene (0.1%, 0.3% cream, or 0.1% lotion), and tazarotene (0.05%, 0.1% cream, gel, or foam) (Zaenglein et al., 2016). Benzyl peroxide either alone or in combination can be considered in all stages of acne. It is available in the form of topical washes and creams. Strengths available for acne therapy range from 2.5% to 10% (Zaenglein et al., 2016).

Atopic Dermatitis

Effective topical therapies are the mainstay of AD treatment. Sufficient dose, sufficient strength, and correct application of topical agents are the fundaments of topical management of AD. As per most recent clinical practice guidelines, following treatment plan (**Table 2**) can be applied for patients with mild, moderate, and severe AD (Wollenberg et al., 2016).

Table 1 Treatment outline of acne vulgaris

Severity	*Treatment outline*
Mild	Single agent therapy: Benzoyl peroxide (BP) **or** topical retinoid **or** Topical combination therapy[a]: BP + antibiotic **or** Retinoid + BP **or** Retinoid + BP + antibiotic
Moderate	Topical combination therapy[a]: BP + antibiotic **or** retinoid + BP **or** retinoid + BP + antibiotic **or** oral antibiotics + topical retinoid + BP **or** oral antibiotics + topical retinoid + BP + topical antibiotics
Severe	Oral antibiotics + topical combination therapy[a]: BP + antibiotics **or** retinoid + BP **or** retinoid + BP + antibiotics **or** oral isotretinoin

[a]The drug may be prescribed as a fixed combination product or as separate component.

Table 2 Treatment of atopic eczema for adults

Baseline *Basic therapy*	***Mild*** *SCORAD <25*	***Moderate*** *SCORAD 25–50*	***Severe*** *SCORAD >50*
Simple eczema • Educational programs • Emollients bath oils • Avoidance of clinically relevant allergens	Transient eczema • Therapy with TCS class II • TCIs • Antiseptics incl. silver, silver coated textiles	Recurrent eczema • Therapy with topical tacrolimus or class II or class III TCS • Wet wrap therapy • UV therapy (UVB 311 nm, medium dose UVA1) • Psychosomatic counseling • Climate therapy	Persistent eczema • Hospitalization • Systemic immunosuppression with: ◦ Cyclosporine A ◦ Oral TCS ◦ Dupilumab ◦ Methotrexate ◦ Azathioprine ◦ Mycophenolate mofetil ◦ PUVA ◦ Alitretinoin

SCORAD, Scoring of atopic dermatitis, a composite score; *TCS*, topical corticosteroids; *UV*, ultraviolet; *UVA*, ultraviolet A; *UVB*, ultraviolet B; *PUVA*, psoralen and ultraviolet A; *TCIs*, topical calcineurin inhibitors. *Source: Wollenberg, A., Barbarot, S., Bieber, T., Christen-Zaech, S., Deleuran, M., Fink-Wagner, A., Gieler, U., Girolomoni, G., Lau, S., Muraro, A., Czarnecka-Operacz, M., 2018. Consensus-based European guidelines for treatment of atopic eczema atopic dermatitis in adults and children: part II. J. Eur. Acad. Dermatol. Venereol. 326, 850–878.*

Topical corticosteroids (TCS) are the mainstay of treatment in AD. The dose, frequency, duration of therapy, and quantity of application may vary from one patient to another and depends on the severity and site of the AD. Diluted topical corticosteroids with wet wrap dressing may be useful for short-term periods in acute AD. In mild AD, a small amount of TCS twice to thrice weekly (approximately 15 g in infants, 30 g in children, and 60–90 g in adults allows good maintenance (Wollenberg et al., 2016). A variety of skin changes such as scars, stretch marks, and hypertrichosis may develop as side effects of TCS. These side-effects should be recognized and patient must be counseled adequately in order to avoid noncompliance (Aubert-Wastiaux et al., 2011; Lee et al., 2015). Topical calcineurin inhibitors (TCIs) such as tacrolimus ointment and pimecrolimus cream have shown efficacy in reducing the symptoms, severity, and extent of AD (Carr, 2013). In children, twice-weekly treatment with tacrolimus 0.03% ointment has been observed to be effective and cost-saving in children with moderate to severe AD (Thaci et al., 2010). Twice-weekly application of tacrolimus ointment may reduce relapses. Patients should be advised for effective sun protection (Wollenberg et al., 2018). Phototherapy is recommended as a second line therapy in AD when TCS and TCIs are not effective (Alldredge et al., 2013). Ultraviolet (UV) light sources have immunosuppressive, anti-inflammatory as well as antipruritic effects on skin which ultimately benefits AD patients (Hong et al., 2008).

Psoriasis

Topical treatments are the standard of care in mild to moderate psoriasis (*affects <5% body surface area*). TCS are useful as monotherapy in patients with mild psoriasis (Menter et al., 2009). TCS are effective because of their anti-inflammatory, immunosuppressant, antimitotic, and antipruritic properties (Alldredge et al., 2013). TCS can be used as monotherapy 1–2 times daily or combined with other topical agents, UV light, and systemic agents (Cornell and Stoughton, 1985). Topical vitamin D analogs such as calcitriol or calcipotriene ointment show 70%–74% improvement in treating psoriasis (Menter et al., 2009). Use in combination with TCS may provide added benefit (Kragballe et al., 1991). For moderate to severe cases of psoriasis with minimal response to topical therapies, management with ultraviolet B (UVB), or psoralen plus ultraviolet A (PUVA) phototherapy is recommended (Menter et al., 2009). In severe psoriasis (*affects >5% body surface area*), systemic therapies with or without topical agents or phototherapy is recommended. Systemic therapies include PUVA; the systemic retinoid, acitretin; cyclosporine and methotrexate. Photochemotherapy is used to control severe, recalcitrant, disabling plaque psoriasis. More than 80% of psoriatic patients experience clearing of symptoms after 10–20 treatments over the course of 4–8 weeks, which can be maintained with periodic (twice monthly) treatments (Alldredge et al., 2013).

Fungal Infections

Topical treatments are the mainstay in the management of superficial fungal infections. Any infections, covering >20% of body surface area (nail, follicular, or widespread) should be treated systemically due to poor penetration of topical applications (Baran and Kaoukhov, 2005). In Invasive fungal infections, topical applications are slightly ineffective due to poor penetration; however, newer agents such as ciclopirox and amorolfine have shown improved efficacy (Bohn and Kraemer, 2000). Oral antifungals are often associated with risks of side effects and interaction with other drugs which in turn affects the efficacy of the drug therapy as well as patient's compliance. Newer classes such as itraconazole and terbinafine are better options. For *Tinea unguium* (Onychomycosis) initial therapy, nail scrapping and culture is recommended. Terbinafine 250 mg/day or itraconazole 200 mg/day can be recommended after culture results. The duration of therapy is varied from 6 weeks (finger nail) to 12 weeks (toenail) and in some cases,

therapy may be required for 6–12 months for toenail infections. Therapeutic outcome can be confirmed when a 25% reduction in size of the infected nail has been achieved. Griseofulvin can be recommended as an alternative if the patient is contraindicated to itraconazole or terbinafine. The adverse effects of itraconazole or terbinafine include rash, headache, and gastrointestinal (GI) distress. Toxicity of griseofulvin includes hypersensitivity reactions, dermatitis, GI distress, and neurologic complications (Crawford and Hollis, 2007). An alternative to daily therapy for fingernail infections called antimycotic pulse therapy has been approved. A pulse course of itraconazole 200 mg twice a day for 1 week/month in two or four cycles appears to be safe and effective treatment for toenail onychomycosis caused by some nondermatophyte molds alone or in combination with dermatophytes (Chen et al., 1999; De Sá et al., 2014). Efinaconazole and tavaborole are the newest topical agents available to treat onychomycosis (Elewski et al., 2013; Gupta et al., 2014). However, systemic therapy is recommended for the successful outcomes. Treatment failure can be either relapse or re-infection. Immunocompromised, diabetes and congestive heart failure patients are more prone to treatment failure. The use of combination therapy (topical + systemic) may improve therapeutic outcome (Ameen et al., 2014). *Tinea capitis* treatment should focus on cleaning the contaminated combs and brushes. Topical therapy may not penetrate into hair follicles. Hence systemic therapy is recommended (Meadows-Oliver, 2009). Daily shampooing with antifungal agents (ketoconazole 2% or selenium sulfide 1%) along with oral therapy is recommended. For *Tinea barbae* removal of mustache or beard is recommended (Goldstein et al., 2000) followed by antifungal shampoo application. In some cases, oral therapy can be recommended. Most cases of *Tinea pedis* are self-treated with nonprescription topical antifungals. These include butenafine hydrochloride, clotrimazole, miconazole nitrate, terbinafine hydrochloride, and tolnaftate, considering safe and effective treatment for mild to moderate fungal skin infections (Newton and Popovich, 2012).

Counseling Patients About Common Skin Disorders

Adherence to treatment and understating of own disease is crucial in the management of skin disorders. Environmental, emotional, and hormonal factors must be discussed with patients suffering from acne. Emerging data suggest that high glycemic index (GI) diets and some dairy products like skim milk may influence acne (Eichenfield et al., 2014). Patients should be advised to complete the course of systemic antibiotics to prevent antibiotic resistance. All possible medication side effects should be discussed with the patients along with the management strategies. Education about the disease, treatment expectations, and prevention of recurrence, should be made clear to the patient to improve adherence (Eisman and Sinclair, 2014). In case of fungal infections, patients should be counseled about the importance of proper foot hygiene, wearing breathable footwear, cotton socks, keeping nails clean and short to expedite healing (Alldredge et al., 2013; Dipiro et al., 2016).

Role of Community Pharmacist in Health Care Team—Current and Future Trends in Management

Skin disorders are often considered minor health ailments. However, the long-term impact of untreated skin conditions may affect patients physically and psychologically. Community pharmacists are the most accessible professionals to provide advice for skin disorders (Tucker and Duffy, 2014). Since self-care is a cornerstone for many skin disorders, community pharmacists can play an important role in providing advice to patients about drug management, personal hygiene, and lifestyle modifications. To make an appropriate treatment plan for a skin condition, pharmacist should have considerable knowledge on diagnosis. A review of the literature revealed that pharmacist participation in self-care of skin conditions is valuable, but their dermatological diagnostic skills need to be further developed (Tucker et al., 2014). This section will focus on the current and future roles of pharmacists in the management of four major skin disorders (i.e., acne vulgaris, AD, psoriasis, and fungal infections) which has been the focus of this chapter.

Diagnosis, Counseling, and Consultation Roles in Dermatological Care

Pharmacist needs to be an expert in making a provisional and differential diagnosis of common skin disorders. They should be adequately trained to make a clinical judgment in assessing the severity of the disease before recommending any OTC medicines. Similarly, the side effects of the drugs dispensed must be known by the pharmacists and the patient must be counseled properly to avoid noncompliance. Self-reported adherence to dermatological treatment has been estimated to be about 60%, which means certain factors to nonadherence still need to be addressed (Richards et al., 1999). Pharmacist's consultation on common skin disorders may help to improve patients' HRQoL. AD is reported to affect the HRQoL of patients and their caregivers and insufficient consultation is among the reasons of parental dissatisfaction toward AD treatment (Cork et al., 2003). In a study conducted among parents having children with AD, pharmacists' interventions regarding proper use of emollient was reported to make a significant impact on therapy outcomes (Carr et al., 2007). Similarly, community pharmacists are known to play a vital role in counseling patients regarding safe and effective use of topical corticosteroids for AD (Lau and Donyai, 2017; Smith et al., 2016).

Pharmacist-led steroid counseling for skin conditions shows that lack of confidence among pharmacists creates a mistrust and fear of steroid use among patients (Raffin et al., 2016). Since self-medication is common among patients with psoriasis, community pharmacists can play an important role in the disease management through follow up with their patients and

developing innovative strategies to enhance patients' understanding of their disease and its management. According to a survey conducted on consumer satisfaction and economic evaluation of pharmacist-led dermatological consultations, it was reported that pharmacist's advice appeared to be cost-effective for both the consumer and the government (Lindblad et al., 2006).

Role as "Initial Screener" and "Final Checker" in Dermatological Care

Disease management by a coordinated team of health care professionals ensures better treatment outcomes. Dermatological disorders demand an interprofessional team effort involving doctors, nurses, and pharmacists in order to improve patients' adherence and HRQoL. A focus group investigated the team efforts of dermatologists as "*diagnosis maker*" and "*prescribers*," nurses as "*the coach*," and pharmacists as "*initial screener*" and "*final checker*" (Lindblad et al., 2006). Patients reported that there was a lack of holistic approach in dermatological disorders management; even though dermatologists wish to collaborate with pharmacists, but lack of time prohibits them to do so.

Community pharmacies must have an agreement between the dermatologists and nurses to share patients' data for a complete patient history in order to develop effective therapeutic care plans. Conversely, primary care providers are in immediate need of refining their skills to handle dermatological conditions in order to cultivate trust in their patients (Federman et al., 2001). For mild to moderate skin conditions, hospital admissions are not commonly seen. However, in severe cases, patients may need hospitalization to overcome the acute phase of the disease. It is also evident from certain case reports that wrong drug administration, drug–drug interactions, or anaphylactic reactions due to certain antibiotics used for acne management may lead to hospitalization (Christodoulou et al., 1999; Kent and Drummond, 1989). Hospital pharmacists must be well trained to handle complicated skin conditions in order to provide optimal care to the patients.

Health Promotion Roles in Dermatological Care

The role of community pharmacists in health promotion is well established (Anderson, 2000). Specific to skin conditions, pharmacists can get involved in a variety of health promotion activities such as appropriate use of skin products to prevent skin cancer (Mayer et al., 1998; Ring et al., 2007). Pharmacists' advice on proper use of emollient is reported to reduce the severity of eczema and prevent disease exacerbation (Carr et al., 2007). Emotional stress has long been associated with the exacerbation of acne, AD, and psoriasis (Chiu et al., 2003; Garg et al., 2001; Heller et al., 2011). Community pharmacist-led stress reduction programs may help patients to understand their health condition and to prevent the recurrence of their disease (Kabat-Zinn et al., 1998; Winchell and Watts, 1988). Pharmacists can also play their role in screening psychiatric disorders in patients with skin diseases (Picardi et al., 2004).

Roles in Medicine Use Review and Personalized Dermatological Care

Community pharmacists constitute the third largest group of health care professionals in the world, and despite their potential role in managing minor ailments (Mansell et al., 2015; Taylor and Joubert, 2016) and promoting the safe and effective use of medicines, outside the hospital setting (Carr et al., 2007; Mossialos et al., 2015), they remained underutilized (Mossialos et al., 2015). In skin care, community pharmacists could play a major role, particularly in helping those patients with skin complaints that do not visit general medical practitioners frequently. Community pharmacists are also known to compound individualized therapies for dermatological problems which continue to improve in both esthetic and therapeutic aspects of customized medications, offering alternatives strategies for dermatology care (Community pharmacy, 2018). Supporting patients with long-term skin conditions is also critical. Medicine use review (MUR) service is another effective means to help patients with conditions such as eczema and psoriasis, which require a high degree of self-management (Pharmaceutical Services Negotiating Committee, 2014).

Pharmacist Remuneration in Dermatological Care

Historically, community pharmacists' remuneration is solely based on retail activities (Mossialos et al., 2015); usually they are not paid for services. However, in the recent years, limited models of practices around the world have been introduced whereby, pharmacists can be paid for "Patient Centered Activities-Services" (Law et al., 2012; Rigby, 2010). These remunerated services are highly variable which range from emergency contraception services to minor health ailments (Houle et al., 2014). Minor ailments programs are operational in Saskatchewan, England, and Northern Ireland (Davidson et al., 2009; Northern Ireland Executive, 2018; Pharmaceutical Services Negotiating Committee, 2018).

In Saskatchewan, Pharmacy Services Compensation Program for minor health ailment including acne, a net amount of $18 is paid to pharmacists per consultation (Pharmacy Association of Saskatchewan, 2018). Similarly, an increasing number of pharmacists are now working in collaboration with other health care professionals, providing a wide range of services; under these collaborative systems remuneration of services is influenced by various factors, including, value of services, budgetary constraints, the payer perspective, and the attitude of physicians, pharmacists, and patients (Bernsten et al., 2010). Despite these roles of pharmacists in dermatological care, there are limitations in the current community pharmacy practice models, including lack of space in maintaining patient privacy, access to patient prior record and clinical history, which could be overcome by information sharing between the physicians and the pharmacists (Lindblad et al., 2006).

Conclusion

Skin disorders are common conditions which affect patients of all ages. Community pharmacists can play a vital role in addressing issues related to safe and effective interventions including personal hygiene and lifestyle modifications. There are a variety of treatments available for common skin disorders. The pharmacological and nonpharmacological therapies can be individualized as per patient's needs. Identification and resolution of drug-related problems make pharmacist key players in skin disease management.

Management of Infectious Diseases and the Pharmacist's Role—Antibiotic Stewardship

Eamon Duffy[*,†], **Mark Thomas**[†,‡], [*]Department of Pharmacy, Auckland City Hospital, Auckland, New Zealand; [†]Department Infectious Diseases, Auckland City Hospital, Auckland, New Zealand; [‡]Department of Molecular Medicine and Pathology, Faculty of Medical and Health Sciences, University of Auckland, Auckland, New Zealand

Introduction and Need

Infectious diseases are among the most common reasons for patients to receive medical treatment. Approximately 10% of consultations in primary care are for infectious diseases (Hemkens et al., 2017), and infectious diseases are the principal reasons for approximately 10% of hospital admissions (McLaws et al., 1988). Furthermore, approximately 5%–15% of adults admitted to hospital develop nosocomial infections (Allegranzi et al., 2011; Graves et al., 2003).

Fortunately, very many human infectious diseases can be successfully treated with antimicrobial medicines. Almost all bacterial and fungal infections and a large number of major viral infections can be cured or controlled. The remarkable success of antimicrobial treatment in very many infections has led to a common belief that antimicrobial treatment will be beneficial for almost every infection. Consequently, patients often seek medical attention for relatively minor infectious diseases, including many for which there is no effective antimicrobial treatment. Unfortunately, in very many developed and developing countries, this has resulted in excessive prescribing and dispensing of antimicrobials (Van Boeckel et al., 2014).

In most developed countries, approximately 90% of total antimicrobial dispensing is for people in the community and approximately 10% is for people in hospital (Duffy et al., 2018). The number of antimicrobial courses dispensed per 1000 population per year varies widely between countries. For example, the number of antimicrobial courses dispensed per 1000 population, during 2015, was 323 in Sweden (Swedres-Svarm, 2016) but was approximately four times higher—1280 in Australia (Australian Commission on Safety and Quality in Health Care, 2017). Many studies suggest that approximately 30%–50% of antimicrobials dispensed in the community are inappropriate, providing no significant health benefit for the patient (Dyar et al., 2016; Fleming-Dutra et al., 2016). A similar proportion of hospital antimicrobial prescribing is inappropriate (Reddy et al., 2015).

An inevitable consequence of sustained high levels of antimicrobial consumption has been a relentless increase in the prevalence of antimicrobial resistance in the microbes that commonly colonize humans. The spread of antimicrobial resistance in these commensal microbes has dramatically reduced the utility of many antimicrobial agents. For example, penicillin, which was active against almost all strains of *Staphylococcus aureus* when discovered in the 1920s (Fleming, 1929), is now active against only 10%–15% of strains (Chambers, 2001). Similarly, resistance to quinolone antibiotics, such as ciprofloxacin, in *Escherichia coli* has risen from less than 5% in the early 1980s, (Wise et al., 1983) to more than 30% in recent years (Ip et al., 2017). In some human pathogens, such as *E. coli*, *Klebsiella pneumoniae*, *Pseudomonas aeruginosa*, and *Acinetobacter baumanii*, strains have emerged that are resistant to all but a small number of antimicrobial agents. These highly resistant strains inevitably will spread globally and pose a major threat causing large numbers of untreatable infections (Huang et al., 2017). These untreatable infections will result in increased deaths and disability from infection and dramatically challenge the acceptability of many medical procedures that currently depend on effective treatment of infectious complications, such as intensive care of severely ill patients, invasive surgery, and solid organ and bone marrow transplantation (O'Neill, 2014).

The rapid global spread of clones of many common human pathogens that are resistant to almost all antimicrobials has led to increased awareness of the need for actions to limit the dissemination and health impacts of these organisms. These actions include improved infection control and enhanced immunization, to try to slow the spread of microbes within the community and within health-care facilities; enhanced testing for antimicrobial resistance and provision of the results of such testing, to increase prescribers' awareness of the risk that infection may be due to resistant organisms; and education of prescribers and the public to reduce inappropriate antimicrobial use and thus reduce the selective pressure that favors the proliferation of antimicrobial resistant microbes.

Antimicrobial stewardship (AMS) is a set of coordinated strategies intended to (1) reduce inappropriate antimicrobial use, (2) optimize prescribing with regard to antimicrobial selection, dose, route of administration, and duration of treatment, to maximize clinical benefits and limit unintended adverse effects, and (3) slow the emergence of antimicrobial resistance (Dellit et al., 2007). AMS has a long history. Alexander Fleming, who discovered penicillin, stated in 1945 that "*the thoughtless person playing with penicillin is morally responsible for the death of the man who finally succumbs to infection with the penicillin-resistant organism*" (Anonymous 1945). In the introduction to Good Antimicrobial Prescribing published in 1982 AM Geddes wrote:

Table 1 Useful resources for pharmacists engaged in AMS services

Nation	*Organization*	*Guideline (date published)*	*Site*
Australia	Australian Commission on Safety and Quality in Health (ACSQHC)	Antimicrobial stewardship clinical care standard (2014)	https://www.safetyandquality.gov.au/publications/antimicrobial-stewardship-clinical-care-standard/

United States	Centers for Diseases control and Prevention (CDC)	Core elements of hospital antibiotic stewardship programs (2017)	https://www.cdc.gov/antibiotic-use/healthcare/implementation/core-elements.html

"Much has been said and written about the abuse of antibiotics and the dire effects that can result. There are predictions of widespread bacterial resistance, possibly culminating in 'supergerms' resistant to all antimicrobial compounds" (Geddes 1982). The emergence in recent years, of multiple "superbugs," including extremely drug resistant *Mycobacterium tuberculosis* (XDRTB) and carbapenem-resistant *Enterobacteriaceae* (CRE), has demonstrated the prophetic nature of these predictions and led to a much greater emphasis on AMS in both hospital and community practice.

AMS teams, that usually include a pharmacist, an infectious diseases physician, and a clinical microbiologist, now are common in most large hospitals in developed countries. The core functions of these teams include (1) ensuring that clinicians have ready access to appropriate antimicrobial prescribing guidelines, (2) ensuring that there are effective systems to limit the prescribing of antimicrobials of last resort to prolong their utility, (3) ensuring that reporting of antimicrobial susceptibility results by the clinical microbiology laboratory is designed to encourage prudent antimicrobial prescribing, and (4) conducting prospective audit with feedback and intervention to improve antimicrobial prescribing. AMS teams within hospitals have the potential to improve patient outcomes, reduce costs, and reduce the incidence of infection due to antimicrobial resistant microbes (Dellit et al., 2007).

In many countries, AMS is less developed in the community than it is in hospitals. There are however some striking exceptions. The Swedish Strategic Program against Antibiotic Resistance (STRAMA) was started in 1994 as an informal network of clinicians within each of the 21 Swedish counties, with funding from central government since 2006 (Molstad et al., 2008). The level of community antimicrobial consumption in Sweden is among the lowest in developed nations and continues to decline, with a sustained, approximately 1.2% reduction in total consumption during each year between 2005 and 2016. Not surprisingly the prevalence of antimicrobial resistance in bacterial pathogens has remained very low in Sweden when compared with most other countries (Molstad et al., 2008). A national, community-based, campaign ("Antibiotics are not automatic"), resulted in an approximately 5% reduction in community antibiotic prescriptions, during each year between 2002 and 2007, across all regions of France (Sabuncu et al., 2009). A UK national campaign set a target of a 1% annual reduction in total community antimicrobial prescribing between 2013 and 2018 (Johnson et al., 2015). After 2 years, there had been a 6.8% reduction in total antimicrobial prescriptions per head of population (Global and Public Health Group/10200, 2017).

It is very likely that the need for AMS services, within hospitals and the community, will increase dramatically in the next decade. An increase in the incidence of infections due to multiresistant microbes will require more pharmacists with the expertise to advise on use of last-line antimicrobials. Concurrently increased clinician and public concern about the rising risk of untreatable infections is likely to result in greater demand for pharmacists to enhance efforts to reduce inappropriate prescribing. **Table 1** lists some especially useful resources for pharmacists engaged in AMS services.

The Role of the Pharmacist in Antimicrobial Stewardship

Improving the appropriate use of antimicrobials is necessary across all facets of health care and pharmacists are well placed to deliver and lead this improvement, in both the secondary and primary care settings. As with all conditions, pharmacists advise on optimal treatment for infection, taking into account pharmacokinetic and pharmacodynamic parameters such as renal function and drug concentrations.

In secondary care, pharmacists are well established as key members of the AMS team. International guidance on the delivery of AMS in secondary care and who should be involved always includes the need for pharmacist involvement, if not pharmacist leadership (Barlam et al., 2016; Duguid and Cruickshank, 2011; NICE, 2015). As members of this team pharmacists have often led the development of appropriate antimicrobial prescribing guidelines, introduced audit and feedback of prescribing habits, reviewed medication use, and provided expert pharmacological input into medicines management (McLellan et al., 2016; Weier et al., 2017; Wickens et al., 2013). Traditionally, the involvement of pharmacists in AMS has been from individuals working within a multidisciplinary infectious diseases team; however, AMS is increasingly incorporated into the standard clinical practice of all pharmacists (Brink et al., 2016; DiDiodato and McArthur, 2017).

Case study: Optimizing the route and dose of antimicrobial therapy Optimizing antimicrobial prescribing is one of the main purposes of an Antimicrobial Stewardship program. This includes selecting the optimal antimicrobial agent, together with the

optimal dose, duration, and route of administration in order to maximize benefit and minimize adverse effects for patients. With fewer new antimicrobials being brought to the market, (Butler et al., 2017) more research is being undertaken to look at optimal use of existing agents.

Scenario: A patient is being managed at your institution with an infected wound. Methicillin susceptible Staphylococcus aureus (MSSA) has been isolated from debrided tissue and the patient commenced on treatment with intravenous flucloxacillin 1 g every 6 h. The patient is referred to you by the ward pharmacist for review on your AMS ward round.

AMS ward rounds have demonstrated improvements in antimicrobial prescribing across a range of settings (Cairns et al., 2015). This type of ward round review is different to the traditional infectious disease review for expert advice in clinically complex scenarios. Pharmacists and physicians review patients referred to the AMS service for optimization of their therapies, for example, narrowing spectrum, switching from intravenous to oral therapy, and optimizing dosing.

On review, the patient had completed 72 h of intravenous antibiotic and was clinically stable, afebrile, and eating a normal diet. You need to consider whether the patient is suitable for conversion to an oral antibiotic regimen.

Promoting intravenous to oral switching is a key part of an AMS program due to the clear benefits of reduced morbidity, reduced length of stay, reduced intravenous cannula-associated hospital acquired infections, and reduced healthcare costs. Implementation though is often challenging to achieve with limited uptake, despite the clear evidence of benefit without any compromise in clinical efficacy. Switching criteria can be used to make the process more consistent and consensus guidelines suggest the following key parameters, improving or stable vital signs, resolved fever, a functioning gastro-intestinal tract, a well-absorbed oral option, and an infection that doesn't require prolonged intravenous therapy (e.g., endocarditis) (Akhloufi et al., 2017).

You decide that the patient could be changed to an oral antibiotic, but together with the patient you note that taking oral flucloxacillin 4 times a day on an empty stomach may be logistically difficult. You need to consider whether to change the dosing regimen or switch to a broader spectrum oral antibiotic, such as cefalexin taken less frequently.

Flucloxacillin has a short half-life necessitating frequent dosing, every 6 h, and has historically been recommended to be taken on an empty stomach based on studies showing reduced absorption in fasting as compared to fed patients. The key pharmacokinetic-pharmacodynamic target for flucloxacillin is, as for all beta-lactams, $fT>MIC$, so AUC or Cmax measurements are less important for efficacy, and any impact on these may not be clinically relevant, if $fT>MIC$ is maintained. A recent study has demonstrated that flucloxacillin taken at a dose of 1 g every 8 h with food achieves sufficient concentrations to meet targets for all *Streptococcus pyogenes* and most *Staphylococcus aureus* isolates from skin and soft tissue infections (Gardiner et al., 2018). Treating patients with the narrowest spectrum agent for their infection is a tenet of AMS. The benefits gained from utilizing broader spectrum antibiotics for practical purposes, for example, once daily dosing or palatability, should always be carefully weighed against the harms incurred, for example, greater microbiome disturbance and development of antimicrobial resistance.

In smaller, or more remote, settings there may be limited access to Infectious Disease physicians or Clinical Microbiologists. In these situations, pharmacists are often the best placed clinicians to establish themselves as the leads for AMS, working together with regional specialists to deliver improved care to their patients. In settings where this has been implemented, there have been reductions in inappropriate antimicrobial use, and consequent reductions in the adverse effects of antimicrobial therapy, such as *Clostridium difficile* colitis (PHA Canada, 2017; Yam et al., 2012).

Working in primary care, pharmacists can be involved in delivering AMS, either through their community practice and also by working in a facilitator role with primary care physicians or general practitioners to improve prescribing (Essack et al., 2017; RPS, 2017). In this role, pharmacists are undertaking many of the same tasks that colleagues in secondary care have established as key functions of an AMS program.

In order to improve prescribing, AMS teams must be able to monitor the use of antibiotics. The measures used will differ depending on the population being surveyed, for example, in the hospital setting defined daily doses (DDD) or days on therapy (DOT) per 1000 occupied bed days are the commonly used measures of antimicrobial consumption, while in the community setting the number of antimicrobial prescriptions dispensed or DDDs per 1000 population are the commonly used measures. Pharmacists are involved in monitoring antimicrobial consumption, and expenditure on antimicrobials, using pharmacy dispensing data to produce monitoring and usage reports, as well as in assessing reports for intended or unexpected changes, that may have resulted from changes in policy or clinical practice.

Case study: an audit of inpatient antimicrobial dispensing that led to improved prescribing and better patient outcomes

An audit of total antimicrobial dispensing in a regional secondary care hospital in New Zealand found that the overall level of dispensing was less than in two large New Zealand tertiary hospitals, but that the level of dispensing of lincosamides (principally clindamycin) was higher than in any other hospital in New Zealand or Australia (Hopkins, 2014). Lincosamides were dispensed at a rate of 3.2 defined daily doses (DDDs)/100 inpatient days, while the rates of dispensing were only 0.8 and 2.1 DDDs/100 inpatient days in two tertiary hospitals in New Zealand (Ticehurst and Thomas, 2011; Beardsley et al., 2011) and were less than 3.0 DDDs/100 inpatient days in 34 large public acute hospitals in Australia (South Australian Department of Health, 2011).

The clinician performing the audit of antimicrobial dispensing at this hospital then looked for adverse consequences of the very high rate of lincosamide consumption. Treatment with a lincosamide was found to be associated with a 14% incidence of *Clostridium difficile* associated diarrhoea (CDAD). The incidence of disease in patients treated with clindamycin was surprisingly high; twice the incidence reported in an outbreak of CDAD in a US hospital that also had a very high rate of clindamycin dispensing (Pear et al., 1994). Treatment with clindamycin has repeatedly been shown to be strongly associated with CDAD in hospitalized patients

Table 2 Standard elements of AMS programs[a]

Element	*Purpose*
Leadership Commitment	To dedicate the resource and support the program
Accountability	Having a clear clinician leader
Drug Expertise	Pharmacist involvement
Action	Implementing activities such as standard reviews or audit and feedback
Tracking	Monitor prescribing and resistance patterns
Reporting	Provide reports on prescribing to prescribers
Education	Ongoing for all clinicians involved in antimicrobial use

[a]Modified from: Centres for Disease Control and Prevention, 2014. Core Elements of Hospital Antibiotic Stewardship Programs. US Department of Health and Human Services, CDC, Atlanta, GA. Available from: http://www.cdc.gov/getsmart/healthcare/implementation/core-elements.html.

(Bignardi, 1998; DePestel and Aronoff, 2013) and reducing the rate of clindamycin dispensing has resulted in the control of nosocomial outbreaks of CDAD (Pear et al., 1994).

The mechanisms by which treatment with broad-spectrum antimicrobials causes CDAD remain unclear, but the commonly accepted explanation is that these medicines disrupt the normal flora of the colonic mucosa, and thus enhance the proliferation of *C. difficile* (Buffie et al., 2015). Reducing inappropriate prescribing of broad-spectrum antimicrobials is a common goal of hospital AMS programs, and has been shown to reduce the prevalence of colonization by antimicrobial resistant bacteria, the incidence of infection caused by antimicrobial resistant bacteria, and the incidence of CDAD, in hospital inpatients (Baur et al., 2017). Given that the mortality of CDAD is commonly 10%–30% (Bloomfield et al., 2012) reducing the incidence of this disease is an important goal of AMS programs.

Recognition of the very high rate of clindamycin dispensing within the regional hospital led to an AMS program intended to change the clinician prescribing behavior and reduce the incidence of CDAD. The annual level of dispensing of clindamycin within the hospital fell dramatically during the subsequent 6 years, from 1103 DDDs in 2011 to 640 DDDs in 2017 (Richardson, 2019, personal communication). This large reduction in clindamycin consumption was associated with a dramatic reduction in the incidence of CDAD, which fell from 69 cases in 2011 to 18 cases in 2017 (Gilbert, 2019, personal communication). This example illustrates the beneficial outcomes that can result from an audit of antimicrobial dispensing within an institution or region.

The development and regular review of prescribing guidelines are core components of AMS programs. Pharmacists lead in this area, writing guidelines in collaboration with infection specialists and other relevant specialists, for example, respiratory physicians for pneumonia or general surgeons for peritonitis, in order to gain maximal acceptance of the developed guideline. On-going review is also needed to ensure practice remains up-to-date with the latest evidence and recommendations (**Table 2**).

An effective way of supporting appropriate antibiotic use is through restricting the prescription of very broad-spectrum or specialist agents. With traditional paper-based prescribing, this is often a role of the pharmacist, who will decline to dispense restricted antimicrobials unless appropriate authorization or approval has been obtained, for example, from an infection specialist. With electronic prescribing, systems can be developed with pharmacist input, either to restrict the ability to prescribe some antibiotics or to provide decision support that encourages the prescriber to prescribe alternative agents (Schuts et al., 2016). Restricting antibiotics is a hard-stop measure to ensure appropriate use, and is sometime seen as confrontational or dis-empowering to the prescriber, but has repeatedly been shown to be one of the most effective ways to improve antibiotic usage (Davey et al., 2017).

Patient's reported allergies influence the choice of antibiotics used and can sometimes lead to prescription of unnecessarily broad-spectrum agents, especially when patients report penicillin allergy. Over 90% of patients with a history of penicillin allergy have negative skin testing and will experience no increased risk of adverse reactions if treated with a penicillin (Blumenthal et al., 2017; Park et al., 2011). In consultation with patients, pharmacists can evaluate the patient's allergy history and determine if they are likely to have true allergy, using questionnaires or skin testing. Identifying patients without true allergy allows the prescriber to use first line beta-lactam-based therapy in a number of scenarios (du Plessis et al., 2019).

As medicines experts, pharmacists are involved in all aspects of the medication management pathway and new roles and functions within this pathway, more than just dispensing, are becoming available to assist in appropriate use of antimicrobials.

Prescribing of antimicrobials has traditionally been the domain of doctors, dentists, and midwives; however, this is changing in many countries where pharmacist prescribing is becoming more accepted. In the United Kingdom, nonmedical prescribers, including pharmacist and nurse prescribers, were responsible for 6.5% of all antibiotic prescriptions in 2017. The majority of these nontraditional prescribers work in primary care and often are better than traditional prescribers in their level of adherence to prescriber guidelines (Courtenay et al., 2017a), including recommending nonantibiotic strategies to patients as appropriate. Pharmacist prescribers in the United Kingdom have also been shown to be appropriately managing patients' expectation of antimicrobial treatment for respiratory tract infections, a common condition where antibiotics have frequently been overprescribed (Courtenay et al., 2017b). Patient expectation is thought to be a large driver for community prescribing of antibiotics due to the interactional nature of primary health care. It is therefore promising to see pharmacists dealing with this issue well and having appropriate strategies for managing this while maintaining patient satisfaction.

In many countries, pharmacists are also supplying antibiotics without prescription. It is therefore important that those pharmacists are able to make informed decisions about the legal status of antibiotics, appropriate choice and monitoring of patients, and when to refer to a designated prescriber. Evidence suggests that in many situations antibiotics are supplied when they are inappropriate or unnecessary (Chang et al., 2017; Hadi et al., 2016; Kalungia et al., 2016; Shet et al., 2015). Pharmacists in primary care must be engaged with AMS efforts to ensure that supply is appropriate in all situations. With appropriate training and support of the community, pharmacist supply of antibiotics in primary care can be a success. In New Zealand, strict criteria were established in conjunction with infectious disease specialists and the support of the medical fraternity, for primary care pharmacists to supply trimethoprim to women with cystitis without prescription following an accreditation training program. Follow-up reviews of supply by trained pharmacists showed high levels of satisfaction from treated women and no increase in overall antibiotic usage or subsequent prescription of second-line agents by general practitioners (Gauld et al., 2017). Providing advice about appropriate self-care, and non antibiotic treatment, for self-limiting infections such as gastroenteritis or upper respiratory tract infections, is also an important function of community pharmacists in assisting in reducing antibiotic use.

Other options for pharmacist-led optimization of prescriptions include the use of automatic stop and IV to oral switch policies. As part of standard clinical review, pharmacists may identify patients who are clinically improving and who meet criteria to have their therapy modified in line with local guidelines. Automatic stop policies are useful to encourage prescribers to consider and document treatment durations, as otherwise pharmacists may enact a stop of a prescribed antibiotic at a recommended course duration, for example, 7 days which is adequate for most uncomplicated infections. Intravenous to oral switch policies can be applied to patients who no longer need treatment with intravenous therapy and are suitable for oral therapy, thus reducing the time devoted to nursing care, the risks of infection and thrombosis of intravascular cannulae, and health-care costs (Schuts et al., 2016).

A key strategy to reduce antimicrobial resistance is prevention of infection. Vaccination is a highly effective way of reducing the incidence of infectious diseases and a promising area of pharmacist involvement. Primary care pharmacy is well placed as a community-based health care provider to offer vaccination to at-risk members of the community. Influenza infection is a common precursor to antibiotic use, either appropriately for post-influenza bacterial pneumonias or inappropriately for purely viral infections. Reducing influenza spread and therefore antibiotic use is therefore desirable from an AMS standpoint. Modeling has suggested that utilization of community pharmacies in pandemic influenza vaccination campaigns could significantly reduce the time to achieve high levels of vaccine coverage, and thus reduce the incidence of disease (Schwerzmann et al., 2017). This has been supported by studies looking at the impact of pharmacies offering routine autumn influenza vaccination. Eligible patients are more likely to receive vaccination (Drozd et al., 2017), and higher vaccination rates were seen regardless of the role pharmacists played in the vaccination process (Isenor et al., 2016). Pharmacists may be involved as educators of vaccinators or of patients, facilitators of vaccine supply, or direct administrators of vaccines to patients. While most evidence is seen in primary care, significant improvements in the proportion of vaccinated inpatients were achieved with the introduction of a pharmacy technician-led vaccination program (Hill et al., 2017). Similarly beneficial effects have also been demonstrated in programs where pharmacists have been involved in vaccination against pneumococcal disease (Pizzi et al., 2017).

While antibiotic use is very widespread, with 65% of respondents to a WHO survey across 12 countries having used antibiotics within the previous 6 months, knowledge among the general public about appropriate use of antibiotics is relatively poor (WHO, 2015). Educating the public and specifically patients about the appropriate use of antibiotics is very important. Pharmacist-initiated educational interventions have been shown to increase patients' knowledge of appropriate antibiotic use and antibiotic resistance (Rodis et al., 2004). This educative role should also be part of an overarching involvement in the promotion of public health initiatives as part of practice. Primary care or community pharmacists are particularly well placed to engage in health promotion messaging, with continual engagement of their local community and population (APHA, 2006). In addition to taking an opportunity to increase general knowledge, and potentially influence future decision making and understanding, pharmacist counseling around antibiotic use can have immediate impacts on AMS. Improving patient adherence to antimicrobial prescriptions can be critically important in reducing development of antimicrobial resistance and has been clearly demonstrated in infections such as tuberculosis and HIV (Clark et al., 2007; Saberi et al., 2012). Pharmacist-directed patient counseling resulted in significantly greater adherence to their treatment regimen in patients with tuberculosis (Clark et al., 2007). A meta-analysis of pharmacist provided counseling showed similar findings with regard to the levels of adherence to their antiretroviral medications in patients with HIV infection, with consequent benefits in the suppression of HIV infection and the need for hospital admission (Saberi et al., 2012).

While optimizing the use of existing antimicrobials is a critically important component of preventing the development and spread of antimicrobial resistance, there is clearly a need for research and development of novel agents to treat multiresistant organisms. Research- and academic-based pharmacists play a large role in the development of these agents, with expertise in drug development, pharmaceutical formulation science, and clinically based research identifying pharmacokinetic and pharmacodynamic properties.

Bacterial Infections and the Role of the Pharmacist

Syed Tabish R. Zaidi*, Naomi E. Weier†, *University of Leeds, Leeds, West Yorkshire, United Kingdom; †Division of Pharmacy, School of Medicine, University of Tasmania, Hobart, TAS, Australia

Learning Objectives

After reading this paper, readers will be able to:

- Understand the various factors that determine the clinical effectiveness of antibacterials.
- Recognize the various clinically relevant classes of antibacterials and the commonly used antibacterials within each class.
- Appreciate the role of the pharmacist in optimizing antibacterial therapy in practice.

Take-Home Messages

- Numerous antibiotic classes exist. Different antibacterials in the same class will have different indications, routes of administration, contraindications, and adverse effects.
- Potential routes of administration include oral, intramuscular, intravenous, inhalation, nasogastric, nasoenteric, and percutaneous endoscopic gastrostomy (PEG). The oral route of administration is appropriate in most situations as it does not require vascular access, often has less serious adverse effects, and is cheaper.
- Increasing antimicrobial resistance is being seen in both hospital- and community-acquired infections, and multidrug-resistant organisms are associated with higher mortality and a high economic cost. Inappropriate use of antibacterials contributes to this increasing resistance.

- The pharmacist has an essential role in optimizing the use of antibacterials in practice. This can include being involved in therapeutic drug monitoring, recommending appropriate antibacterial therapy and doses, recommending a change from intravenous to oral therapy when appropriate, and providing education to medical and nursing staff and patients.

Introduction

Accidental discovery of penicillin by Alexander Fleming in the year 1928 has revolutionized the practice of medicine across the globe (Gaynes, 2017). Today, there are numerous classes of antibacterials and each class has a number of unique members. In fact, a summary of all the available antibacterials is beyond the scope of this paper and can be found elsewhere. The following discussion covers some of the contemporary issues surrounding the pharmacotherapy for bacterial infections followed by the clinical applications of such issues specific to each class of antibacterial. Importantly, all these contemporary issues are related to the effective use of antibacterials and may contribute toward limiting the ever-increasing threat of antimicrobial resistance (AMR). Recent modeling data have shown that AMR is becoming a global problem that may lead to the death of 10 million individuals a year by the year 2050 (O'Neill, 2016).

Bacterial infections continue to make a large contribution to morbidity and mortality, especially in developing countries. The use of certain medical treatments such as chemotherapy and the presence of conditions such as the human immunodeficiency virus (HIV) infection can increase a person's risk of complications from serious bacterial infections, which is seen in both developed and developing countries. While the discovery and development of antimicrobials has improved the survival of people who have contracted various bacterial infections, increasing resistance has meant that treatment options for certain infections are diminishing. Ensuring antibacterials are used judiciously and appropriately is an essential role of the pharmacist and may assist in improving the time that certain antibacterials are effective for (Hauser et al., 2016; Rossi, 2018; World Health Organization, 2001).

Types of Bacteria and Clinical Spectrum of Antibacterials

Given the fact that the clinical use of antibacterials is often targeted at certain types of bacteria, it is important to understand the broader classification of these organisms. The most frequently used clinical classification of bacteria is based on two distinct criteria: Gram stain and oxygen consumption. Hans Christian Gram in the year 1884 developed a method of staining bacteria with a crystal violet-iodine complex and a safranin counterstain (Coico, 2005). Bacteria containing a distinguished cell wall retain this complex after treatment with alcohol and appear purple and, therefore, are called Gram-positive bacteria as they retain the Gram stain. On the contrary, bacteria without a distinct cell wall do not retain the complex after treatment with alcohol and appear pink. They are therefore called Gram-negative bacteria (Beveridge, 1999; Coico, 2005). Gram-positive and Gram-negative bacteria are further subclassified as per their morphological appearances as bacilli (rod-shaped) or cocci (sphere-shaped).

Bacteria vary in their oxygen requirements. Anaerobic bacteria do not require oxygen and obtain energy through fermentation or anaerobic respiration (Werth, 2018i). These bacteria are commonly seen in the gastrointestinal tract, vagina, dental crevices, and chronic wounds with impaired blood supply. Aerobic bacteria need oxygen for energy and use aerobic cellular respiration to produce energy. Facultative bacteria can survive with or without oxygen and will adapt based on if oxygen is present. Fermentation or anaerobic respiration is used if oxygen is not present and aerobic cellular respiration occurs when oxygen is present (Werth, 2018i).

Antibacterials can be broadly classified as broad and narrow spectrum. Antibacterials that are effective against a variety of bacteria such as Gram-positive and Gram-negative bacteria are categorized as broad-spectrum antibacterials, whereas those that are effective against limited bacteria are considered narrow spectrum. **Table 1** shows a summary of major antibacterial groups and their respective spectrum; specific information about the example antibacterials is provided under the Notes section of this table. It is important to note that the table is intended to provide a clinically relevant summary of spectrum, and therefore it may not represent a theoretical and microbiologically accurate summary of the quoted antibacterials.

Source of Infection

Quite often the obvious signs and symptoms of an infection may provide clues about the location of the source of the infection. Nevertheless, occasionally the source of infection can be hard to locate. Ironically, locating the main source of infection is often challenging in serious and life-threatening infections such as septicemia and septic shock. Presence of bacteria in the bloodstream should be taken seriously and every attempt should be made to detect the source of infection so the most suitable treatment is commenced. Failure to identify and control the source of infection has been associated with high patient mortality (Vincent, 2016). Controlling the source of infection is particularly important in internal and external abscesses as specific surgical techniques are equally important to treat the infection as the initiation of appropriate antibacterial treatment (Korownyk and Allan, 2007). Pharmacokinetics properties of antibacterials differ considerably between various classes and within each class. Certain antibacterials may not be effective in treating an infection despite being effective against the bacteria due to their inability to penetrate into the source of infection. For example, vancomycin has very limited penetration into respiratory fluids, and therefore it is not the treatment of choice for a methicillin-resistant *Staphylococcus aureus* (MRSA) pneumonia infection (Rubinstein et al., 2008).

Table 1 Antibacterial spectrum of the major antibacterial groups (Antibiotic Expert Group, 2015; Australian Commission on Safety and Quality in Health Care, 2016; Baldwin et al., 2008; BPAC, 2011, 2012; Breilh et al., 2013; Gonzalez and Spencer, 1998; Kang and Park, 2015; MEDSCAPE, 2018b,c; Pham and Bartlett, 2014; Rossi, 2018; Smith and Pham, 2016; Stanaway, 2001; Werth, 2018a,b,c,d,e,f,h,j,l; World Health Organization, 2001; Zhanel et al., 2007)

Class of antibacterial	*Spectrum*	*Example*	*Notes*
Aminoglycosides	Broad	Amikacin	Amikacin has the broadest spectrum, and often effective for infections resistant to gentamicin and tobramycin (structure of amikacin is less susceptible to inactivating enzymes)
	Narrow	Gentamicin	Most common aminoglycoside used due to low cost and efficacy. Similar activity against Gram-negative bacilli to tobramycin, but more effective against *Serratia marcescens* and less effective against *Pseudomonas aeruginosa*
Carbapenems	Broad	Meropenem	Carbapenems have a broad spectrum of activity. Meropenem is used for empirical treatment of nosocomial or life-threatening infections when other antibiotics are inappropriate or when multidrug Gram-negative bacteria are suspected
	Limited	Ertapenem	More limited spectrum of activity compared to imipenem, meropenem, and doripenem as not effective against *P. aeruginosa* and *Enterococcus* spp. May be dosed once daily (half-life of approximately 4 h) making it a suitable treatment option for community-acquired infection and outpatient intravenous therapy
Cephalosporins	Broad	Ceftriaxone	Cephalosporins are broad-spectrum antibiotics and should not be used when antibiotics with a narrower spectrum will be effective. Third-generation cephalosporins (like ceftriaxone) have the broadest spectrum of activity. Active against *Haemophilus influenzae*, some Enterobacteriaceae, some Gram-positive organisms (particularly streptococci). Intravenous or intramuscular administration
	Moderate	Cefalexin	Effective for staphylococci and streptococci infections, and against some Gram-positive anaerobes. First-generation cephalosporin—oral administration
Fluoroquinolones (quinolones)	Extended	Moxifloxacin	Moxifloxacin is effective for Gram-positive infections (including staphylococci and streptococci), many Gram-negative infections and against anaerobic infections. It is not effective against *P. aeruginosa*
	Broad	Ciprofloxacin	Ciprofloxacin is effective for infections caused by Gram-negative bacteria (e.g., *H. influenzae*), enteric Gram-negative rods, Gram-negative cocci, some Gram-positive cocci, *P. aeruginosa*, and intracellular organisms (e.g., Legionella). Not effective against anaerobic bacteria
Glycopeptides	Narrow	Teicoplanin, vancomycin	Bactericidal, prevent formation of peptidoglycan polymers which inhibits synthesis of bacterial wall. Used for severe infections caused by Gram-positive pathogens (e.g., Enterococci, methicillin-resistant *Staphylococcus aureus*, *Clostridium difficile*). More experience with vancomycin and cheaper than teicoplanin, therefore the glycopeptide recommended
Lincosamides	Broad	Clindamycin	Clindamycin may be used as an alternative to penicillins and cephalosporins for patients with severe allergy
Macrolides	Broad	Erythromycin	Indications for erythromycin include upper and lower respiratory tract infections, rheumatic fever prophylaxis, chlamydial infections and prevention and treatment of pertussis
Nitroimidazoles	Broad	Metronidazole, tinidazole	Indications include Gram-positive and Gram-negative anaerobic bacterial infections, protozoal infections, intestinal and extraintestinal amoebiasis, bacterial vaginosis, and surgical prophylaxis. Have a similar spectrum of activity, with some cross-resistance
Penicillins	Broad	Amoxicillin+clavulanic acid	Amoxicillin + clavulanic acid is used for infections such as pneumonia, urinary tract infection, bites and clenched fist injuries, acute otitis media, and sinusitis not responding to amoxicillin
	Narrow	Dicloxacillin	Indicated for Staphylococcal skin infections, Streptococcal infections, pneumonia, pharyngitis, osteomyelitis, and septic arthritis. May be used interchangeably with flucloxacillin
Rifamycins	Broad	Rifampin	Rifabutin, rifampin, and rifapentine have a similar spectrum of activity, and effective for infections caused by most Mycobacteria and Gram-positive bacteria, and some Gram-negative bacteria
Tetracyclines	Broad	Doxycycline	Spectrum of activity includes Gram-positive and Gram-negative bacteria, Chlamydia, Rickettsia, Mycoplasma, spirochaetes, and some nontuberculous mycobacteria and protozoa. Doxycycline is the tetracycline of choice in most cases, and is better tolerated than minocycline and tetracycline. Doxycycline should be taken with food or milk

Table 2 Intention of antibacterial treatment (Antibiotic Expert Group, 2015)

Intention of treatment	*Appropriate example*	*Inappropriate example*
Prophylactic	Single dose of cefazolin half an hour before incision in most clean-contaminated surgeries	Multiple doses of cefazolin or scheduled doses of cefazolin in a patient undergoing clean-contaminated surgery where there is no sign of infection
Empiric	Broad-spectrum antibiotics in a patient admitted with septic shock while pending diagnostic workup	Continued use of broad-spectrum antibiotics after 72 h in the absence of diagnostic rationale (Microbiology/Radiology, etc.)
Directed	Pneumonia that has been confirmed to be caused by *Streptococcus pneumoniae* is treated with benzylpenicillin until the patient significantly improves, then changed to amoxicillin for a total of 7 days treatment	Continuing to use broad-spectrum antibiotics after the pathogen has been confirmed and could be effectively treated with a narrower spectrum antibiotic

Intention of Antibiotic Use and Ongoing Review

Given the unprecedented increase in AMR, it is important to clarify and document the intention of any antibacterial use and a plan for ongoing review. Antibacterial treatment can be broadly classified into prophylactic, empiric, and directed treatment (**Table 2**). Regardless of the intention of the initial treatment, it is crucial that all antibacterial treatments are reviewed within an appropriate time frame and decisions are made regarding the total duration of treatment.

Many bacterial infections are empirically treated based on a presumptive diagnosis that is guided by the clinical history and physical presentation. In practice, empirical treatment should be guided by local epidemiological data on the most likely causative pathogens as well as local patterns of resistance and susceptibility. The antimicrobial with the narrowest spectrum of activity should be used to treat the suspected pathogen(s). If cultures are required, these should be taken prior to beginning empirical treatment where possible (Antibiotic Expert Group, 2015; World Health Organization, 2001). If antibiotics are used empirically, the dosage regimen should be based on recommended treatment guidelines and treatment should be reviewed after 48–72 h (Antibiotic Expert Group, 2015).

Directed treatment is when an organism has been identified as the source of infection in a given patient and the treatment is directed towards eradicating that organism. Adequate specimens for microbiological testing should be obtained before antimicrobial therapy is begun where possible (World Health Organization, 2001). Once culture results are obtained it is important to determine whether the results identify true infection, or colonization or contamination, to ensure antimicrobial treatment is only initiated or continued when appropriate. Treatment duration should be based on evidence where possible and the shortest possible duration should be used (Antibiotic Expert Group, 2015).

Prophylactic treatment with antibacterials aims to prevent infection and is used in situations where there is a significant risk of infection. It may be primary prophylaxis (where it is used to prevent an initial infection), secondary prophylaxis (when used to prevent the recurrence or reactivation of an infection), or used to remove a colonizing organism in order to prevent an infection. Prophylactic treatment should only be used when evidence exists for its effectiveness or when there are serious consequences (morbidity or mortality) if an infection develops. Some prophylactic regimens are evidence-based; however, most practices in this area are either based on expert opinion or have low evidence to support their use (Antibiotic Expert Group, 2015; Enzler et al., 2011).

Pharmacokinetics and Pharmacodynamics

Pharmacokinetics is what a body does to a medicine, whereas pharmacodynamics is what a medicine does to the body. As such, absorption, distribution, metabolism, and elimination of antibacterials are important pharmacokinetic factors that determine the effectiveness of these medicines. On the contrary, the relationship of an antibacterial concentration with that of the antibacterial effect is an important pharmacodynamics parameter that determines the clinical effectiveness of these medicines.

Pharmacokinetics

Adequate absorption of the antibacterial is essential for antibiotics administered through the oral route. Various antibacterials can have impaired absorption if taken with or without meals while others are not affected by food. Fluoroquinolones are best taken on an empty stomach, at least half an hour before food or 2 h after food (Rossi, 2018). The same applies to the penicillinase-resistant penicillins dicloxacillin and flucloxacillin (Rossi, 2018). On the contrary, certain antibiotics (e.g., nitrofurantoin and cefuroxime) should be taken with food to improve absorption (Rossi, 2018). Some antibacterials have intrinsically poor oral absorption, and therefore oral treatment should only be used when a local action is desirable or as a maintenance treatment to finish a regimen. Neomycin, an oral aminoglycoside, and vancomycin, a glycopeptide, are often used in clinical practice for surgical bowel preparation and treatment of *Clostridium difficile* infection, respectively (Kumar et al., 2013; Rossi, 2018).

Distribution of an antibacterial at the site of infection is one of the crucial steps that determines its clinical effectiveness. Some bacteria are concentrated inside the cell, and therefore antibacterials that are capable of penetrating cells are required to achieve the

needed antibacterial effect. Macrolides such as erythromycin and fluoroquinolones such as ciprofloxacin are some of the antibacterials that can distribute inside the cells and are effective treatment options for pneumonia caused by *Legionella pneumophila* and *Mycoplasma pneumoniae* (Cilloniz et al., 2016). Other examples that highlight the importance of adequate distribution at the site of infection are penetration of antibiotics in bone, meninges, and endocardium tissues when treating osteomyelitis, meningitis, and endocarditis.

The metabolism characteristics of individual antibacterials can affect the suitability of these medicines in various patient populations. Penicillins and cephalosporins usually have poor oral absorption. Quite often these medicines are formulated as a salt for better absorption and rely on metabolism to release the active antibacterial molecule. A number of antibacterials become inactivated by hepatic enzymes and, although in the majority of cases no dose adjustments are required in patients with hepatic insufficiency, some antibacterials such as antituberculars, tetracyclines, and macrolides require dose reduction in severe hepatic impairment (Rossi, 2018).

Elimination takes many forms when it comes to antibacterials, though most active antibacterials or their inactive metabolites are excreted in urine. Therefore, renal function plays an important role in eliminating antibacterials from the human body. The majority of beta-lactams such as aminopenicillins (ampicillin), extended-spectrum penicillins (piperacillin), the majority of all four generations (first, second, third, and fourth) of cephalosporins (e.g., cefazolin, cefuroxime, cefotaxime, and cefepime), and carbapenems (meropenem, imipenem, ertapenem and doripenem) are eliminated via the kidneys and require dose adjustments in renal impairment (Antibiotic Expert Group, 2015). Inadequate dose reduction of the abovementioned antibacterials in renal impairment has been associated with negative patient outcomes such as seizures, tubular damage leading to further worsening of kidney function, and increased incidence of adverse effects due to higher drug concentrations (National Institute for Health and Care Excellence, 2019).

Pharmacodynamics

A number of pharmacodynamics parameters relate to antibacterials such as dose–response curve, the minimum inhibitory concentration (MIC) and its derivatives such as MIC_{50} and MIC_{90} (minimum concentration of antibacterial that inhibits 50% and 90% of the bacterial growth), and relationship of MIC with serum concentration and area under the curve (AUC) of individual antibacterials (Levison and Levison, 2009; Schwarz et al., 2010). Another important pharmacodynamics concept of antibacterials is the postantibiotic effect, that is, the ability of the antibacterial to show bacteriostatic (halting the growth of bacteria) or bactericidal (killing bacteria) effects despite dropping of its serum concentration beneath MIC_{50} or MIC_{90}. The discussion later will be limited to two of the most contemporary issues informing clinical practice, namely, the relationship between the ratio of serum concentration of antibacterials and MIC, and the postantibiotic effect.

Pharmacodynamically, antibacterials can be classified in three major groups. The first group is antibacterials that exhibit maximum bacterial killing when the serum concentration is maintained above the MIC for an extended period of time or a time-dependant killing effect is observed (often abbreviated as T > MIC). The second group, concentration dependent killing, covers antibacterials that achieve maximum bacterial killing when highest possible peak concentrations are achieved. The third group of antibacterials achieves best bacterial killing effects when a certain ratio of area under the curve and MIC is achieved. The second and third groups of antibacterials also exhibit variable degrees of postantibiotic effect. Specific examples of all these three pharmacodynamics parameters are shown in **Table 3**.

Route of Administration

The most appropriate route of administration for antibiotic therapy will depend on the clinical presentation; however, in most situations, the oral route is most appropriate. Oral therapy has numerous advantages, including removing the requirement for vascular access, is often linked with less serious adverse effects, and is more cost-effective (through both the cost of the drug and administration costs) (Antibiotic Expert Group, 2015; World Health Organization, 2001).

Table 3 Pharmacodynamics-based classification of antibacterials with few examples

Group of antibacterials	*Preferred pharmacodynamic parameter*	*Example regimen*
Penicillins	Time dependant killing (T > MIC)	Benzylpenicillin 1.6–2.4 g every 4 h as 30–60 min infusion in meningitis or endocarditis
Carbapenems		Meropenem 1–2 g every 6–8 h for the treatment of hospital-acquired pneumonia
Aminoglycosides	Cmax/MIC	Gentamicin 5–7 mg/kg daily
Macrolides		Azithromycin 2 g once for community-acquired pneumonia
Quinolones	AUC/MIC	Ciprofloxacin 400 mg every 8 h is better than 400 mg every 12 h to achieve the target AUC/MIC of 125 for pneumonia caused by *Pseudomonas aeruginosa*
Glycopeptides		Vancomycin 2 g every 6–8 h has been used instead of the traditional every 12 h to achieve better clinical cure rate in methicillin-resistant *Staphylococcus aureus*

Other routes of administration include nasogastric, nasoenteric, PEG, and parenteral (usually intravenous). The parenteral route of administration is appropriate when the oral route is not practical or possible—gastrointestinal absorption is either significantly reduced through patient factors such as vomiting or the drug is already poorly bioavailable and reduced absorption will accentuate this, higher doses are needed which is difficult to achieve with oral treatment, urgent treatment is required, or when the preferred antimicrobial treatment is not available in an oral formulation. The patient should be changed to oral therapy when possible (Antibiotic Expert Group, 2015).

Nebulized antibiotics are sometimes used; however, this should only be done in specific situations. Topical use of antibiotics should only be used for certain indications, and generally antibiotics used topically should be from different classes than those available for systemic treatment (Antibiotic Expert Group, 2015).

Adverse Effects

Like all other medicines, use of antibacterials is associated with adverse effects. A number of adverse effects are common with most antibacterials such as gastric upset, mild nausea, mild diarrhea, dizziness, and skin rashes (Dancer, 2004). Fortunately, most of the common adverse effects are tolerable and disappear once the antibacterial course is completed and therefore do not interfere with the treatment of infections. Nevertheless, some antibacterials have serious adverse effects and the risk of these adverse effects should be weighed against the benefits associated with their use. For example, the use of aminoglycosides is associated with nephrotoxicity and ototoxicity, the use of fluoroquinolones in young children and adolescents is linked with bone deformity, and the use of the antitubercular drug isoniazid has been associated with hepatic failure and subsequent death in some patients (Ali and Goetz, 1997; Takayama et al., 1995; Wu et al., 2007).

Summary of Major Antibacterial Classes

The discussion so far has been restricted to the general concepts of antibacterials and some of the contemporary issues in optimizing antibacterial regimens. The following section will briefly summarize the clinical indications, usage, and adverse effects profile of each antibacterial class followed by a section on the role of pharmacists in optimizing antibacterial regimens.

Aminoglycosides

Owing to the significant nephrotoxicity and ototoxicity of aminoglycosides, these antibacterials are reserved for clinical indications where other less toxic antibacterials are either contraindicated or ineffective. As such, the most common indications for aminoglycosides use are treatment of serious Gram-negative bacteria infections such as septicemia in combination with penicillins, hospital-acquired pneumonia, and treatment of endocarditis (Gonzalez and Spencer, 1998; Werth, 2018a).

The use of aminoglycosides is contraindicated in patients who have had an allergic reaction to an aminoglycoside in the past, and also contraindicated in patients who have previously experienced vestibular or auditory toxicity when taking an aminoglycoside. They should be used with caution in patients with neuromuscular disease (such as myasthenia gravis) due to an increased risk of muscle weakness and respiratory depression. In patients with hypocalcemia, hypermagnesemia, general anesthesia, and large transfusions of citrated blood, there is an increased risk of neuromuscular adverse effects when aminoglycosides are used (Rossi, 2018; Werth, 2018a).

Common adverse effects associated with aminoglycoside use include nephrotoxicity and ototoxicity. Infrequently, they can cause anaphylaxis, bronchospasm, neuromuscular blockade, oliguria, and peripheral neuropathy. Nephrotoxicity is often reversible, and usually presents as nonoliguric renal failure that gradually worsens through increased serum creatinine and proteinuria. However, it may also present as acute tubular necrosis. Ototoxicity occurs in 2%–4% of people treated with aminoglycosides, and is reversible approximately 50% of the time (Rossi, 2018; Werth, 2018a).

Carbapenems

Doripenem, ertapenem, imipenem, and meropenem are the most notable examples of carbapenem antibacterials. Carbapenems have the broadest spectrum of antibacterial activity and are usually reserved for serious life-threatening infections caused by bacteria that are resistant to other first-line antibacterials. Due to ertapenem and imipenem having the potential to cause seizures, using these antibiotics in combination with other drugs that increase the risk of seizures may potentiate this risk, therefore combination should be avoided, if possible. Carbapenems can also reduce the concentration of valproate, if given in combination, and increasing the dose of valproate may not overcome this. It is generally recommended to avoid this combination (Rossi, 2018; Zhanel et al., 2007). Carbapenems are contraindicated in patients who have had a history of allergy to carbapenems. Due to cross-reactivity between penicillins, cephalosporins, and carbapenems, care should also be taken in patients who have an allergy to penicillins or cephalosporins. Use of carbapenems is also contraindicated in patients with an immediate or severe hypersensitivity to penicillins (Rossi, 2018).

Cephalosporins

There are five generations of cephalosporins (beta-lactam antibiotics), which classify cephalosporins in the order that they were developed. The most notable member of the first generation is cefazolin, and it is most commonly used to treat skin and soft tissue infections and as a surgical prophylaxis for clean-contaminated surgeries (Rossi, 2018; Werth, 2018c; Yuson et al., 2018). Cephalosporins have good penetration into most body fluids and the extracellular fluid of the majority of tissues, which is enhanced when inflammation is present (Werth, 2018c). Second and third generations of cephalosporins are active against Gram-positive and Gram-negative bacteria, but are ineffective against enterococci, methicillin-resistant staphylococci, and anaerobic Gram-negative bacilli (except for cefotetan and cefoxitin). Ceftriaxone, cefotaxime, ceftazidime, and cefepime are the only cephalosporins that reach the cerebrospinal fluid in high enough concentrations for the treatment of meningitis (Werth, 2018c).

Cephalosporins are contraindicated in patients with a history of an allergy to cephalosporins or who have had an immediate or severe hypersensitivity reaction to penicillins. As there is cross-reactivity between carbapenems, cephalosporins, and penicillins, care should be taken if patients have had an allergic reaction to carbapenem or penicillin antibiotics (Rossi, 2018; Werth, 2018c).

Adverse effects associated with cephalosporins include hypersensitivity/allergic reactions, *C. difficile*-induced diarrhea, leukopenia, thrombocytopenia, gastrointestinal effects (e.g., diarrhea, nausea, and vomiting), rash, headache, dizziness, and superinfection (such as with *Enterococcus* spp. and *Candida*, in particular when broader-spectrum cephalosporins are used and with prolonged treatment). Pain at the injection site may occur with intramuscular administration and thrombophlebitis is possible with intravenous use (Rossi, 2018; Werth, 2018c).

Fluoroquinolones (Quinolones)

Fluoroquinolones are concentration-dependent bactericidal antibiotics and inhibit DNA gyrase and topoisomerase IV, thereby inhibiting bacterial DNA synthesis. Resistance to fluoroquinolones is increasing worldwide so careful use is advised to optimize their clinical use. They are contraindicated in patients who have had a previous allergic reaction to fluoroquinolones, as well as in patients who have disorders that predispose them to arrhythmias (such as prolonged QT interval, significant bradycardia or uncorrected hypokalemia or hypomagnesemia). Traditionally, fluoroquinolones have been contraindicated in children because they can cause cartilage lesions and damage; however, the evidence to support this is weak. Fluoroquinolones should only be used in children and adolescents for severe infections if the benefit seen is greater than the risk of arthropathy (Rossi, 2018; Werth, 2018d).

Common adverse effects of fluoroquinolones include rash, itch, and gastrointestinal effects (e.g., nausea, vomiting, diarrhea, abdominal pain, and dyspepsia). Tendon damage is also possible, and risk factors include current corticosteroid use, age >60 years, organ transplant (kidney, heart, or lung), renal impairment, rheumatoid arthritis, hyperparathyroidism, musculoskeletal disorders, diabetes, and athletes in training. Patients should be advised to stop taking fluoroquinolones and see their doctor if they experience sore or inflamed tendons. When fluoroquinolones are taken orally their absorption can be reduced if aluminum, magnesium, calcium, zinc, or iron supplements are taken at the same time, and their doses should be separated by 2 h (Rossi, 2018; Werth, 2018d).

Glycopeptides

The glycopeptides include teicoplanin and vancomycin. They are bactericidal, and work by preventing the formation of peptidoglycan polymers that inhibit the synthesis of the bacterial wall. They are used to treat severe infections caused by Gram-positive pathogens (e.g., *Enterococci*, MRSA, and *C. difficile*). There is more experience with vancomycin that is cheaper and therefore the glycopeptide recommended to be used. Glycopeptides should be used with caution in patients with hearing impairment or receiving treatment with ototoxic medicines (e.g., aminoglycosides) as the risk of ototoxicity may be increased, particularly if vancomycin is used. The risk of nephrotoxicity may also be increased if patients are taking nephrotoxic drugs concurrently (e.g., aminoglycosides), and renal function and drug concentration should be monitored in these situations. Similarly, in patients with renal impairment the risk of ototoxicity and nephrotoxicity may be increased (particularly with vancomycin) and the dose should be reduced (Kang and Park, 2015; Rossi, 2018).

Side effects associated with parenteral administration include nausea and hypersensitivity. Red man syndrome may also occur (more common with vancomycin), and symptoms due to the release of histamine can occur (e.g., fever, chills, erythema, rash on the face and upper torso, hypotension, angioedema, and itch). Due to the potential risk of ototoxicity, hearing should be monitored if treatment is prolonged. Renal function and complete blood count should also be monitored at least once a week, and this should be more frequent if treatment is prolonged and/or a high dose of antibiotic is being used, and in patients with reduced renal function (including the elderly) (Rossi, 2018).

Lincosamides

The lincosamides class includes clindamycin and lincomycin. They are bacteriostatic antibiotics, and act by binding to the 50S ribosomal subunit that inhibits protein synthesis. Due to a similar mechanism of action, cross-resistance occurs between lincosamides and macrolides for *Staphylococci* and *Streptococci* infections. There is also complete cross-resistance between clindamycin and lincomycin. They are not active against *Enterococci*. While lincomycin is the cheaper antibiotic, clindamycin is often used in

preference because it is more potent. Adverse effects of lincosamides include diarrhea (which may be mild to severe), nausea, vomiting, abdominal pain/cramps, rash, itch, and contact dermatitis when used topically. *C. difficile* infection can occur infrequently. When administered intravenously, hypotension and thrombophlebitis may occur rarely, and cardiac arrest is possible with rapid injection. When given intramuscularly pain, induration and sterile abscess may occur. If patients are receiving prolonged treatment complete blood count, hepatic, and renal function should be monitored (Antibiotic Expert Group, 2015; Rossi, 2018; Werth, 2018e).

Macrolides

Macrolides are mainly bacteriostatic, and bind to the 50S ribosomal subunit that inhibits the synthesis of bacterial protein. They also have anti-inflammatory and immunomodulatory effects, which is used in diffuse panbronchiolitis and cystic fibrosis. Macrolides generally have poor oral absorption. There is a risk of potentially fatal cardiac arrhythmias occurring if clarithromycin or erythromycin is administered in conjunction with astemizole, cisapride, pimozide, or terfenadine. Therefore, macrolides are contraindicated in conjunction with these drugs. Gastrointestinal upset is most common with oral erythromycin, but is less common with the use of clarithromycin and azithromycin. Numerous drug interactions can occur with macrolides (BPAC, 2012; Werth, 2018f).

