Scholarly work on narratives of illness and health underpins the conceptual development of medication narratives. Illness is an individual's own subjective experience of being unwell. People can experience an illness, even when doctors are unable to diagnose a definitive disease state as the underlying cause of the illness. Narratives are one way that people living with illness can make sense of being ill and share this experience with others (Frank, 2013). Mike Bury (1982) was one of the first scholars to study illness narratives and he conceptualized them as a form of biographical disruption. This involved disruption in taken for granted assumptions and behaviors, disruption in explanatory systems, and also the mobilization of resources to cope with this disruption caused by illness. Gareth Williams (1984) explored how narratives are involved in processes of narrative reconstruction. Narrative reconstruction involves not only making sense of the disruption caused by illness but also making sense of why the illness happened to them in the first place. He posits that narratives can be engaged in reconstructing individuals' lives amid the ruptures and fragmentation created by illness, making the present experience of illness make sense in terms of the biography of an individual's life.

Lars-Christer Hydén (1997), drawing on the earlier work of Mike Bury (1982) and others, posits five functions of illness narratives. First, illness narratives allow for the transformation of events and experiences of illness that make sense out of illness, giving form and coherence to the new life lived with illness. Second, illness narratives allow for a reconstruction of the ill person's life history, giving new meaning to illness in the context of this life history and allowing for a reconstruction of identity—who I am—through illness. Illness narratives also provide a medium for explaining and understanding illness, including making sense of why the illness happened and why it happened when it did. Further, illness narratives can be told strategically, to produce particular effects in social interaction with others, including by explaining or offering up excuses for particular behavior. We might think of this as the performative function of illness narratives. Lastly, illness narratives can collectivize individual experience, using storytelling to link up the personal and private sphere with the realms of the social and political.

People tell stories by drawing on narrative types that are available within their social and cultural milieu. Several scholars have developed typologies or genres of illness narratives that can allow for the sorting of stories about illness into broad categories. These typologies may be useful to pharmacists and others undertaking their own research on medication narratives by offering ways of conceptualizing a typology of medication narratives, or for comparing the differences and similarities in medication narratives, as they are emplotted within different kinds of illness narratives.

Arthur Frank (2013) described three ideal types of illness narratives based upon the plots or general storylines around which they are organized, primarily on how and if they ultimately resolve themselves. What Frank calls *restitution narratives* are stories of living through illness and being restored to health, with emphasis in these narratives being placed on the remedy, the cure, and life after illness. Survivors' narratives about cancer are a classic form of restitution narrative. In contrast, *chaos narratives* are those stories that are characteristically chaotic, lacking in coherence and narrative order. They are stories that are often told when narrators are still swallowed up by the chaos and uncertainty of illness, incapable of reflecting on and making sense of illness in their lives. They are stories of time without sequence, which often makes them uncomfortable listening for others. *Quest narratives* seek to turn illness into a journey that has a purpose, something to be gained from living through the experience, which can become a *boon* that is offered up to others through narrative. While restitution narratives are often about, as Frank (2013) describes it, the triumph of medicine over illness, quest narratives are moral stories about the triumph of the self through illness. They are told to teach others how to live with illness.

In another work, Frank (2007) develops a further typology of five kinds of illness narratives based on the thematic content, or dramas, around which they are organized. An illness narrative that focuses on (1) the drama of genesis elaborates on what caused the illness to happen when it did. Gareth Williams' (1984) work, already discussed, explores these types of narratives. What Frank describes as (2) the drama of emotion work draws on Arlie Russell Hochschild's (1979) conception of emotion work as the labor that people do to modulate their emotions in the presentation of self to others. In illness narratives, emotion work can be seen in those stories of individuals regulating their emotions when disclosing illness to others, or seeking to appear cheerful in the face of a dire prognosis. We can think of emotion work as akin to what Margaret Wetherell (2012) described as *affective practices*. Stories about (3) the drama of fear and loss also involve a sort of emotional work or affective practice in managing loss (of physical functioning, of a professional identity, of relationships, or of a sense of life as it was before illness) and fear (of worsening illness, of the future, or of death). Telling these kinds of narratives can be especially therapeutic for those who tell them. Stories about (4) the drama of meaning allow people with illness to make meaning about their illness and to find new meaning in life through illness. And lastly, for Frank, stories about (5) the drama of selfinvolve the making up a new kind of self, a changed self, but one made new through the experience of living with illness. It is possible to imagine how medicines could be scripted into each of these narrative types. Understanding this scholarly work on illness narratives can inform research on medication narratives.

Medicines are also scripted into stories about health, that is, stories of preserving health and enhancing health (Bissell et al., 2006). Narratives about medicines for the preservation and enhancement of health may include those stories about taking

(or perhaps, resisting) the use of statins by otherwise healthy people at risk for heart disease. They may include stories about the use of cognitive enhancing drugs, such as Modafinil, by students or professionals to reduce sleepiness, increase cognitive performance, and gain an edge in their studies or their profession. They may be found in narratives about the modification of bodies, such as in stories of women who use hormonal contraceptives to cease monthly menstruation. Such medication narratives will likely proliferate in the future as discourses of healthism, healthy living, and aesthetic and performance enhancement become ever more entrenched in popular culture, and as the pharmacogenetics industry continues to flourish. Arthur Frank (2006) wrote about how health narratives do work as both subjectifiers and connectors. They offer up stories around which people can construct who they are and who they ought to become, but they also connect diverse sites, linking doctor's offices, hospital clinics, health consumers, the investment sector with a financial stake in health products, and personal practices of health preservation and enhancement. Medication narratives about health also offer important sites for critique of the extension of (bio)medicine into health and risk (Clarke et al., 2010) and of the pharmaceuticalization of health. As Adrian's story below illustrates, narratives about medication use for health or performance enhancement offer compelling case studies to stimulate discussion during pharmacy education and training.

While narrative approaches to understanding use, resistance to, and meaning making about medicines are only just beginning to make scholarly inroads into pharmacy practice, a number of scholars have taken up similar approaches to understanding human engagements with medicines drawing on qualitative data; their work may serve as meaningful examples of the potential for exploring stories about medicines. Greenhalgh (2017) provides an auto-ethnographic account constructed through narratives of her experiences of adjuvant chemotherapy for breast cancer. Ballantyne (2016) has explored the experiences of medicines users within the broader "field" of medications where their use is constantly negotiated among a number of key actors, including physicians, pharmacists, government regulatory bodies, the pharmaceutical industry, and users themselves. Both Pound et al. (2005) and Murdoch et al. (2013) have explored how medicine taking can be resisted, particularly within the context of adherence discourses.

Medication Narratives as Empirical Exemplars

The exemplars below are designed to help you recognize medication narratives when you see them in the various forms in which they occur. Medication narratives can be embedded in naturally occurring talk or text, or they can be elicited within the context of a research interview or focus group. They can be spoken, written, or even created through images, such as artwork, photographs, or video. Below we explore several examples of medication narratives drawn from our own research and from publicly available sources to demonstrate the breadth in content, forms and media that can be used to tell stories about medications. In the context of pharmacy practice research, medication narratives are likely to be drawn from elicited data: the text of research interviews, focus groups, or from oral accounts told during ethnographic fieldwork. Yet we draw on the examples below to illustrate how medication narratives are, in fact, everywhere, and these publicly accessible sites can be rich sources for data collection and analysis.

The first empirical exemplar is drawn from our own research on narratives of living with and taking medicines to manage postural tachycardia syndrome (PoTS), a dysfunction of the autonomic nervous system that causes an excessively fast heart rate and fainting or near fainting upon standing. Magdalene's story tells of a specific, time-limited event involving medicines, one in which she experienced a sudden onset of symptoms in hospital and was given medication that she did not want when she was unable to consent. This excerpt is drawn from a longer narrative that was originally written for the website of a PoTS patient organization.[1]

> I was admitted to the hospital and, after a day, I was sent to the ICU because my heart rate was up to 180 beats per minute lying down. The staff kept telling me to calm down, and I told them I couldn't. It's not like I could control this!!!! After a couple days and some beta blockers and other meds, I was moved to a normal hospital room. Every time I ate, I passed out. I couldn't move and could barely talk for 2 or 3 hours each time. At this time, I was on a liquid-only diet. Meanwhile, I had 8 doctors all come in one day to see me, including my primary care doctor, a neurologist, and a psychiatrist. Each one told me that this was all anxiety and that they wanted me to take a medicine for anxiety. Also, they said that I was a female and trying to do too much with school and work. I WAS SO ANGRY! After the first 3 doctors, I was so angry that by the 8th, I was enraged! NO ONE WOULD LISTEN TO ME!!!!!!!!!!!!!!!!!! I knew that it wasn't anxiety and that there was something very wrong with me . . . The doctors treated me like complete crap and told me that I was a woman at the age of 23, trying to finish school, and that my body was just shutting down. They said that I was too stressed and couldn't control my emotions, so that was why I was in the position I was in!!!!!!!! At one point I passed out and was unable to talk, and the doctor ordered the nurses to give me anxiety medicine so that I would stop having the episode. I couldn't tell them that I didn't want it because I couldn't talk. They knew that I didn't want to take it because I had refused it earlier. It was unbelievable. At this point, my heart rate was at 120 beats per minute. I could barely walk. I had Parkinson-like symptoms. My breasts had filled with milk from the domperidone. Every time I threw up, I passed out, and every time I ate, I passed out. After 7 days, they told me that since my heart rate was better, there was no reason for me to stay there and that they wanted to send me to a nursing home because I was unable to take care of myself. My mom said no, that she would take care of me. I left the hospital.

Medication narratives can also tell stories about the meanings that medicines have in people's lives lived with illness. These stories can be about specific events, but they can also be more reflective, drawing together multiple experiences, and engaging

[1] Accessible at: https://www.dinet.org/content/member-stories/mystery-magdalene-r85/

social and cultural perceptions of medicine taking. Shelley, who is living with fibromyalgia and Lyme disease, does this in a story posted to her personal blog, Chronic Mom,[2] when she speaks of how taking opioids to manage her pain has changed her life.

> My pain levels had basically gotten so high I was almost bedridden. I couldn't take care of my kids, I couldn't work, I couldn't do anything that required walking or standing of any sort. Luckily for me I had been a patient of my doctor for some time before I broached the subject of pain relief. She knew me well by then and had no problem prescribing a low dose of Hydrocodone.
>
> This changed my life.
>
> Last week I went camping with a bunch of teenage girls. I was walking miles and miles every day. I was staking down tents in rainstorms, I was frantically running around trying to stop a tent from flooding, I was playing physical games, and I was sleeping on an uncomfortable cot without my heating pad. I was in a lot of pain, by the end of the week I couldn't even walk normally because my muscles were so stiff from the pain, but I did it and I had a blast. The reason that I could do it was because I took 1 pain pill each night so I could sleep. Without that pain pill I never would have made it. My pain level would have gotten so high I wouldn't have been able to sleep, especially in such uncomfortable conditions. I would have lost sleep and as I lost sleep my pain levels would have climbed even higher. Once the painsomnia cycle begins there's no ending it, it's an endless cycle of misery that I was able to avoid due to my pain medication.
>
> My camping experience is only one small example of how pain medication has changed my life. Two weeks after my camping trip I'm going on vacation with my family. We're going to 5 different National Parks and we're going to do a lot of hiking. I love being outdoors and I love exposing my city kids to nature. I'm still limited in what I can do (I won't be rock climbing or going on 12 mile hikes anytime soon), but I could never have done even a little of this before pain medication.
>
> Some might consider these activities optional. After all I don't need to be a camp counselor and I don't need to go on vacation with my kids. Is it really worth the "risk of addiction" just so I can have fun once in a while? Anyone with common sense would say yes it is. And for those who have no common sense they can read my story and realize I've been on the same dose of pain medication since 2014 so clearly I'm not an addict. And for those who have no common sense and no empathy and still think I don't need pain medication, I would point out that I can actually be a productive citizen when I have access to pain medication. Instead of being bedridden I have a life.