Nitroimidazoles

The nitroimidazole class of antibacterials includes metronidazole and tinidazole. They are bactericidal, and are believed to inhibit DNA synthesis. They are indicated for the treatment of Gram-positive and Gram-negative anaerobic bacterial infections, protozoal infections (e.g., giardiasis and trichomoniasis), intestinal and extraintestinal amoebiasis, bacterial vaginosis, and surgical prophylaxis. They should be used with caution in patients with a history of central nervous system disorders (e.g., seizures) as they are neurotoxic and can aggravate existing conditions, and in patients with a history of blood dyscrasias as they may cause leukopenia. Common side effects include gastrointestinal adverse effects and central nervous system effects. Alcohol should be avoided while patients are taking nitroimidazoles and for 72 h afterwards as a disulfiram-like reaction may occur. If treatment is for longer than 10 days, blood count and neurotoxic reactions should be monitored (Antibiotic Expert Group, 2015; MEDSCAPE, 2018a; Pasupuleti et al., 2014; Rossi, 2018; Werth, 2018g).

Penicillins

Penicillins are bactericidal beta-lactam antibiotics, and work by binding to penicillin-binding proteins that interrupt the synthesis of bacterial cell wall peptidoglycans. This mechanism causes cell lysis or death. Beta-lactamases are produced by some bacteria that inactivate beta-lactam antibiotics. Beta-lactamase inhibitors include clavulanic acid, sulbactam, and tazobactam, and prevent this activation from occurring (Rossi, 2018; Werth, 2018j).

Hypersensitivity reactions can occur with penicillins, and their use is contraindicated in patients who have a history of immediate or severe hypersensitivity. Cross-reactivity between penicillins, cephalosporins, and carbapenems can occur. While penicillins are generally well tolerated, potential adverse effects include gastrointestinal effects, pain and inflammation at the injection site (less common with benzylpenicillin), superinfection (e.g., candidiasis), and *C. difficile* infection. When high-dose treatment is used for longer than 10 days, complete blood count and renal and hepatic function need to be monitored (Rossi, 2018; Stanaway, 2001; World Health Organization, 2001; Werth, 2018j).

Rifamycins

Rifamycins are bactericidal, and inhibit RNA polymerase that is bacterial DNA-dependent, which suppresses RNA synthesis. Rifabutin, rifampin, and rifapentine are similar in their pharmacokinetics, spectrum of activity, and adverse effects. Rifampin is more likely to cause hepatitis and allergies, whereas rifabutin can cause neutropenia and uveitis. Rifampin is also more potent (compared to rifabutin) in inducing transporter proteins such as P-gp and hepatic and intestinal CYP enzymes. Potential adverse effects associated with rifamycins include gastrointestinal effects, rash, hepatitis, central nervous system effects, and myelosuppression. Rifampin, rifabutin, and rifapentine may cause a red–orange discoloration of body fluid (i.e., urine, saliva, sweat, sputum, and tears) and may stain contact lenses; patients should be advised of this (Rossi, 2018; Werth, 2018l).

Tetracyclines

Tetracyclines are bacteriostatic, and bind to the 30S subunit of the ribosome to inhibit bacterial protein synthesis. They are effective for infections such as those caused by *Rickettsia* species, *Mycloplasma* species, *Chlamydophila* species, *Chlamydia* species, spirochetes, and protozoa. Tetracyclines are contraindicated in combination with oral retinoids due to the increased risk of benign intracranial hypertension and in children younger than 8 years due to its potential to discolor teeth, cause enamel dysplasia, and cause deformities and bone growth inhibition through being deposited in bone. However, for severe infections where other treatment is unsuitable, tetracyclines may be used in children. Systemic lupus erythematosus may be worsened by tetracyclines (rarely). Metallic cations (e.g., aluminum, calcium, magnesium, and iron) may decrease the absorption of tetracyclines and if taken in

supplements or other formulations the dosing should be separated by 2 h from tetracyclines. Adverse effects associated with tetracyclines include gastrointestinal effects, photosensitivity, rash, stomatitis, fungal overgrowth, fatty liver, esophageal ulcers, and *C. difficile*-associated disease. Patients should be advised to avoid sun exposure and to wear sunscreen and protective clothing while being treated with tetracyclines. Tetracyclines should also be taken with a large glass of water and patients should avoid lying down for 1 h after taking the tetracycline to avoid esophageal damage (Rossi, 2018; Werth, 2018m).

Other Antibacterials

A greater number of antibacterials exist that are not covered in the above section and, in fact, a discussion of all such medicines is beyond the scope of this paper. Therefore, the following discussion will be limited to those antibacterials that are in common clinical use such as colistin, linezolid, trimethoprim, and trimethoprim/sulfamethoxazole.

Colistin is an older antibacterial of the late 1950s that was abandoned due to its neurotoxicity and nephrotoxicity in the early 1970s as relatively safer alternatives were discovered (Werth, 2018k). Colistin use has been recently resurrected because of the emergence of multidrug-resistant bacteria resistant to carbapenems and extended spectrum penicillins (Werth, 2018k). Colistin is available as a methate salt that needs to be converted to its active form. Conflicting evidence is available on the most effective dose of colistin; some clinicians advocate for a high-dose approach, whereas others advocate a low-dose approach. Nevertheless, high-dose colistin has been associated with a greater degree of nephrotoxicity and discontinuation of treatment (Benattar et al., 2016). Colistin use should be well guarded, as it is the only antibacterial that is effective against carbapenem-resistant Gram-negative bacteria.

Linezolid is an oxazolidinone antibiotic that is effective against multidrug-resistant Gram-positive bacteria. Linezolid is available as an injectable and oral dosage form and has an excellent bioavailability to ensure early transition to oral treatment (Dzintars and Pham, 2018). Linezolid also offers superior tissue penetration compared to vancomycin and has been shown to achieve similar clinical cure rates and lower toxicity in MRSA pneumonia when compared to vancomycin (Wang et al., 2015). As linezolid is effective against the treatment of vancomycin-resistant enterococci, routine clinical use of linezolid is rightly discouraged (Dzintars and Pham, 2018).

Trimethoprim and a combination of trimethoprim with sulfamethoxazole is perhaps one of the oldest antibacterials that is still used extensively. Both antibacterials are antimetabolites and disrupt the bacteria's utilization of folic acid that is integral to their protein synthesis (Werth, 2018n). Trimethoprim is the first-line agent for uncomplicated urinary tract infections, whereas the combination with sulfamethoxazole is used for skin and soft tissue infections, upper respiratory tract infections, and as a chemoprophylaxis for opportunistic infections in immunocompromized patients. Trimethoprim with sulfamethoxazole is the drug of choice for the treatment and prevention of *Pneumocystis jirovecii* pneumonia (Dzintars, 2018).

Role of the Pharmacist in Optimizing Antibacterials

With increasing AMR being seen for commonly available antibiotics, there has been an increased focus on ensuring antibiotics are used appropriately and judiciously (World Health Organization, 2001). Pharmacists, as medication experts who have a unique knowledge of areas such as pharmacokinetics and pharmacodynamics principles, have an essential role in promoting optimal use of antibiotics and improving their use in practice. Pharmacists are identified as essential members of the antimicrobial stewardship (AMS) team; however, all pharmacists working in clinical practice have an important role to play in providing education and advice to patients and other health professionals and making recommendations to improve the management of bacterial infections where required (Bond, 2015; Liaskou et al., 2018). The following section will discuss the role of pharmacists in optimizing antibacterials in three distinct yet interrelated categories: therapeutic drug monitoring, antimicrobial stewardship, and education and counseling of patients.

Therapeutic Drug Monitoring

Pharmacists can play a vital role in measuring the levels of various antibacterials to individualize drug treatment in high-risk patients, thus minimizing adverse effects while maximizing the therapeutic effects. Aminoglycosides and vancomycin are two of the most frequently studied antibacterials; a therapeutic monitoring service of these drugs can make a considerable difference in achieving positive patient outcomes.

One study based in a hospital in Boston looked at the impact pharmacist involvement had in improving aminoglycoside use and optimizing therapy (correct treatment, dose, and frequency). Patients receiving aminoglycosides were identified and referred to the pharmacist, and the pharmacist was responsible for reviewing therapy daily, making recommendations where required, and writing consult notes in the patient's chart. Pharmacist intervention occurred in 50% of cases. After pharmacists were involved in reviewing therapy the percentage of patients receiving optimal aminoglycoside therapy increased from 44% to 80%. Patients who had not been reviewed by a pharmacist also had a higher rate of acute renal function changes and nephrotoxicity (Greenwood et al., 2009).

A multicenter study reviewing the role of pharmacists in managing aminoglycosides and vancomycin in 961 US hospitals involving 199,088 patients found significant differences in various clinical and process outcomes between hospitals that do and do not have clinical pharmacists managing these antibacterials. The study found higher in-patient mortality of around 7%, higher length of stay of around 14%, higher drug and laboratory charges of around 8%, and >30% rise in the incidence of hearing loss and renal impairment when aminoglycosides or vancomycin treatments were not reviewed by a clinical pharmacist (Bond and Raehl, 2005).

Traditional practice of therapeutic monitoring of antibacterials has been restricted to medicines with significant toxicity profiles. However, recent adoption of pharmacodynamics-based antibacterial dosing (**Table 3**) is leading the way for therapeutic drug monitoring to enhance the antibacterial effects of these medicines. Experts have argued for the measurement of the serum drug concentration of beta-lactam antibacterials in high-risk patients such as those who are obese, critically ill, elderly, and those undergoing continuous renal replacement therapies (Huttner et al., 2015; Wong et al., 2018). Augmented renal clearances of up to 1.5–2 × normal renal clearances have been noted in young patients experiencing sepsis. Therefore, close monitoring of the antibacterial level and appropriate dosing calculations to maintain the required drug concentrations is critical for such patients (Mahmoud and Shen, 2017). Pharmacists are well placed to offer their professional opinion not only about the suitability of the best available analytical method to measure the serum drug concentration but also to estimate the doses required to meet the clinical needs of their patients.

Antimicrobial Stewardship

Pharmacists are considered an integral part of any AMS initiative in hospital settings. This is because hospital pharmacists have a long history of safeguarding the use of antibiotics and implementing antibiotic restriction policies in their practice settings (Lawton et al., 2000). A comprehensive review of all the published studies demonstrating the value of pharmacists' participation is beyond the scope of this discussion; however, it is important to note that the guidelines of most professional bodies recommend infectious diseases physicians and pharmacists at a minimum are included as part of an antimicrobial stewardship team (Australian Commission on Safety and Quality in Health Care, 2018; Barlam et al., 2016; Oberje et al., 2017).

Pharmacy departments are uniquely positioned to safeguard the access to antibacterials due to their operational responsibilities of supplying medications in health-care settings. As such, pharmacy departments and pharmacists representing them can enforce the restriction policies of antibacterial prescribing. Studies have shown that implementing a structured restriction policy can serve as an effective means in limiting the inappropriate use of antibacterials (Claeys et al., 2018; Davey et al., 2017; Lee et al., 2018).

Pharmacists can also play a more active role in engaging with doctors at the point of prescribing. Participation of pharmacists in daily antimicrobial clinical rounds has been shown to reduce the usage of carbapenem antibacterials to around 40% of the baseline values (Al-Somai et al., 2014). Pharmacists' participation in routine patient care rounds has been effective in improving antibacterial use, as well as patient outcomes in a variety of settings (Apisarnthanarak et al., 2015; Dubrovskaya et al., 2017).

Another aspect of AMS where pharmacists have shown an impact is the implementation of AMS-related computer applications such as web-based approvals initiatives for restricted antibacterials and computerized decision support systems with or without the electronic order entry system (Evans et al., 2015; Nault et al., 2017; Ohashi et al., 2017). Pharmacists are experienced in clinical computing applications as most drug dispensing software has capabilities of computerized decision support such as dose adjustments in renal impairment, detection of drug–drug interactions, and alerts for contraindications (Cufar et al., 2012; Fox et al., 2015). Therefore, pharmacy departments are often asked to play a leading role in the development and implementation of computerized initiatives surrounding AMS.

Research has also looked at the role of the pharmacist in identifying and confirming penicillin allergies in patients. While it is common for patients to identify as being allergic to penicillin (up to 10% of the population in the United States and United Kingdom state they have a history of penicillin allergy), it is estimated that only 10% of these people are truly allergic to penicillin (Drug and Therapeutics Bulletin, 2017). While administering a penicillin to a person who is truly allergic can lead to serious adverse events or death, inappropriate labeling can mean a patient is exposed to adverse effects or inappropriate treatment (including the use of broad-spectrum and/or more expensive antibiotics) that is not required. Pharmacists have been shown to effectively manage a penicillin allergy-testing program to identify patients who have been incorrectly labeled as being allergic to penicillin (Gugkaeva et al., 2017).

Academic detailing of doctors and nurses is another unique area where pharmacists can play an important role as antimicrobial stewards (Wathne et al., 2018). It is a well-known fact that pharmaceutical companies spend a significant amount of money and resources to shape prescribing behaviors involving their medicines (Wood et al., 2017). Pharmacists have been shown to provide effective academic detailing programs to improve the rational use of medicines, including but not limited to antibacterials (Ndefo et al., 2017; Wathne et al., 2018).

Education and Counseling of Patients

Pharmacists often routinely provide patient education and counseling related to medicines. Patients' perceptions of the effectiveness of antibiotics and expectations for antibiotic prescriptions are known determinants of inappropriate antibiotic prescribing by doctors (Coenen et al., 2006). Pharmacists often provide consultations for upper respiratory tract symptoms in community pharmacies and can educate patients about the importance of AMR and the ineffectiveness of antibacterials in managing common viral infections. Increasingly, pharmacists are getting involved in initiatives to improve the management of common community-based presentations and can offer specific interventions such as delayed antibacterial dispensing according to a particular criteria or a comprehensive educational program to reduce the demand of antibacterials (Avent et al., 2018; Essack et al., 2018).

Antibacterials constitute a significant proportion of day-to-day pharmacy practice and will continue to offer opportunities and challenges for pharmacists working in acute care settings and community health. Pharmacists have shown that they can contribute significantly to optimizing the use of antibacterials through their medication knowledge and skills. The role of pharmacists in infectious diseases will continue to evolve and the future will offer unique opportunities for the profession.

Management of Infectious Diseases and the Pharmacist's Role: Fungal Infections

Faizan Mazhar*, Mohammad Ismail†, Fahadullah Khan†, Shahzad Akram§, Ejaz Cheema¶, *Department of Biomedical and Clinical Sciences L. Sacco, "Luigi Sacco" University Hospital, Università di Milano, Milan, Italy; †Department of Pharmacy, University of Peshawar, Peshawar, Khyber Pakhtunkhwa, Pakistan; §Pharmaceutical Care Department, King Abdul-Aziz Medical City, National Guard Health Affairs, Riyadh Saudia Arabia; ¶School of Pharmacy, University of Birmingham, Edgbaston, Birmingham, United Kingdom

Learning Objectives

At the end of this chapter, the reader will be able to

- Develop basic understanding of the epidemiology, etiopathogenesis, and clinical manifestations of fungal infections.
- Understand the relative benefits and risks of all available systemic antifungal agents with respect to patient characteristics and routes of administration.
- Identify the key roles of pharmacists in optimizing the drug therapy through patient-oriented care plan, therapeutic drug monitoring, patient education, evaluation of therapeutic outcomes, and monitoring of adverse drug effects.

Introduction

Fungal pathogens are widespread in nature and are adaptable to all ecosystems, including air, water, soil, plants, and human body. Fungi mainly reproduce by forming spores that are spread by air, water, and direct contact with infected source. The inhalation of

airborne spores and inoculation into skin and mucous membrane are the major modes of transmission of fungal infections into human beings.

Fungal infections being difficult to be differentially diagnosed are associated with significant mortality despite the presence of a number of antifungal agents. Fungal infections commonly affect immunocompromised individuals such as individuals with cancer or acquired immunodeficiency syndrome (HIV/AIDS) and those undergoing organ transplant (Garbee et al., 2017). Fungal infections are also prevalent in nosocomial settings. *Candida* spp., *Aspergillus* spp., *Mucorales*, *Fusarium* spp., and other molds including *Scedosporium* spp. are the common nosocomial fungal pathogens. Therefore, early diagnosis, reversal of underlying host defects, and initiation of effective pharmacological therapy continues to be the mainstay of treating fungal infections (Perlroth et al., 2007).

Mucocutaneous Fungal Infections

Mucocutaneous infections are superficial infections of the mucosal surfaces and skin that are commonly caused by Candida species, primarily the *Candida albicans*. Mucocutaneous candidal infections are among the most common infections worldwide, having unique treatment requirements that may last for months or years (Brown and Chin, 2017). The following sections discuss the various types of candida infections including vulvovaginal candidiasis (VVC), oropharyngeal candidiasis (OPC), and esophageal candidiasis (EC).

Vulvovaginal Candidiasis

VVC, whether asymptomatic or symptomatic, refers to the infections in women whose vaginal cultures are positive for *Candida* species. Based on episodic frequency, VVC may be classified as sporadic or recurrent, which is essential for understanding the pathophysiology and selection of effective pharmacotherapy. Complicated VVC is difficult to treat and requires special consideration for successful treatment, whereas uncomplicated VVC refers to sporadic infections and are susceptible to all types of antifungal therapy (Dovnik et al., 2015).

Epidemiology and Etiology

Vulvovaginal complaints are considered to be the most common reason for women to seek medical care, of which, vaginitis accounts for 20%–25% of the total cases (Paladine and Desai, 2018). VVC is the second most common cause of vaginitis after bacterial vaginosis. An estimated 75% of women will have at least one occurrence of VVC during their lifetime.

C. albicans is the major pathogen responsible for VVC, accounting for 80%–92% of symptomatic episodes (Brown and Chin, 2017). The rest are caused by non-*C. albicans* species, predominantly the *Candida glabrata*.

Pathophysiology and Risk Factors

Candida organisms are dimorphic that exist in two distinct forms: blastospores that are responsible for the transmission and spread and germinated form that causes tissue invasion and symptomatic infections. In order to colonize vagina, attachment of *Candida* species to mucosal walls is vital. The process of attachment is a complex phenomenon. For colonization, not only the candidal surface structure is important but the presence of receptors on epithelial cells is also essential for attachment. Therefore, women having a high number of epithelial receptors are at higher risk of colonization compared with others (Brown and Chin, 2017).

Several risk factors that are linked to higher rates of VVC and increased vaginal colonization with *Candida* include high estrogen levels, hormone replacement therapy, oral contraceptives, intrauterine device, pregnancy, sexually active women, poorly controlled diabetes, corticosteroid use, and oral-genital contact (Goncalves et al., 2016).

Antibiotics, particularly the broad-spectrum agents, may also increase the risk of VVC by inhibiting the growth of protective vaginal bacterial flora (e.g., *Lactobacillus* spp.), resulting in the overgrowth of *Candida*. Furthermore, an excess of refined carbohydrates, douching, and tight-clothing may also predispose patients to a higher risk of VVC. Alterations in the vaginal environment by any of the aforementioned factors permit the overgrowth of organisms that are normally suppressed, resulting in the increased risk of vulvovaginitis (Arfiputri et al., 2018).

Clinical Presentation and Diagnosis

Patients with VVC may present with symptoms of vulvar pruritus, irritation, dyspareunia, and/or external dysuria with or without abnormal vaginal discharge. Vaginal examination often reveals erythema and edema of the labia and vulva, excoriations from scratching, and thick white discharge. In patients with VVC, vaginal pH appears normal (4–4.5), while elevated pH suggests the presence of bacterial infection. Diagnosis should be confirmed with microscopic examination of vaginal secretions. Microscopic examination reveals the presence of blastospores or pseudohyphae. The presence of yeast cells or hyphae can be determined by a wet mount preparation with saline and 10% potassium hydroxide preparation. *Candida* cultures are not recommended for uncomplicated VVC; however, cultures are required if microscopic examinations are inconclusive or a recurrence is suspected (Workowski et al., 2015).

Pharmacological Management

Vulvovaginal candidiasis is commonly caused by *C. albicans*, but other *Candida* species may also be implicated in its etiology that contributes to uncomplicated (90%) or complicated (10%) disease (Pappas et al., 2016). The complicated disease is characterized by the presence of a severe or recurrent infection, infection with non-*C. albicans* species, and/or infection in an immunocompromised host (Pappas et al., 2016).

Various topical and systemic antifungal agents can be used for the treatment of vulvovaginal candidiasis. All antifungal agents including oral or topical formulations have a comparable efficacy with no specific drug or route of administration considered as superior to the other (Sobel, 2007; Watson et al., 2002). Furthermore, studies report a similar response to antifungal therapy in HIV-positive and HIV-negative individuals. The Infectious Diseases Society of America (IDSA) 2016 guidelines recommend topical antifungal agents as the first-line therapy for the treatment of uncomplicated vulvovaginal candidiasis with a cure rate of 90% or more (Watson et al., 2002). Alternatively, a single dose of oral fluconazole (150 mg) may be used (Pappas et al., 2016). However, complicated vulvovaginal candidiasis should be treated with intravaginal medications (topical formulations) for 5–7 days or with 3 doses of oral fluconazole (150 mg) administered at an interval of 71 h (Sobel et al., 2001).

Most candida species except *Candida krusei* and *C. glabrata* respond well to fluconazole therapy; however, treatment of non-*C. albicans* infection is often challenging and requires special consideration for antifungal susceptibility (Sobel, 2007). *C. glabrata*-related infections should initially be treated with boric acid capsules (600 mg once daily) for 14 days or nystatin vaginal suppositories (100,000 units) for 14 days (Sobel et al., 2003). Topical flucytosine (17%) and amphotericin-B (3%), either alone or in combination, for a duration of 14 days should be considered in patients refractory to boric acid or nystatin (Sobel et al., 2003; White et al., 2001).

Recurrent vulvovaginal candidiasis is defined as an occurrence of four or more episodes of symptomatic infection within a year (Sobel et al., 2004). Recurrent infections should initially be treated with topical or oral fluconazole for a duration of 10–14 days, followed by maintenance therapy with fluconazole (or other antifungal agent) for a minimum of 6 months (Donders et al., 2008; Rosa et al., 2013; Sobel et al., 2004). Oral fluconazole (150 mg) once weekly is the most preferred regimen for maintenance therapy with 90% or more cure rates (Sobel et al., 2004). Alternatively, topical clotrimazole cream (200 mg) twice weekly or clotrimazole suppositories (500 mg) once weekly can be considered (Iavazzo et al., 2011; Witt et al., 2009) (**Table 1**).

Oropharyngeal and Esophageal Candidiasis

OPC is an opportunistic infection which is commonly caused by *Candida* species. In humans, *Candida* are considered as normal flora of the gastrointestinal (GI) and genitourinary (GU) tracts that are capable of transforming from commensal organisms to pathogenic forms, resulting in the symptomatic mucosal infections.

Epidemiology and Etiology

The exact prevalence of OPC is difficult to determine as the risk of these infections varies with the presence of certain underlying medical conditions. The prevalence of OPC, as part of the normal oral flora, shows large geographic variations; however, an estimated 35% prevalence of the infection has been projected in several studies (Ghasempour et al., 2011). The incidence of

Table 1 Recommended intravaginal regimens for the treatment of vaginal candidiasis

Drug	*Formulation(s)*	*Dosage*
Butoconazole	• 2% cream (OTC)	• 5 g intravaginally daily for 3 days
Clotrimazole	• 1% cream (OTC) • 2% cream (OTC)	• 5 g intravaginally daily for 7–14 days • 5 g intravaginally daily for 3 days
Miconazole	• 2% cream (OTC) • 4% cream (OTC) • 100 mg vaginal suppository (OTC) • 200 mg vaginal suppository (Rx) • 1200 mg vaginal ovule (OTC)	• 5 g intravaginally daily for 7 days • 5 g intravaginally daily for 3 days • 1 suppository intravaginally daily for 7 days • 1 suppository intravaginally daily for 3 days • 1 ovule intravaginally daily for 1 day
Nystatin	• 100,000-unit vaginal tablet (Rx)	• 1 tablet intravaginally daily for 14 days
Terconazole	• 0.4% cream (Rx) • 0.8% cream (Rx) • 80 mg vaginal suppository (Rx)	• 5 g intravaginally daily for 7 days • 5 g intravaginally daily for 3 days • 1 suppository intravaginally for 3 days
Tioconazole	• 6.5% ointment (OTC)	• 5 g intravaginally daily for 1 day
Fluconazole	• 150 mg tablet (Rx)	• One tablet × 1 day

OTC, over the counter; Rx, prescription only.

Table 2 Predisposing factors for oropharyngeal candidiasis

Local factors
• Denture wearing
• Smoking
• Atopic constitution
• Inhalation steroids
• Topical steroids
• Hyperkeratosis
• Imbalance of the oral microflora
• Quality and quantity of saliva
General factors
• Immunosuppressive diseases
• Impaired health status
• Immunosuppressive drugs
• Chemotherapy
• Endocrine disorders
• Hematinic deficiencies

Source: Information fromMillsop, J.W., Fazel, N., 2016. Oral candidiasis. Clin. Dermatol. 34, 487–494.

OPC and EC is an indicator of the suppression of immune system, often developing in infants, elderly, and in the immunocompromised patients. Oral candida colonization has been reported in around 40%–70% of healthy children and adults. The risk for candida colonization is higher in children with dental caries and in elderly wearing dentures (Daniluk et al., 2006; Rozkiewicz et al., 2006). The incidence of EC is the highest among diabetic patients or individuals who receive higher doses of corticosteroids.

C. albicans is the major causative pathogen of OPC. However, only a small number of infections are related to *C. glabrata*, *Candida tropicalis*, *Candida parapsilosis*, *Candida guilliermondii*, *C. krusei*, or *Candida dubliniesis* (Meiller et al., 1999; Redding et al., 2004; Redding et al., 2000).

Pathophysiology and Risk factors

There is an apparent association between oral candidiasis and the influence of local and general predisposing factors. The local predisposing factors (**Table 2**) are able to promote the growth of the yeast or influence the immune response of the oral mucosa. The risk of candida infections is higher in patients with diabetes, HIV/AIDS, and in those undergoing chemotherapy. In general, predisposing factors are often related to an individual's immune and endocrine status. Drugs as well as diseases which suppress the adaptive or the innate immune system can also affect the susceptibility of the mucosal lining (**Table 2**) (Millsop and Fazel, 2016).

To invade the mucosal lining, the fungus must adhere to the epithelial surface. Penetration into mucosal wall is facilitated by the secretion of protease enzymes, especially the secretory aspartyl proteinases and phospholipase B (Reichart et al., 1995; Sherwood et al., 1992).

Clinical Presentation and Diagnosis

Painless, creamy white, plaque-like lesions of the oral mucosa represent the most common characteristics of OPC. Symptoms of OPC include a painful mouth, burning sensation on the tongue, and dysphagia. A presumptive clinical diagnosis is usually made according to the appearance of lesions and the ability to easily scrape off the superficial plaque. Culture is not required to make a diagnosis and does not distinguish colonization from infection (Farah et al., 2010; Leigh et al., 2004). However, in patients with infection refractory to treatment, cultures should be considered to identify the causative agent associated with the infection.

Untreated OPC can lead to the development of EC; however, about 10% of EC cases do occur in the absence of OPC. Symptoms of EC may include dysphagia, odynophagia, and retrosternal pain. A reliable diagnosis of EC can be made by endoscopic evaluation of lesions, together with histopathologic evidence of *Candida* on tissue biopsy. Fungal cultures of esophageal brushings are not useful in the diagnosis of EC because they do not distinguish between colonization and infection, but are helpful in identifying more resistant *Candida* spp.

Pharmacological Management

Oropharyngeal and esophageal candidiasis is commonly associated with compromised immunity such as patients with HIV/AIDS, diabetes mellitus, use of corticosteroids, antimicrobial therapy, and use of dentures (Bodhade et al., 2011; Pappas et al., 2016). Effective therapies for the management of these diseases such as the use of antiretroviral therapy for HIV infection and disinfection of dentures can reduce the incidence of OPC or EC and its relapse (Schwarcz et al., 2013) (**Table 3**)

Table 3 Antifungal agents used in the treatment of oropharyngeal candidiasis

Topical (mild disease)			
Drug	*Form*	*Dosage*	*Comments*
Amphotericin B	Lozenge, 10 mg	Slowly dissolved in mouth 3–4×/day after meals for 2 weeks minimum	Negligible absorption from gastrointestinal tract.
	Oral suspension, 1 mg/mL	1 mL swish-and-swallow, 4×/day for 2 weeks	
Nystatin	Cream	Apply to affected area 3–4×/day	Negligible absorption from gastrointestinal tract.
	Pastille, 100,000 U	Dissolve 1 pastille slowly after meals 4×/dayd, usually for 7 d	
	Oral suspension, 100,000 U	1 mL swish-and-swallow,4×/day for 2 weeks	Contains sucrose, prolong use may be cariogenic
Clotrimazole	Cream	Apply to the affected area 2–3 times daily for 3–4 weeks	Requires frequent application
	Solution	5 mL 3–4 times daily for 2 weeks minimum	
Miconazole	Oral gel	Apply to the affected area 3–4 times daily	Occasional mild local reactions. Avoid in pregnancy and liver disease.
	Cream	Apply twice per day and continue for 10–14 day after the lesion heals	
Systemic (moderate–severe disease)			
Primary regimen			
Fluconazole	Capsules	100–200 mg/day once daily for 7–14 days	Interacts with anticoagulants, terfenadine, cisapride, and astemizole. Contraindicated in pregnancy and liver and renal disease. May cause nausea, diarrhea, headache, rash, liver dysfunction.
Alternative regimens			
Itraconazole	Solution	200 mg/day taken immediately after meals for 7–14 days	Interacts with terfenadine, cisapride, and astemizole. Contraindicated in pregnancy and liver disease. May cause nausea, neuropathy, rash.
Posaconazole	Oral suspension	400 mg orally twice daily for 3 days, then 400 mg every day for 7–14 days	Take with full meal and/or acidic carbonated beverage (e.g., ginger ale).
Voriconazole	Tablet	200 mg twice daily for 7–14 days	Reduce maintenance dosage by 50% in mild to moderate hepatic impairment
Caspofungin	Intravenous infusion	70 mg loading dose, then 50 mg/day i.v. for 7–14 days	Dosage adjustment with concomitant use of an enzyme inducer (e.g., rifampin, Patients receiving carbamazepine, dexamethasone, efavirenz, nevirapine, or phenytoin) is recommended

i.v., intravenously; p.o., per oral.

Source: Adapted from: Pappas, P.G., Kauffman, C.A., Andes, D.R., 2016. Clinical practice guideline for the management of candidiasis: 2016 update by the Infectious Diseases Society of America. Clin. Infect. Dis. 62 (4), e36–e37; Ellepola, A.N.B., Samaranayake, L.P., 2000. Oral candidal infections and antimycotics. Crit. Rev. Oral Biol. Med. 11 (2), 172–198.

Oropharyngeal candidiasis

Most patients with oropharyngeal candidiasis respond to the topical treatment. However, relapse following topical therapy is common, particularly in patients with HIV/AIDS. For mild diseases, clotrimazole troches (10 mg) 5 times daily or miconazole mucoadhesive tablets (50 mg) once daily for 7–14 days is the recommended first-line therapy. Alternatively, 4–6mL of nystatin suspension (100,000 units/mL) or 1–2 nystatin pastilles (200,000 units) 4 times daily for 7–14 days may be used (Pappas et al., 2016).

Oral fluconazole and itraconazole solutions are more effective than ketoconazole and itraconazole capsules and are recommended as first-line therapies for the treatment of moderate to severe diseases (Pappas et al., 2016; Queiroz-Telles et al., 2001). Oral fluconazole should be used at a dose of 100–200 mg, once daily for 7–14 days. In the case of resistance to fluconazole, once daily itraconazole solution (200 mg) is suggested with cure rates between 64% and –80% (Pappas et al., 2016). Posaconazole has a similar efficacy as fluconazole and has been approved by the Food and Drug Administration for prophylaxis in high-risk patients (Pappas et al., 2016). Posaconazole suspension (400 mg) twice daily for 3 days followed by once daily administration for a maximum of 28 days may be used as an alternative to itraconazole solution (Skiest et al., 2007). Other alternatives for the management of fluconazole-resistant diseases are voriconazole (200 mg) twice daily or amphotericin-B deoxycholate oral suspension (100 mg/mL) 4 times daily (Pappas et al., 2016).

The refractory disease should be treated with intravenous echinocandins such as caspofungin, micafungin, or anidulafungin (de Wet et al., 2004; Krause et al., 2004; Villanueva et al., 2001, 2002). Caspofungin 70 mg loading dose followed by 50 mg once daily, micafungin 100 mg once daily, or anidulafungin 200 mg loading dose followed by 100 mg once daily should be used. Alternatively, oral or intravenous amphotericin-B deoxycholate at a dose of 0.3 mg/kg/day can be used (Pappas et al., 2016). Moreover, adjuvant therapy with granulocyte-macrophage colony-stimulating factor or interferon-gamma may be considered (Bodasing et al., 2002; Vazquez et al., 2000).

Long-term therapy with fluconazole (100 mg) 3 times weekly is an effective approach for the prevention of OPC, particularly in immunocompromised patients due to the increased risk of refractory disease (Bodhade et al., 2011; Patel et al., 2012). On the contrary, oral amphotericin-B deoxycholate, nystatin solution, and itraconazole capsules have limited efficacies and are best avoided for the prevention of OPC (Pappas et al., 2016).

Esophageal candidiasis

Fluconazole is more effective than ketoconazole, itraconazole capsule, and flucytosine, while it has similar efficacy as itraconazole solution for the treatment of EC, with most patients achieving resolution of symptoms in 7 days (Pappas et al., 2016; Sobel et al., 2001). The IDSA 2016 guidelines recommend the use of oral fluconazole (200–400 mg) once daily for 14–21 days as the recommended first-line therapy. Alternatively, intravenous fluconazole (400 mg) once daily or high-dose intravenous echinocandins including micafungin (150 mg), caspofungin (70 mg loading dose followed by 50 mg once daily), or anidulafungin (200 mg) may be considered for patients who cannot tolerate oral therapy (de Wet et al., 2004; de Wet et al., 2005; Krause et al., 2004; Pappas et al., 2016). Moreover, amphotericin-B at a dose of 0.3–0.7 mg/kg/day may be used in EC. De-escalation to oral fluconazole should be considered once the patient is able to tolerate the oral therapy (Pappas et al., 2016).

Patients refractory to fluconazole should receive itraconazole solution (200 mg/day) or intravenous or oral voriconazole (200 mg twice daily) for 14–21 days (Ally et al., 2001; Pappas et al., 2016). Alternatively, posaconazole suspension (400 mg) twice daily or the extended-release tablets (300 mg) once daily may be used. Intravenous echinocandins (micafungin, caspofungin, or anidulafungin) or amphotericin-B (0.3–0.7 mg/kg\day) for a duration of 14–21 days can be used as an alternative. Chronic preventive therapy with fluconazole (100–200 mg) 3 times weekly is recommended in patients with refractory disease particularly in the immunocompromised patients (Goldman et al., 2005; Pappas et al., 2016) (**Table 4**).

Invasive Fungal Infections

Invasive fungal infections (IFIs) pose a significant threat to immunocompromised patients. The most frequently occurring IFIs are those caused by *Candida* spp. and *Aspergillus fumigatus*. However, previously uncommon and new pathogens are also on the rise (Chen et al., 2010; Richardson and Lass-Flörl, 2008). Timely diagnosis and management of IFIs are necessary for optimal clinical

Table 4 Antifungal agents used in the treatment of esophageal candidiasis

Drug	*Dosage*
Azole therapy	
Fluconazole	400 mg as a loading dose and then 200– 400 mg daily for 14– 21 days given p.o. or i.v.
Itraconazole	200 mg p.o. twice daily
Voriconazole	200 mg p.o./i.v. twice daily
Posaconazole	Oral suspension, 400 mg twice daily
Echinocandins	
Caspofungin	70 mg i.v. on day 1 followed by 50 mg i.v. every 24 h. less toxic alternative to intravenous amphotericin B
Micafungin	150 mg i.v. per day
Anidulafungin	200 mg i.v. on day 1 followed by 100 mg/day i.v.
Amphotericin B	
Amphotericin B deoxycholate	0.3–0.7 mg/kg daily as single infusion Infection with *C. glabrata* or *C. krusei* may require higher doses (0.7 mg/kg)

i.v., intravenously; p.o., per oral.

outcomes. However, despite the availability of highly effective antifungal therapies, the mortality rates for IFIs remain high (30%–80%) (Chen et al., 2010).

Epidemiology and Etiology

The true burden of IFI is probably underestimated because of the absence of reliable diagnostics tools. IFIs are relatively uncommon compared with superficial fungal infections; however, they are of great medical concern because of their disproportionately high rates of mortality. Widespread adoption of aggressive immunosuppressive therapy among certain patient populations (e.g., chemotherapy, transplants) together with the increased use of invasive devices such as central venous catheters (CVC) contribute toward the varying epidemiology of IFIs (Enoch et al., 2017).

Candida species are undoubtedly the most important species among the opportunistic fungal infections, accounting for 8%–10% of all nosocomial bloodstream infections with an incidence rate of 6–23 infections per 100,000 persons annually in the United States (Pfaller et al., 2006). Recently, the incidence of invasive candidiasis (IC) has significantly increased, most commonly affecting patients at the risk of opportunistic infections, such as the elderly or the immunosuppressed patients (Lamoth et al., 2018). On the contrary, a significant decrease has been reported in the incidence rates of neonatal IC (Aliaga et al., 2014; Cleveland et al., 2012). IC is associated with a high mortality rate between 10% and 49% and a prolonged hospital stay of 3–30 days (Pfaller et al., 2006). Candidemia is associated with a significant economic burden that is estimated to be one billion dollars each year in the United States (Pfaller et al., 2006). Moreover, a worldwide shift has been reported from *C. albicans* to non-*C. albicans* species. (Lamoth et al., 2018).

Invasive aspergillosis is not as common as the milder allergic forms of aspergillosis and is most commonly caused by *A. fumigatus* (Richardson, 2005). A recent increase in the incidence of *Apergillus* infections has been reported, though little is known about the relative occurrence due to the presence of specific species (Richardson, 2005). With the increasing number of solid organ and stem cell transplant recipients and the emergence of newer immunosuppressive agents, the incidence of *Aspergillus* infections is changing. Approximately, 1%–15% patients with cystic fibrosis suffer from allergic bronchopulmonary aspergillosis (ABPA) (Stevens et al., 2003). As much as 2.5% of asthmatic patients also suffer from ABPA that makes it approximately 4.8 million people affected with the disease (Denning et al., 2013). Of these ABPA-affected patients, as much as 400,000 also suffer from chronic pulmonary aspergillosis (CPA) (Denning et al., 2013). Invasive aspergillosis has been reported to be the most common fungal infection in stem cell transplant recipients and second most common fungal infection among solid organ transplant recipients during 2001–06. (Pappas et al., 2010).

Pathophysiology and Risk factors

A complex interplay of host and pathogen factors influences the acquisition and development of invasive fungal infections (Carver, 2017). A breach in skin or mucosal surfaces (serve as primary barriers to infection) allow the organism to enter the deeper tissues and bloodstream (Carver, 2017).

The most common route of infection is the respiratory tract, where aerosolized fungi pathogens are inhaled into the lungs (Garcia-Vidal et al., 2013). The first response to this invasion is phagocytosis led by neutrophils and monocytes/macrophages in the alveoli and bronchioles (Garcia-Vidal et al., 2013). These cells have receptors for fungal cell wall components termed pathogen-associated molecular patterns (PAMPs) that lead to the activation of intracellular signaling pathways. This activation triggers the inflammatory response, thus increasing the neutrophil accumulation and macrophage cytokine production (Garcia-Vidal et al., 2013). Ingested yeasts are killed by oxidative and non-oxidative mechanisms (Segal, 2009). Patients with low CD4 cells and those on treatment that inhibit cellular immunity (chemotherapy, high-dose corticosteroids, or tumor necrosis-α blockers such as infliximab) are at a high risk of acquiring localized mucosal infections with *Candida* species, but not at risk for getting invasive candidiasis/candidemia. Neutropenia is a major risk factor for IFI, particularly for the disseminated infections caused by *Candida* and *Aspergillus* species (Carver, 2017).

Clinical Presentation and Diagnosis

Invasive candidiasis encompasses several infectious syndromes broadly categorized as candidemia or deep-seated infections (infections of tissue sites beneath mucosal surfaces) (Clancy and Nguyen, 2012). Approximately, one-third of all patients with invasive candidiasis fall within any of the following three groups at the time of diagnosis: (1) patients with uncomplicated candidemia in the absence of deep-seated candidiasis most frequently arising from an infected catheter; (2) candidemia associated with deep-seated candidiasis most frequently arising from the gastrointestinal tract or secondary seeding from a separate infection site; and (3) deep-seated candidiasis without candidemia (Clancy and Nguyen, 2013).

Invasive candidiasis is most frequently diagnosed by the blood culture that probably identifies the majority of patients with candidemia alone, fewer patients with mixed deep-seated disease and intermittent candidemia, and virtually no patients who have an infection limited to deep tissues at the time of culture (Clancy and Nguyen, 2013). As a result, half of all episodes of invasive candidiasis are not detected by blood cultures alone. Therefore, a negative blood culture cannot rule out the possibility of invasive candidiasis, especially in the patients with multiple underlying risk factors for infection. Currently, the most frequently used test is the serum β-D-glucan test (Fungitell, Associates of Cape Cod Inc.).

Signs and symptoms of IA are predictably not revealed in the immunocompromised host. Fever is common but nonspecific for infection and may be accompanied by pleuritic chest pain, cough, hemoptysis, and/or friction rub (Bicanic and Harrison, 2014; Walsh et al., 2008). Neurologic signs, including seizures, hemiparesis, and stupor, may be present in patients with dissemination to the brain (Bicanic and Harrison, 2014). Cutaneous plaques or papules characterized by a central necrotic ulcer or eschar occur in up to 10% of patients with disseminated disease; however, concomitant blood cultures are often negative. Respiratory cultures, including sputum, bronchial washings, or bronchoalveolar lavage have a low sensitivity for the diagnosis of IA but have a high positive predictive value in the immunocompromised patients (Bicanic and Harrison, 2014). The galactomannan test and other nonculture-based strategies, such as serum β-glucan serve as complementary methods to confirm the results from microbiologic, histopathologic, and radiographic investigations directed toward diagnosing IA (Bicanic and Harrison, 2014). The section "Further reading" provides references to the sources that authors have deemed useful to a reader seeking additional information on the clinical manifestations and diagnosis of IA.

Pharmacological Management

Invasive Aspergillus

Empirical therapy should be initiated, while patients suspected with invasive pulmonary aspergillosis (IPA) are being investigated (Cornely et al., 2007; Greene et al., 2007). The IDSA 2016 guidelines recommend voriconazole as the initial therapy for the treatment of IPA (Herbrecht et al., 2002). Alternatively, liposomal amphotericin-B or isavuconazole may be used (Cornely et al., 2007; Maertens et al., 2016). Echinocandins should preferably be used in patients who are intolerant to azole and polyene antifungals (Patterson et al., 2016). However, combination therapy with voriconazole and echinocandins may be considered in selected patients (Marr et al., 2004; Singh et al., 2006). The IDSA 2016 guidelines recommend a minimum of 6–12 weeks of therapy depending upon the degree and duration of immunosuppression, site of disease, and the resolution of symptoms. Preventive therapy following successful eradication of infection is recommended in order to prevent relapse (Cordonnier et al., 2010; Liu et al., 2014; Patterson et al., 2016).

An individualized approach is needed for patients who have refractory or progressive IPA despite conventional therapy. The selection of therapy should be based on the severity and extent of infection and comorbidities (Patterson et al., 2016). In general, a recurrent infection is treated with antifungal agents such as amphotericin-B, micafungin, caspofungin, posaconazole, or itraconazole. Addition of an antifungal agent to the existing therapy or combination of antifungal agents from different classes other than those used previously is recommended (Patterson et al., 2016). Surgical resection of localized necrotic lesion may be considered in selected patients (Dolton et al., 2012; Kuderer et al., 2007; Marr et al., 2004; Patterson et al., 2016).

Adjuvant measures such as dose escalation or complete withdrawal of the immunosuppressive therapy (whenever possible), administration of colony-stimulating factors or granulocyte transfusion, and recombinant interferon-gamma need to be considered in patients suspected or diagnosed with neutropenia (Kuderer et al., 2007; Martinez et al., 2013; Patterson et al., 2016; Price et al., 2015). Surgery can be performed in patients with localized disease for debridements such as invasive fungal sinusitis or localized cutaneous disease (Didier et al., 2014). In patients diagnosed with aspergillosis, continuation of chemotherapy or bone marrow transplantation should be based on the risks and benefits (Patterson et al., 2016).

Tracheobronchial aspergillosis (TBA) commonly affects the lung transplant recipients. It does not require antifungal therapy except in symptomatic and immunocompromised patients (Patterson et al., 2016; Soubani and Chandrasekar, 2002). In non-immunocompromised patients, bronchoscopic removal of mucoid impaction is recommended (Krenke and Grabczak, 2011; Soubani and Chandrasekar, 2002). However, the systemic antifungal agents (triazoles) or intravenous amphotericin-B (lipid formulation) are recommended in immunocompromised patients as invasive disease cannot be ruled out. Antifungal therapy needs to be continued for at least 3 months or until the complete resolution of symptoms (Patterson et al., 2016). Dose escalation or withdrawal of immunosuppressive therapy may be considered (if feasible). Moreover, bronchoscopic debridement can be performed in selected patients (Patterson et al., 2016).

Invasive Candidiasis

In candidemia, the source of infection including the central venous catheter should be identified and rectified at the earliest. Echinocandins (caspofungin, micafungin, or anidulafungin) are the recommended first-line therapy in both neutropenic and nonneutropenic patients (**Table 5**) (Aguilar-Zapata et al., 2015; Glöckner, 2011; Mayr et al., 2011). Fluconazole may be used in selected patients who are not critically ill and are unlikely to be resistant to fluconazole (Pappas et al., 2016). Azole susceptibility should be tested in the bloodstream and other clinically relevant *Candida* isolates. Echinocandin susceptibility should also be tested in patients who had previously been treated with echinocandin and those suffering from infections of *C. glabrata* or *C. parapsilosis* (Pappas et al., 2016). *C. glabrata*-related infection should be treated with high-dose fluconazole or voriconazole (has additional fungal coverage such as *C. krusei*) with prior susceptibility testing. Lipid formulation of amphotericin-B may be considered in patients who are intolerant or have resistant infection (Ben-Ami, 2018; Pappas et al., 2016). The IDSA 2016 guidelines recommend to continue therapy for 2 weeks after negative blood culture for candida infection and resolution of symptoms (Pappas et al., 2016).

Oral step-down therapy is recommended in clinically stable nonneutropenic and neutropenic patients with candidiasis (those who have *Candida* isolates that are susceptible to fluconazole and who have negative repeat blood cultures). Oral step-down therapy

Table 5 Antifungal treatment approach to opportunistic invasive fungal infections

Condition or treatment group	*Recommended treatment regimens*
Invasive candidiasis or candidemia	

Nonneutropenic adults	• An echinocandin is recommended as initial therapy.
	  ◦ caspofungin 70 mg i.v. loading dose, then 50 mg i.v. daily
	  OR
	  ◦ micafungin 100 mg i.v. daily
	  OR
	  ◦ anidulafungin 200 mg i.v. loading dose, then 100 mg i.v. daily) is recommended as initial therapy.
	• An alternative for patients who are not critically ill and who are considered unlikely to have fluconazole-resistant *Candida* spp[a] is fluconazole 800 mg (12 mg/kg) oral loading dose, then 400 mg (6 mg/kg) orally daily.
	• A lipid formulation of amphotericin B (3–5 mg/kg i.v. daily) is an alternative if there is intolerance, limited availability, or resistance to other antifungal agents.

Neutropenic patients	• An echinocandin is recommended as initial therapy.
	  ◦ caspofungin 70 mg i.v. loading dose, then 50 mg IV daily
	  OR
	  ◦ micafungin 100 mg i.v. daily
	  OR
	  ◦ anidulafungin 200 mg i.v. loading dose, then 100 mg i.v. daily
	• A lipid formulation of amphotericin B (3–5 mg/kg i.v. daily) is a less attractive alternative because of the potential for toxicity.
	• For patients who are not critically ill and who have had no prior azole exposure, an alternative is fluconazole 800 mg (12 mg/kg) oral loading dose, then 400 mg (6 mg/kg) orally[b] daily.
	• In situations in which additional mold coverage is desired, voriconazole[c] 400 mg orally (or 6 mg/kg i.v.) twice daily for two doses then 200 to 300 mg orally (or 3–4 mg/kg i.v.) twice daily can be used.

C. glabrata and C. krusei infections	• An echinocandin is preferred over amphotericin B for treatment of candidemia due to *C. glabrata* and *C. krusei.* • In situations in which additional mold coverage is desired, voriconazole[c] 400 mg orally (or 6 mg/kg i.v.) twice daily for two doses then 200 to 300 mg orally (or 3 to 4 mg/kg i.v.) twice daily can be used.
C. auris infection	• Initial therapy with an echinocandin at the doses provided above
Aspergillosis	
	• [d]Voriconazole 6 mg/kg i.v. every 12 h×2 doses, then 4 mg/kg i.v. every 12 h. • Voriconazole 4 mg/kg oral every 12 h OR • Lipid formulations of amphotericin B (5 mg/kg/day i.v.) OR • Echinocandin: caspofungin (70 mg/day i.v.×1, then 50 mg/day i.v. thereafter), micafungin (100–150 mg/day i.v.), OR • Posaconazole 300 mg every 12 h i.v. day 1, then 300 mg i.v. daily • Posaconazole delayed-release tablet 300 mg twice daily, day 1, then 300 mg daily • [c]oral suspension: 200 mg TID; tablet: 300 mg BID on day 1, then 300 mg daily, i.v. 300 mg BID on day 1, then 300 mg daily, itraconazole suspension (200 mg p.o. every 12 h) OR • Combination therapy (refer to the text)

i.v., intravenous; p.o., per oral; BID, twice a day; TID, three times a day.

The doses above are intended for patients with normal organ function. The fluconazole dose requires adjustment in the setting of renal insufficiency; the caspofungin and voriconazole doses may require adjustment in hepatic insufficiency. Refer to monograph of individual drug.

[a]Fluconazole should be considered a first-line option only in patients who are stable, have no previous exposure to azoles, and are not at high risk for C. glabrata infection (e.g., older adults, underlying malignancy, diabetic).

[b]Since fluconazole is highly bioavailable, oral therapy is appropriate for most patients. i.v. therapy (at the same dose) should be given to patients who are unable to take oral medications, who are not expected to have good gastrointestinal absorption, or who are severely ill.

[c]patients with suspected aspergillosis should initially be started on i.v. therapy.

[d]Therapeutic drug monitoring should be considered due to widely variable pharmacokinetics; refer to the Fig. 1.

*Source: Data from Pappas, P.G., Kauffman, C.A., Andes, D.R. et al., 2016. Clinical practice guideline for the management of candidiasis: update by the Infectious Diseases Society of America. Clin. Infect. Dis. 62, e1; Centers for disease control and prevention. recommendations for treatment of Candida auris. https://www.cdc.gov/fungal/diseases/candidiasis/c-auris-treatment.html.; Patterson, T.F., Thompson, I.I.I.G.R., Denning, D.W. et al. 2016. Practice guidelines for the diagnosis and management of aspergillosis: 2016 Update by the Infectious Diseases Society of America. Clin. Infect. Dis. **63**, e1–e60.*

should be considered after 5–7 days of therapy initiation. Fluconazole in a dose of 400 mg orally once daily is the usual recommended oral step-down therapy (Pappas et al., 2016). For *C. glabrata* infection, fluconazole 800 mg (12 mg/kg) orally daily or voriconazole 200–300 mg (3–4 mg/kg) orally twice daily should be used for patients with fluconazole- or voriconazole-susceptible isolates.

For chronic disseminated candidiasis, initial treatment with amphotericin-B (lipid formulation) or with an echinocandin for several weeks followed by oral fluconazole until resolution of lesions (takes several months) has been recommended (Spellberg et al., 2006). Early discontinuation of therapy results in the increased risk of relapse, whereas short-term treatment (1–2 weeks) with nonsteroidal anti-inflammatory drugs or corticosteroids may be considered in patients with persistent fever.

Osteoarticular candidiasis should be treated with fluconazole or with an echinocandin for the initial 2 weeks, followed by fluconazole therapy for 6–12 months. Surgical debridement may be considered in some patients (Gamaletsou et al., 2012; Miller et al., 2015).

Candidiasis affecting the central nervous system should be treated with liposomal amphotericin-B either alone or in combination with flucytosine (Raman Sharma, 2010; Sanchez-Portocarrero et al., 2000). Step-down therapy with fluconazole should be considered in patients following improvement in their condition. Moreover, therapy needs to be continued until resolution of symptoms with no apparent CSF and radiological abnormalities.

Addressing predisposing factors is the initial approach for treating candida associated urinary tract infections. Antifungal therapy is recommended in patients who are at high risk for dissemination including neutropenic patients, low birth weight infants (<1.5 kg) and patients who undergo urologic manipulation (Achkar and Fries, 2010). High-risk patients should be treated in a similar fashion as candidemia. Oral fluconazole or amphotericin-B deoxycholate is recommended for patients undergoing urologic procedures that should be initiated few days before the procedure and should continue to be administered until few days after the procedure (Behzadi et al., 2015; Fisher et al., 2011).

Role of Pharmacists

Pharmacists have a critical role in the management of patients with fungal infections due to the several limitations of antifungal agents, including drug resistance, pharmacokinetics, toxicities, dosage form preferences, and cost. No single antifungal agent is considered appropriate for all patients and the treatment must be individualized and frequently modified for achieving optimal outcomes. Within a health care team, the pharmacist is responsible to assess and manage the drug interactions and recommend potential drug or dosage changes based on the individual patient characteristics, susceptibility testing, and therapeutic drug monitoring. Application of such knowledge and skills by pharmacists can substantially improve the probability of successful treatment by reducing the drug-related toxicities in patients with both superficial and life-threatening invasive fungal infections (Agrawal et al., 2016; Bauters et al., 2005). This section discusses the role of pharmacists in different domains of fungal disease management such as the product selection, patient counseling, antifungal susceptibility testing, therapeutic drug monitoring, identification and management of drug-related oral candidiasis, and monitoring/management of adverse drug reactions related toantifungal therapy.

Identification and Management of Drug-Related Oral Candidiasis

Many drug-related factors contribute toward the etiology of OPC and EC. Those at risk for candidiasis include patients with asthma who use an orally inhaled corticosteroid (van Boven et al., 2013), elderly wearing dentures (Aoun and Berberi, 2017), patients on long-term antidepressant therapy (with possible resultant xerostomia) (Cockburn et al., 2017), home-care patients undergoing treatment with cytotoxic drugs (Mosel et al., 2011), patients receiving high doses of oral corticosteroids and those with diabetes mellitus (Kanda et al., 2003). By reviewing patient profiles and taking a proper medical and drug history, pharmacists can identify patients with a greater risk of candidiasis due to the close correlation between these conditions (**Table 6**). In addition, patient counseling and education regarding various aspects can reduce the chances of OPC and EC in such high-risk patients.

Table 6 Questions for counseling patients on oropharyngeal candidiasis

Questions for counseling patients on oropharyngeal candidiasis
• Do you smoke or use any tobacco products?
• Do you wear dentures?
• How often do you brush your teeth? Clean your dentures? see your dentist for regular checkups?
• Do you suffer from any chronic illness (e.g., diabetes Mellitus, arthritis, rheumatic heart disease, asthma, seizure disorder, hypertension, etc.)?

Source: Information from Vozza, I., Cavallè, E., Corridore, D., Ripari, F., Spota, A., Brugnoletti, O., Guerra, F., 2015. Preventive strategies in oral health for special needs patients. Annali di Stomatologia 6, 96–99.

Xerostomia

Xerostomia is a condition in which salivary flow is limited or arrested. An estimated 20% of elderly have xerostomia (Nadig et al., 2017; Shinozaki et al., 2012). Drugs with anticholinergic activity and those that cause volume depletion (antihypertensives, antihistamines, antipsychotics, antidepressants, and diuretics) may affect treatment outcomes of OPC. Patients with xerostomia may have inadequate saliva to dissolve troches. For drug-induced xerostomia, using the lowest effective dose or switching to an alternative medication may help. Chewing xylitol gum enhances the salivary flow and helps control *Streptococcal mutans*-associated infections; however elderly who wear dentures may be unable to chew gum (Plemons et al., 2014).

Several artificial saliva preparations that provide more viscosity and lubrication than water are available generally without prescription and are dispensed as sprays, liquid rinses, gels, and lozenges. These compounds typically contain a unique mixture of multiple components in each preparation such as carboxymethylcellulose, polyethylene glycol, sorbitol, and electrolytes (Kho, 2014). They do not stimulate natural salivary gland production and must be considered as a replacement therapy. The artificial saliva is best used at bedtime and periodically throughout the day; however, their relief is temporary and has a variable efficacy (Alves et al., 2004; Rhodus and Bereuter, 2000; van der Reijden et al., 1996). These products should be applied to the inner lips, buccal mucosa, tongue and hard palate. Patients should be informed of the normal diurnal variation in saliva flow that decreases with time and has an altered composition at night (Hardt et al., 2005).

Denture wearing

Denture stomatitis is present in more than 40% of denture wearers (Puskar et al., 2012). Patients wearing dentures should be advised to clean the denture and avoid wearing it overnight. Pharmacists can also counsel patients on denture care procedure. Denture wearers should be advised to remove dentures before going to bed that should be then brushed vigorously and should be soaked in a solution of chlorhexidine gluconate or a dilute solution of bleach (10 drops in a denture cup filled with water). They should then be rinsed thoroughly.

Inhaled corticosteroid users

Steroid inhaler users should also be advised to brush and rinse the palate after each inhalation. Pharmacists should review the proper aerosol inhalation technique and consider the need for inhaler chamber (spacer) or an alternative metered-dose inhaler device if needed (Ng, 2013). Patients should also be advised to avoid smoking and consumption of alcohol.

Selection of Antifungal Dosage Form

Pharmacists can also play an important role in product selection by considering various factors including cost, length of therapy, formulation, convenience, and ease of use. Antifungal creams should be used at bedtime, preferably with a sanitary pad to help absorb any leakage. Ovules (vaginal suppository) have an added advantage that allows them to be used at any time of the day. Various formulations of amphotericin-B provide the most reliable and broad-spectrum therapeutic alternatives. However, the use of amphotericin-B deoxycholate is accompanied by their dose-limited toxicities, most importantly by their infusion-related reactions and nephrotoxicity. For patients with severe hepatotoxicity or instances when there is a suspected risk of drug interactions between azoles (as a class) and other agents, switching to a lipid formulation of amphotericin-B is recommended. Although, there is a limited knowledge to date with isavuconazole, it is a suitable alternative for patients with renal dysfunction and those who cannot receive intravenous voriconazole due to its cyclodextrin vehicle (Bauters et al., 2005).

Patient Counseling

Patient counseling by pharmacists should include information on the proper use of medications. Topical agents require frequent dosing and prolonged contact time (20–30 min) with the mucosal surface. Rough surfaces of tablets and troches may irritate sensitive mucosa. Topical agents containing sucrose or dextrose may increase the risk of caries or cause elevated blood sugar levels in patients with diabetes. Daily fluoride rinses can help reduce the risk of caries when used with an agent containing sucrose or dextrose (Stein Gold and Rosen, 2016). Moreover, vaginal formulations (creams or gels) necessitate the need for providing instructions to patients on cleaning the applicator when using reusable applicators. Oil-based topical antifungal creams or suppositories can weaken latex condoms and diaphragms and can consequently reduce their efficacy (Workowski and Bolan, 2015). Female patients with VVC should be advised to continue therapy even if their menstrual period begins. Pharmacists should also recommend the adoption of basic nonpharmacologic approaches for the treatment and prevention of VVC such as keeping the genital area clean and dry, avoidance of constrictive clothing, undergoing vaginal douching, and avoiding the prolonged use of soaps and perfumes in hot tubs (Workowski and Bolan, 2015).

Antifungal Susceptibility Testing and Antifungal Resistance

The need for reproducible and clinically relevant antifungal susceptibility testing has been prompted by the increased number of invasive fungal infections, expanding use of new and established antifungal agents and the emergence of antifungal resistance (Johnson, 2008; Pfaller, 2008). For instance, patients with an HIV infection are prone to the development of antifungal resistance

Table 7 Indications for antifungal susceptibility testing

- *C. glabrata* isolated from blood or deep sites (e.g., normally sterile fluids, tissues, abscesses) should be tested for susceptibility to fluconazole, voriconazole, and an echinocandin.
- Mucosal candidiasis that is unresponsive to usual antifungal therapy.
- Invasive disease that is unresponsive to the initial antifungal regimen.
- Clinical failure in patients with invasive disease caused by species with significant rates of acquired resistance (particularly among the azole antifungal agents).
- Invasive disease caused by unusual fungal species for which antifungal susceptibility patterns have not been well established or are unpredictable.

Source: Data from Pfaller, M.A., 2005. Antifungal susceptibility testing methods. Curr. Drug Targets, 6, 929; Rex, J.H., Pfaller, M.A., Has antifungal susceptibility testing come of age? Clin. Infect. Dis. 35, 982; Pappas, P.G., Kauffman, C.A., Andes, D. et al., 2009. Clinical practice guidelines for the management of candidiasis: update by the Infectious Diseases Society of America. Clin Infect Dis. 48, 503; Pfaller, M.A., Wu, W.L., 2001. Antifungal susceptibility testing: new technology and clinical applications. Infect. Dis. Clin. N. Am. 15, 1227; Spellberg, B. J., Filler, S.G., Edwards, J.E. Jr., 2006. Current treatment strategies for disseminated candidiasis. Clin. Infect. Dis. 42, 244.

and emergence of non-*C. albicans* candida species, particularly the *C. glabrata*. Susceptibility to antifungal agents varies between species of candida genus. Therefore, identification of the specific *Candida* spp.-associated infections and susceptibility testing will help in the selection of appropriate antifungal agents for their treatment. Among the *Candida* isolates, cross-resistance between fluconazole, itraconazole, voriconazole, and posaconazole has been reported (Pfaller, 2012). However, none of the triazoles exhibits meaningful activity against fluconazole-resistant isolates of *C. glabrata*, whereas voriconazole and posaconazole are active against the intrinsically fluconazole-resistant *C. krusei*. Pharmacists need to be aware of potential cases where antifungal susceptibility testing should be employed (Table 7).

Therapeutic Drug Monitoring of Antifungal Agents

Therapeutic drug monitoring (TDM) of antifungal agents may be useful in certain clinical scenarios, but it is not recommended in all patients with IFI. In general, an antifungal must meet the following criteria to be considered eligible for TDM:

1. A sensitive assay must be available in the clinical laboratory or possibly in a reference laboratory that will report results back in a timely fashion. Otherwise, the impact of TDM on clinical decisions would be limited.
2. An antifungal agent must have documented drug–drug interactions that would warrant the use of TDM.

Currently, four antifungals (flucytosine, itraconazole, voriconazole, and posaconazole) are considered to meet the aforementioned criteria and have established indications or guidelines for TDM (Andes et al., 2009; Ashbee et al., 2014).

The two primary indications for measuring serum drug concentrations are to document known concentration-related toxicities including central nervous system (auditory and/or visual hallucinations) and hepatic toxicities caused by voriconazole, and to document the drug exposure when adequate absorption is in question or when there is a lack of clinical response. A growing consensus from clinical experience and case reports suggests several circumstances where TDM would be helpful and would therefore be justified. Fig. 1 shows an overview of those clinical scenarios along with a sample algorithm for antifungal TDM in clinical practice.

Some of the triazoles (posaconazole, voriconazole, and itraconazole) have variable absorption rates that can lead to inadequate therapy. Given the pharmacodynamic profile and long drug half-lives of these agents, obtaining trough concentrations of these agents is necessary for monitoring their efficacy and/or absorption. TDM is particularly indicated for posaconazole suspension provided there are concerns about its gastrointestinal absorption. The oral bioavailability of posaconazole tablets and capsules is better than the suspension, although considerable variation exists, suggesting the need for TDM. The tablet and oral suspension formulations of posaconazole are not considered interchangeable due to their different dosages and pharmacokinetics. Voriconazole should be taken on empty stomach for an optimal response. Itraconazole shows absorption variability; capsule formulation requires the presence of adequate gastric acid, while acidic medium is not required for the absorption of the oral formulation.

On the contrary, both intravenous and oral formulations of isavuconazole have a number of advantages, including a long half-life that allows for once-daily dosage, excellent oral bioavailability, few adverse effects, and a wide spectrum of activity against *Candida*, *Aspergillus*, and some *Mucorales* (Falci and Pasqualotto, 2013). Early evidence suggests that the apparent need for TDM is low; however, any definite conclusions must be deferred until further clinical evidence about isavuconazole is available (Schmitt-Hoffmann et al., 2006).

Monitoring and Management Plan of Adverse Reactions and Drug Interactions of Antifungal Treatment

Antifungal therapy can be associated with a number of potential adverse effects. It is very important for pharmacists to be aware of all possible drug toxicities that allow them to provide concrete recommendations to prescribers and patients. The most common acute adverse effects include nephrotoxicity with amphotericin-B and infusion-related reactions with conventional and lipid-based amphotericin-B formulations and echinocandins. Potential adverse effects associated with antifungal therapy and their suggested management are outlined in Table 8.

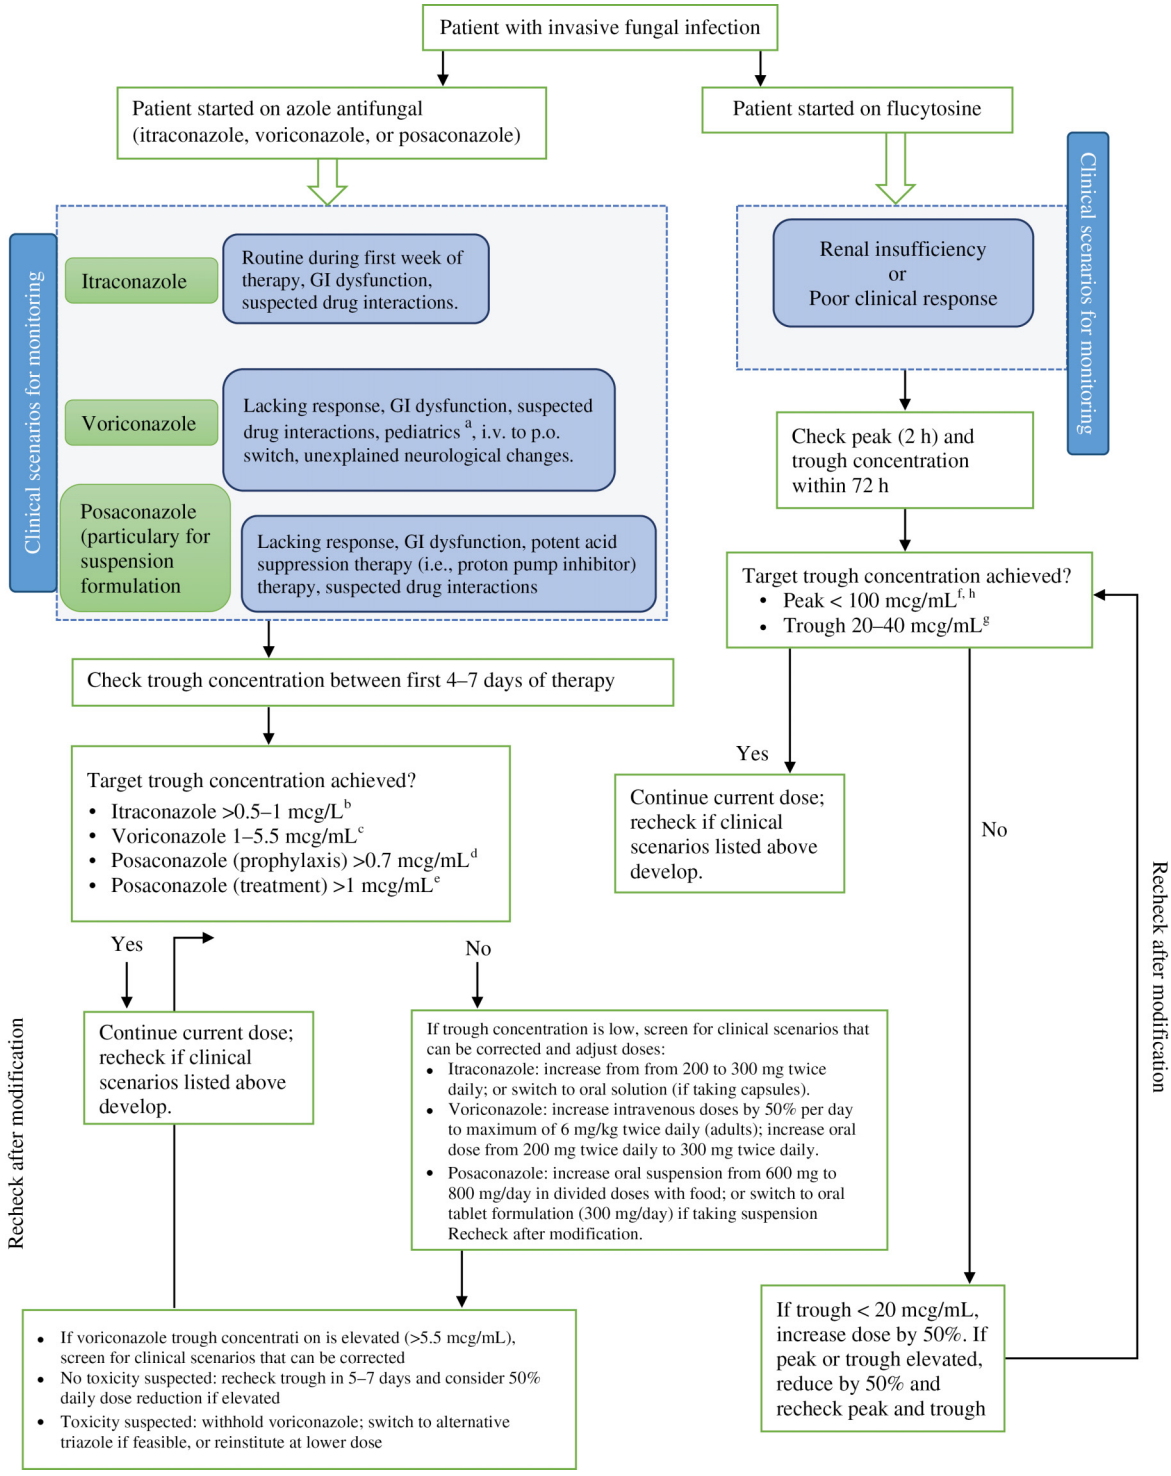

Figure 1 Clinical algorithm for antifungal therapeutic drug monitoring.

[a] Pediatric patients display accelerated linear clearance of voriconazole. Therefore, higher daily voriconazole dosing (7 mg/kg every 12 h) without a loading dose are recommended to achieve similar exposures to adults. Some children may require doses as high as 12 mg/kg every 12 h to achieve similar serum drug exposures to adults. Therefore, therapeutic drug monitoring is recommended. [b] Itraconazole serum troughs associated with efficacy, 0.5–1 mcg/mL; limited retrospective data have associated troughs of >3 mcg/mL with increased adverse effects. [c] Voriconazole troughs >1 mcg/mL are associated with a higher probability of clinical response; troughs >5.5 mcg/mL are associated with higher incidence of CNS adverse effects.[d] Posaconazole troughs of <0.7 mcg/mL are associated with higher incidence of breakthrough fungal infections during prophylaxis. [e] Posaconazole troughs >1.0 mcg/mL were associated with higher probability of treatment response for invasive aspergillosis. Currently, no recommended trough threshold has been defined for toxicity.[f] Flucytosine peak concentrations >100 mcg/mL associated with increased risk of myelotoxicity. [g] Flucytosine trough concentration of 20–40 mcg/mL recommended to prevent the rapid selection of resistance in yeast. [h] In patients receiving flucytosine orally at recommended doses, peak concentrations and trough concentrations are not significantly different. i.v., intravenous; p.o., per oral; GI, gastrointestinal.

Voriconazole therapeutic drug monitoring in patients with invasive mycoses improves efficacy and safety outcomes. Clin. Infect. Dis. 46, 201–211.

Table 8 Antifungal adverse reactions, their monitoring and management plan

Drug/Adverse reaction	*Clinical picture*	*Management/comment*
Liver injury/Hepatotoxicity		
Incidence is highest with itraconazole and voriconazole, followed by amphotericin B formulations, posaconazole, and the echinocandins/fluconazole.	↑ Serum aminotransferases ↑ Serum alkaline phosphatase ↑ Total bilirubin.	• Closely monitor transaminases, particularly in the first weeks and months of therapy. • Mild increases in serum transaminases (i.e., less than three times the upper limit of normal) often resolve spontaneously even with continued therapy. • Considering switch to alternative antifungals if liver injury markers remain elevated or continue to increase over several days • Switched from one class of antifungal to another (e.g., triazole to lipid amphotericin B) or to another drug in the same class (e.g., voriconazole to posaconazole) depending on clinical situation, infection status, and risk of toxicities or drug interactions with the alternative therapy.
Gastrointestinal distress: Main concern with oral antifungal formulations—particularly, itraconazole solution and posaconazole suspension.	Difficulty in swallowing, heartburn/reflux, nausea/vomiting, and dyspepsia.	—
Fluconazole		
Alopecia and chapped lips	—	Reversible after discontinuation of the agent
Itraconazole		
Triad of hypertension, hypokalemia, and peripheral edema	—	Contraindicated in patients with evidence of ventricular dysfunction or with a history of congestive heart failure.
Gastrointestinal distress	Due to cyclodextrin solubilizer.	Switch to another azole
Voriconazole		
Vision changes	• Abnormal vision, including photopsia or flashes of light. • Transient effects are temporally associated with drug dosing, occurs within 30 min of oral or IV administration. Symptoms usually last for approximately 30 to 60 min but can be prolonged for h.	• Generally, subside with continued therapy over several weeks. • Counsel patients regarding potential effects on operating a motor vehicle is warranted.
Neurologic toxicity	• Must be distinguished from minor vision changes, such as photopsia, is that of visual hallucinations which represent neurologic toxicity that has been linked to serum concentrations of voriconazole >5.5 mcg/mL. • Patients with neurologic toxicity may also have confusion, agitation, myoclonic movements, and auditory hallucinations. • Peripheral demyelinating neuropathy of the lower extremities, reported mostly in transplant recipients who are also taking tacrolimus.	• Consider therapeutic drug monitoring. • Screen for drug–drug interactions.
Skin toxicity	• Photosensitivity reaction.	Sun avoidance should be encouraged in patients who have experienced photosensitivity reactions during voriconazole therapy.
Periostitis	• Observed in patients on chronic treatment, appears to be due to fluoride excess and typically presents as bone pain, elevated alkaline phosphatase, and characteristic findings along the periosteum of affected bones on plain radiographs and bone scans.	Voriconazole should be discontinued in patient who develops periostitis.

(*Continued*)

Table 8 Antifungal adverse reactions, their monitoring and management plan (*cont.*)

Drug/Adverse reaction	*Clinical picture*	*Management/comment*
Cardiac toxicity	• Reported in severely ill patients with multiple comorbidities and/or concomitant use of other drugs that also could have prolonged the QT interval	See drug monograph for the management of drug interactions.
Alopecia and nail changes	• Common problems in patients taking voriconazole for a prolonged period	Reversible upon discontinuation
Posaconazole		
Renal dysfunction	• i.v. formulation of posaconazole contains the cyclodextrin vehicle, sulphobutylether-beta-cyclodextrin (SBECD) which can accumulate in the setting of renal dysfunction.	• Avoid in patients with renal insufficiency (CrCl $<$50 mL/min). • Consider IV isavuconazole as it does not contain the SBECD.
Isavuconazole		
Shortening of the QT	• In contrast with most other azoles, which cause prolongation of the QT interval), isavuconazole cause shortening of the QT interval.	Absolute contraindication in patients with familial short QT syndrome.
Echinocandins		
Hepatotoxicity	See above	See above
Infusion and hypersensitivity reactions	• Rash, pruritus, hypotension, bronchospasm, and angioedema. • Such reactions have been reported with anidulafungin when the drug is infused at a rate that exceeds 1.1 mg/min.	Slow infusion rate is advisable.
Injection site pain (Incidence is caspofungin $>$micafungin $>$ anidulafungin)		• Slow the infusion rate. • Administer in a more dilute solution.
Amphotericin b deoxycholate		
Infusion-related reactions	• Nausea, vomiting, chills, and rigors usually occurring either during infusion (within 15 min to 3 h following initiation) or immediately following administration of the dose.	• May require the use of a phenothiazine, such as promethazine (usual adult dose 12.5–25 mg every 4–6 h p.o., i.v. OR prochlorperazine (usual adult dose 10 mg IM or i.v. or 25 mg PR every 4 to 6 h), or ondansetron. • The addition of hydrocortisone (usual adult dose 25 mg) or heparin (usual final concentration 500 to 1000 U/L) to the infusion may lessen infusion-related thrombophlebitis. • Other ways to minimize amphotericin B–induced thrombophlebitis include: ◦ Infusion of the drug using a central line. ◦ Use of alternate infusion sites. ◦ Avoid final amphotericin B infusion concentrations exceeding 0.1 mg/mL.
Nephrotoxicity	• Reversible and often transient decline in glomerular filtration rate with the net effect is an elevation (above baseline) in the serum creatinine concentration • Risks of severe nephrotoxicity increase with diuretic-induced volume depletion or the concurrent administration of another nephrotoxin (such as an aminoglycoside, cyclosporine, nephrotoxic cancer chemotherapy, or foscarnet)	• Salt loading • Use of lipid formulations of amphotericin B: The liposomal preparation does not contain deoxycholate, which has direct tubular toxicity

Table 8 Antifungal adverse reactions, their monitoring and management plan (*cont.*)

Drug/Adverse reaction	*Clinical picture*	*Management/comment*
Electrolyte abnormalities	Hypokalemia, hypomagnesemia, and hyperchloremic acidosis are reflections of an increase in distal tubular membrane permeability following intravenous administration of amphotericin B

Torsades de pointes associated with voriconazole use. Transpl. Infect. Dis. 9, 33–36.

Potential drug–drug interactions must also be carefully assessed and monitored in patients receiving long-term antifungal therapy. All azoles inhibit one or more cytochrome enzymes to a variable degree, particularly at the doses used to treat the invasive diseases. Thus, clinicians should monitor the symptoms of antifungal drug toxicities that could result from drug–drug interactions. Over 1000 azole drug interactions can occur and some of those interactions can lead to undetectable blood levels of triazole antifungals (Lempers and Brüggemann, 2016). For instance, concomitant intake of warfarin with any product containing miconazole (including topical) should be used with caution due to the increased risk of bleeding (Miki et al., 2011). Therefore, all patients receiving triazole antifungal agents should have their drug regimens carefully screened, preferably with an electronic medication database such as Lexicomp Lexi-Interact or Micromedex Drug-Reax (Lempers and Brüggemann, 2016).

Conclusions

Fungal pathogens cause a number of infections ranging from mild superficial to life-threatening systemic infections. Species of genus *Candida* and *Aspergillus* are commonly involved in various mucocutaneous and invasive opportunistic infections. The risk of fungal infections is common in immunocompromised individuals, including patients with an HIV-infection, malignancy, patients with recent transplantation, and those who are using corticosteroids. Appropriate selection of drug therapy, antifungal susceptibility, route of administration, and nature of disease are all crucial for the successful eradication and prevention of the recurrence of fungal infections. Pharmacists with their expertise can optimize the antifungal therapy by recommending the appropriate dosage form, provision of patient education, individualization of dosages by virtue of therapeutic drug monitoring, and management of adverse effects and drug–drug interactions.

Glossary

Aerosolized fungi pathogen Extremely small (microscopic) airborne fungi.
Candidemia The presence of candida species in the blood stream.
Commensal organisms A symbiotic relationship between two organisms in which one organism benefits from the other without harming it.
Douching Rinsing of the vaginal cavity with water or other solutions.
Dysphagia Difficulty in swallowing.
Hemiparesis Paralysis or neurologic weakening of one side of the body.
Hyphae Filamentous structure forming the structure of fungi.
Mucocutaneous Relating to the mucous and skin including the nasal, oral, and vaginal cavities.
Odynophagia Severe pain during swallowing
Refractory A condition that does not respond to therapy.
Xerostomia Abnormal dryness of the mouth.

Pharmacotherapy of Viral Infections and the Role of Pharmacists in the Prevention and Treatment of Viral Diseases

Naomi E. Weier*, Syed Tabish R. Zaidi†, *University of Tasmania, Hobart, TAS, Australia; †University of Leeds, Leeds, United Kingdom

Learning Objectives

After reading this chapter, readers will be able to:

- Identify the disease burden caused by viral infections to society.
- Describe the pathophysiology of common viral infections, including human papilloma virus, herpes simplex, herpes zoster, varicella zoster virus, influenza, cytomegalovirus, and hepatitis.
- Select appropriate treatment options for the management of common viral infections.
- Compare and contrast antivirals available in a particular drug class and select the most appropriate treatment for an individual patient.
- Appreciate the role of the pharmacist in optimizing the prevention and treatment of viral infections in patients.

Take Home Messages

- Viral infections in humans will invade their hosts by compromising the first line of defence such as epithelial barriers in the respiratory, digestive, or reproductive tracts.
- Different viral infections will lead to different complications and consequences. Some viruses increase the risk of cancer (e.g., human papillomavirus), while others, once contracted, are lifelong infections and flare-ups of symptoms occur periodically (e.g., herpes simplex).
- Choice of antiviral treatment will depend on numerous factors, including the type of infection, the age of the patient and presence of other comorbidities, dosing schedule, proven efficacy, and safety profile.
- Vaccination is a key strategy in preventing infection for many types of viruses. The influenza vaccination needs to be done annually due to different strains of influenza predominating in different years.

- Pharmacists working in community and hospital settings can play an important role in the prevention and optimal treatment of viral infections.

Introduction

Global burden of viral diseases is enormous. It is estimated that influenza alone is responsible for more than half a million deaths annually (Iuliano et al., 2018). In 2013, viral hepatitis was responsible for 1.4 million deaths worldwide (Brown et al., 2017).

Many viral infections in humans will invade their hosts by initially crossing epithelial barriers in the respiratory, digestive, or reproductive tracts, which may or may not involve infecting the epithelial cells. Viruses use varying strategies to cross this natural barrier into the body, such as utilizing immune system cells (e.g., macrophages, dendritic cells) or utilizing the epithelial cells to gain access. The mechanism by which the virus enters the host cell and causes infection is important in designing treatment strategies to cure these viral infections (Cohen, 2016; Grove and Marsh, 2011).

Treatment will depend on the type of viral infection and individual patient characteristics and can include antiviral therapy, symptomatic treatment, and nonpharmacological strategies. While some viruses are curable, others are persistent, and the focus of the treatment is on managing viral load and controling symptoms. Depending on the virus, prevention may involve vaccinations, following general hygiene measures, or both. Given the inherent complexities of managing human immunodeficiency virus (HIV), a discussion of its prevention and treatment is beyond the scope of this chapter.

Disease State

Human Papillomavirus

Human papillomavirus (HPV) has been identified as the most common sexually transmitted infection in the United States (Centers for Disease Control and Prevention, 2017a). It affects both males and females, and there are over 100 different forms of the virus (Queensland Government, 2017).

HPV is the main cause of cervical cancer, although the type of HPV virus will determine the likelihood of it leading to cancer—HPV-6 and HPV-11 are types classified as "low risk," while HPV-16 and HPV-18 are "high-risk" types (Steben and Duarte-Franco, 2007). It is possible for someone to be infected with multiple types of HPV (Juckett and Hartman-Adams, 2010).

In additional to cervical cancer, HPV is also implicated in (Gearhart, 2017; Steben and Duarte-Franco, 2007):

- anogenital warts, which are often found not only in moist areas (e.g., perianal area, vagina, labia, vulva) but may also be found in dry areas, such as the penile shaft. All external genital warts are caused by HPV (most commonly by HPV-6 and HPV-11)
- anal cancer
- warts in areas other than the genitals (e.g., oral warts, respiratory papillomas)
- cutaneous disease in areas other than the genitals (e.g., verruca vulgaris, verruca plana)
- epidermodysplasia verruciformis.

Risk factors for HPV infections include increasing numbers of sexual partners, sex beginning at an early age, lack of condom use (although this is only about 70% effective in preventing transmission as genital contact still occurs), history of sexually transmitted infections, and tobacco use (Juckett and Hartman-Adams, 2010).

Herpes Simplex

There are two types of herpes simplex viruses—herpes simplex virus type 1 (HSV-1) and herpes simplex virus type 2 (HSV-2). They are responsible for causing recurrent infection, commonly on the skin, mouth, lips, eyes, and genitals. HSV-1 is often contracted during childhood by coming into contact with oral secretions of someone who has the virus and has traditionally been associated with infection of the mouth and face, most commonly leading to "cold sores." HSV-2 typically infects the genitals and is mainly contracted either during childbirth if the mother has an active infection or after someone becomes sexually active (Ayoade, 2017; Kaye, 2016). More recent information, however, has suggested that HSV-1 is also an important cause of genital herpes, with transmission occurring during oral sex (World Health Organization, 2015).

Transmission of the herpes simplex virus occurs through close contact with a person who is shedding the virus. This may be through coming into contact with a herpes sore, skin containing the herpes infection or genital or oral secretions (Centers for Disease Control and Prevention, 2017b; Victoria State Government, 2018a).

The signs and symptoms that present depend on where the infection is present on the body, and whether it is an initial infection or reactivation of the virus. Initial infections will also generally present with systemic symptoms, a longer duration, and a greater risk of complications, while recurrent episodes generally have milder symptoms and shorter episodes. People who are immunocompromised are more likely to experience symptoms that are more severe, longer lasting, and widespread, and episodes are more likely to recur (Ayoade, 2017).

Herpes labialis, or "cold sores," is the reactivation of the oral herpes virus infection. Tingling, itching, or burning at the site of infection (most commonly on the lips or around the mouth) may initially occur for the first day or so, before one or more red,

fluid-filled blisters appears. The blister(s) erupt and ulcerate and can last for 7–10 days. Herpes labialis can recur, though the frequency at which this occurs varies between people (American Academy of Dermatology, 2018; Ayoade, 2017; Pringle, 2013; World Health Organization, 2017).

Varicella Zoster Virus

The varicella zoster virus is a highly infectious virus that only affects humans, and primarily occurs during winter and early spring (Pergam et al., 2009; Victoria State Government, 2018b). While chickenpox is highly contagious, shingles is less so (Victoria State Government, 2018b). The virus causes chickenpox and shingles (or herpes zoster), with chickenpox generally being a mild illness in childhood (Anderson, 2018). Following the initial infection, the varicella zoster virus remains dormant in the cranial nerve and dorsal root ganglia, which can be reactivated years later as herpes zoster (Anderson, 2018; Pergam et al., 2009). Second episodes of chickenpox may occur, but it is rare (Victoria State Government, 2018b). Viral spread is usually through contact with the lesions or airborne through respiratory droplets, and occasionally through things that are soiled from discharge from the vesicles (the scabs cannot transmit infection) (Pergam et al., 2009; Victoria State Government, 2018b).

Varicella zoster infection is characterized by a vesicular rash that is widespread and itchy, and accompanying symptoms can include malaise and fever. The rash initially appears as small lumps, which change into blisters before scabbing (Centers for Disease Control and Prevention, 2016; NSW Government, 2018).

Herpes Zoster

Herpes zoster is a result of the varicella-zoster virus remaining dormant in the dorsal root ganglia, often for many years, and reactivating leading to herpes zoster, or shingles (Janniger, 2018). As over 90% of adults have had varicella-zoster, the majority of the population is at risk of herpes zoster (Wehrhahn and Dwyer, 2012).

Diagnosis is mainly based on clinical signs and a patient history, though laboratory tests can be used in atypical cases. Laboratory studies available include direct fluorescent antibody, polymerase chain reaction testing, or Tzanck smear of vesicular fluid (Janniger, 2018; Wehrhahn and Dwyer, 2012).

Influenza

Influenza viruses are single-stranded RNA orthomyxoviruses. Three types of influenza viruses occur—types A, B, or C; however, types A and B are the ones that most likely lead to severe disease in humans (Australian Government Department of Health, 2017). These two types will cause similar symptoms, but laboratory tests can differentiate between the two (WHO Collaborating Centre for Reference and Research on Influenza, 2018). Yearly outbreaks and epidemics of the influenza virus are due to constant mutations, which also require annual updates to the influenza vaccine. Infections most commonly occur during the winter season, but infections can appear throughout the year and in locations close to the equator infection may occur during the year (Australian Government Department of Health, 2017; WHO Collaborating Centre for Reference and Research on Influenza, 2018).

Transmission is through respiratory droplets and through coming in contact with respiratory secretions. The incubation period is on average 2 days but can be between 1 and 4 days—those infected with influenza are infectious from 1 day prior to symptom onset. Viral shedding is highest during the first 3–5 days of sickness; however, young children can shed the virus for up to 7–10 days, and this may be longer in patients who are severely immunocompromised (Australian Government Department of Health, 2017; SA Health, 2012).

Symptoms of influenza can include cough, sore throat, nasal congestion, fatigue, fever, headache, and muscle aches. Vomiting and diarrhea may occur though more commonly in children than adults. Influenza may be suspected in patients presenting with fever greater than 38°C and symptoms of cough or sore throat if no other explanation of symptoms is apparent. Uncomplicated influenza generally resolves within a week; however, symptoms of cough or fatigue may be more prolonged (Australian Government Department of Health, 2017; Centers for Disease Control and Prevention, 2018a; SA Health, 2012; WHO Collaborating Centre for Reference and Research on Influenza, 2018).

Cytomegalovirus

Cytomegalovirus (CMV) infection is an opportunistic infection and carries a high risk of morbidity and mortality in patients with an impaired immune system, such as those receiving stem cell or solid organ transplants. Patients are at greatest risk in the first 100 days following the organ transplant (Biron, 2006). It is a double-stranded DNA virus and a member of the human herpes viruses. Transmission occurs easily through bodily fluids or the placenta. In patients who are immunocompetent, the infection is usually benign, and minimal (if any) symptoms are present. The infection remains dormant following initial infection, although reactivation occurs if the immune system is compromised (e.g., from chemotherapy or when immunosuppression occurs for transplants) (Biron, 2006).

CMV is a common infection, particularly in children. In the United States, it is estimated that by the age of 5 years, nearly one in three children have been infected (Centers for Disease Control and Prevention, 2018b). If a woman is initially infected with the virus while pregnant, there is a risk that her unborn baby will also become infected, which has the potential to cause disability (e.g.,

hearing or vision loss, small head size, cerebral palsy, delayed development or intellectual disability, or rarely death) (NSW Government, 2017). This risk is highest if a woman has an initial CMV infection during pregnancy and when this occurs in the first half of the pregnancy. Australian studies have found that in 1000 live births, approximately 6 babies will have congenital CMV infection and 1–2 of these babies will have a permanent disability. If a virus reactivates in a pregnant woman, it does not usually cause issues to either the woman or the fetus (Centers for Disease Control and Prevention, 2018b; NSW Government, 2017).

Hepatitis A

Hepatitis A is an RNA virus that causes acute infection. While young children may not have any symptoms, older children and adults can experience symptoms, such as anorexia, malaise, and jaundice. This infection is spread through feces, including when feces contaminate the hands, objects, water, or food, which then is ingested through the mouth. Transmission can occur through children in childcare centers who are not toilet trained, sexual and household contacts of people who are infected with hepatitis A, traveling to countries with a high risk, and drug use (both injecting and noninjecting). Diagnosis is made by serologic testing. There is no specific antiviral for hepatitis A, and the treatment is supportive (Government of South Australia, 2012; Rutherford, 2017).

Hepatitis B

The hepatitis B virus consists of circular, double-stranded DNA. It is commonly transmitted in developing areas and can be spread through body fluids (e.g., blood, semen, vaginal secretions). It is estimated that approximately 2 billion people worldwide are infected with hepatitis B virus, and 350 million of these people have chronic infection. Infection may be immune or chronic (Australian Government Department of Health, 2017; NSW Government, 2013; Pyrsopoulos, 2017; Victoria State Government, 2018c).

Transmission may spread through numerous ways, including transmission from mother to child during pregnancy or childbirth; having sex without a condom; skin penetration with contaminated equipment (e.g., sharing needles, needle stick injuries, tattooing); and sharing objects that may contain blood (e.g., toothbrushes, razors). Groups that are at particularly high risk of contracting hepatitis B infection include those who inject drugs, men who have sex with men, and people with sexual partners or family members that have hepatitis B (NSW Government, 2013; Victoria State Government, 2018c).

Hepatitis C

Hepatitis C affects approximately 2% of adults in the United States (Wilkins et al., 2010). It is transmitted through blood to blood contact, and the majority of people (80%) with the infection will develop chronic infection (NSW Government, 2016). Infection is often initially asymptomatic, but symptoms can develop within 1–3 months of the infection. Symptoms can include loss of appetite, nausea (and potential vomiting), tiredness, abdominal pain, jaundice, dark urine, and pale stools. Symptoms may continue for a few days to a few weeks and then improve (NSW Government, 2016). Consequences of infection include cirrhosis, decompensated disease, liver cancer, and death (Khoo and Tse, 2016). Six different genotypes exist for the hepatitis C virus (Khoo and Tse, 2016).

Condition Management

Pharmacological Management

Neuraminidase Inhibitors

A number of neuraminidase inhibitors are available in different parts of the world—zanamivir, oseltamivir, peramivir, and laninamivir—and are indicated for the treatment and prevention of influenza (McKimm-Breschkin, 2013; Moscona, 2005). Differences in the structure of neuraminidase inhibitors mean that resistance can develop to the drugs as a class as well as individual neuraminidase inhibitors (McKimm-Breschkin, 2013).

Influenza viruses have three surface proteins—hemagglutinin, neuraminidase, and M2 protein. Neuraminidase inhibitors, by blocking neuraminidase, prevent new virions being released from the cell surface (McKimm-Breschkin, 2013). In addition, they prevent neuraminic acid from being digested in mucus and limit the virus from spreading through the respiratory epithelium (Democratis et al., 2006). Because neuraminidase is present in both influenza virus type A and B, it makes it an ideal site for treatment and prevention of the influenza virus (Democratis et al., 2006). The influenza virus replicates in the respiratory tract and peaks at 24–72 h after illness onset, meaning that neuraminidase inhibitors (that act on replication) need to be administered as soon as possible for maximum effect (Moscona, 2005). Initiation of treatment 36–48 h after symptom onset is recommended for maximal benefit in reducing times until symptom resolution (Democratis et al., 2006).

Zanamivir

Zanamivir was the first neuraminidase inhibitor developed. It has poor oral bioavailability and is not absorbed. It is delivered through oral inhalation (**Table 1**) (Democratis et al., 2006; McKimm-Breschkin, 2013). The inhaled formulation allows high concentrations of the drug to be delivered to the respiratory tract, and due to minimal systemic absorption no dose adjustment is required in renal dysfunction (Eiland and Eiland, 2007; McKimm-Breschkin, 2013). Similarly, there is a lack of drug interactions

Table 1 Neuraminidase inhibitors (Alame et al., 2016; Centers for Disease Control and Prevention, 2018c; Daiichi-Sankyo, 2016; de Jong et al., 2014; Eiland and Eiland, 2007; Greene et al., 2013; Jefferson et al., 2014; Kashiwagi et al., 2012; Kohno et al., 2010; McKimm-Breschkin, 2013; Moscona, 2005; Rossi, 2018; Tochino et al., 2017)

Drug	*Adult dose*	*Pediatric dose*	*Adverse effects*	*Comments*
Zanamivir	Treatment: 10 mg twice daily inhaled	Children ≥5 years: same as adult dose	• Headache • Throat/tonsil pain • Cough • Nasal symptoms • Bronchospasm	• No dosage adjustment required in renal impairment • Concentrates in respiratory tract and fast onset of action (within 10 s) minimizes risk of resistance developing; resistance has not been seen in immunocompetent patients • Well tolerated—adverse effects similar to placebo • Use with caution in patients with chronic airways disease as shown to cause hypersensitivity-related bronchospasm
Oseltamivir	75 mg twice daily (oral) for treatment 75 mg once daily (oral) for prophylaxis	Treatment: Orally twice daily dose • <12 months: 3 mg/kg • ≥1 year, ≤15 kg: 30 mg • ≥1 year, >15-23 kg: 45 mg • ≥1 year, >23-40 kg: 60 mg • ≥1 year, >40 kg: 75 mg	• Nausea • Vomiting • Headaches • Psychiatric symptoms (e.g., delirium, abnormal behavior)	• Reduce dose in renal impairment • Influenza treatment duration: 5 days • Prophylaxis duration: 10 days • May be taken with or without food (with food may reduce nausea and vomiting) • Conflicting results for risk of psychiatric adverse effects
Peramivir	≥18 years: 600 mg intravenously as a single dose	N/A	Mild to moderate • Diarrhea • Nausea • Vomiting • Abnormal behavior, cough, pyrexia in young children • Severe adverse effects: reduced neutrophil count, prolonged QT interval	• Given as intravenous infusion over 15–30 min • Useful for critically ill patients and patients unable to tolerate other routes of administration • Well tolerated, similar adverse effects compared to placebo (more common in young children)
Laninamivir	40 mg as a single inhalation	• Children ≥10 years: 40 mg as a single inhalation • Children <10 years: 20 mg as a single inhalation	• Psychiatric adverse effects (e.g., abnormal behaviors) • Diarrhea • Nausea • Dizziness	• Adverse effects similar to other neuraminidase inhibitors • One study found significantly fewer adverse effects versus oseltamivir • Adverse effects commonly seen on days of use, majority appear within the first 3 days and resolve or improve within 3 days

with zanamivir, and it does not have an effect on CYP450 enzymes, although it should be used with caution in people with a milk allergy as the inhalation contains milk protein or lactose (Eiland and Eiland, 2007). Children and elderly patients may also have difficulty inhaling the full dose properly, which may reduce the efficacy of treatment (Eiland and Eiland, 2007; Rossi, 2018). While intranasal and intravenous formulations of zanamivir have been studied, neither of these formulations are marketed (Eiland and Eiland, 2007). Studies have found that zanamivir improves resolution of influenza symptoms by 1–2 days when treatment is started within 36–48 h after illness onset (Moscona, 2005).

Zanamivir is also indicated as prophylaxis against influenza A and B. One study found that zanamivir 10 mg once daily for 10 days had an 81% protective efficacy against influenza. The sooner zanamivir is taken after exposure to influenza, the more effective it is as preventative treatment, and it has been suggested that a long delay may lead to treatment failure. It is recommended that treatment is started within 36 h of exposure (Monto et al., 2002; Rossi, 2018).

Oseltamivir

Oseltamivir was the next neuraminidase inhibitor designed and is taken orally as the prodrug oseltamivir phosphate and converted hepatically to the active oseltamivir carboxylate (McKimm-Breschkin, 2013). Generally, oseltamivir is more effective against influenza A viruses (H3N2) than N1 subtype viruses (McKimm-Breschkin, 2013). See **Table 1** for dosing recommendations.

Oseltamivir has been shown to be effective as both treatment and prophylaxis in older patients (including those who received the influenza vaccination) and was well tolerated (Dutkowski, 2010; Moscona, 2005). Similarly, oseltamivir has been shown to be effective in children in reducing the duration of symptoms and is well tolerated, with vomiting being the most common adverse effect seen in one study of children (Heinonen et al., 2010).

Oseltamivir is also indicated for the prevention of influenza, with one study showing that it had 89% protective efficacy of individuals (Welliver et al., 2001).

Peramivir

Peramivir has low oral bioavailability and is available as an intravenous formulation in certain countries around the world (Alame et al., 2016; McKimm-Breschkin, 2013). It is licensed by the Food and Drug Administration (FDA) for use in adults 18 years of age and over for the treatment of uncomplicated influenza and is effective against both influenza A and B. Due to its ability to tightly bind to its target neuraminidase site and slow time for dissolution, it has a half-life of over 24 h, making it longer acting than oseltamivir and zanamivir (which have a half-life of 1.25 h) (Alame et al., 2016). In addition, when administered intravenously, peak plasma concentration occurs immediately after administration and does not undergo significant metabolism by the liver, meaning dosage adjustment is not required in hepatic impairment (Alame et al., 2016). Peramivir doesn't have an effect on glucuronidation, isn't a substrate for CYP enzymes or P-glycoprotein transport, and does not inhibit P-glycoprotein (Alame et al., 2016). Peramivir is mainly renally excreted, and 90% of the drug is excreted unchanged—patients with renal impairment therefore require adjusted doses (Alame et al., 2016).

Laninamivir

Laninamivir is the most recent neuraminidase inhibitor that has become available, and while based on zanamivir, is a long-acting formulation that is administered by oral inhalation. It is administered as a single 40 mg dose of the prodrug laninamivir octanoate, which is converted to the active laninamivir in the lungs (**Table 1**) (Ikematsu and Kawai, 2011; McKimm-Breschkin, 2013). As the concentration of laninamivir in the lungs required to inhibit replication of the influenza virus is present for at least 5 days, a single dose can be used to treat influenza (Ikematsu and Kawai, 2011). Research has suggested that laninamivir is effective treatment for influenza A (H1N1)pdm09, seasonal influenza A (H1N1), and influenza B viruses; however, further research in this area is needed to confirm its efficacy (Kashiwagi et al., 2016).

Laninamivir has also been shown to be an effective treatment for postexposure prophylaxis against influenza, in both patients who have and have not received the influenza vaccination. One study compared neuraminidase inhibitors and found that there were no significant differences in the time taken to alleviate fever or any other influenza symptoms, indicating that laninamivir was as effective as other neuraminidase inhibitors available (Tochino et al., 2017). Another study in 2016 found laninamivir 40 mg as a single dose was effective in preventing influenza. This study was in patients who lived in the same household as someone with influenza, and patients received laninamivir within 48 h of symptom onset in the person with influenza (Kashiwagi et al., 2016). While it had previously been demonstrated that laninamivir given at an inhaled dose of 20 mg daily for 2–3 days was effective in preventing influenza in household contacts, this more recent research found that the higher, single-dose treatment was also effective. Laninamvir has an advantage over other treatments such as oseltamivir and zanamivir as it is a single dose, compared to these other antivirals which require multiple dosing. This has the potential to improve adherence and offer a convenient dosing option, which could be particularly useful in certain target groups such as health-care workers working in pandemic settings (Kashiwagi et al., 2016).

Being an inhalation, laninamivir may not be suitable for all patients. Younger children (particular those younger than 3 years) have difficulty inhaling the drug meaning it may not be suitable for this age group and oseltamivir is instead preferred (Tochino et al., 2017). One strategy to ensure the medication is taken correctly by patients is by having the patient inhale laninamivir in front of a health professional (such as a doctor, pharmacist or other health professional) (Tochino et al., 2017).

Adamantanes

The adamantanes—amantadine and rimantadine—can be used to treat or prevent influenza A (Moscona, 2005). Unfortunately, their treatment can rapidly lead to resistance developing (within 48–72 h after beginning treatment). Resistant strains can be transmitted to susceptible individuals, and immunocompromised patients taking these drugs can shed this virus for a long period of time. Adamantanes are also associated with potentially serious adverse effects. Due to these limitations, they are rarely used as treatment for influenza, and their place in therapy lies mainly in prevention during epidemics (Democratis et al., 2006; McKimm-Breschkin, 2013; Moscona, 2005).

Guanine Analogues

Guanine analogues include aciclovir, famciclovir, ganciclovir, penciclovir, valaciclovir, and valganciclovir. While aciclovir, famciclovir, and valaciclovir are all indicated for the treatment of herpes simplex and shingles, valaciclovir is also indicated for prevention of cytomegalovirus after organ transplantation. Ganciclovir and valganciclovir are indicated for CMV (both treatment and prevention in patients receiving bone marrow and solid organ transplants) (Rossi, 2018). Penciclovir is available as a topical treatment for herpes labialis (Medscape, 2018a).

Aciclovir, famciclovir, and valaciclovir are indicated for the treatment of herpes zoster and have been found to be safe and effective (Janniger, 2018; Rossi, 2018). They work by inhibiting viral DNA polymerase, which subsequently prevents the herpes zoster virus from replicating (Janniger, 2018). Guanine analogues may reduce the length of time that new vesicles form, the number of days until complete crusting occurs, and the days of discomfort. The earlier treatment is started the more effective they are in reducing the duration of herpes zoster and preventing or limiting the severity of associated post herpetic neuralgia. They should

ideally be started within 72 h of symptom onset; however, some research has found them to be effective in reducing pain even if started after 72 h (Janniger, 2018).

Aciclovir, famciclovir, and valaciclovir may also be used for the management of genital herpes (Emmert, 2000; Rossi, 2018). Treatment of initial infection is recommended, particularly if the patient also presents with systemic symptoms and is immunocompromised (Emmert, 2000). Treatment of recurrent infections episodically aims to reduce symptoms as well as transmission of infection—it will not reduce the frequency of recurrences (Emmert, 2000). Treatment of recurrent infections should also occur as soon as possible after symptoms first appear (Wald et al., 2002).

The use of treatment for suppression of recurrent genital herpes infection varies between individuals as recurrent infections are often mild and infrequent. Generally, treatment of subsequent infections occurs if patients experience more than six outbreaks per year (Emmert, 2000). These treatments have an effectiveness of 70%–80% in treating symptomatic recurrences (Emmert, 2000). Aims of suppressive therapy include reducing the severity and frequency of symptoms, reducing transmission of the virus to sexual partners and infants of infected mothers, and reducing transmission of associated viral diseases (e.g., HIV) (Emmert, 2000).

Oral herpes labialis may be managed with oral aciclovir, valaciclovir, or famciclovir, while topical aciclovir and penciclovir are also available (but not as effective as oral treatment). Because viral shedding only occurs for a short period of time in recurrent infections, short treatment durations are generally effective. Treatment is aimed at managing recurrent infections, although oral aciclovir and valaciclovir may be used as daily suppressive therapy (Usatine and Tinitigan, 2010).

Valaciclovir, ganciclovir, and valganciclovir are used for the prevention and treatment of CMV (Biron, 2006; Rossi, 2018). When used to treat the infection, its use should continue until symptoms have improved and blood antigenemia has resolved (Tan, 2014). When used as prophylaxis, treatment usually begins at the time of the transplant, with doses often lower than those used to treat an active infection (Biron, 2006). Ganciclovir and valganciclovir are now considered first-line treatment for the prevention of CMV in patients undergoing transplants (Biron, 2006). Patients undergoing transplants will undergo regular testing after the transplant for either CMV 65 pp65 antigenemia or CMV DNA, and when replication is seen treatment will begin. The cut-off point for when treatment should begin is not certain, however, and different thresholds for beginning treatment have been used (Tan, 2014). Ganciclovir and valganciclovir are also used for the treatment of CMV retinitis in AIDS. Because it usually takes 3–6 months after starting antiretroviral therapy for the immune response to improve, maintenance therapy needs to continue after initial treatment until CD4 counts are above 100/mm^3 and are stable or continuing to improve. Maintenance treatment can be ceased when CD4 counts are above this for several months and lesions on the retina are stable and not progressing (Tan, 2014).

Aciclovir

Aciclovir was the first guanine analogue to be developed (De Clercq, 2000). Although effective and cheaper than other guanine analogues, it has limited oral bioavailability (15%–30%) (intravenous administration can give concentrations 10-fold higher). Due to the low oral bioavailability, frequent dosing is required (Beutner et al., 1995; Emmert, 2000), which has the potential to impact on patient acceptability as well as adherence. Aciclovir is available as tablets, intravenous injection, and topical formulations. It is the preferred guanine analogue to use in pregnancy due to extensive clinical experience and is the most common treatment for the management of herpes zoster in children (Janniger, 2018; Rossi, 2018). The half-life is 2.5 h, and dosage adjustment is required in renal impairment (Emmert, 2000). It has good penetration into most body tissues, including the brain and placenta (Emmert, 2000).

Aciclovir binds viral DNA polymerase and terminates replication. Because replication can end after 48 h of a recurrence of genital herpes, if aciclovir treatment is to be effective it needs to begin early (Emmert, 2000). Aciclovir is also indicated for the treatment of primary genital herpes, with a recommended dose of 400 mg orally three times a day for 5–10 days (Emmert, 2000; Rossi, 2018). While oral therapy is effective for treatment of primary infection, intravenous treatment may be required in patients who are immunocompromised or have severe infection (Emmert, 2000). Aciclovir is effective in reducing time of viral shedding, time until lesions are crusted or healed, local pain, and constitutional symptoms (Emmert, 2000). Treatment of initial infection will not impact on the frequency or number of recurrent infections, or influence the long-term history of the infection (Emmert, 2000).

Aciclovir can also be used as suppressive therapy at 400 mg orally twice a day for adults (Emmert, 2000). It has been shown to reduce frequency by up to 80% and prevent recurrence in up to 45% of patients (Emmert, 2000). Resistance to aciclovir has not been seen in patients who are immunocompetent, however, it is recommended to cease therapy once a year to determine whether ongoing therapy is necessary (Emmert, 2000). Aciclovir has been shown to have a small benefit when taken to treat recurrent episodes of genital herpes—it should be taken early on when prodrome symptoms begin (within minutes to hours) (Emmert, 2000).

Treatment regimens for recurrent infection can differ slightly, with oral recommendations for adults including 400 mg three times a day or 800 mg twice a day for 5 days or 800 mg three times daily for 2 days (Emmert, 2000; Rossi, 2018). One study investigated the efficacy of the 2 day treatment regimen on the premise that in immunocompetent patients the duration of viral shedding is short in recurrent infections. It found that compared to placebo, aciclovir 800 mg three times a day for 2 days significantly reduced lesion duration, the episode, and viral shedding. This regimen, being shorter, is likely to be more convenient and acceptable to patients than the longer treatments. These results were also similar to other studies comparing valaciclovir and famciclovir with placebo for the treatment of recurrent genital herpes infection (Wald et al., 2002).

For herpes zoster, the recommended dose is 800 mg five times a day orally for 7 days for adults. Lower doses have not been found to be effective, suggesting that higher plasma/tissue concentrations are required for optimal efficacy (Beutner et al., 1995; Rossi, 2018). Aciclovir reduces the time to rash healing, reduces acute pain severity, and some studies have also found that it

reduces the risk, severity, and duration of chronic pain associated with herpes zoster. Aciclovir has also been found to reduce the risk and severity of particular complications of herpes zoster ophthalmicus (Beutner et al., 1995). There has, however, been shown to be viral strains resistant to aciclovir emerging, suggesting agents such as valaciclovir and famciclovir may have an increasing role in the treatment of herpes zoster in the future (Janniger, 2018).

Aciclovir is indicated for the treatment of oral herpes labialis. Oral treatment in adults of 400 mg 5 times a day for 5 days has been shown to be effective in reducing viral shedding, time until lesions heal, and duration of lesion pain when started early in the prodrome stage. Oral treatment is indicated in certain patient groups for the treatment of oral herpes labialis, such as when severe infection is present or in patients who are immunocompromised (Rossi, 2018). In addition, aciclovir may be used to treat herpetic gingivostomatitis in young children, at a dose of 15 mg/kg 5 times a day for 7 days. This has been shown to be effective in reducing the time that oral lesions are present and viral shedding, in addition to reducing the time until the resolution of fever, and eating and drinking difficulties (Usatine and Tinitigan, 2010).

Aciclovir may be used as suppressive therapy to prevent recurrences of oral herpes labialis in patients who have frequent episodes. One study looking at oral suppressive therapy at 400 mg twice a day compared to placebo found that aciclovir led to a 53% reduction in the number of clinical recurrences and a 71% reduction in the number of virus culture-positive recurrences (Usatine and Tinitigan, 2010).

Aciclovir 5% topical cream is also available and indicated for the treatment of minor recurrent episodes of oral herpes labialis (Expert Group for Dermatology, 2015; Medscape, 2018b; Spruance et al., 2002). The cream base allows aciclovir to penetrate the skin more effectively compared to an ointment base (Spruance et al., 2002). It is recommended that aciclovir cream be applied to the lesion 5 times a day (every 4 h while awake) when the symptoms first appear for 4–5 days (Expert Group for Dermatology, 2015; Medscape, 2018b). Aciclovir cream has been shown to be well tolerated, with the incidence of adverse effects similar to patients using the vehicle cream only. The most common adverse effects reported include headache, cracked lips, and dry lips (Spruance et al., 2002).

Aciclovir in general has been found to be safe and well tolerated (Emmert, 2000). Adverse effects are often mild and can include nausea, vomiting, headache, and a rash. Rarely, lethargy, seizures, delirium, and tremulousness have been seen in patients who are renally impaired. In patients who are dehydrated or have renal dysfunction aciclovir may crystallize in the renal tubules leading to elevated creatinine (which is reversible) or occasionally acute tubular necrosis (Emmert, 2000).

Valaciclovir

Valaciclovir is the prodrug for aciclovir and has been found to produce plasma levels of aciclovir significantly higher (three to fivefold) than aciclovir itself. Conversion to aciclovir occurs rapidly after oral administration, and 1000 mg of valaciclovir converts to 700 mg aciclovir (Beutner et al., 1995; De Clercq, 2000). It has been found to be very effective in preventing herpes zoster and CMV in patients following renal transplant (De Clercq, 2000).

One study compared the efficacy and safety of valaciclovir 1000 mg three times daily for 7 or 14 days to oral aciclovir 800 mg fives times daily for 7 days in immunocompetent adults 50 years of age or older with herpes zoster. During a 6 month evaluation, it was found that valaciclovir for either 7 or 14 days significantly hastened pain resolution from herpes zoster compared to aciclovir (median pain duration was 38 and 44 days with valaciclovir for 7 or 14 days, compared to 51 days for those treated with aciclovir). Adverse effects were also similar between treatment groups, which supports the use of valaciclovir with easier dosing regimens and some advantages over aciclovir, and a similar safety profile (Beutner et al., 1995).

When given to treat an initial genital herpes infection, the recommended dose of valaciclovir is 500 mg orally twice daily for 5–10 days (Rossi, 2018). Valaciclovir is indicated for preventative therapy for genital herpes, at a recommended dose of 500 mg once daily orally or 1000 mg daily in patients with ten or more recurrences a year who experience breakthroughs with the lower dose (Emmert, 2000; Rossi, 2018). When taken to treat recurrent infections, it has been shown to be slightly more effective than aciclovir (Emmert, 2000). Treatment for recurrent infection in adults is 500 mg twice daily for 3 days, which has been shown to be equally effective to 500 mg twice daily for 5 days (Emmert, 2000; Rossi, 2018; Wald et al., 2002).

Valaciclovir may be used for the treatment and prevention of oral herpes labialis recurrent infection. The adult recommended dose for the treatment of an episode is 2000 mg orally twice a day for two doses in those with severe infection (patients who are HIV positive should take 1000 mg twice a day for 5–10 days) (Rossi, 2018). Valaciclovir has been studied as preventative treatment at a dose of 500 mg daily orally. One study looked at suppressive treatment in patients who had four or more recurrences in the previous year. Treatment for 16 weeks found that 60% of people taking valaciclovir did not have a recurrence during the study period compared to 38% of patients taking placebo. The median time until the first recurrence was 13.1 weeks with valaciclovir treatment compared to 9.6 weeks with placebo (Usatine and Tinitigan, 2010).

Valaciclovir is approved for the prevention of CMV infection in patients following organ transplant (Biron, 2006; Rossi, 2018). It has several advantages as a potential treatment option for this indication as it has low toxicity and good oral bioavailability (Ong et al., 2015). Valaciclovir is given orally at a dose of 2000 mg four times a day for 90 days (Rossi, 2018). One study looking at the use of valaciclovir in patients undergoing renal transplant found that treatment significantly reduced the risk of and delayed the onset of CMV infection compared to placebo. In addition, valaciclovir was also shown to reduce the risk of acute graft rejection (Ormrod et al., 2000). Other research has found that valaciclovir is more effective than oral aciclovir in preventing CMV antigenemia and has similar efficacy to ganciclovir in preventing CMV infection (Ong et al., 2015; Ormrod et al., 2000). High dose valaciclovir being used for a prolonged period of time has been linked with a potentially fatal thrombotic microangiopathy (TMA)-like syndrome when used in patients who are immunocompromised, with a higher risk appearing to be

linked to patients with advanced HIV disease. Close monitoring of symptoms suggesting TMA should be done if immunosuppressed patients are receiving prolonged treatment of high-dose valaciclovir (Ormrod et al., 2000).

The adverse effects of valaciclovir have been shown to be similar to those of aciclovir and are mostly mild. Nausea and headache were found to occur in more than 10% of patients in one study. Other side effects include vomiting, diarrhea, constipation, asthenia, dizziness, anorexia, abdominal pain, and dyspepsia. One study found severe headache occurred in one patient taking valaciclovir 1000 mg 3 times a day for 14 days for herpes zoster (Beutner et al., 1995).

Famciclovir

Famciclovir is the prodrug for penciclovir (De Clercq, 2000). It has been shown to be equally effective to aciclovir for the treatment of herpes simplex infections in patients who are immunocompromised and may be more effective than aciclovir in reducing pain and promoting more rapid healing when used for herpes zoster (De Clercq, 2000; Janniger, 2018). It has an oral bioavailability of 77%, and is quickly converted to its active form (Emmert, 2000). Famciclovir has a much longer intracellular half-life compared to aciclovir (10 times longer) (Emmert, 2000).

Famciclovir has a recommended dose of 250 mg 3 times a day for 5–10 days for treating an initial infection of genital herpes (Emmert, 2000; Rossi, 2018). Evidence suggests that famciclovir is as effective as aciclovir in the treatment of an initial genital herpes infection (Emmert, 2000). Famciclovir may be used as preventative therapy for genital herpes, at a recommended dose of 250 mg twice daily (Emmert, 2000). When taken to treat recurrent infections, it is slightly more effective than aciclovir (Emmert, 2000). Treatment regimes for recurrent infection for adults include 125 mg orally twice a day for 5 days or 500 mg initially, then 250 mg twice a day for three doses, or 1000 mg twice a day for one day (Emmert, 2000; Rossi, 2018).

Famciclovir is indicated for the treatment of recurrent oral herpes labialis infections. Famciclovir at a dose of 1500 mg as a single dose or 750 mg twice a day for one day when taken within 1 h of prodromal symptoms appearing have both been shown to be more effective than placebo in improving healing time, with no significant difference between the two dosing regimes (Usatine and Tinitigan, 2010).

Ganciclovir

While ganciclovir has been shown to be at least as effective as other guanine analogues for the management of herpes simplex viruses 1 and 2, it was developed mainly for the treatment of CMV and can be given either intravenously or orally (De Clercq, 2000). It is now considered the gold standard treatment of CMV in most situations and is first-line treatment for CMV infection in patients having undergone transplants (Biron, 2006). Ganciclovir is favored as optimal treatment for multiple CMV infections, including CMV pneumonitis and CMV encephalitis/myelitis (Tan, 2014). It is available as an intravenous formulation and should not be used intramuscularly or subcutaneously (Biron, 2006; Rossi, 2018). An advantage of ganciclovir as an intravenous treatment is that if multiple organs are involved it allows generalized treatment. It is also beneficial in patients with renal impairment as the dose can be tailored precisely as required, compared to "rounding" doses that is needed if an oral formulation is used (Tan, 2014).

Treatment or induction with ganciclovir is generally ganciclovir IV 5 mg/kg every 12 h, and the duration will depend on the indication. Treatment/induction for CMV retinitis or CMV pneumonitis will continue for 14–21 days, prevention of CMV will continue treatment for 7–14 days, and when used for CMV colitis in HIV/AIDS treatment will continue for 21–42 days. Maintenance treatment is ganciclovir IV 5 mg/kg daily or 6 mg/kg once a day for 5 days each week. When used to prevent CMV infection after transplant treatment will continue for up to 120 days or more following transplant. Ganciclovir should only be used in children on the advice of a pediatric infectious diseases physician (Rossi, 2018).

Resistance to ganciclovir is possible and occurs due to mutations in either UL97 or UL54 genes (Biron, 2006). Risk factors for resistance developing include a high virus load, prolonged treatment with ganciclovir, and the use of oral ganciclovir (Limaye, 2002). Drug-resistant CMV may be treated with combination treatment of ganciclovir and foscarnet (Tan, 2014). Adverse effects associated with ganciclovir include hematologic abnormalities (e.g., neutropenia, thrombocytopenia, and anemia), and can potentially cause reproductive toxicity in the long term (Biron, 2006). An oral formulation of ganciclovir was developed in an attempt to improve administration convenience; however, it has a low oral bioavailability (5%) meaning it is only suitable for maintenance (not induction) therapy. The oral formulation needs to be taken three times a day, and the potential for increasing resistance due to low bioavailability and subsequent viral suppression limits its convenience and usefulness. In practice, this formulation has now been replaced by valganciclovir (Biron, 2006). Ganciclovir is considered to be carcinogenic and should be handled cautiously using hazardous drug precautions (Rossi, 2018).

Valganciclovir

Valganciclovir is the prodrug of ganciclovir and is indicated for the treatment and prevention of CMV in patients receiving stem cell or solid organ transplants (Biron, 2006; Rossi, 2018). Mild infection in patients who are immunosuppressed can generally be treated with oral valganciclovir. It is also indicated for the treatment of CMV retinitis in patients with AIDS (Tan, 2014). It was developed in an attempt to improve oral bioavailability of ganciclovir. Valganciclovir is rapidly metabolized to ganciclovir after oral administration in the intestinal wall and liver, with an oral bioavailability of approximately 60% (Biron, 2006). Valganciclovir at a dose of 900 mg orally once a day provides ganciclovir exposure equal to that from intravenous ganciclovir at a dose of 5 mg/kg once daily and 1.7-fold greater than exposure from ganciclovir orally 1000 mg three times a day (Biron, 2006).

Research has supported the efficacy of valganciclovir as a treatment option, with one study finding that valganciclovir was not inferior to ganciclovir treatment of CMV retinitis in patients with AIDS (Tan, 2014). Other studies looking at the use of valganciclovir in patients who have undergone solid organ transplant has found it to be an effective treatment option (Tan, 2014). The recommended dose in adults for initial treatment of CMV retinitis is 900 mg orally twice a day for 14–21 days. Maintenance treatment is continued at 900 mg orally once daily, which is also the recommended dose for the prevention of CMV following a transplant (Rossi, 2018). Adverse effects are similar to those seen with the use of ganciclovir (Rossi, 2018).

Penciclovir

Penciclovir is indicated for oral herpes labialis. It is available as a 0.1% cream and should be applied when symptoms first appear every 2 h while awake for 4 days (Medscape, 2018a). One study compared penciclovir cream to placebo in healthy adults and found there was a marginal improvement in healing time in those using penciclovir (4.8 compared to 5.5 days) (Usatine and Tinitigan, 2010). Adverse effects include mild erythema, reaction at the application site and headache (Medscape, 2018a).

Antivirals for Hepatitis C

Traditionally treatment for hepatitis C revolved around pegylated interferon-alfa and oral ribavirin, however, due to its associated adverse effects, interferon-alfa is no longer recommended as a treatment. Ribavirin, however, may be used as part of combination treatment (Dhawan, 2018).

Direct-acting antivirals (DAAs) are an effective treatment option for hepatitis C (particularly genotype 1), with a cure rate of over 90% provided patients are adherent to therapy. They are also well tolerated, available as oral tablets and will have a treatment course of 12–24 weeks. These antivirals are often advantageous over traditional treatments for hepatitis C, which were associated with severe adverse effects and prolonged treatment courses (Dhawan, 2018; Khoo and Tse, 2016; NSW Government, 2016). Choice of treatment will depend on whether the disease is cirrhotic or noncirrhotic, and if the patient is treatment naïve or has had treatment previously (Khoo and Tse, 2016). Specialist review is required before initiating therapy in patients with current or prior decompensated cirrhosis (e.g., encephalopathy, previous variceal bleeding, refractory ascites) (Khoo and Tse, 2016).

Choice of treatment depends on a number of patient factors, including renal impairment (many DAAs are renally cleared) and potential drug–drug interactions (Khoo and Tse, 2016). Many treatment regimens have once daily dosing. Potential adverse effects include fatigue, headache, nausea, and insomnia; however, they are not common and are often mild. They rarely lead to ceasing treatment (Khoo and Tse, 2016). Reviewing treatment response occurs 12 weeks after finishing the treatment and is determined by assessing hepatitis C viral load by polymerase chain reaction. It is important that patients are aware that although serology may remain positive following successful treatment, this does not mean they are protected and reinfection may occur (Khoo and Tse, 2016).

A number of combination treatments are now available. These include ledispasvir/sofosbuvir; elbasvir/grazoprevir; obitasvir/paritaprevir/ritonavir/dasabuvir; ombitasvir/paritaprevir/ritonavir; sofosbuvir/velpatasvir (Dhawan, 2018).

Hepatitis C virus (HCV) protease inhibitors include asunaprevir, boceprevir, paritaprevir, and simeprivir. Boceprevir and telaprevir were the first protease inhibitors available; however, they have been superseded by antivirals with greater efficacy and better safety profiles. HCV protease inhibitors exert their effect by altering replication of the virus through inhibition of NS4/4A serine protease (Dhawan, 2018; Rossi, 2018).

- Asunaprevir is indicated for the treatment of chronic hepatitis C (genotype 1) in patients with compensated liver disease, including cirrhosis, in combination with daclatasvir. The recommended dose is 100 mg twice a day orally. Research has found this combination of treatment to be successful in reaching a sustained viral response. Common adverse effects associated with this combination treatment include headache, fatigue, diarrhea, nasopharyngitis, and nausea. It is recommended to avoid this combination treatment in pregnancy and breastfeeding, and adequate contraception should be ensured while it is being used. Asunaprevir is metabolized by CYP450 3A and is a moderate inhibitor of CYP2D6, so there is a potential for drug interactions (Anon, 2016a; Rossi, 2017).
- Boceprevir is indicated for the treatment of chronic hepatitic C genotype 1. It is one of the early protease inhibitors, and while effective, resistance was shown to develop early. It is indicated for use in combination with peginterferon-alfa and ribavirin, at an adult dose of 800 mg 3 times a day orally. Adverse effects associated with boceprevir include anemia and dyguesia (Kwo and Vinayek, 2011; Rossi, 2017; Rowe and Mutimer, 2011)
- Paritaprevir is used in combination with ritonavir, ombitasvir, and dasabuvir with or without ribavirin for the treatment of hepatitis C. The concentration of paritaprevir is increased when it is combined with ritonavir (which inhibits the metabolism of paritaprevir by CYP450 3A4), and this is the sole purpose of ritonavir in this combination as it has no impact on the hepatitis C virus. Paritaprevir is available in combination packs with ritonavir, ombitasvir, dasabuvir, and ribavirin. This treatment regimen is effective in treating genotype 1b infection and may also be used for genotype 1a infection if patients have not previously received treatment and do not have cirrhosis (although ribavirin will be needed in this case for optimal response). The combination treatment with five medications is an effective treatment option; however, caution is needed before recommending use to ensure drug interactions and contraindications are avoided (Anon, 2016b; Rossi, 2018).
- Simeprevir is indicated for hepatitis C genotypes 1 and 4 and is used in combination with perginterferon alfa and ribavirin. It may also be used in combination with sofosbuvir for genotype 1a (Dhawan, 2018). The adult dose is 150 mg orally once daily (Rossi, 2017).

Sofosbuvir is a HCV polymerase inhibitor and inhibits NS5B polymerase, which has a key role in the replication of the virus. It is indicated for the treatment of genotypes 1, 2, 3, and 4 as combination treatment. It may be used in patients with hepatocellular carcinoma and awaiting liver transplantation to prevent recurrence of infection (Dhawan, 2018).

HCV NS5A inhibitors include daclatasvir, ledipasvir, and ombitasvir. They work by inhibiting NS5A, which is important for viral RNA replication (Dhawan, 2018; Rossi, 2018).

- Daclatasvir is indicated for chronic hepatitis C genotypes 1 and 3 in combination with sofosbuvir. It may also be used in combination with ribavirin depending on the genotype and other patient factors, such as whether cirrhosis is present or post liver transplantation. The recommended dose for adults is 60 mg orally once a day, with dosage adjustment required if used in conjunction with strong CYP3A4 inhibitors or moderate CYP3A4 inducers (Dhawan, 2018; Rossi, 2018).
- Ledipasvir is used in combination with sofosbuvir as oral treatment for genotypes 1, 4, 5, or 6. Treatment is available as a combination tablet, with the recommended dose for adults being 1 tablet once a day (containing ledipasvir 90 mg and sofosbuvir 400 mg) (Dhawan, 2018; Rossi, 2018).
- Ombitasvir may be used in combination with paritaprevir and ritonavir for genotype 4 infection without cirrhosis. This combination may also be used with dasabuvir for genotype 2 infection (Dhawan, 2018).
- Elbasvir is a HCV NS5A inhibitor and is indicated to be used in combination with grazoprevir (a HCV NS3/4A protease inhibitor) for treating genotypes 1 and 4 infection, with or without ribavirin. Research has found that response to therapy was high in patients who had previous unsuccessful treatment with peginterferon/ribavirin, and that adding ribavirin to the combination treatment improved response. The most common side effects associated with this treatment were fatigue, headache, and nausea, with anemia also being a common adverse effective when ribavirin was also part of the treatment regimen. There is potential for drug interactions as both elbasvir and grazoprevir are partially metabolized by oxidation (mainly by CYP450 3A). Strong inducers of CYP3A are contraindicated for use in combination with elbasvir and grazoprevir. Elbasvir/grazoprevir is available as a tablet containing 50 mg elbasvir and 100 mg grazoprevir, and is taken at a recommended dose of 1 tablet daily (Anon, 2017; Dhawan, 2018).

Dasabuvir is a non-nucleoside NS5B RNA-dependent polymerase inhibitor that suppresses viral replication. It may be used in combination with ombitasvir/paritaprevir/ritonavir for genotype 1 infection and may also be used in patients with compensated cirrhosis or concurrent infection with HIV (Dhawan, 2018).

Other Antivirals

Ribavirin

Ribavirin is indicated for the treatment of hepatitis C and also respiratory syncytial virus (RSV). It is an antiviral nucleoside analogue (Dhawan, 2018; Rossi, 2018).

Ribavirin impairs RNA and DNA synthesis, which in turn inhibits viral replication. When used to treat hepatitis C infection, ribavirin has been shown to have an effect on the virus and/or the host and the host's immune response to the virus. Ribavirin treatment may lead to an early increase in mutation of the hepatitis C virus; however, this appears to be transient. When used as part of combination therapy for hepatitis C, the risk of mutation has not been shown to be increased. When used to treat RSV ribavirin has been shown to inhibit RSV particle release and RSV gene expression by epithelial cells in the airway that are infected and reduce IL-8 secretion, IL-8 mRNA expression, and nuclear factor-kappa B activation (Martin and Jensen, 2008; Rossi, 2018).

As monotherapy, it has little impact on the hepatitis C virus, however, is much more effective when used in combination with interferon-alfa. The recommended dose depends on which treatment it is used in combination with. When taken orally ribavirin has a rapid absorption, with time to reach maximum concentration being approximately 1.5 h, and has rapid distribution and prolonged elimination. Despite its extensive absorption, its absolute bioavailability is approximately 50%, which is likely due to first-pass metabolism. It takes approximately 4 weeks to reach steady state after multiple dosing and due to slow elimination the half-life after multiple dosing is approximately 298 h. Ribavirin is mainly cleared renally and often accumulates in patients with renal dysfunction. It is not cleared effectively with hemodialysis (Dhawan, 2018; Glue, 1999; Martin and Jensen, 2008; Rossi, 2018).

When taken orally, the most significant adverse effect of ribavirin is hemolytic anemia, which is commonly seen in patients taking interferon plus ribavirin for hepatitis C infection. Factors that can influence haemolysis include the amount of interferon used, platelet level prior to treatment and haptoglobin phenotype. Hemoglobin decrease has also been associated with lower creatinine clearance at baseline, higher baseline hemoglobin levels, and greater age. Reduced bone mineral density has also been seen with ribavirin use; however, there has been conflicting results. Other potential adverse effects include reticulocytosis, decreased CD4 cell count in people with HIV infection (which is reversible), insomnia, irritability, fatigue, dizziness, nausea, and sweating (Martin and Jensen, 2008; Rossi, 2018).

Peginterferon Alfa

Peginterferon alfa is indicated for the treatment of hepatitis B and C. The formulation of peginterferon alfa leads to a drug with better pharmacokinetics and a more convenient dosing schedule compared to conventional interferon alfa. Peginterferon alfa-2a is given as a subcutaneous dose of 180 μg once a week in adults for 48 weeks for chronic hepatitis B infection (Lau et al., 2005; Medscape, 2018c; Rossi, 2018).

Research has found that when used for the treatment of hepatitis Be antigen (HBeAg) positive chronic hepatitis B, peginterferon alfa-2a when given either as monotherapy or in combination with lamivudine was more effective than using lamivudine alone in leading to HBeAg seroconversion or hepatitis B DNA levels below 100,000 copies/mL (Lau et al., 2005). When used in patients with chronic hepatitis C and cirrhosis, peginterferon alfa-2a given at a dose of 180 μg once a week subcutaneously has been found to be an effective treatment dose (Heathcote et al., 2000).

Adverse effects associated with interferon alfa include pyrexia, fatigue, headache, myalgia, and psychiatric disorders such as depression (Lau et al., 2005; Rossi, 2018).

Prevention

Prevention strategies for viral infections will depend on the infection. Vaccines are available for a number of viral infections (e.g., HPV, varicella zoster, herpes zoster, influenza, hepatitis A and B). Other general prevention strategies include practicing good hygiene, such as using a condom if infections can be transmitted sexually, covering sores and cuts, avoid sharing eating and drinking utensils, discarding used tissues properly, washing hands regularly, covering mouth and nose when coughing or sneezing, and regularly cleaning and disinfecting surfaces that are touched.

Role of Pharmacists in Optimizing Antiviral Treatment

As medication experts, pharmacists have many opportunities to contribute to optimal management of viral infections and use of antiviral medicines. This includes education and counseling of patients to ensure treatment is taken correctly and only when required, referring patients for management by a medical practitioner where required, and optimizing the dosage and safety of antiviral medicines. The scope of pharmacists' involvement in the prevention and treatment of viral diseases will depend on their practice setting.

Role of Community Pharmacists in Managing Viral Presentations

Pharmacists working in primary care settings have numerous opportunities to be involved in managing and optimizing treatment of viral infections. This can range from counseling and education of the public, supplying antiviral medicines, and providing immunization services to prevent viral infections.

Upper respiratory tract infections (URTIs) are often viral in origin; however, despite this antibiotics are commonly prescribed for these infections (Zoorob et al., 2012). One study in England found that 41% of acute cough presentations, 82% of bronchitis cases, and 88% of rhinosinusitis presentations were prescribed an antibiotic (Pouwels et al., 2018). While various factors may contribute to this high rate of antibiotic prescribing, one Australian study found that the main reason for inappropriate prescribing was to meet patient expectations (Fletcher-Lartey et al., 2016). This highlights the important role that pharmacists can play in educating patients about treatment for URTIs such as influenza. Key points that pharmacists can highlight to patients with influenza include:

- Antibiotics do not treat viral infections, which is the cause of the many URTIs. Antibiotics can cause side effects and also increase the risk of resistance developing when used inappropriately. Do not expect that your doctor will prescribe you antibiotics.
- Treat the symptoms (e.g., paracetamol can be used to treat fever, headache, and aches and pains).
- Drink plenty of fluids to avoid dehydration.
- Rest until the infection has cleared, particularly if very unwell (Dolin, 2018).

Receiving the annual influenza vaccine is an important prevention strategy against influenza and associated complications. Pharmacists have a key role in educating patients on the benefits of the influenza vaccine, dispelling myths associated with the vaccine, and answering patient questions. In some countries, pharmacists can administer the influenza vaccine to patients, playing an additional crucial role in increasing vaccination rates against influenza. Research has reported that offering pharmacist-administered influenza vaccinations has increased the accessibility of immunization leading to higher uptake rates. A Canadian study reported that patients were satisfied with the service they received from pharmacists administering the vaccination, and 18% of patients had not received the influenza vaccine the previous year (Poulose et al., 2015). An Australian study also found high patient satisfaction with pharmacist-administered influenza vaccines (Burt et al., 2018).

Topical and oral antiviral medicines (e.g., famciclovir) for the treatment of cold sores are available without a prescription from pharmacists in certain countries. Having treatment available without a prescription increases the accessibility for the patient, particularly when treatment is recommended when symptoms first occur. Pharmacists have a responsibility to discuss with the patient their request to ensure that the supply is appropriate, provide education to the patient to ensure that the medicine is taken correctly, as well as provide general advice on the management of cold sores. Pharmacists must also ensure that the treatment is being used for the approved indication and not for other indications (e.g., genital herpes) (Cunningham et al., 2012). If the requested treatment is inappropriate, pharmacists should discuss with the patient what the particular medicine is indicated and approved for and provide advice on the most appropriate management of the presenting condition (e.g., referral to a medical practitioner for further review and management).

Patients will often seek advice of their pharmacist on symptoms they are experiencing, and pharmacists are in a position to provide recommendations on the most appropriate treatment or when the patient should see another health professional such as a medical practitioner. Pharmacists can play a key role in facilitating early review and treatment for particular viral infections (e.g., herpes zoster) to optimize management of the infection and reduce the risk of complications.

Role of Hospital Pharmacists in Managing Viral Presentations

Pharmacists working in acute care settings may be more likely to encounter different viral presentations compared to pharmacists working in primary care, and the focus of their role may be different. Nevertheless, pharmacists in this setting have a vital role in contributing to optimal use of antiviral medicines.

Management of hepatitis C carries with it a number of complexities, including identifying and managing potential drug–drug interactions, as well as managing adverse effects and providing patient education. Pharmacists, as medication experts, have a crucial role to play in this area. Pharmacists have a role to play in reviewing prescribed treatment to ensure dosing is correct and recommending any adjustments based on renal or hepatic function, identifying and managing potential drug–drug interactions (including potential interactions with nonprescription medicines), providing patient education and managing adverse effects that may arise. A study in the United States found that the pharmacist was a key member of the interdisciplinary team and played a crucial role in identifying and managing potential drug–drug interactions (Langness et al., 2017).

As ganciclovir is carcinogenic, it should be handled using hazardous drug precautions. Staff handling and administering ganciclovir may not be aware of this risk or the precautions needed when handling this medicine. Pharmacists can therefore play a key role in educating staff on the risks associated with handling ganciclovir, and hazardous drug precautions that should be taken (Rossi, 2018). These include

- Only staff appropriately trained should handle hazardous medications.
- Staff must use approved equipment and clothing when handling hazardous drugs.
- Drug must not come into contact with the skin, mucosal, or serosal areas when preparing or administering the drug.
- Skin contact, aerosolization of powder into the air, and cross-contamination with other medicines must be avoided, and strategies should be implemented to facilitate this.
- Staff must refer to local policies or guidelines available on safe handling of hazardous drugs (Rossi, 2018).

Ganciclovir is the active metabolite of valganciclovir; therefore, any adverse effect associated with ganciclovir can also be applied to valganciclovir. Valganciclovir tablets and oral solution should therefore also be handled with caution. The manufacturer recommends that the tablets should not be broken or crushed and that contact with skin or mucous membranes with broken or crushed tablets, powder, or solution should be avoided. Reconstitution of the solution should be done with caution, and inhalation avoided. It is also recommended to use gloves when reconstituting the solution and the outer surface of the bottle and cap and table should be wiped after reconstitution (Roche Products Limited, 2008; Roche Products Pty Limited, 2018). Pharmacists have a key role in ensuring safety of both themselves and other staff when handling these medicines.

Dosage adjustments of antiviral medicines may be required based on patient factors such as renal or hepatic function. Pharmacists have a key role to play in reviewing prescribed doses and making recommendations for dosage adjustments where required to support the quality use of medicines and optimize safety. In addition, monitoring of certain parameters (e.g., complete blood count, liver enzymes) may be required with the use of certain antiviral medicines. Pharmacists can provide education to other health professionals on the requirements of monitoring and the intervals for when this monitoring should occur and can follow-up on this to ensure required monitoring is being carried out (Jiang et al., 2014).

Monitoring for potential adverse effects is another key role pharmacists can play in optimizing the use of antiviral medicines. Pharmacists can play a key role in providing advice for when a presenting symptom may be due to an adverse effect and then make recommendations for how this can be managed. Pharmacists also play an essential role in providing education to patients about their medicines, which includes potential side effects that may be experienced and what to do if these occur. This role is relevant to pharmacists working in both community and hospital pharmacy settings (Olea et al., 2018).

Nutritional Anemias

Clare Wall*, Nicola Gillies†, *Department of Nutrition, University of Auckland, Auckland, New Zealand; †Liggins Institute, University of Auckland, Auckland, New Zealand

Learning Objectives

1. Describe the epidemiology and etiology of vitamin B_{12} and iron deficiency anemias.
2. Describe the clinical presentation and diagnosis of vitamin B_{12} and iron deficiency anemias.
3. Describe the pharmacological and nonpharmacological management and monitoring of vitamin B_{12} and iron deficiency anemias.
4. Describe the role of the pharmacist in the health-care team's management and monitoring of vitamin B_{12} and iron deficiency anemias.
5. Describe the pharmacist's role in the interprofessional team with respect to the management of vitamin B_{12} and iron deficiency anemias.

Take Home Messages

- Anemia is a common condition, affecting around one-third of the population globally. Iron and vitamin B_{12} deficiencies are two causes of "nutritional anemias," and iron deficiency is the most frequent cause of anemia worldwide.
- The clinical signs and symptoms of iron and vitamin B_{12} deficiency and related anemias are not specific, and laboratory investigations are required to confirm a diagnosis. Once a diagnosis is made, it is critical to establish the underlying cause of iron or vitamin B_{12} deficiency, as this determines the therapeutic strategy. Close monitoring of patients undergoing treatment is critical to ensure that the correct diagnosis is made, and lifelong therapy is required for some patients.
- Oral iron therapy is the most common strategy to correct iron deficiency anemia; however, parental therapy is indicated in some cases. Intramuscular hydroxycobalamin infusion is the most frequently used therapeutic strategy to correct patients with clinical vitamin B_{12} deficiency; however, the use of high-dose oral supplementation is increasing. Ensuring dietary adequacy of iron and vitamin B_{12} is an important measure to prevent recurrent deficiency for patients without severe malabsorptive causes of deficiency.
- Pharmacists have an important role to play in the inter-professional team in the management of patients presenting with iron and vitamin B_{12} deficiencies, ranging from subclinical deficiency to anemia. They are an important first contact for patients with mild deficiencies to ensure that they undergo appropriate hematological investigations to obtain a correct diagnosis before supplementation begins. Compliance with therapy and interactions with supplementation can be a challenge, particularly with oral iron therapies, and pharmacists have the potential to significantly improve therapeutic outcomes through adequate patient counseling with respect to management of side effects and maximizing absorption.

Introduction to Anemia

Anemia is a condition where either the number of red blood cells or their oxygen-carrying capacity is inadequate to meet an individual's physiologic needs. The term "nutritional anemia" was first defined in a 1968 World Health Organization technical report as "a condition in which the hemoglobin content of the blood is lower than normal as a result of a deficiency of one or more essential nutrients, regardless of the cause of such deficiency" (WHO Scientific Group, 1968).

Anemia was estimated to account for 9% of the total global disability burden from all conditions in 2010 (FAO, 2017), and affected approximately 27% of the world's population in 2013 (Kassebaum et al., 2016). Population groups most vulnerable to anemia include infants and young children, adolescents, and women of reproductive years. The burden of anemia comes with a range of consequences that vary at different life stages—in children anemia is associated with poor cognitive outcomes, or with poor birth outcomes in pregnancy such as low birth weight, prematurity, as well as maternal and perinatal mortality (Balarajan et al., 2011). More importantly, the consequences of anemia are not limited to the individual, but have wide-reaching societal and economic impacts across low-, middle-, and high-income countries.

Globally, the top three causes of anemia are considered to be iron deficiency, hemoglobinopathies, and malaria, with iron deficiency as the leading cause (Kassebaum et al., 2016). Although this chapter will be focusing on 'nutritional anemias' it is important to recognize that there are a range of causes and classifications within the wider context of anemias.