In our increasingly virtually networked age, social media and video hosting platforms can be sites for the creation and sharing of medication narratives. The popularity of YouTube as a video blogging platform has made possible the proliferation of video blogs, or *vlogs*, about experiences with illness and medications. Claudia's story[3] about her experiences with her antidepressant and anti-anxiety medications illustrates not only how videos have come to offer compelling media for the telling of stories about medicines, but also as her talk about medication pricing and access shows us, medication narratives are sites where the personal can be linked up with the social and the political.

> I think I started taking antidepressants when I was fourteen and I've gone through periods when I haven't been on them and I've tried different ones. And at the moment, the venlafaxine that I'm on, I think it's okay. It's hard to tell. The quetiapine is an anti-anxiety, I believe. I take that at night and it helps me to sleep. It really makes me tired so it helps me sleep. So that's supposed to stop me from having panic attacks, but I'm having a lot at the moment, but I'm not sure if that's to do with the medication or not. The venlafaxine is odd because it's a very unpleasant medication to be on. I don't know if any of you guys are on it. If you are, then tell me your own stories about venlafaxine. But if you forget to take a dose, then it makes me sick. It makes me very sick. It can give you a headache. You feel awful if you forget to, you know if you've forgotten to take your venlafaxine. Also it tastes, mine tastes really bad. They don't have to because sometimes they have a coating, but mine are not really coated very much, so every morning I have to psych myself into swallowing this tablet because if it goes on your tongue it's just disgusting. To get myself to swallow it, I honestly try to think of Daenerys from Game of Thrones when she's eating that heart, and I just think to myself like, 'Keep it down. It's okay. Just keep it down. Swallow it. Keep it down. It's all good.'

The excerpt above from Claudia's story focuses on what it is like to take medicines, the experience of swallowing them, what they taste like, how they make her feel, what they are supposed to do in her body. Later in her narrative, she moves from a focus on the personal to a critique of the structural issues surrounding medication use, particularly of prescription fees under the British National Health Service.

> I only recently found out, I always thought medication in the UK was free because I've always had my antidepressants and stuff free, but I realized that that's actually because we're on a low income. I thought everyone had that, and I've just recently realised that if you're over a certain income then you have to pay for your own antidepressants and things. I think that's quite bad. I feel like they're kind of vital to be honest, and I don't think it's fair that you should have to pay for those. I also heard the other day that apparently sometimes you have to pay for your own cancer medication, and I was so ignorant I didn't even realise. I think that's appallingly bad. So I really wish that there was something that could be done about that.

Our last exemplar demonstrates how narratives about medication can also be embedded within broader narratives of health and bodily enhancement. In recent years, the term "bio-hacking" has emerged to describe various bodily practices of self-experimentation, often drawing on tools of the Quantified Self movement, to maximize personal health and performance. This can involve the consumption of health or cognitive enhancing medicines of various sorts, including natural supplements, functional foods, over the counter medicines, and prescribed pharmaceuticals, including pharmaceuticals purchased through quasi-legal global networks, such as in Adrian's narrative below.[4] Adrian tells the story of how he decided to use Modafinil, a cognitive enhancing medication, how he procured it from a source in India, and his experience of 3 days of self-experimentation. His narrative takes the form of a

video review, constructing Modafinil as a consumer good, about which information is shared informally amongst users and potential users.

> I first started a couple of days ago. I got it in the afternoon, which wasn't a great idea. I was really excited for it, so basically I just popped a tab then and there. Then I got a Skype call from my mate back in Australia and we ended up just chatted for like two hours, so I didn't even use it for anything productive. So I didn't really test how well it worked on that first day, which is a shame. But the next morning, actually that night, I didn't get to sleep until about 1:30. I just couldn't sleep. While I didn't feel super focused or super energetic or anything. I just couldn't sleep. My mind was still flowing, you know. One o'clock in the morning I felt like I should have just gone and read a book, you know, gone and done some work. I was just still in the zone. This stuff has a really long half life and I started with 200 mg as well. It's a really long half-life. This one here is actually Modalert. [My supplier] actually offers four different ones. Modalert is the fastest acting one that they do sell, so the other ones are going to have an even longer half-life. This is something like around twelve to fourteen hours half-life, which basically means that you're going to have trouble sleeping if you take these like anywhere after midday. If you're going to bed like midnight, you're going to have some real trouble with that. So you should be taking these things first thing in the morning.
>
> How it worked exactly, I'm not one hundred percent sure. I don't know they know all the effects and exactly how it works. But it affects your dopamine receptors, is one of the main things it does, so it does actually wear off after awhile. So basically you build up a tolerance after several days. I do recommend not to use this more than three or four days per week and every so often you should actually cycle it. So I've taken it three days in a row. The first day I didn't really test it much. The second day was yesterday. That was really good. I took it first thing. I got a lot done. I was basically doing things like writing. I wrote a massive blog post yesterday about all my business plans for basically 2016 and beyond, what I've got planned so far and it ended up being nearly 4,000 words long. I normally kind of hate writing. I don't mind it. I think I'm okay at writing, but it's just something I get bored of. It's not bringing me an instant return, so I'll write for half an hour and smash out a quick 1,500, 2,000 word article and post it up there without really reading it. But I took my time with this one. I actually spent two, three hours writing and brainstorming and thinking. I was just focused on this.

Why Study Medication Narratives in Pharmacy Practice?

Studying narratives allows for the exploration of how stories are structured and how they work to produce the effects in the teller and others that they do. It also allows us to be attentive to who is producing narratives, including how and why they are produced, the ways in which they are experienced by others, their effects on their audiences, and how and why particular narratives are accepted, while others may be contested or refused altogether (Squire et al., 2013). According to Squire and colleagues (2013, p. 2), "narratives carry traces of human lives that we want to understand." Being attentive to all the work that narratives do means garnering insight on these aspects of human lives, which can have critical implications for pharmacy education, practice, and research. Bissell et al. (2006) discuss several reasons why studying medication narratives can be important to the field of pharmacy practice, which we elaborate on below.

Improving Patient Care

At the individual level, pharmacists and other health professionals need to be attuned to the fact that they listen to and participate in the creation of narratives in their everyday work. The patient standing at the pharmacy counter telling of their struggles with medication dosing or their strategies for remembering to take their medicines at the right times is engaging in narrative work. Being attuned to listening to narratives in everyday speech can help health professionals to better understand their patients, their medication use experiences, and their beliefs about medicines in ways that can improve patient care. Such stories may convey insights that help to explain individuals' adherence to medication regimens or their resistance to using medicines exactly as prescribed. They may also help health professionals to understand how others, including family, carers or other professionals, are integrally involved in patients' medication use practices.

Enhancing Pharmacy Teaching and Training

The development of a field of "narrative pharmacy" in much the way that the field of narrative medicine (Charon, 2007; DasGupta and Charon, 2004; Greenhalgh and Hurwitz, 1998) has developed in recent decades would be an asset to the professional development and training of new pharmacists and pharmacy researchers at undergraduate and postgraduate levels. Such an approach would encourage more case-based learning and "teaching through stories," which may enhance pharmacy professional education. Attention to narratives may also enhance pharmacists' and pharmacy students' understandings of the role of pharmacists in patients' lives. Pharmacists have their own narratives to tell about medicines in their personal and professional lives, and are cast into the stories that patients tell about medicines. Medication narratives may be especially useful in pharmacy education and training as tools for stimulating reflection and discussion on the roles that pharmacists play in the stories their patients tell and how they might influence how patients create meaning about medicines in their lives. For example, stories like that told by Claudia above that engage with and critique structural barriers to medicines, such as prescription pricing, can help pharmacists and other health professionals to better understand how personal experiences with medicines are mediated by social, cultural, and political factors and may stimulate controversy and debate on pharmacy ethics. The stories posted to the

Health Talk website,[5] created by the charity DIPEx and the Health Experiences Research Group from the University of Oxford's Nuffield Department of Primary Care Health Sciences, may be a valuable resource for drawing narratives about medications into teaching and professional training.

Engaging the Use of Narrative in the Healing Process

Several scholars have posited that narratives have a crucial role to play not only in making sense of illness but also in the healing process itself (Broom, 1997; Frank, 2013; Greenhalgh and Hurwitz, 1998; Kleinman, 1988). Stories about illness may help people to make sense of the disruption in their lives caused by the onset of illness (Bury, 1982) and they may allow them to reconstruct the past in light of the present, making sense of illness in the context of their life stories (Williams, 1984). Storytelling is one form of social interaction, and Frank (2013) asserts that people tell stories not only for themselves, as a means of constructing or reconstructing their own identities in the face of illness, but also for others. Stories told by others may also help people to find their way through illness or through the experience of taking medicine, facilitating healing, recovery, or coping with a long-term chronic illness. Stories about medicines may be beneficial tools to utilize in patient education and support activities.

Engaging Narrative Approaches in Pharmacy Practice Research

There is a long history of narrative research in the humanities and social sciences. Drawing these approaches into pharmacy practice research may not only generate new research questions and initiatives within pharmacy practice but can also engage pharmacy researchers in contributing to theoretical and methodological work on narratives of illness and health that span the disciplines. Such engagement may foster stronger interdisciplinary ties with the humanities and social sciences and may catalyze future interdisciplinary scholarship in social pharmacy.

How Can We Study Medication Narratives?

Narratives are quite literally everywhere. Narratives can be written, spoken, or crafted via images (artwork, photographs, or video). They can be elicited, as in the research or journalistic interview, or they can be collected from extant sources, such as in the text of online blog posts or YouTube videos. They can be lengthy, telling an entire life story, or they may be only a few sentences long and recount a discrete, time-limited event.

The most common form of narrative analyzed in narrative research is that collected in the course of the research interview. Depending on the nature of the interview, the entire interview may consist of one long, sequential narrative, or it may be made up of many different narratives, reflecting the course of the conversation between researcher and subject. One approach for eliciting narratives about medicines in people's lives is the Free Association Narrative Interview (FANI), a method that is described in detail by Hollway and Jefferson (2008). Ryan et al. (2007) discuss an example of the format of a semi-structured interview guide for eliciting medication narratives in research interviews with medication users. They suggest that such interviews ought to seek the elicitation of rich stories about medicines, starting with broad questions about a person's experience of health and illness throughout their life, before zooming into query more specifically their beliefs about and experiences of medicine taking. They should conclude by offering a space for reflexivity and the consideration of medicines' use within the broader social context.

The analysis of medication narratives should not, however, be restricted only to those elicited in the context of research interviews, focus groups, or ethnographic work with medication users. The Internet, particularly the proliferation of social media-based support networks, personal websites, patient organizations, and video sharing platforms, has made a wealth of extant stories about illness, health, and medicines readily accessible. In our recent exploratory research, we analyzed medication narratives embedded within narratives of living with one particular chronic illness, Postural tachycardia syndrome, a form of dysautonomia or a dysfunctioning of the autonomic nervous system. These stories were collected, with permission, from the websites of patient organizations. It is important to note, however, that analyzing qualitative data collected from publicly accessible Internet sources raises a number of important research ethics issues, which must be attended to in much the same ways as in other forms of human subjects research (Grinyer, 2007; Heilferty, 2011).

There is a great deal of variation and debate over the theoretical underpinnings of narrative analysis, and there are multiple approaches to analyzing narratives based on a number of related but divergent theoretical approaches. Some scholars approach narratives with an emphasis on analyzing events (Labov and Waletzky, 1967; Patterson, 2013); others with an emphasis on the narration of experience, social meanings, and representation (Riessman, 2008; Squire et al., 2013). Some have approached the analysis of narratives through the lens of poststructuralism and the work of Michel Foucault (Tamboukou, 2013). Others have sought to analyze visual narratives (Bell, 2013) or the social interactions facilitated by social media as forms of narrative (Davis, 2013). Andrews et al.'s (2013) edited volume on *Doing Narrative Research* as well as Catherine Kohler Riessman's book on *Narrative Methods for the Human Sciences* (2008) may be helpful guides to conducting narrative analyses. Anderson and Kirpatrick's (2016) discussion of narrative interviewing in a clinical pharmacy context and Fraser's (2004) detailed discussion of

[5] Accessible at: http://www.healthtalk.org/

line by line coding and analysis of narratives may also be helpful to understanding how to conduct narrative analyses about medications.