Chapter Focus

This chapter will focus on iron and vitamin B_{12}, which are two micronutrients that contribute to distinct forms of anemia. Iron is an essential component of hemoglobin, myoglobin, and cytochromes and is required for the oxygen transport and cellular respiration (Anderson and McLaren, 2012). Vitamin B_{12} plays a central role in the folate/methionine cycle and DNA synthesis, and is therefore required for erythropoiesis (Moll and Davis, 2017; Reynolds, 2006).

The remainder of this chapter will outline the epidemiology, etiology, diagnosis, management, and future projections of nutritional anemias relating to iron and vitamin B_{12} deficiencies.

Anemia Epidemiology

The global prevalence of anemia was estimated to be 27% in 2013 (Kassebaum et al., 2016), and iron deficiency remains the most common cause (Kassebaum et al., 2016). However, it is important to note that the data regarding the epidemiology of anemia are relatively unreliable, as it is often ascribed to iron deficiency regardless of its true cause.

Globally, the most vulnerable population group is children aged 0–5 years, followed by adolescence, women (particularly during pregnancy), and older adults (de Benoist et al., 2008; Stevens et al., 2013; WHO, 2017). This reflects the fact that each of these groups experiences a greater physiologic demand for iron, and is therefore more susceptible to deficiency. Childhood and adolescence are periods of rapid growth and development with elevated demands for iron, as is pregnancy to meet the needs of the fetus, placenta, and expanded maternal blood volume (Stevens et al., 2013). Women of reproductive years are particularly vulnerable to deficiency secondary to menstruation, which is compounded by the fact that diets are typically low in bioavailable iron in women across many low- and middle-income countries (Torheim et al., 2010). The elderly are also considered to be an at risk group, and although the prevalence and etiology of anemia among this group has not been well characterized (WHO, 2017), this is projected to become a substantial burden in the future due to the increasing proportion of older adults in the population (Patel and Guralnik, 2007).

Etiology of Nutritional Anemias

Nutritional anemias result when the intake of certain nutrients is inadequate to meet the demands for red blood cell and hemoglobin (Hb) synthesis (Balarajan et al., 2011). Deficiency of iron and vitamin B_{12} both contribute to the development of anemia due to their distinct roles in erythropoiesis, though there are easily distinguishable changes that occur to the shape, size, and color of the red blood cells in the case of either deficiency. Microcytic anemia occurs with iron deficiency, where the red blood cells are smaller with a reduced hemoglobin content, while megaloblastic anemia occurs in the case of vitamin B_{12} deficiencies where red blood cells are enlarged (WHO, 2017). However, anemia is a late stage of these micronutrient deficiencies and there are sequential changes in status that occur before a diagnosis of anemia is made, and not all deficiency states will reach anemia, yet may require pharmacological intervention (WHO, 2017).

Iron Deficiency

The etiology of iron deficiency anemia (IDA) is multifaceted and depends on an individual's age, medical condition, comorbidities, and concomitant therapies. Common examples of factors involved in the etiology of iron deficiency and IDA are outlined in **Table 1** (Lopez et al., 2016).

Table 1 Factors contributing to the development of iron deficiency and iron deficiency anemia

Cause	*Example*	*Comment*
Inadequate dietary intake	• Vegetarian or vegan diets • Complementary foods in infancy	This is rarely the sole cause of iron deficiency anemia
Blood loss	• Digestive tract: colonic and gastric carcinoma, inflammatory bowel disease • Parasites (hookworm, malaria) • Ulcers • Surgery • Hemodialysis • Nonsteroidal anti-inflammatory drugs	
Malabsorption	• Celiac disease • Gastrectomy • *Helicobacter pylori* • Gut resection, bypass gastric surgery • Atrophic gastritis or bacterial overgrowth • Proton-pump inhibitors, H2 antagonists, achlorhydria • Interaction with nutrient components	
Association with anemia of chronic disease	• Chronic heart failure • Cancer • Chronic kidney disease • Rheumatoid arthritis • Obesity • Inflammatory bowel disease	
Genetic disorders	• Iron-refractory iron deficiency anemia	

Table 2 Factors contributing to vitamin B_{12} deficiency

Cause	*Example*	*Comment*
Inadequate dietary intake	• Vegan diets or diets relatively low in animal-based foods (meat, poultry, seafood, dairy, eggs)	Maternal diets that are strictly vegetarian or vegan during pregnancy or lactation can lead to inadequacy in infants. Most common cause of subclinical deficiency
Food-bound cobalamin malabsorption	• Gastric resection • Proton pump inhibitor use • Persistent infection with *Helicobacter pylori*	This occurs when there is a release of cobalamin from its binding proteins in food and occurs in states of gastric dysfunction or reduced gastric acid secretion
Malabsorption	• Pernicious anemia (loss of intrinsic factor) • Ileal resection • Gastric resection • Chron's disease • Celiac disease • Metformin • Oral contraceptive pill	Factors that may lead to clinical deficiency and anemia
Infection	• *Helicobacter pylori* • *Giardia lamblia*	
Inherited disorders	• Imerslund- Gräsbeck syndrome • Hereditary intrinsic factor deficiency • Transcobalamin deficiency	

Table 3 Major distinctions between clinical and subclinical vitamin B_{12} deficiency

	Clinical deficiency	*Subclinical deficiency*
Phenotype	Clinical disease Biochemical changes[a]	No clinical findings Biochemical changes[a]
Role of malabsorption	Major causative role	Mild or no role
Prognosis and cause	Usually progressive	Usually static or fluctuating Rarely progresses to clinical deficiency
Need for therapy	Mandatory	Unknown
Prevalence	Very low (<0.1% in adults, 1%–2% in elderly)	Higher than clinical deficiency

[a]Elevated methylmalonic acid and homocysteine can be significant in clinical deficiency, but mild elevations may also occur in subclinical deficiencies.

Vitamin B_{12} Deficiency

As with IDA there are a number of factors contributing to the development of vitamin B_{12} deficiency and associated anemia, with major causes and examples outlined in **Table 2** (Carmel, 1995, 2000, 2013).

It is important to distinguish subclinical vitamin B_{12} deficiency from clinical deficiency, as these are two distinct conditions, as summarized in **Table 3** (Carmel, 2013). Vitamin B_{12} turnover is very small, and as depletion is rare, transiently poor intake or changes in absorption does not have a clinically relevant impact on body stores. Clinical deficiency however results from more significant depletion of body stores, such as in the case of failed cobalamin internalization with pernicious anemia, and has the potential to progress to megaloblastic anemia (Carmel, 2013).

Clinical Presentation of Nutritional Anemias

Iron Deficiency

Patients with IDA may present with symptoms associated with a range of anemias, only some of which are associated with specific signs of iron deficiency. Clinical features depend on the severity of deficiency, the patient's age, comorbidities, and speed of onset, and some patients may even remain asymptomatic (Lopez et al., 2016).

As Hb concentration falls, oxygen-carrying capacity is compromised, resulting in the classic symptoms of anemia—fatigue, shortness of breath, and diminished work capacity (WHO, 2017). Other symptoms that result from hypoxic functioning include exertional dyspnea, vertigo, headaches, tachycardia, and a cardiac systolic flow murmur. In more severe cases, patients may present with dyspnea at rest, angina pectoris, and hemodynamic instability (Moll and Davis, 2017). Symptoms ranging from common through to rare IDA are summarized in **Table 4**.

Table 4 Clinical presentation of iron deficiency anemia

Very frequent	*Frequent*	*Rare*
Pallor of the skin, conjunctivae, and nail beds	Dry and rough/damaged skin or hair, alopecia	Hemodynamic instability
Fatigue	Atrophic glossitis (inflammation of the tongue)	Syncope (fainting)
Dyspnea (shortness of breath)	Restless leg syndrome	Koilonchydia (spoon-shaped fingernails)
Headaches	Cardiac murmur	Plummer-Vinson syndrome (esophageal webs)
Angular stomitis	Tachycardia	Pica (urge to consume nonnutritive items, e.g., dirt, starch, raw pasta)
Chelitis (inflammation and small cracks in the corners of the mouth)	Neurocognitive dysfunction	
Reduced work capacity	Angina pectoris	
	Vertigo	

Vitamin B_{12} Deficiency

As with IDA, patients with macrocytic anemia due to vitamin B_{12} deficiency will present with general symptoms of anemia such as fatigue. However, the defining feature of clinical vitamin B_{12} deficiency is unexplained neuropsychiatric symptoms, which tend to be myelopathic or neuropathic in nature (e.g., numbness and tingling in the hands and feet). Additional symptoms of vitamin B_{12} deficiency might include poor memory, confusion, depression, and difficulty in maintaining balance. In pediatric cases, signs of a vitamin B_{12} deficiency include failure to thrive, developmental delays, and impaired movement. However, as with iron deficiency, many of these symptoms are not specific and may result from a number of medical conditions besides vitamin B_{12} deficiency (Carmel, 2013).

Diagnosis of Nutritional Anemias

A diagnosis of anemia is made when Hb concentrations fall below established cutoff values, which are summarized in **Table 5**. It is important to note that although the World Health Organization recommends these guidelines, the values used still vary across laboratories and countries. Other blood measures that may be used for diagnostic purposes include hematocrit, mean cell volume, blood reticulocyte count, blood film analysis, or Hb electrophoresis, though these are less frequently used (World Health Organization, 2011).

Iron Deficiency

To confirm that the anemia is caused by iron deficiency, additional measures of iron status are required. The hematological tests used in the diagnosis of iron deficiency and IDA are summarized in **Table 6** (Goddard et al., 2011; Pasricha et al., 2010; World Health Organization, 2001).

Summary of the Diagnosis of Iron Deficiency Anemia

The World Health Organization recommends the use of Hb in combination with serum ferritin for the diagnosis of iron deficiency and IDA (World Health Organization, 2004). Typically, investigations will include a complete blood count, reticulocyte count, and serum iron indices, and the underlying cause should be established in all patients during diagnosis. **Fig. 1** summarizes the steps involved in the investigation and management of IDA.

Table 5 Recommended hemoglobin (g/L) cutoff values for the diagnosis of anemia

	Anemia			
Population group, age	*No anemia*	*Mild*	*Moderate*	*Severe*
Children, 6-–59 months	≥110	100–109	70–99	<70
Children, 5–11 years	≥115	110–114	80–109	<80
Children, 12–14 years	≥120	110–119	80–109	<80
Nonpregnant women, 15 years and older	≥120	110–119	80–109	<80
Pregnant women	≥110	100–109	70–99	<70
Men, 15 years and older	≥130	110–129	80–109	<80

Table 6 Summary of laboratory tests used to confirm iron deficiency anemia

Test	*Cutoff value*	*Rationale and advantages*	*Disadvantages*
Serum ferritin	<12–15 μg/L Thresholds of 100 μg/L have been suggested for chronic kidney disease or 200 μg/L for patients undergoing dialysis	• Measures total iron body stores • Most powerful test for iron deficiency • Highly sensitive	• Affected by inflammation and liver disease • Investigations should also include C-reactive protein
Serum soluble transferrin receptor	N/A	• A measure of the intensity of erythropoiesis and demand for iron • Useful to differentiate IDA from anemia of chronic disease • Not affected by inflammation	• Lacks standardization • Not routinely conducted
Transferrin saturation	<16% <20% in the presence of inflammation	• Inexpensive • Well established	• Low specificity • Wide diurnal variation
Mean cell volume	<80 fL	• Widely available	• Microcytosis can also occur in other causes of anemia (e.g., thalassemia) • May be normal at early stages of iron deficiency anemia

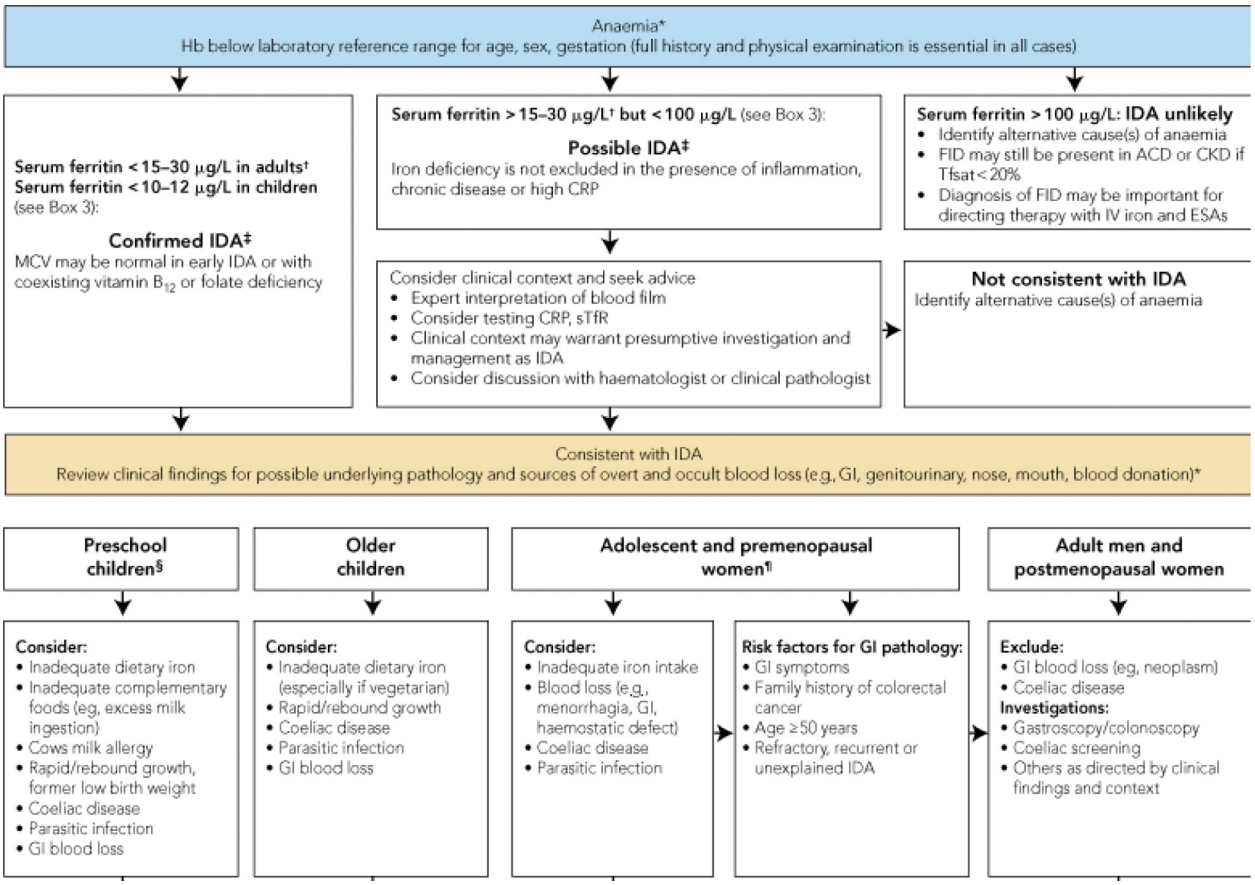

Figure 1 Summary of the tests used to investigate and confirm iron deficiency anemia. *Source: Figure reproduced from Pasricha et al. (2010).*

Table 7 Summary of laboratory tests for the investigation of vitamin B_{12} deficiency

Test	*Finding*	*Notes*
Full blood count	• Characteristic finding of clinical deficiency is macrocytic anemia	• Macrocytosis and anemia will not always be present in individuals with clinical deficiency • Leucopenia and thrombocytopenia may also be present
Blood film	• Hypersegmented neutrophils (defined as >5% of neutrophils with 5 or more lobes) • Oval macrocytes	• Not sensitive or specific in early cobalamin deficiency (Westerman et al., 1999)
Mean cell volume	• Elevated	• Not a specific indicator of vitamin B_{12} deficiency. Other causes should be excluded (e.g., alcohol excess or drugs) (Galloway and Hamilton, 2007). • Neurological impairment can occur in individuals presenting with normal values, and the absence of an elevated mean cell volume should not exclude further cobalamin testing (Healton et al., 1991).
Anti-intrinsic factor antibody Note that all patients suspected of pernicious anemia should be tested.	• Positive	• Identifies patients requiring lifelong cobalamin replacement. • Can be helpful in identifying the cause for those with an unclear cause of deficiency

Vitamin B_{12} Deficiency

As with IDA, further investigation is required to diagnose vitamin B_{12} deficiency. **Table 7** summarizes the hematological tests used for the initial investigation of vitamin B_{12} deficiency (Carmel, 2000; Carmel and Sarrai, 2006; Devalia et al., 2014).

A summary of laboratory tests used to confirm a diagnosis of vitamin B_{12} deficiency are summarized in **Table 8** (Devalia et al., 2014; Heil et al., 2012; Hvas and Nexo, 2006; Hvas et al., 2001). It is important to note that there is no gold standard test available, and each test has its own advantages and disadvantages, as outlined in **Table 8**.

Table 8 Summary of laboratory tests used to diagnose vitamin B_{12} deficiency

Test	*Cutoff value Clinical deficiency*	*Advantage Subclinical deficiency*	*Disadvantage*	
Serum total vitamin B_{12}	<150 ρmol/L in adults	Not defined	• Easily accessible • Cheap	• Does not reflect cellular status • Functional cobalamin deficiency can occur with normal serum concentrations • Falsely low results during pregnancy and folate deficiency • Variation in reference ranges • Sensitivity and specificity uncertain
Plasma homocysteine	>15 μmol/L		• High sensitivity • Functional marker of deficiency	• Poor specificity (also elevated with folate and vitamin B_6 deficiency, and with renal impairment) • Influenced by lifestyle factors (smoking, alcohol intake, coffee consumption) • Special procedure for sample handing is required • Limited value when used alone.
Plasma methylmalonic acid	Between 0.27 and 0.75 μmol/L in adults	Not defined	• Functional marker of deficiency • High sensitivity	• Concentrations also elevated with renal impairment and small bowel bacterial overgrowth. • Greater specificity than homocysteine, but specificity is still debatable. • Not easily accessible • Expensive
Plasma holo-transcobalamin	<32 ρmol/L has been suggested		• The active fraction of total cobalamin • Expected to have high sensitivity	• Further research required to evaluate its clinical utility • Specificity not yet known.

Summary of the Diagnosis of Vitamin B_{12} Deficiency

Suboptimal vitamin B_{12} levels may occur with nonspecific symptoms and no anemia, while patients with classical clinical features of deficiency may have serum cobalamin levels that lie within a normal range. A range of laboratory tests should be used to determine an underlying functional or biochemical deficiency (Devalia et al., 2014). Total serum B_{12} is the most practical and least expensive measure at a population-level, while methylmalonic acid and homocysteine assays offer greater sensitivity this is offset by being more expensive. It is also important to note that universally accepted cutoffs to define deficiency are lacking other than for serum total vitamin B_{12}. Folate status should also be measured in individuals with suspected deficiency given the close interrelationship between their metabolism.

Of note, it has been suggested that early diagnosis may not be worth the risk of over-diagnosing subclinical deficiency, particularly as this is likely to remain metabolically and clinically stationary for a number of years, and treatment benefits are not yet clear (Carmel and Sarrai, 2006).

Management of Iron Deficiency Anemia

As with the diagnosis of IDA, clear clinical practice guidelines for its treatment are still unavailable. Historically, the guidelines for treatment of iron deficiency have been based on perceptions of safety and efficacy, rather than on evidence-based research.

Pharmacological Management

Oral Therapy

Oral iron therapy remains the preferred therapy for the treatment of iron deficiency as opposed to intravenous infusion as it is safe, generally adequate for most patients, cost-effective, relatively well-tolerated, and associated with less burden for the patient and health-care provider.

Oral iron therapy preparations

The two main forms of supplemental iron available are ferrous and ferric preparations. Ferrous iron salts are the most efficiently absorbed form, and there are a number of preparations available, including ferrous fumarate, ferrous sulfate, and ferrous gluconate. Although ferrous fumarate has the greatest absorption, ferrous sulfate and ferrous gluconate are the preferred oral preparations, and both are relatively inexpensive with good bioavailability (Goddard et al., 2011; Lopez et al., 2016; New Zealand Formulary, 2018).

Ferric bisglycinate is the only ferric preparation available. It is an enteric-coated, delayed-release supplement that is generally well-tolerated with fewer gastrointestinal complaints than the ferrous solutions. However, ferric bisglycinate is not often recommended due to significantly lower absorption than ferrous iron salts. For infants and young children, oral therapies are also available in drop, syrup, or bead form to facilitate ease of supplementation and dose titration (New Zealand Formulary, 2018).

Additional over-the-counter preparations include polysaccharide iron complexes, ferric citrate, ferrous ascorbate, ferrous succinate, carbonyl iron, and heme iron polypeptide. These do not differ significantly in their effectiveness or side effects and all are relatively inexpensive and widely available (Auerbach and Adamson, 2016).

Dose of oral iron therapy

The dose of elemental iron used to treat IDA depends on the patient's age, estimated severity of deficiency, and the urgency with which it needs to be corrected. Generally, the recommended dose in adults is 100–200 mg/day for three months (Auerbach and Adamson, 2016; Schrier and Auerbach, 2018), and for children is 3 mg/kg of body weight per day (up to 60 mg/day). This is most easily achieved for children with the use of ferrous sulfate liquid (elemental iron of 6 mg/mL) at doses of 0.3–0.45 mL/kg/day. This may be increased to an initial dose of 0.9 mL/kg/day split into 2–3 doses per day in cases of severe deficiency (Melbourne TRCH, in press; New Zealand Formulary, 2018). After the deficiency state has been corrected, oral iron should be continued for three months to ensure that stores are adequately replenished (New Zealand Formulary, 2018).

For individuals with reduced iron stores but have not yet developed IDA, the approach to therapy should be individualized according to their etiology and severity of deficiency. It has been recommended to replace iron stores in these patients as it is likely to improve symptoms they may be experiencing, and failure to treat is likely to lead to the development of IDA (Schrier and Auerbach, 2018).

Intravenous Therapy

Historically, replacement strategies have been used with caution due to their risk for fatal anaphylactic reaction. However, this risk is now exceedingly low with the wide removal of high-molecular-weight iron dextran from the market. It is important to note that although the key advantage of intravenous therapy is the rapid replacement of iron, the rate at which Hb increases does not actually differ between intravenous and oral iron (Auerbach et al., 2008).

Indication for Intravenous Therapy

In adult and pediatric cases where oral supplementation is not tolerated or effective, iron may be replaced through intravenous infusion. The main indications for parental iron therapy include the following:

1. Malabsorption secondary to anatomic or physiologic conditions (e.g., gastric resection, atrophic gastritis, or celiac disease);
2. Intolerance to gastrointestinal side effects of oral therapy;
3. Ongoing blood loss that exceeds the capacity of oral iron;
4. Coexisting inflammatory states that interfere with regular iron homeostasis (Lopez et al., 2016; Maslovsky, 2005).
   Note that intravenous therapy is not recommended for pregnant women (especially in the first trimester), as evidence is lacking to support its safety and use during pregnancy and should be used cautiously in people with an immune or inflammatory condition (e.g., asthma or rheumatoid arthritis) as they may have a higher risk of allergic reaction (Agency, 2013).

Intravenous Preparations and Dose

There are number of standard iron preparations available for use, including iron sucrose, sodium ferric gluconate, ferric carboxymaltose, iron isomaltoside, ferumoxytol, and low-molecular-weight iron dextran (Lopez et al., 2016), though the availability of each does vary between countries. These are equally effective in treating iron deficiency, and the major differences between the preparations include cost, formulary and purchasing agreements, and the number of visits required to administer a full dose (Auerbach and Deloughery, 2016).

Iron carboxymaltose is the preferred preparation in most settings, as it can deliver up to 1000 mg of iron in 15 min and has an excellent safety profile (Baird-Gunning and Bromley, 2016). However, if a larger dose of iron is required in a single sitting, iron polymaltose may be the preferred preparation, though this may take up to 5 h for complete infusion of up to 2500 mg (Baird-Gunning and Bromley, 2016).

The dose of iron administered depends on whether the goal is to treat anemia or to fully replace iron stores. The dose is generally calculated using the Ganzoni formula, which is based on the patient's body weight, current and target Hb level, and iron stores. A fixed dose of approximately 1000 mg is often sufficient to treat anemia and provide additional storage iron, while not causing iron overload (Schrier and Auerbach, 2018). Iron infusions are typically carried out in secondary care; however, some general practice clinics have started to offer this treatment to patients. During the infusion, patients must be closely monitored to observe for any adverse effects that may develop particularly allergic reaction.

Summary of Pharmaceutical Management of Iron Deficiency

Oral supplements have a benefit over parenteral therapies for a number of reasons and are generally the preferred choice because they are cost-effective, eliminate the potential for infusion reactions, and they are the only form of iron supplementation available to patients from resource-poor settings. However, parenteral therapies are appropriate in certain cases, such as for patients who are unable to tolerate gastrointestinal side effects of oral therapy, those with severe or ongoing blood loss, and those with severely impaired absorption.

Nonpharmacological Management

Dietary Intervention

Indication for Dietary Intervention

In cases of mild deficiency (please refer to **Table 5** for definitions), dietary intervention should be considered before pharmacological strategies are required. While increasing dietary intake alone will not be adequate to treat IDA, increasing iron consumption and optimizing its absorption are valuable strategies in the secondary prevention of iron deficiency once iron levels are restored.

Bioavailability of Dietary Iron

The two forms of dietary iron are heme and non-heme. In the heme form, iron is complexed as ferrous iron (Fe^{2+}) in Hb, this is present in animal-based foods, including meat, poultry, and seafood. In the non-heme form, iron is complexed as ferric iron (Fe^{3+}), and this is present in plant-based foods, such as vegetables, cereals, cacao, and dried fruit, as well as in fortified foods (Food and Nutrition Board, 2001). Neither form has particularly high bioavailability, though heme iron is relatively greater with estimates of 12%–25% compared to <5% bioavailability of non-heme iron (Food and Nutrition Board, 2001).

Including sources of heme iron should be encouraged given its more efficient absorption; however, there are techniques that can improve the absorptive capacity of non-heme iron as summarized in **Table 9**. It can be challenging to avoid all foods containing polyphenos, phytates, and oxalates, though it has been suggested that this can be countered by including a source of ascorbic acid with the meal. However, with easily isolated nutrient components (e.g., tea or coffee), it is best to leave a space of 1–2 h between these and a meal rich in dietary non-haem iron (Hurrell and Egli, 2010). When appropriate, dietary advice should be sought for how this can be managed effectively without compromising overall dietary adequacy (Hurrell and Egli, 2010).

Table 9 Factors influencing non-haem iron absorption

Factor	*Effect*	*Examples/recommendations*
Ascorbic acid	Positive	• Citrus fruits (e.g., glass of orange juice) • Dark green leafy vegetables • Bell peppers • Strawberries • Kiwifruit Ascorbic acid supplements
Meat, fish, and poultry	Positive	
Phytates	Negative	• Whole grains • Cereals • Soy • Nuts • Legumes
Oxalates	Negative	• Spinach and other leafy greens • Nuts • Grains • Legumes
Calcium	Negative	• Dairy products • Calcium supplements
Polyphenols	Negative	• Vegetables and fruit • Cereals • Legumes • Tea • Coffee • Wine

Infants

Breast milk contains highly bioavailable iron, but this is not in sufficient amounts to meet the needs of infants older than 4–6 months (Baker and Greer FR, 2010). For this reason, some guidelines suggest that infants who are exclusively or primarily breastfed from the age of 4 months onward are given prophylactic daily iron supplements (1 mg/kg) until they begin to eat iron-containing complementary foods, such as iron-fortified cereals or pureed meats (Baker and Greer FR, 2010). As infants and younger children have a lower overall dietary intake, meeting iron requirements from natural food sources alone is challenging, and food-based strategies should also include the consumption of fortified foods (Baker and Greer FR, 2010).

Blood Transfusion

A universally accepted threshold for transfusing red blood cells in patients with IDA is unavailable. Guidelines sometimes specify certain Hb values as an indication to transfuse; however, the patient's clinical condition and symptoms should be an essential part of making this decision (Murphy et al., 2001). There are a number of adverse outcomes associated with transfusion, such as fluid overload, and a range of immunological and infectious events. Accordingly, blood transfusions are not recommended to correct iron deficiency unless the individual has severe IDA that compromises end-organ function, such as cardiac failure, or where IDA is complicated by severe, acute ongoing bleeding (Pasricha et al., 2010). Transfusion has been indicated for pregnant women with Hb levels below 6 g/dL due to the risk of impaired fetal oxygenation, which can result in low amniotic fluid volumes, fetal cerebral vasodilation, and fetal death (Acog, 2008). The goal of blood transfusion is to restore Hb to a safe, but not necessarily normal range (BPACNZ, 2013).

Management of Vitamin B_{12} Deficiency Anemia

Pharmacological Management of Vitamin B_{12} Deficiency

For patients presenting with classical megaloblastic anemia, there is a clear treatment pathway, while patients with low vitamin B_{12} concentrations of unknown significance pose a challenge for treatment. Management of these patients is based on clinical judgment, as the benefits of replacing vitamin B_{12} in those with subclinical deficiency remain unknown.

Intramuscular Injection

Standard clinical practice for the treatment of vitamin B_{12} deficiency in many countries is intramuscular replacement with hydroxocobalamin at a dose of 1 mg. This is administered three times per week for 2 weeks, or every second day for those patients with

neurological involvement until no further improvement is seen. Thereafter, maintenance intramuscular replacement is given either 3-monthly for life for those with cobalamin malabsorption secondary to failure of intrinsic factor, or 2-monthly for patients with neurological involvement (Devalia et al., 2014).

Hydroxocobalamin is preferred over cyanocobalamin as it is retained in the body for longer and can therefore be administered less frequently. It is generally well-tolerated, though some side-effects may be experienced including itching, chills, fever or hot flushes, exanthema, nausea, and dizziness (Carmel and Sarrai, 2006).

Oral Therapy

High-dose oral cyanocobalamin (1000–2000 mg dose) is available for use in several countries, and also widely available on the Internet. Although only a small fraction of a large dose is absorbed via passive, intrinsic factor-mediated absorption, this is adequate to meet requirements for most individuals. It has been suggested that this strategy is as effective as intramuscular injections and have the additional benefits of fewer visits to medical centers, which can relieve health-care costs and reduced discomfort that is associated with injections (Vidal-Alaball et al., 2005). However, oral cyanocobalamin is contraindicated in individuals with poor absorptive capacity, particularly in those with pernicious anemia.

Lower dose oral cyanocobalamin (50 μg dose) is also widely available and can improve serum B_{12} and biochemical markers in borderline cases, and the role of this treatment in those with subclinical deficiency is under active research. Careful consideration should be taken if low dose supplements are prescribed, as this strategy risks suboptimal treatment of latent and emerging pernicious anemia, and possible inadequate treatment of neurological symptoms (Devalia et al., 2014).

Nonpharmacological Management

As with iron deficiency, the long-term strategy recommended for the control of vitamin B_{12} deficiency is the consumption of a diet that meets recommendations.

However, dietary intervention to correct vitamin B_{12} deficiency is more limited than in the case of iron, as vitamin B_{12} is predominantly found in animal-based foods, including shellfish, red meats, fish, poultry, dairy products, and eggs, though it can also be found in some fortified plant-based products, such as fortified nutritional yeast, breakfast cereals, or non-dairy milks (Institute of Medicine, 1998). Individuals following vegetarian or vegan diets may have difficulties in obtaining adequate vitamin B_{12} through diet alone, and those on a vegan diet in particular should be recommended to consider pharmacological intervention. There are some claims of adequate vegan alternatives to fortified foods or supplements, such as algae (e.g., spirulina, nori, or chlorella), mushrooms, or barley grass. However, the concentrations are either inadequate to meet an individual's requirements (mushrooms) or are vitamin B_{12} analogs (algae). Only chlorella and nori contain true vitamin $B_{12,}$ though the content is largely dependent on the growing conditions of the microorganisms, and is not considered an adequate source of plant-based dietary vitamin B_{12} (Watanabe et al., 2014). Those with severe malabsorption as the underlying cause of deficiency will also require supplementation, as diet alone will not be sufficient to meet their physiologic requirements.

Summary of Vitamin B_{12} Management

High-dose oral and intramuscular injection routes appear to be equally effective in the replacement of vitamin B_{12} in those with adequate absorptive capacity. Intramuscular injection with hydroxocobalamin remains the preferred choice, but moving to oral supplementation in the future may have additional benefits in terms of cost and comfort. A treatment pathway for patients presenting with borderline deficiency or unclear clinical symptoms remains a challenge for health professionals, and clinical guidelines are unavailable.

Monitoring and Measuring of Iron and Vitamin B_{12} Deficiency

Any treatment prescribed for the correction of iron or vitamin B_{12} deficiency should also include a strategy for measuring an individual's response.

Iron Deficiency

Although standard recommendations for monitoring iron status following supplementation have not been established, it is expected that Hb concentration should improve by approximately 1 g/L, per day and be approximately 20 g/L higher after 3–4 weeks of supplementation (New Zealand Formulary, 2018). However, completely restoring iron stores with a subsequent improvement in Hb and hematocrit usually takes around 4 months. For children with IDA, it is recommended that ferritin and reticulocyte response is checked four weeks after treatment is commenced (Melbourne TRCH, in press). As iron overload can be fatal in children, regular iron studies are necessary when high-dose therapy is used in pediatric patients (Melbourne TRCH, in press).

If the patient is managing iron deficiency through oral therapy, there are a number of reasons as to why they might not be responsive to therapy, as summarized in **Table 10**, which should be investigated to determine whether intravenous therapy is appropriate.

Table 10 Causes of non-responsiveness of iron status to iron therapy

Cause	*Notes*
Inadequate iron intake	• Patient not complying with supplementation. • Patient taking a supplement with insufficient iron concentration
Inadequate iron absorption.	• Intestinal disorders (e.g., celiac disease, inflammatory bowel disease) • Impaired gastric acid secretion • Gastric or intestinal bypass procedures • *Helicobacter pylori* persistence • Coexisting inflammation • Concomitant consumption of inhibitors of iron absorption
Ongoing iron losses or requirements that exceed the dose of supplementation or absorptive capacity	• Recurrent or undiagnosed gastrointestinal blood losses (e.g., malignancy, peptic ulcer) • Other sources of recurrent blood loss (e.g, menorrhagia, or inherited bleeding disorder)
Coexisting condition that interferes with bone marrow response to supplementation	• Concomitant vitamin B_{12} or folate deficiency • Coexisting bone marrow disease
Incorrect diagnosis of anemia	• Anemia of chronic disease or renal failure • Hemoglobinopathy

Once Hb and red cell indices have returned to a normal range, these parameters should be monitored at regular intervals. It has been recommended that iron status markers and full blood counts are taken monthly for the first 3 months, and then every 3 months for a year after Hb concentrations have returned to a normal range (Goddard et al., 2011).

Vitamin B_{12} Deficiency

There is no consensus regarding how the treatment effect of cobalamin supplementation should be monitored. Although patients may experience increased energy levels in the first 24 hours following treatment, the hematologic response will only begin several days later. It has been suggested that reticulocytes should be checked 1 week after treatment is initiated, Hb after 1–2 months, and mean corpuscular volume should have returned to normal by 8 weeks after intervention. Homocysteine and methylmalonic acid levels are expected to normalize during the first week of treatment, and if not this would suggest an incorrect diagnosis. Cobalamin and holo-transcobalamin measures are not informative as these will increase with cobalamin treatment, regardless of its therapeutic effectiveness (Carmel, 2008). Neurologic improvement should be observed within the first week and tends to be complete within 6–12 weeks, though this follows a less predictable course (Healton et al., 1991).

Follow-up every 1–3 years is suggested for all patients with an unknown cause or without hemodynamic compromise and should include clinical reevaluation in conjunction with cobalamin and methylmalonic acid or homocysteine assays (Carmel, 2008). Incomplete response to treatment should alert clinicians to consider other causes of anemia and/or neurological disease. Residual neurologic disability is estimated to affect 6% of patients with neurologic symptoms and is likely to persist if it still remains after 6–12 months of treatment (Healton et al., 1991).

Role of the Pharmacist in the Management of Nutritional Anemias

Role in the Health-Care Team

Pharmacists have the potential to play an essential role in the management of patients with anemia, as they have the expertise to take on the following roles:

1. *Initial screening of patients for iron/vitamin B_{12} deficiency or anemia and collection of clinical information.* It is essential for pharmacists to have a good understanding of the etiology, clinical signs and symptoms, course of disease, and management of anemia. When an individual begins to experience symptoms of fatigue and ill health, they will often first seek advice from a pharmacist on supplementation options. This provides the pharmacist with an ideal opportunity to look for early warning signs of anemia and make a timely referral to physicians as required. The pharmacist should consider the patient's duration of fatigue, previous history of nutrient deficiencies, lifestyle factors (questions regarding diet, work, or social stresses) medication, and supplement use in their collection of clinical information.
   Although pharmacists working in a general practice or in hospitals have access to patient health records, community pharmacists do not yet have this opportunity. Similarly, general practitioners do not have access to pharmacy records, and any medicines or over the counter supplements purchased by a patient at community pharmacies remain unknown. Providing community pharmacists access to patient records would allow them to check the relevant medical history and hematological results of customers who present to community pharmacists complaining of symptoms of fatigue. In turn, this could help prevent

inappropriate use of supplements, which as previously mentioned might mask or delay the treatment of underlying conditions, further delaying appropriate hematological investigation and management if symptoms are temporarily alleviated by an over the counter supplement.

2. *Referral if medical assistance or input from other health-care providers is required*. If a nutritional anemia or deficiency is suspected that requires further investigation to diagnose, patients should be promptly referred through to their medical provider with detail of relevant clinical information.
   However, depending on the primary care system in place, there are barriers for direct referral of patients between health professionals. For example, if a patient presents at a pharmacy with symptoms and a clinical history that would suggest benefit from a referral to a dietician that has not been acted upon by a physician, the pharmacist often has little option other than the traditional route of referral to the general practitioner first.
3. *Therapy regime management and modification*. Managing polypharmacy is where a pharmacist's expertise plays an essential role in the multidisciplinary approach to a patient's care. Their extensive pharmaceutical knowledge should contribute to considerations that take place regarding each patient's optimal medication regimen, particularly when comorbidities and polypharmacy are involved as clear clinical guidelines are not yet available for nutritional anemias.
   This would involve ensuring that medicines are used appropriately, and are stopped when no longer appropriate, and to consider opportunities for lifestyle changes or non-medical therapies.
4. *Taking lead in the development of guidelines for the management and monitoring of nutritional anemia or deficiency*.
   Pharmacists, alongside other health professionals, should advocate for and develop guidelines for the management of nutritional anemias. This is particularly important for subclinical nutritional deficiencies, as guidelines are currently unavailable, and early identification and treatment can either prevent later disease development if managed correctly or can have a detrimental effect if underlying conditions are masked.
5. *Simple dietary recommendations* Pharmacists should be able to provide simple information on how to improve dietary intake and/or bioavailability of iron and vitamin B_{12}. This should include rich sources of iron or vitamin B_{12} (please refer to nonpharmacological management section) and factors that might enhance (e.g., ascorbic acid) or inhibit (tannins in tea and coffee, oxalates, phytates) iron absorption. If the patient is interested in further dietary information, refer them to a registered dietician or nutritionist who can assist in tailored advice.

Counseling in Pharmacologic Management of Nutritional Anemias

Providing patient education has the potential to significantly improve patient outcomes through enhanced advocacy and compliance with treatment regimens. Pharmacists are encouraged to take adequate time to counsel their patients through face-to-face interviews and provide patients with educational brochures that summaries the information provided. Counseling should outline goals of Hb recovery, cover management of side effects, how to maximize absorption from their oral supplement, lifestyle modifications, and possible drug interactions.

This may be challenging for the pharmacist to thoroughly complete; however, as prescribing and management discussions are still routinely performed with their general practitioner or specialists in the case of nutritional anemias. Accordingly, pharmacists have more limited opportunities to see patients in a primary care setting as part of a practice team and direct contact with the patient is often brief, not always desired, and has little scope for a detailed consultation (Tarn et al., 2006).

Counseling in the Management of Iron Deficiency

Gastrointestinal Side Effects to Oral Iron Therapy

Oral iron supplementation is associated with a number of common gastrointestinal side effects, which pose a barrier to the adherence of oral iron therapy (Cancelo-Hidalgo et al., 2013). The pharmacist should take care to explain each of the possible side effects and provide advice on how to manage these symptoms. Gastrointestinal symptoms are often-dose related, and though there is little evidence to recommend a specific strategy, the approaches to improve compliance outlined in **Table 11** may be suggested by the pharmacist (Goddard et al., 2011; Lopez et al., 2016; Pasricha et al., 2010). Patients should also be advised to contact their general practitioner or specialist if symptoms persist.

Enhancing Absorption of Oral Iron Supplements

Pharmacists should counsel all patients on how to maximize absorption from their oral iron supplement. The following advice should be provided:

1. Avoid nutrient components that can reduce the absorption of iron (please refer to **Table 9** for details).
2. Take oral iron between meals
3. Bioavailability of iron is enhanced under acidic conditions, and supplements should be taken alongside a source of ascorbic acid (e.g., a glass of orange juice). Although ascorbic acid does enhance absorption, patients should be made aware that this does also increase the frequency of gastrointestinal side effects.

Table 11 Common gastrointestinal side effects to oral iron therapy and approaches to management of symptoms.

Side effect	*Approach to manage symptom*
Epigastric discomfort Flatulence and bloating Nausea and vomiting Black/green or tarry stools	1. Taking supplements with meals, though this will reduce absorption by up to 40%. 2. Taking the prescribed dose at bedtime 3. Dividing the total prescribed dose into smaller doses 2–3 times per day. Note this may require the use of a lower-dose iron preparation (e.g., ferrous sulfate liquid), as controlled release preparations should be swallowed whole. 4. Prescribing the lowest effective dose 5. Intermittent dosing schedules (e.g., from every second day to once weekly). 6. Changing oral preparations to a reduced dose of elemental iron (e.g., switching from ferrous sulfate to ferrous fumarate) 7. Slow release preparations are often recommended (however, there is inadequate evidence to support this strategy).
Black discoloration of teeth (liquid supplementation)	If liquid ferrous sulfate is prescribed, recommend patients to dilute the liquid preparation with water, drink this through a straw, and follow with a glass of water to reduce dental discoloration (Australian, in press)
Constipation	1. Prescribing the lowest effective dose of oral iron or prescribing an intermittent dosing regimen if constipation is dose-related. 2. Gradually increasing dietary fiber. Patients should be warned that this can initially increase abdominal distention and flatulence. 3. Gradually increasing fluid intake 4. Light physical exercise 5. Advising patients to attempt to defecate soon after waking and postprandially. 6. Soluble fiber supplements (e.g., Metamucil) or osmotic laxatives (e.g., Movicol) are often recommended to prevent iron-induced constipation; however, it should be noted that these may require adequate dietary fiber intake in order to be effective and should therefore be used with caution

Drug Interactions

Oral iron supplementation can reduce the absorption of other medicines, and patients should be advised to take the following preparations at least two hours apart from oral iron supplements (Baird-Gunning and Bromley, 2016);

1. Tetracyclines (e.g., doxycycline, minocycline)
2. Quinolones (e.g., ciprofloxacin, moxifloxacin, norfloxacin)
3. Antacids containing aluminum, magnesium, and calcium.
4. Calcium supplements and calcium-rich foods (milk and other dairy products)

Administration of iron should also be spaced apart from drugs that might reduce its absorption, including oral bisphosphonates, levodopa, carbidopa, methyldopa, and thyroid hormones. An increase in gastric pH will also reduce the absorption of oral iron, which should be considered when a patient is prescribed proton pump inhibitors and antacids (Baird-Gunning and Bromley, 2016). Oral zinc and iron products have been shown to reduce each other's relative bioavailability (Lynskey and Machin, 2012).

Counseling in the Management of Vitamin B_{12} Deficiency

A common misuse of cobalamin is as a cure for fatigue and other nonspecific symptoms. Education of the patient around use of cobalamin supplements helps to prevent patients from ceasing treatment once they achieve symptomatic improvement, which typically precedes adequate hematological improvement.

Drug Interactions

Vitamin B_{12} supplements have the potential to interact with certain medications, while some medications might negatively affect an individual's vitamin B_{12} status. Some common examples are provided below, and patients should be advised on these as appropriate:

1. Proton pump inhibitors—interfere with vitamin B_{12} absorption from food by slowing the release of gastric acid into the stomach (Howden, 2000).
2. H2 receptor antagonists—interfere with vitamin B_{12} from food by slowing the release of hydrochloric acid into the stomach (Force and Nahata, 1992).
3. Metformin—may reduce the absorption of vitamin B_{12} through a number of mechanisms (Buvat, 2004).

Advances in the Management of Nutritional Anemias

Therapeutic Advances

There is ongoing research in the development of new therapeutic strategies for the treatment of nutritional anemias, and pharmacists with active research roles have a critical role in this. Pharmacists should be involved in leading the decision of how to implement

these into guidelines, and close collaboration is required between scientists, clinical investigators, and health professionals to deliver optimal therapies to the greatest number of patients worldwide.

An example of this is the discovery of the potential to target the hepcidin-ferroportin system as a therapeutic strategy. Ferroportin is a membrane transporter that stimulates the uptake of iron by intestinal epithelial cells and the egress of iron from macrophage. Hepcidin is a small peptide secreted by the liver and binds ferroportin to stimulate its degradation, leading to reduced intestinal absorption of iron and subsequent accumulation within the reticuloendothelial system. Downregulating hepcidin in patients with IDA could enhance uptake of iron and its release from reticuloendolothelial stores (Ganz and Nemeth, 2011; Sankaran and Weiss, 2015). Although hepcidin is not upregulated in all cases of IDA as it is in anemia of inflammation or anemia of chronic disease, patients presenting with these concomitant conditions may also benefit from such treatment, though this would require accurate investigation into the underlying cause of patients with IDA, and further research to determine the benefit of this therapeutic strategy in patients where chronic disease or inflammation is not the primary cause of anemia. There have been different approaches to target various regulatory steps of the hepcidin pathway in an attempt to pharmacologically control its expression. This includes hepcidin-sequestering agents (antibodies, anticalins, and aptamers), inhibitors of the BMP/SMAD or IL-6/STAT3 pathways, inhibitors of hepcidin transduction, or ferroportin stabilizers (Poli et al., 2014; Sun et al., 2012).

Liposomal oral iron preparations may provide relief to gastrointestinal side effects in the future and are under evaluation. These preparations consist of iron encased in a phospholipid coat containing ascorbic acid and prevent direct contact between the intestinal mucosa and iron (Pisani et al., 2015).

Pharmacy-Managed Clinics

There is an opportunity for better integration of the pharmacist in the management of patients with nutritional anemias in the setting of a pharmacist-managed clinic (PMC), which is an example of effective pharmacist–physician collaborative practice. These have been shown to improve patient outcomes across a range of clinical settings worldwide, and beneficial effects have consistently been reported with respect to cost-effectiveness, patient adherence to and knowledge about pharmacotherapy, and therapeutic outcomes (Aspinall et al., 2012; Snider et al., 2012; Vivian, 2002; Wallgren et al., 2012). Accordingly, PMCs have emerged as models that provide superior patient outcomes and are also associated with a reduced economic burden to primary health care (Armor et al., 2010; Gupta et al., 2015).

Recent studies have investigated the effect of clinical pharmacists actively managing outpatients with renal anemia, and it was found that having pharmacists actively involved was associated with improved therapeutic outcomes (Ohnishi et al., 2011). Following this, a randomized control trial was recently conducted in Jordan, where the role of clinical pharmacists in the management of adult patients diagnosed with IDA was investigated in an outpatient setting. It was found that having the input of clinical pharmacists improved these patients' outcomes. This improvement related to a number of interventions from the pharmacist, including patient counseling, which was conducted face to face in private and in simple layman's language, the provision of pamphlets to simplify this educational material and to assist in remembering instructions, good rapport was also developed between patients and clinical pharmacists where patients were able to ask diverse questions about drug information, patients were also able to call the clinical pharmacist and ask any questions they might have relating to IDA, drug interactions, laboratory tests, or the date of follow-up visits. From the perspective of the clinical pharmacist, an improvement in patients' knowledge of IDA and the importance of therapy was observed, which translated to increased compliance with therapy. As patients were comfortable with providing information to their pharmacist, pharmacists were then able to better recommend individualized iron therapy regimens. A high proportion of the pharmacist's recommendations were then accepted by physicians due to the collaborative relationship that had been built, and physicians were able to ask drug information questions relating to IDA and other medications and conditions. These collaborative relationships lead to positive clinical outcomes with respect to the patient's health status, with three new cases of coeliac disease diagnosed. This study highlights the importance of the clinical pharmacist's role in outpatient settings for the treatment of IDA and the benefit of physician–pharmacist collaborations (Tahaineh and Khasawneh, 2018).

Although further research in this field is required, it is foreseeable that clinical pharmacists will have a more closely integrated role in the collaborative care of outpatients with nutritional anemias, particularly in the primary care setting, with ongoing monitoring and dynamic treatment strategies provided by the pharmacist. The development and implementation of pharmacist-managed anemia programs is predicted to lead to enhanced patient awareness and education, alongside close monitoring and evaluation of the efficacy of treatment, translating to improved clinical outcomes for the patient, as well as helping to relieve the heavy burden on physicians in the primary setting through better use of other health professionals. However, further education of pharmacists would be required, with possible change in the delivery of curriculum if such models are to have widespread implementation in the future. Clear guidelines would need to be in place for PMCs, which could be universally adapted across various clinical settings. Guidelines should include the purpose, background, required knowledge and skills of pharmacists, the pharmacist's roles, the steps in patient education and counseling process, content, and documentation.

Intravenous Therapy

In more recent years, there has been an increasing use of intravenous therapies in the community. For example, iron carboxymaltose has been made available for dispense in the community by PHARMAC in New Zealand, and infusion can be performed in general practice clinics rather than hospital inpatient or outpatient settings. Wider implementation of this has the potential to positively affect hospital services as there would be a reduced hospital pharmaceutical expenditure and demand on hospital

infusion clinics, while also allowing the patient to receive therapy closer to their homes (Pharmac, 2017). However, this does require a concerted effort between hospital and community physicians and pharmacists to ensure that such programs are rolled out effectively.

Clinical Pharmacy Considerations in Special Population: Drug Dose Adjustment in Hepatic Impairment

Jiayi (Jay) Gong, Auckland City Hospital, Auckland, New Zealand

Learning Objectives

- Describe the pathophysiology of liver disease and how to assess the severity of liver disease.
- Understand the pharmacokinetic alterations in patients with chronic liver disease with respect to medication use.
- Understand the pharmacodynamic alterations in patients with chronic liver disease with respect to medication use.
- Provide a clinical perspective on dosage adjustment and medication use in hepatic impairment.

Introduction

The liver plays a major role in medication absorption, distribution, metabolism, and clearance. In clinical practice, both the pharmacokinetic and the pharmacodynamic properties of medications are equally important. This chapter aims to outline some pharmacokinetic principles related to medication dosing, pharmacodynamic considerations of medication use, and some general principles of medication dosing in liver disease.

Pathophysiology of Liver Disease

Liver disease can be acute or chronic in nature. Chronic liver disease will lead to cirrhosis and portal hypertension, and in this group of patients, medication dosing adjustment is of more relevance (Lewis and Stine, 2013). The common etiologies of chronic liver disease can be numerous: alcoholic liver disease, nonalcoholic fatty liver disease, viral hepatitis, and rarer forms including hereditary diseases such as Wilson's disease.

Dosing adjustment of medications is required in liver cirrhosis, due to an array of pathophysiological changes in the liver that may influence medication pharmacokinetics (Le Couteur et al., 2005). Cirrhosis is a process whereby the normal liver parenchyma is converted to abnormal nodules, leading to a reduction in hepatic blood flow. These changes lead to the development of portal hypertension and reduction in the number and activity of the functional cells of the liver (hepatocytes) (Le Couteur et al., 2005). Ultimately, this will cause the manifestation of several complications including esophageal varices, variceal bleeding, ascites, encephalopathy, and hepatorenal syndrome, which all contribute to changes in the pharmacokinetic parameters and pharmacodynamic effects of medications. Cholestasis also occurs as a consequence of liver disease, where there is impairment in the secretion of bilirubin due to intrahepatic and extrahepatic processes that lead to the development of lesions in the biliary tract (Zollner and Trauner, 2008). Liver cirrhosis can affect multiple organs—most notably the kidneys, resulting in hepatorenal syndrome. This causes severely impaired renal function, in which medication doses will require adjustments for renal impairment in addition to hepatic impairment.

Assessing Liver Function

The term liver function test (LFT) is a misnomer. The best indices of impaired hepatic metabolic capacity are elevated bilirubin, low serum albumin, and coagulopathy (raised international normalized ratio, prothrombin time or ratio) (Bollinger, 2017). This impairment reflects in the function of the liver to synthesize protein, coagulation factors, and the ability to metabolize medications. An elevated non-differentiated serum bilirubin may indicate hemolysis and/or cholestasis. The presence of cholestasis may indicate impaired elimination of medication excreted into the bile ducts (Limdi and Hyde, 2003). The liver enzymes, alanine transaminase (ALT) and aspartate transaminase (AST) may indicate hepatocyte injury but have limited use for medication dosing in hepatic impairment (Limdi and Hyde, 2003). Unlike serum creatinine for renal function, there is no single biochemistry marker available to measure liver function.

There are two commonly used liver disease classification scores to assess the severity of liver disease: the Child-Turcotte-Pugh (Child-Pugh) score and the Model for End-Stage Liver Disease (MELD) score. The Child-Pugh score has been used to estimate the prognosis of patients with liver cirrhosis. The parameters included in the scoring include serum concentrations of bilirubin, albumin, the prothrombin time, and the presence of hepatic encephalopathy and ascites (Pugh et al., 1973). The MELD score was intended to gauge prognosis of patients awaiting liver transplantation. This score may be more accurate in assessing severity of liver disease, as it only takes into account objective biochemical markers as opposed to potentially subjective assessments of encephalopathy and ascites (Malinchoc et al., 2000).

In reality, pharmaceutical manufacturers often use the Child-Pugh score to make dose adjustment recommendations in patients with liver disease. However, the reasons for this preference are unclear. The recommendations are usually conservative and are likely based on pharmacokinetic modeling instead of real-world patient based data. Thus, it is critical for the pharmacist to use their clinical judgment and advise the treatment team on how best to manage the patient's medications, in the context of their liver disease.

Pharmacokinetic Alterations in Chronic Liver Disease and Considerations in Medications Use

Hepatic Clearance

In clinical practice, the use of hepatic clearance is impractical and very time consuming to offer significant benefit. Moreover, hepatic extraction of medications is not a pharmacokinetic parameter that is readily available in common and easily accessible references. Thus, this chapter will only introduce the key equations and the underlining principles in relation to alterations in pharmacokinetics. Hepatic extraction is how efficient the liver is at eliminating a medication, depending on blood flow (Johnson and Thomson, 2008).

Hepatic clearance (CL_H) is defined as the volume of blood from which medication is removed completely by the liver per unit time. It is thus a function of hepatic blood flow (Q_H) and the hepatic extraction ratio (E_H) of the medication (Johnson and Thomson, 2008):

$$CL_H = Q_H \times E_H$$

Since E_H also depends on liver blood flow, the intrinsic clearance of the unbound medication (CL_{int}), and the fraction of the unbound medication in the blood (fu), the following important equation for CL_H can be derived:

$$CL_H = Q_H \times \frac{fu \times CL_{int}}{Q_H + fu \times CL_{int}}$$

This equation is based on a pharmacokinetic model most frequently used to describe the relationship between hepatic medication clearance and the three primary determinants of hepatic elimination: blood flow, medication binding in the blood, and the intrinsic clearance (activity of enzymes and transporters) (Johnson and Thomson, 2008). Medications can be categorized according

to how efficiently the substance is removed from the circulation by the liver via the extraction ratio. There are three categories for the extraction ratio:

1. High extraction ratio ($E_H > 0.7$)
2. Low extraction ratio ($E_H < 0.3$)
3. Intermediate extraction ratio ($0.3 < E_H < 0.7$)

In clinical practice, these equations may be of limited use, but their implications in medication dosing needs to be appreciated. The hepatic clearance of highly extracted medications approaches and becomes limited by liver blood flow:

$$E_H > 0.7, \text{ i.e., } Q_H \ll fu \cdot CL_{int} \rightarrow CL_H \cong Q_H$$

This means that these medications are so well metabolized, that there is a lower oral bioavailability. Note that there is little difference in intrinsic clearance between healthy and diseased individuals, irrespective of the enzymatic and transporter capacity activity of the liver (i.e., CL_{int}) (Verbeeck, 2008). This is because secondary diseases from portal hypertension (such as esophageal varices and portosystemic shunting) have the most impact on the clearance of orally administered medications. Therefore, this would mean that these medications would bypass "first-pass" metabolism. A common example of this in practice is the dosing of morphine with a hepatic extraction of 0.76 (Delcò et al., 2005), which is considered as a highly extractable medication. In liver cirrhosis, the oral bioavailability of morphine can be increased to 100% from around 50% in normal patients (Hasselström et al., 1990). The dose should be conservative (at least half of the normal dose), due to its many-fold increase in oral bioavailability. Therefore, the dose will need to be titrated carefully as per individual patient response. The potential for adverse effects will be elevated due to the increased risk of accumulation. This may lead to constipation and sedation, both of which can precipitate and exacerbate hepatic encephalopathy (Lewis and Stine, 2013). The starting and maintenance dose of these highly extractable medications should be reduced.

On the other hand, medications may be poorly extracted and their hepatic clearance is mainly affected by intrinsic hepatic clearance:

$$E_H < 0.3, \text{ i.e., } Q_H \gg fu \cdot CL_{int} \rightarrow CL_H \cong fu \cdot CL_{int}$$

These medications have a low extraction ratio and tend to have higher oral bioavailability (≥70%) as they are not extensively metabolized by the liver. The clearance of these medications is more reliant on the activities of enzymes and transporters such as cytochrome P450 (CYP450) enzymes. However, these medications are less affected by liver cirrhosis as they already have a relatively high oral availability and do not depend on hepatic blood flow, which means the presence of portosystemic shunts is unlikely to affect these medications (Delcò et al., 2005). Therefore, medications with a low extraction ratio can generally be started at a normal dose if a rapid response is required, while their maintenance dose should be reduced.

The last class of medications is those with intermediate extraction ratios of between 30% and 70% (e.g., calcium channel blockers, statins and amiodarone). Clearance is both determined by blood flow across the liver and intrinsic clearance. Thus, both the maintenance dose and the starting dose should be at the lower range of normal.

In summary, it is generally accepted in clinical practice that medications with a high extraction ratio or low oral bioavailability, should have their starting dose reduced by half, while medications that have a low extraction ratio or high oral bioavailability should have their starting dose reduced by a quarter. See **Table 1** for some examples of drugs with high and low extraction ratios (Sloss and Kubler, 2009).

Absorption

Gastrointestinal dysfunction has often been observed in patients with liver disease and in particular those with cirrhosis. It has been shown that cirrhotic patients have delayed gastric emptying (Chander et al., 2013; Kalaitzakis, 2014). In clinical practice, it is recommended to avoid slow release or modified release preparations in this group of patients. The use of modified release medications in these patients would likely lead to further delay in medication release, causing difficulty in predicting response and potential toxicity.

Table 1 Examples of medications with high and low extraction ratios (Sloss and Kubler, 2009)

High extraction ratio medications	*Low extraction ratio medications*
Antipsychotics, e.g., haloperidol	NSAIDs
Calcium channel blockers	Warfarin
Morphine	Paracetamol
Antidepressants	Phenytoin
Beta-blockers (some), e.g., propranolol	Amiodarone

Table 2 Bioavailability of certain medications in non-cirrhotic patients compared with patients with cirrhosis

Medication	*Bioavailability in non-cirrhotic subjects*	*Bioavailability in cirrhotic subjects*	*Fold increase*	*Reference*
Carvedilol	0.19	0.83	4.4	Neugebauer et al. (1988)
Labetalol	0.33	0.63	1.9	Homeida et al. (1978)
Metoprolol	0.50	0.84	1.7	Regårdh et al. (1981)
Midazolam	0.38	0.76	2.0	Pentikainen et al. (1989)
Morphine	0.47	1.00	2.1	Hasselström et al. (1990)
Propranolol	0.36	0.60	1.7	Branch et al. (1977)

As suggested above, the bioavailability of many medications will be elevated in hepatic impairment. This increase is a result of changes in hemodynamics, such as portosystemic shunting due to portal hypertension. This will cause the flow-limited medications to have a reduced clearance leading to a significant increase in serum level. Transjugular intrahepatic portosystemic shunt (TIPS) can be used for the management of complications related to cirrhosis. This is a nonselective portosystemic shunt aimed at reducing portal hypertension. It minimizes the risk of variceal bleed and recurrence of ascites. The presence of TIPS can substantially elevate the oral bioavailability of flow-dependent medications such as midazolam (Chalasani et al., 2001). This allows the medication to bypass presystemic hepatic first-pass metabolism, which is a major determinant of oral bioavailability. See **Table 2** for some examples of changes in oral bioavailability of medications between non-cirrhotic patients and patients with cirrhosis.

Medication Distribution

Ascites and edema are common complications of liver cirrhosis and this will increase the volume of distribution for hydrophilic medications. Consequently, the loading dose of a medication may need to be increased for a rapid effect to be observed (Delcò et al., 2005). Edema and ascites do not affect the elimination of medications, so the maintenance dose should not require alteration (Delauter et al., 2000). However, the protein binding profile of medications may affect distribution around the body. A low level of albumin may increase distribution and the free serum level of medications (Delcò et al., 2005). Medications with a high protein binding profile (>90%) and a narrow therapeutic index (e.g., phenytoin), should be monitored for their free serum level to minimize risks of toxicity.

Renal Dysfunction in Liver Disease

A large number of medications are primarily excreted via the kidneys. Therefore, renal function must also be evaluated to determine medication dosing. It is difficult to evaluate renal function in patients with cirrhosis, since their serum creatinine poorly represents renal function. This is due to a poor nutritional status resulting in muscle atrophy, impaired synthesis of creatine, and the dilutional effect of edema and ascites on serum creatinine (Figueiredo et al., 2000). A study was published by Francoz et al. (2014) comparing various methods of calculating renal function to actual measured renal function in patients with liver disease. The paper examined the following methods of calculating renal function: Cockcroft-Gault, Modified Diet in Renal Disease-4 (MDRD-4), MDRD-6, and Chronic Kidney Disease Epidemiology Collaboration (CKD-EPI). It showed that most methods of calculating renal function tended to overestimate the glomerular filtration rate (GFR) by as much as 25 mL/min. The most accurately calculated GFR was via the MDRD-6 method. It provided the truest estimate of renal function in a patient with liver disease (Francoz et al., 2014). Ideally, if hospital resources are available, all patients on the waiting list for liver transplant should have a measured renal function. This will enable optimal dosing of medications that are primarily eliminated renally, thereby minimizing the risk of toxicity.

Metabolism

Medication metabolism mainly occurs via the liver through enzymatic activities of the sinusoidal and canalicular transporters (Liu and Pang, 2005; Pang et al., 2009). This determines the important parameter of hepatic intrinsic clearance (CL_{int}). Medication metabolism usually involves two phases in the liver. The first phase involves reactions such as hydrolysis, oxidation, and reduction. These reactions are reliant on the CYP450 class of enzymes. The second phase involves the attachment of molecules, via glucuronidation and acetylation. Besides inactivation of medication, changes in metabolism will affect "pro-drugs." "Pro-drugs" are medications that require metabolism to be active, and some are heavily reliant on the CYP450 enzymes. In patients with liver disease, these medications will have a decrease in effect due to failure to convert to active metabolites (e.g., codeine conversion to morphine).

In chronic liver disease, there is a decrease in enzymatic activity and hence, metabolism of medications. This is related to a loss of hepatocytes and impaired function of existing cells. In a study by Frye et al. (2006), a validated cocktail approach was used to study the effect of liver disease on multiple CYP450 enzymes. It was shown that the CYP450 enzymes had a progressive

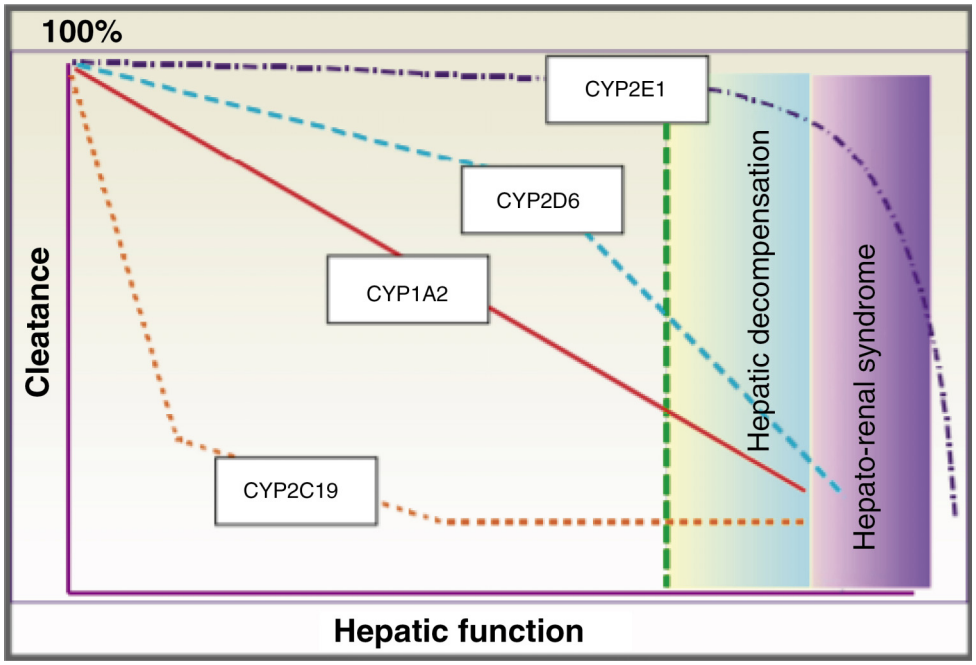

Figure 1 Sequential progressive model of hepatic dysfunction. The ordinate shows how plasma clearance, starting at 100% when hepatic function is normal, decreases for substances eliminated predominately by metabolism via individual CYP450 isoforms in the liver. *Source: Reprinted with permission from the American Society for Clinical Pharmacology and Therapeutic from Frye, R.F., Zgheib, N.K., Matzke, G.R., Chaves-Gnecco, D., Rabinovitz, M., Shaikh, O.S., Branch, R.A., 2006. Liver disease selectively modulates cytochrome P450—mediated metabolism. Clin. Pharmacol. Ther. 80 (3), 235–245.*

nonuniform reduction in activity (Frye et al., 2006). The authors proposed that a "sequential progressive model of hepatic dysfunction" may better quantify the loss in activity of liver enzymes with respect to the severity of liver disease (Fig. 1). According to this model:

- CYP2E1 activity is maintained mostly throughout the liver disease until decompensation and end-stage.
- CYP2D6 and CYP1A2 have a more gradual decline over the course of the disease with CYP2D6 showing more resilience earlier on in the progression of liver disease.
- CYP2C19 appears to sharply decline at the earlier stages of chronic liver disease.

The largest subset of the CYP450 enzymes is the CYP3A family. They are the main enzymes responsible for metabolizing more than 50% of medications commonly prescribed (Verbeeck, 2008). In a clinical study involving midazolam as a CYP3A probe, it was shown that the activity of CYP3A activity decreases with the severity of liver disease (Albarmawi et al., 2014). The authors demonstrated that patients with Child-Pugh Class A had similar midazolam clearance as the control group (non-cirrhotic patients). Conversely, compared to the control group, the clearance in patients with Child-Pugh Class B was decreased to 23% and only 14% in those with class C. This study demonstrates that CYP3A enzyme metabolism decreased with the severity of live disease. There was also a good correlation of results between using the Child-Pugh and MELD scores which suggests that either scores can be used interchangeably as a marker for metabolic CYP3A capacity (Albarmawi et al., 2014). Finally, phase two reactions such as glucuronidation have conflicting data on how they are affected in liver disease. It is generally accepted that medications that only depend on phase two reactions remain largely unaffected and are preferred in patients with liver disease (Lewis and Stine, 2013). Examples include mycophenolate, lorazepam, and lamotrigine (Marcellin et al., 2001; Parker et al., 1996).

Pharmacokinetic-Related Cases

PK Case 1

A 45-year-old female patient with a history of liver cirrhosis due to chronic alcoholism was admitted to the hospital with refractory ascites. Her biochemistry was mostly unremarkable, except mild hyponatremia that was thought to likely be due to dilutional effects of ascites. TIPS was decided as an appropriate procedure to manage her ascites.

- Patient current medications include: spironolactone 400 mg daily, furosemide 80 mg twice daily, and carvedilol 6.25 mg twice daily.
- Postoperatively, the patient was prescribed oral morphine 10 mg as required every 4 h for pain and regular paracetamol.

Commentary/expert opinion

TIPS is a nonspecific shunt to alleviate portal pressure. Once inserted, medications would bypass first-pass metabolism and greatly increase in bioavailability (Chalasani et al., 2001). As per **Table 1**, morphine bioavailability will effectively double, so starting dose should be half of normal.

There are two important tasks that the pharmacist must complete in this case. The first is to calculate the GFR in a patient with cirrhosis using the MDRD-6 equation and consider if morphine is appropriate since morphine elimination is heavily dependent on renal function (Micromedex, 2018). Second, if the patient has adequate renal function, the clinical pharmacist should recommend changes to the oral morphine dose to be 5 mg as required every 4 h and titrate as needed. However, if morphine was deemed inappropriate (poor renal function) and opioids are still required, fentanyl is preferred due to its shorter half-life and inactive metabolites, thereby minimizing the chance of accumulation (Lewis and Stine, 2013). Regarding her other medications, carvedilol bioavailability may also increase due to bypassing first pass metabolism (see **Table 2**). Her diuretic oral bioavailability is unlikely to change. However, once TIPS has been inserted, portal pressure should normalize and her ascites should resolve over time. Thus, the need for continuing her carvedilol and diuretics should be reviewed.

PK Case 2

Patient with liver cirrhosis on ribavirin for the treatment of hepatitis E was admitted to the hospital with a myocardial infarction requiring percutaneous coronary intervention with stenting. In view of elevated prothrombin ratio (1.3), cardiology team started the patient on clopidogrel instead of ticagrelor, with aspirin. As the clinical pharmacist you have been asked to review the patient.

Commentary/expert opinion

First, identify that clopidogrel is a "pro-drug" and is activated via the CYP450 enzymes. CYP2C19 plays a key role in the biotransformation of clopidogrel to its active form (Micromedex, 2018). As per **Fig. 1**, CYP2C19 has a steep decline in its metabolizing function at the earliest stages of liver cirrhosis, which means it is unlikely that the patient will receive an effective dose of clopidogrel, thereby increasing the risk of stent thrombosis. Ticagrelor, however, is not reliant on biotransformation to be active but produces an active metabolite via CYP3A4-3A5 (Micromedex, 2018). Thus, it would produce a more reliable antiplatelet effect compared to clopidogrel. The clinical pharmacist should involve the treatment team to weigh up the increased bleeding risk and stent thrombosis, which may lead to another episode of myocardial infarction.

PK Case 3

A patient was admitted to the hospital due to acute alcoholic hepatitis, with a history of alcoholic cirrhosis and is started on the alcohol withdrawal scale. The patient has deranged LFTs with a gamma-glutamyl transferase (GGT) of more than 4 times the upper limit. The medical team started the patients on diazepam for withdrawal.

Commentary/expert opinion

As the clinical pharmacist, you should first assess the severity of the patient's liver disease and confirm that the liver is cirrhotic from past medical histories. Once confirmed, the use of diazepam should be queried given that diazepam has a long half-life and is metabolized by CYP3A4 to active metabolites (Micromedex, 2018). Diazepam metabolism in a patient with cirrhosis will be significantly impaired as per previous discussions, depending on the severity of the patient's liver disease, extending the half-life of diazepam and its metabolites. So an alternative benzodiazepine that is metabolized via an alternative pathway and produce inactive metabolites should be considered. Lorazepam and oxazepam should be considered as alternatives, given that both are metabolized via phase two reactions (glucuronidation) and produce inactive metabolites (Lewis and Stine, 2013). Other considerations that the pharmacist should have are the dose conversion between diazepam to either lorazepam or oxazepam, and the particular withdrawal scale tailored to the severity of the signs of withdrawal.

Understand the Pharmacodynamic Alterations in Chronic Liver Disease Patients with Respect to Medication Use

Sedatives and Opioids

Patients with chronic liver disease are more sensitive to the effects of sedatives, anxiolytics, and opioids. Various mechanisms have been proposed: greater permeability of the blood-brain barrier, increased GABAergic tone and increased number of GABA receptors (Caputo et al., 2011). Both sedatives and opioids may precipitate hepatic encephalopathy and subsequent liver decompensation. Opioids may further contribute to decompensation by causing constipation. This will then impair the excretion of toxins, which may lead to the development and worsening of encephalopathy (Verbeeck, 2008). It is recommended to wean off all chronic sedatives, especially benzodiazepines (when possible). Further sedatives should be avoided in the future. Prior to prescribing and administering opioids and sedatives, the presence of hepatic encephalopathy must be excluded.

It is important that the clinical pharmacist is aware of the symptoms of hepatic encephalopathy and liver decompensation. Insomnia is a possible consequence of mild to moderate hepatic encephalopathy and the use of sedatives would only cause further deterioration, while being ineffective in treating insomnia (Ferenci, 2018). The clinical pharmacist should also be aware of agents traditionally not considered to be sedatives, but may still have sedating and central nervous system effects. Such medications include

the phenothiazine class of medications and antiemetics such as cyclizine, which can be sedating and constipating. It is best to avoid these classes of medications or use sparingly in patients with liver disease.

Nephrotoxics and Antihypertensives

These include the likes of angiotensin converting enzyme inhibitors (ACEI) or angiotensin receptor blockers (ARB), alpha blockers, nonselective beta blockers, and nonsteroidal anti-inflammatory medications (NSAID). Diuretics, including loop diuretics and aldosterone antagonists such as spironolactone, are common therapies in patients with liver disease for the management of ascites. However, the use of these agents should still be closely monitored to minimize the risk of hypotension and kidney injury as these medications will decrease intravascular volume. The risks and benefits of continuing diuretics should be weighed against the need for ongoing paracentesis for the management of ascites.

Both the American and European international guidelines on the management of ascites recommend caution with the use of ACEI and ARB in patients with ascites and cirrhosis (EASL, 2010; Runyon and AASLD, 2009). The main blood pressure support in a cirrhotic patient is mediated by the renin-angiotensin-aldosterone system and is activated to maintain blood pressure and autoregulate renal perfusion (Vlachogiannakos et al., 2001). Thus, if an ACEI is on board, patients will be at risk of experiencing severe hypotension and deterioration in renal function. The European guideline has suggested the avoidance of alpha-blockers in patients with ascites which have been shown to increase sodium and water retention (EASL, 2010).

Evidence from observational studies have shown that nonselective beta-blockers should be avoided in patients with recurrent ascites (Sersté et al., 2010) and spontaneous bacterial peritonitis (Mandorfer et al., 2014). The beta blocker would likely cause hypotension and decrease in renal perfusion, leading to increased patient mortality. Thus, nonselective beta blockers should be used with caution in selected patients. The current American and European guidelines predate the observational studies and thus have not incorporated them into their recommendations. However, many centers have adopted the recommendation into their usual practice.

NSAIDs should be avoided in patients with cirrhosis as they increase sodium retention and further vasoconstrict afferent arterioles in the nephrons. This causes deleterious effects on renal function and ascites (EASL, 2010; Runyon and AASLD, 2009). NSAIDs should also be avoided in patients with esophageal varices. NSAIDs can affect platelet aggregation leading to bleeding and rupture of varices that may be life threatening (Yoshida et al., 2013).

Pharmacodynamic-Related Cases

PD Case 1

The general medicine house officer has started oral tramadol at 100 mg every 6 h for a patient complaining of nonspecific pain, admitted with mild alcoholic hepatitis. The patient is a chronic alcoholic with liver cirrhosis. The patient biochemistry results are all normal with an albumin of 32 g/L, slightly elevated bilirubin (68 μmol/L) and INR 1.6. There are no signs of encephalopathy.

Commentary/expert opinion

In this case, the pharmacist should question whether tramadol is an inappropriate agent to be used at this stage of alcoholic hepatitis, given that the patient may be withdrawing from alcohol. The patient will be at risk of seizures and tramadol may further lower the seizure threshold. The dose of tramadol in the context of liver disease should also be queried. Depending on the resources available, the starting dose for immediate-release tramadol may vary between 25 and 50 mg every 6 h to every 12 h (Lewis and Stine, 2013). Thus, the starting dose should be decreased to 50 mg. The main monitoring required for tramadol is nausea, constipation, changes in mental state, and sedation.

The clinical pharmacist should also have an understanding on how liver cirrhosis affects how tramadol act. Tramadol is extensively metabolized in the liver via CYP2D6 producing O-desmethyl-tramadol which is the main metabolite responsible for tramadol's opioid activity (Micromedex, 2018). Tramadol itself is more responsible for the neurochemical effects on serotonin and noradrenaline receptors. As per **Fig. 1**, CYP2D6 decreases in function with worsening of liver disease. Thus, in liver cirrhosis, tramadol may have a reduced opioid effect with an increased serotonergic and noradrenergic effects due to reuptake inhibition, similar to that of venlafaxine—an antidepressant (Reeves and Cox, 2008).

PD Case 2

A patient was admitted with acute hepatitis due to hepatitis B virus, with mild encephalopathy—receiving treatment with lactulose. The patient has developed intractable nausea and is unable to maintain daily intake of nutrition. In addition, the patient received both intravenous ondansetron and metoclopramide with little improvement.

Commentary/expert opinion

There are a limited number of options to use for the treatment of intractable nausea due to local hospital restrictions, with remaining therapies including dexamethasone, droperidol, and chlorpromazine. It is up to the clinical pharmacist to decide which of the remainder is appropriate for this patient. They must weigh up how the medication may interact with patient's liver disease and treating the nausea. Dexamethasone, in this case would be contraindicated, since it would further suppress the immune system and

allow breakthrough proliferation of the hepatitis B virus as we are attempting to suppress viral replication via oral treatment (Reddy et al., 2015). Chlorpromazine has a wide range of activities targeting multiple receptors that mediate vomiting response. It is however, anticholinergic and histaminergic causing sedative effects. These central acting effects will likely worsen encephalopathy and thus should be avoided (Lexicomp, 2018).

Droperidol would be the agent of choice in this case even though it is centrally acting due to its dopamine antagonism in the chemoreceptor trigger zone (Sandoz, 2010). Droperidol does not have anticholinergic effect, thus it has less chance of precipitating encephalopathy. The usual dose for droperidol would be 0.625–1.25 mg up to every 6 h; but given the acute liver decompensation and droperidol being extensively metabolized by the liver, it would be advisable to start with half the usual dose at 0.3125 mg every 6 h.

PD Case 3

A patient was admitted to the hospital with sepsis likely due to spontaneous bacterial peritonitis (SBP) and was started on empiric therapy of intravenous cephalosporin. Patient continued to be febrile after 24 h, and the team considered adding in an aminoglycoside to broaden the antimicrobial coverage. The patient currently has signs of decompensation, including encephalopathy and ascites. However, patient's biochemistry is mostly unremarkable, with normal serum creatinine but low albumin, and deranged LFTs of three times the upper limit.

Commentary/expert opinion

In this case, the clinical pharmacist needs to appreciate the degree of decompensation. It is likely that the normal serum creatinine is unlikely to reflect the patient's true normal renal function and that other parameters such as urine output and serum urea should also be assessed. A number of factors mentioned above may contribute to this uncertainty such as dilution due to ascites and likely decreased perfusion due to refractory ascites (Francoz et al., 2014). Thus, the patient would be at high risk of acute kidney injury and nephrotoxic effects of aminoglycoside (Molitoris, 2018). The clinical pharmacist should advise an alternative antibiotic that is less nephrotoxic and would provide similar antimicrobial coverage to aminoglycosides depending on regional microbial sensitivity.

A Clinical Perspective on Dosage Adjustment and Medication Use in Hepatic Impairment

In general, rarely, do manufacturer data sheets provide clear guidance on dosage adjustment in varying severities of liver disease (Spray et al., 2007). Most references would only provide general guidance in nonspecific hepatic impairment, without considering the differences between non-cirrhotic and cirrhotic patients. The severity of cirrhosis (MELD or Child-Pugh scores) is not usually taken into consideration. However, in the event that a medication data sheet does offer clear dosing guidance in the context of liver disease, this would be a good starting point.

As a clinical pharmacist reviewing patients' medication therapy, there are a few main points to consider:

- The pharmacist should elicit a clear history of the patient's liver disease, including the presence and severity of cirrhosis and portal hypertension.
- The pharmacist should independently evaluate the severity of the patient's cirrhosis, by calculating the MELD or Child-Pugh score to estimate the impairment of hepatic clearance of medications.

Portal hypertension would normally indicate the presence of varices, which leads to medication bypassing first pass metabolism. Note that if patients only have LFT derangement with no history of cirrhosis, then medication adjustment is not necessary, although the pharmacist will need to investigate if the LFT derangement is caused by the medications due to hepatotoxicity.

In a patient with an acute worsening of liver cirrhosis, for example, when the patient deteriorates to category B from A based on Child-Pugh grades, the pharmacist should search for formal recommendations on dose adjustment of medication either in the literature or as recommended by the manufacturer where available. Otherwise the pharmacist should use other resources to check the pharmacokinetic characteristics of the medication to determine if, and to what extent, acute liver decompensation will affect medication metabolism. The extraction ratio, oral bioavailability, metabolizing pathways and excretion should all be considered by the pharmacist to determine if the current therapy will require any immediate intervention. Therefore, the pharmacist needs to have sound knowledge on these aspects and be familiar with the resources that are useful in determining the relevant parameters.

The clinical pharmacist may also be required to review long-term medications in a patient with stable and chronic liver disease. It is important that the clinical pharmacist has a clear history of when each medication was started, the duration of therapy, indication, and risk of hepatotoxicity. Medications that may be hepatotoxic should be stopped to prevent further liver injury. Similarly, medications that have narrow therapeutic indices and are highly protein bound (e.g., phenytoin), would have an increased free serum concentration over time, due to decreased albumin which can lead to toxicity. In these instances, the pharmacist should request free serum levels of the medication (when available) and undertake therapeutic drug monitoring. If the serum concentration measurement is not available, then an alternative agent that is not affected by protein binding and liver disease should be considered. In any case, advising the team on expected response rates and adverse effects related to medication accumulation is of clinical benefit.

Conclusion

There is a profound complexity in dose adjustment of medications in hepatic impairment due to the interplay of pharmacokinetic and pharmacodynamic parameters of medicines in chronic liver disease. The important question may not necessarily be about dosing, but rather, the appropriateness in the first place. For example, if the medication has the potential to be hepatotoxic or nephrotoxic. In most cases, following the cautionary dosing of "start low and go slow" is recommended.

Clinical Pharmacy Considerations in Special Populations: Geriatrics

Jennifer E. Isenor*, Susan K. Bowles†, *Dalhousie University, Halifax, NS, Canada; †Centre for Health Care of the Elderly, Halifax, NS, Canada

Learning Objectives

- Describe risks factors for medication-related adverse effects in older people, including physiologic and prescribing.
- Describe the atypical presentation of medication-related adverse effects in older people, particularly as they relate to functional changes.
- Discuss the role, tools available and related evidence for pharmacists in medication management for older people.

Take Home Messages

- The population globally is aging and with it the number of medications taken.
- Older people are at increased risk of adverse events from medications due to a variety of factors, including changing physiology, polypharmacy, and use of potentially inappropriate medications.
- Polypharmacy and the use of potentially inappropriate medications is exacerbated by the prescribing cascade, in which a medication-related adverse effect is misdiagnosed as another condition and treated with a new prescription, increasing the number of medications, potential adverse effects, and potential for drug interactions.
- Pharmacists provide care to older patients in a variety of settings, including community pharmacy, ambulatory clinics, long-term care, specialized geriatric clinics, general acute care units, and specialized geriatric units.
- Pharmacist-led interventions, as well, as collaborative work on interprofessional teams, have been found to improve medication use in older adults in these diverse clinical practice settings.

- Medication management, most often referred to in the literature as general pharmacist clinical intervention or as medication review, has been shown in a variety of clinical settings to improve medication use and patient outcomes, as well as having cost benefits.
- A variety of tools are available to assist pharmacists in identifying potentially inappropriate medications for reassessment and potential discontinuation in older people, including the Beers Criteria, the Drug Burden Index, the Medication Appropriate Index (MAI), STOPP/START, and STOPPFrail.
- Pharmacists offer a variety of supports around medication adherence, which includes devices, such as dossettes or specialized packaging, as well as, therapeutic optimization to minimize dosing frequency.
- Pharmacists are aware of the potential changes in hearing, vision, dexterity and cognition when providing medications to older people and assist in finding solutions to allow the safe and effective use of medications when age-related changes impair abilities (e.g. decreased dexterity requiring easy open medication vials).

Introduction

The world's population is aging. In 2013, it was estimated that 12% of the world's population was 60 years of age or older (Hohl et al., 2017a). In North America, adults 65 years of age and older represent approximately 16% of the Canadian and 13% of the US population, respectively (Heuberger and Caudell, 2011; Holmes et al., 2006). Similar trends are observed in Europe, Asia, and the Pacific Region (Marshall et al., 2013; Steinman et al., 2011). Over the next 40 years, the proportion of older individuals is projected to double, representing 25%–30% of the world's population (Hohl et al., 2017a).

Aging is associated with the onset of a number of chronic diseases often treated with medications, the result of which is older persons using more medications compared to younger individuals. Across multiple international jurisdictions it is estimated that persons 65 years of age and older account for one-third to half of recipients of all prescribed medications and almost two-thirds of prescription drug costs (Canadian Institute for Health Information, 2016; Craftman et al., 2016; Duerden et al., 2013; Qato et al., 2008; Wastesson et al., 2018).

The use of multiple medications is referred to as polypharmacy, which can be either appropriate or problematic (Marcum et al., 2012a). Appropriate polypharmacy refers to use of multiple medications for complex or multiple conditions where medications have been optimized according to best evidence and demonstrate benefit to the patient (Marcum et al., 2012a). In contrast, problematic polypharmacy occurs when medications do not provide the intended benefit and/or cause harm (Marcum et al., 2012a).

Problems associated with polypharmacy include nonadherence, inappropriate medication use, drug–drug or drug–disease interactions and adverse drug events (Hajjar et al., 2007). Nonadherence is important as it can be associated with therapeutic failure or adverse drug withdrawal events (Marcum et al., 2012b). Clinically important drug–drug and drug–disease interactions are more likely to occur as the number of medications increases (Doan et al., 2013; Hanlon et al., 2017). These interactions can also cause serious adverse drug events (Gnjidic and Johnell, 2013; Hanlon et al., 2011; Juurlink et al., 2003). Likewise, use of potentially inappropriate medications are associated with an increased risk of adverse drug events (Hudhra et al., 2016; Walsh et al., 2016).

Adverse drug events are common in older adults and are an important contributor to morbidity and mortality (Herr et al., 2015; Hohl et al., 2001; Maher et al., 2014). Moreover, adverse drug events can present atypically as disease exacerbation, cognitive decline, falls, functional decline or urinary incontinence resulting in their being overlooked as medication-related effects (Corsonello et al., 2009, 2014; Hilmer et al., 2009; Onder et al., 2018; Peron et al., 2011). This can sometimes lead to use of another medication to manage the condition without recognizing that it has been caused by a drug, often referred to as the "prescribing cascade" (Rochon and Gurwitz, 2017a).

Perhaps the most challenging aspect of caring for older patients is finding the appropriate balance between the benefits and potential harms of medications. As the medication experts on the health care team, pharmacists have an important role to play in ensuring the safe and effective use of medications among this growing population, regardless of their practice setting, for example, community pharmacy, long-term care, acute care.

Medication Use in Older Adults

Polypharmacy

Polypharmacy refers to the use of multiple medications, although a standard definition has not been agreed upon. It is frequently defined based on a specific threshold for the number of medications, ranging from 5 to 10, that a person is taking (Gillette et al., 2015; Hajjar et al., 2007). Defining polypharmacy based on number of medications alone is now being questioned as it does not address the issue of medication appropriateness (Gillette et al., 2015; Hanlon and Hajjar, 2018). The World Health Organization defines polypharmacy as "the administration of an excessive number of drugs" or "the administration of many drugs at the same time" (WHO Centre for Health Development, 2004). This has been expanded by some to include therapeutic duplication, use of more medications than clinically indicated, use of ineffective medications, use of potentially inappropriate medications and drug–drug interactions (Bushardt et al., 2008; Fulton and Allen, 2005; Gillette et al., 2015).

Despite the lack of a standard definition for polypharmacy, review of the literature demonstrates three consistent themes regarding medication use in older adults: (1) Medication use is high in older adults, (2) inappropriate use of medications is common, and (3) polypharmacy increases the risk of medication-related harms.

Medication Use

Firstly, medication use is high in persons 65 years of age and older on an international basis. A recent review of Canadian publicly funded drug programs found that, on an annual basis, approximately 66% of persons 65 years of age and older were prescribed five or more drug classes, 26% prescribed at least 10 and 8% prescribed 15 or more (Canadian Institute for Health Information, 2016). These data are consistent with that observed in other jurisdictions. A large European study, across 11 countries, found that half of the study population (mean age 72 years) were taking six or more medications on a daily basis (Fialova et al., 2005). A second European study in six countries observed 39% of patients receiving home care were using five or more medications concurrently and 23% were using ten (Giovannini et al., 2018). Data from the United States demonstrated an increase from 31% to 36% of an older population using five or more medications concurrently between the years of 2005 and 2011 (Qato et al., 2016).

Medication use is even higher in the nursing home setting. Among Canadian seniors residing in nursing homes, 48% were prescribed 10 or more drug classes, with an average of 9.9 drug classes in 2016 (Canadian Institute for Health Information, 2016). The European SHELTER study found that almost half of long-term care residents were prescribed between five and nine medications and approximately one in five were prescribed ten or more medications (Onder et al., 2013). In the US Nursing Home Study, 40% of long-term care residents were prescribed nine or more medications (Dwyer et al., 2010).

Prescription drugs, over-the-counter products, vitamins, and natural health products all contribute to medication use in older persons. Medication classes commonly used by older community dwelling adults include statins, ACE inhibitors, diuretics, beta-blockers, antiplatelets, and oral antihyperglycemic agents (Canadian Institute for Health Information, 2016; Morgan et al., 2012b; Qato et al., 2016; Quinn, 2017). Self-medication with over-the-counter medications, vitamins and supplements is also common among older adults living in the community. Thirty to thirty-eight percent of prescription drug users report use of over-the-counter agents and 46%–64% report the use of vitamins, herbal products or supplements (Morgan et al., 2012a; Qato et al., 2016). Analgesics (acetaminophen and NSAIDs), antacids, laxatives, and vitamins are reported most frequently (Goh et al., 2009; Qato et al., 2016). Common supplements used included fish oils and glucosamine (Goh et al., 2009; Loya et al., 2009; Qato et al., 2016). Patterns of prescription drug use are somewhat different for residents of long-term care facilities with higher use of antidepressants, antipsychotics, and opioids, although cardiovascular medications (statins, ACE inhibitors, and beta-blockers) are frequently prescribed to this population as well (Canadian Institute for Health Information, 2016; Dwyer et al., 2010; Onder et al., 2012).

Multiple factors are associated with medication use in older persons; including age, gender, presence of chronic diseases, number of health care visits and multiple prescribers (Alldred et al., 2016; Castioni et al., 2017; Hovstadius and Petersson, 2012; Niclos et al., 2018). Among these, age and comorbidity are most frequently identified (Duerden et al., 2013; Hovstadius and Petersson, 2012). As people age, they develop more chronic diseases, resulting in application of disease-based guidelines and increasing numbers of medications prescribed (Canadian Institute for Health Information, January 2011; Department of Health (UK), 2001; Federal Interagency Forum on Aging-related Statistics, June 2016; Wehling, 2011). Guidelines commonly recommend multiple drugs for management of a single condition, resulting in numerous drugs being added to the therapeutic regimen. The impact of guidelines on the number of drugs is more pronounced in those with multiple comorbidities as they see different specialists for each individual condition and have medication prescribed for each disease accordingly (Wehling, 2011). Primary care providers are often hesitant to change or discontinue medications initiated by other prescribers, especially if started by a specialist or during hospital admission, causing the overall number of medications to increase over time (Anthierens et al., 2010). Yet the generalizability of disease specific guidelines in an older, frail population are questionable as this group is usually excluded from clinical trials on which guidelines are based (Bourgeois et al., 2017; Cherubini et al., 2011; Dodd et al., 2011; Konrat et al., 2012). Furthermore, guidelines tend to focus primarily on longevity rather than symptom control without consideration of the time to benefit in the context of life expectancy. This can result in the addition of medications without adequate thought given to the potential benefits of drug therapy versus the risk of medication-related harms based on patient specific factors (Cox et al., 2011; Holmes et al., 2006).

Inappropriate Medication Use

One study of older ambulatory adults found that 16% had a therapeutic duplication, 55% were taking medication without a clear clinical indication, and 30% were taking medications that were ineffective (Rossi et al., 2007). A second study showed that 57% of American veterans were taking at least one medication that was not effective, not indicated or a therapeutic duplication (Steinman et al., 2011). In the nursing home setting up to one-third of residents are prescribed at least one medication that is not clinically indicated (Brulhart and Wermeille, 2011; Silva et al., 2015; Stuijt et al., 2008). Among hospitalized patients, 30% were discharged with at least one medication without a clear indication with 25% of these started during hospitalization (Hajjar et al., 2005).

Rates of potentially inappropriate medication use in older adults vary depending on the population studied and the criteria used to define inappropriate use. Both explicit and implicit criteria are available. Beers, STOPP, and STOPPFrail are examples of explicit criteria whereas the Medication Appropriateness Index (MAI) represents implicit criteria (see "Medication Review" section below for more details on these criteria) (American Geriatrics Society, 2018; Hanlon and Schmader, 2013; Lavan et al., 2017; O'Mahony et al., 2015). Regardless of the clinical setting or the criteria used, the more medications that are taken the more likely a potentially inappropriate medication will be used (Buck et al., 2009; Fialova et al., 2005; Hanlon et al., 2004a; Hudhra et al., 2016). Likewise,

potentially inappropriate medication use, regardless of criteria used, is associated with adverse drug effects and other medication-related harms (Hudhra et al., 2016; Lund et al., 2010; Walsh et al., 2016).

Medication-Related Harms and Adverse Drug Events

Adverse drug events occur frequently in older adults, in outpatient, hospital and long-term care settings (Handler et al., 2006; Maher et al., 2014; Parekh et al., 2018). Adverse drug events are reported in up to 35% of outpatients and 40% of hospitalized seniors (Maher et al., 2014). Furthermore, up to 50% of older adults will experience an adverse drug event upon discharge from hospital (Parekh et al., 2018). In the United States, it is estimated that adverse drug events are responsible for over 3.5 million physician visits, 1 million emergency department visits and 125,000 hospital admissions per year (Office of Disease Prevention and Health Promotion, 2018). Within acute care settings, adverse drug events are estimated to account for one in three hospital-related adverse events and increased length of hospital stay by almost 5 days (Office of Disease Prevention and Health Promotion, 2018). Medications commonly reported as causing adverse drug events include anticoagulants, antihyperglycemic agents, corticosteroids, NSAIDs, opioids, psychotropic medications, and drugs with significant anticholinergic effects (Hanlon et al., 2014; Maher et al., 2014; Onder et al., 2018).

Most adverse drug events in older adults are preventable and result from an exaggeration of the pharmacologic effect of a medication rather than being idiosyncratic in nature. Age-related physiologic changes contribute to the vulnerability of older adults to adverse drug reactions. Reduced elimination of some medications increases both the peak and duration of effect (Reeve et al., 2017; Sera and McPherson, 2012). Changes to receptors may enhance sensitivity to certain agents (Reeve et al., 2017; Sera and McPherson, 2012). Frailty may also play a role as declining functional reserves and impaired homeostatic mechanisms can render an older person more susceptible to the pharmacologic effect of some medications (Hubbard et al., 2013; Reeve et al., 2017).

However, the most important risk factor for adverse drug events is the number of medications that someone is taking. A study of older veterans found that the odds of being hospitalized for an adverse drug event was increased almost three-fold (OR 2.85, 95% CI 1.03–7.85) for those taking five to eight medications and almost four-fold (OR 3.90, 95% CI 1.43–10.61) when nine or more medications were taken (Marcum et al., 2012a). In the long-term care setting, residents taking nine or more medications had twice the odds (OR 2.33, 95% CI 1.54–3.52) of experiencing an adverse drug event in comparison to those taking fewer drugs (Nguyen et al., 2006). Many adverse drug events are related to drug–drug or drug–disease interactions.

The greater the number of medications the higher the probability of a clinically important interaction occurring (Hanlon et al., 2017; Maher et al., 2014). Drug–disease interactions often present atypically as geriatric syndromes (cognitive impairment, falls, and urinary incontinence) or functional decline and may not be recognized as being medication-related (Onder et al., 2018).

Medication Use and the Physiologic Changes of Aging

Normal aging is associated with physiologic changes that alter the pharmacokinetics (absorption, distribution, metabolism, and renal elimination) and pharmacodynamics of medications. These changes contribute to the risk of medication related harms in older adults.

Drug Absorption

Several age-related changes with potential to impact the oral absorption of medications have been reported. These include increased gastric acidity and reductions in gastrointestinal motility, splanchnic blood flow and the surface area of the intestinal mucus membrane (Hubbard et al., 2013). However, recent studies have demonstrated that such changes may not occur in fit or robust older adults (Hubbard et al., 2013). Furthermore, there is little data evaluating the effect of these changes on drug absorption in frail, older individuals (Hubbard et al., 2013).

Drug interactions may be the most important consideration with respect to oral absorption of medications, as administering multiple medications at the same time increases the potential of one drug affecting the absorption of another. For example, administration of L-thyroxine with antacids, calcium and iron supplements, or proton pump inhibitors may impair the absorption of this agent, leading to a poor therapeutic response (Skelin et al., 2017). Likewise, absorption of quinolone antibiotics may be reduced by concomitant use of calcium or iron supplements, resulting in therapeutic failure (Lomaestro and Bailie, 1991). Drug disease interactions may also play a role. Decreased blood flow to the gastrointestinal tract secondary to congestive heart failure can result in poor absorption of some agents used to treat the condition, such as furosemide, compromising the therapeutic response (Delafuente, 2008).

Distribution

Three age-related changes have the potential to alter drug distribution in older adults: (1) reduction in total body water; (2) increase in body fat with a corresponding decrease in lean body mass; and (3) reduction in serum albumin (Delafuente, 2008; Hubbard et al., 2013; Reeve et al., 2017).

Total body water is estimated to decrease by 10%–15% with aging, affecting the distribution of hydrophilic medications such as gentamicin or lithium. This can result in higher serum concentrations in an older adult compared to a younger person given the same dose, thereby increasing the risk of toxicity (Turnheim, 2003). Likewise, a reduced lean body mass will also result in higher serum concentrations of some medications, such as digoxin (Delafuente, 2008). Conversely, increased adipose tissue affects the distribution of lipophilic agents, such as amiodarone or diazepam (Turnheim, 2003). While peak serum concentrations of these agents may be lower, duration of effect can be prolonged as the drug will be stored in the fat tissue, prolonging the half-life (Delafuente, 2008; Turnheim, 2003).

Many medications bind to the serum protein, albumin, which has been shown to decrease by 5%–15% with aging, with further reductions related to frailty (Delafuente, 2008). For highly protein bound medications, such as phenytoin, this can result in an increase in the pharmacologically active unbound drug relative to the inactive bound portion. In most cases, the increased levels of unbound drug are accompanied by an increase in elimination through normal metabolic or renal pathways without any clinically important differences in therapeutic response or toxicity (Reeve et al., 2017). However, for some narrow therapeutic index medications, such as phenytoin, serum concentrations of total drug may fall within the normal range but patients may be exhibiting signs and symptoms of toxicity as total concentrations do not accurately reflect serum concentrations of unbound drug (Delafuente, 2008).

Metabolism

The liver, which functions as the primary site for metabolic elimination of most medications, undergoes a number of age-related changes, although their impact on therapeutic effect and toxicity remains unclear (Delafuente, 2008). Important changes involve reduction in hemoperfusion which affects the bioavailability of some medications subject to high extraction during the "first pass" through the liver (Klotz, 2009). With reduced liver blood flow, less drug is extracted resulting in greater bioavailability and higher serum concentrations (Klotz, 2009). Examples of high extraction drugs with greater bioavailability in older adults include beta-blockers, such as labetalol and propranolol (Klotz, 2009).

Metabolism of low extraction medications is dependent on the amount of metabolizing enzymes present in the liver (Turnheim, 2003). Phase II or conjugation type metabolism is generally not affected by the aging process but some age-related changes to Phase I type metabolism, via the Cytochrome (CYP) P450 system, have been reported (Delafuente, 2008; Turnheim, 2003). Metabolism via the CYP 2D6, CYP 3A4, and CYP 2C9 is generally thought not to be different in older adults, whereas metabolism via CYP 1A2 and CYP 2C19 may be reduced, although the clinical importance of this remains to be determined (Delafuente, 2008).

Elimination

Numerous studies demonstrate that renal function declines with normal aging, related to fewer functioning renal glomeruli, reduced renal blood flow and tubular function (Delafuente, 2008; Hubbard et al., 2013; Turnheim, 2003). On average, creatinine clearance is estimated to decline by 1 mL/min per annum beginning at age 40, requiring that medications predominantly eliminated by the kidney undergo dosage reduction in older adults (Bell et al., 2013; Delafuente, 2008). Presently, the Cockcroft-Gault equation remains the most widely used tool for renal drug dosing in older individuals (Bell et al., 2013; Delafuente, 2008).

Prescribing Cascade

The prescribing cascade may exacerbate issues around medication inappropriateness and polypharmacy. A prescribing cascade is considered to begin when an adverse drug reaction to a previously prescribed medication is misidentified as a new medical condition and a new medication is prescribed to treat the new "medical condition" (Rochon and Gurwitz, 1997). A commonly described example, is the prescribing of a nonsteroidal anti-inflammatory drug that causes an increase in blood pressure that leads to the prescribing of an antihypertensive medication (Rochon and Gurwitz, 1997). An expanded prescribing cascade has recently been proposed that also includes the treatment of the new "medical condition" with nonprescription medications (which may be initiated by the patient) or the use of a medical device (e.g. pacemaker device insertion to treat bradycardia from a drug interaction) (Rochon and Gurwitz, 2017b). Clinicians must keep in mind the prescribing cascade and consider all new signs and symptoms as possibly caused by current therapy. This also serves as a reminder of the importance of reviewing all medications and supplements when reviewing a patient's therapy, as there may be nonprescription medications or supplements being taken that can be causing the symptoms.

Role of Pharmacist

Practice Settings

Pharmacists provide care for older people in a variety of settings, including community pharmacies, outpatient clinics, acute care hospitals, geriatric rehabilitation units, assisted living and long-term care facilities. Reviews of the evidence have shown that pharmacist interventions, regardless of practice setting, reduced the occurrence of drug related problems in the elderly (Hanlon et al., 2004b).

In the community pharmacy, pharmacists see older people in the pharmacy on a regular basis with studies from the United Studies showing that an estimated 55% of adults visit a pharmacy in any given week, 58% in Ireland visit more than once a month and a study from the United Kingdom finding that 70% of those 65–74 and 67% of those 75 and over collecting a prescription from the pharmacy in the previous month, giving the pharmacist many opportunities to review medications (Boardman et al., 2005; Grabenstein et al., 2002; Steyer et al., 2004; The Pharmaceutical Society of Ireland). The identification and management of drug-related problems in older adults by community-based pharmacists have been associated with decreased medication-related problems, including, therapeutic duplication and decreased number of medications used, as well as some indications of improved clinical and economic outcomes (Nkansah et al., 2010; Vinks et al., 2009; Westerlund and Marklund, 2009). In many community-based pharmacy settings, additional medication management services also include formal medication reviews, which have been shown in a review of systematic reviews to result in a range of benefits for clinical outcomes (Jokanovic et al., 2017).

In long-term care, pharmacists provide a variety of clinical services, including regular medication reviews (often 2–4 times per year), family care conferences, and consultations with the interprofessional team. Pharmacists are often charged with keeping statistics on medication use and ensuring formulary medications are used. Pharmacists in long-term care settings have been shown to improve care through identification and resolution of medication-related problems (Pepe et al., 2018; Thiruchelvam et al., 2017a).

In acute care, clinic and rehabilitation settings pharmacists often review older people's medications on admission and then offer further recommendations during rounds (which may be daily or several times per week) with the team and through chart notes. Their involvement has been shown to improve medication use, including decreased medication errors, improved monitoring of potential drug interactions and decreased use of potentially inappropriate medications (Cortejoso et al., 2016; Komagamine and Hagane, 2017).

As members of interprofessional teams, pharmacists are the medication experts, providing medication recommendations for optimal patient care. Studies have shown that the addition of a pharmacist on the team results in improvement of chronic disease management and quality use of medicines (Chisholm-Burns et al., 2010; Tan et al., 2014).

Preventing Adverse Drug Reactions

A key role for pharmacists in the care of older people is in preventing adverse drug reactions (ADRs). Due to a variety of reasons, older people are at greater risk of adverse reactions to medications, even at appropriate doses. It is estimated that ADRs occur 10%–35% annually in community-dwelling adults and that nearly 9% of hospital admissions are due to ADRs in older adults (Gray et al., 1999, 2018; Oscanoa et al., 2017). Active monitoring for adverse effects should take place in all clinical settings (Steinman et al., 2011). Pharmacists can play a key role in this active monitoring by regularly reviewing the medications of their older patients to ensure that adverse reactions are not experienced. It may not be obvious that an adverse reaction is related to a medication, as another medication has been prescribed to treat the adverse reaction, which is then not apparent (prescribing cascade), but adds to pill burden and potential for further adverse reactions. Medication reviews are often the mechanism for finding and preventing adverse drug reactions with varying levels of evidence seen in each clinical setting.

Medication Reviews

Pharmacists lead medication management efforts through a variety of interventions. One of the most studied is medication reviews, which can be performed in a variety of settings. Medication reviews has been defined as "a structured, critical examination of a patient's medicines with the objective of reaching an agreement with the patient about treatment, optimizing the impact of medicines, minimizing the number of drug-related problems (DRPs) and reducing waste" (Clyne et al., 2008).

Medication reviews in community settings have been shown in an overview of 31 moderate to high quality systematic reviews to improve medication management, including identification and resolution of drug-related problems, and some studies also showed improvement in surrogate markers for chronic disease management and improvements in the number and appropriateness of medications (Jokanovic et al., 2017). The same overview also found improvements reported in medication adherence and quality of life for those completing a medication review with a pharmacist (Jokanovic et al., 2017).

A systematic review from 2017 of the impact of medication reviews on medication use in residential aged care facilities (also known as long-term care) included 20 studies (Thiruchelvam et al., 2017b). Of those 8 of the 12 clinical trials were pharmacist-led medication reviews and the remaining four were team-based reviews and 8 of the 10 observational studies were pharmacist-led medication reviews with 2 being team-based reviews (Thiruchelvam et al., 2017b). The review found reductions in the number of medications prescribed, reductions in inappropriate medications, and reductions in adverse outcomes (e.g. deaths, hospitalization) in the groups that received medication reviews (Thiruchelvam et al., 2017b).

Medication reviews are often not completed or studied as a separate component of medication management in hospital, compared to community and long-term care and are often imbedded within general medication management services. Many studies have instead focused on medication reconciliation, which is generally considered a technical function and not extensive like a medication review, although it may be a component of a medication review (Mekonnen et al., 2016). Despite this, a recent study conducted in Canada found that early in-hospital medication review in the emergency department reduced hospital-bed utilization in high-risk patients under 80 years of age compared to those who did not receive medication review (Hohl et al., 2017b). Unfortunately, the benefits were not seen in those over 80 years of age (Hohl et al., 2017b). A study form Ireland found that pharmacist-led medication reviews in hospital prevented adverse drug events and benefited females and those 65 years of age and older the most (Kearney et al., 2017).

A variety of tools exist to assist pharmacists in identifying the medications that may be most harmful during medication reviews. A few are summarized below.

Beers Criteria

The Beers Criteria was first published by the American Geriatrics Society (AGS) in 1991 as a list of potentially inappropriate medications to use in older adults (Beers et al., 1991). Publication of the 2018 update is pending (American Geriatrics Society, 2018). In the interim, the 2015 version is the current version being used (By the American Geriatrics Society 2015 Beers Criteria Update Expert Panel, 2015). The Beers Criteria presents a list of medications where the risk of harm outweighs potential

benefits (American Geriatrics Society, 2018). It also lists high-risk drug–drug interactions to avoid and identifies agents requiring renal dosing adjustments (American Geriatrics Society, 2018). The various iterations of the Beers Criteria have been found to be helpful in reducing inappropriate medication usage through identification of medications associated with health issues, such as confusion, falls, and mortality that can be avoided when prescribing or considered for stopping (By the American Geriatrics Society 2015 Beers Criteria Update Expert Panel, 2015).

STOPP/START and STOPPFrail

First published in 2008 as a screening tool for reviewing medications in older people with a list of criteria for medications that may be inappropriate and reviewed with consideration to STOPP (Screening Tool of Older Persons' Prescriptions) and criteria for potentially indicated medications that should be reviewed for consideration to START (Screening Tool to Alert doctors to Right Treatment) (Gallagher et al., 2008). The tool was updated to add in additional evidence-based criteria and remove any obsolete criteria with version 2 being published in 2014 (O'Mahony et al., 2015). STOPP criteria includes medications that present a high risk relative to benefit in older adults, increase the risk of falls, clinically important drug–drug and drug–disease interactions as well as common therapeutic duplications (O'Mahony et al., 2015). STOPPFrail is similar to STOPP but incorporates frailty and life expectancy (Lavan et al., 2017). STOPP/START has been validated and used in a variety of settings, including community practice, acute care and long-term care, and in several jurisdictions (including Europe, Asia, and North America) (Hill-Taylor et al., 2013). The strongest evidence for benefits of its use are in acute care and long-term care settings, where it has been shown to reduce use of potentially inappropriate medications, reduce falls, and decrease length-of-hospital stay and costs (Hill-Taylor et al., 2016; O'Mahony et al., 2015). Evidence for its usefulness in community practice are not as strong, with one study finding that most drug-related problems identified during a medication review not being associated with STOPP/START criteria (Verdoorn et al., 2015).

Comparisons of STOPP/START and Beers

The Beers Criteria, STOPP, and STOPPFrail criteria are grouped by organ system and provide explanation as to why a particular medication is considered to be potentially inappropriate (American Geriatrics Society, 2018; Lavan et al., 2017; O'Mahony et al., 2015).

A study published in 2016 compared Beers 2003, Beers 2012, STOPP/START version 1, and STOPP/START version 2 in reviewing patient medications in an acute geriatric medicine unit and found STOPP/START version 2 resulted in the greatest reduction of medications (Boland et al., 2016). A study published in 2018 compared Beers 2015 with STOPP version 2 to assess frequency and factors associated with potentially inappropriate medication use, as well as patients' satisfaction (Sakr et al., 2018). More potentially inappropriate medications were identified with Beers 2015 criteria compared to STOPP criteria, but noted that Beers is less specific, as it does not take the patient's clinical condition into consideration (Sakr et al., 2018). Patient satisfaction was increased with the absence of potentially inappropriate medications, regardless of the tool used (Sakr et al., 2018).

Drug Burden Index

The Drug Burden Index (DBI) is an evidence-based risk assessment tool developed to measure the cumulative exposure to anticholinergic and sedative medications commonly used in older adults (Hilmer et al., 2007). DBI score has been found in many studies across many countries (Australia, Canada, Finland, the Netherlands, New Zealand, UK, and US) to be associated with poorer physical function, reduced quality of life, frailty, falls, and hospital readmission (Kouladjian et al., 2014). DBI may be used to target medications that may be considered for discontinuation.

Medication Appropriateness Index

The Medication Appropriateness Index guides clinical judgment through the use of ten questions about clinical indication, therapeutic duplication, medication effectiveness given patient specific factors, dosing and duration of therapy, practicality of directions, drug–drug and drug–disease interactions as well as cost considerations (Hanlon and Schmader, 2013). Higher MAI scores have been significantly associated with unscheduled ambulatory or emergency department visits, hospital admission, and lower quality of life (Hanlon and Schmader, 2013).

Once potentially inappropriate medications are identified, a planned approach to decreasing doses and/or discontinuing medications can be planned.

Screening and Monitoring

Pharmacists frequent encounters with patients in the community offer many opportunities to screen for potential health issues, such as dementia. A community pharmacist with regular interaction with an older person can often notice changes in cognition before it is apparent to other care providers who may see the patient less often. Pharmacists in community may then screen these individuals using validated tools, such as the Mini-Mental State Exam (MMSE) and Montreal Cognitive Assessment (MoCA) (Nasreddine et al., 2005; Tombaugh and McIntyre, 1992). The MMSE was developed as a brief screening tool to assess the severity of cognitive impairment and document change over time (Tombaugh and McIntyre, 1992). The MoCA was also developed as a brief screening tool, but with a focus on identifying those with mild cognitive impairment that may have scored within the normal range on the MMSE (Nasreddine et al., 2005). If the practice setting and skillset of the pharmacist allow, a comprehensive geriatric assessment may also be performed (Rockwood et al., 1998). Results can be used to follow up with the primary care provider. Ongoing

monitoring may be performed by the pharmacist to ensure any medications started, such as cholinesterase inhibitors, are meeting the goals of therapy. Pharmacists in other settings may also use these tools for screening and monitoring; however, it is more likely that other team members may be completing the tests or that the pharmacist has a specialized role, such as in an ambulatory geriatric clinic, in which it is part of their usual practice to use these screening tools.

Economic Considerations

Many older people are on fixed budgets due to limited pensions and government supports. Despite many jurisdictions providing some insurance coverage to older people, not all do, and when they do there are often co-payments and medications that are not covered. Pharmacists should have an understanding of the funding supports for older people in their jurisdiction, so they can serve as an advocate for older people by ensuring that medications used are not only safe and effective, but also acceptable financially.

Dosing/Formulations

Dexterity decreases with age and with many conditions, such as osteoarthritis. Ensuring that medication supplies are provided in a way that is usable by the patient, such as easy open vials and accessible multidose packaging, is an important component of medication management. Counseling on the importance of keeping medications that are not in safety formats (e.g. child-resistant safety vials) away from children and pets is a crucial component of easy access medication packaging.

Some older people will have difficulty swallowing, so consideration for alternate formulations (e.g., liquid, dissolvable) and specialty compounding must be considered. When splitting or crushing tablets, use drug information resources available to ensure it is safe and that a controlled-release mechanism is not altered. The same with opening capsules, ensure the capsule is not required for appropriate drug delivery (e.g. delayed release).

Adherence Aids

A variety of options can be used to assist in adherence. Creating medication calendars that patients can mark off each day may assist some people. Others may be more tech savvy and benefit from alerts on smartphones. Frequently multidose, multidrug packaging is used, such as blister packages and refillable dosettes. Ensuring that patients and caregivers understand how to use the packaging is important and often missed. Automatic refills and refill reminders may also assist with adherence.

Another way to improve adherence is simplifying medication regimens, ideally to once-daily dosing, as more frequent dosing is associated with decreased adherence (Claxton et al., 2001; Coleman et al., 2012). When possible, choose medications with less frequent dosing and if appropriate dose at the same time, for example if all medication are dosed once daily, give them at the same time, such as the morning, unless they must be spaced due to a potential drug interaction or a medication must be given at bedtime. Regular medication reviews and deprescribing should also assist in streamlining the medication regimen and minimizing pill burden.

Communication

Many older people have hierarchical views on healthcare and will see the physician's orders as more important than pharmacist recommendations. It is key to communicate in a professional manner that does not undermine other professionals, while still ensuring the appropriate medications are used and dosages adjusted if necessary. Making it clear that the pharmacist is part of the care team and works closely with the physician or other primary care provider to ensure optimal medication use may improve acceptance of medication changes.

Some older adults may have low levels of education and health literacy. Ensuring they understand how to properly use medications and know when to follow up with the pharmacist and/or other primary care provider may take additional communication strategies. Avoid asking questions like "Do you have any questions?" and "Do you understand?", as these closed-ended questions will often prevent further communication. Additional notes on medications may be required to assist in understanding instructions on use, such as adding images to vials, like a rising sun for morning and a moon for bedtime.

Older adults have declining vision and may require larger font sizes on printed materials. Other strategies such as use of magnifying glasses, pictorial labels, different textures and shapes of containers, and audible labels may also help (Smith and Bailey, 2014). Clear verbal communication is crucial to ensure understanding. Recorded messages around medication use and instructions may also be useful.

Decreased hearing is also common with aging. Many older people find coping strategies for loss of hearing, such as reading lips. When possible, be aware if there is a "good ear" and "bad ear" and try to position yourself on the "good ear" side. If they prefer to read lips, then ensure you enunciate well, face them straight on, and avoid looking away.

Older adults with cognitive impairment and early dementia may have diminished capacity, but are still able to care for themselves and make decisions. They may require more discussion and time to comprehend instructions. Keep this in mind during communications.

It is also important to keep in mind that older people often share medications with friends, family, and acquaintances. A 2014 systematic review summarized 19 studies from 9 countries and found 5%–51.9% of people (children to older adults) borrowed

prescription medications and that 6%–22.9% loaned prescription medication to someone else (Beyene et al., 2014). This reinforces the significance of pharmacists providing clear communication to all patients, including their elderly patients, about the importance of prescription medications being intended for an individual patient and not taking from others or loaning to others.

Clinical Pharmacy Considerations in Special Population: Pediatrics

Sara M. Hanning*, Natalie J. Medlicott†, Elizabeth A. Oliphant*,‡, *School of Pharmacy, The University of Auckland, Auckland, New Zealand; †New Zealand's National School of Pharmacy, University of Otago, Dunedin, New Zealand; ‡Starship Children's Health, Auckland District Health Board, Auckland, New Zealand

Learning Objectives

At the end of this chapter, the reader should be able to:

- Describe the physiology of the developmental stages of the pediatric population and how this influences pharmacokinetics;
- Explain off label and unlicensed medicine use for children;
- Recall the importance of formulations with respect to pediatrics;
- Describe the role of the pharmacist in caring for pediatric patients.

Take Home Messages

- The field of pediatrics covers a vast and diverse population, ranging from extremely premature neonates born from around 23 weeks gestation and weighing less than 1 kg, to adolescents approaching adulthood, who on occasion may weigh over 100 kg.
- Significant changes to pharmacokinetic parameters occur as a child develops from birth to adolescence. The three principle contributors to pharmacokinetic variability are size, maturation and organ function. Maturation and organ function primarily

affect children under two years old, whereas in children over two years old, size is the main factor differentiating a child from an adult.

- Dosage forms are particularly important in the pediatric population and need to be able to cater to vastly different sized patients, as well as being suitable for administration to developmentally diverse patients. A lack of licensed products continues to hinder the safe and effective use of medicines in children, and manipulation of products designed for adults is often required to enable the treatment of children.
- Excipients should not be considered inert components of medications. The ability of infants and children to metabolize and eliminate excipients may differ from adults, and thus the potential for toxicity or other unintended effects on the child should be considered when formulation is being selected, especially where multiple medications are used.
- In pediatric practice, the child must be cared for in the context of their family situation, with care taken to provide information, education and advice to both child and parent in line with the age and developmental stage of the child. Information and advice may also need to be provided to those who provide care and/or education to the child. As the child matures, their increasing autonomy should be respected and competence to consent to their own treatment considered.
- With the ongoing increase in professional roles available to pharmacists, pediatric-centered roles are emerging in vaccination, health promotion, primary health care and education, as well as more advanced clinical roles, including prescribing.

Introduction

The phrase "children are not small adults" has become an apt yet somewhat cliché statement when discussing medication for children. It refers to the fact that the pharmacokinetic and pharmacodynamic response to a medication in a child cannot be predicted by extrapolating adult data alone. Children differ to adults in size, body composition, bodily function, sensory maturity, and drug handling ability. Significant variation exists even within the pediatric population. The term pediatric encompasses neonates through to adolescents, with distinct physical, metabolic, and psychological differences across this age range. Further, the spectrum of diseases is broad, ranging from mild self-limiting illnesses to fatal disease, including those seen exclusively in children through to genetic disorders that present during childhood, as well as many of the same conditions seen in adults.

The International Council for Harmonisation of Technical Requirements for Pharmaceuticals for Human Use (ICH) E11 classification divides the pediatric population into neonates (covering preterm and full term newborn infants from birth to 27 days old), infants and toddlers (28 days to 23 months), preschool children (2–5 years), school children (6–11 years), and adolescents (12 up to 16 or 18 years, depending on region) (European Medicines Agency, 2001). In practice, preschool and school children are generally combined and adolescent dosing often mirrors that of an adult. This classification system is aimed at the pharmaceutical industry to rationalize medicine licensing in children. However, many medicines are not licensed for use in children, resulting in nearly 70% of children hospitalized in both Europe and the United States (US) receiving at least one unlicensed or off-label medicine during a hospital stay (Conroy et al., 2000; Yang et al., 2011). Where a medicine is used in this way, safety, quality, and efficacy cannot be assumed and pharmacists have an important role in ensuring that the medication is appropriate for a patient given the limited information available. In 2007, the European Union (EU) introduced a Pediatric Regulation with the view of improving the health of children up to 18 years of age by supporting the development and accessibility of medicines for children and improving data available regarding their use. The Pediatric Regulation offers incentives for manufacturers to investigate drug development for children prior to marketing authorization of new drugs. However, there are ethical, technical, and practical challenges involved in conducting pediatric clinical trials, which perhaps explains why only three pediatric use marketing authorizations have been granted in the ten years since inception of the Regulation in 2007 (Tomasi et al., 2017). Similarly, the US Food and Drug Administration (FDA) have the Best Pharmaceuticals for Children Act (last amended 2007). The US and EU represent large pharmaceutical markets for newly developed drugs and have the potential to influence the global pharmaceutical industry.

This chapter will explore pertinent considerations for a pharmacist with regard to medicines use in children. These include dosage form, dosing and off label medicine usage. Specific conditions will not be discussed in detail. The pharmacist plays a vital and varied role in ensuring children receive effective medicines that are also safe. The role of the pharmacist will be discussed in detail later on in this chapter.

An Overview of the Pediatric Population

A normal pregnancy is considered to be 40 weeks from the first day of the last menstrual period and a baby born before 37 weeks gestation is defined as preterm. Births at less than 28 weeks are classed as extremely preterm, but as most infants born from 25 weeks onwards respond well to initial stabilization in the delivery suite they routinely receive neonatal intensive care in well-resourced settings. Resuscitation is not usually performed in neonates born at less than 23 weeks gestation as they rarely survive long enough to be discharged from hospital and may have overwhelming disability. Given the significant maturation that occurs across this gestational period, the developmental differences between patients at birth can be significant.

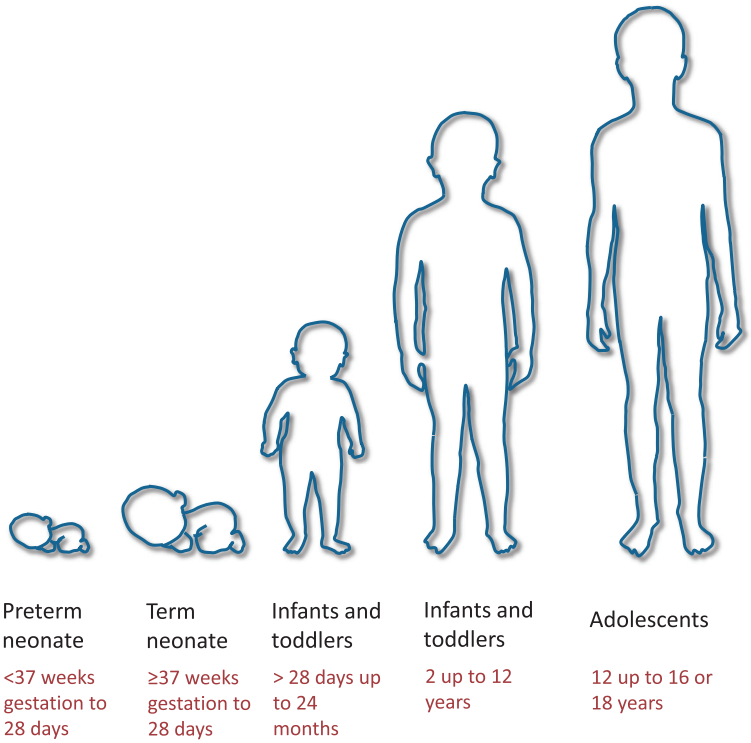

Figure 1 Developmental age groups for drug dosing.

Physiology

Significant physiological changes occur throughout childhood as organ systems develop and mature, particularly during the first 12 months of life and then again at puberty. Although puberty involves marked physiological changes, there is limited impact on drug handling. Developmental changes in the first 12 months of life have the most significant implications for drug therapy as these changes affect the pharmacokinetics of drugs. Different doses (e.g., mg kg^{-1}) or dosing intervals may be required, and adverse effects may be more prevalent if these changes are not taken into account. Additionally, some drugs may not be effective for all age groups. For example, sucrose is an effective analgesic for minor procedures in neonates (though the optimal dose has not been identified), but is ineffective in older children (Stevens et al., 2013). The age brackets that are often considered pharmacologically important for drug dosing are shown in Fig. 1.

Pediatric vital signs are considerably different to adult values and change with age. These changes are outlined in Table 1.

The transition from fetus to neonate involves substantial cardiovascular changes triggered by aeration of the lungs. Before birth, lungs are filled with fluid and gas exchange takes place across the placenta. Blood bypasses circulation to the lungs, instead being shunted from the aorta to the left pulmonary artery via the ductus arteriosus. Within minutes of birth, aeration of the airways and gas exchange region of the lungs takes place as a result of the hydrostatic pressure gradient created when the neonate first inhales.

Table 1 Pediatric normal vital signs according to age

Age	*Heart rate (beats per minute)*	*Blood pressure (mm Hg)*	*Respiratory rate (breaths per minute)*
Premature	120–170	55–75/35–45	40–70
0–3 months	100–150	65–85/45–55	35–55
3–6 months	90–120	70–90/50–65	30–45
6–12 months	80–120	80–100/55–65	25–40
1–3 years	70–110	90–105/55–70	20–30
3–6 years	65–110	95–110/60–75	20–25
6–12 years	60–95	100–120/60–75	14–22
12+ years	55–85	110–135/65–85	12–18

Source: Reprinted from Hartman, M.E., Cheifetz, I.M., 2016. Pediatric emergencies and resuscitation. In: Kliegman, R., Stanton, B., St Geme, J., Schor, N. (Eds.), Nelson Textbook of Pediatrics, 20th ed., with permission from Elsevier.

Initiation of breathing involves the interaction of biochemical, neural, and mechanical factors (Alvaro and Rigatto, 2012), triggering a decrease in pulmonary vascular resistance and subsequent increase in pulmonary blood flow. After birth, the ductus arteriosus is no longer required and generally closes within two days. This significant rearrangement in circulation is essential for survival and results in a circulatory system that mirrors that of an adult. The transition can be difficult for preterm neonates, whose lungs are immature, and lung injury can result from mechanical ventilation. Sometimes, the ductus arteriosus does not close, a condition called patent ductus arteriosus. When medical treatment is required to close this duct, nonsteroidal antiinflammatory drugs (NSAIDs) such as indomethacin or ibuprofen are often the first choice. More recently, paracetamol has been reported to be an alternative option with fewer side effects (Dang et al., 2013; Dowd et al., 2018). If these medical treatment options are contraindicated or unsuccessful, then a surgical procedure may be required.

Pharmacokinetic Changes

An understanding of pharmacokinetics is essential in determining the dose needed to achieve the target concentration of a medicine for therapeutic effect. In children, the three principal contributors to pharmacokinetic variability are size, maturation, and organ function. Maturation and organ function primarily affect children under two years old, whereas in children over two years old size is the main factor differentiating a child from an adult (Anderson and Holford, 2013). Changes in pharmacokinetic parameters that occur throughout childhood are detailed below.

Absorption

Absorption describes the distribution of a drug from site of administration into the plasma and is a fundamental step prior to drug action for all routes of administration except intravascular, when drug is delivered directly into the systemic circulation. Three factors that influence drug absorption and are different in pediatrics compared with adults are gastrointestinal (GI) function, blood flow to the site of administration and skin permeability.

The surface area of the GI tract is proportionately larger in infants compared with adults, which can lead to varied drug absorption that cannot be directly predicted from adult data. Gastric emptying time is unpredictable and irregular in neonates, although this may be due to food type as opposed to age (Bonner et al., 2015). Variation in gut microflora and high levels of beta-glucuronidase add to the variability of oral absorption. It is well reported that the gastric pH is neutral at birth, but information regarding the maturation of pH over this neonatal period is contradictory (Yu et al., 2014). Premature neonates have a relatively higher gastric pH due to reduced acid secretion by the immature gastric mucosa. This can lead to higher absorption of acid labile drugs such as penicillin and reduced absorption of weak acids such as phenobarbitone. By the age of 12, the structure and function of the GI tract is comparable to that of an adult.

Absorption (particularly from the intramuscular route) is affected by blood flow at the administration site. While neonates have reduced muscle blood flow and contractions, there is also a rich supply of capillaries so intramuscular absorption may be higher in infants than in older pediatric patients (Anderson, 2017). Rectal absorption also depends on blood supply, which varies depending on placement of the dosage form (usually suppository or enema) within the rectum. Rectal absorption can therefore be difficult to predict in children, particularly in neonates.

Neonates have thin, permeable skin and throughout childhood the epidermis is hydrated and perfused more so than in adults. The surface area to body volume ratio in neonates and young children is also greater than in adults. This facilitates higher systemic absorption of topically applied drugs than occurs in adults, including of topical steroid creams, and this may lead to systemic effects and toxicity.

Distribution

Drug distribution in pediatrics is influenced by differences in body composition, low levels of plasma proteins, and maturity of physiological barriers such as the blood brain barrier. These factors change as a child grows and alter the distribution of a drug in the body. Bodyweight alone may vary by over 100-fold in the pediatric population. Premature neonates can be born as young as 23 weeks gestation weighing less than 500 g and obese adolescents can weigh greater than 100 kg.

Neonates and infants have a lower percentage of body fat than adults with a body composition reported to be about 75% water, compared with 50%–60% in adults (Woo, 2004). Therefore, larger doses relative to body weight of water soluble drugs (such as gentamicin) and lower doses of lipid soluble drugs (such as diazepam) are often required (Conroy, 2003). One measure of size is body weight, which is often used to calculate pediatric drug doses. However, there is debate around whether this is appropriate (Anderson and Holford, 2017; Young and Korotzer, 2016), particularly as body weight is not directly proportional to pharmacokinetic parameters. Further, as childhood obesity becomes more endemic (Skinner et al., 2018), body composition and drug lipophilicity are becoming increasingly important considerations. Doses should be capped (usually at the adult dose) for any given drug, even if the child's body weight suggests otherwise based on pediatric weight-based dosing.

Serum albumin, alpha-1-acid glycoprotein and total protein concentrations are lower than adults in the first year of life, resulting in lower levels of plasma protein binding and higher levels of the free drug. This means that lower total drug concentrations may be necessary to avoid drug toxicity and have the same effect seen in older children and adults. However, there is still considerable debate in the literature on whether changes in protein binding result in sufficient changes in free drug concentration to cause clinically significant adverse effects, if drug clearance is unchanged. In the neonate and especially the preterm neonate, reduced drug clearance is often seen and it may be this effect that dominates so that dose reduction is required (Anderson, 2017). Adult levels of albumin are

observed from about 12 months of age (Suggs, 2000). Protein binding is further altered in neonates due to increased competition from bilirubin and free fatty acids. In neonates, the blood brain barrier has higher permeability, which can lead to an increase in drug distribution to the brain and enhanced central nervous system effects at equivalent mg kg^{-1} doses.

Metabolism

Drug metabolism occurs via enzymatic reactions, mostly in the liver. Neonates have immature livers, so cannot metabolize foreign substances as well as children and adults. By the time a child is a year old, liver enzyme activity has increased such that the rate of drug metabolism is typically higher than adults, which can lead to a shorter plasma half-life for drugs primarily eliminated by hepatic metabolism. This is most likely due to their larger size of the liver relative to the body. Metabolic pathways mature at different rates, so the predominant pathway may differ with age. For example, glucuronidation is reduced in neonates, which can lead to accumulation of drugs that are metabolized via this pathway. Sulfation is higher in neonates than older children and adults (Miller et al., 1976). As a result, paracetamol is primarily metabolized by sulfation in neonates rather than glucuronidation, but the sulfation pathway is more easily saturated. To overcome these issues, paracetamol doses used in neonates are lower than in infants and older children (Anderson et al., 2000). Chloramphenicol accumulates in neonates as it cannot be efficiently glucuronidated, leading to toxicity known as "Grey Baby Syndrome" with symptoms including cyanosis, abdominal distension, vomiting, cardiovascular collapse, irregular respiration, and in some cases death (Mulhall et al., 1983).

Excretion

Elimination of most drugs or their metabolites occurs in the kidneys through glomerular filtration, active secretion and tubular secretion. Only free drug is filtered by the glomerulus and excreted. Neonates have reduced renal excretion due to functionally immature kidneys, leading to a longer half-life for drugs excreted primarily via this organ. Elimination rate rapidly increases after the first week of life as glomerular filtration rate (GFR) increases (**Fig. 2**). Adult parameters for GFR are reached by 9 months and tubular function matures when the infant is about 12 months old. GFR is the most useful indicator of kidney function and creatinine clearance is often used as a marker for GFR. The Schwartz equation is the most widely used formula for estimating GFR in children. It has been modified several times since it was first developed in the 1970s and uses serum creatinine, height and an empirical constant to estimate the GFR (Schwartz et al., 1976). In the first week of life, creatinine levels in the neonate reflect that of the mother, therefore, GFR is difficult to estimate. No single method for predicting pediatric drug clearance based on adult values is suitable for all drugs or all age groups (Mahmood, 2006). However, as neonates have significantly lower renal function compared with adults,

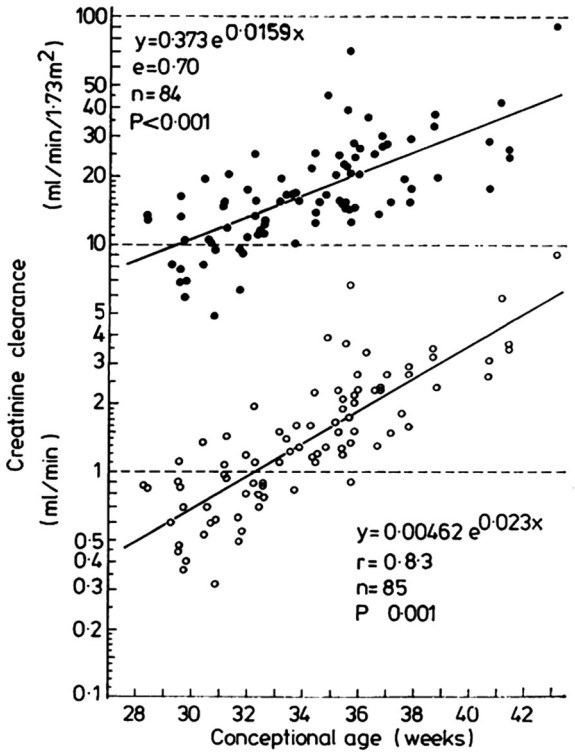

Figure 2 Creatinine clearance, corrected (closed circles) and uncorrected (open circles) for body surface area, plotted against conceptional age. In this and subsequent figures the regression statistics were calculated from x (conceptional age) expressed in days, although the axis is marked in weeks for convenience. *Source: Reprinted with permission from Al-Dahhan, J., Haycock, G.B., Chantler, C., Stimmler, L., 1983. Sodium homeostasis in term and preterm neonates. I. Renal aspects. Arch. Dis. Child. 58, 335–342.*

Table 2 Factors that influence administration of a medicine

Influence	*Explanation*
Capability	Relates mostly to age, physical development, and coordination, but also psychological development and understanding
Influence of illness	Acute illness may lead to a child being frightened and uncooperative. Vomiting may limit use of oral route. Children requiring continuing medication for long-term illnesses can be trained/persuaded to take their medicine, but to improve compliance it is ideal to have a range of dosage forms so pediatric patients and caregivers have a choice
Convenience for parent/caregivers	In addition to child preference, ease of administration for parent/caregivers requires consideration
Childcare/school	Clear instructions and route of administration are important when a medicine needs to be given at childcare facilities/school. The development of longer acting formulations may be required to avoid administration during school hours
Adolescence	As adolescents develop independence, they will often become responsible for their own medicine administration. There is a chance of rebellion where they will reject medicines previously taken and discrete, portable forms are important
Disability	Some disabilities may limit the ability for a pediatric patient to take their own medicine and limit appropriate dosage forms
Cultural differences	Acceptability of different routes of administration and taste may differ by geographical region as well as religion

dose adjustments are required to maintain a constant drug level and prevent overdose in the same way as adults with renal impairment. This may be achieved by decreasing the dose, increasing the dosing interval, or a combination of these two approaches. For example, the dose and frequency of gentamicin varies depending on gestational age at birth and postnatal age.

Dosage Forms for Children

When it comes to medicines for children, dosage form becomes important. The ability for a child to take a medicine is influenced by a number of factors, which are summarized in **Table 2**. Flexible dosing is required so that a single formulation may be used for a broad range of ages and bodyweight. Whereas solid oral dosage forms such as tablets and capsules are the most commonly used and desirable form in adults, many children cannot swallow these dosage forms and the strengths are often inappropriate, especially for young children. The age at which a child is able to swallow solid oral dosage forms varies considerably between children and depends on the formulation, especially tablet or capsule size. Oral liquid dosage forms offer flexible dosing and are considered easier for children to swallow. However, accurate measurement devices are needed to obtain correct dose volumes and the toxicity of excipients needs to be considered, especially in the very young neonate.

A variety of more patient centric dosage forms are being developed, which have the potential of improving dosage forms for children (Hanning et al., 2016). For more detailed descriptions of dosage forms being developed for children, the reader is referred to the additional reading section at the end of this chapter. A summary of some key advantages and disadvantages of dosage forms to consider for pediatrics are presented in **Table 3**. It is important that the pharmacist understands these dosage forms in order to explain to children and their caregivers and in some cases, prescribers, about their use.

Neonatal Considerations

Neonates in intensive care are exposed to many drugs via intravenous (i.v.), enteral, and other routes. Inserting an i.v. line into a neonate can be a significant challenge due to their small, fragile veins. Maintaining i.v. access using peripheral catheters is difficult in this population, so where prolonged i.v. access is needed, a peripherally inserted central catheter (PICC) is often placed. Placement of a PICC can be difficult and complications include infiltration, phlebitis, occlusion, leakage, effusion and edema (Colacchio et al., 2012). Alternatively, central catheters can be inserted via the umbilical vein or arteries in the first day of life, and provide relatively easy access to the central circulation for the administration of medications, fluids, and for blood sampling.

Challenges in i.v. drug delivery include flow rate, fluid volume and accuracy of volume. Typically, an i.v. fluid infusion rate of 10–20 mL h^{-1} is appropriate for a full term neonate and 3–5 mL h^{-1} for a neonate weighing less than 1 kg (Koren, 1997). Neonates often require small doses of medication, which, combined with the slow infusion rate, can mean that it takes a long time for the drug to reach the bloodstream. An example is gentamicin, where dose volume can be as low as 0.2 mL. It has been demonstrated that there is a discrepancy between the intended and actual dose of gentamicin received following infusion of low dose volumes of less than 1 mL into slow-flowing lines over 30 minutes (Sherwin et al., 2009). A proposed solution to ensure complete and timely gentamicin delivery is to inject a bolus of low-dose-volume drug solution into a slow flowing line, followed by an appropriate fluid volume to flush the drug from injection site into the patient (Medlicott et al., 2013).

The risk of error is compounded when using low dose volumes, where rounding doses and manipulation of dosage forms become essential when appropriate dosage forms are not available. Manipulation increases the risk of computational error and rounding can significantly alter the dose. Rounding should be accounted for at the point of prescribing so that the person administering the medicine (usually nurse or caregiver) is not faced with an unmeasurable volume. It is generally considered acceptable to report up to two decimal places so long as an appropriate measuring device is available and those measuring are

Table 3 Possible advantages and disadvantages of dosage forms for delivery of medicines to the pediatric population

Dosage form	*Possible advantages*	*Possible disadvantages*
Oral tablets, capsules	Commercially available Quality assured	Dose adjustment difficult Difficult for children to swallow
Oral mini tablets	Small enough for children as young as 6 months to swallow	Possible/perceived choking risk May need to take many tablets to achieve desired dose
Oral liquids (solutions, syrups, suspensions, emulsions)	Flexible dosing possible Generally considered the most appropriate option for children from birth to 8 years	Task masking and stability can be challenging Many drugs are not commercially available in this form, require extemporaneous compounding and information around this may be limited
Orodispersible/chewable dosage forms (films, tablets, wafers)	No need to swallow an intact tablet Easy to administer	Flexible dosing difficult Possible choking risk Acceptable mouthfeel and taste masking is challenging
Rectal suppositories/enemas	No need to mask the taste of drug Avoids enteral route	Not suitable for all drugs Not considered acceptable by some patient groups Variable absorption, can be erratic especially in neonates
Subcutaneous injection	Suitable when enteral route not appropriate Less invasive than i.v. or i.m.	Painful Requires frequent administration Only useful for small volumes
Intravenous injection	Fast acting Rapid response to dose titration Overcomes any problems with absorption	Requires trained personnel Increased risk of infection May be difficult to access vein Not generally suitable for long-term treatment
Intramuscular injection	Fast acting Possibility of prolonged duration of action	Painful due to lower muscle mass, reduced muscle perfusion especially in infants
Topical creams, gels, ointments	Local drug delivery Ease of administration	Higher risk of toxicity from drug and/or excipients in neonates and infants If not rapidly absorbed, may be wiped off by child
Transdermal	Long acting Painless Easy to administer	Difficult to adjust dose Absorption may be higher in neonates and young children than in older children
Inhalers	Rapid acting local drug delivery to lungs Spacer or mask can be used with metered dose inhalers to enable administration to young children	Not all devices (nebulizers, dry powder inhalers) are suitable for young children
Eye, ear, nasal drops, and sprays	Local drug delivery	Difficult to administer particularly to young children Absorption may be higher in neonates and young children

familiar with using the device accurately. Ensuring dose accuracy in enteral syringes is difficult, with heterogeneity when using different syringe brands, sizes, and dose volumes. This highlights the importance of using the closest syringe size to the dose volume and avoiding small volumes (0.25 mL and less) (Arenas-Lopez et al., 2017).

Excipients

Recommending an appropriate pediatric formulation requires consideration of both the active pharmaceutical ingredient and the excipients. Excipients are defined as everything in a formulation other than the active drug. This includes flavoring agents, coloring agents, preservatives, suspending agents, fillers, and solubilizers. While excipients have been historically considered to be inert components of a formulation, it is now well known that excipients have their own toxicity issues, safety concerns, and potential for allergic reactions (Table 4). Excipients are important components of all medicinal products, especially for pediatric formulations where oral liquid dosage forms are often desired. Some excipients that are suitable in adult formulations may not be appropriate for pediatric use. As with active ingredients, this is often due to differences in ability to metabolize and eliminate some excipients, especially in neonates and infants. The effect of excipients can be cumulative if a patient has been prescribed more than one medicine. Combinations of excipients from all medicines need to be considered.

An open access, evidence-based Safety and Toxicity of Excipients for Pediatrics (STEP) database has been developed collaboratively between the European and United States Pediatric Formulation Initiatives. This user-designed resource is a compilation of clinical and nonclinical safety and toxicity details of excipients from various sources (European Paediatric Formulation Initiative (EuPFI), 2017; Salunke et al., 2013). The STEP database provides a useful platform to retrieve data pertaining to a particular excipient. It has application both in the development of new dosage forms and in the manipulation of existing adult formulations for children.