Future of Medication Narratives

Medication narratives (Bissell et al., 2006; Ryan et al., 2007) remain an emergent concept in the field of Pharmacy Practice. Much further theoretical and methodological elaboration remains to be done, as does much empirical application of the concept. Further scholarly work may:

- Explore how various theoretical approaches, from Labovian (Labov and Waletzky, 1967) to more experience-centered and thematic approaches (Riessman, 2008; Squire et al., 2013), as well as Foucauldian, feminist, or postcolonial perspectives may be applied to research on narratives of medication use.
- Elaborate on the methodological strategies for conducting narrative analysis on stories about medications and the meaning of medications in peoples' lives. For example, how is narrative analysis done on narratives about medicines? How may it differ from methodological approaches to understanding illness narratives or other forms of personal storytelling?
- Underpin the development of empirical research on experiences of taking medication for the management of chronic illness, the management of health risks (such as high cholesterol or hypertension), and for the enhancement of health, cognitive performance, or bodily aesthetics.
- Explore how medication narratives may be used to improve patient care in a health care or community pharmacy setting.
- Evaluate student experiences of using medication narratives as a component of case-based learning in pharmacy education.

Multimedia Annex

In this video narrative, Claudia describes her experiences of taking antidepressant and antianxiety medications, including their taste, how they make her feel, and how she manages to swallow them. She also links her personal story up with the broader social and political context through a critique of prescription pricing under the British National Health Service.

Website link: https://www.youtube.com/watch?v=vpNVyLSdPOs

In his video review of Modafinil, Adrian describes 3 days of self-experimentation with the cognitive enhancing medication, including how he procured it from a supplier based in India, how he used it, how it made him feel, and his personal recommendations to other users.

National Medicine Policies Impacting on Pharmacy Practice

Anna Birna Almarsdóttir, Janine M. Traulsen, University of Copenhagen, Copenhagen, Denmark

The policies concerning and affecting medicines are discussed, debated, and decided on many levels—global, international, national, and local. The majority of policies which impact pharmacy practice can be found at the national level. Previously, policy makers at the national level paid little attention to medicine production by the pharmaceutical industry or the quality or availability of medicines for consumption by their citizens. This meant that most countries did not regulate the safety and efficacy of medicines. Governments trusted the pharmaceutical industry to test their products for safety and efficacy prior to market release. As long as pharmaceutical companies and pharmacies sold unadulterated medicines at prices that the market could bear, it was the market and not the state that had the responsibility for policing pharmaceutical products. In the 1960s all this began to change, mainly as a result of the Thalidomide scandal, in which women who took thalidomide for nausea in pregnancy gave birth to babies with deformed limbs.

The World Health Organization (WHO) has for decades, encouraged nations to take responsibility and to formulate and implement comprehensive national medicine policies (NMPs), and the WHO message has had an effect. Since 1985 NMPs in low-income countries were established and increased rapidly, with the largest increase between 1985 and 1999. It was only in the mid-1990s that wealthier countries began formulating NMPs. Since the late 1990s NMP has become a global concern and a national endeavor and the number of NMPs has been increasing worldwide. Since the early 2000s the highest proportional increase in NMPs has been in high-income countries, providing appropriate medicines of assured quality, in appropriate quantities, at reasonable and affordable prices. The percentage of NMPs increased across all income categories but the highest proportional increase was seen in high-income countries, from 18% in 1999 to almost 80% in 2011 (Hoebert et al., 2013).

Defining National Medicine Policy

What is NMP and why is it important? In brief, a NMP is a common framework used to address and solve problems associated with pharmaceuticals; it is a commitment to a goal, and provides guidelines for action. NMP involves all the major actors in the pharmaceutical field including actors in both the public and private sectors (World Health Organization, 2001). WHO emphasizes that NMPs be designed as an essential part of health policy, fitting into the framework of the health care system as well as already existing national health policies. Developing a NMP is a complex process that must be country specific since every country and national health system is unique. However, one common goal, found in all NMPs, is to ensure equitable access, good quality, and rational use of medicines.

WHO emphasizes that a NMP must have a physical existence, i.e., be presented and printed as an official government statement which serves as a public declaration of the aspirations, aims, decisions, and commitments of the national government. To ensure that the various government measures do not conflict with existing measures, it is important that the goals and responsibilities are clearly defined and understood. In addition, NMPs should be dynamic and not stagnant—they should be written in such a way that they are capable of accommodating changes over time.

Most NMP s prioritize medium-to long-term goals set by the government for the pharmaceutical sector including not only the public and private sectors but also all the main actors in the pharmaceutical field. An effective NMP formulates and identifies major strategies for attaining these goals. It should be mentioned that although NMPs are best to deal with most pharmaceutical problems there are cases/issues that can and should be managed at a global or regional level. These are usually problems which extend beyond the boundaries of national borders, and are better managed, for example, by the European Medicines Agency (EMA) centralized

registration process and/or by regional groups which collaborate to harmonize regulation and pricing information as well as coordinate NMPs across countries within their regions (Hoebert et al., 2013; Vogler et al., 2017).

The politics influencing NMP are complex and influenced by a variety of other policy decisions. Pharmaceutical policy is an overlap of three existing fields of policy: public health policy, health care policy, and industrial policy (Traulsen and Almarsdottir, 2005a). Developing a NMP is a long and complicated process which requires knowledge of public health demands as well as economic goals and objectives. This means that policy makers are faced with overlapping and often competing regulatory tasks. In the first place, the goal of public health policy is to contribute to the overall public health by guaranteeing safe, high quality, and efficacious medicines. Thereafter is the enormous task of balancing health care budgets and controlling health and drug costs, which is the realm of national health care policy. Finally, given the economic contribution of the pharmaceutical sector to the state, policy makers are faced with the task of promoting a regulatory environment conducive to supporting and encouraging business through industrial policy. Taken together these three policy inputs—two concerned with health and one with commercial interests have a tremendous effect on pharmacy practice (Traulsen and Almarsdottir, 2005a).

The complexity does not end here, it must be remembered that the process of designing and planning a NMP is only the beginning: NMPs must be implemented, monitored, evaluated and last but not least there must be mechanisms available for revising and updating the NMP to remain useful and durable.

Policy Makers' View of Pharmacy and Pharmacists

The overall aim of policymakers is to ensure adequate and accessible health care, welfare, and general wellbeing of its citizens. The issues in NMPs that are relevant for the pharmacy sector and pharmacy profession are based on how policy makers view pharmacies and pharmacists. However, on closer inspection we find two conflicting views of pharmacy and pharmacists—they are either seen as part of a commercial business or as part of (and contributors to) the health care sector (Traulsen and Almarsdottir, 2005b).

On the one hand, when the pharmacy sector is viewed as a commercial enterprise it is seen as making a positive contribution to the economic good of the community. It follows that from this perspective policymakers view pharmacists as business (wo)men. On the other hand, when the pharmacy sector is considered a part of the health care sector it is seen as contributing to health services. Here policymakers view pharmacies as local health care centers—the first contact the public has with the health care system and with academically trained professionals. Pharmacists are viewed as the most easily accessible health care professionals, and their role is to use their extensive education about pharmaceuticals (from development to dispensing) to contribute to the overall public health goals of the community.

When analyzing which of these views dominate in a particular policy debate it is important to consider the two perspectives in the context of the policy. In other words, is the emphasis to lower drug expenditures or to increase patient safety and provide new and useful services for patients?

Both of the above mentioned views can be found at the roots of a conflict the profession has been struggling with since its conception: commercial interests versus professional interests. Despite centuries of regulation, there is no universal consensus on how policymakers perceive and regard pharmacy (and pharmacists). When perceived of as a business, policy makers are inclined to legislate pharmacy just like any other commercial enterprise, emphasizing financial and economic frameworks. In contrast, when pharmacies are accepted as part of the health care sector and pharmacists as academically trained health care professionals who provide a public service, they are inclined to regulate and legislate within the framework of other established health care policies and services.

An example of these two views of the pharmacist could be observed in the late 1990s when the liberalization of pharmacy ownership was debated in Denmark. Initially the policy debate focused on the pros and cons of a free market and competition in the pharmacy sector. The debates shifted focus toward the need for responsible public control of medicines which prioritized safety and access to medicines including the role of pharmacies as health care institutions and by default pharmacists as health care professionals (Larsen et al., 2006).

The contrasting views of pharmacies as businesses vs. health care centers are evident in policy decisions concerning ownership of community pharmacies. There is a wide variety of ownership models for pharmacies but the two most common distinctions are between systems where only pharmacists are allowed to own and run community pharmacies (the case in many countries, for example, Denmark, Finland, Spain, and France) and systems with nonstipulated ownership policies such as in the USA, UK, and Norway where pharmacies are often part of a commercial chain (either pharmacy or supermarket chain). Powerful commercial and economic interests have influenced the rhetoric and policymaking regarding ownership and the professional ownership monopoly has been under siege in the past decades especially in the Nordic countries (Almarsdottir and Traulsen, 2006).

When the view of pharmacies as health care centers is dominant, the personnel of pharmacies are highly regulated as to their required competencies. This aspect was quite clear during the recent policy changes made in Sweden which went from a state owned monopoly (quite rare in the pharmacy world) to a free ownership model in 2009. During the debates about the freeing up of the state monopoly, the rhetoric centered quite often on which members of the workforce should be required to fill prescriptions and give advice to patients (Statens Offentliga Utredningar, 2008). A wide variation exists between countries regarding the requirements necessary for becoming a pharmacist (i.e., length of academic study and on the job training). This variation also includes the training and requirements for other pharmacy personnel available in different countries such as assisting or allied professions (i.e., technicians) (International Pharmaceutical Federation, 2006).

In most countries' with free ownership policies NMPs require that the person in charge of the day-to-day running of the pharmacy be educated as a pharmacist (see Chapters 102, 104–112 in this Encyclopedia). The pharmacist can then delegate responsibilities for work tasks to other pharmacists or to assistants with a variety of training and backgrounds (see Chapter 103 in this Encyclopedia). The general trend, in counties with highly liberal pharmaceutical distribution policies, is that the pharmacy owners usually have the power and authority to select the composition of assisting personnel and are able to hire as inexpensive personnel as possible for tasks that have no legislative requirements.

Pharmacy practice in hospitals has not been exempt from this duality between the commercial and professional interests, although it has been developing in a different way. NMPs affect hospital pharmacy practice differently according to country, however, a common thread can be found in that there is increasing pressure to minimize the cost of medicines to the hospital. The pressure comes from policy makers at the highest levels. Their goal is to stop the escalating cost of health care. Hospital pharmacy practice is very much concerned with negotiating tenders and managing staff. In this climate one finds pharmacists working largely on tasks that seek to meet demands for cost containment. How this dual view of policy makers on the national level affects pharmacy practice and the profession's work will be dealt with below.

NMPs and the Sale of Medicines in Community Pharmacies

National policies affect the role of pharmacy practitioners (pharmacists and allied personnel) through a range of mechanisms. The privileges, requirements, and duties of pharmacists have their roots in history (see Chapter 702). Health systems vary tremendously across the globe and this makes for a variety of payment structures for pharmacy services. In national health care systems, national policies have a direct impact on the payment structure, i.e., how much is paid for dispensing medicines. In other health care systems private health insurers have a large say in what is paid for. Nevertheless, all systems have to abide by the overarching goal of health care systems to make medicines affordable and accessible.

The privileges and duties that pharmacies have through NMPs are not static; they are rapidly moving and follow shifts that affect most—if not all—professions. The issues that are on the move will be dealt with below and have to do with the right to sell prescription medicines and the remuneration for doing this or for providing other services. In addition, NMPs regarding over-the-counter (OTC) medicines are rapidly changing as well as the patients' copayment for medicines and insurance costs.

Sale of Prescription Medicines

Most NMPs privilege pharmacies with the procurement and sale of prescription medicines. This centuries old privilege makes for an important part of the viability and raison d'etre for pharmacies—although to a varying degree according to country. This backbone and mainstay of pharmacy is slowly eroding in most countries as health care budgets are strained and other actors in the health care market vie for this privilege.

There are a number of strategies employed by policymakers to curb costs of pharmaceuticals without losing out on safety and effectiveness of medicines in the population. Those NMPs that affect pharmacy practice in the primary sector are setting profit margins on the sale of medicines, reference pricing, and generic substitution, and switching prescription medicines to OTC status.

When policy makers limit margins on medicines they can either do this by fixing margins to certain percentages or by introducing fees per capita and/or prescription in an attempt to reduce the incentive to sell more medicines. Reference price lists for reimbursement of medicines in their simplest form mean that the price of a certain pharmaceutical product within a class of drugs is set as a reference for other similar drugs (generic or therapeutic equivalents). The reference drug is usually the least expensive in the class. If a patient or physician decides to use a more expensive drug, the patient is required to pay the difference between what would have been reimbursed for the cheaper drug and the price of the selected more expensive drug. The use of reference pricing requires a system of generic substitution or generic prescribing. The principle at work here is that pharmacies (often in cooperation with patients and the prescribers), are able to substitute less expensive generic versions of medicines. Generic prescribing also affects pharmacy practice in the hospital sector.

Positive lists (also called formularies) are lists of pharmaceuticals approved for reimbursement by the insurer or paid for by the health care system. Such lists are often compiled by expert committees who evaluate the therapeutic value of each drug, largely based on results from clinical trials, but sometimes on results from pharmacoeconomic analyses. The lists are often organization specific, so not made as NMPs, although they can be. The World Health Organization has drawn up a Model List of essential drugs that can be put into a NMP (World Health Organization, 2003). Although their list is primarily intended to meet the principal health needs of a community with very limited resources rather than to support cost-containment, the WHO advocates its use for determining the pharmaceutical needs of a population and therefore providing a basis for a national medicines list (World Health Organization, 2001).

NMPs often seek to manage the prices of medicines, the margins that pharmacies can have, and sometimes even the total profits of the pharmacies nationwide. Strict price controls are often applied to community pharmacies for prescription and even OTC medicines. In some instances this means that there is a fixed price allowed for medicines which leads to no competition on prices. Price setting is mostly done through negotiations at the manufacturer level with large payers (who can be national health insurers or governmental bodies dealing on behalf of the insurance system). The end price of a medicine affects the income of community pharmacies but many other factors in the market impact on pharmacy profits besides those that have to do with the

margins and profit ceilings allowed. Currently prescribed pharmaceuticals are no longer the mainstay of the income of pharmacies and sale of other products (OTCs and other goods) play an even more important role (Almarsdottir and Traulsen, 2005).

Over-the-Counter Medicines and Other Goods Sold in Pharmacies

One issue that affects the practice of pharmacy in the community is OTCs and the decision as to which drugs are OTC is often found in NMPs. OTCs are medicines that are sold directly to a customer and do not require a prescription from another health profession (see Chapter 720 in this Encyclopedia). The policy decision which allows a medicine to be sold as an OTC is based on knowledge about the safety profile of the drug but this is not to say that the drug is without safety issues. Switches from prescription to OTC (also referred to as reclassification of medicines) has been practiced widely in the last two decades. This practice has been seen as serving two purposes: first, to save time and money for the patient who avoids a visit to a physician and at the same time saves the prescription charge at the pharmacy. Second, third party payers save due to a reduction in physician visits and the shift of drug costs to the patient. This practice has had a big effect on pharmacists and pharmacy staff who are important advisers in the choice of self-medication (Almarsdottir and Traulsen, 2005). The switch from prescription to OTC products has in many cases meant that pharmacies play a larger role in advising patients on the use of these medicines.

Another aspect concerning OTCs are whether they are allowed to be sold outside pharmacies in stores (such as drug stores and supermarkets) that do not employ health professionals with special knowledge about medicines. In cases where this is allowed, the practice is often a result of public pressure for more access to the specific widely used medicines such as nicotine replacement products and pain medications. Another important actor who stands to benefit from this type of NMP is retailers of health products.

Whereas retail businesses have been reaching into the realm of community pharmacy, pharmacy has in turn sought to regain lost ground through the sale of other goods, be they health care related (such as vitamins and bandages) or not health related (such as food and beverages). NMPs often deal with this issue by specifying what a community pharmacy can and cannot sell.

Patient Copayment and Insurance for Medicine Costs

What patients pay for their medicines and how they are insured for medicine costs varies greatly according to countries. It can vary from national or regional publicly funded health care systems such as the UK and the Nordic countries, to highly regulated private health insurer markets such as the Netherlands and Germany, to free market for insurance such as the USA. These widely varying systems all have a commonality in that NMPs usually stipulate access to medicines for all citizens. The variation lies in whether NMPs stipulate equal access (often seen in national/regional publically funded systems) or basic access (privately funded systems). In these latter types of systems, there are often special programs available which address the needs for access by vulnerable populations such as the elderly, minorities, and indigent populations.

Clinical Services (Cognitive Services) Provided by Pharmacists or Their Staff

NMPs can to a large or moderate degree govern the prices, profits, and reimbursement for medicines. Moreover, national policymakers can affect pharmacy practice through the extent to which pharmacists are allowed to practice or be remunerated for clinical services (often termed cognitive services). Examples from such national systems are England, Denmark, and Australia. The UK National Health Service (NHS) has been seen by many within pharmacy as a trailblazer for remunerating pharmacist cognitive services and engaging pharmacy practitioners in more clinical work, both in the community and in hospitals. In 1986 a seminal report was published based on the work of the Nuffield Foundation Pharmacy Inquiry Committee (Nuffield, 1986) which had far reaching and (in the 1980s) bold recommendations on how to involve pharmacists in health care and public health. From then on many changes have been made to improve the training of pharmacists and to introduce new pharmacist-led health services in all health care sectors. One of the most notable changes can be seen in the use of community pharmacies in dealing with minor ailments and in how pharmacy is used in public health prevention and promotion (Anderson, 2007). Another change was that pharmacists in the UK started to get involved in supplementary prescribing of medicines through contracts with physicians (Cooper et al., 2008). An example of a country where the development has been slower is Denmark, where only two services have been remunerated through the national health services scheme. One is a service to improve the use of inhaler devices for asthmatics and COPD patients, and the other is a consultation service for newly diagnosed chronically ill patients about their medicines to support adherence (Kaae et al., 2016). Vaccinations at community pharmacies are currently becoming a widespread service offered in many countries, either remunerated by insurers or paid out-of-pocket by the customers. Lastly, Australia started a program of Home Medication Reviews in 2001 which funded community pharmacists and medical practitioners to work collaboratively with the patient, the patient's caregivers and, when appropriate, other health practitioners to address issues concerning the use of medicines (Cipolle et al., 2012). The availability and accessibility of pharmacies has been mentioned and this has contributed to policy makers' interest in utilizing the competencies of the workforce there.

As mentioned above, the view policymakers have of community pharmacy as a shop or a health care center impacts remuneration patterns. This means that if they see it as a shop, they will not be willing to compensate pharmacies for anything other than the sale of medicines. Similarly, policymakers' thrust for cost cutting and cost containment in drug procurement in the secondary sector has

made for a more product-focused work environment for hospital pharmacists which can make it difficult for hospital pharmacists to find the time and space to provide much needed clinical services (Almarsdottir and Granas, 2015).

Division of Labor Between Pharmacists and Other Health Care Professionals in Relation to Medicines

The role of most health care professionals is subordinate in one way or another to that of physicians. Whether someone is a community pharmacist or a hospital pharmacist, their professional role is ultimately controlled, or at least limited, by the authority and dominance of the medical profession, and the relationship is contentious (Turner, 1995). This subordination stems from the historic strong position of physicians in relation to national policymakers where pharmacists have traditionally not had such a strong voice and therefore not been able to affect NMPs to a large extent. It is not impossible though to have a large impact on implementing and instituting clinical pharmacy services as seen in 1980s with the advent and subsequent implementation of the Nuffield report in the UK and the strong advocacy of the American Society of Health-System Pharmacists (ASHP) in USA (Zellmer, 2006).

While on the one hand pharmacists can be seen as infringing on the physicians' traditional task of prescribing, on the other hand pharmacists are encountering the problem of dispensing physicians. By law in most countries, dispensing physicians are allowed to sell drugs to patients in certain remote and thinly populated areas, often places where there are no pharmacies. However, because selling medicine can be a very lucrative business, many developing countries have dispensing physicians in even the most populated areas, including large capital cities (Trap et al., 2002). Policy discussions about who should be allowed to prescribe and who should be allowed to dispense continue, because the inherent conflict of interest in allowing the same profession to prescribe and sell drugs has been and still is an overriding concern.

Shifts in the division of labor in the pharmacy are a direct result of political and economic changes in society as a whole and NMPs have dealt with this issue of using the manpower optimally. The division of labor between pharmacists and pharmacy technicians is a case in point. Traditionally helpers and assistants to pharmacists, pharmacy technicians' jobs and training have been increasingly regulated and upgraded in many countries, and more and more frequently technicians have been taking over tasks previously performed by pharmacists. The upgrading of the skills and knowledge of the pharmacy technicians varies from country to country. In some countries, pharmacy technicians have little if any training, and obviously pose no threat to the pharmacist. In others (i.e., in Denmark and the Netherlands) they are highly trained and have even been taking over tasks previously seen as pharmacists' roles both in community and hospital pharmacies. It was seen in the debates about liberalizing community pharmacy ownership in Sweden that the legal requirements for the composition of pharmacy personnel was a very contentious issue. It seemed that policymakers were quite unsure of the competencies of the various professional categories and which of these were really needed to work in community pharmacies (Statens Offentliga Utredningar, 2008).

Concluding Remarks

NMPs have a great impact on pharmacy practice and there are a number of issues and actors at play. Pharmacists are of course also an important actor defining the role of pharmacists—i.e., as drug product or health care providers. Throughout the ages pharmacists themselves have been instrumental in shaping their profession through their ideas and visions. New and expanding roles for the pharmacy profession were sometimes inspired by external events but were often the result of the pharmacists' own prerogative. One example of a profession mediated idea is the vision and development of pharmaceutical care as a professional role for pharmacists and expanding their role through clinical pharmacy (Hepler and Strand, 1990). Professional organizations of pharmacists throughout the world have not only embraced these expanding roles, they have also contributed by further developing them (American College of Clinical Pharmacy, 2017; European Society of Clinical Pharmacy, 2017). However, there are also reactionary or status quo tendencies seen in the pharmacy profession as they do not see themselves as patient care providers but prefer to continue doing what is known as their field of work—namely dispensing medicines (Rosenthal et al., 2010).

Glossary

Clinical pharmacy Clinical pharmacy is a health specialty, which describes the activities and services of the clinical pharmacist to develop and promote the rational and appropriate use of medicinal products and devices. Clinical pharmacy includes all the services performed by pharmacists practicing in hospitals, community pharmacies, nursing homes, home-based care services, clinics, and any other setting where medicines are prescribed and used.

Cognitive pharmacist services The use of specialized knowledge by the pharmacist for the patient or health professionals for the purpose of promoting effective and safe drug therapy.

National medicines policy or national drug policy (NMP) A common national framework used to address and solve problems associated with pharmaceuticals; it is a commitment to a goal, and provides guidelines for action. NMP involves all the major actors in the pharmaceutical field including actors in both the public and private sectors. Most NMPs prioritize

medium-to long-term goals set by the government for the pharmaceutical sector including all the main actors in the pharmaceutical field. An effective NMP formulates and identifies major strategies for attaining these goals.

Patient copayment The part of the health care cost (i.e., the cost of a medicine) that is paid by the patient. Copayment for services generally is meant to instill cost awareness in the user of health care services, thus reducing unnecessary use.