Table 4 Examples of excipients that are reported to have higher toxicity in pediatrics compared to adults

Excipient	*Purpose*	*Age group affected*	*Effect*	*Reference*
Benzyl alcohol	Preservative	Neonates (especially low-birth weight premature infants). Best avoided in children under three years old	Intraventricular hemorrhage, metabolic acidosis, seizures, gasping, increased mortality, cerebral palsy, and developmental delay at high levels	Brown et al. (1982), Dawson and Nahata (1991) and Shehab et al. (2009)
Benzoic acid, benzoates	Preservative, cosolvent	Neonates	May increase risk of jaundice in neonates	Committee for Medicinal Products for Human Use (CHMP) (2013)
Ethanol	Solvent	Neonates, infants	Accumulation of acetaldehyde leading to neurotoxicity, intoxication	Committee for Medicinal Products for Human Use (CHMP) (2006) and Whittaker et al. (2009)
Propylene glycol	Solvent preservative	Children under four years old and particularly preterm neonates	Reduced ability to metabolize leading to accumulation and neurotoxic effects Alcohol competitively inhibits propylene glycol metabolism, exacerbating this effect	Committee for Medicinal Products for Human Use (CHMP) (2017), Shehab et al. (2009) and Whittaker et al. (2009)

Solvents such as ethanol and propylene glycol are found in many medicinal products to improve drug solubility, including those for children. A study conducted in the United Kingdom evaluated exposure of 38 premature neonates born at less than 30 weeks gestation and weighing under 1.5 kg to ethanol and propylene glycol (Whittaker et al., 2009). Ethanol exposure was found to be 0.2–1.8 mL per week, which for such low-weight babies is the equivalent of 1–7 alcoholic units per week. European Medicines Agency (EMA) guidelines have since recommended safety limits for ethanol of 6 mg kg^{-1} day^{-1} for children younger than 6 years and 75 mg kg^{-1} day^{-1} for children between 6 and 12 years old (Committee for Medicinal Products for Human Use (CHMP), 2014). Despite this, there are products on the market that contain ethanol at concentrations above these limits for some children. An example is furosemide oral liquid, which contains up to 0.1 mL ethanol per 4 mg furosemide. According to the British National Formulary for Children (BNF-c) (BMJ Group, 2015), the recommended oral dosage of furosemide for children is 0.5–2 mg kg^{-1} every 24 hours, which depending on the formulation used can equate to up to 20 mg kg^{-1} ethanol—well above the proposed safety limits for children under six years of age. Neonates are unable to fully metabolize propylene glycol, which can lead to accumulation and toxic effects. High doses of propylene glycol have been associated with cardiovascular, respiratory and hepatic adverse events, and toxic effects on the central nervous system in newborns and infants (Lim et al., 2014). Alcohol competitively inhibits propylene glycol metabolism, thus further exacerbating this effect (Shehab et al., 2009). These excipients should be avoided where possible, particularly in neonates up to 14 days old. The FDA recommends that the total amount of propylene glycol and alcohol from all medicines are taken into consideration in pediatrics up to 6 months of age (FDA, 2011). The EMA have proposed safety limits for propylene glycol of 1 mg kg^{-1} day^{-1} in neonates up to 28 days, 50 mg kg^{-1} day^{-1} in children from 1 month to 4 years and 500 mg kg^{-1} day^{-1} for children from 5 to 17 years old (Committee for Medicinal Products for Human Use (CHMP), 2017).

When considering a dosage form for a pediatric patient, total daily sodium and fluid intake from all sources need to be considered. Administration of excessive fluid can lead to volume overload, particularly in neonates and cardiac patients. Any fluid restriction must include all medicines and nutrition. For example, a neonatal cardiac patient weighing 3.2 kg may have a maximum fluid allowance of 7.5 mL h^{-1} immediately following surgery, with medication infusions accounting for a significant portion of this (Owens and Musa, 2009). In order to meet nutritional requirements for growth, careful consideration must be given to the composition of all i.v. fluids administered. Where possible, dextrose is used as a diluent for i.v. infusions as the calories provided add to the overall caloric intake, compared with sodium chloride which has no caloric value.

Electrolytes are often included in parenteral formulations to maintain isotonicity and avoid pain, irritation and damage to tissues at the administration site. Large quantities of sodium or potassium in parenteral formulations can cause electrolyte imbalances. In most healthy neonates, the maximum recommended daily sodium intake is 3.0 mmol kg^{-1} day^{-1} according to the BNF-c (BMJ Group, 2015), with UK guidelines recommending a maximum of 400 mg (17.4 mmol) sodium per day for children up to 12 months old (Scientific Advisory Committee on Nutrition, 2003). Sodium load is also an issue in older children, where food sources must be taken into account.

Oral liquid formulations that are acidic or contain sugar can have a cariogenic effect. This is an important consideration for long term therapy and can have life-long implications. Where possible, sugar free formulations are recommended.

Off-Label Medicine Use and Manipulation of Licensed Medicines

Ideally, commercially manufactured medicines would be available for all age groups with no further manipulation required. Realistically however, the expense of developing such commercial products that are appropriate for children from preterm neonates through to adolescents may be prohibitive. Fig. 3 shows the ideal decision pathway when providing oral liquid medicines to children who are unable to swallow solid oral dosage forms. At the very least, standard concentrations and best practice guidelines

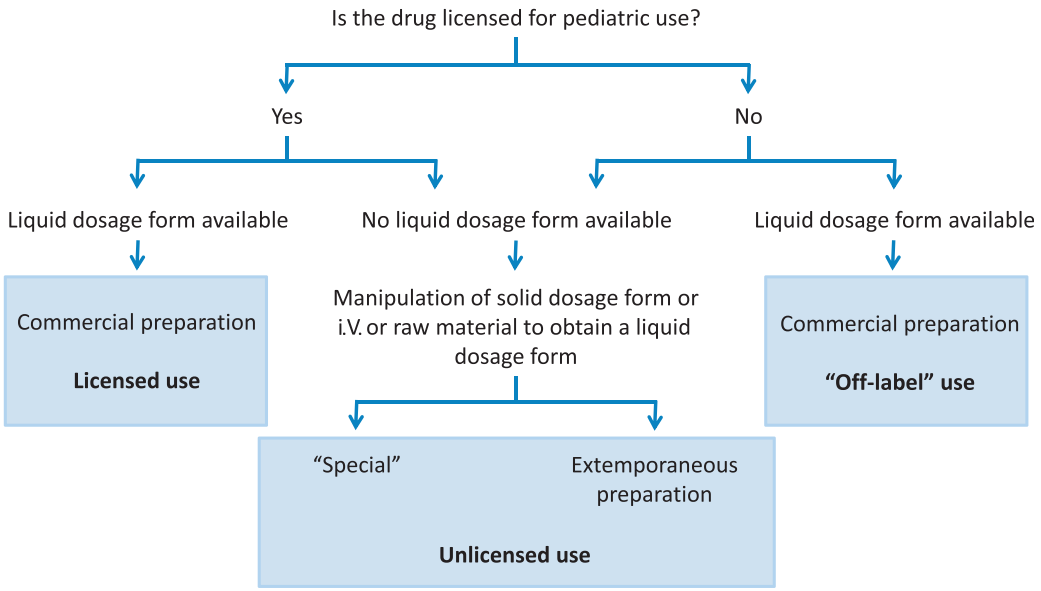

Figure 3 Decision pathway for providing oral liquid doses to children when tablets/capsules are not appropriate. *Source: Based on Standing, J.F., Tuleu, C., 2005. Paediatric formulations—getting to the heart of the problem. Int. J. Pharm. 300, 56–66, with permission from Elsevier.*

should be available at a state or national level. Indeed, there has been a move toward standardization of guidelines and formularies. Many regions have developed their own formularies including the British National Formulary for Children (BNF-c), Dutch Pediatric Formulary, New Zealand Formulary for Children (NZFc), Guida all'uso dei farmaci per i bambini (Italy), Spanish Pediamecum, and Australian Medicines Handbook for Children (AMHc). Pediatric Formularies should be evidence-based. As many medicines remain unlicensed for use in children, it is vital that the scientific background to support pediatric use is known and a risk-benefit assessment for pediatric use been performed.

Extemporaneous compounding is defined as the preparation of a therapeutic product for a patient, in response to an identified need. Medicines for pediatric patients often need to be extemporaneously compounded to produce an acceptable dosage form. Compounding generally takes place in community and hospital pharmacies, although specialist compounding facilities are available in some regions. Extemporaneous compounding has inherent risks including calculation errors, administration errors if different drug concentrations are prepared and quality concerns associated with unregulated manufacturing practice. The regulatory changes to increase the number of medicines licensed for use in children will help mitigating these risks through the availability of more evidence-based, standardized formulae.

Packaging and Compatibility of Medicines

Even packaging of medicines for children is challenging. From a practical point of view, small-volume syringes (0.1, 0.2, 0.5 mL) are difficult to label with all mandatory details as the size of the label is significantly bigger than the available surface for labeling. Ideally, all medicines will have a child resistant closure (CRC), however this may not always be possible and caregivers may need to be taught how to use them. It should be noted that these are child resistant, not child proof and care must be taken to store all medicines where children cannot access them.

Interactions between the medicine and packaging need to be considered. For example, aluminum can be leached from glass following contact with calcium gluconate solution. Accumulation of aluminum may have adverse effects on bone mineralization and neurological development in children (and adults with renal impairment). Therefore, calcium gluconate injection packed in small-volume glass containers is contraindicated for use in children younger than 18 years. Another example is amiodarone. When administering amiodarone as a continuous i.v. infusion, the administration set must be free of polyvinyl chloride (PVC) to reduce loss of amiodarone by adsorption to the PVC bag. The administration set must also be free of the plasticizer diethylhexylphthalate, or it may leach from the infusion bag into the solution, resulting in administration and potential toxicity to the child.

Where multiple medicines and fluids are prescribed, consideration must be given to the compatibility of these. For example, coadministration of ceftriaxone with calcium-containing solutions can result in particulate formation. To avoid this, ceftriaxone manufacturers advise the avoidance of any calcium-containing infusions (including intravenous nutrition), even via different infusion lines or sites, within 48 hours after the administration of ceftriaxone (AFT Pharmaceuticals, 2016). Coadministration of intravenous nutrition with any medicine using the same i.v. access is not recommended as compatibility may be problematic. Variation in the composition of intravenous nutrition formulations means published data on compatibilities is rarely available. Furthermore, potential interactions with enteral feeds must be considered. This may be particularly problematic with neonates, as they require frequent feeds, as well as those older children who are continuously tube fed.

Box 1

Vitamin K (phytonadione) is routinely given to neonates to facilitate normal clotting and prevent hemorrhagic disease until the intestinal tract acquires the bacteria necessary to synthesize vitamin K. It is given as a single intramuscular dose as soon as possible after birth, at a dose of 0.5 mg to 1 mg depending on regional guidelines.

Place of Pharmacotherapy in Children

When considering pharmacotherapy in children, risk versus benefit needs to be evaluated, particularly in young children. Recognizing when a child is ill or in pain is a complex process. Parents and caregivers often have an intimate knowledge of their child with respect to their behavior and may recognize signs of illness based on a departure from what is "normal" for their child. This concept of normality depends on the developmental stage of the child as well as a comparison to how the child usually behaves. During assessment of a child's symptoms, time is needed to determine whether they are exhibiting behaviors outside their normal range.

As with adults, the decision to prescribe medication should follow an assessment of the risk to benefit ratio for the specific patient. In pediatrics, the risks posed by a medicine may be different to those in adults and formulation and licensing considerations also need to be taken into account. Some medicines have been demonstrated to be beneficial in preventing disease, so are routinely given to children (Box 1).

Role of the Pharmacist

As in adult medicine, pharmacists are involved in many aspects of pediatric patient care. In primary care, they may advise on the management of common childhood conditions, undertake health promotion activities (including those related to vaccination, breastfeeding, and the safe use of medicines), procure appropriate formulations, dispense medicines, advise on manipulation and administration of medicines and extemporaneously compound products suitable for pediatric patients. In secondary and tertiary care settings pharmacists are involved in the provision of care including providing medicines reconciliation services, advice on the safe and effective use of medicines in individual patients or specific subgroups of pediatric patients, preparation of medicines and intravenous nutrition, the provision of medicines counseling for children, adolescents, their parents and caregivers, and the education of health care professionals. In other settings, pharmacists may work with regulatory authorities to ensure that medicines intended for children are safe and effective, or be involved in research projects that focus on the pediatric population.

However, in contrast to adult medicine where care is often focused on a single patient, pediatric care focuses on the family of which the child is a part. Decisions regarding the child's medical care are made in the context of the family, and the beliefs of the parents, while endeavoring to act in the best interest of the child.

Consent and Parental Care

Unless revoked by the courts, parents have overall responsibility for the care of their child, and are generally considered to be best placed to understand the needs of their child/children, and to make appropriate decisions in their best interests. As such, they are able to consent to medical investigations and treatment on their child's behalf until the child reaches an age where they are competent to do this themselves. However, this responsibility must be viewed in the context of the ongoing development of the child and their increasing capacity for rational decision making and autonomy, as well as the societal responsibility to protect the child from harm (Committee on Bioethics, 2016).

The right of the responsible adult (parent or caregiver) to consent to (or refuse) treatment is not absolute and is better viewed as a responsibility to represent the interests of their child rather than a right to express the caregiver's own views. In cases where the child is at significant risk of serious harm or neglect, the state (and in turn the medical system) has a responsibility to ensure that the best interests of the child are represented and that effective medical treatment is provided, regardless of the social, cultural, or religious beliefs of the parent (Committee on Bioethics, 2016). In extreme cases this may require legal advice and representation, which may result in the courts vesting the ability to provide consent in an independent guardian.

The legal framework varies by jurisdiction but in general, adults (most commonly those over the age of 18, though the legal age of majority varies by country) are presumed competent to consent unless their decisions or actions provide evidence to the contrary (Larcher and Hutchinson, 2010). The legal competence of an adolescent aged between 16 and 18 varies by jurisdiction, and may be split between different ages, with adolescents in the UK, for example, generally able to consent to treatment from the age of 16, but only able to veto treatment that will prevent serious harm or death from the age of 18 (Larcher and Hutchinson, 2010). Below the age of legal majority, a minor may provide their own consent to treatment in three broad categories (Committee on Bioethics, 2016):

- Specific exemptions for particular categories where there is concern that adolescents may not access care if parental consent is required (generally care relating to sexual health, such as contraception, and in some jurisdictions for mental health care);

- Legal emancipation—those who are considered independent of their parents (self-supporting and living separately; married or on duty with armed forces) may be considered emancipated, and have responsibility for their own decision making;
- "Mature minor" exceptions, which recognize that some adolescents are sufficiently mature and intelligent enough to understand the risks, benefits, and alternatives in a given situation, appraise these and form a well-reasoned decision. This ability is often known as "Gillick competence," following a landmark legal case in the UK in 1985 where Lord Scarman concluded "*Parental right to determine whether their minor child below the age of 16 will have medical treatment terminates if and when the child achieves sufficient understanding and intelligence to enable them to understand fully what is proposed*" (Gillick v West Norfolk and Wisbech AHA, 1985).

A child's ability to consent to or refuse treatment requires that they are able to understand the nature, purpose, and consequence of the proposed course of action. Competence is assessed in the context of the decision to be made, with decisions that entail significant risk or with potentially catastrophic consequences (e.g., accepting or refusing transplantation or chemotherapy) requiring a higher level of competence than minor decisions (e.g., deferring venepuncture, or minor surgery). With this in mind, the inclusion of the child in the decision-making process should increase over time as their maturation permits.

Counseling

In most pediatric settings, patient counseling needs to be provided for both the child being treated and their parents. Such information must be targeted appropriately as described in the subsections below.

Parents and Caregivers

In addition to standard drug information provided to adult patients (indication, possible drug interactions, duration of therapy, importance of adherence, possible adverse events, etc.), parents or caregivers need to be provided with information to enable them to accurately and safely administer the medication to their child. Pharmacists should ensure the parent has access to a suitable measuring device if required and that they know how to measure the medicine accurately using the device, and may need to provide advice on how to get the child to take the medicine. Parents also need to know how to obtain the medication (depending on the medication and the jurisdiction this may be from a standard community pharmacy, supplied directly by a pediatric hospital or manufactured on request by a specific "special products" manufacturer) and how to store it when they do obtain it. Advice on storage of the medication (use of a child-resistant closure and storage out of reach of the child) should be provided to minimize the risk of accidental overdose or poisoning (Box 2).

The Child

Children and adolescents are entitled to receive information on their treatment and medications in a form that they can understand. The information provided to the child will need to take into account the age and developmental stage of the child, their intellectual ability, and interest in the information. Tailoring the information delivery, for instance by playing games such as "memory" using medicine names and indications may be of more interest to the child patient than a typical medication counseling conversation. Toys such as dolls and medical equipment are often used to explain procedures to children and prepare them for new experiences. Adolescents in particular may have concerns relating to standing out from their peers, and these should be elicited and addressed to enhance compliance with treatment.

Virtual reality is emerging as a valuable tool in pediatric medicine, both as a distraction technique during procedures that are uncomfortable or require the child to lie still, or as a preparation technique that allows the child to experience the environment (e.g., radiology department) they will be visiting before they go there.

The Multidisciplinary Team

The multidisciplinary team plays an important role in pediatric practice. In the community setting and in rural or regional settings, care may be provided by general medical and nursing staff who care for both adult and pediatric patients. However, in the tertiary care setting, care is generally provided by specialist pediatric staff who have training and experience in pediatric patient care. In addition to team members such as medical, nursing, physiotherapy, occupational therapy, dietetics, and pharmacy often seen in the adult setting, the pediatric team works closely with those involved in the care and education of the child. Parents and/or caregivers are an integral part of the team, as are teachers and hospital play specialists.

Large tertiary children's hospitals often include a hospital school, which oversees the education of children who, due to ill-health, have experienced (or are expected to have) significant absence from their regular school. Teachers at the hospital school liaise closely with the child's usual school and their medical team to ensure that disruption to the child's education is minimized, so that academic progress is maintained as much as is possible and that reintegration into their usual school is facilitated. Education is tailored to the individual needs of each patient and may involve teaching in a hospital classroom, at the bedside, at home, or via distance methods such as online education, phone, fax, or email contact. In some cases hospital schools will also cater for the siblings of hospital patients, particularly when specialist care for one child requires the family to temporarily relocate to another area for treatment or investigations. In many cases the child does not require admission to a specific hospital school, but their ongoing care may require

Box 2

Helping Children to Take Medicines

(Best Practice Advocacy Centre New Zealand, 2014; PHARMAC et al., 2017)

- Be confident, calm, and firm, but kind, about medicine taking—the medicine needs to be given. However, if it is proving impossible to persuade the child take it, try again in about half an hour.
- If the child refuses to take the medicine, consider alternative formulations or medicines that may be available.
- Explain to the child that the medicine is to make them feel better. Reverse psychology may help—telling the child it is very special and that they can only have it once/twice/three times a day can often help!
- Sticker charts, where the child earns a sticker for each time they take their medicine and is rewarded with a treat (e.g., a trip to the park, or a toy car, etc.) after a predetermined number of stickers can be useful in rewarding and encouraging good behavior. For young children, rewards need to be frequent to be effective; older children can earn more stickers before rewards are given.
- Give the child choices where possible—having the medicine before or after their bath, what they would like to drink after the medicine, which sticker they would like for a sticker chart.
- In the hospital setting, play specialists are often a useful source of information and resources and can assist in teaching children to take medicines.
- Tablets may slip down easier with a spoonful of semisolid food—consider if the medicine can be given with apple sauce, yoghurt, or ice-cream. The jet of water obtained from a drink bottle can help carry tablets to the back of the mouth in older children.
- Capsules float on water. To teach a child to swallow capsules, have them look down at the floor. Slip the capsule into their mouth, then ask them to take a big drink of water or other fluid. The capsule should float on the liquid, and slip down as the liquid is swallowed.
- Oral liquids should be measured accurately using an oral syringe or medicine measure.
  - Babies may be wrapped gently to stop arms flailing. Use a syringe to administer medicine to the inside of the cheek (this avoids the bitter taste buds on the tongue). Administer medicine toward the back of the cheek so it dribbles down the throat rather than being spat out. Some medicines may be mixed with a little breast milk or formula, but medicines should not be mixed with bottles or large quantities of food, as if the portion is not finished the correct dose will not be given.
  - For older children, allowing them to use a straw to sip the medicine may distract them from the taste of the medicine. Follow with a small quantity of water through the straw to ensure the whole dose is given.
- If the child complains about the taste of the medicine:
  - Follow with a taste of something the child likes—breast milk, juice, or flavored sauces.
  - Encourage the child to suck an ice block before taking the medicine to numb the taste buds.
  - Encourage the child to hold their nose while taking the medicine (this also helps dull the sense of taste).
  - Consider trialing tablets or capsules instead of a liquid.
- Eye drops—have the child lie down with their head in the caregivers lap and eyes closed. Place drops in the corner of the eye near the nose, then allow child to open the eyes and blink to spread the drops.

input from, or understanding of, their condition on the part of their usual teacher and school. The pediatric team often works closely with the school to ensure the child's educational and medical needs are met.

Play is an integral part of a child's life and is how they learn. Play specialists (also known as hospital/health play specialists or child life therapists, depending on jurisdiction) provide therapeutic play and recreation programs for children of all ages in health care setting, utilizing a playroom environment and bedside play. Play activities may be used to explain investigations, tests, procedures, and treatments to children and prepare them for these, or to support their general learning and development. They also provide procedural support and distraction pre- and postoperation, at an appropriate developmental level. Play specialists also provide support to siblings and families, and can contribute to the clinical decision making process through their observations of the child and their family. From a pharmacist's point of view, play specialists can be of great value in working with children to teach them to take medications, and advising on their ability to comply with treatment options.

Vaccination

Vaccination involves the administration of an antigen to a patient in order to generate an immune response and subsequent immunological memory. The vaccine contains either attenuated (weakened) microbes, killed whole microbes or fragments of the microbe or the toxins it releases. The small amounts of these introduced into the body parenterally or via the oral or nasal mucosal routes are recognized as foreign by the innate immune system, which in turn stimulates the cells of the adaptive immune system, the T and B lymphocytes, to produce antibodies. This generates an immunological memory, which allows the immune system to quickly recognize the microbe in the future and mount a more rapid and effective immune response, preventing the disease or reducing its severity. Depending on the vaccine type, repeated doses over a period of time may be required to generate an effective immune response. Vaccines containing killed microbes or fragments of a microbe commonly require multiple successive doses to be effective, while a single dose of a live attenuated vaccine may be sufficient on its own (New Zealand Ministry of Health, 2017).

Very young children are at particularly high risk of developing severe disease as their immune system is immature. Newborn babies rely in part on maternal antibodies received from their mothers for active protection against a wide range of illnesses and to attenuate infections so infants can generate an active immunity without severe illness. Where the mother has antibodies to a disease,

Box 3

Paracetamol (acetaminophen) is arguably the most widely used medicine for children. In some countries (previously), paracetamol has been given prophylactically before and after vaccinations to reduce fever. However, paracetamol has also been shown to reduce immune response to vaccination and therefore the authors do not recommend its use for this indication.

these are transferred from the mother to the baby via the placenta from approximately 28 weeks of gestation. Babies born before this age will have little or no maternal antibodies, while babies born beyond 28 weeks gestation, but still prematurely, will have received lower levels of maternal antibodies than a full-term baby and will hence have a reduced duration of protection from illness. Maternal antibodies are also actively transported into breast milk, and the presence of these antibodies in the breast milk is one of the reasons breast milk is preferred over formula, especially in preterm and newborn infants (New Zealand Ministry of Health, 2017).

As passive immunity wanes and the immune system develops, vaccines are introduced to generate protection from diseases that can have significant consequences. Each country will have their own schedule of vaccinations depending on the resources available and the diseases of most risk in that country. These vaccination schedules typically start at six weeks of age and cover diseases such as polio, measles, diphtheria, pertussis, and rubella. Vaccination programs vary in effectiveness, due mainly to the extent of uptake of the vaccine. Smallpox has been eradicated, and extensive vaccination programs in the past few decades have led to polio being close to eradicated worldwide. Other vaccine-preventable diseases such as measles and mumps continue to cause periodic epidemics in a number of countries.

Pharmacists have a role to play in providing evidence-based information on immunization and encouraging parents to have their children immunized appropriately. In recent years there has been a significant increase in jurisdictions allowing pharmacists to perform immunizations, though in many places this is restricted to vaccinating older children and adults (e.g., with the annual influenza immunization) and pharmacist vaccination programs often do not yet include all childhood schedule vaccinations (Box 3).

Emerging and Future Roles of the Pharmacist

Historically, the role of the pharmacist has primarily been concerned with compounding and dispensing medications and providing primary health care. However, in more recent times, pharmacists have progressively become more involved in clinical roles. In the past decade there has been widening agreement that the scope of practice for pharmacists is expanding to increasingly provide more patient-focused care. Pharmacists have broader roles and responsibilities for providing independent clinical services and working as part of collaborative health teams and an expansion in both the number and type of pharmacist-provided services is taking place in all practice settings (International Pharmaceutical Federation (FIP), 2017). Correspondingly, there is an increase in both the role of the pharmacy technician and a rise in automation of the dispensing process, as more routine aspects of the role are delegated to enable pharmacist time to be used on clinical care.

The role and responsibilities available to clinical pharmacists vary considerably by geographical location. In some countries, advanced roles are rapidly becoming reality. For example, the Scotland National Health Service published a vision document in 2013 that described the aim to have all pharmacists accredited as independent prescribers by 2023, in order to provide clinical care to patients in the community (The Scottish Government, 2013). The intention of this scheme is to optimize the complementary skills of doctors and pharmacists, with diagnosis continuing to be completed by doctors and postdiagnosis management being assigned to prescriber pharmacists (The Scottish Government, 2013). In other countries, pharmacists are only just becoming established members of the health care team, and more advanced roles will take some time to develop. Alongside the development of advanced clinical roles, enabling developments are required concurrently in legislative and regulatory arenas, the infrastructure of the health system and pharmacy education and training to support these roles (International Pharmaceutical Federation (FIP), 2017). In some cases there is resistance to the development of new roles by other health professionals who fear the loss of part of their own scope (and possibly funding) due to the emerging pharmacist role. A significant barrier to implementation is often provision of funding to support the advanced roles, particularly in the community setting. In many countries, members of the public are used to accessing advice from a community pharmacist, but historically funding for services have been limited to the payment of dispensing fees, with additional income derived from retail sales. For advanced services to be sustainable, remuneration for pharmacist time must be provided by the patient and/or a funding body (whether government or an insurance scheme).

Advanced Clinical Roles

While clinical pharmacist roles have been established for some time, specialization and integration within health care teams continues to increase. Following the trends in medicine, which initially saw pediatrics develop as a specialty followed by subspecialists in the different areas of pediatric medicine, pharmacists continue to develop subspecialist interests and knowledge in different areas of pediatrics. Where once pediatric pharmacy was a specialist role in itself, a large tertiary pediatric hospital may now include pediatric pharmacists working specifically in different specialties such as renal, infectious diseases and antimicrobial stewardship, cardiology and neonatal or pediatric intensive care. In many cases, their role within these teams continues to grow,

with pharmacists increasingly developing niche roles in both in-patient and out-patient settings in much the same way they do in adult settings. For example, having a pharmacist working in a pediatric complex care clinic has been shown to be beneficial in identifying, preventing, and resolving medicines-related issues at The Hospital for Sick Children (SickKids) in Toronto, Canada (Tjon et al., 2017).

Recent years have also seen a growing trend of embedding clinical pharmacists in primary care settings such as general practice. While this has mainly focused on adult patients to date, as these roles increase in number and scope it is likely that these pharmacists will become involved in pediatric patient care as well. With the ongoing development of electronic health resources it is likely that specialist pediatric pharmacists will over time have an increased ability to provide advice and input on patient care from a distance, allowing patients in more rural or remote communities to benefit from specialist knowledge. There is also a growing trend in the introduction of advanced practice credentialing, which sees pharmacists recognized as having specialist knowledge and skills in a particular area, including pediatrics (International Pharmaceutical Federation (FIP), 2017).

Pharmacist Prescribers

Many developed countries are establishing pathways to independent prescribing for pharmacists in specialized areas of practice. Pediatrics is no different in this regard, and pharmacist prescribers are well established in pediatric settings in some countries, such as the UK where over half the neonatal intensive care unit (NICU) pharmacists who responded to a recent survey were qualified independent prescribers (Mulholland, 2018). Conversely, in New Zealand where pharmacist prescribing is in its infancy, as at June 2017 there were only 14 pharmacist prescribers out of a total of 3718 registered pharmacists (Pharmacy Council, 2017), and only one of these was practicing in pediatrics.

Educators

For many years, the route to training as a pediatric pharmacist has been an informal one, consisting mainly of on-the-job learning and teaching and mentoring by a more experienced pharmacist. Pediatric pharmacists have always thus had a role in teaching more junior colleagues the fundamentals of pediatric practice, as well as being responsible for their own learning within their specialty or subspecialty.

With the expansion of pediatric pharmacist roles there is a need for specialist training for pediatric pharmacists, and experienced pediatric pharmacists have an emerging role in the development of training material for newly established postgraduate programs. For example, in 2016, Liverpool John Moores University started a Masters Certificate of Professional Development in Medicines Use in Pediatrics and Neonates course as a distance learning program for pharmacists and other health care professionals who wish to develop their role or expand their knowledge and expertise in pharmaceutical care for children and neonates (Aragon-Cuevas, 2017).

Similar expansions in roles and specializations are also occurring in other health professions, and experienced pediatric pharmacists are also finding their expertise is needed in teaching other health professions, particularly with the increase in nonmedical prescribers, who generally require postgraduate education in pharmacology as part of their training as a prescriber.

Vaccinators

Currently, many countries allow pharmacists to administer vaccinations to predefined population groups—mainly adults, and in some cases older children and pregnant women. Pharmacist vaccination does not generally include routine childhood immunization schedule vaccinations, but as the pharmacist vaccinator workforce grows and the role becomes more established and widely accepted it is likely that this will emerge as a role for pharmacists to increase their involvement with pediatric patients.

Public Health Promotion and Care

In some countries, pharmacists are involved in the provision of health care and education as part of public health campaigns. New Zealand has high rates of rheumatic fever and much effort has been expended in decreasing the impact of this disease. "Sore throat clinics" have been set up in schools, general practices, pharmacies, after-hours medical centers, and pathology laboratories to swab the throats of children presenting with a sore throat and prescribe antibiotics for those at risk of Group A Streptococcus (GAS) infection leading to rheumatic fever. Children and young people aged 4–19 years who identify as Māori and Pacific and/or live in the areas of highest social deprivation are assessed and treated at these clinics at no cost to the family. In a formative review of these services, pharmacy clinics were popular with patients due to perceived accessibility, affordability, and acceptability, and were particularly noted for their short wait times, seeing patients on a drop-in basis and generally completing swabbing within 10 minutes of arrival, compared to general practices where patients reported often being unable to get an appointment for 2–3 days or having to wait for prolonged periods at after-hours clinics (Litmus Limited, 2016). Pharmacists working within these services are able to supply antibiotics to patients using this service who meet the criteria, either at the time of swabbing or on confirmation of GAS infection on the swab, depending on the set-up of the service. In the aforementioned review, pharmacy-provided services were also noted to be particularly vigilant at explaining the importance of taking the full course of antibiotics even after the sore throat symptoms disappeared, refuting any concerns regarding inappropriate antibiotic usage (Litmus Limited, 2016).

There is considerable scope for the development of future roles based on a similar model, with pharmacists being involved in health promotion activities or providing health care on an assess-and-treat basis for various conditions, either as independent prescribers or under delegated authority in accordance with the regulatory requirements in individual jurisdictions. There is also the potential for pharmacists to become involved in health promotion activities such as collaborating with other providers in the provision of healthy lifestyle programs.

Summary

Children form a distinct and important group with specific considerations that must be taken into account when prescribing and administering medications. Physiologic changes during childhood result in changes to pharmacokinetic parameters, which may result in different doses and formulations being required at different ages.

Dosage forms are particularly important in the pediatric population and need to be able to cater to vastly different sized patients, as well as being suitable for administration to developmentally diverse patients. A lack of licensed products continues to hinder the safe and effective use of medicines in children, and manipulation of products designed for adults is often required to enable the treatment of children. Consideration must be given to the dose, route of administration, volume, and excipients of a formulation.

The role of the pharmacist in the pediatric setting is similar to that of those working with adults, but the team involved in the care of the child often includes those who provide care and education to the child, including parents, teachers, and play specialists, and information provided by the pharmacist must be carefully tailored to the recipient. With the ongoing increase in professional roles available to pharmacist, pediatric-centered roles are emerging in vaccination, health promotion, primary health care, and education, as well as more advanced clinical roles, including prescribing.

Learning Objectives

Upon completion of this chapter, the reader will be able to:

- Describe physiological changes during pregnancy and factors that affect pharmacokinetics of drugs during pregnancy.
- List drugs that are contraindicated and safe to use during pregnancy and lactation.
- Describe the epidemiology, pathophysiology, clinical presentation, and complications of various medical disorders that occur during pregnancy such as hypertension, diabetes, coagulation abnormalities, gastrointestinal and psychiatric disorders.
- Discuss the management of the various medical disorders of pregnancy.
- Describe the epidemiology, pathophysiology, clinical presentation, and management of abnormalities that occur during induction of labor and delivery such as preterm labor.
- Describe the role of the pharmacist in patient management of disorders that occur during pregnancy and lactation.

Take Home Messages

1. Several factors affect the pharmacokinetics of drugs during pregnancy and lactation.
2. Drugs are classified into five categories based on evidence of known risk to fetus. Similarly, drugs are classified into five categories based on pharmacokinetics of secretion into breastmilk.
3. Hypertension and its complications occur in about 10% of all pregnancies. Hypertension can be treated using labetalol, methyldopa, and sometimes delivery of the placenta is essential to treat preeclampsia (PE) with acute complications. Aspirin may be useful in the prevention of hypertensive disorders of pregnancy.
4. Gestational diabetes mellitus is a common cause of hyperglycemia during pregnancy. Lifestyle modifications and self-monitoring of glucose are recommended for management. Insulin is the first-line treatment, while metformin can be considered as well.
5. Hematological disorders that occur during pregnancy include both coagulation as well as bleeding disorders. Management involves normalization of clotting factor or platelet levels and anticoagulation. Vaginal delivery is preferred.
6. Gastrointestinal tract disorders in the form of nausea and vomiting of pregnancy is one of the most common disorders that occur during pregnancy and affects up to 90% of pregnancies. Nonpharmacologic approaches such as ginger and pharmacologic management with a combination of thiamine and pyridoxine are effective.
7. Mental health disorders occur during or in the immediate postpartum period. Depression is the most common mental health disorder. Psychotherapy is the initial treatment of choice for mild to moderate depression, while antidepressants are reserved for severe major depression.
8. Preterm labor is a concern among pregnant women. Prevention is more important as it is difficult to predict. Vaginal progesterone therapy or cervical cerclage has been tried without much success. Therefore, screening for risk factors is important.
9. Clinical pharmacists have an important role to play in the management of disorders during pregnancy and lactation. Pharmacists have the skills and competence to:
    a. obtain patient medication history and assess current medication management
    b. obtain evidence on safety and efficacy of current and potential medications
    c. develop medication management plan and monitor response to therapy
    d. perform therapeutic drug monitoring

Introduction

Pregnancy is a common physiological state that most women experience during their reproductive years. However, some pregnant women experience pathological disorders that warrant medical attention during pregnancy or in the immediate postpartum period. On the other hand, women with preexisting diseases often become pregnant. This chapter focuses on clinical pharmacy considerations in pregnancy and the key aspects of the clinical management of common disorders of pregnancy.

Clinical Pharmacy Considerations in Pregnancy

Physiological Changes in Pregnancy

Pregnancy is characterized by a number of physiological changes in several organ systems (Soma-Pillay et al., 2016). There is a gradual increase in plasma volume throughout normal pregnancy. As early as 8 weeks, there is an increase in cardiac output by 20%. Peripheral vasodilation leads to decrease in systemic vascular resistance that allows an increase in cardiac output. Due to renal vasodilation, an increase in renal blood flow occurs by 50%. Pregnancy is a hypercoagulable state accompanied by an increase in the levels of certain clotting factors, such as VIII, IX, and X, are increased. Fibrinogen levels rise also significantly and fibrinolytic activity

Table 1 Pregnancy risk categorization of drugs

Pregnancy risk category	*Definition*
Category A	Adequate and well-controlled studies have failed to demonstrate a risk to the fetus in the first trimester of pregnancy (and there is no evidence of risk in later trimesters).
Category B	Animal reproduction studies have failed to demonstrate a risk to the fetus and there are no adequate and well-controlled studies in pregnant women.
Category C	Animal reproduction studies have shown an adverse effect on the fetus and there are no adequate and well-controlled studies in humans, but potential benefits may warrant use of the drug in pregnant women despite potential risks.
Category D	There is positive evidence of human fetal risk based on adverse reaction data from investigational or marketing experience or studies in humans, but potential benefits may warrant use of the drug in pregnant women despite potential risks.
Category X	Studies in animals or humans have demonstrated fetal abnormalities and/or there is positive evidence of human fetal risk based on adverse reaction data from investigational or marketing experience, and the risks involved in use of the drug in pregnant women clearly outweigh potential benefits.

is decreased. This could be attributed to the changes in levels of hormones. Because of the physiologic changes inherent in pregnancy, this can lead to substantial underdosing, or, in some cases, excessive dosing of drugs.

Factors Affecting Pharmacokinetics of Drugs During Pregnancy

Several factors affect the absorption, distribution, metabolism, and excretion of drugs during pregnancy (Koren and Pariente, 2018; Pariente et al., 2016). Some of the key factors include:

- Increase in total body weight and fat
- Delayed gastric emptying and increased transit time
- Increased cardiac output and renal blood flow
- Decreased albumin concentration with reduced protein binding
- Altered hepatic cytochrome P450 enzyme activity

Risk Categorization of Drugs for Use in Pregnancy

Drugs are generally classified into various categories based on the level of evidence and the risk to the fetus. The risk categorization of drugs in pregnancy is detailed in **Table 1** (Food and Drug Administration, 1980). It is important to note that since 2015, the US FDA is transitioning from the letter category of pregnancy risk to a new format that is simpler and easy to interpret. Per the Pregnancy and Lactation Labeling Rule (PLLR), the pregnancy and lactation part of the product label will be categorized in three categories. The first category is "Pregnancy", the second "Lactation" and the third "Females and Males of Reproductive Potential". The third category is newly created and has information related to on pregnancy testing , recommendations on contraception and the effect of the drug on fertility. https://www.fda.gov/downloads/aboutfda/reportsmanualsforms/reports/economicanalyses/ucm427798.pdf; https://www.fda.gov/drugs/developmentapprovalprocess/developmentresources/labeling/ucm093307.htm

The tables list some commonly used drugs that are contraindicated (**Table 2**) (Cooper et al., 2004; Viguera et al., 2007) and safe (**Table 3**) (Lalonde, 2011) to use during pregnancy. This is not an exhaustive list of drugs, and health-care practitioners should refer to other resources to determine whether the medications they intend to prescribe are safe.

Clinical Pharmacy Considerations in Lactation

Use of Drugs in Breastfeeding and Lactation

Breastfeeding is the gold standard for infant nutrition. It provides all essential elements for nutritional, emotional, cognitive, and immunological needs. The World Health Organization (WHO) recommends exclusive breastfeeding for the first 6 months of infant's life, after which, complementary foods are introduced, and breastfeeding continues up to 2 years of age or beyond (WHO, 2018). Around 80%–90% of mothers initiate breastfeeding, while 40% of them exclusively breastfeed their 0–6 months infant (WHO, 2018). During this period, mothers with chronic medical conditions or acute illnesses might need to be on medications, which necessitate the understanding of medication use, transfer to milk, as well as safety of use to milk production and to breastfed infants.

Table 2 Commonly used drugs contraindicated in pregnancy

Drugs	*Adverse effects*
Antibiotics	
Chloramphenicol	Grey baby syndrome
Ciprofloxacin	Cartilage abnormalities
Sulfonamides	Brain damage due to hyperbilirubinemia
Tetracyclines	Bone development affected, yellowing of teeth
Anticoagulants	
Warfarin	Fetal warfarin syndrome (nasal hypoplasia)
Antidepressants	
Lithium	Ebstein's anomaly
Antiepileptics	
Sodium valproate	Cleft lip and cleft palate
Anti-neoplastic drugs	Multiple birth defects
Hormonal preparations	
Progestins	Cryptorchidism
Or Estrogen	Hypospadias
	Clitoral hypertrophy
Diethylstilbestrol	Cancer of female genital tract
Thalidomine	Phocomelia, amelia

Table 3 Commonly used drugs considered safe in pregnancy

Antibiotics
Amoxycillin
Ampicillin
Cephalosporins
Erythromycin
Analgesics
Acetaminophen
Endocrine
Levothyroxine
Insulin
Vitamins
Folic acid
Vitamin B6
Antihypertensives
Hydralazine
Methyldopa
Anticoagulants
Heparin

Factors Affecting Pharmacokinetics of Drugs During Breastfeeding

Certain drugs have the potential to cause adverse effects on infants receiving breastfeeding. In such circumstances, withholding breastfeeding may be warranted. Considering the large number of medications available in the market, generally, most of the medications are not of a concern for breastfeeding (Hotham and Elizabeth, 2015). Several factors play a role in determining the transfer of drugs into breast milk. These include breast milk, drugs, and maternal- and infant-related factors.

Breast Milk

Breast milk characteristics affect drug transfer (Chaves and Lamounier, 2004). Lipid and protein compositions in the milk vary between initial stages of lactation (e.g., colostrum compared to mature milk), and even vary between stages of breastfeeding (e.g., foremilk versus hindmilk). These variations affect the amount of drug transferred from mother's plasma into the milk.

Pharmacological Properties of Drugs

Pharmacological properties of drugs play a major role in determining the transfer of drugs into the breast milk. Drugs with low molecular weight (e.g., less than 200 Da) are secreted more easily into milk than drugs with a higher molecular weight. As milk is acidic (pH 6.5), drugs that are weak bases tend to concentrate in the milk. Fat-soluble drugs and drugs that have low plasma protein binding characteristics reach the milk compartment more easily than highly protein bound drugs. Furthermore, drugs with long half-life remain in the bloodstream for longer duration, and consequently, in the milk. Drugs with poor oral bioavailability are preferred during breastfeeding, as their absorption is poor by the infant. Heparin has a large molecular weight and poor oral bioavailability, so it would not be expected to be appreciably excreted into breastmilk or absorbed by the infant. On the other hand, lithium has low molecular weight with no protein binding, making it readily excreted into the milk. Drugs with known toxicity in infants such as antineoplastic or radioactive drugs should be avoided regardless of their pharmacological properties (Burkey and Holmes, 2013; Chaves and Lamounier, 2004; Hotham and Elizabeth, 2015; Sachs and Committee On, 2013).

Maternal-Related Factors

Factors affecting drug metabolism or excretion in the mother might impact on drug concentration in the milk. Patients with liver or renal diseases may have higher levels of drug in the milk due to increased circulation of drug in the mother's bloodstream. Furthermore, the route of administration of medication affects its concentration in the plasma, and subsequently in the breast milk. Several topical and inhaled medications reach the bloodstream in minimal amounts. The dose as well as the duration of treatment also impact on the safety of drug use during lactation (Burkey and Holmes, 2013; Chaves and Lamounier, 2004; Hotham and Elizabeth, 2015; Sachs and Committee On, 2013).

Infant-Related Factors

Infant-related factors include age, renal and hepatic handling, and volume of milk intake. Hepatic and renal functions are more efficient in older infants compared to newborn, where the effect of drugs is more pronounced. The effect of ingested drugs is even stronger in preterm infants as organ functions are more immature. On the other hand, younger infants consume less volume of milk compared to older infants, which also has an impact on the amount of exposure to the drug (Chaves and Lamounier, 2004; Hotham and Elizabeth, 2015).

Measurement of Infant Exposure to Drugs During Lactation

The amount of infant exposure to drugs is measured using milk-to-plasma ratio, and absolute and relative infant doses methods, which are enumerated below (Burkey and Holmes, 2013; Chaves and Lamounier, 2004; Hotham and Elizabeth, 2015; Sachs and Committee On, 2013). Milk-to-plasma ratio estimates the relative amount of drug in the milk; the lower the ratio, the lower the concentration of drug in the milk.

$$\text{Milk} - \text{to} - \text{plasma ratio} = \frac{\text{drug concentration in milk}}{\text{drug concentration in plasma}}$$

The absolute infant dose is equal to drug concentration in milk multiplied by the volume of milk ingested. However, accurate measure is difficult to obtain. An estimation of the relative infant dose is used according to this equation:

$$\text{Relative infant dose } (\%) = \frac{\text{Absolute dose } (\mu g/kg/day) \times 100}{\text{Maternal dose } (\mu g/kg/day)}$$

A relative dose of 10% or more is of concern. Lithium is an example, where breastfeeding is generally of a concern. Careful monitoring for blood levels for mother and infant is required, while some authors recommend avoiding breastfeeding.

Minimizing Infant Exposure to Drugs While Lactating

- Use the lowest effective dose when a drug is needed.
- Select a drug with a large molecular weight, short half-life, low lipid solubility, poor absorption, high protein binding, large volume of distribution, and low serum concentrations, when possible.
- Temporarily hold breastfeeding if toxic drug is used (along with breastmilk expression).
- Time period to resume breastfeeding is determined based on half-life of the drug.
- Continuation of breastfeeding might not be possible if lengthy period of treatment is needed.

Metoclopramide and domperidone increase prolactin production indirectly. They interfere with dopamine action of decreasing prolactin secretion by the pituitary gland. These medications are used to increase milk supply, however, such use is off-label.

Table 4 Drugs that are a concern while breastfeeding

Hazard to infant	*Hazard to milk production*
Amiodarone	Amantadine
Chemotherapeutic/antineoplastic agents	Pseudoephedrine
Radioactive substances	Phenylephrine
Certain psychotropic medications	Bromocriptine
Chloramphenicol	Cabergoline
Retinoids	Tamoxifen
	Raloxifene

Commonly Used Drugs Contraindicated During Breastfeeding

Only few medications are contraindicated in breastfeeding. Medications with a potential or actual hazard for the breastfed infant or to breast milk production are best avoided while breastfeeding. Table 4 provides examples for these medications.

Categorization of Drugs for Use During Breastfeeding

Medications are categorized for their safety in breastfeeding according to Hale's categories as follows: L1, safest; L2, safe; L3, moderately safe; L4, possibly hazardous; and L5, contraindicated (Hale, 2012). This categorization is based on the pharmacokinetic aspects for breastfeeding mothers and their infants and based on recently published scientific articles.

Clinical Pharmacy Considerations in Commonly Encountered Disorders of Pregnancy

Hypertensive Disorders of Pregnancy

Hypertensive disorders are some of the major health issues complicating up to 10% of pregnancies worldwide and are the leading cause for maternal, fetal, and infant morbidity and mortality (Duley, 2009; Hutcheon et al., 2011; Umesawa & Kobashi, 2017). A number of guidelines classify hypertensive disorders of pregnancy (HDP) into four categories based on the timing of diagnosis and associated signs and symptoms: (1) chronic or preexisting hypertension; (2) gestational hypertension (GH); (3) preeclampsia-eclampsia; and (4) chronic hypertension with superimposed PE (Butalia et al., 2018; Magee et al., 2014; Report of the National High Blood Pressure Education Program Working Group on High Blood Pressure in Pregnancy, 2000). A 2017 systematic review of several epidemiological studies, conducted in different regions globally, reported a prevalence of GH and PE that ranged from 1.8%–4.4% and 0.2%–9.2%, respectively (Umesawa and Kobashi, 2017).

Etiology and Pathophysiology of Hypertensive Disorders of Pregnancy

The etiology of HDP is still unknown; however, the pathophysiologic mechanisms of such conditions have been discussed in multiple scientific studies and reviews (Gude et al., 2004; Hutcheon et al., 2011; Mammaro et al., 2009). During healthy pregnancy, the invasion of uterine tissues by the embryonic trophoblasts and the remodeling of maternal spiral arteries into larger vessels, to accommodate adequate placental perfusion, ensure normal placental development and adequate exchange of blood and nutrients to the fetus (Gude et al., 2004; Mammaro et al., 2009). On the other hand, abnormal trophoblast invasion and vascular remodeling induce placental ischemia and oxidative stress, causing the placenta to release inflammatory mediators into the mother's circulation. Such mediators damage the endothelial cells of the vascular circulation, consequently, reducing the ability of the blood vessels to relax and inducing cellular protein leakage resulting in one or more of the HDPs (Granger et al., 2002; Gude et al., 2004; Mammaro et al., 2009). Several risk factors have been associated with the development, or worsening, of hypertensive disorders during pregnancy. Some examples of modifiable and nonmodifiable risk factors are obesity, alcohol intake, preexisting hypertension or diabetes, multiple pregnancies, and previous history of GH or other complications encountered during pregnancy (Hutcheon et al., 2011; Mustafa et al., 2012; Umesawa and Kobashi, 2017; Uzan et al., 2011; Vest and Cho, 2014). Although the only cure for these conditions is placental delivery, several protocols have been developed to guide the management of women with HDP.

Clinical Presentations and Complications of Hypertensive Disorders of Pregnancy

PE is a multisystem disease where proteinuria is often a marker of kidney damage but could also indicate damage in other organs such as the brain, liver, and retina (Karumanchi and Granger, 2016; Umesawa and Kobashi, 2017). Thus, the clinical presentation of preeclamptic mothers can vary widely, ranging from no or mild signs and symptoms, such as generalized edema or infrequent urination, to severe and life-threatening manifestations such as visual disturbances, unusual headache, epigastric pain, seizures, or even death (MacKay et al., 2001; Muti et al., 2015; Riaz et al., 2011). In addition, HDP carry significant risk of fetal and maternal short-term and long-term complications. In the short term, HDP can result in premature delivery, fetal growth restriction, and neonatal developmental delays. In the long term, it can result in recurrent PE and remote maternal chronic diseases (renal disease,

chronic hypertension, diabetes mellitus, cardiovascular diseases). Furthermore, it can lead to complications such as ischemic heart diseases or stroke in offsprings in their adulthood (Brown et al., 2013; Hutcheon et al., 2011; Kajantie et al., 2009; Mannisto et al., 2013).

Management of Hypertensive Disorders of Pregnancy

The treatment of HDP depends on the different BP categories defined by international guidelines (Butalia et al., 2018; Magee et al., 2014; Mammaro et al., 2009). For example, according to Hypertension Canada's 2018 guidelines for the management of hypertension in pregnancy, antihypertensive therapy is recommended for both "severe" (≥160/110 mmHg) and "nonsevere" (≥140/90 mmHg) hypertension (Butalia et al., 2018). On the other hand, the American College of Obstetricians and Gynecologists guideline recommends the initiation of antihypertensive agents for the treatment of "severe BP elevation" (≥160/110 mmHg), while only close monitoring is recommended for "mild hypertension" (140-159/90–109 mmHg) (American College of, Gynecologists, & Task Force on Hypertension in, 2013).

The most common first-line BP lowering agents for the treatment of HDP are labetalol, methyldopa, and nifedipine (Butalia et al., 2018; Kattah and Garovic, 2013; Magee et al., 2014). Moreover, another means of treating severe PE, or related complications, is the early termination of pregnancy. However, in stable mothers beyond 34-weeks' gestation, the administration of a 48-h course of corticosteroids before delivery is recommended to help preserve the fetal lung maturity (Butalia et al., 2018; Magee et al., 2014). In addition, during an eclamptic seizure, the administration of magnesium sulfate is superior to other conventional anticonvulsants, such as phenytoin or diazepam, and is considered a first-line therapy (Kattah and Garovic, 2013). Furthermore, in women at high risk of PE, including those with a history of recurrent PE, preventative measures such as the administration of low-dose aspirin (80 mg/day) can be undertaken, as means of counteracting inflammation, and calcium supplementation (Butalia et al., 2018; Kattah and Garovic, 2013; Magee et al., 2014).

Diabetes During Pregnancy

Diabetes mellitus (DM) is a chronic metabolic disorder, which is considered to be a rapidly growing global burden that predisposes individuals to a wide array of economic, health, and social consequences (American Diabetes Association, 2012b). According to the International Diabetes Federation (IDF), the prevalence of DM has reached 425 million adults in 2017, 204 million of whom were women (Cho, 2017). In addition, hyperglycemia (abnormally elevated blood glucose), the hallmark characteristic of DM, is the most common complication encountered during pregnancy, and was evident in 21.3 million live births worldwide in the year 2017 (Cho, 2017).

Furthermore, hyperglycemia first detected during pregnancy (HFDP) is classified into two categories based on the severity of blood glucose elevation: (1) diabetes mellitus in pregnancy (DIP) and (2) gestational diabetes mellitus (GDM) (Hod et al., 2015). DIP, the more severe form, is defined as either a preexisting disease (type1 or type 2 pregestational DM), or a previously undiagnosed DM first detected during pregnancy (overt DM). On the other hand, GDM, the milder form of hyperglycemia, is the most common type of HFDP, underlying up to 86.4% of the hyperglycemic cases encountered during pregnancy worldwide in 2017.

Etiology and Pathophysiology of Diabetes During Pregnancy

The etiology of GDM is explained by the pathophysiologic events that occur during pregnancy. In normal pregnancy, the physiologic state of glucose metabolism and insulin response is altered (Barbour et al., 2007; Catalano et al., 1999; Hodson et al., 2013; Law and Zhang, 2017; Sonagra et al., 2014). Healthy gestation is characterized by up to 50% decrease in insulin-mediated glucose disposal, in addition to an estimated 200%–250% increase in insulin secretion as a compensatory mechanism for the increased insulin resistance observed with advanced gestation. The mechanism for such metabolic changes in pregnancy is attributed to the secretion of placental-derived hormones and proinflammatory mediators that hinder the insulin signaling pathways (Barbour et al., 2007; Catalano et al., 1999; Christian and Porter, 2014; Hodson et al., 2013). Women at risk of prolonged insulin resistance states (obesity, family history of DM/GDM, genetic predisposition for glucose intolerance, polycystic ovarian syndrome, and pancreatic beta-cell dysfunction) are those prone to developing GDM and other implications responsible for maternal and fetal-related morbidity (Catalano, 2010; Catalano et al., 1999; Law and Zhang, 2017).

Clinical Presentation and Complications of Diabetes During Pregnancy

According to the American Diabetes Association (ADA), GDM is often diagnosed during the second or third trimester, although it can, less commonly, be detected during early pregnancy. In addition, other than reporting the classic symptoms of diabetes (polydipsia, polyuria, polyphagia), women with GDM are usually asymptomatic (American Diabetes Association, 2012a; NICE Guideline [NG3], 2015). Therefore, clinical guidelines recommend screening for GDM at 24–28 weeks' gestation via the 75 g-oral glucose tolerance test (OGTT) and fasting blood glucose (FBG), or at the first prenatal visit for those with known risk of developing overt diabetes (American Diabetes Association, 2012a; NICE Guideline [NG3], 2015; Whalen and Taylor, 2017).

Screening for hyperglycemia is crucial since DM increases the risk of developing short- and long-term maternal and fetal/neonatal complications, such as cesarean delivery, the need for labor induction, secondary chronic DM/hypertension, eclampsia, macrosomia, birth trauma, secondary DM in the offspring, and perinatal mortality (Hartling et al., 2013). Since the risk of developing such

complications increases with progressive hyperglycemia, the treatment of hyperglycemia is recommended by means of achieving optimal glycemic control, HbA1c <6%–6.5% and FBG <5.3 mmol/L.

Management of Diabetes During Pregnancy

Several management modalities have been recommended to counteract insulin resistance and reduce the risk of hyperglycemia-related complications (Buchanan et al., 2012; Hartling et al., 2013; Landon et al., 2009; Poston et al., 2017). Essentially, lifestyle modification (diet, physical activity, and weight management) and glucose-self monitoring are recommended for all pregnant women with hyperglycemia (Viana et al., 2014; Wang et al., 2017). Pharmacologic interventions are added for those who do not achieve glycemic targets with lifestyle management or those who present with higher initial degrees of hyperglycemia. Moreover, insulin is the first-line pharmacologic agent recommended for the treatment of GDM, owing to its adequate efficacy and safety profiles (American Diabetes Association, 2012a; NICE Guideline [NG3], 2015). In addition, the observed efficacy and short-term safety of metformin and glyburide support their use for the treatment of hyperglycemia as adjunctive or alternative therapy (Gui et al., 2013; Langer et al., 2000). However, unlike insulin, both metformin and glyburide cross the placenta; although long-term safety data are lacking for both agents, metformin is preferred since glyburide was associated with higher risk of macrosomia and neonatal hypoglycemia (Nachum et al., 2017).

Hematological Disorders of Pregnancy

Pregnancy is associated with the promptness of several changes to multiple organ systems in order to accommodate for the "growing fetoplacental unit" (Bauer, 2018). One of the most common dramatic physiologic changes that occur during pregnancy is an alteration to the process of hemostasis (Bauer, 2018; Katz and Beilin, 2015; Townsley, 2013). Although such physiologic changes aim to ameliorate the risk of ante/postpartum bleeding, pathologic states can further complicate pregnancy through the exacerbation of underlying/inherited hematologic disorders or the development of acquired disorders of coagulation (Katz and Beilin, 2015; Lefkou and Hunt, 2012). Coagulopathy in pregnancy can be classified as (1) inherited coagulopathies, such as von Willebrand disease (vWD) and hemophilia A and B; (2) acquired coagulopathies, such as amniotic fluid embolus and liver disease, causing disseminated intravascular coagulation (DIC) secondary to uncontrolled activation of the coagulation cascade; and (3) qualitative and quantitative platelet abnormalities, such as gestational thrombocytopenia (GTP), immunological thrombocytopenic purpura (ITP), and disorders of platelet aggregation (Katz and Beilin, 2015; Lefkou and Hunt, 2012).

von Willebrand disease (vWD), the deficiency of von Willebrand factor (vWF), the carrier protein of factor VIII), is the most common (~1%) hereditary blood-clotting disorder in the general population and was observed to be among the most frequent (up to 11.9%) blood disorders of pregnancy associated with history of menorrhagia (Dilley et al., 2001; James et al., 2004; Kujovich, 2005; Lillicrap, 2013; Nichols et al., 2008; Philipp et al., 2003; Saxena et al., 2003). On the other hand, while hemophilia A and B (severe deficiency of factor VIII and IX, respectively) are rare in females, the carrier status happens to be more prevalent, with 35% of carriers having factor concentrations below the normal range (Chi et al., 2008; Katz and Beilin, 2015). In addition, despite the overall low prevalence of DIC in pregnancy (up to 0.35% in population-based studies), it is relatively high in those with pregnancy-specific complications that tend to exacerbate the condition, for which the prevalence of DIC reached up to 83% of pregnancies complicated by amniotic fluid embolism and 21% of those complicated by hemolysis, elevated liver enzymes, and low platelets (HELLP) syndrome (Callaghan et al., 2012; Erez et al., 2014; Gilbert and Danielsen, 1999; Rattray et al., 2012; Shamshirsaz and Clark, 2016; Sibai et al., 1993). Furthermore, platelet defects are the most common hematological disorders encountered during pregnancy (Katz and Beilin, 2015; Lefkou and Hunt, 2012; Philipp et al., 2003, 2005). A platelet count below the normal threshold ($150–400 \times 10^9$/L) is often found in 5%–8% of all pregnancies, whereby GTP is the most common cause (75%) of this physiological, mild platelet count reduction (S. A. Hale et al., 2012; Lefkou and Hunt, 2012; Philipp et al., 2005).

Etiology and Pathophysiology of Hematological Disorders of Pregnancy

Normal gestation is characterized by a hypercoagulable state, which serves as a physiologically adaptive mechanism to maintain the placental function and to protect the mother against excessive hemorrhage during, or after, delivery (1). This phenomenon is obtained through a shift in the balance between the hemostatic system and the fibrinolytic system that favors clot formation (S. A. Hale et al., 2012). On one hand, a significant increase in coagulation factors (II, VII, VIII, IX, X, XII, XIII, and von Willebrand factor), prothrombin, and plasma fibrinogen, accompanied by a decrease in Protein S levels, is observed during pregnancy (Hellgren, 2003; Paidas et al., 2005). On the other hand, the fibrinolytic activity decreases, due to the gradual increase of plasminogen activator inhibitors (PAI)-1 and PAI-2 derived from the placental tissues, which then returns to normal levels upon placental delivery. Consequently, compared with nonpregnant women, an otherwise healthy pregnant woman is at an increased risk of thrombosis (Bauer, 2018; Katz and Beilin, 2015; Townsley, 2013). However, it can be difficult to quantify the range of spectrum between the hemorrhagic risk and the thromboembolic risk in those with pregnancies complicated by coagulation disorders. Although some congenital bleeding disorders may improve secondary to the pregnancy-induced prothrombic state, acquired and functional bleeding problems are at risk of worsening throughout gestation and during or following delivery. Thus, pregnant women with history of coagulopathy (personal or family history), history of bleeding abnormalities (e.g., menorrhagia and epistaxis), evidence of antepartum trauma (e.g., placental abruption), or known consumption of causative agents (e.g., aspirin, alcohol) must be thoroughly evaluated by a multidisciplinary team. Accordingly, factor levels must be checked at conception, at 28 and 34 weeks' gestation, and before delivery or other invasive procedures (Dunkley et al., 2009; Lee et al., 2006).

Clinical Presentations and Complications of Hematological Disorders of Pregnancy

The clinical presentation of coagulation disorders in pregnancy is often related to the clinical classification of the disease (type and severity) and the particular coagulation factors/proteins involved. For example, pregnant women with classical vWD-type 1 (mild factor deficiency) are often asymptomatic or present with easy bruising, since normal factor levels are attained throughout gestation. However, pregnancy can exacerbate the bleeding tendency in those with vWD-type 3 (complete factor absence), leading to an increase in the risk of bleeding episodes (Laffan et al., 2014; Lefkou and Hunt, 2012). Another instance is while women with ITP rarely bleed and carry the risk of passing down neonatal thrombocytopenia (up to 14%), those with GTP are asymptomatic and carry no transplacental risks to the fetus. Furthermore, apart from the high prevalence of maternal morbidity and mortality associated with the HELLP syndrome, other maternal and fetal complications associated with blood disorders in pregnancy can include: prolonged/excessive bleeding with miscarriages or spontaneous abortions, prolonged/excessive bleeding postpartum (as factors' levels fall to prepregnancy levels), treatment-related complications (thrombosis, infections, etc.), bleeding/infections secondary to invasive monitoring methods, transplacental transfer of antifactor/antiplatelet antibodies, and neonatal intracranial hemorrhage upon delivery (Dunkley et al., 2009; Gernsheimer, 2016; Lee et al., 2006; Lefkou and Hunt, 2012).

Management of Hematological Disorders of Pregnancy

The management of bleeding disorders in pregnancy depends on the type, subtype, and severity of the disorder ((Dunkley et al., 2009; Lee et al., 2006). Generally, patients should be provided with a "birth plan," indicating their preferences, disease information, and treatment plan (Dunkley et al., 2009; Lee et al., 2006). In addition, normalization of factor/platelet levels, especially in those with severe disorders, should be attained as close as possible to labor and delivery, while aiming to maintain those levels for up to 7 days after delivery. The treatment/prophylaxis modalities available for patients, or carriers, of bleeding disorders in pregnancy are 1-desamino-9-d-arginine vasopressin, tranexamic acid, recombinant proteins (preferred), and blood components (plasma and cryoprecipitate). Such methods aim to achieve clot stabilization, increase factor concentration, and directly activate the coagulation cascade (Katz and Beilin, 2015). However, given the increased risk of venous thromboembolism encountered during labor and delivery, prophylactic anticoagulation is considered for parturient women for whom hemostasis is achieved (Dunkley et al., 2009; Katz and Beilin, 2015; Lee et al., 2006). Moreover, owing to the lack of safety data on the appropriate mode of delivery in such patients, vaginal delivery and neuraxial anesthesia are recommended, unless a clinical judgment presumes otherwise.

Gastrointestinal Tract Disorders During Pregnancy

Gastrointestinal tract (GIT) symptoms such as nausea, vomiting, heartburn, diarrhea, and constipation are common in pregnancy. Pregnancy may also complicate GIT diseases such as inflammatory bowel disease (IBD) and gastroesophageal reflux disorder (GERD). Therefore, other pathologic conditions and causes should be considered during the evaluation of a pregnant patient who presents with these GIT symptoms. The common GIT symptoms and disorders of pregnancy may be associated with adverse health outcomes and decreased quality of life in the mother and the fetus (Ayyavoo et al., 2014; Bustos et al., 2017; Gomes et al., 2018; Wood et al., 2013). Nausea and vomiting of pregnancy is a common occurrence, affecting 50%–90% of pregnant women (Body and Christie, 2016; Ebrahimi et al., 2010). However, the incidence of hyperemesis gravidarum, a more severe form of vomiting in pregnancy, is much lower, occurring in about 0.3%–3% of pregnant women (London et al., 2017). This has significant effect on the patient's quality of life, daily activities, and work capacity (Ayyavoo et al., 2014; Wood et al., 2013). GERD is another common GIT symptom of pregnancy, and its incidence is reported to be from 17% to 45% (Vazquez, 2010, 2015). It usually begins at the end of the first trimester and can significantly impair the patient's quality of life. However, complications of GERD such as esophagitis, bleeding, and strictures are not commonly reported (Body and Christie, 2016). Furthermore, constipation is also a common symptom experienced during pregnancy with a prevalence rate ranging from 11% to 44% (Bradley et al., 2007; Prather, 2004; Rungsiprakarn et al., 2015; Shi et al., 2015).

Etiology and Pathophysiology of Common Gastrointestinal Tract Disorders of Pregnancy

Several body systems including the GIT undergo important physiological and structural alterations and adaptations during pregnancy to allow fetal development and the mother's well-being (Body and Christie, 2016; Gomes et al., 2018; Tan and Tan, 2013). For instance, increased levels of hormones, such as progesterone, contribute to delayed gastric emptying (Gomes et al., 2018; Tan and Tan, 2013). In addition, there is increased gastric acidity due to increased production of gastrin by the placenta (Tan and Tan, 2013). On the other hand, the growth of the fetus in the uterus may also result in anatomical alteration of abdominal organs and can result in the common GIT symptoms of pregnancy such as nausea, vomiting, diarrhea, heartburn, and constipation.

Although, the exact mechanism of nausea and vomiting is not completely understood, it is believed that elevated level of progesterone has an inhibitory effect on the smooth muscle of the pylorus and small bowel, decreasing gastrointestinal motility, and delaying gastric emptying (Body and Christie, 2016). GERD is also believed to be associated with a similar mechanism. Multiple pregnancies have been associated with more prevalent and severe symptoms due to the higher levels of human chorionic gonadotropin (Matthews et al., 2015). Furthermore, psychological factors such as anxiety, depression, unwanted pregnancies, and negative relationships with family may also play an important role in the pathogenesis of nausea and vomiting of pregnancy and have been linked to a higher prevalence (Body and Christie, 2016; Gomes et al., 2018). Furthermore, pregnancy-induced diarrhea may be due to elevated levels of prostaglandins.

Clinical Presentations and Complications of Common Gastrointestinal Tract Disorders of Pregnancy

Nausea and vomiting symptoms begin early (between the 4th and 6th week of gestation), reach their peak between the 8th and 12th week, and typically cease around the 20th week of gestation (Body and Christie, 2016). Although the term "morning sickness" is popularly used to refer to nausea and vomiting of pregnancy, these symptoms persist throughout the day in the majority of affected women (Lee & Saha, 2011). Other differential diagnosis for pregnancy-induced nausea and vomiting include GERD and peptic ulcer disease. Most women with nausea and vomiting of pregnancy have normal vital signs and other physical examination findings (Lee and Saha, 2011). Hyperemesis gravidarum is associated with severe nausea and excessive vomiting that usually start before the end of the 22nd week of gestation (Bustos et al., 2017). It is characterized by prolonged vomiting leading to dehydration and electrolytic imbalance, nutritional deficiency, ketonuria, and a weight loss of more than 5% of prepregnant weight, often leading to hospitalization and other fatal outcomes (American College of Obstetricians and Gynecologists, 2015; London et al., 2017; Verberg et al., 2005). Patients also commonly present with excessive salivation (ptyalism) and heartburn. These have been the most commonly used criteria for the diagnosis of hyperemesis gravidarum (American College of Obstetricians and Gynecologists, 2015). Electrolytes and acid–base abnormalities may include hyponatremia, hypokalemia, and hypochloremia (London et al., 2017). Mild elevation in enzymes such as lipase, amylase, and liver transaminases are also often found in patients with hyperemesis gravidarum (Lee and Saha, 2011). Patients may also present with signs and symptoms of severe dehydration such as tachycardia, orthostatic hypotension, dry skin, and lethargy (Lee and Saha, 2011; London et al., 2017).

Heartburn is presented as a burning sensation in the upper part of the GIT including the throat (Richter, 2005). Complications such as erosive oesophagitis, bleeding, and strictures are rare in heartburn during pregnancy (Body and Christie, 2016; Richter, 2005; Vazquez, 2015); therefore, diagnostic investigations such as endoscopy, oesophageal manometry, and pH studies are not routinely conducted (Richter, 2005; Vazquez, 2015). The diagnosis of pregnancy-induced heartburn is mainly based on clinical history and physical examination.

Management of Nausea and Vomiting of Pregnancy

A number of nonpharmacologic and pharmacologic approaches are used for the treatment of nausea and vomiting of pregnancy including hyperemesis gravidarum. These include lifestyle and dietary changes, pharmacotherapy, intravenous fluid replacement, and nutrition therapy. Most women will not require pharmacotherapy and can be managed with dietary modifications and other nonpharmacologic options. Dietary guidelines and recommendations have been proposed to tackle the intensified sense of smell and metallic taste that appears to aggravate nausea and vomiting (Ebrahimi et al., 2010). The dietary recommendations include (1) small frequent meals and avoidance of fatty foods and fresh vegetables that can delay gastric emptying; (2) maintaining adequate hydration and electrolytes through daily consumption of 1.5–2 L of water or drinks containing glucose, salt, and potassium; (3) avoiding strong tasting and odorous foods (e.g., spicy and food with metallic taste); (4) eating simple dry carbohydrates (e.g., crackers and biscuits) before getting out of bed in the morning; and (5) snacking on high protein diets and nuts between meals (American College of Obstetricians and Gynecologists, 2015; Body and Christie, 2016; Bustos et al., 2017; Ebrahimi et al., 2010).

Ginger (*Zingiber officinale*) has traditionally been used and is considered a nonpharmacologic option for the treatment of pregnancy-induced nausea and vomiting (Giacosa et al., 2015). Multiple preparations of ginger are available including dietary supplement forms, or extracts in teas and capsules (Ebrahimi et al., 2010). A Cochrane review has evaluated nine randomized controlled trials (RCTs) involving ginger (Matthews et al., 2015). Another recent meta-analysis of RCTs suggests that ginger improved nausea symptoms in pregnancy compared to placebo, but did not significantly decrease vomiting episodes (Viljoen et al., 2014). The reviewers conclude that ginger could be considered as a harmless and potentially effective alternative for the treatment of pregnancy-induced nausea and vomiting.

Both thiamine (vitamin B1) and pyridoxine (vitamin B6) have been studied for their antiemetic properties, have proven effective, and are indicated as routine supplements in patients with nausea and vomiting (Body and Christie, 2016). Pyridoxine dose of 10–40 mg/day has been used to reduce the severity of nausea and vomiting symptoms, but could be used in higher doses up to 200 mg/day (American College of Obstetricians and Gynecologists, 2015; Vutyavanich et al., 1995). Histamine receptor blockers (anti-H1), such as diphenhydramine, dimenhydrinate, cyclizine, cinnarizine, and doxylamine, are considered first-line treatment, because no adverse fetal effects have been found (Body and Christie, 2016; Magee et al., 2002). Doxylamine has the advantage of being safe when symptoms begin. The American College of Obstetricians and Gynecologists recommends doxylamine either alone or in combination with pyridoxine as first-line treatment for pregnancy-induced nausea and vomiting (American College of Obstetricians and Gynecologists, 2015). Diclectin (also marketed as Diclegis in USA) is a delayed-release formulation containing a combination of doxylamine succinate 10 mg and pyridoxine HCl 10 mg, recommended in a standard dose of four tablets daily (one in the morning, one in the afternoon, and two at bedtime).

Phenothiazines such as chlorpromazine, perphenazine, prochlorperazine, promethazine, and trifluoperzaine are also considered first-line treatment options (Body and Christie, 2016; Magee et al., 2002). Finally, metoclopramide, a dopamine antagonist with upper GIT motility stimulant effect, has been used for the treatment pregnancy-induced nausea and vomiting. Given the limited safety data and its potential extrapyramidal side effects on both the fetus and the mother, metoclopramide is considered a second-line option (Body and Christie, 2016). Serotonin receptor antagonists such as granisetron and ondansetron are used for the treatment of severe nausea and vomiting and hyperemesis gravidarum (Lee and Saha, 2011), although their safety in pregnancy is controversial (Bustos et al., 2017; Siminerio et al., 2016).

Management of Heartburn During Pregnancy

The first-line treatment for heartburn in pregnancy is dietary and lifestyle modification, including reduction of fatty foods intake as well as reducing the size and frequency of regular meals (Body and Christie, 2016; Vazquez, 2010). Other commonly recommended lifestyle measures for heartburn in pregnancy include raising the head of the bed and caffeine intake reduction. Vazquez et al., in their clinical review found that antacids (with or without alginates) provide effective relief of heartburn of pregnancy. The review, however, conclude that there is no definitive evidence of effectiveness for H_2-receptor antagonists, proton pump inhibitors, and dietary and lifestyle modifications (Vazquez, 2015).

Psychiatric Disorders During Pregnancy

Mental disorders are common during and after pregnancy (Howard et al., 2014; Kent, 2011). In fact, prenatal and postnatal period represents the highest prevalence of mental disorders in women (Howard et al., 2014; Kent, 2011; Pereira et al., 2012). Despite delivering a baby is a happy moment, many women develop depressive disorders during the postnatal period (Howard et al., 2014). The manifestation of postpartum depression ranges from mild symptoms that are typically self-limiting to minor or severe depression. This can lead to adverse outcomes for the mother and the baby, if left untreated (Grigoriadis et al., 2013; Howard et al., 2014; Stein et al., 2014).

Depression is the most frequent mental disorder of pregnancy affecting nearly 20% of women (i.e., one in every five) (Bennett et al., 2004; Pereira et al., 2012). This has adverse consequences not only on the mother's health and well-being but may also affects the infant's development (Grigoriadis et al., 2013; Norhayati et al., 2015; O'Hara and McCabe, 2013; O'Hara and Wisner, 2014; Pereira et al., 2012). In general, the prevalence of postpartum depression is estimated to be between 10% and 15% (Bennett et al., 2004; Couto et al., 2015; Pereira et al., 2012). Onset of postpartum depression occurs before, during, or after pregnancy. However, among women whose postpartum depression begins postdelivery, onset is most common within the first few months of parturition, with the first month postpartum representing the peak prevalence of depressive symptoms (Iwata et al., 2016).

Etiology and Pathophysiology of Postpartum Depression

The pathophysiology of postpartum depression is not fully understood, and it is unknown whether it represents a distinct subtype of depression or not (Iwata et al., 2016; O'Hara and Wisner, 2014; Yonkers et al., 2011). However, key factors implicated in postpartum depression include hormonal changes and dysregulation (Meltzer-Brody, 2011; O'Hara and McCabe, 2013), genetic susceptibility and epigenetics (Couto et al., 2015; Meltzer-Brody, 2011), psychological factors, and social and economic factors (Ghaedrahmati et al., 2017; O'Hara and McCabe, 2013). Postpartum depression is associated with fluctuations in hormonal levels of estrogen, progesterone, cortisol, oxytocin, and thyroid hormone (Meltzer-Brody, 2011; Norhayati et al., 2015; O'Hara and McCabe, 2013; O'Hara and Wisner, 2014; Yonkers et al., 2011). It has been suggested that women with postpartum depression may be particularly sensitive to sudden decline in gonadal steroids (Meltzer-Brody, 2011; O'Hara and Wisner, 2014). Furthermore, elevated levels of neurotransmitter monoamine oxidase-A in the cortex are associated with postpartum depression. This could lead to the metabolism and depletion of neurotransmitters such as norepinephrine, dopamine, and serotonin, leading to depression (Sacher et al., 2015).

Several possible risk factors associated with postpartum depression have been identified. The risk factors could be classified into psychological, biological, obstetrical, socioeconomic, and lifestyle (Ghaedrahmati et al., 2017). Identified risk factors include, but are not limited to, previous history of depression, antenatal depression, family history of psychiatric illness or postpartum depression, high levels of postnatal stress, stressful life events during or after pregnancy, poor social support (e.g., economic and emotional support) in the puerperium, young age (e.g., 13–19 years), multiparity, unintended pregnancy, fear of childbirth, season of delivery, adverse pregnancy and neonatal outcomes, and childcare stress (Ghaedrahmati et al., 2017).

Clinical Presentation and Symptoms of Postpartum Depression

Symptoms of postpartum depression and other nonperinatal types of depression appear to be similar. The Diagnostic and Statistical Manual, Fifth Edition (DSM-5) outlines the diagnostic criteria for a major depressive episode. The criteria include depressed mood most of the day (e.g., feels sad, empty, hopeless, appears tearful), markedly diminished interest or pleasure in all, or almost all, activities most of the day, significant weight loss when not dieting or weight gain, insomnia or hypersomnia nearly every day, psychomotor agitation or retardation nearly every day, fatigue or loss of energy nearly every day, feelings of worthlessness or excessive or inappropriate guilt (which may be delusional) nearly every day, diminished ability to think or concentrate, or indecisiveness, nearly every day, and recurrent thoughts of death, recurrent suicidal ideation without a specific plan, or a suicide attempt or a specific plan for committing suicide. In addition, the above symptoms should cause clinically significant distress or impairment in social, occupational, or other important areas of functioning and that that the episode is not attributable to the direct physiological effects of a substance or to another medical condition.

The episodes of postpartum depression vary in their severity, which guides selection of treatment regimen. Postpartum depression may resolve spontaneously or with treatment, or develop into a chronic depressive disorder (Fitelson et al., 2011; Howard et al., 2014). The adverse consequences of postpartum depression include impairment of maternal functioning, poor infant nutrition and health, interference with breastfeeding, abnormal development and cognitive impairment of the infant, and impairment of maternalinfant bonding, care of the infant, and relationship with partner (Grigoriadis et al., 2013; Pereira et al., 2012; Stewart, 2011).

The following symptoms should prompt a clinician to suspect postnatal depression: sadness for at least 2 weeks, concerns about her ability to care for the infant, anxiety about the health of the infant, negative perception of infant temperament and behavior, lack of interest in the infant's activities, lack of response to support, nonadherence to postnatal care, frequent nonroutine visits to the obstetrician or pediatrician, and use of tobacco, alcohol, or illicit drugs (Pearlstein et al., 2009; Yonkers et al., 2011). The US Preventive Services Task Force practice guidelines recommend that clinicians (including obstetricians, gynecologists, and pediatricians) should screen all postpartum women for depression and ensure follow-up for potential diagnosis and treatment (Siu et al., 2016). This is also in line with the recommendations of the American College of Obstetricians and Gynecologists and the National Institute for Health and Care Excellence (NICE) guidelines. Screening for postnatal depression is emphasized because it is associated with negative sequela, it is highly prevalent, underdiagnosed, and amenable to treatment (Milgrom and Gemmill, 2014). Currently, standardized and validated screening tools are available and the most commonly used is the Edinburgh Postnatal Depression Scale (EPDS), a 10-item tool that can be completed in 5 min (Milgrom and Gemmill, 2014).

Management of Postpartum Depression

Psychotherapy is the initial treatment of choice for mild to moderate postpartum major depression (Fitelson et al., 2011; Meltzer-Brody, 2011; O'Hara & McCabe, 2013; Stewart, 2011). Psychotherapy alone is appropriate if the depressive disorder does not include suicidal ideation or obvious impairment of function. Furthermore, psychotherapy alone is a reasonable alternative to antidepressants in patients with severe postpartum depression and a previous history of poor response to antidepressants or if they decline pharmacotherapy (National Institute for Health and Care Excellence, 2014). Psychotherapy approaches for the treatment of postpartum major depression include cognitive behavioral therapy, behavioral activation, nondirective counseling, and psychodynamic psychotherapy. Antidepressants such as selective serotonin reuptake inhibitors (SSRIs), serotonin-norepinephrine reuptake inhibitors (SNRIs), and bupropion are indicated if psychotherapy is not successful, or it is declined by the patient, or if the patient has responded to an antidepressant previously (Fitelson et al., 2011; Kim et al., 2014; Meltzer-Brody, 2011; O'Hara and McCabe, 2013; Stewart, 2011). Furthermore, combination of psychotherapy and pharmacotherapy is beneficial for some patients. The benefits of using antidepressants outweigh the potential risks to the infant in patients who are breastfeeding.

In general, the choice of an antidepressant depends primarily on history of prior treatment. In addition, the selection of the antidepressant in breastfeeding mothers also depends on prior treatment history and potential risk for the mother and the infant. However, there is no compeling evidence regarding safety differences among commonly used antidepressants. SSRIs such as sertraline, paroxetine, and citalopram are recommended for patients with severe major depression who are breastfeeding and are antidepressant-naïve because of their demonstrated efficacy and tolerability for postpartum depression (Kim et al., 2014; Meltzer-Brody, 2011; O'Hara and McCabe, 2013; Weisskopf et al., 2015). Fluoxetine, fluvoxamine, and escitalopram are used less frequently for the initial treatment of postpartum depression in breastfeeding mothers (Weisskopf et al., 2015). It is worthwhile to mention that SNRIs, atypical antidepressants such as bupropion and mirtazapine, and tricyclics antidepressants, such as nortriptyline, are reasonable alternatives to SSRIs (O'Hara and McCabe, 2013; Sie et al., 2012).

Preterm Labor

Preterm labor is defined as "regular contractions of the uterus resulting in changes in the cervix that start before 37 weeks of pregnancy" ("American College of Obstetricians and Gynecologists frequently asked questions"). It occurs in approximately 12% of all pregnancies, leading to the delivery of a premature baby (American Pregnancy Association). Therefore, preterm labor is a major cause of perinatal morbidity (e.g., neonatal disability such as blindness) and mortality. Due to the high cost of caring for a premature baby, it is important to identify women at risk of premature labor so that they can be monitored closely for the signs and symptoms.

Etiology and Pathophysiology of Preterm Labor

The underlying causes of preterm labor include inflammation and infection, vaginal bleeding during the first trimester, pathological uterine distension and the activation of the maternal or fetal hypothalamic–pituitary–adrenal (HPA) axis, and chronic stress (Lockwood and Berghella, 2018b). There are several risk factors for preterm labor such as history of preterm births, multiple pregnancy, uterine over distention, uterine anomalies, cervical incompetence, bacterial vaginosis, bleeding in early pregnancy, poor socioeconomic status, elderly or adolescent age, tobacco use, and poor nutrition. However, the most important risk factor is previous history of preterm labor (Schleussner, 2013). A history of one preterm labor increases the risk of recurrence in future pregnancies by 14.3%.

Clinical Presentation of Preterm Labor

The signs and symptoms of preterm labor that a pregnant woman will experience include pain in the lower back, light vaginal bleed, mucus discharge from the vagina, cramping similar to the one experienced in menstruation, and frequent contractions (every 10 min or less) (Lockwood and Berghella, 2018b; MedlinePlus). Upon presentation to a physician with the signs and symptoms suggestive of preterm labor, a comprehensive diagnostic evaluation is performed after obtaining history and preforming standard physical examination. Other investigations and evaluation performed include speculum examination (to estimate cervical dilation, examine for uterine bleeding, check if fetal membrane is intact or ruptured), cervical examination, transvaginal ultrasound (to determine length of the cervix), and ultrasound imaging (to determine any abnormalities to the fetus, or placenta) ("American College of

Obstetricians and Gynecologists frequently asked questions," Lockwood and Berghella, 2018b). Furthermore, laboratory tests are done to check for infection (e.g., group B streptococcus in the vagina, bacteria in the urine or sexually transmitted infections such as gonorrhea, chlamydia, and bacterial vaginosis) and fetal fibronectin protein level in vaginal discharge. The presence of fetal fibronectin (a protein that supports the amniotic sac to stay connected to the interior of the uterus) in the vaginal discharge is a predictor of spontaneous preterm birth. Based on the findings from the history and physical examination, imaging, and lab tests, an accurate diagnosis of preterm labor is made on the basis of the frequency of regular contractions (i.e., ≥6 contractions/h), dilation of the cervix (>3 cm) between 24 and 37 weeks of gestation, vaginal bleeding, ruptured membranes, and the presence of fetal fibronectin in the vaginal secretions (Rundell and Panchal, 2017).

Management of Preterm Labor

Due to the difficulty of predicting preterm labor even in women at high risk, prevention is therefore very important. Primary prevention of preterm labor with the goal of reducing the number of preterm labor cases focuses on risk factor avoidance before and during pregnancy. These risk factors targeted for primary prevention include avoiding smoking or smoking cessation, maintaining healthy bodyweight, adopting proper nutrition prior to pregnancy and during pregnancy, and effectively managing stress (Schleussner, 2013). For women with a history of spontaneous preterm delivery, progesterone therapy (injection or vaginal) starting around 16–24 weeks of gestation and continuing until 34 weeks of gestation is effective in preventing spontaneous preterm delivery (Fonseca et al., 2007). However, vaginal progesterone from 22–24 to 34 weeks of pregnancy was not efficacious in reducing preterm birth in women at high risk of preterm birth (Norman et al., 2016). A surgical procedure (cervical cerclage) that involves placing a suture around the cervix has been performed in women with shortened cervix or structural defects of the cervix to reduce the risk of preterm delivery, but its efficacy has not been proven *via* prospective randomized trials (Simcox and Shennan, 2007). However, meta-analyses have revealed perinatal morbidity and mortality reduction of the cervical cerclage surgical procedure in high-risk pregnant women with a single fetus, who have previous history of spontaneous preterm birth, and shortened cervix (Berghella et al., 2011).

The main goal of treatment of pregnant women (less than 34 weeks' gestation) with preterm labor is to provide an intervention that will give the newborn the best chance of survival with minimal complications. Treatment measures include a course of corticosteroids (e.g., betamethasone), tocolytic drugs for up to 48 h (e.g., nifedipine), antibiotics that target group B streptococcus, and magnesium sulfate (Lockwood & Berghella, 2018b). The role of the tocolytic agent for up to 48 h is to reduce uterine contractions (i.e., painful, palpable contractions that last longer than 30 s each and occur more than three times in 30 min), thereby delaying delivery so that the corticosteroid can maximally improve fetal lung maturity. During this period, the pregnant woman can be transferred to an institution that provides advanced care for preterm infants. Classes of tocolytic drugs include calcium channel blockers (e.g., nifedipine), oxytocin-receptor antagonists (e.g., atosiban), prostaglandin-synthase inhibitors (e.g., indomethacin), β_2-agonists (e.g., terbutaline, salbutamol), nitric oxide donors (e.g., nitroglycerin), and magnesium sulfate (Hubinont and Debieve, 2011). Nifedipine and atosiban are the most widely used tocolytics in practice (Walker and Thornton, 2016). In the randomized controlled APOSTEL III trial that compared the effectiveness and safety of 48 h of treatment with nifedipine and atosiban in women threatened with preterm birth, both medications had similar perinatal outcomes (i.e., composite of adverse perinatal outcomes, which included perinatal mortality, bronchopulmonary dysplasia, sepsis, intraventricular hemorrhage, periventricular leukomalacia, and necrotizing enterocolitis) (van Vliet et al., 2016).

The purpose of administering corticosteroids is to reduce the neonatal morbidity and mortality by speeding up the maturation of the lungs, brain, and digestive system of the developing fetus ("American College of Obstetricians and Gynecologists frequently asked questions"). It is most effective when given between 24 and 34 weeks of pregnancy (Rundell and Panchal, 2017; Schleussner, 2013). A Cochrane review found that a single course of antenatal corticosteroid (betamethasone, dexamethasone, or hydrocortisone) is associated with a significant reduction in perinatal death, neonatal death, significant reduction in moderate/severe respiratory distress syndrome, and reduction in the need for mechanical ventilation (Roberts et al., 2017).

Magnesium sulfate is usually administered to pregnant women prior to week 32 of pregnancy (24–32 weeks) when they are at risk of delivering within the next 24 h to provide neuroprotection against cerebral palsy [American College of Obstetricians and Gynecologists frequently asked questions," Lockwood and Berghella (2018a,b); UpTODate 2018 Preterm labor]. Antibiotics are administered because of the association of vaginal bacterial infections with preterm labor and preterm rupture of membranes; hence, it makes sense to administer prophylaxis against bacterial infections ("American College of Obstetricians and Gynecologists frequently asked questions," Lockwood and Berghella, 2018b). Intrapartum antibiotic prophylaxis targeting group B streptococcus is therefore given to all pregnant women in premature labor who are likely to deliver (Hughes et al., 2017).

Induction of Labor

Full-term delivery occurs when a baby is delivered anytime from the gestational age of 37–42 weeks (Spong, 2013). In general, pregnant women will go through spontaneous labor by 42 weeks of gestation and deliver the baby. There are three stages of spontaneous labor. During the first stage, there is uterine contraction and complete cervical dilation. This is followed by the second stage where the baby is delivered. The third stage is the delivery of the placenta, and it carries the risk of postpartum hemorrhage (Dresang and Yonke, 2015). Beyond 42 weeks of pregnancy, there are some risks associated with the pregnancy, hence the need to induce labor.

Etiology and Pathophysiology of Labor Induction

When labor is induced with medication or *via* other methods to stimulate the contraction of the uterus to allow vaginal delivery, it is referred to as labor induction ("American College of Obstetricians and Gynecologists frequently asked questions"). During the 38th week of pregnancy visit, there should be discussion about induction of labor between the 41st and 42nd weeks of pregnancy if needed (National Collaborating Centre for Women's and Children's Health Clinical Guideline). In addition to prolonged pregnancy, another reason for labor induction is the rupture of membranes after 34 weeks of pregnancy. Other reasons to induce labor are hypertensive disorders, maternal medical complications, death of the fetus, restriction of fetal growth, chorioamnionitis, multiple pregnancy, and vaginal bleeding (WHO). Elective induction, which usually occurs after 39 weeks of pregnancy, refers to labor induction for nonmedical reasons such as living far away from the delivery center.

Management of Induction of Labor

Medications used in labor induction include vaginal prostaglandin E2, misoprostol, and mifepristone (National Collaborating Centre for Women's and Children's Health Clinical Guideline). Examples of contraindications for labor induction include placenta previa, vasa previa, active genital herpes umbilical cord prolapse, and transverse fetal lie (Lockwood and Berghella, 2018a).

Early Pregnancy Loss

Early pregnancy loss usually occurs in the first trimester of pregnancy. It is the loss of intrauterine pregnancy. The risk factors include previous early pregnancy loss, maternal smoking, advanced maternal age, exposure to teratogens, and fetal chromosomal abnormalities ("American College of Obstetricians and Gynecologists frequently asked questions," Lockwood and Berghella, 2018a, 2018b). Some of the preventive measures of early pregnancy loss include pharmacologic (e.g., estrogen, aspirin) and nonpharmacological therapies (counseling). Other modifiable risk factors (e.g., maternal diabetes, maternal weight, exposure to teratogens) could be managed/prevented to minimize the chances of early pregnancy loss. After definitive diagnosis of early pregnancy loss, treatment options include expectant management (i.e., complete expulsion of the fetus within 8 weeks), medical treatment (oral mifepristone plus vaginal misoprostol or misoprostol alone if mifepristone is unavailable), or surgery to evacuate the uterus.

The Role of Pharmacist in Pregnancy and Lactation

Challenges of Medication Management in Pregnancy and Lactation

Medication management during pregnancy and lactation is complex and represents a challenge to health-care professionals including the pharmacists. One prime concern is safety of fetal or infant exposure to drugs in the uterus or through breastfeeding. This is further compounded by conflicting evidence on safety/efficacy and lack of evidence regarding risks and benefits of medications in pregnancy and lactation (Grzeskowiak, 2015). Considering the physiological, pharmacokinetic, and pharmacodynamics changes that occur during pregnancy and lactation, the transfer of medication to the fetus and breastfed infant, and the efficacy and safety of medications are extremely essential in managing these patients (Burkey and Holmes, 2013). Furthermore, as pregnant and lactating women are not involved in clinical trials, this restricts the availability of evidence for managing medical conditions in this population (Burkey and Holmes, 2013). The limited role of risk categorization of medications in the decision making for safety of medications is another problem faced by health-care providers, where risk–benefit ratio assessment is difficult (Pernia, 2016).

The presence of these challenges while managing pregnant and lactating women highlights the important role of clinical pharmacists in optimizing medication use. As medication experts, clinical pharmacists contribute toward therapeutic decision making, influence prescribing and therapeutic recommendations, and improve overall health outcomes.

The Role of Clinical Pharmacists in Pregnancy and Lactation

The concepts of clinical pharmacy practice while providing care to pregnant and lactating women are the same as in other populations, but with more emphasis on the needs of these specialized populations. The general roles of clinical pharmacist include:

- Obtaining evidence regarding the safety and efficacy of medications, critical appraisal of obtained information, and providing drug information to health-care providers and patients.
- Obtaining accurate medication history and assessing current medication management.
- Developing medications management plan, monitoring therapeutic outcomes, and recommending changes if needed to achieve desired therapeutic goals.
- Performing therapeutic drug monitoring and accurately interpreting results and implementing changes in patients' drug therapy.
- Assessing allergy, side effects, and adverse drug reactions.
- Developing and implementing evidence-based guidelines and formulary in the setting of practice.
- Conducting medication use audits and improving the quality use of medications.

Other Specialized Roles of Clinical Pharmacists in Pregnancy and Lactation

In addition to the general practice concepts of clinical pharmacy, clinical pharmacists dealing with pregnant and lactating women provide specialized education to patients and health-care providers and contribute to research activities related to obstetrics and gynecology or women health in general (Burkey and Holmes, 2013; Grzeskowiak, 2015; Samuel and Einarson, 2011).

Patient education is a key area where a clinical pharmacist plays an essential role. Women receiving chronic medications for their medical conditions require education regarding medication management before, during, and after pregnancy. Clinical pharmacist provides education for lactating women about the safety or risk of infant exposure while the mother uses medications, the need for infant monitoring, and the timing between medications intake and breastfeeding, if needed. Medication adherence can be enhanced with the proper counseling about the safety and importance of taking medications as prescribed. Furthermore, clinical pharmacy contributes to family planning clinics through assessing eligibility for contraceptive and educating women about its proper use.

Clinical Pharmacy Considerations in ICU

Janattul-Ain Jamal[*], Mohd-Hafiz Abdul-Aziz[†], Bianca Levkovich[†], Jason A. Roberts[§,¶,†], [*]Hospital Tengku Ampuan Afzan, Kuantan, Malaysia; [†]University of Queensland Centre for Clinical Research, The University of Queensland, Brisbane, Australia; [‡]Monash University, Australia; [§]Royal Brisbane and Women's Hospital, Brisbane, Australia; [¶]Centre for Translational Anti-infective Pharmacodynamics, The University of Queensland, Brisbane, Australia

Introduction

Critical illness is a complex syndrome that usually involves dysfunction of multiple organ systems and caring for a critically ill patient in the intensive care unit (ICU) is not a straightforward process (Bersten et al., 2014). Patients cared in the ICU have a higher mortality and receive twice as many regular drugs as compared to the patients in the general ward (Kane-Gill et al., 2017). The ICU is

a complex environment, which usually involves usage of multiple combinations of drugs with rapidly changing dosing in line with patients' clinical response and organ function. This extremely busy environment creates a situation with an increased likelihood of drug errors, and consequently, a higher rate of adverse events (Benkirane et al., 2009; Cullen et al., 1997; Garrouste-Orgeas et al., 2010; Merino et al., 2012; Rothschild et al., 2005; Valentin et al., 2006). In a 1-year prospective observational study involving two ICUs in the United States (US), Rothschild and colleagues reported an adverse event rate of 80.5 events per 1000 patient-days (Rothschild et al., 2005). In this study, 223 serious errors were reported (149.7 serious errors per 1000 patient-days) with drugs being responsible in 78% of the errors. Of all the reported adverse events, approximately 50% of the cases were deemed to be preventable. Importantly, reports such as these are not isolated and have been increasingly documented and observed in numerous ICUs across different countries (Aljadhey et al., 2013; Ewig et al., 2017; Gokhul et al., 2016; Jennane et al., 2011). In the context of the financial burden incurred, countries such as the United States currently spend more than US 100 billion dollars annually on the care of critically ill patients, representing more than 8% of the country's total health-care expenditure (Coopersmith et al., 2012).

With specialized knowledge and skills in niche areas such as disease pathophysiology, pharmacology, pharmacotherapeutics, and pharmacoeconomics, the role of a clinical pharmacist is crucial for optimizing patient care in the ICU through the promotion of safe, effective, as well as economical, usage of medicines (Preslaski et al., 2013). The importance of the clinical pharmacist in the ICU is further epitomized by the findings of a prospective, observational, multicenter study (PROTECTED-UK), which was conducted over a 2-week period in 21 ICUs across the United Kingdom (UK) (Rudall et al., 2017; Shulman et al., 2015). In this study, the contributions made by clinical pharmacists to the care of critically ill patients were substantial; interventions were made in approximately 1 in 6 of all prescribed drugs and importantly, two-thirds of these interventions were deemed to be of moderate to high clinical impact (Shulman et al., 2015). Additionally, drug errors were also inversely correlated with the presence of a consultant clinical pharmacist, suggesting that the availability of an experienced clinical pharmacist may lead to more effective prescribing in the ICU.

Clinical pharmacists have demonstrated value in improving the quality, safety, and efficiency of patient care, and these have been achieved in the setting of increasingly complex ICU population. As intensive care practice continues to advance with respect to patient and technological complexity, clinical pharmacists are well placed to promote and further expand their services in the ICU.

Clinical Pharmacist Contributions to the Multidisciplinary Critical Care Team

The role of hospital pharmacists has gradually evolved over the past 30 years from traditional dispensing responsibilities to becoming an integral part of the multidisciplinary team in specialist areas such as the ICU (Jurado and Steelman, 2013; Preslaski et al., 2013). This role shift has allowed clinical pharmacists to be physically present in the ICU providing direct patient care and serving as the pharmacotherapy and medicines management experts. Clinical pharmacists' specialized knowledge on pathophysiology, pharmacology, pharmacotherapeutics, and pharmacoeconomics positions them to assist clinicians and other critical care members with pharmacotherapy-decision making that increases the likelihood of therapeutic success and improves drug management systems. Increasing evidence supports improvement in patient therapeutic outcomes through interventions made by clinical pharmacists working in the ICU as a member of a multidisciplinary critical care team consisting of intensivists, critical care nurses, respiratory care practitioners, rehabilitation therapists, and other allied health practitioners (e.g., dieticians, physiotherapists) as well as nonclinicians such as spiritual care providers and social workers (Donovan et al., 2018). The unique contribution and specific expertise of members of the critical care team is pivotal in the provision of optimal care in the ICU and addresses the diverse needs of critically ill patients and their family members. The following sections below briefly review the unique roles of selected healthcare providers and members of the multidisciplinary critical care team in the ICU.

Intensivist

An intensivist is a physician who has completed a fellowship in critical care medicine and specializes in the care of critically ill patients in the ICU. The intensivists are highly trained in the management of various conditions commonly encountered in the ICU and they are proficient with the technical procedures and devices used in the critical care setting. Intensive care delivery and patient outcomes can be optimized by an intensivist-led, high-intensity, multidisciplinary critical care team in the ICU. They are often the leaders of the critical care team and are primarily responsible to coordinate and facilitate patient care. Increasing data have suggested that patient survival, ICU length of stay, and drug safety can be improved in units with high-intensity intensivist staffing (Banerjee et al., 2011; Cavallazzi et al., 2010; Nishisaki et al., 2012; West et al., 2014).

Critical Care Nurses

Critical care nurses are pivotal to the hour-to-hour running and operation of the ICU as they perform the majority of patient assessment, evaluation, and care in the unit. All nurses working in an ICU should be trained and certified in critical care nursing. Optimal numbers of nurses in the ICU have been associated with improved patient survival, adverse drug events reduction, and shortened length of hospital stay (Burns and Earven, 2002; Danckers et al., 2013; Neuraz et al., 2015; West et al., 2014).

Respiratory Care Practitioners

Respiratory care practitioners play an important role in caring for both intubated and nonintubated patients in the ICU. They are directly involved in all aspects of respiratory care of critically ill patients and perform their tasks according to physician's orders and approved protocols. Multidisciplinary ICU care involving respiratory care practitioners has been associated with early patient

mobility and optimal weaning from mechanical ventilation (Balas et al., 2013; Ely et al., 1996; Girard et al., 2008). Respiratory care practitioners are also vital in arterial blood gases monitoring and airway management (Bishop et al., 2001; McConnell et al., 2016). In some countries, this role is shared by critical care nurses and physiotherapists.

Dieticians

As malnutrition is common in the ICU, the specialized expertise of a dietician is needed to optimize nutrition delivery in critically ill patients thereby preventing negative clinical outcomes in these patients such as infection, poor wound healing and prolonged ventilator support. Critically ill patients achieve nutritional goals faster with nutritional recommendations from dietician and additionally, they are capable of performing tasks such as placement of feeding tubes and the initiation of enteral and parenteral nutrition in the ICU (Brantley et al., 2014; Braunschweig et al., 1988; Cresci and Martindale, 2003; Peterson et al., 2010; Taylor et al., 2014).

Rehabilitation Therapists

Rehabilitation therapists, which may include a physical therapist, occupational therapist, and speech pathologist, are needed in the ICU to promote early rehabilitation in critically ill patients that is essential for the improvement of functional and cognitive outcomes. ICU patients on mechanical ventilator who receive early physical therapy demonstrated longer ventilator-free days, shorter duration of ICU and hospital stay, shorter duration of delirium, as well as better motor and cognitive outcomes at hospital discharge (Alvarez et al., 2017; Morris et al., 2008; Schweickert et al., 2009). Speech pathologists are mainly responsible to facilitate communication and to assess and manage dysphagia in critically ill patients in the ICU (Baumgartner et al., 2008; de Mestral et al., 2011; Rumbach et al., 2016). Interprofessional collaboration with other team members is vital as early rehabilitation programs can and are often delayed due to deep sedation practices, which may impact functional and cognitive outcomes of critically ill patients.

Knowledge and Skill Requirements of Clinical Pharmacist in the ICU

A critical care pharmacist in the ICU is a practitioner who has an expert level of competency in critical care pharmacy practice (Jurado and Steelman, 2013; Preslaski et al., 2013; The Royal Pharmaceutical Society, 2016). The pharmacist provides patient care in the ICU, in a consistent and efficient manner, according to the philosophy of pharmaceutical care. To be able to deliver high-quality clinical pharmacy services in the ICU, a critical care pharmacist should be qualified and well-trained in the niche area of critical care pharmacotherapy. However, the training to become a clinical/critical care pharmacist in the ICU varies throughout the world. In the United States, for example, following didactic and experiential learning, a licensed pharmacist may seek Board of Pharmacy Specialties (BPS) certification to achieve privileges for independent and collaborative practice, which include specialties such as ambulatory care and critical care pharmacy. BPS-certified pharmacists must initially pass a rigorous examination and certification can be renewed or maintained by continuing education or additional testing every 7 years. Some countries, such as Australia and Malaysia, recommend that critical care pharmacist to obtain postgraduate qualifications in clinical pharmacy, which usually include lectures and clinical clerkships/attachments. In the United Kingdom, however, at least 3 years of foundation training (e.g., fundamental clinical training, pharmaceutical manufacturing, medicine information services, pharmacy law and governance, and patient services) are initially required before a pharmacist can begin to specialize in specific aspects of practice. Those interested in the area of critical care will start their specialization and will be working in the ICU under the supervision and guidance of a pharmacist consultant (experienced critical care pharmacist). The competency framework and training pathways, which have been published by the Royal Pharmaceutical Society Faculty, will also guide aspiring critical care pharmacists in the United Kingdom to finally become consultant-level practitioners in the ICU (The Royal Pharmaceutical Society, 2016).

A clinical pharmacist in the ICU should be able to (1) design, implement, monitor, evaluate, and modify treatment regimens to ensure safe and effective as well as economical patient care; (2) retrieve, analyze, evaluate, and interpret scientific evidence to provide medicine information to health-care professionals and patients; (3) participate in the generation of new knowledge on appropriate use of medicines; (4) educate health-care professionals and the public regarding rational use of medicines; and (5) engage in continuing education exercises and programs for self-development. Direct contribution from clinical pharmacists has improved specific therapeutic areas, including the management of infections and thromboembolic events in the ICU as well as optimizing sedation and analgesia in critically ill patients receiving mechanical ventilation. Some examples of these benefits are presented and discussed below and although are not exclusive to interventions in critical care units, highlight the impact of pharmacist clinical activities.

Management of Infections

Li and colleagues investigated the impact of a clinical pharmacist-directed antimicrobial stewardship program versus a nonpharmacist stewardship program in eight ICUs across Zhejiang province in China (Li et al., 2017). During the study period, the clinical pharmacist recommended changes in 38.2% of the antimicrobial orders, and these interventions were made primarily in the context of antimicrobial deescalation and discontinuation. The pharmacist-directed antimicrobial stewardship program demonstrated lower hospital mortality rate (19.3% vs. 29.0%, $p = 0.007$), shorter duration of empirical antimicrobial use (2.7 days vs. 3.0 days, $p = 0.002$), and total antimicrobial use (4.0 days vs. 5.0 days, $p = 0.030$), as well as a lower rate of resistance emergence (23.8% vs.

31.7%, $p = 0.037$) when compared to the nonpharmacist directed program. In this study, the odds of hospital mortality were 43% lower in the clinical pharmacist-directed program (OR 0.57; 95% CI 0.36–0.91, $p = 0.017$).

Gentry and colleagues evaluated the impact of a clinical pharmacist-directed antimicrobial control program in one of the teaching hospitals in Oklahoma (Gentry et al., 2000). Over a 2-year period, the clinical pharmacist reviewed >1000 orders for antibiotics and recommended changes in >50% of these orders primarily on the basis of spectrum of activity and/or dosing appropriateness. These interventions were associated with a 2.4-day decrease in length of hospital stay and a reduction in mortality from 8.28% to 6.61% for patients with infection. The acquisition cost of intravenous antimicrobials was also reduced by 30.8% annually with a total cost saving of US 291,885 dollars.

Okada and colleagues assessed the outcome of a therapeutic drug monitoring (TDM) program in a Japanese hematology ward (Okada et al., 2016). In this retrospective cohort analysis, 145 hematology patients receiving antimicrobials (arbekacin, teicoplanin, and vancomycin) for methicillin-resistant *Staphylococcus aureus* (MRSA) infection were included. The pharmacist-led TDM program had higher rates of target concentration achievement than the traditional program (74.0% vs. 55.0%, $p = 0.05$), which did not involve pharmacists in treatment decision making. Additionally, optimal antimicrobial concentrations (HR 0.46; 95% CI 0.18–0.89, $p = 0.026$) and pharmacist-led TDM interventions (HR 0.43; 95% CI 0.20–0.92, $p = 0.029$) were independent factors associated with reduced hospital stay in patients with lymphoma.

Anticoagulation Therapy

In a recent randomized controlled trial, Lakshmi and colleagues compared the impact of a pharmacist-managed anticoagulation service with usual medical care in 80 stroke patients treated in a tertiary care hospital in India (Lakshmi et al., 2013). In this study, patients who received pharmacist counseling demonstrated better and significant improvement in knowledge scores on oral anticoagulation compared to those who received standard medical care (Δ 8.2 vs. Δ 0.3, $p = 0.001$). During the 6-month study period, 77.4% of patients in the pharmacist-managed group achieved the target international normalized ratio (INR) range as opposed to 46.5% in the standard care group ($p < 0.001$). The patients in the standard care group were more likely to demonstrate supratherapeutic INR levels when compared to those in the pharmacist-managed group (23.6% vs. 8.31%, $p < 0.001$).

To and colleagues evaluated the impact of a clinical pharmacist-directed anticoagulation service in 193 patients with heparin-induced thrombocytopenia receiving direct thrombin inhibitors (To et al., 2011). Compared to patients receiving standard anticoagulation care, in-patient pharmacist-directed anticoagulation service significantly improved the time to achieve therapeutic aPTT by 34% (18.9 h vs. 6.4 h, $p < 0.001$) and the percentage of time within the therapeutic aPTT range by 32% (64.4% vs. 84.7%, $p < 0.001$). The rate of thrombolysis in myocardial infarction (TIMI) major bleeding was also significantly lower in the pharmacist-directed anticoagulation group (0.0% vs. 7.4%, $p = 0.006$).

Saokaew and colleagues compared the anticoagulation control and clinical outcomes between warfarin therapy provided by a clinical pharmacist-managed warfarin clinic and standard medical care in 433 patients in a tertiary care hospital in Thailand (Saokaew et al., 2012). In this study, 284 interventions were performed by clinical pharmacists, and the majority of them (80.3%) were accepted by physicians. The most common intervention was related to warfarin dosing adjustment (88.0%). At the end of the study period (9 months), the pharmacist-managed group had a higher percentage of time within the therapeutic INR range than those receiving standard care (47.7% vs. 39.5%, $p = 0.003$). Rates of major bleeding were 4.4 versus 4.5 events per 100 person-years for the pharmacist-managed and standard care group, respectively.

Sedation and Analgesia

Louzon and colleagues evaluated the benefits of a pharmacist-managed sedation program as compared to a standard, physician-managed program in 70 critically ill patients receiving mechanical ventilation at a large teaching hospital in Orlando (Louzon et al., 2017). When compared to the standard care group, patients who received care via the pharmacist-directed sedation program had less exposure to continuous sedation (150.3 h vs. 252.2 h, $p = 0.003$) and a lower usage of sedative infusions (12.6 infusion drips vs. 27.6 infusion drips, $p < 0.001$), particularly for the benzodiapines (2.7 infusion drips vs. 7.3 infusion drips, $p = 0.003$). The pharmacist-led group also had a reduction in ventilator days (7.4 days vs 8.6 days, $p = 0.07$) and ICU length of stay (11.5 days vs. 16.5 days, $p = 0.011$) when compared to standard care. These clinical benefits have resulted in estimated savings of $1.2 million in direct hospital costs and $183,216 in drug costs.

MacLaren and colleagues investigated the impact of a pharmacist-driven sedation and analgesia protocols compared to empiric-based therapy in 158 critically ill patients in a Canadian ICU (MacLaren et al., 2008). When compared to patients in the empiric-based group, the protocol-based group patients demonstrated significantly lower incidence of agitation (22.4% vs. 11.0%, $p < 0.001$) and pain (9.6% vs. 5.9%, $p < 0.05$). The protocol-based group patients were also more likely to achieve the goal level of sedation (17.2% vs. 29.6%, $p < 0.01$).

Marshall and colleagues evaluated the clinical impact of a sedation protocol both with and without active pharmacist intervention in 156 critically ill patients in two medical ICUs in Boston (Marshall et al., 2008). The majority of interventions made by pharmacists were related either to the initiation of alternative sedative agents (32%) or to discontinuation of continuous sedation (20%). In this before–after study, patients who were managed with pharmacist interventions were observed to have a reduction in the duration of mechanical ventilation (14.0 days vs. 7.4 days, $p < 0.001$), ICU length of stay (380 h vs. 238 h, $p = 0.001$), and hospital length of stay (537 h vs. 369 h, $p = 0.001$) than those managed by the sedation protocol alone.

Reducing Adverse Drug Events in the ICU

One of the earliest and probably best example highlighting pharmacists' vital contribution in the ICU was described by a landmark trial conducted by Leape and colleagues. Leape and colleagues prospectively evaluated the impact of clinical pharmacist participation during medical ICU rounds in the context of reducing the rate of preventable adverse drug events (Leape et al., 1999). During the 8-month study period, pharmacist participation during the medical ICU rounds was shown to significantly reduce the rate of adverse drug events by 66% from 10.4 to 3.5 events per 1000 patient-days.

Bosma and colleagues assessed the clinical and financial impact of interventions made by ICU pharmacists during patient rounds in two ICUs in the Netherlands (Bosma et al., 2018). In this study, 334 critically ill patients were included and 548 interventions were recommended by pharmacists, of which 64.8% of the recommendations were accepted by physicians. The most frequent intervention made was related to the discontinuation of unnecessary drugs for patients (21.7%) and the most commonly involved drugs are gastrointestinal (e.g., proton-pump inhibitors) and antimicrobial agents. On average, between 18 and 23 adverse events were prevented by pharmacist interventions during this study, and this observation corresponds to 0.5 to 0.6 adverse events prevented per patient round. The estimated cost benefit in this study was €128 per accepted intervention.

Tripathi and colleagues performed a retrospective review of medical records, from 2003 to 2013, to evaluate the role of clinical pharmacists in a pediatric ICU (PICU) in Minnesota (Tripathi et al., 2015). During the 11-year period, pharmacists made 27,773 clinical interventions and 79.8% of these were accepted and changed medical treatment. The two most common interventions were changes in drug dosing regimen (52.3%) and drug selection (21.4%). The number of pharmacist interventions significantly increased from 1643 interventions in 2003 to 3566 in 2013 ($p < 0.001$). Each additional hour of pharmacist presence in the PICU led to an additional 191.5 interventions and this presence was thought to prevent 1056 adverse events during the 11-year period. Patients who required pharmacist interventions the most were younger at admission (7.3 years vs. 8.1 years, $p < 0.001$), had prolonged ICU (4.3 days vs. 1.1 days, $p < 0.001$) and hospital stay (11.5 days vs. 3.6 days, $p < 0.001$), as well as a prolonged duration of mechanical ventilation (4.8 days vs. 0.8 days, $p < 0.001$).

A General Approach to Clinical Pharmacy in Critically Ill Patients

Previously, there was no standardized and structured approach to guide clinical pharmacist to provide optimal pharmaceutical care in the ICU. The FASTHUG mnemonic was introduced in 2005 to guide ICU physicians in the management of critically ill patients, ensuring that all essential aspects of patient care are adequately met and delivered (Vincent, 2005). Mabasa and colleagues then modified this approach and developed a new mnemonic for clinical pharmacist (i.e., FASTHUG MAIDENS) to standardize the approach to identify drug-related problems and optimize pharmacotherapy in the ICU (Mabasa et al., 2011). The FASTHUG MAIDENS approach to clinical pharmacy in the ICU is advantageous in several ways including: (1) a standardized and structured approach ensures that the pharmaceutical needs of critically ill patients are met consistently; (2) provide confidence and reduce anxiety among new pharmacist who are not familiar with the ICU environment by providing a stepwise approach to perform their functions; and (3) a good teaching tool for pharmacy students and residents with limited ICU experience (Mabasa et al., 2011; Masson et al., 2013). However, it is still important for pharmacist to have a sound clinical knowledge in the area of critical care pharmacotherapy while using the mnemonic (**Table 1**)

Table 1 FASTHUGS MAINDENS approach to clinical pharmacy in the ICU

Mnemonic	*Explanation*
FASTHUGS	
F	Feeding
A	Analgesia
S	Sedation
T	Thromboprophylaxis
H	Head elevation (30–45 degree)
U	Ulcer prophylaxis
G	Glucose control
S	Stool therapy
MAIDENS	
M	Medication reconciliation
A	Antibiotics
I	Indications for medications
D	Drug dosing
E	Electrolyte, hematology, and other laboratory results
N	No drug–drug interactions
S	Stop dates

Absorption Issues in Critically Ill Patients

The pathophysiological changes associated with critical illness on the gastrointestinal (GI) system have a significant effect on the absorption of drugs (Roberts and Hall, 2013). Clinical pharmacists in the ICU must consider this potential impact on drug dosing, administration, and monitoring. This section will describe potential pathophysiological changes of the GI tract due to critical illness that could affect drug pharmacokinetics (i.e., absorption), and consequently, dosing requirements in critically ill patients.

Pathophysiology Changes During Critical Illness that can Affect Gastrointestinal Function

Altered GI function in critically ill patients is common and has been reported up to 80% of patients receiving mechanical ventilation. Impaired GI function in critically ill patients can be caused by impaired enteric nerve and smooth muscle function, systemic inflammation (e.g., sepsis and/or septic shock), surgery, drugs, electrolyte disturbances, increased intracranial pressure, and underlying concomitant diseases (Heyland et al., 1996; McArthur et al., 1995; Nguyen et al., 2007, 2008). In critically ill patients with sepsis and/or septic shock, the release of endotoxins coupled with stress response may lead to impaired GI motility (Joukhadar et al., 2001, 2002). Preexisting diseases such as diabetes mellitus, GI pathologies and gut surgeries, malnutrition disorders, and other metabolic disorders may also predispose critically ill patients to GI dysfunction. Patients with head injury and increased intracranial pressure are also more likely to have significant delays in gastric emptying (Nguyen et al., 2007). The use of several drugs such as opioids, catecholamines, proton-pump inhibitors, and calcium channel blockers, which are all commonly prescribed drugs in the ICU, may also contribute to the slowing of gastric emptying (Adike and Quigley, 2014; Roberts and Hall, 2013; Stupak et al., 2012). These drugs can alter GI functions through various pharmacological effects including GI hypomotility, pyloric hyperactivity, and prolonging the duration of GI contraction.

Malabsorption leading to malnutrition is one of the major complications of impaired GI function in critically ill patients (Ritz et al., 2000). Reduced GI motility leads to impaired absorption of drugs and more importantly, the essential nutrients that are required by these patients to meet their high metabolic demand.

Common Absorption Issues in ICU Setting

Absorption of drugs in critically ill patients can be impaired when GI motility is reduced as described in the previous section. In the ICU, drugs are most often administered via the intravenous (IV) route to circumvent the erratic and unpredictable absorption associated with impaired GI blood flow and motility in this patient population. During the acute phase of critical illness, peripheral and splanchnic vasoconstriction is likely to impair oral drug absorption, and this phenomenon can be further exacerbated by the use of vasopressors and preexisting diseases (Roberts and Hall, 2013). Importantly, drug administered via IV route provides immediate onset of action through rapid drug delivery into systemic circulation, which is sometimes required in critically ill patients. Although the majority of drugs are administered through IV route, some of the drugs (e.g., beta-blockers and proton-pump inhibitors) in the ICU are also given via the oral route, and therefore the absorption of these oral formulations can be altered in such a situation. In the presence of tube feeding, relevant issues such as drug-feed (e.g., voriconazole, ciprofloxacin) and drug–drug interactions need to be considered (Mimoz et al., 1998; Williams, 2012). Another important issue is when patients receive parenteral nutrition, as there may be incompatibilities with certain commonly prescribed IV drugs in ICU setting (e.g., acyclovir, dopamine, midazolam) (Trissel et al., 1999).

The Use of Nasogastric or Nasojejunal Tube Feeding

The use of nasogastric (NG) or nasojejunal (NJ) feeds are common in the ICU and are indicated for critically ill patients who require short- or medium-term nutritional support. Approximately 25% of critically ill patients on NG feeding are receiving suboptimal nutrients due to GI dysfunction and intolerance (Adam and Batson, 1997). Progressive intolerance to tube feeding may likely lead to GI stasis, diarrhea, and infections in these patients (Power et al., 1998; Shimizu et al., 2011). This leads to inadequate nutrients and suboptimal drug delivery in these patients. Dosing adjustment or alternative treatment may be required when a significant interaction is expected to occur in patients receiving tube feeding. IV drug administration is preferable when oral drug administration is impossible.

The Use of Parenteral Nutrition

In critically ill patients who do not tolerate enteral feedings (oral or tube feeding), the administration of parenteral nutrition is common in this setting as an alternative or supplement to enteral nutrition (Bersten et al., 2014). Parenteral nutrition consists of administration of amino acids, glucose, and fat emulsion with appropriate additives (e.g., vitamins and trace elements) in one mixed solution. Various issues, particularly in relation to interaction due to incompatibility, need to be considered in patients receiving parenteral nutrition and IV drugs. Incompatibilities need to be evaluated from various aspects including IV lines, solutions, and between drug and parenteral nutrition components (Trissel et al., 1999).

Managing Absorption Issues in Critically Ill Patients

Enhancement of nutrient delivery to the GI tract in critically ill patients with impaired GI function can be achieved through direct delivery of nutrients via feeding tubes (Chapman et al., 2013; Ritz et al., 2000; Stupak et al., 2012). Drugs can also be given through

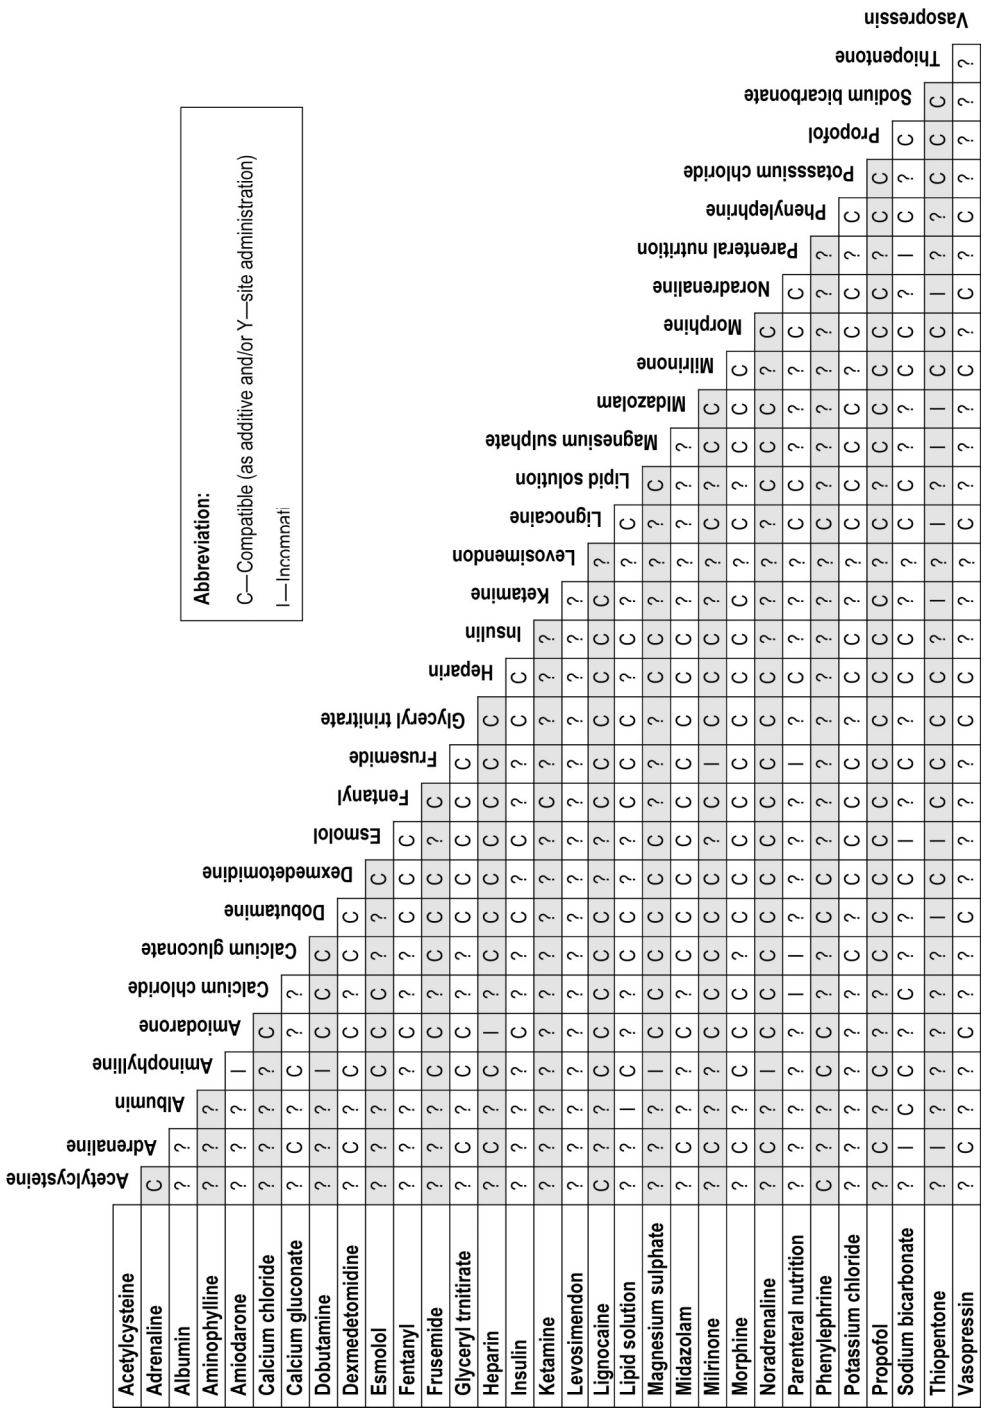

Figure 1 The Y-site compatibility for commonly used drugs in ICU setting

the inserted feeding tubes. Drugs can be crushed, dispersed, or given as the liquid form if available and administered via the feeding tubes in those patients who are unable to swallow oral drugs (Williams, 2008). Liquid formulations can be used but are commonly unsuitable for critically adult patients due to the use of indigestible sugars as sweeteners. Some oral drug formulations cannot be crushed due to more complex formulation (e.g., controlled-release and enteric-coated formulations). Therefore, it is important to identify oral drugs that can be crushed and administered through the feeding tubes. In such a situation where it is contraindicated to crush the oral drug, the IV route of administration should be preferred. Alternatively, choosing an alternative agent (either oral or IV) within the same pharmacological class can be considered. When IV drugs are used, the IV solution compatibility needs to be evaluated particularly when multiple IV drugs are prescribed through limited IV lines (Fig. 1 and Table 2).

Table 2 List of common oral drugs used in ICU setting

Medication(s)	*Oral solution availability*	*Crush tablet for tube feeding*	*Caution*
Acetylsalicylic acid	✓		Do not crush the ER tablet
Gabapentin		✓	Do not crush the ER tablet
Itraconazole	✓		
Metformin		✓	Do not crush the ER tablet
Metoclopramide	✓	✓	
Olanzapine	✓		
Risperdal	✓		
Oxycodone	✓		Do not crush the ER tablet
Phenytoin	✓		
Paracetamol	✓		Do not crush the ER tablet
Ranitidine	✓		
Prednisolone	✓		
Sodium valproate	✓		Do not crush the ER tablet
Theophylline	✓		Do not crush the ER tablet
Tranexamic acid	✓		
Warfarin		✓	
Bisacodyl			Do not crush
Captopril		✓	Unstable in aqueous solution
Carbamazepine	✓		
Esomeprazole		✓	Use oral granules for NG tube administration
Frusemide		✓	
Pantoprazole	✓		Use oral granules for NG tube administration
Propranolol			Do not crush the ER tablet
Metoprolol		✓	Do not crush the ER tablet

ER, extended release; NG, nasogastric.

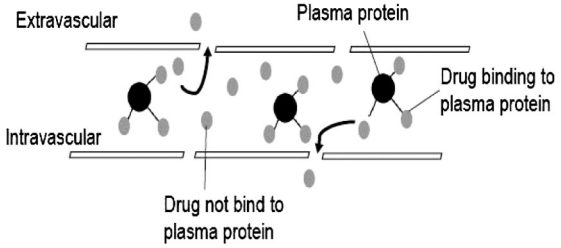
Impaired GI motility in critically ill patients can also be managed through pharmacological interventions (Ritz et al., 2000; Stupak et al., 2012). Dopamine receptor antagonists (e.g., metoclopramide, domperidone) are one of the commonly used drugs that can help improve GI motility, increasing the lower esophageal sphincter tone, and sensitizing the GI system (Doherty and Winter, 2003; Zaloga and Marik, 2000). The macrolide antibiotic erythromycin is another agent that is commonly used in the ICU to promote upper GI motility by stimulating motilin receptors (Janssens et al., 1990). The high potential for drug–drug interactions with this drug and potential for QT-prolongation should be carefully monitored when prescribed. As opioids are commonly used in the ICU for analgesia and sedation, critically ill patients who are prescribed these drugs are predisposed to baseline upper GI dysmotility. Thus, there are several pharmacological agents that are recommended to overcome upper GI dysmotility, including opioid antagonists (e.g., naloxone and methylnaltrexone) and cholecystokinin receptor antagonist (Meissner et al., 2003; Quigley, 2005; Yuan et al., 2000, 2002).

Distribution Issues in Critically Ill Patients

The pathophysiological changes associated with critical illness can result in changes in drug distribution throughout the body. Some concomitant conditions, principally obesity and severe burns, can also affect drug distribution and others, such as infections in specific sites require specific consideration of distribution (Alobaid et al., 2016; Udy et al., 2018). For ensuring optimal drug outcomes for patients, clinical pharmacists need to consider these changes. This section will describe the pathophysiological changes that could change a drug's distribution and the subpopulation of critically ill patients that are most vulnerable to these changes leading to suboptimal exposure of the drugs used.

Pathophysiological Changes during Critical Illness that can Affect Drug Distribution

Molecular weight, degree of ionization, lipid solubility, and protein binding are intrinsic properties that determine drug distribution (Pea, 2018; Varghese et al., 2011). Lipophilic agents, such as ciprofloxacin and fentanyl, have a larger volume of distribution (Vd) and greater tissue distribution (e.g., adipose and muscle tissues). In contrast, hydrophilic agents (such as the beta-lactams and digoxin) are principally restricted to the extracellular space, resulting in a relatively small Vd. By using critically ill patients with septic shock as an exemplar, the pathogenesis of systemic inflammatory response syndrome can lead to capillary leakage causing significant fluid shifts from the intravascular space into the interstitial space. This phenomenon can alter the Vd of hydrophilic drugs. Furthermore, in certain clinical conditions, such as in patients with major burns, this phenomenon can be significantly



Highly protein bound drugs that are commonly used in the ICU

Drugs	Protein binding estimation (%)
Frusemide	>90
Phenytoin	80-95
Acetylsalicylic acid	>90
Warfarin	>95
Valproic acid	80-90
Flucloxacillin	>90
Ertapenem	85-95
Ceftriaxone	85-95
Piperacillin + tazobactam	30-35

Figure 2 The effect of plasma protein changes on drugs that are highly bound to plasma protein.

increased, as a result of the widespread capillary leak and massive interstitial edema. This is further compounded by the aggressive initial ICU management undertaken, which usually includes administration of large volume of IV fluids and the combined use of multiple vasopressors and inotropes to restore normal hemodynamic status (Fig. 2).

Common Drug Distribution Issues in Critically Ill Patients

Some clinical conditions can alter distribution of drugs in critically ill patients potentially leading to treatment failure. Generally, the presence of fluid shifts due to severity of critical illness can alter the distribution of hydrophilic drugs. Drug physicochemical properties (e.g., lipophilicity, molecular size, and ionization properties) need to be considered in certain clinical situations particularly in obese critically ill patients and patients with respiratory and central nervous system (CNS) infection, where special considerations on the dosing or drug administration are required for the drug to reach the target site.

Drug Distribution into the Cerebrospinal Fluid

Central nervous system (CNS) infection is not uncommon in the ICU, particularly in ICUs managing a large number of patients with neurotrauma. CNS infections are associated with substantial morbidity and mortality, permanent disability, as well as prolonged ICU length of stay. Managing nosocomial infections in this subpopulation of critically ill patients is complicated because antibiotic delivery to the site of infection (i.e., cerebrospinal fluid) can be impaired due to inability of the antibiotic to cross the blood–brain barrier (Kumta et al., 2018; Lonsdale et al., 2013). Although antibiotic penetration may be sufficient in the initial stages of CNS infection, difficulty in achieving adequate antibiotic concentration in cerebrospinal fluid in the latter stages of infection has been frequently demonstrated in several clinical studies (Luque et al., 2014). Several factors need to be considered while managing CNS infection, including reduced meningeal permeability that could impair antibiotic distribution into the CSF, and most importantly the physicochemical properties that determines its ability to cross the blood brain barrier. In addition, some antibiotics have different abilities to penetrate into the CSF; some are only able to penetrate the CSF minimally and therefore, an alternative method of administration such as the intraventricular route may be necessary to achieve optimal drug exposure in the cerebrospinal fluid.

Ventriculitis, the inflammation of the ventricles in the brain, and meningitis, an acute inflammation of the meninges, are commonly caused by an infection. Surgically inserted intraventricular devices such as external ventricular drains are common approaches for intracranial pressure monitoring in patients with brain injury; however, these devices predispose patients to an increased risk of developing ventriculitis. Compared to meningitis, low meningeal inflammation may be present in patients with ventriculitis resulting in reduced penetration of certain antibiotics across the blood–cerebrospinal fluid barrier. Conversely, in meningitis, junctions between endothelial cells are opened, and the blood–brain barrier may become more permeable, and CSF outflow may be increased. Thus, passage of hydrophilic antibiotics in ventriculitis such as the beta-lactams and glycopeptides are likely to be reduced (Kumta et al., 2018). The degree of meningeal inflammation influences the penetration of antibiotics into the CSF. While certain drugs such as glycopeptides demonstrate low penetration irrespective of meningeal inflammation, lipophilic agents may have good CSF penetration independent to the degree of meningeal inflammation (Kumta et al., 2018) (**Fig. 3**).

Drug Distribution into the Lungs

Similar to the distribution issue of drugs into the CNS, impaired drug distribution is also significant in critically ill patients with respiratory infections, particularly in those who are intubated and receiving mechanical ventilation (Udy et al., 2013a). Commonly affected drugs include antibiotics and other respiratory agents such as bronchodilators. Changes in the physiology of the respiratory tract due to critical illness, coupled with the impaired ability of the drug to reach the site of the infection or action (i.e., epithelial lining fluid or alveolar macrophage) may complicate dosing for some drugs in these patients. Dosing adjustment and/or alternative route of administration such as nebulization may be required in this clinical scenario (Rello et al., 2017a, 2017b; Sole-Lleonart et al., 2017). Tissue permeability is an important factor that influences drug concentrations in the lung compartments. Hydrophilic antibiotics such as the beta-lactams, carbapenems, and glycopeptides demonstrate poor to moderate lung penetration ranging

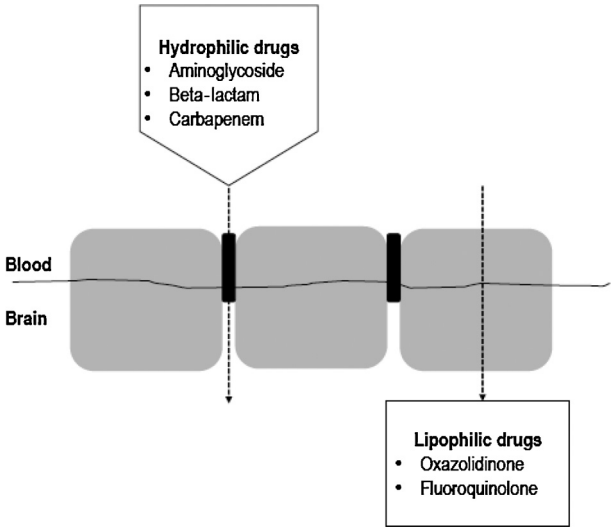


Figure 3 Drug penetration into across the blood–brain barrier.

between 20% and 50% (Jamal et al., 2013). Standard dosing of these drugs rarely achieves optimal exposure in lung compartments and tissues (Abdul-Aziz et al., 2017; Sulaiman et al., 2017). However, lipophilic antibiotics penetrate relatively well into the lung tissues.

Drug Distribution in Critically Ill Obese Patients

Alteration of Vd is also significant for some drugs in critically ill obese patients (Alobaid et al., 2016; Hanrahan et al., 2016). Obesity results in an increase in adipose tissue and lean mass. There can be a significant change in the Vd of both hydrophilic and lipophilic antimicrobials due to increases in both adipose and lean muscle mass. Additionally, regional blood flow to the adipose tissue is significantly lower than the lean mass, thus this will result in lower drug concentrations at the lower part of the subcutaneous adipose tissue. Changes in plasma protein concentration can also affect Vd in obese patients. The use of body size estimators is necessary to ensure more accurate (weight-based) dosing in this population. Patient weight is an important covariate, which predicts larger Vd for drugs such as the aminoglycoside and glycopeptide antibiotics, as well as thiopentone in critically ill obese patients (Velissaris et al., 2014). Higher doses may be required for drugs such as these, at least in the first 24–48 h of therapy, particularly in morbidly obese patients.

Drug Distribution in Burns Patients

Burns patients represent another complex subpopulation of critically ill patients that require particular attention. Burn injuries may result in hemodynamic alterations, including sustained increases in capillary permeability, peripheral and splanchnic vasoconstriction, and myocardial depression. These changes may cause movement of plasma protein into the interstitial space, leading to hypovolemia, systemic hypotension, and hypoperfusion. As the burn injury progresses, the physiological changes may be further complicated by the development of multiorgan dysfunctions. Initiation of immediate and aggressive therapies is warranted such as aggressive fluid resuscitation, the use of inotropes and vasopressors and commencement of organ support, which importantly can affect drug distribution. Generally, it is expected that hydrophilic drugs exhibit larger Vd in patients with burn injury (Jamal et al., 2012). This phenomenon may lead to lower plasma concentration and standard dosing may be suboptimal for hydrophilic drugs (Blanchet et al., 2008; Udy et al., 2018).

Larger Vd has been observed for hydrophilic antibiotics such as the beta-lactams and carbapenems in critically ill burn patients, subsequently leading to lower plasma concentrations. This is important due to risk of significant morbidity and mortality associated with infection in this patient population. In major burns, hypoalbuminemia is pronounced and this is related to the loss of protein-rich fluid via burn wounds, decrease in protein synthesis, and increase in catabolism. This will significantly affect the highly protein-bound drugs causing lower plasma drug concentrations. Therefore, hydrophilic and highly protein-bound drugs may require aggressive dosing adjustment in critically ill burn patients.

Managing Drug Distribution Issues in Critically Ill Patients

In the presence of potential factors that can cause altered drug distribution, dosing adjustment or alternative dosing strategies may be necessary (Roberts et al., 2014). Achieving optimal exposure at the target site can be predicted through the physicochemical characteristics of drugs (i.e., molecular size, lipophilicity, and ionic charge at physiological pH). Various modified approaches to dosing are required, including using higher than standard dosing regimen, measurement of drug concentration at the target site

whenever possible, or alternative dosing strategies (e.g., nebulization) that could enhance drug delivery to its target site (Rello et al., 2017a, 2017b; Sole-Lleonart et al., 2017). When conventional administration fails to achieve the desired therapeutic effect, alternative route of administration into CSF through intraventricular route may be considered for some drugs (Kumta et al., 2018).

Similar to drug penetration into the CSF, many factors need to be considered to ensure optimal medicine distribution into the lung compartments. Identifying drugs that are able to reach the epithelial lining fluid of the airway and alveolar macrophages is important to ensure therapeutic efficacy (Jamal et al., 2013). When the traditional route of administration fails to achieve the desired therapeutic effect, alternative routes of administration such as nebulization may be considered (Rello et al., 2017a, 2017b; Sole-Lleonart et al., 2017).

In critically obese patients, dosing estimation using a body size estimator is important to ensure appropriate drug exposure at the desired target site. Additionally, appropriate dosing estimation may prevent unwanted excessive drug exposure in this population (Alobaid et al., 2016; Hanrahan et al., 2016).

Drug Clearance Issues in Critically Ill Patients

In critical illness, the patient's ability to clear drugs from the body can be either augmented or compromised. Some technologies used in the ICU may contribute to these phenomena. Clinical pharmacists need to understand both the pathophysiological changes and how certain intensive care interventions influence drug clearance (CL) to achieve safe yet effective medicine use. This section will describe the possible pathophysiological changes during critical illness that can affect drugs CL. This chapter will also discuss common issues in the ICU that can cause alteration in drugs CL, which requires dosing adjustment or the use of alternative dosing approaches.

Pathophysiological Changes in Critically Ill Patients that can Affect Drug Clearance

In hyperdynamic state of sepsis where increases in cardiac output are expected, the CL of drugs that are primarily eliminated by the kidneys may be higher due to enhanced renal blood flow (Udy et al., 2011). Administration of inotropes and vasopressors as part of management to restore hemodynamic status of critically ill patients will lead to an increase in cardiac output and subsequently drugs CL, particularly in younger trauma patients without significant organ dysfunction (Udy et al., 2011). As critical illness progresses, this can lead to the development of multiorgan dysfunction, which includes renal and/or liver dysfunction, due to reductionin organ perfusion. Thus, decreased CL and/or metabolism is expected to cause accumulation of drug or its metabolites that could predispose patients to the risk of toxicity. In this clinical situation, dosing adjustment may be necessary. Additionally, the upregulation of CL, in which alternative pathways of CL may occur in the presence of isolated organ dysfunction, may require additional consideration. Drug CL should be carefully estimated to prevent excessive or suboptimal dosing.

Common Drug Clearance Issues in Critically Ill Patients

Changes in drug CL are variable in critically ill patients. Enhancement of drug CL is expected when there is an increase in unbound drug concentration in the systemic circulation, particularly for those that are highly bound to plasma protein. CL can also be augmented when there is an increase in cardiac output due to several factors including systemic physiological changes due to sepsis and/or aggressive ICU management to maintain hemodynamic stability through the use of inotropes and vasopressors. In addition, commencement of extracorporeal treatments for organ support in critically ill patients can also lead to additional drug CL (Jamal et al., 2012, 2015; Shekar et al., 2012b).

However, drug CL can also be reduced in this population, particularly due to organ failure. Thus, one of the most important roles of clinical pharmacists in the ICU is to continuously individualize drug therapy (e.g., drug selection, dose, frequency, administration, and monitoring) for each patient throughout their critical illness and recovery to ensure optimal outcomes.

Augmented Renal Clearance

Augmented renal clearance (ARC) is a phenomenon that is characterized by enhanced elimination of circulating solutes (certain drugs and waste products) by the kidneys and is defined as a creatinine clearance >130 mL/min/1.73 m^2 (Udy et al., 2011). This phenomenon is caused by the inflammatory response during severe sepsis or septic shock leading to increases in cardiac output and blood flow to the major organs (Claus et al., 2013; Udy et al., 2013b, 2014). Additionally, the presence of residual native renal function in these patients, as a response to catabolism and inflammation, may further exaggerate the enhancement of renal elimination. There are several identified risk factors predisposing ARC in critically ill patients including patient-related factors such as younger age and pregnancy and disease-related factors such as traumatic brain injury and burns. The main implication of ARC primarily relates to suboptimal drug exposures, particularly those drugs that are predominantly renally eliminated (e.g., beta-lactam antibiotics and glycopeptides) (Udy et al., 2012). The use of alternative dosing strategies, such as increased doses and frequency, as well as prolonged antibiotic infusion and utilization of TDM is necessary.

Hypoalbuminemia

Hypoalbuminemia in ICU patients can be caused by many factors, which includes underlying diseases that affect liver function, aggressive fluid resuscitation, poor nutritional status, or inadequate protein supplementation during ICU stay. Exaggerated protein loss during critical illness can worsen this condition. Significant exposure changes can occur for drugs that are highly protein bound and primarily renally eliminated (e.g., ertapenem and flucloxacillin) (Ulldemolins et al., 2010, 2011). The higher unbound or free fraction could lead to higher renal CL leading to low plasma drug concentration. The incidence of hypoalbuminemia is common in ICU patients, which has been reported as high as 50% (Finfer et al., 2006). The measurement of unbound drug concentrations is essential and dosing adjustment is required in this clinical condition.