Pharmaceutical care Pharmaceutical care is the responsible provision of drug therapy for the purpose of achieving definite outcomes which improve a patient's quality of life.

Pharmacoeconomic analyses Evaluation of the economic consequences of the use of a drug. This assessment can be made before placing a drug on the market or afterwards, possibly including a comparison with another drug or another health care intervention.

Positive lists Are also called formularies. They are lists of pharmaceuticals approved for reimbursement by the insurer or the lists of drugs that may be used in a particular organization (hospital) without getting a special permission.

Pharmaceutical Company Sponsored Medication Assistance Programs

Suthira Taychakhoonavudh*, Zaheer-Ud-Din Babar†, *Faculty of Pharmaceutical Sciences, Chulalongkorn University, Bangkok, Thailand; †Department of Pharmacy, University of Huddersfield, Queensgate, Huddersfield, United Kingdom

Growing health expenditures per capita has been an issue for all countries, rich or poor. Health spending growth in the United States between 2015 and 2025 was projected to average 5.8% or 1.3% points higher than growth in the country's gross domestic product. United States health expenditure will account for 20% of the total economy by 2025 (Keehan et al., 2016). Similar situations were seen in upper middle-income countries, lower middle-income countries and even in low-income countries (Jakovljevic and Getzen, 2016).

What is Driving the Increase in Health Expenditures All Over the Globe?

The rise in health expenditure is accelerated by several factors including aging population, changing disease pattern from infectious diseases to chronic diseases, and inefficiencies in the healthcare system. Advances in health technology, especially high costs innovative medicines, has been pointed out by many researches as the principle driver for increasing health expenditures (Sorenson et al., 2013; Kesselheim et al., 2016) around the globe.

To contain costs in healthcare, innovative medicines that are mostly high-priced are the target of cost containment strategies. The prices of innovative medicines differ from country-to-country due to differences in healthcare system and healthcare markets (Kesselheim et al., 2016).

Studies found that in the United States where healthcare are offered mainly through market system, the price of the drug is set by pharmaceutical company solely based upon the market exclusivity of the drug (Rosenthal and Graham, 2016; Kesselheim et al., 2016; Savage et al., 2017). The cost of these drugs, even though reimbursable by major health insurance payers, has many hurdles for patients to access, for example, prior authorization, higher out-of-pocket spending, co-payment or co-insurance (Tefferi et al., 2015). Price of drugs in other healthcare systems where universal coverage is achieved, is also high. As a result, coverage decision by major health insurance payers is mostly delayed (Bae et al., 2016; Kandolf Sekulovic et al., 2017). In this case, patient's out-of-pocket spending becomes the major healthcare financing source.

Literature has shown that higher out-of-pocket expenditure can lead to non-compliance of medicines. Patients were reported skipping their medications or refusing to refill their prescriptions when co-payments for their drugs were high. This actually leads to poor health outcomes for the patients. Olszewski et al. (2018) found that patients receiving financial assistance for medicine have longer overall duration of therapy.

The emergence of pharmaceutical company sponsored medication assistance program has been documented in the literature since 1990s. The program primarily provides medication to patients who do not have prescription drug coverage from either public

or private insurance for free. These patient assistance programs are funded by pharmaceutical companies voluntarily. The offerings of these programs are not required by the governments.

We began this chapter by describing the characteristics of pharmaceutical company sponsored medication assistance programs. We then turned to distinguish between this and patient assistance programs sponsored by the government or other programs between pharmaceutical companies and the health insurance payers. Role of pharmaceutical company sponsored medication assistance programs in the United States is also explained.

What is Pharmaceutical Company Sponsored Medication Assistance Program?

Pharmaceutical company-sponsored medication assistance programs are also known as drug company-sponsored patient assistance programs (Choudhry et al., 2009), patient assistance programs (PAPs) (Felder et al., 2011b) or prescription assistance program (PAP) (Gao et al., 2016), medical assistance program (MAP) (Horswell et al., 2008) or pharmaceutical manufacturer assistance programs (PMAPs) (Sarrafizadeh et al., 2004).

These programs offer brand name medicines by pharmaceutical manufacturer to patients at a lower cost or sometimes at no cost. Most programs are for a certain medication and sometimes for a certain indication (Chu et al., 2011). However, some programs are funded for specific diseases by several pharmaceutical manufacturers mostly through non-profit organizations. The latter programs are not only limited to medication but also include financial assistance to the patients for insurance premiums and co-pays, assistance for diagnostic testing, and travel assistance for clinical trials or consultation with disease specialists. Examples of these programs are National Organization for Rare Diseases (NORD): a patient advocacy organization dedicated to individuals with rare diseases, or American Kidney Fund that provides direct financial assistance to kidney patients.

Pharmaceutical companies use patient assistance program as a price discrimination tool to price its product at the profitable level in the market where there is an ability to pay while offering assistance program in the market where affordability is the major criteria for product selection. In a changing pricing environment in pharmaceutical market, assistance program is a win-win pricing tool to limit the use of international reference pricing.

The terms patient assistance program has also been used elsewhere for government patient assistance program. However, these programs are mainly funded and operated by the government and are different from pharmaceutical company sponsored medication assistance programs. The purpose of the government-funded programs is to help its citizens have better access to medicines. Details of the program vary with the criteria set by the government. In the United States, government patient assistance program are run separately by each state or country. List of government patient assistance programs in the United States can be found on the website of National Resource Center for Prescription Assistance Plan (501(C)(3) organization, 2019).

Examples of government PAPs in the United States include:

- Pennsylvania prescription assistance program for older adults (The Pharmaceutical Assistance Contract for the Elderly or PACE program): The program provides prescription assistance for older adults in the state, and provides low-cost prescription medication to qualified residents aged 65 and older. To be eligible for PACE program, a person must also have an income in the income range determined by the state of Pennsylvania.
- The Madison County Commission SENIOR Rx Program: The program helps low-income Madison County residents, aged 55 years and above who do not have prescription drug coverage for free or at a low-cost. The medicine, however, only includes medication for chronic illness(es) or condition(s).
- AIDS Drug Assistance Program (ADAPs): The program provides HIV/AIDS drug to HIV-infected patients. Funded mainly by the federal government through the HIV/AIDS bureau under the Health Resources and Service Administration, the program, however, differs significantly from one state to another. Each state has an authority to determine drugs to be listed in its ADAP formulary. Variation in drug coverage, both antiretroviral drugs as non-HIV medications, were found in each ADAPs state (Smith and Buchanan, 2001).
- 340B program (340b health, 2018): The program was created in 1992 by the United States federal government requiring pharmaceutical companies to provide Medicaid-covered outpatient drugs at cheaper price to eligible government healthcare facilities or "covered entities". The program aimed to serve the Medicaid as well as uninsured seeking care in those health facilities.

Government Prescription Assistance Programs in Countries Other than United States

Government prescription assistance program have also been found in other countries for example, Philippines government medical assistance program.

Philippines Government Medical Assistance Program

In 2016, Philippines Ministry of Health (MOH) published guidelines on the availability of medicine assistance funded under the President's p1billion fund (Department of Social Welfare and Development, 2016, 2017). The program helps patients who seek medical assistance. Funded by the office of the president, the program provides free medication mainly to indigenous and vulnerable patients.

In some settings, the term patient assistance programs have also been used for risk-sharing programs or managed entry agreement program. The differences are that patients who receive pharmaceutical products from pharmaceutical company sponsored medication assistance programs are patients who could not access pharmaceutical products mainly because it is not reimbursed by their health insurance or the patient themselves do not have insurance coverage. However, risk-sharing programs are between pharmaceutical manufacturers and health insurance payers, and they share the risks and uncertainties that arise in reimbursement decision-making. These programs would not be mentioned here in this chapter but readers can get more information from '*Managed entry agreements for pharmaceuticals: the European experience.* EMiNet, Brussels, Belgium' (Ferrario and Kanavos, 2013).

Role of Patient Assistance Program in United States Healthcare System

Access to medicine in the United States healthcare system mainly depends on patient's health insurance status. Patient assistance programs are used as a safety net for patients who cannot access their medications through their current health insurance status (Felder et al., 2011a). The Pharmaceutical Research and Manufacturers of America (PhRMA) decided to launch "PPA program" to facilitate patients enrolling in patient assistance program offered by the company that are PhRMA members. The PPA program was launched in 2005. In 2018, PhRMA reported on its website that PPA sponsored by pharmaceutical industry has helped more than 10 million US residents (Pharmaceutical Research and Manufacturers of Americas PhRMA, 2018).

Pharmaceutical sponsored patient assistance program is not limited to uninsured patients; it can be accessed by underinsured as well. Underinsured are mostly overlooked since they have health insurance coverage, yet have to pay a large amount of their income on health care. The Commonwealth Fund study has found that even though Affordable Care Act reduced uninsured population by nearly 2 million from 2010 to 2012, the number of underinsured increased from 29.9 million to 31.7 million (Cathy Schoen et al., 2014).

US population who are insured but most at risk of underinsured are, for example, Medicare beneficiaries who have low income but not low enough to be eligible for Medicaid or low-income subsidy for Medicare Part D. Medicare beneficiaries who are qualified for Medicaid except they have a high spend down amount; beneficiaries under private commercial insurance plan have high deductibles or copays or have formulary restrictions.

Although the use of pharmaceutical sponsored patient assistance programs can be helpful for patients who otherwise would not be able to access these medications, the process of acquiring these drugs under PPA can be challenging. The website of the PPA programs shows that in 2018 more than 200 patient assistance programs were offered by 80 pharmaceutical companies. Most programs, however, offered access to only one or two specific drugs [Partnership for Prescription Assistance (PPA), 2019]. It was reported that the structure of PPAs, application process as well as benefits offered varied widely (Zafar et al., 2015).

Each program has different eligibility criteria and documentation requirements. Eligibility criteria include patients' income level, for which some require proof-of-income documents while some do not, patient's insurance status, drug coverage status, and United States residency status.

Medications offered via patient assistance program range from medications for chronic diseases for example, Lipitor (atorvastatin), Advair Diskus (fluticasone propionate and salmeterol) to medications for acute illness, for example, Nexium (esomeprazole) and high cost medicines, for example, anticancer biological drugs. However, programs are generally not appropriate for acute illness where medication should be taken as soon as possible as the application process for patient assistance program takes quite some weeks.

Some companies offer assistance programs for vaccines For instance, Merck has vaccine patient assistance program as well as nutrition support therapy and Abbott offers nutrition patient assistance program. The trend in medication offerings and patient assistance program has changed as medications for controlling chronic conditions were among the most commonly requested for patient assistance program in 2006 (Chauncey et al., 2006). Currently, anticancer drugs are the most frequent group of medication sought under patient assistance program as the price of these medicines are surprisingly high at approximately $10,000 or more per month. Study by Olszewski et al. (2018) has shown that more than one third of patients receiving cancer medication used financial assistance to offset out-of-pocket costs. Examples of patient assistance programs offered in the United States are listed in **Table 1**.

Enrolling in Pharmaceutical Company Sponsored Medication Assistance Programs in the United States

Patient Assistance Program Enrollment Process in United States

The number of patient assistance programs has been increasing with the increasing complexities of the program offered by each company. The enrollment process of all patient assistance programs can be summarized into four steps:

Step 1: Patient locating patient assistance program application form for the medicine he/she would like to enroll in.

Before enrolling in any patient assistance program, a patient needs to determine if the needed medication has patient assistance program offered. Some programs do not require patients to complete an application form at all, while some program require application form to be filled in by the patient. Patient assistance program application form is usually available online from the pharmaceutical company website. Some company, however, would send an application form only to patient or healthcare professional per request especially for specialty medications and high-cost medications.