Renal Replacement Therapy

The commencement of renal replacement therapy (RRT) complicates drug use (John and Eckardt, 2007; O'Reilly and Tolwani, 2005). Alteration in drugs CL is expected. Variable RRT modalities and settings lead to varying dosing requirements (Bogard et al., 2011; Jamal et al., 2015; Pea et al., 2007). Intermittent hemodialysis (IHD) is a conventional dialysis approach, not commonly utilized in ICU patients, particularly because it can worsen the unstable hemodynamic status of critically ill patients. This type of RRT mostly applies the principle of diffusion method, a passive transport of solute removal that includes drugs. An alternative technique to IHD, the sustained low efficiency dialysis (SLED) or extended daily dialysis (EDD), has similar principle of solute removal. Thus, CL of similar drugs can be the same. Continuous renal replacement therapy (CRRT) offers different type of solute removal; it can be through passive transport (diffusion) or active transport (convection) or a combination of both. The efficiency of solute removal is higher as compared to the traditional dialysis method. Thus, excessive drug CL can occur during this type of dialysis. However, although CRRT is expected to be continuous, interruption or sudden termination of CRRT can occur due to many reasons, such as during transporting or mobilizing the patient, clot to the hemofilter, or certain ICU procedures (Fealy et al., 2002; Kellum and Ronco, 2010). Thus, efficiency of CRRT and drug CL itself can be erratic and sometimes unpredictable. Patients might be predisposed to toxic accumulation, particularly in those without residual native renal function. The role of clinical pharmacists in proactively planning and actively monitoring and adjusting dosing of drugs is extremely important. Close drug concentration monitoring or dose adjustment may be required where available.

Extracorporeal Membrane Oxygenation

Extracorporeal membrane oxygenation (ECMO) is increasingly being used in adult patients with cardiac and/or respiratory failure. During ECMO, circulating blood from a patient is exteriorized onto the artificial surfaces of circuit tubing and an "artificial lung" (i.e., the oxygenator) membrane in order to provide circulatory and/or respiratory support. Like other critically ill patients, patients on ECMO receive multiple drugs that include sedatives and analgesics, antibiotics, anticoagulants, and vasoactive agents. Data from circuit experiments reveal significant sequestration of certain drugs in the ECMO circuit and the extent of loss depends on their physicochemical properties, type and age of the circuit, and the pumps used (Shekar et al., 2012a, 2012b; Sinnah et al., 2017). Drugs that are unstable at physiological temperature such as meropenem and lipophilic agents such as fentanyl and midazolam are more significantly affected. Alterations in drug exposure are more pronounced for lipophilic drugs and may result in therapeutic failure. Sequestration of drugs in the circuit may have implications on both the choice and dosing of a particular drug prescribed during ECMO. Various alternative approaches to dosing have been recommended in critically ill patients receiving ECMO such as using alternative drugs, higher and aggressive dosing regimens, and close drug level and therapeutic monitoring to ensure for optimal dosing (Cheng et al., 2018).

Indwelling Surgical Drains

Intra-abdominal disease involves pathologic changes such as abscesses, perforation, and ischemia of the bowel. Local increases in fluid volumes within the peritoneal cavity can occur secondary to fluid shifts from the intravascular space to the interstitial space as a result of capillary leak, fluid therapy for restoration of intravascular volume, and inflammatory fluid collections. Ileus can develop due to increased intra-luminal pressure that can impair fluid movement into and out of the gut. This eventually develops a "third space" effect where fluid expansion can occur in the gut lumen. This can increase hydrophilic drug distribution. In patients with indwelling surgical drains, enhanced drug CL, particularly hydrophilic agents, is expected (Adnan et al., 2012). Standard dosing can be suboptimal in this condition due to loss of drug into the "third space" and enhanced CL through the indwelling surgical drain.

Managing Drug Clearance Issues in the Critically Ill Patients

Identifying patients at risk of developing ARC is important. Drug dose adjustment may be required in certain clinical condition to ensure optimal therapy (**Fig. 4**).

Drugs that are highly protein bound may require dose adjustment, particularly in the presence of hypoalbuminemia. The measurement of free drug concentrations may be required, particularly for drugs where the action cannot be observed in a timely manner, such as antimicrobials and antiepileptics, to ensure optimal drug exposure at the site of infection and action.

In patients receiving extracorporeal treatments (e.g., RRT and ECMO), enhanced drugs CL through the extracorporeal treatment can lead to suboptimal dosing and exposure. Dose adjustment is necessary in these patients (Cheng et al., 2018; Kielstein and Burkhardt, 2009, 2011). Frequent drug concentration monitoring may offer additional benefit in ensuring optimal exposure at the

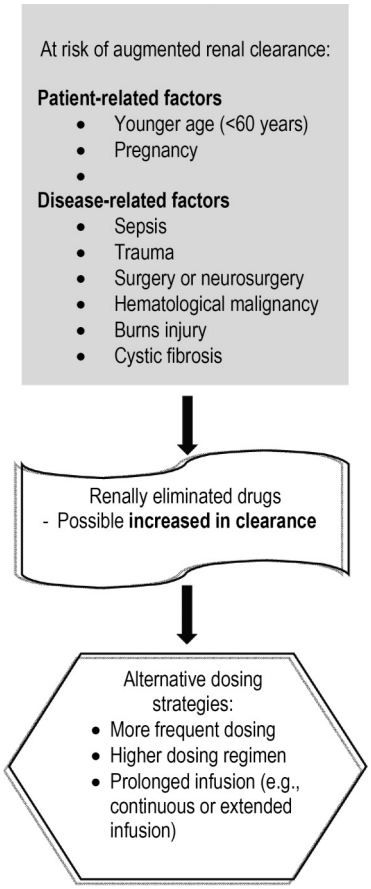

Figure 4 Drug dosing strategies in patients at-risk of ARC

target site. A similar dosing approach is also applied in those patients receiving indwelling surgical drains, in which additional loss of drug with inflammatory fluid through the drains is expected.

Promotion of Best Pharmacy Practice in ICU

ICU patients have complex pathophysiology and therapeutic needs. The ICU is an acute, high stakes, high risk, and high technology environment where change occurs frequently and rapidly. The multidisciplinary ICU team, including clinical pharmacists, works cooperatively to achieve the best outcomes for the hospital's sickest patients. Clinical pharmacy practice in the ICU is integral to the safe and effective use of drugs in critically ill patients. Internationally, reductions in ICU patient mortality, adverse events, and cost have been demonstrated with direct pharmacist involvement in the ICU. Clinical pharmacists can contribute in several ways to optimize pharmacotherapy in the ICU.

Standardized Practice Guidelines and Protocols

Variability in critical care practice has been observed at local, regional, national, and international levels and contributes to increased risk of adverse drug events, staff training, and costs. Standardization of drug practices in critical care settings can facilitate reductions in unwarranted variation and decrease these risks and costs. The development of user-friendly evidence-based guidelines and protocols to support drug selection, dosing, administration, and monitoring is a simple intervention that can be led by a clinical pharmacist and involve the multidisciplinary team (Leguelinel-Blache et al., 2018). At a more sophisticated level, the success observed in the United Kingdom in formulating and adopting a national standard for preparation of drug infusions is a relevant example that is being replicated elsewhere. In order to capitalize on the increased use of technological solutions such as electronic medical records with clinical decision support and "smart" infusion pumps, there is likely to be increased interest in more evidence-based standardized care.

Altered Drug Dosing Approaches

Beyond standard drug dosing and delivery for ICU patients for certain clinical condition, approach such as utilizing the TDM services to guide for optimal therapy could be beneficial to optimize outcome of pharmacotherapy (Abdul-Aziz et al., 2018; de la Pena et al., 2000; Roberts et al., 2008, 2010). Development of dosing nomograms for individual patients can be done based on data from various drug PK studies (Minichmayr et al., 2018). Mathematical models can be used to describe drug behavior relative to measures of organ functions (Vinks, 2002). Dosing simulations can be performed to describe the best dosing regimen required to overcome changes in drug exposures in critically ill patients that can lead to suboptimal patient outcomes. Using dosing–software that is equipped with data derived from a PK model can help to more accurately predict dosing requirement of an individual patient, which saves costs and time while managing critically ill patients (Jelliffe et al., 1993; Roberts et al., 2011).

TDM ensures that all patients achieved the desired therapeutic drug exposure by measuring drug concentration and adapt the dose accordingly (Roberts et al., 2010). For example, for antibiotics, TDM has been expanded beyond the traditional practice, where now TDM of drugs such as the beta-lactams, quinolones, oxazolidinone, daptomycin, and colistin has been widely practiced to ensure great therapeutic achievement. Using dosing software, a recommendation based on patient data derived from TDM can facilitate an immediate decision of accurate initial drug dosing even for drugs with variable PK (Abdul-Aziz et al., 2018; Roberts et al., 2017).

The development of a closed-loop system helps to fill gaps in strategies to optimize drug dose optimization (Rawson et al., 2018). It is minimally invasive and utilizing a microneedle electrochemical sensor technology, where drug concentrations at the dermal interstitial fluid (ISF) can be monitored and estimated without invasive plasma sampling. The system then will allow for the optimization of drug therapy either as continuous or bolus administration to achieve predefined therapeutic goal. This approach can offer precision of drug therapy in various clinical settings.

Continuing Education Exercises

As is the case in all specialty practice areas, clinical pharmacists can contribute to practice beyond bedside care by contributing to education of students, novice, and even expert pharmacist and multidisciplinary colleagues. In the ICU environment, where drug use is continuous and often essential to facilitate care, clinical pharmacists can provide nursing and medical staff with education at both a general and specific patient level to optimize medicines management and patient outcomes. Team-based learning such as simulation and crew resource management is increasingly being used in ICU to support all multidisciplinary team members to contribute effectively, and pharmacists are encouraged to participate in these learning opportunities.

Generation of New Knowledge through Research Undertaking

Due to the relative youth of ICU as a specialty and the rapid progress in technology, clinical and practice research is increasing exponentially. Clinical pharmacists at all levels can be involved in this research. More junior staff may be involved in data collection for ongoing or established research projects or may undertake their own quality assurance or improvement project to address an observed shortcoming in current local practice for example following implementation of a new guideline or protocol. Established practitioners should be contributing to or developing local research to explore questions from clinical practice, which are not adequately answered in the existing evidence and to test new innovations. While more advanced practitioners should be contributing to broader multidisciplinary research on a larger scale. Seeking mentors and advocates within the local multidisciplinary team or broader networks is important in the skills development for research and education.

Continuing education and research in ICU setting are necessary to enhance knowledge and improve practice in this area. Through collaboration or worldwide networking, research data of various ICU population background can help to fill gaps in practice that ultimately can facilitate the standardization of ICU care.

Irritable Bowel Syndrome (IBS)

Ben Basger, The University of Sydney, NSW, Australia

Learning Objectives

- Know the symptoms of IBS
- Understand the way in which IBS is diagnosed
- Have knowledge of the factors believed to contribute to IBS symptoms
- Be aware of alarm symptoms
- Understand the level of evidence for different treatments
- Appreciate the patients' perspective of their condition
- Be aware of the substantial placebo effect of treatments
- Be able to discuss the role of complementary medicines
- Have the ability to explain the condition to patients in plain English

Take Home Messages

- Functional gastrointestinal disorders such as IBS are disorders of gut–brain interaction resulting in any combination of the following: motility disturbance, visceral hypersensitivity, altered mucosal and immune function, altered gut microbiota, and altered central nervous system processing.
- There is no definitive diagnostic test for IBS and no obvious abnormality can be shown. Patients and/or doctors may therefore perceive uncertainty around the diagnosis. This may result in more testing and specialist referrals.
- Multiple comorbidities may occur in up to two-thirds of patients with IBS consisting of somatic symptoms, pain syndromes, other gastrointestinal disorders, and psychiatric disorders. Multiple medication intolerances or adverse effects may also occur.
- Psychological distress (anxiety or depression) may be secondary to the gut disturbance, where concurrent dysbiosis and moderate inflammation may induce a circulating cytokine reaction.
- IBS subtypes probably result from several contributory factors, which include infection, genetic factors, intestinal immune dysfunction, psychosocial factors, food sensitivities or intolerances, dysbiosis, and abnormalities in bile acids and serotonin activity.
- Where IBS is present, a prolonged search for an alternative explanation or diagnosis is futile, financially inappropriate and time-consuming. It has led to the use of nonevidence-based medicines and consultation with alternative health practitioners.
- Differential diagnoses in IBS are extensive. When diagnostic criteria are satisfied, alarm signs are absent, the history and physical examination suggest IBS and recommended blood tests are normal, the risk of missing organic disease is rare.
- Often people may only want to know why they have symptoms and whether they should be concerned.
- Patients may have misconceptions about IBS, such as it could turn into cancer and increase the risk of inflammatory bowel disease.
- Doctors may have limited awareness of the effect of IBS on patients' lives or patient beliefs about the causes of IBS
- Patients may care more about triggering factors than etiology; they may be more interested in how to manage the symptoms and minimize their effect on daily life.
- The placebo response rate in IBS treatment trials has been found to be 30%–40%.

- Psychological therapies improve many symptoms, do not cause adverse drug effects, and address the significant psychological aspects of FGIDs. While patient resistance may occur, so too may a lack of positive endorsement by health-care professionals.
- General recommendations include regular exercise, stress management, and dietary considerations. This encompasses the concept of putting one's health first rather than second to life events and looking after oneself to best cope with a condition that causes intestinal and extraintestinal problems.
- Referral to a dietician for consideration of exclusion diets, assessment of fiber intake, and use of a FODMAP diet feature in treatment recommendations.
- Currently, there appears to be no clinically useful way of identifying specific disturbances in the gut microbiota of people with IBS. In the future, it may be possible to develop designer probiotics containing organisms that are known to have an impact on symptoms, rather than the current trial and error approach.
- Some herbal medicines improve global symptoms. However, the methodological quality of clinical trials has generally been poor. In addition, purity and consistency concerns have been raised, as well as lack of a clear understanding of the active ingredients
- Evidence for the effectiveness of antispasmodics, motility agents, and antidepressants appear to be much weaker than that for antidiarrheals, laxatives, and prosecretory agents.
- The possible management of gastrointestinal conditions by fecal microbiota transplant needs a significant amount of research. There are questions to be answered over the safety of donor material, the dose, and the best route of administration of the material to the recipient.

Introduction

Irritable bowel syndrome (IBS) is a common chronic functional gastrointestinal disorder (FGID) characterized by the presence of altered bowel habits, abdominal pain, distention, and bloating. Gastrointestinal conditions may be broadly classified into two: organic and functional disease, with functional disorders accounting for most patients with chronic gastrointestinal symptoms (Keely et al., 2015). The term "functional" has been used to describe a disorder that affects function or performance, causing signs or symptoms of an organic disease, but with no obvious evidence of structural or physiologic abnormalities. Treatment strategies are therefore limited and focus on symptoms rather than cure. However, emerging evidence suggests that distinct pathophysiological disturbances may account for the symptoms of IBS (Ford et al., 2017). Other conditions described as FGIDs include functional dyspepsia, functional constipation, and functional diarrhea. The disturbed gut function and intrusive symptoms caused by IBS impair quality of life and in many people coexist with other FGIDs—commonly functional dyspepsia (Linedale and Andrews, 2017).

Functional disorders can be classified according to the Rome criteria, whose development began in 1988 when a team of experts worked to develop consensus criteria for the diagnosis of IBS. The Rome Foundation classification of FGIDs is based primarily on symptoms rather than physiological criteria. This is because of limited evidence that physiological disturbance (e.g., motility) fully explained patient symptoms and that symptoms are what patients describe to health-care providers. While IBS was not the only FGID, at that time there existed no overarching operational definition or classification for them. The first set of criteria ("Rome I") for 21 functional GI disorders were compiled into a book in 1994. Studies began being published using these criteria, which progressed their acceptance and further use and development through Rome II (1999–2000), III (2006), and IV (2016). Rome III differed from Rome I and Rome II with the use of more evidence-based rather than consensus-based data. This was because a greater number of research studies published using the Rome criteria allowed for more precise patient selection and presented data more representative of these disorders (Drossman, 2016).

To advance the field of FGIDs, Rome IV addressed limitations and made changes, which have included an improved definition of FGIDs that was positive (rather than by the exclusion of other disease); representative of current scientific knowledge and nonstigmatizing to better reflect current understanding; limiting the use of the term "functional," which while entrenched in the literature was considered imprecise and to some degree stigmatizing; adding new information such as the contribution of the microbiome to improve understanding of the luminal aspects of GI function; removing the term "discomfort" because not all languages had a word for "discomfort," because it had different meanings in different languages and because of its ambiguous meaning to patients; and changing (increasing) the frequency with which patients report abdominal pain (Lacy et al., 2016). The Rome IV criteria represent the current standard for diagnosing IBS (Ford et al., 2017).

Rome IV defines functional gastrointestinal disorders as disorders of gut–brain interaction resulting in GI symptoms causing any combination of the following: motility disturbance (change in movement of food and waste through the gastrointestinal (GI) tract), visceral hypersensitivity (heightened experience of pain in internal organs), altered mucosal and immune function, altered gut microbiota (the community of microorganisms) and altered central nervous system processing—how the brain sends and receives messages from the GI tract. The contribution of these factors may be variable. For example, an individual who develops IBS after infective gastroenteritis may have more influence from mucosal immune dysfunction with altered microflora, compared to another individual with IBS who has a lifelong history of chronic symptoms and psychiatric comorbidities relating to altered CNS regulation of GI function (Drossman, 2016).

Because there is no definitive diagnostic test for IBS and no clear abnormality can be shown, the patient and/or doctor may perceive uncertainty around the diagnosis. Uncertainty appears likely to make people feel uncomfortable, which may then result in more testing and specialist referrals. That is why making a criteria-based diagnosis (i.e., based on the patient's

history), selecting only those investigations that are relevant and communicating the diagnosis confidently and effectively to the patient is important in the treatment of IBS (Linedale and Andrews, 2017). IBS is not a diagnosis of exclusion, but a characteristic symptom complex that can usually be identified by asking a few simple questions (Talley and Holtmann, 2016).

IBS can be classified into four subtypes: IBS with diarrhea-predominant symptoms (IBS-D), IBS with constipation-predominant symptoms (IBS-C), IBS with mixed symptoms of constipation and diarrhea (IBS-M), and unsubtyped IBS (i.e., it does not meet the criteria for the other subtypes). This is based on patient's reports of the proportion of time they have had hard or lumpy stools versus loose or watery stools (Ford et al., 2017). Women are more likely than men to seek medical attention and to report IBS-C (Halland and Saito, 2015).

When food enters our intestine, the undigested components are utilized by the intestinal microbes, collectively called the microbiota. The microbiota is dominated by bacteria belonging to the phyla Firmicutes, Bacteroidetes, and Actinobacteria. These microbes inhabit the various regions in the GI tract, of which the colon is most densely populated. The microbiota has a major impact, not only on processes that occur in the GI tract but also on systemic functions and may have an important role in IBS (Barbara et al., 2016). Their activities include the maturation and continued education of the host immune response; protection against pathogen overgrowth; regulation of intestinal endocrine functions and neurologic signaling; biosynthesis of vitamins, neurotransmitters, and multiple other compounds with as-yet unknown targets and metabolism of bile salts (Lynch and Pedersen, 2016).

Evidence supports that the microbiome is significantly altered in patients with IBS when compared with normal patients. Microbial diversity is decreased in IBS, with diminished amounts of Lactobacilli and Bifidobacteria, while aerobes and mucosal bacteria are more abundant than in the normal gut. Studies have also shown specific alterations in patients with constipation predominant-IBS, where sulfate producing bacteria are increased and lactate producing bacteria are decreased (Malikowski et al., 2017).

Determining a patient's predominant symptom pattern guides management because the subgroups respond differently to different treatments. However, symptom patterns can change over time (Sultan and Malhotra, 2017a) and this, together with emerging evidence that IBS is unlikely to be one disease (Ford et al., 2017), may make management challenging.

Incidence and Burden of Disease

The prevalence of symptoms of IBS in the community has been found to vary according to geography, with a pooled prevalence from a meta-analysis of population-based studies of 7% in South East Asia, 12% in northern Europe and North America, 21% in South America, and 14% in Australia (Lovell and Ford, 2012). Global estimates of prevalence have varied from 5% to 15% (Halland and Saito, 2015). Depending upon the criteria used and methods of data collection, prevalence according to country has been reported to vary from as low as 1% to as high as 45% (Lovell and Ford, 2012). Prevalence of each of the four subtypes of IBS (IBS-C, IBS-D, IBS-M, and IBS-U) has been found to be similar in magnitude. The odds of IBS were significantly lower in people aged 50 years or more and there was a female preponderance, with a pooled odds ratio of 1.67 in women versus men. In fact, it has been stated that the syndrome mostly affects people aged 20–30 years (Hookway et al., 2015). Women were more likely than men to seek medical attention and to report abdominal pain and constipation (odds ratio 2.38), whereas men more commonly reported diarrhea (Chey et al., 2015; Ford, 2012). There were only a small number of studies reporting the prevalence of IBS according to socioeconomic status. They revealed no significant difference in prevalence of IBS in those of higher socioeconomic status compared with those of medium or lower socioeconomic status (Lovell and Ford, 2012).

Multiple comorbidities may be associated with IBS such as somatic (i.e., physical symptoms for which there is no identifiable physical cause) pain syndromes (e.g., fibromyalgia, temporomandibular joint pain), other gastrointestinal disorders (e.g., dyspepsia), and psychiatric disorders (e.g., anxiety, major depression) (Chey et al., 2015). Comorbidities may be present in up to two-thirds of patients. Multiple medication intolerances or adverse effects are also frequently encountered (Sayuk and Gyawali, 2015). Longer duration of disease, severity of somatic syndromes, and co-morbid anxiety and depression all predict worse outcomes (El-Serag et al., 2004). While psychological distress (anxiety or depression) commonly accompanies IBS, it may be that in some cases these symptoms of distress begin after and are secondary to the gut disturbance, where concurrent dysbiosis and moderate inflammation may induce a circulating cytokine reaction (Talley and Holtmann, 2016).

In most patients, IBS is a chronic relapsing disease. A systematic review showed that during long-term follow-up of clinic-based IBS patients, IBS symptoms persisted in most patients over a period of several years, but a substantial minority became symptom free within 2 years. Approximately two-thirds of patients either retained the original symptom severity or worsened (El-Serag et al., 2004). Patients may also migrate between different IBS subtypes, most commonly from IBS-C or IBS-D to IBS-M. However, these findings are complicated by the effect of treatments introduced by the doctor or patient, so that it is difficult to judge symptom variation from the effect of medical interventions (Chey et al., 2015).

The financial impact of IBS for patients can be substantial. It has been reported that the average cost per patient per annum was $742 (£490, €667) to $7547 in the United States, compared with £90 to £316 in the United Kingdom and €567 to €862 in France. Further, the average number of sick days taken per person per year was 30 in the United States. About 30% of people with IBS seek regular medical care, and in the United States, an estimated 12% of primary care visits and about 30%–50% of gastrointestinal consultations were related to IBS (Halland and Saito, 2015).

Etiology

Although subtyping of IBS currently guides management, each subtype probably results from several contributory factors. IBS likely includes several diseases with their own pathophysiology that present with similar symptoms. This may account for the heterogeneous response to treatment. That is, irrespective of whether symptoms arise from the gut, after infective gastroenteritis or from the brain, they are similar (Chey et al., 2015; Ford et al., 2017).

Factors related to pathogenesis have included (Barbara et al., 2016; Camilleri, 2012a, 2016; Chey et al., 2015; Ford et al., 2017; Halland and Saito, 2015; Keely et al., 2015; Malikowski et al., 2017; Sayuk and Gyawali, 2015; Theoharides et al., 2015):

1. **Infection—**After acute bacterial, protozoal, or viral gastroenteritis, IBS-type symptoms may persist in 10%–20% of patients and may be due to mild persistent inflammation or increased number of intestinal mast cells. Mast cells are immunologic (allergy) cells originating from stem cells, which store and release mediators (chemical messengers) like tumor necrosis factor and interleukin-6 (IL-6), which may cause abdominal cramps and diarrhea. Mucosal permeability may be increased with altered expression of tight junction proteins resulting in increased fluid secretion or activation of sensory mechanisms, resulting in IBS-D.
2. **Genetic factors—**Functional alterations of host mucosal immune response to microbial pathogens may alter bowel barrier function. Genetic susceptibility may confer a predisposition to immune activation in a subset of patients. For example, colonic transit has been found to be associated with inflammation-susceptibility genes that include toll-like receptor 9 (TLR9) and the genes encoding cadherin 1 (CDH1) and IL-6. Genetic factors (e.g., KLB—the gene-encoding klotho-β and mutation of GUCY2C (the gene encoding the guanylate cyclase C receptor) may also confer a predisposition to increased bile acid synthesis or increased enterocyte (intestinal cell) secretion, resulting predominantly in accelerated transit time and diarrhea. These factors result in familial aggregation in IBS. Genetic factors may also be involved in causing visceral hypersensitivity. Apart from effects on ion transport and barrier function, altered mucosal expression of genes may cause immune dysfunction.
3. **Intestinal immune dysfunction—**The intestinal mucosa of some IBS patients shows increased activation of the innate (i.e., the same immune mechanisms that each of us inherit) and adaptive (the immune system adaptations that occur according to individual environmental exposure) immune system. Functional symptoms are mediated by interaction of innate and adaptive responses and share immune pathways with food allergy and inflammatory bowel diseases. Abdominal pain is associated with increased localization of leucocytes, particularly mast cells, at enteric nerves. In addition, secretion of histamine (released from mast cells) drives smooth muscle contraction that contributes to symptoms of pain and constipation in IBS. Histamine release can also drive chloride-led water transport across the epithelium, manifesting as diarrhea and "leaky gut syndrome," increasing exposure to antigen and food allergens and driving dysbiosis (i.e., disturbance of the microbiome). Dysbiosis contributes to the loss of immune homeostasis and increase in T-helper 17 (Th17) cells that can drive eosinophilia in a Th17/GM-CSF (GM-CSF = granulocyte-macrophage colony-stimulating factor) dependent manner, while Th2 cytokines signaling and GM-CSF can also activate eosinophils to release tissue-damaging peroxidases. When tissue damage and inflammation persist, further "gut homing" immune cells are recruited from the circulation, perpetuating the inflammation. For example, it has been found that serum titers of the inflammatory cytokines interleukin 1b (IL-1b), tumor necrosis factor alpha (TNF-α), and IL-6 correlate positively with both IBS symptoms and the inflammation that also occurs in inflammatory bowel disease.
4. **Psychosocial factors—**Although it is unclear as to whether the etiology of disease lies with the psychological or gastrointestinal symptoms of IBS, there is increasing evidence to suggest that there is a bidirectional association along the gut–brain axis, such that IBS symptoms start in a significant number of patients before psychological distress develops. For example, there is a significant correlation of circulating levels of TNF-α with symptoms of anxiety. Notwithstanding this, psychosocial factors are often present. Women are more likely to have experienced verbal, sexual, or physical abuse, which may contribute to brain–gut dysfunction. In some patients, hypervigilance (abnormally increased arousal, responsiveness to stimuli, and screening of the environment for threats) and catastrophizing may lead to gastrointestinal and nongastrointestinal symptom amplification. Mood disorders (stress, anxiety, depression, and maladaptive coping strategies) or somatization (i.e., reports of symptoms such as back pain, headaches, and chest pains for which there is no apparent organic cause and which probably reflect a disorder of brain or emotional functioning) significantly increase the likelihood of developing functional gastrointestinal disorders.
5. **Food sensitivity/intolerance—**The majority of IBS patients associate ingestion of a wide range of foods with symptoms, particularly abdominal bloating and pain. The contribution of true food allergies is probably small, whereas food intolerances are common. The effect of food could be mediated through direct interactions between dietary components and mucosal receptors that may have been sensitized to these stimuli, or via down-stream events triggered by dietary components such as the release of gut hormones, changes in epithelial morphology, generation of immune responses, or altered signaling between the gut and the brain. Patients frequently report reduced consumption of milk products, wheat products, spicy foods, alcohol, and certain fruits or vegetables that are high in poorly absorbed short-chain carbohydrates and sugar alcohols (e.g., onions) and in fermentable oligosaccharides, disaccharides, monosaccharides, and polyols (FODMAPs; e.g., grapes and pears). While malabsorption of sugars such as lactose, fructose, and sorbitol may mimic the features of IBS, maldigestion of complex carbohydrates may be more prevalent, which may then provide substrate for the generation of short-chain fatty acids (SCFAs) by colonic bacteria. This may stimulate colonic transit. FODMAPs can yield methane, hydrogen, and carbon dioxide implicated in bloating. Osmotically active carbohydrate by-products may precipitate fluid secretion and enhance intestinal contraction, leading to diarrhea. Many IBS patients report symptoms in response to wheat-containing products, reminiscent of

the sensitivity to gluten that characterizes celiac disease, despite negative celiac serology and normal small intestinal morphology. Data on the above dietary adjustments in IBS are variable.

6. **Intestinal microbiota—**Lifestyle and diet are crucial determinants of microbiota composition and function. The fermentation of complex carbohydrates by microbiota, such as fibers and resistant starches, produce SCFAs, which act as fuels for intestinal cells and serve as signaling molecules. Carbohydrate fermentation also results in the formation of intestinal gases. This may induce intestinal reflex responses through bowel distention that causes inadequate relaxation of the diaphragm, pushing out the abdomen and causing visible abdominal distention. Intestinal microbiota may also be involved in the pathogenesis of IBS due to findings such as fecal microbiota substantially different in IBS and postinfectious IBS compared with healthy controls, with reduced microbiota diversity; innate and adaptive immune activity directed toward microbiota-derived molecules, such as the expression of toll-like receptors (TLRs) in the mucosa (TLR9 is an inflammation susceptibility gene); abnormal concentrations of fermentation end products in some patients due to different levels of SCFAs; probiotics (which seek to alter the microbiota) that have been shown to improve abdominal pain, bloating, and flatulence; increased levels of firmicutes or ratio of firmicutes to bacteroidetes, modified by antibiotics or probiotics. Currently, research continues into the role of microbiota and major limitations still hamper the definition of the role of the microbiota. There appears no consensus on the nature of the microbial signatures that may be consistently (either positively or negatively) correlated to FGIDs. These inconsistencies may relate to several factors including methodological differences, variations in sample sources, intrinsic variability between subjects, differences in subject selection and definition of study populations, overlap between the various FGIDs, and differences in diet, therapy, or other environmental exposures.
7. **Bile acids—**Bile acids play a central and critical role in the digestion and absorption of fat and fat-soluble vitamins. An efficient enterohepatic circulation ensures appropriate concentrations in the gut. Concentrations increase with a high fat diet, with changes in the microbiome (increase in firmicutes and reduction in bacteroidetes) observed. Bile acids have a variety of physiological effects of relevance to the FGIDs; on motility, intestinal secretion, membrane permeability, and visceral sensation. They act as signaling molecules, with effects beyond the GI tract. Luminal bile acid signaling to enteric nerves may cause increased sigmoid and rectal motility, with malabsorption identified in significant numbers of patients with IBS-D. Altered metabolism of bile acids by colonic bacteria and an elevated rate of synthesis of bile acids have also been identified.
8. **Serotonin—**Serotonin (5-hydroxytryptamine [5-HT]) is an amine primarily contained in the gut (95%) and only minimally in the brain (5%). Serotonin is synthesized from tryptophan mainly in enterochromaffin cells (90%) and autonomic nerves. Synthesis and release of serotonin occurs through bowel wall distension and the influence of factors, which include food, amino acids, hyper-osmotic solutions, and glucose. SCFAs, which may be produced in increased amounts by intestinal microbiota fermentation of carbohydrate substrates, can also promote the release of serotonin. Serotonin stimulates afferent neurons, which synapse in the myenteric plexus with ascending and descending neurons to evoke motility- and secretion-induced reflexes and transmit information to the brain. Serotonin reuptake transporter (SERT) terminates serotonin action. Hypofunction of SERT may increase serotonin concentrations leading to gut hypercontractility, hypersensitivity, diarrhea, and pain. Hyperfunction may result in IBS-C. These findings are reflected by the effect of selective serotonergic agonists (e.g., prucalopride) and antagonists (e.g., alosetron, ondansetron) on different subtypes of IBS. The enteroendocrine and immune systems are widely interconnected, immune cells being proximal to enterochromaffin cells. Immune cells (including B and T lymphocytes, monocytes, macrophages, and dendritic cells) express serotonergic receptors and mast cells, macrophages and T cells synthesize serotonin from tryptophan. Serotonin is chemotactic for dendritic cells, mast cells, and eosinophils and may participate in the recruitment of these immune cells in the intestinal mucosa. Low-grade inflammation, such as has been detected in FGIDs can, in turn, contribute to altered serotonin synthesis and reuptake through changes in SERT expression. T helper-1 (Th1) responses generate IFN-gamma (interferon) and TNF-a, which inhibit SERT.

Diagnosis

Despite the prevalence of IBS, frustration and dissatisfaction in patients and doctors resulting from the diagnostic process, which may include insufficient or excessive investigations and repeat consultations and reinvestigation, has been noted. The diagnostic process should ideally involve

- Making a provisional diagnosis based on application of criteria
- Using targeted investigations to exclude other causes
- Communicating the diagnosis effectively to the patient to ensure acceptance and ownership (Linedale and Andrews, 2017).

While these components are true for any disease, they appear particularly important in IBS, for which there is no definitive diagnostic test or obvious abnormality. This may generate doubt about the diagnosis, creating a desire for more consultations and testing. Where IBS is present, a prolonged search for an alternative explanation or diagnosis is futile, financially inappropriate and time-consuming. It may encourage unrealistic expectations and delay effective management. It may result from the use of unclear or uncertain language used by general practitioners and specialists to patients due to lack of confidence in diagnosing and managing IBS (Linedale and Andrews, 2017). It may also create a desire in the patient to seek alternative and complementary medicines.

An estimated 70%–80% of the world's population use non-Western medicine in the form of herbal preparations for their primary health care. The predominant user group of complementary medicines in Australia comprises younger women (under 35 years old)—the group in which IBS symptoms appear to be most common. In Australians aged 50 years or more, 46% have been reported to use complementary medicines, of whom 87% use them alongside conventional therapy. The 10 most commonly used herbal preparations in Australia include peppermint (Byard et al., 2017), a medicine with antispasmodic properties useful for treating abdominal spasm and cramps in IBS. Other medicines (such as slippery elm [Ulmus rubra]) may expose patients to high cost and false claims.

In the absence of established structural lesions to account for IBS symptoms, there is currently no accurate, noninvasive test. Research has focused on developing novel biomarkers such as genes, proteins, or metabolites to aid in diagnosis. However, studies examining all currently described approaches to diagnosing IBS have found that biomarkers performed no better than symptom-based criteria (Ford et al., 2017).

IBS presents with a characteristic symptom complex. Patients present with long-standing abdominal pain, directly linked to a disturbed bowel habit (diarrhea, constipation, or both). They also often have bloating, sometimes with visible distention. The pain may be relieved or aggravated by defecation. With pain, the stool is often altered in frequency or form (Talley and Holtmann, 2016).

Guidelines (Hookway et al., 2015) recommend that a diagnosis of IBS be considered only if the person has abdominal pain or discomfort that is relieved by defecation or is associated with altered bowel frequency or stool form. This should be accompanied by at least two of the following four symptoms:

- Altered stool passage (straining, urgency, incomplete evacuation)
- Abdominal bloating (more common in women than in men), distension, tension, or hardness
- Symptoms made worse by eating
- Passage of mucus.

Other features such as lethargy, nausea, backache, chronic fatigue, fibromyalgia, and bladder symptoms are common in people with IBS and may be used to support the diagnosis.

Although physical examination is usually normal in patients with IBS, mild abdominal tenderness may be present. A digital rectal examination has been recommended in patients with IBS-C to exclude dyssynergic defecation, a condition that arises from the inability to coordinate with the abdominal wall, anal sphincter, and pelvic floor muscles in a way that enables normal defecation. This is important to exclude in patients with constipation, with anorectal symptoms such as bleeding and pain and to rule out rectal cancer (Chey et al., 2015; Sultan and Malhotra, 2017a).

Alarm or "red flag" symptoms—all people presenting with possible symptoms of IBS should be asked if they have any of the following "red flag" indicators and referred for further investigations such as

- Unintentional or unexplained weight loss
- Rectal bleeding
- Family history of bowel or ovarian cancer
- A change in bowel habit to looser or more frequent stools (or both) persisting for more than 6 weeks in a person aged over 60 years

All people should also be assessed for the following and referred for further investigations if necessary:

- Anemia
- Abdominal masses
- Rectal masses
- Markers for inflammatory bowel disease

Other clinical alarms to elicit and exclude in the diagnostic process include new onset symptoms in the last 6 months in a person aged greater than 50 years; abdominal pain awakening a patient from sleep; documented unexplained fever; family history of inflammatory bowel disease; family history of celiac disease; enlarged lymph nodes (Ford, 2012; Sultan and Malhotra, 2017a).

Testing—guidelines (Hookway et al., 2015) recommend that in people who meet the IBS diagnostic criteria, the following tests should be undertaken to exclude other diagnoses:

- Full blood count
- Erythrocyte sedimentation rate or plasma viscosity
- C-reactive protein
- Antibody testing for celiac disease (endomysial antibodies or tissue transglutaminase antibodies).

The following tests are not necessary to confirm the diagnosis in people who meet the IBS diagnostic criteria; ultrasound, rigid or flexible sigmoidoscopy, colonoscopy, barium enema, thyroid function test, fecal ova, and parasite test, fecal occult blood, and hydrogen breath test (for lactose intolerance and bacterial overgrowth).

Fecal calprotectin has been stated to be very good at discriminating between functional and organic lower gastrointestinal disease. Increased levels occur due to neutrophil degranulation in the mucosal inflammation of inflammatory bowel disease. In a

young patient with at least 6 months symptom duration and no alarm symptoms, negative test results (levels less than 40 μg/g) provides strong confirmation of functional disease (Linedale and Andrews, 2017).

Other suggestive symptoms include gastrointestinal symptoms that wax and wane for more than 2 years and are exacerbated by psychosocial stress; the presence of other gastrointestinal functional disorders such as nonulcer or functional dyspepsia and the presence of psychiatric comorbidity (Sultan and Malhotra, 2017a).

Differential diagnoses in IBS are extensive. When diagnostic criteria are satisfied, alarm (or red flag) signs are absent, the history and physical examination suggest that IBS and recommended blood tests (above) are normal, and the risk of missing organic disease is rare—it may be as low as 1%–3%. Expert consensus is that doctors should limit evaluation to fulfilment of the Rome criteria if no alarm symptoms are present (Ford, 2012; Sultan and Malhotra, 2017a).

Although identifying patients with IBS-D or IBS-C may be straightforward, patients with IBS-M may require a more detailed history to determine whether a mixed bowel pattern represents the disease state or is a consequence of medical intervention. All medicines (prescribed, over-the-counter or complementary and alternative) that may affect IBS symptoms should be considered. These include medicines commonly associated with constipation (see Table 1 in the chapter on constipation) and those that may produce loose motions (such as magnesium-containing products, metformin, and nonsteroidal anti-inflammatory drugs). IBS-M patients who report periods without a bowel movement or small hard stools followed by multiple stools of varying consistency (interpreted as diarrhea) may have IBS-C, with periods of progressive stool accumulation resulting in bowel purging (Chey et al., 2015).

Studies have shown that more than one in four people with IBS-D have evidence of bile acid diarrhea, found on testing by administering a bile acid radiolabeled with the gamma-emitting isotope selenium-75 (known as ^{75}SeHCAT [^{75}Se-homocholyl-taurine] testing). Whole-body retention is measured by means of a scanning gamma-camera after seven days. However, this test may not be readily available. Biochemical testing of blood (e.g., testing for serum 7α-hydroxy-4-cholesten-3-one [C4, a bile acid precursor]) may also be coming into use. A therapeutic trial of a bile acid sequestrant may represent an easier alternative (Ford et al., 2017).

Treatment

Once the patient understands and accepts the diagnosis of IBS, management needs to cater to those concerns, beliefs and symptoms most troubling to the patient, as it has been stated that IBS of itself does not need or mandate management. Often people may only want to know why they have symptoms and whether they should be concerned (Linedale and Andrews, 2017).

In a qualitative study to understand patients experiences and expectations for management of IBS, it was found that IBS entailed serious reordering of patient's daily lives; a significant percentage of patients believed that the condition turned into cancer and increased the risk of inflammatory bowel disease; etiology was viewed as a personal attribute or caused by the occurrence of some discrete event in the past; it was felt that current medical knowledge could not contribute to effective relief; diagnosis and treatment was a confusing and frustrating process; many patients felt that they should have had more tests; there was dissatisfaction with the often unclear explanation by their general practitioner (GP); and patients cared more about triggering factors than etiology. They were more interested in how to manage the symptoms and minimize their effect on daily life; dissatisfaction with GP's was more about the lack of current knowledge of causes and effective treatments of IBS rather than GPs themselves, who were perceived as trying their best (Casiday et al., 2009b). These findings identified many of the issues discussed above.

A qualitative study was also conducted to understand GPs explanatory models and management strategies. It was found that although most GPs had a realistic understanding of current knowledge about IBS, the many unresolved questions regarding background and management had a negative impact on their attitudes toward patients suffering from IBS. They often viewed IBS resulting from disordered bowel activity in response to people's response to their environment, rather than of the environment itself. They had limited awareness of the effect of IBS on patients' lives or patient beliefs about the causes of IBS (Casiday et al., 2009a).

Placebo use—When considering the money spent on nonevidence based complementary and alternative medicines (CAMs), the placebo response should be considered. The placebo response rate in IBS treatment trials has been found to be 30%–40% (Ford et al., 2017). For example, in a placebo randomized controlled trial using acupuncture, patients were divided into three groups: a "waiting list" that controlled for any effects of assessment and observation (Hawthorne effects), as well as the effects of the natural course of the illness and regression to the mean; "limited interaction," providing placebo treatment with minimal interaction with the practitioner; or "augmented interaction," providing placebo treatment with a defined positive patient–practitioner relationship. The placebo treatment was delivered with a validated sham acupuncture device. An incremental improvement in symptoms was found in a manner resembling a graded dose escalation of component parts. An enhanced relationship with a practitioner, together with the placebo treatment, provided the most robust effect, indicating that such factors as warmth, empathy, duration of interaction and the communication of positive expectation might indeed significantly affect clinical outcome. The percentage of patients reporting adequate relief was comparable with the responder rate in clinical trials of drugs then currently used in the treatment of irritable bowel syndrome (Kaptchuk et al., 2008).

In another study, the clinical efficacy of open-label placebos (i.e., where patients are told that the treatments are placebos) compared with no treatment was investigated in a systematic review and meta-analysis (Charlesworth et al., 2017). Only five trials met inclusion criteria. The clinical conditions were irritable bowel syndrome, depression, allergic rhinitis, back pain, and attention deficit hyperactivity disorder. Notwithstanding the limited number of studies, the moderate risk of bias, and lack of blinding,

open-label placebos were found to have a medium-sized effect in reduction of symptoms (standardized mean difference 0.88 (0.62–1.14), $P < 0.00001$, I2 = 1%) (Charlesworth et al., 2017).

In a study of qualitative responses on perceptions of placebo use by USA patients, it was found that a lack of harm and potential benefit were the most common themes to justify acceptability of placebo use. Responses citing potential benefit were associated with higher education. Of the minority of respondents who judged it never acceptable for doctors to recommend placebo treatments, the most often referenced rationale was obligation of the doctor to do more. Additional themes emerged around the issue of whether a doctor was transparent about placebo use, including honesty, patient's right to know, and power of the mind (Ortiz et al., 2016). Perhaps people selling alternative therapies do a better job of selling them than health-care professionals do when recommending evidence-based approaches.

Treatment; Nonpharmacological

General recommendations—Several general recommendations can be made (eTG complete, 2016; Halland and Saito, 2015; Hookway et al., 2015; Sultan and Malhotra, 2017a) and include

- Patient education, reassurance, and reinforcement—education about the role of psychological stressors; awareness of dietary triggers; assistance with the development of self-management strategies; reassurance that there are no long-term sequelae; explanation that the cause of IBS is multifactorial, so treatment may need to address different aspects simultaneously, e.g., psychological health, gut microbiota; acknowledgement that their symptoms have physiologic causes that are real but poorly understood and that they may be able to control symptom triggers.
- Regular exercise—walking may reduce symptoms, bloating, and gas production. Exercise improves gas transit and defecatory patterns and may reduce stress. Yoga has also been shown to benefit, as it focuses attention on muscle contraction and relaxation.
- Stress management—meditation, support groups, and adequate sleep.
- Eating—have regular meals and take time to eat, drink at least eight cups of fluid (water, herbal teas) a day, restrict tea and coffee to three cups a day, reduce intake of alcohol and fizzy drinks, and limit fresh fruit to three portions a day.

Management should be based on the nature and severity of symptoms. The treatments discussed below assume that choice is determined by the predominant symptom(s).

Psychological therapies—The rates of psychological disorders such as anxiety, depression, and bipolar affective disorder are two- to threefold higher in patients with IBS than in controls without IBS (Ford, 2012). Treatments such as cognitive behavioral therapy (CBT), hypnotherapy, and multicomponent psychological therapy have shown robust results and reproducibility across numerous studies. Their numbers needed to treat have been estimated at 2–4, with the caveat that the efficacy of psychological interventions outside the context of a structured clinical trial was not known (Halland and Saito, 2015). The efficacy of hypnotherapy has been shown to be similar to that of another type of nonpharmacologic treatment; a low FODMAP (fermentable oligosaccharides, disaccharides, monosaccharides, and polyols) diet (Ford et al., 2017).

CBT has been shown to improve quality of life and reduce symptom severity, especially with symptoms such as pain perception and comorbid depressive and anxiety disorders, with a number needed to treat superior to most drug therapies. Limited studies suggest that combining pharmacotherapy with behavioral therapies may provide the best symptom relief and quality of life (Sultan and Malhotra, 2017a).

There appeared to be a difference of opinion as to when psychological treatments should be commenced. On the one hand, it has been suggested that they are probably best reserved for patients who fail more conventional treatments (Ford, 2012). One guideline recommendation stated that they should be considered in people who do not respond to drug treatments after 12 months and who develop a "continuing symptom profile (described as refractory IBS)" (Hookway et al., 2015). The benefit of early use in management has been stated to be unclear, especially given the difficulty many patients have finding appropriate providers (Ford et al., 2017).

However, a case has been made for more frequent use of psychological interventions (Linedale and Andrews, 2017). Such treatments offer global rather than targeted symptom control; are as effective as antidepressants; double the number of patients who experience symptomatic improvement compared with patients who receive "usual physician treatment," "supportive therapy," or "symptom monitoring"; have been shown to directly affect visceral hypersensitivity and gastrointestinal motility when gut-directed hypnotherapy has been used; do not cause adverse drug effects and address the significant psychological aspects of FGIDs. While patient resistance may occur, so too may a lack of positive endorsement by doctors. Complaints of affordability should be considered in the context of the money spent on CAMs (Linedale and Andrews, 2017).

Dietary therapies—Many patients strongly associate IBS symptoms with ingestion of certain foods. This may suggest food intolerance, though immunologically mediated food allergy is uncommon in IBS. There is no available investigation that can accurately identify all the foods causing a patient's symptoms (eTG complete, 2016). If food intolerance is clinically suspected, the appropriate investigation is a trial of an exclusion diet—that is, excluding food groups or components of food groups from the diet. Such diets are implemented for the shortest time possible to assess symptom improvement, are supervised by a dietician, and are only used after screening for eating disorders. A food diary may identify common food triggers such as caffeine, alcohol, carbonated drinks, fatty food, fiber, lactose-containing food, and wheat. Evidence supporting elimination diets is limited (Sultan and Malhotra, 2017a). If there is no clear benefit from initial dietary therapy, a low FODMAP diet could be considered, also under

the supervision of a dietician. Sensitivity to food chemicals (such as sulfites in dried fruit and salicylates in fruits and vegetables) is possible but rare (eTG complete, 2016).

Fiber—Adequate fiber intake (e.g., 25 g daily for females and 30 g daily for males) is recommended in treating patients with IBS-C. This can be done by gradually increasing the intake of fruit and vegetables, as fiber-related gas production may exacerbate bloating and flatulence. Soluble fiber is preferred. A less fermentable soluble fiber supplement (e.g., psyllium) or a nonfermentable insoluble fiber supplement (e.g., sterculia) can be recommended, while making sure of adequate fluid intake to maximize their effect (eTG complete, 2016; Sultan and Malhotra, 2017a). Psyllium has been shown to be beneficial in the management of IBS (Ford et al., 2017).

FODMAPs—FODMAPs (fermentable oligosaccharides, disaccharides, monosaccharides, and polyols) are fermentable carbohydrates that are poorly absorbed from the gastrointestinal tract and become substrates for bacterial metabolism in the large bowel, which result in bloating, altered intestinal motility, and abdominal discomfort/pain in those susceptible people with visceral hypersensitivity. A diet low in FODMAPs has been shown to significantly reduce global symptom scores in IBS, provide the greatest short-term gains in up to three quarters of patients, and improve the quality of life (Ford et al., 2017). An odds ratio of 1.81 (1.11–2.95) has been reported for efficacy from six randomized controlled trials (Linedale and Andrews, 2017). It can be recommended regardless of subtype and is supervised by a dietician. The impact of long-term restriction of FODMAPs on the gut microbiota is yet to be established. Long-term use of a low FODMAP diet is therefore not recommended and tolerated FODMAP-containing foods need to be reintroduced to normalize the diet (Linedale and Andrews, 2017).

Probiotics—The gut microbiota may be altered by diet (particularly fiber), probiotics, or antibiotics. Currently, there appears to be no clinically useful way of identifying specific disturbances in the gut microbiota of people with IBS (eTG complete, 2016). Species in probiotics shown to be of benefit in trials measuring improvement in global symptom scores have been Bifidobacterium and *Lactobacillus plantarum* (Ford et al., 2017). In a summary of the efficacy of treatments for FGIDs in recent systematic reviews (15 trials, $n = 1838$), probiotics were shown to have an odds ratio of 2.24 (1.81–2.75), a gain of symptom improvement above control of 13.5% and a NNT of 7–8 (Linedale and Andrews, 2017). Probiotics should not be used in people who are immunocompromised as they may result in infection.

In addition to bacteria, the gut microbiota contains a variety of other organisms such as viruses, particularly in the form of phages, fungi, and yeasts. However, there is little information on their role in IBS (Pearson and Whorwell, 2017)

It seems reasonable to conclude that probiotics have a positive effect in patients with IBS, but different preparations may not be as effective as others. In addition, the benefits may take time to accumulate, and they are probably best suited to the milder forms of the condition. In the future, it may be possible to develop designer probiotics, containing organisms that are known to have an impact on symptoms rather than the current trial and error approach (Pearson and Whorwell, 2017).

Treatment; Pharmacological

Overview—Most of the currently available treatment options for IBS focus on relieving individual symptoms. Patients with constipation-predominant IBS (IBS-C) may be administered osmotic laxatives, guanylate cyclase-C agonists such as linaclotide and plecanatide or a chloride channel activator such as lubiprostone (see below). Patients with diarrhea-predominant IBS (IBS-D) are treated with opioids; loperamide is the standard over the-counter medication. Eluxadoline recently received approval from the US Food and Drug Administration (FDA), and alosetron, a 5-HT3 antagonist, is an older drug that was approved for IBS-D. Both eluxadoline and alosetron are associated with warnings from the FDA regarding risks of pancreatitis, especially in patients with prior cholecystectomy or ischemic colitis, respectively. Medications used to treat pain associated with IBS-D (i.e., antidepressants and pain modulators) work in the central nervous system to try to reduce the pain arising in the gut. Symptoms revolving around bloating and distention may be treated with diets, including the FODMAP diet, as well as antibiotics and probiotics. However, the evidence supporting the use of these approaches is relatively limited given the small clinical trials in which they have been tested (Camilleri, 2017).

Laxatives—In addition to the information provided on laxatives in the chapter on constipation, the following recommendations have been made;

- Discourage people with IBS-C from taking lactulose (Hookway et al., 2015). It is broken down by colonic flora and produces excessive gas (Sultan and Malhotra, 2017a).
- Advise people with IBS how to adjust their doses of laxative according to the clinical response. Titrate the dose according to stool consistency, with the aim of achieving a soft, well-formed stool (corresponding to Bristol stool form scale type 4) (Hookway et al., 2015).
- Manage constipation in IBS as for functional constipation (eTG complete, 2016).
- Stimulant laxatives may cause considerable cramping and pain in patients with IBS (eTG complete, 2016).

Herbal medicines—The use of herbal medicines for the treatment of irritable bowel syndrome is common, particularly if patients are dissatisfied with traditional treatments. Some clinical trials have shown a benefit for symptomatic treatment of this condition. A Cochrane systematic review identified and included 75 randomized clinical trials evaluating the effects of various herbal preparations (including single herbs or mixtures of different herbs) for treating people with irritable bowel syndrome (Liu et al., 2006). Compared with placebo, a standard Chinese herbal formula, individualized Chinese herbal medicine, STW 5

(Iberogast—see below) and STW 5-II, the Tibetan herbal medicine Padma Lax, the traditional Chinese formula Tongxie Yaofang and Ayurvedic preparation showed significantly improvement of global symptoms. Compared with conventional therapy in 65 trials testing 51 different herbal medicines, 22 herbal medicines demonstrated a statistically significant benefit for symptom improvement, and 29 herbal medicines were not significantly different than conventional therapy. In nine trials that evaluated herbal medicine combined with conventional therapy, six tested herbal preparations showed additional benefit from the combination therapy compared with conventional monotherapy. No serious adverse events from the herbal medicines were reported (Liu et al., 2006).

The review showed that some herbal medicines improve global symptoms such as abdominal pain, diarrhea, and/or constipation. However, the methodological quality of most of the clinical trials evaluating these herbs was generally poor. In addition, purity and consistency concerns have been raised (Sayuk and Gyawali, 2015), as well as lack of a clear understanding of the active ingredients (Chey et al., 2015).

STW 5 (Iberogast) is a liquid multiherbal supplement containing bitter candytuft, angelica root, chamomile flowers, caraway fruit, St Marys thistle, lemon balm leaves peppermint leaves, celandine, and liquorice root. In vitro it has been shown to affect gastrointestinal transit, reduce gastric tone, and small intestinal secretion. In animal models, components have been shown to bind both muscarinic (M3) and serotonergic (5-HT_3 and 5-HT_4) receptors. These findings appear to provide plausible mechanisms to explain the clinical benefits (Halland and Saito, 2015). Iberogast has been reported to have a relative risk of symptom improvement with intervention compared to control of 1.9 (1.15–3.14) and a gain (i.e., gain of symptom improvement above control) of 15–25% in FGIDs (Linedale and Andrews, 2017).

Antispasmodic drugs—(peppermint oil, hyoscine butylbromide, mebeverine); some patients have abnormal gastrointestinal motility and contractility of smooth muscle (Ford et al., 2017). Antispasmodics may help to control abdominal pain and occasionally diarrhea (eTG complete, 2016). They are used on as as-needed basis. They all reduce pain by reducing smooth muscle contraction and may reduce visceral hypersensitivity (Sultan and Malhotra, 2017a). While a clinically meaningful improvement from randomized and nonrandomized controlled trials has been demonstrated (Linedale and Andrews, 2017; Sultan and Malhotra, 2017a), it has also been stated that benefit of anticholinergic agents in IBS is questionable—they may be useful in patients with abdominal pain but are likely to cause adverse effects (Australian Medicines Handbook, 2018). These anticholinergic adverse effects may affect people with IBS-C and the elderly, who are more sensitive to adverse effects such as dry mouth, blurred vision, constipation, and confusion. The American Gastroenterological Society suggested using antispasmodics over no drug treatment in patients with IBS. However, this represented a conditional (weak) recommendation based on low-quality evidence (Weinberg et al., 2014).

Motility agents—Many motility agents have been withdrawn or reintroduced with caution due to safety issues. Examples include cisapride (which has serotonergic prokinetic effects) because of cardiac side-effects: alosetron (a 5-HT_3 receptor antagonist) due to a small number of cases of ischemic colitis and tegaserod (a partial 5-HT_4 receptor agonist with predominantly motor effects in the gut), due to cases of severe central and peripheral ischemia (Enck et al., 2010).

Domperidone is a dopamine antagonist for which only a few studies of efficacy in IBS have been published in the past with a very low number of patients included. Its NNT has been found to be 9–10 [OR: 1.65 (0.74–3.68)] indicative of moderate efficacy. However, none of the studies met quality criteria (Enck et al., 2010). Its use is problematic in patients with prolonged QT intervals or in combination with drugs that inhibit liver cytochrome 3A4.

Prucalopride is a 5-HT_4 receptor agonist that increases gastrointestinal motility. It has been shown to be effective (i.e., greater than three spontaneous complete bowel motions per week) in chronic idiopathic constipation for only 20%–30% of patients compared with 10%–13% for placebo. Further study is needed to establish efficacy compared to (and in combination with) other laxative regimens and with long-term use (Australian Medicines Handbook, 2018). There has been no evidence to support the use of prucalopride in patients with IBS-C (Tse et al., 2017).

Alosetron has been shown to reduce abdominal pain, IBS-related global symptoms, and diarrhea in patients with IBS-D by increasing colonic compliance and reducing intestinal transit (Sultan and Malhotra, 2017b). The American Gastroenterological Society (AGA) (Weinberg et al., 2014) stated that the overall quality of the evidence was moderate (due to downgrading for inconsistency). When limited to consideration of abdominal pain improvement as the primary outcome, the quality of the evidence was greater (high). Several important caveats should be noted; alosetron was only FDA approved for use in women, and because of concerns about idiopathic, non-dose-dependent ischemic colitis (approximately 1 case/1000 patient-years), the drug was voluntarily withdrawn from the market and subsequently reintroduced only under a specific physician-based risk management program. The AGA suggested using alosetron (over no drug treatment) in patients with IBS-D to improve global symptoms. This was a conditional (weak) recommendation based on moderate evidence (Weinberg et al., 2014).

Prosecretory agents—lubiprostone is a prostaglandin derivative and linaclotide and plecanatide are 14- and 16-amino acid peptides, respectively, that act on the guanylate cyclase C receptor (Camilleri, 2012b). Lubiprostone and linaclotide act on intestinal enterocytes to increase fluid (through chloride and bicarbonate) secretion into the gastrointestinal tract, accelerating transit. Their effects appear to be modest, with nausea (lubiprostone) and diarrhea (linaclotide) the main adverse effects (Ford et al., 2017). Both have been shown to improve global, abdominal, and constipation symptoms in IBS-C (Chey et al., 2015). Additionally, linaclotide reduces abdominal pain through an effect on pain fiber activity, but this may take up to 12 weeks to reach its maximal effect (Halland and Saito, 2015; Sultan and Malhotra, 2017a).

An algorithm for the management of chronic constipation in IBS-C patients has been developed (Tse et al., 2017). It suggested that after lifestyle modifications (e.g., dietary fiber, fluid, and exercise), those IBS patients with constipation predominant

symptoms and/or predominant functional abdominal pain should be commenced on a prosecretory agent. Additional options for constipation predominant symptoms included laxatives (stimulant or osmotic). Additional agents suggested for patients with predominant functional abdominal pain consisted of pharmacological (e.g., antidepressants, antispasmodics) and nonpharmacological (e.g., meditation, relaxation, and hypnosis) treatments (Tse et al., 2017).

The American Gastroenterological Association (AGA) has recommended using linaclotide over no drug treatment in patients with IBS-C. This represented a strong recommendation based on high-quality evidence. They added that patients' who place a high value on avoiding diarrhea and avoiding higher out-of-pocket expenses associated with linaclotide may prefer alternate treatments (Weinberg et al., 2014). For lubiprostone, the ACA has recommended its use (over no drug treatment) in patients with IBS-C. This represented a conditional (weak) recommendation based on moderate-quality evidence. The same comment was made regarding higher out-of-pocket expenses associated with lubiprostone; alternate treatments may be preferred (Weinberg et al., 2014).

Antidepressants—Australian guidelines state that there is "some evidence" that tricyclic antidepressants (TCAs) and selective serotonin reuptake inhibitors (SSRIs) reduce visceral hypersensitivity, which improves abdominal pain and appears to provide global symptom relief (eTG Complete, 2016). Their mechanism of action was unclear (Sultan and Malhotra, 2017a). The benefit was not restricted to patients with anxiety or depression. Despite doses being lower than those used to treat depression or anxiety, anticholinergic and other adverse effects may occur, with SSRIs recommended as an alternative (eTG complete, 2016). It has been suggested that different antidepressants can be leveraged to address different IBS subtypes—TCAs (because they may cause constipation) in IBS-D and SSRIs (because they may have prokinetic effects) for IBS-C (Chey et al., 2015).

National Institute of Health and Care Excellence (NICE) guidelines (Hookway et al., 2015) state that TCAs should be considered as second-line treatment if laxatives, loperamide, or antispasmodics have not helped. SSRIs should be considered only if TCAs are ineffective. These recommendations were based on very low-quality randomized controlled trials and no trials which met United States Federal Drug Authority (FDA) approved end points (Ford et al., 2017).

The AGA suggested using TCAs (over no drug treatment) in patients with IBS (Weinberg et al., 2014). This represented a conditional (weak) recommendation based on low-quality evidence. With respect to SSRIs, they found that pooled estimates from 5 RCTs of 6- to 12-week duration showed no improvement in global relief symptoms. Also, four RCTs of 6- to 12-week duration showed no improvement in abdominal pain, with the risk of important adverse effects being minimal. The AGA suggested against using SSRIs for patients with IBS. This represented a conditional (weak) recommendation based on low-quality evidence (Weinberg et al., 2014).

The relative risk of symptoms not improving with intervention compared to control in 11 clinical trials of TCAs (n = 744) in FGIDs was stated to be 0.66 (0.56–0.79); the gain of symptom improvement over control 20%; and the number needed to treat (NNT) = 4 (3–6) for IBS-D only. Findings for SSRIs (7 trials, n = 356) in patients who had comorbid depression or anxiety were stated to be similar (Chey et al., 2015; Linedale and Andrews, 2017). Antidepressants represent a low-cost option.

Opioid antidiarrheals—(codeine, diphenoxylate, loperamide). Opioid receptors are found throughout the gastrointestinal tract. Opioid receptor agonists act to reduce pain perception and slow intestinal transit. Loperamide acts on μ-opioid receptors to reduce stool frequency and increases stool consistency. It can be used prophylactically when diarrhea is anticipated. It is preferred as it does not cross the blood–brain barrier (Chey et al., 2015). The AGA found that available data investigating the use of loperamide specifically for the treatment of patients with IBS-D, as opposed to symptomatic relief of diarrhea for other disease states, were very limited. Two older RCTs that had enrolled 42 patients failed to show a significant benefit in global relief of IBS-related symptoms. However, the quality of evidence from these trials was deemed very low due to methodological concerns and sparse data. There was, however, a large body of indirect evidence from a variety of other settings that showed the efficacy of loperamide in reducing stool frequency. Therefore, because of low cost, wide availability, and minimal adverse effects, loperamide could be viewed as a useful adjunct to other IBS-D therapies. The AGA "suggested" using loperamide (over no drug treatment) in patients with IBS-D. This represented a conditional (weak) recommendation based on very low-quality evidence (Weinberg et al., 2014). In practice, bile acid sequestrants such as cholestyramine have been used to treat diarrhea, although they have not been rigorously evaluated (Chey et al., 2015).

Eluxadoline influences bidirectional brain–gut signaling through the endogenous opioid system. Enteric opioid receptors μ, κ, and δ are involved in the regulation of gut motility, secretion, and sensation. The μ-opioid activation has an inhibitory effect on motility and secretion and is the primary mechanism through which loperamide exerts its effects. Expression of the κ-opioid receptor is increased in states of chronic visceral hypersensitivity, thought to play an important role in the abdominal pain component of IBS. Antagonism of the δ receptor counteracts the constipating effects of μ-opioid activation resulting from increased sphincter tone and inhibition of colonic peristalsis while enhancing the μ- and κ-opioid receptor-mediated effects on visceral sensation. Eluxadoline, a μ- and κ-opioid receptor agonist and δ-opioid receptor antagonist, was developed with the intention of utilizing this mixed opioid profile to treat both the diarrhea and abdominal pain associated with IBS-D (Barshop and Staller, 2016). It has been shown to be effective in simultaneously relieving the symptoms of abdominal pain and diarrhea in IBS-D. The most common side effects noted were constipation, nausea, and abdominal pain and the most serious was risk of spasm in the sphincter of Oddi, which may result in pancreatitis (Fox, 2016).

Asimadoline, a k-opioid antagonist, that does not cross the blood–brain barrier, may have peripheral analgesic effects and therefore be effective for abdominal pain associated with IBS (Halland and Saito, 2015). It has been stated to reduce sensation in response to colonic distention and to increase sensory thresholds. It had no significant effects on gastrointestinal transit or colonic motility, unlike μ-opioid receptor agonists, which relieve pain but retard gastrointestinal transit (Camilleri, 2012b).

Antibiotics—Antibiotics might benefit patients by altering gut flora, which may be inherently different from that of people without IBS. Or they may simply reduce the number of colonic bacteria, thereby reducing the amount of intestinal gas (Halland and Saito, 2015). Rifaxamin is a nonaminoglycoside semisynthetic poorly absorbed antibiotic derived from rifamycin. It inhibits bacterial RNA synthesis. It has a broad antimicrobial spectrum against gram positive and negative and aerobic and anaerobic bacteria. The AGA stated that pooled data from 2 RCTs showed a small but beneficial effect based on the combination of improvement in abdominal pain plus improvement in stool consistency in patients treated with rifaximin. Three RCTs demonstrated an improvement in IBS-related global symptoms. Additionally, these studies showed small improvements in abdominal pain and bloating, although these were of uncertain clinical significance. It was important to note that patients were treated for 2 weeks only and there is no evidence to support repetitive treatment. Although side effects were minimal, the cost of treatment for many patients may be quite high. At the time of publication of the AGA guidelines, rifaximin was not approved by the FDA for the treatment of IBS-D. The AGA suggested using rifaximin (over no drug treatment) in patients with IBS-D. This represented a conditional (weak) recommendation based on moderate-quality evidence (Weinberg et al., 2014). Rifaximin rarely causes drug interactions as it is not absorbed from the gastrointestinal tract. However, as it is a P-glycoprotein substrate, using it with strong P-glycoprotein inhibitors (e.g., amiodarone, carvedilol, various macrolides, and verapamil) may increase the systemic concentration of rifaximin. Clinical implications of this are unknown (Australian Medicines Handbook, 2018).

Bile acid binders—In some studies, approximately 30% of patients with IBS-D have increased bile acid levels in the stool (Corsetti and Whorwell, 2016). The presence of chenodeoxycholate in the stool of healthy subjects has been associated with accelerated colonic transit, increased stool frequency, and decreased stool consistency. It has therefore been hypothesized that the use of bile acid sequestrants (e.g., colesevelam, cholestyramine, colestipol, or a farnesoid X receptor agonist such as obeticholic acid) could be useful in the treatment of patients with IBS-D. Because bile acid diarrhea appears to be so common in patients with IBS-D, it has been suggested that a trial of a bile acid sequestrant could be first-line treatment to exclude this possibility (Corsetti and Whorwell, 2016; Halland and Saito, 2015). In the future, a biomarker-therapeutic combination that includes a screening blood test (e.g., serum C4 or serum FGF19) would identify patients who have an abnormality in bile acid homeostasis or synthesis. This may offer a diagnostic approach to identify bile acid diarrhea among patients presenting with IBS-D. A combined diagnostic and therapeutic approach will indicate the optimal treatment for the individual patient who has bile acid malabsorption rather than empirically treating all patients and hoping for the best (Camilleri, 2017).

Drugs under development—At least three therapeutic agents are now being developed (Camilleri, 2017):

- A sodium/hydrogen exchanger inhibitor (tenapanor) indicated for patients with IBS-C. Tenapanor works by inhibiting sodium uptake in the colonic mucosa to alter the fluidity of content in the bowel.
- A neurokinin-2 receptor antagonist (ibodutant) that employs a visceral analgesic approach in patients with IBS-D.
- A histamine H1-receptor antagonist (ebastine) that works as a visceral analgesic.

Fecal Microbiota Transplantation (FMT)—FMT has been practised in an uncontrolled manner for many years and has often been viewed with scepticism. However, since demonstration of superior efficacy compared to conventional treatment for recurrent *Clostridium difficile* infection, interest in the utilization for FMT in other gastrointestinal conditions has intensified. Currently, there have been no randomized, well-designed, controlled trials of this approach in IBS, although there have been case reports of its benefit. The possible management of gastrointestinal conditions by FMT needs a significant amount of research. There are questions to be answered over the safety of donor material, the dose, and the best route of administration of the material to the recipient (Pearson and Whorwell, 2017).

Role of the Pharmacist

What to Tell the Patient

After listening to what the patient has been told about IBS, it could be explained that there is no definitive diagnostic test and no clear abnormality can be shown for your symptoms. Current medical knowledge cannot provide all the answers we need. This does not mean that we know nothing about the causes of your symptoms, which we believe are related to disturbances in several body systems. More than one of these disturbances may occur at the same time. Although there are many possible causes for your symptoms, the risk of your doctor misdiagnosing IBS is rare when he/she makes sure there are no dangerous symptoms present like bleeding or weight loss, when a small number of recommended tests are negative, when physical examination is normal and when certain criteria for IBS are satisfied. These criteria are called "ROME IV" criteria. We do know that IBS does not turn into some other condition or make another condition (such as cancer or inflammatory bowel disease) more likely. We also know that IBS causes no permanent damage to your body.

We believe that there is a strong connection between the gut and the brain. Sometimes what is going on in the gut affects the brain, and sometimes the brain can affect gut function. For example, stress can affect your gut, and changes in the bacteria in the gut (called the "microbiome") can send messages to your brain. Your gut may be more sensitive to what you eat and drink compared to people who don't have IBS. This may cause it to spasm and hurt, or to hurry up or to slow down. If you can identify the factors that cause your symptoms and change or avoid them, you may not need to take any medicine at all. Or you may need to take medicine

only during the times it is most troublesome. If you tell me the symptoms that cause you the most discomfort, I can tell you the medicines that are most effective for them.

If your doctor has explained that all the appropriate steps have been taken to be sure of the diagnosis, then searching for other explanations for your symptoms or diagnoses is not necessary. It may cause you frustration, take lots of time and money, and you may end up buying medicines or herbs that have not been shown to work.

General recommendations that are made include minimizing or avoiding life events that trigger symptoms, identifying dietary triggers and regular exercise, which moves the gut along and elevates mood. This encompasses the concept of putting ones' health first rather than other lifestyle activities like ones' job. It also means looking after oneself to best cope with a condition that can affect other parts of the body besides the gut.

It is likely that there is more than one cause for your symptoms, which means that treatment may need to address different aspects simultaneously.

You may know that probiotics have been used to treat IBS. We know that the microbiome may be significantly altered in patients with IBS. However, at present, there appears to be no useful way of identifying specific disturbances in the gut microbiota. In the future, it may be possible to develop designer probiotics containing organisms that are known to have an impact on symptoms, rather than the current trial and error approach. It is true that in some people, probiotics reduce symptoms, depending upon the strains of bacteria contained in them.

We know that certain treatments can be very beneficial, such as psychological therapies. They obviously cannot cause the side effects that often occur with medicines, and they address the brains considerable contribution to causing gut problems. There use will depend upon finding a psychologist and establishing a good rapport. We also know that diet can be very important. A dietician can advise about exclusion diets, assess fiber intake, and assess the need and supervise a special type of diet (called the FODMAP diet), which has been shown to help.

Some types of herbal medicines have also been shown to reduce symptoms, such as one called "iberogast" or STW 5, a multiherbal preparation. Unfortunately, the quality of trials testing herbal products has generally been poor. In addition, purity and consistency concerns and lack of a clear understanding of the active ingredients has occurred.

What the Pharmacist Should Know

- Multiple comorbidities may occur in up to two-thirds of patients with IBS consisting of somatic symptoms, pain syndromes, other gastrointestinal disorders and psychiatric disorders. Multiple medication intolerances or adverse effects may also occur.
- Doctors may have limited awareness of the effect of IBS on patients' lives or patient beliefs about the causes of IBS.
- Patients may have misconceptions about IBS. For example, they may believe that some discrete event in their past caused it.
- Patients may care more about triggering factors than etiology. They may be more interested in how to manage the symptoms and minimize their effect on daily life.