Table 1 Example of pharmaceutical company sponsored patient assistance program offered in the United States healthcare market

Drug group	*Example of drugs offered patient assistance program*	*Details of the patient assistance program*	*Eligibility criteria*
Non-communicable diseases	• Insulin lispro injection (Humalog) • Dulaglutide (Trulicity)	• A 120-day supply of medicine will be shipped to the doctor's office • Enrollment period is 1 year • Refills are requested by fax refill form by the prescriber	• Have no insurance or have Medicare Part D and have a household annual adjusted gross income ≤400% federal poverty line (FPL) • Healthcare provider has prescribed a medication • A permanent, legal resident of the United States or Puerto Rico • Not enrolled in Medicaid, full low income subsidy (LIS, "Extra Help") or Veterans (VA) Benefits • If patients are a Medicare Part D patient, they have spent $1100 on prescription medication this calendar year.
Infectious disease	Lamivudine	• Refills are sent at no cost for up to 12 months after enrollment • Each refill must be requested at least 3 weeks before existing supply of medicine runs out	• Live in one of the 50 states, District of Columbia or Puerto Rico • Have no prescription drug benefits through anyinsurer/payer/ program • Meet certain income eligibility requirements
Immunosuppressive	Cyclosprorine	• The majority of products are dispensed in a 30 or 90 day supply • All products will be shipped directly to the physician's office	• Have limited or no private or public prescription coverage • Income at or below 600% of FPL • Must reside in the United States, Puerto Rico or the United States Virgin Island
Antipsychotic	Aripiprazole (Abilify)	• The amount of drug supply is various. • The drug will be sent to doctor's office or patient's home • Patient can re-apply yearly	• May have insurance • Eligible Medicare part D patient • Have income at or below 300% of Federal Poverty Level (FPL) • Must reside in United States
Cancer	Denosumab	• Medications are provided through the HealthWell Foundation • Includes assistance on coinsurance or copayment required as well as insurance premium	• Diagnosed with the disease eligible • Income level falls within eligibility criteria • Receiving treatment in the United States.
Oral contraceptive	Levonorgestrel		• Must have no prescription coverage for needed medicine • Not a Medicare part D eligible patient • Must be residing in the United States or Puerto Rico
Vaccines	Hepatitis B vaccine (Engerix-B)	• Prior to enrolling patients, prescribers must register in the program • For patient enrollment, prescribers must fax the completed and signed application • Applicant will be eligible to receive vaccine for up to one year • Patient can receive subsequent doses of vaccine by having the prescriber complete the dose authorization request form	• Have no third party coverage for Vaccines OR be enrolled in a Medicare Part D Prescription Drug Plan and have spent at least $600 on prescription medicines through your Medicare Part D Prescription Drug Plan during this calendar year • Be an adult, age 19 or older • Live in one of the 50 states, District of Columbia or Puerto Rico • Have a household income within program eligibility criteria
Nutrition supplement	• Calcilo XD powder • Cyclinex-1 powder • Ensure • Glucerna	• Providing products at no cost to individuals in need	• Have no healthcare coverage for the requested product and do not have access to alternative sources of coverage or funding. • Review on a case-by-case basis.

All of these factors are time consuming and thus hinder patient assistance programs. Study by Gellad et al. (2011) has found that only 1.3% of seniors who are Medicare beneficiaries reported participating in an industry-sponsored patient assistance program. In response to this problem, many resources are available to help healthcare professionals as well as patients to navigate through the information regarding these programs.

Examples of resources are listed as follows:

- *NeedyMeds*: A non-profit organization aims at helping patients finding the assistance programs they need for medicines as well as health care. The website not only offers database of manufacturer-sponsored and government prescription assistance programs but also database on disease-based assistance programs as well as free- and low-cost healthcare facilities.
- P*artnership for Prescription Assistance (PPA*): PPA is mainly sponsored by America's biopharmaceutical research companies. The website has a list of Pharmaceutical Research and Manufacturers of America (PhRMA) member company programs available for download. Mainly sponsored by industry, PPA's website offers both public and private sponsored patient assistance programs.
- *RxAssist*: This web-based medication assistance resource center also provides searchable database about prescription assistance programs as well as other program related to pharmaceutical access. RxAssist, however, does not operate any medication programs.
- *MEDBANK of Maryland*: It is funded mainly through state and foundation grants, as well as monetary donations from individual sponsors. The organization aims at helping uninsured and underinsured residents of Maryland, who are eligible for patient assistance programs to gain access to brand-name prescription medicines. MEDBANK also offers an in-house pharmacy service to increase the speed at which patients can receive their medications.
- Medicare website: Medicare also provides database of patient assistance program. Patient assistance programs can be searched using drug name. The website provides data on program name, eligibility criteria, benefits offered, contact of the program.

Patient should then check their eligibility criteria for the patient assistance program, sought. The majority of patient assistance programs base their eligibility criteria partially on income level of the patient. Other eligibility criteria used by pharmaceutical companies include patient's insurance status, drug coverage status, and United States residency status. The last factor is crucial for facilities serving recent immigrants or undocumented residents or who are not yet US citizens and who are mostly uninsured or underinsured.

Step 2: Patient completes patient assistance program form and prepares required supporting documentation, for example, proof-of-income documents.

Application Process

The details of the application form and how to complete it vary from program-to-program. Application form provides demographic information on patient, including date of birth, address, financial status as well as disclaimers and disclosures. Patients usually need to submit financial documentation, for example, federal income tax forms, and social security benefit letters. Patient's or guardian's signature is needed to complete the submission. Most applications also need information regarding the prescriber name, office address, contact information and license number of the prescriber. Information pertaining the requested medication including the name, strength and dosage of the medication. Prescriber signature is also required to complete the application process (Needy Meds Organization, 2019; Gilead Sciences Inc., 2019, Nastad Organization, 2019).

Required supporting documentation is needed to test the eligibility of the patients. Thus, proof-of-income documents such as tax returns or social security statement and the prescription and patient's clinical information including International Classification of Diseases (ICD) diagnosis code or confirmation from a physician that the medications are being used for an approved indication of patient assistance program are also usually required by the pharmaceutical company.

To simplify the application process, some health care facilities, for example The University of North Carolina (UNC) Health care system (Mitchell et al., 2018), The University of Texas M.D. Anderson Cancer Center (MDACC) (Felder et al., 2011a) or a smaller private ambulatory care facility like Altamont Internal Medicine and Pediatrics (AIMP) in upstate New York (Sarrafizadeh et al., 2004), have created a systematic approach to deal with a large number of patient assistance programs.

Step 3: Patient submits completed patient assistance program form along with other documents to the pharmaceutical company.

The submission can be done either by fax, e-mail, or an online platform developed by the manufacturers. Some manufacturers require the application with the patient's signature and submission of the original application along with other documents. Pharmaceutical company then reviews the submitted applications. This process normally takes 4–6 weeks.

Step 4: Medicine from Patient assistance program is received by the patient.

To be enrolled in the program requires patient to submit their application directly to a pharmaceutical company's PAP for the medication needed. Once approved, the requested medication will be delivered either directly to the patient or to the physician's office/clinic. Some programs, however, provide voucher for patient to use as a discount at a retail pharmacy.

Empirical Evidence of Impact of Patient Assistance Programs

Involvement of healthcare providers in patient assistance programs process would undoubtedly improve patient access to needed medication as well as better coordination of pharmaceutical care provided. A systematic review of patient assistance programs effectiveness has found that most studies do not consider the use of patient assistance program alone but together with the

enrollment assistance plus some other medication services (e.g., counseling) (Felder et al., 2011b). The study found that patient assistance programs along with enrollment assistance, are significantly associated with an improvement in patient health outcomes for example, patient's glycemic control and lipid control (Felder et al., 2011b).

However, implementing patient assistance programs into the healthcare settings means financial burden to the healthcare facility. Study by Clay and colleagues on costs of patient assistance program implementation showed that clinic need to pay an extra of $81,835 per year or approximately $10.42 for an enrollment in one program. Costs are higher when manufacturers require patient to submit their applications for every single refill (Clay et al., 2007). Mounts and colleagues (2005) have listed costs associated with patient assistance program application process, which includes pharmacy technician time and salary, use of telephone and fax, postal charges and stationeries (paper, ink for printer, copy machine), computer software for patient assistance program management, computer and printer, internet access and usage of area of the facility.

The major costs in patient assistance program are personnel costs. Some organization may decide to use pharmacist while some use pharmacy technician or administrative staff to manage patient assistance program enrollment process. It was estimated by Sarrafizadeh and colleagues that the total pharmacist time needed to process each medication order was approximately one hour per year. Another study found that pharmacists spend an average of 12 h/month while physicians spend 20 h/month on patient assistance program in their healthcare facilities. Other staffs were reported to spend on average 79 h/month on patient assistance program activities (Duke et al., 2005).

Provider-Patient Communication and Patient Assistance Programs Enrollment in United States

Despite its potential to increase patients' access to medication, few people are aware of these programs (Gellad et al., 2011) especially in the vulnerable population, for example, African Americans (Pisu et al., 2010). Given the complexity of patient assistance program enrollment, patients usually acquire this information from their healthcare providers. However, it was seen that provider-patient communication on patients' need for financial assistance is very rare. Study by Wilson and colleagues found that only one-third of elderly who had financial issue in accessing the medication needed discussed the issue with their physician (Wilson et al., 2007). Others have concluded similarly on provider-patient communication in healthcare (Piette et al., 2004; Alexander et al., 2004; Alexander et al., 2003).

Use of Pharmaceutical Company Sponsored Medication Assistance Program in Other Health Care Systems

Report by the Access to Medicine Foundation showed that the use of pharmaceutical company sponsored medication assistance program is not limited to only United States. It was found that 13 multinational pharmaceutical companies have implemented some kind of patient assistance program in at least 45 different countries covering more than 19 cancer medicines (Access to Medicine Foundation, 2017). Example of these initiatives and how each country manage these programs are listedas follows:

Canada

Pharmaceutical manufacturers have also implemented patient assistance programs in Canada to increase access to high cost drug especially cancer drugs. Patient assistance programs mostly are available when the medicines are not reimbursed by government. Some provinces like Ontario have the official guidance on how to procure and dispense unfunded drugs while some provinces like Vancouver does not have any standard consistent approach available (Kletas and de Lemos, 2018).

The situation in Canada is similar to what happen in the United States where the number of these programs has increased over the past few years. The BC Cancer Agency, an organization responsible for setting the cancer care standard in Vancouver has developed an official guidance along with a provincial repository containing information on all programs related to cancer medicines available in the market (Kletas and de Lemos, 2018). The repository is maintained centrally by the Drug Information Services. The drug information pharmacists were employed at the center to identify any new patient assistance programs when it became available. Information on patient assistance programs in the repository includes name of the program, contact information, eligibility criteria, other types of assistance offered (e.g., compassionate use of drug, financial assistance on special laboratory tests and the other financial assistance offered to patient). The funding status of the cancer drugs offering patient assistance programs were classified into four categories (Kletas and de Lemos, 2018):

- Class I: Reimbursed for active cancer or approved treatment or approved indication only
- Class II: Reimbursed for approved indications only. Completion of a special form—Class II Approval Form— is necessary prior for dispensing drugs. In addition, where indicated, approval from Tumor Group Chair or delegate is required for reimbursement
- Restricted funding: Reimbursement for approved indications only. Completion of the Compassionate Access Program application form is necessary to provide the appropriate clinical information for each patient
- Not funded

The BC Care Agency has created a repository to update the patient assistance programs by actively searching for upcoming drug therapy available in the market (Kletas and de Lemos, 2018; BC cancer, 2019). This systematic approach to deal with the changing structure of the patient assistance programs can be applied to other health systems to facilitate better access to information on these programs.

Asia-Pacific

Evidence has shown that even in the healthcare system where patient assistance programs implementation framework is in place, the patient assistance programs are not fully utilized. Given the significant benefits of high-cost innovative medicine, the need to access to these drugs in this region is very high.

Malaysia

Many manufacturer sponsored patient assistance programs are available in Malaysia and they are called patient access schemes (PAS). The numbers of patient access schemes has increased in the past few years. In May 2018, the government issued the guidelines for the implementation of these programs. Patient access scheme in Malaysia is similar to patient assistance program in other countries as it provides medication mostly without costs to patients who have no access to medications.

The unique characteristic of patient access scheme in Malaysia is that the scheme proposed by the industry need to be agreed upon by Malaysian Ministry of Health (MOH). In Malaysia, medications needed to be listed in national formulary so that the government can reimburse them.

The regulation of patient access scheme in Malaysia currently requires pharmaceutical companies to submit information on the drug, the program (program details, start and end date, expected number of patients enrolled in the program, etc.). The committee will then review, assess, and make a decision on approval of the scheme. The scheme that does not get approval by the committee would not operate its program in Malaysia's public hospitals. (Ministry of Health Malaysia, 2018)

The patient access scheme in Malaysia is managed independently by the pharmaceutical company that proposes the program. Several online resources developed by the pharmaceutical companies become available to facilitate the redemption of medication as well as provide healthcare professional to monitor the patients in the program.

Thailand

Thailand achieved its universal health coverage in 2001. Similar to Malaysia, access to medicines in Thailand is mostly through the reimbursement of public health insurance. National list of essential medicines (NLEM) is the reimbursement list used by the three main public health insurance in Thailand. Patient assistance program available in Thailand were mostly for medicines not listed in national list of essential medicine. In this situation, patient out-of-pocket spending becomes the major source of financing these high cost innovative medicines (Tanvejsilp et al., 2019).

Kittirotruchi and colleagues have found variation in the structure of patient assistance programs as well as the application processes and the management of these programs in Thailand (Kittirotruji et al., 2018).

Vietnam

In 2017, the National Assembly of Vietnam adopted a new law on Pharmacy allowing pharmaceutical companies to provide free drugs to healthcare facilities through patient assistance programs (The Union for International Cancer Control's, 2018). The program, however, is sponsored by pharmaceutical company through a special fund. Vietnam Ministry of Health has to approve the patient assistance program before its launch and implementation in the country (Biospectrum Asia, 2018).

International Patient Assistance Programs

The most recognized international patient assistance program is the Glivec International Patient Assistance Program (GIPAP) (Lassarat and Jootar, 2006). The program is an international donation program sponsored by Novartis Pharma AG. The program administrator is The Max Foundation, a nonprofit, nongovernmental organization (NGO). The program aims to facilitate access to imatinib, the innovative treatment for chronic myeloid leukemia (CML) and GI stromal tumor (GIST) for patients in developing countries. It was reported that since program inception in 2001, more than 50,000 patients suffering from CML and GIST in 80 countries have received their imatinib through this program. The program has donated more than 2.3 million monthly doses of imatinib (Garcia-Gonzalez et al., 2015).

Using World Health Organization (WHO) guidance on drug donations(WHO, 2010), GIPAP has developed its own program structure that includes medical and financial eligibility criteria. The eligibility criteria and program structure of GIPAP are quite similar across countries.

The Max Foundation has grown its program to partner with other pharmaceutical companies. The program now includes eight anticancer medications including nilotinib, ponatinib, sunitinib maleate, temsirolimus, crizotinib, dasatinib, and bosutinib. The

program, however, needs participation of volunteer healthcare professional. These healthcare professionals support the application process, documentations, appointment reminders, and requesting and dispensing the medicines.

Future Trends and Challenges

With the advances in health technology and with the new high cost medicines, the number of patient assistance program will keep rising in the future. They are considered as safety net for patients when no other means to provide medicines are available. The concerns include transparency as well as the need for a more systematic approach. This systematic approach should include repository of all patient assistance program, application process, dispensing as well as monitoring process for patients. These programs should also be evaluated objectively, even as more evidence is needed for their impact on patient health outcome, compliance,and financial burden as well as on the health system.

Pharmaceutical Pricing Policies

Sabine Vogler, WHO Collaborating Centre for Pharmaceutical Pricing and Reimbursement Policies, Gesundheit Österreich GmbH (GÖG /Austrian Public Health Institute), Vienna, Austria

Context

Relevance of Pricing Policies

Ensuring affordable access to essential medicines (i.e. those medicines that satisfy the priority health needs of the population (WHO, 2017a)) is a major policy objective globally (United Nations, 2017). One-third of the world's population; however, is estimated to have limited or no access to essential medicines (WHO, 2011). One of the key barriers is the high price of medicines. In many countries, particularly in low- and middle-countries (LMIC), essential medicines are largely unaffordable for patients who have to pay out-of-pocket (Cameron et al., 2011; Lu et al., 2011; WHO, 2004). Governments have been urged to regulate medicine prices to keep them at a level that is affordable (WHO, 2013). This is done through so-called pharmaceutical pricing policies.

Numerous countries have made progress toward Universal Health Coverage (UHC) which means that all people and communities can use the promotive, preventive, curative, rehabilitative, and palliative health services they need, of sufficient quality to be effective, while also ensuring that the use of these services does not expose the user to financial hardship (WHO, 2018). Many high-income countries have publicly funded, solidarity-based health care systems in place that aim to provide affordable access to needed medicines. With the advance of new medicines (e.g. in the areas of oncology or Hepatitis C) with high price tags in recent years; however, policy makers even in rich countries have been struggling to make these medicines affordable through the solidarity-based health system while not jeopardizing the financial sustainability of that system. High-income countries have implemented a variety of pharmaceutical pricing policies but they are seeking to optimize and develop alternative policies (Expert Panel on effective ways of investing in Health, 2018; Vogler et al., 2017b, 2018b).

Pharmaceutical pricing policies are key because medicines are no normal goods and health care, including pharmaceutical, systems are not normal competitive consumer markets. Patients may be in high need for medicines and health technologies (i.e. they have high price elasticity), medicines can be subject to risks (safety concerns that require responsible handling and use), and there is, sometimes considerable, information asymmetry between the parties involved (e.g. between the prescribing doctor and the patient).

Concepts and Definitions

Prices

A price is defined as "the value component of expenditure" (WHO Collaborating Centre for Pharmaceutical Pricing and Reimbursement Policies, 2016) whereas expenditure combines both volume and value components. The Organisation for Economic Co-operation and Development (OECD) defines expenditure as "the values of the amounts that buyers pay, or agree to pay, to sellers in exchange for goods or services that sellers provide to them or to other institutional units designated by the buyers" (OECD, 2008).

The medicine price is the price related to one or more medicines. It may relate to different market segments (e.g. outpatient or inpatent market, on-patent or off-patent market, prescription-only medicines or nonprescription medicines, orphan medicines, reimbursement segment) and may be defined as different price types.

The price type refers to the stage at which the price is set since the price likely increases as the medicine moves along the supply chain. The MWPP price taxonomy[1] (Vogler et al., 2018c) defines four major price types that are common in the outpatient sector of countries with solidarity-based health systems:

- Ex-factory price (synonyms: manufacturer price, ex-manufacturer price, and manufacturer's selling price): the price at the level of industry, charged by a pharmaceutical manufacturer.
- Wholesale price (synonyms: pharmacy purchase price, pharmacy purchasing price): the price charged by wholesalers to the retailers (usually community pharmacies); it is based on the ex-factory price and additionally includes any remuneration for pharmaceutical wholesale (e.g. in the form of a wholesale markup or a wholesale margin).
- Pharmacy retail price (synonyms: consumer price, public price) net: the price charged by community pharmacies to the general public; it is based on the pharmacy purchasing price and additionally includes any pharmacy remuneration (such as a pharmacy markup, a pharmacy margin, or dispensing fee). If net, it does not include value-added tax (VAT) or other taxes.
- Pharmacy retail price (and synonyms) gross: The pharmacy retail price including VAT and/or other taxes.

Further price types such as Cost Insurance Freight (CIF), the tender or procurement price, the hospital price and the reimbursement price exist (Vogler and Martikainen, 2016). The latter describes the maximum amount paid by a third party payer (WHO Collaborating Centre for Pharmaceutical Pricing and Reimbursement Policies, 2016) since in many publicly funded health care systems the price of medicines eligible for reimbursement is only partially covered by the public payer and patients have to cover the remainder (Vogler and Martikainen, 2015).

While the MWPP price taxonomy relates to high-income countries with price regulation, there might be more stages (and price types) in non-price regulated settings. The World Health Organization/Health Action International (WHO/HAI)

[1] MWPP stands for manufacturer price, wholesale price, pharmacy retail price net, and pharmacy retail price gross. It can also be read as referring to the actors involved: manufacturer, wholesaler, pharmacy, and patient.

methodology to measure medicine prices, availability, affordability and price components (WHO and HAI, 2008) defines five stages:

- First stage: manufacturer's selling price (MSP), which is the price the manufacturer charges for the medicine, and/or the CIF price for imported medicines. The latter reflects the costs of insuring and shipping the medicines to the countries of destination; there are different shipping terms (such as Ex-Works, Free on Board, and Delivered Duty Unpaid) that vary with regard to the split of costs between seller and buyer.
- Second stage: "landed price" that describes the cost of a medicine after it has arrived in a country, has cleared all customs and import requirements and is then supplied to the main distributor (e.g. the importer, the wholesaler or a Central Medical Store). The landed price contains the import tariffs, inspection and port charges (including costs for quality control testing), importer's markup, local transport costs and any national taxes that are levied on the medicines purchased by the importer or supplier as add-ons to the MSP or CIF.
- Third stage: wholesale selling price or Central Medical Stores price. This price component contains any wholesale markups added by the wholesaler (or Central Medical Stores) as well as regional or state taxes levied at this stage and transport costs to move goods from the wholesaler to the retailer.
- Fourth stage: retail price (in the private sector) and dispensary price (in the public sector). A major component adding to the previous stage is the retail markup that pharmacies and other retailers add to cover their costs, including their profit. Additionally, local or town taxes may be levied at this stage.
- Fifth stage: "dispensed price" which contains the sales taxes such as a value-added tax (VAT) or a general sales tax (GST) and fees (e.g. a dispensing fee) that are collected when the medicine is dispensed.

Similarities between the two taxonomies are obvious. The major difference between the MWPP price taxonomy and the WHO/HAI methodology is that the latter specifies the landed price as a separate price component to account for the different intermediaries that may charge tariffs and that it explicitly considers taxes levied at any stage.

Consideration of different price types is key in the design of pharmaceutical pricing policies.

Pharmaceutical Policies

Governments can take different action to achieve defined objectives. These are referred to as policies or regulation. In the area of medicines, the term "regulation" often relates to issues of patient safety, quality, and effectiveness (i.e. regulatory functions such as marketing authorization, inspection and surveillance of market actors, pharmacovigilance, advertisement, and provision of independent information on medicines to professionals and the public (World Health Organization, 2003), whereas policy or policies usually describe government action that aims to ensure or improve affordable and equitable patient access to essential medicines. The term "policy" (or "policies") is frequently used in the context of setting and controlling medicine prices but the notion "price regulation" also exists.

It is important to note that policies (and regulations) are actions by governments and not by private sector representatives. Price sector actors (e.g. pharmaceutical industry) can develop and implement strategies to achieve their objectives. For instance, a pharmaceutical company can design a pricing strategy that aims to maximize profits (e.g. price discrimination by charging different prices to different countries). The approaches of private sector actors; however, are not policies but strategies and plans. In this chapter, pharmaceutical pricing policies that governments can implement will be described.

Pharmaceutical pricing policies are defined as "regulations and processes used by government authorities to set the price of a medicine as part of exercising price control" (WHO Collaborating Centre for Pharmaceutical Pricing and Reimbursement Policies, 2016). A medicine price, that represents the value component of expenditure, is not the sole element that governments might want to address to reduce pharmaceutical expenditure. For instance, pharmaceutical policies that address volume (e.g. prescribing budgets for doctors) may also be implemented.

In countries with advanced UHC, linkage between pricing and reimbursement (i.e. coverage of expenditure by a third party payer such as a social health insurance/national health service) can be strong. In many countries, the scope of price control relates to the reimbursement market, that is to those medicines that are, at least, partially funded by the state (Vogler et al., 2008, 2018a). As a result, pharmaceutical pricing policies also include reimbursement elements, as their description is shown in the following subsections. The presentation and discussion of pricing policies is split into two parts: on policies undertaken when the price is first set (cf. Section Pharmaceutical Pricing Policies at Launch) and on pricing policies along the supply chain (Section Pharmaceutical Pricing Policies in the Supply Chain).

Pharmaceutical Pricing Policies at Launch

This section presents pharmaceutical pricing policies targeted at the price type that is the first one being regulated (or controlled). This section could also have been entitled "pharmaceutical pricing policies at manufacturer price level" because the ex-factory price is the first price type controlled. In some countries, however, medicine prices are set at the level of the wholesale price (see also Section Distribution Remuneration), so the general term "at launch" appears to be more appropriate. The distinction is made between "price at launch" and further price types along the supply chain (e.g. pharmacy retail price) for which specific pricing policies apply.

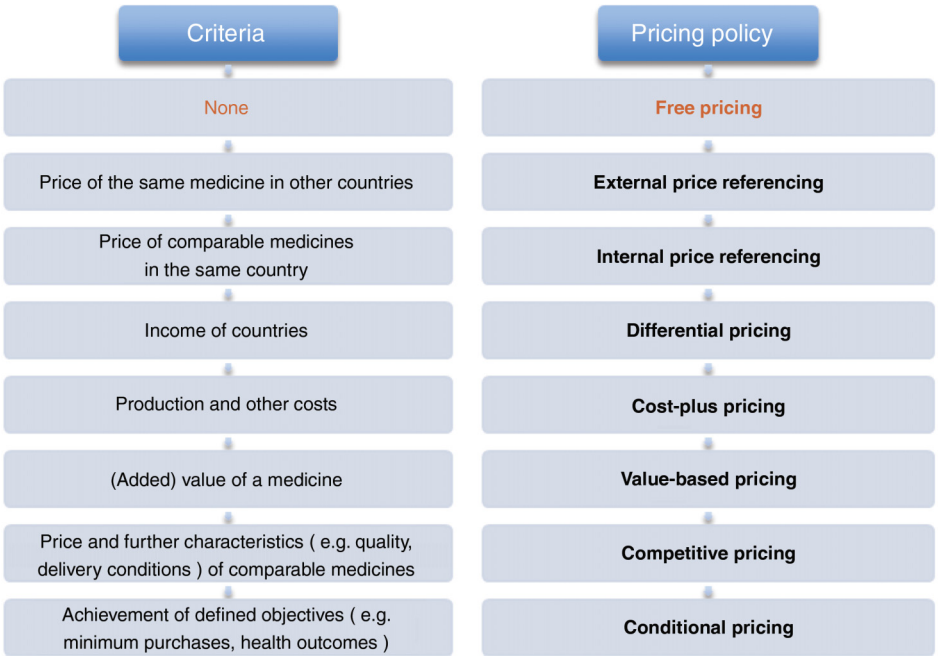

Figure 1 Taxonomy of pharmaceutical pricing policies at launch. Source: The author

Governments may use different criteria to set medicine prices, resulting in different pharmaceutical pricing policies. Criteria include, among others, the prices of the same medicine in other countries or in the same country (policies of external price referencing (EPR) and internal price referencing), production costs (cost-plus pricing) and the (added) therapeutic value of a medicine (value-based pricing). For an overview of key criteria and resulting pricing policies, see Fig. 1.

Each pricing policy has benefits and limitations, and some may be more appropriate for specific medicine groups. The characteristics of major pricing policies at launch will be discussed in the following.

Free Pricing

Free pricing defines a pricing policy in which governments allow pharmaceutical companies to determine the price of the medicine. It could be argued that free pricing is not a pricing policy because it does not relate to any actions taken by a public authority but it is, in fact, government inaction. For completeness, it is, however, described below.

Use

Free pricing is probably the most commonly used pharmaceutical pricing "policy" all over the world. In numerous countries, particularly in LMIC, there is no price regulation in the private sector (Babar, 2015; Cameron et al., 2011). In high-income countries with solidarity-based reimbursement systems (e.g. European countries), medicines that are not reimbursed by a public payer (similarly to the "private sector") tend to be out of scope of government's price control (Vogler and Martikainen, 2015).

Benefits

From a public health perspective, there are no arguments in favor of free pricing since there is evidence that unregulated medicine prices tend to be higher than prices in regulated settings (WHO, 2013). From an industry perspective, there are arguments in favor of free pricing, particularly for nonfunded medicines (private sector, nonreimbursement segment). By leaving medicines to full competition, it was hoped to "help to establish a viable market outside the state sector for some medicines" (European Commission, 2002). It should be remembered, however, that competition is only possible if alternatives exist.

Limitations

Free pricing is linked to the risk of higher prices given the lack of control. Studies have shown that unregulated prices (e.g. in the private sector) were, often considerably, higher than prices achieved through tenders or other pricing policies (Babar, 2015; Babar et al., 2018; Cameron et al., 2009). This is particularly an issue if availability of medicines in the public sector is limited and many essential medicines are only accessible in the private sector against out-of-pocket payments. Unregulated high medicine prices are usually unaffordable for patients and their carers, or they drive them into catastrophic payments (Wagner et al., 2011; Xu et al., 2003). This is why the WHO Guideline on Country Pharmaceutical Pricing Policies recommends that countries "use a

combination of different pharmaceutical pricing policies that should be selected based on the objective, context, and health system" (WHO, 2013).

External Price Referencing

External price referencing, abbreviated EPR and also known under the synonyms of external reference pricing, international price comparison, international price benchmark, and international reference pricing, describes "the practice of using the price(s) of a medicine in one or several countries to derive a benchmark or reference price for the purposes of setting or negotiating the price of the product in a given country" (WHO Collaborating Centre for Pharmaceutical Pricing and Reimbursement Policies, 2016).

Use

EPR is a commonly used pricing policy. In Europe, for instance, EPR has been implemented in 26 of the 28 Member States of the European Union (all but Sweden and the United Kingdom) and in further countries such as Iceland, Norway, Switzerland, and Turkey (Rémuzat et al., 2015; Vogler et al., 2016a). EPR is also applied in some African countries (e.g. Egypt, South Africa), in some countries in the Asia-Pacific region (e.g. Malaysia, Japan, and South Korea), in some Latin American countries (e.g. Brazil, Colombia, and Mexico) and in Canada (Espin et al., 2014; Schneider and Vogler, 2018). EPR is not a pricing policy solely used in high-income countries, but also in LMIC (Espin et al., 2011, 2014). The number of countries that have introduced EPR has increased over time.

EPR is predominantly used for on-patent medicines that are subsidized by the state and applied in the outpatient sector (Espin et al., 2014; Leopold et al., 2012b; Toumi et al., 2014; Vogler et al., 2016a).

Benefits

There is evidence that EPR has been able to lower medicine prices (Filko and Szilagyiova, 2009; Håkonsen et al., 2009; Leopold et al., 2012a; Merkur and Mossialos, 2007; WHO, 2013; Windmeijer et al., 2006). EPR's effectiveness appears to be strongest immediately after its implementation but it tends to "fade out" after some time (Vogler et al., 2016a).

EPR has been described as "a relatively simple and easy-to-apply system" (Espin et al., 2011). While it does require some effort and capacity (see below), it is fair to note that EPR can be implemented with fewer investments compared to other policies such as value-based pricing. Furthermore, it may be assumed that use of EPR in many countries all over the world has likely contributed to its introduction in other countries since policy makers may consider EPR's popularity as a proxy for its effectiveness. In any case, many countries have gained experience with EPR that they can share with other countries.

In general, pharmaceutical pricing policies can be designed in different formats, and this is also and particularly true for EPR. In practice, countries have opted for different methodological designs (Espin et al., 2014; Leopold et al., 2012b). Simulations have shown that changes in the methodology (e.g. consideration of discounted prices, regular price revisions, and different methods to calculate the benchmark prices) can impact medicine prices achieved through this policy (Toumi et al., 2014; Vogler et al., 2016a).

Limitations

Major limitations concern the availability of medicines on the market and price transparency (and, as a result, limited negotiating power of payers).

Delays in market launches of medicines, often of considerable duration, were observed in countries that have lower price levels or smaller market volumes. To avoid lower benchmark prices calculated through the EPR methodology, pharmaceutical companies are incentivized to launch medicines first in countries with higher prices, and delay, or not launch, in lower-priced countries (Danzon and Epstein, 2008; Danzon and Towse, 2003; Danzon et al., 2005; Espin et al., 2011; Kanavos et al., 2010; Kanavos et al., 2017; Kyle, 2007; Rémuzat et al., 2015; Stargardt and Schreyögg, 2006; Toumi et al., 2014; Vogler et al., 2016a).

EPR's capacity to robustly inform policy makers about the price situation in other countries is strongly distorted by the fact that "real" prices are frequently not known. Confidential discounts granted by industry to public payers are common, particularly for high-priced medicines (Morgan et al., 2017; Vogler et al., 2012). By referencing official list prices instead of real discounted prices, payers risk overpaying (Bouvy and Vogler, 2013). This information asymmetry also limits their negotiating power, for instance in a potential follow-up negotiation, since they are not on an even level playing field with the pharmaceutical industry that has the full picture of the prices in all countries where the medicine is marketed. There is no evidence that payers actually have got "the best deal" as suppliers pretended to offer to them (Vogler and Paterson, 2017).

Finally, it should be acknowledged that EPR, though "simpler" than other policies still requires capacity-building to ensure the performance of high-quality EPR. The methodological design should enable the achievement of the intended policy objectives and should contain solutions for challenges (e.g. missing data because medicines are not yet marketed in some countries, exchange rate volatility) (Kanavos et al., 2010; Vogler et al., 2016a).

Internal Price Referencing

Internal price referencing is defined as the practice of using the price(s) of identical medicines (which corresponds to level 5 of the Anatomical Therapeutic Chemical classification system (ATC) of the WHO) or similar products (ATC 4 level) or even therapeutically equivalent treatment (not necessarily a medicine) in a country to derive a benchmark or reference price for the purposes of setting or

negotiating the price or reimbursement of the product in a given country (WHO Collaborating Centre for Pharmaceutical Pricing and Reimbursement Policies, 2016).

A prerequisite for internal price referencing is availability of comparable medicines. Thus, internal price referencing is usually implemented after patent expiry of a substance when generic or biosimilar medicines enter the market.

One variant of internal price referencing is a so-called generic (or biosimilar) price link. This policy refers to the practice of setting the price of a generic (or biosimilar) medicine in relation to the originator medicine, usually at a certain percentage lower than the originator price. Another internal price referencing policy is a so-called reference price system (RPS). In a RPS, identical medicines (ATC 5 level) or similar medicines (ATC 4 level) are clustered in a reference group. A third party payer funds a maximum amount (=reference price), while the patient must pay the difference between the reference price and the actual pharmacy retail price of the medicine, in addition to any co-payments (e.g. prescription fee, percentage co-payment of the medicine price).

Use

Internal price referencing is in place in many countries with solidarity-based pharmaceutical reimbursement systems, in the form of a price link and/or a RPS. In Europe, for instance, 22 of the 28 European Union (EU) Member States have a RPS (all but Austria, Cyprus, Luxembourg, Malta, Sweden, and the UK) (Gombocz and Zimmermann, 2017). A price link, however, between a biosimilar and its reference product is less common. According to a study relating to 2016 data, 30 out of 42 surveyed countries (40 countries of the WHO European region, Canada, and South Africa) reported having a generic price link in place but only 15 of them also applied this link policy to biosimilar medicines (Vogler and Schneider, 2017).

Benefits

The implementation of internal price referencing is rather easy. It is a policy that ensures, by definition, lower prices of alternative medicines. In addition, an RPS encourages patients to ask for lower-priced medicines because they would otherwise be charged higher co-payments for high-priced medicines. For private sector actors (e.g. industry), internal price referencing increases planning security because, in case of a price link, for instance, they know in advance the price that will be set as the extent of requested price difference is stipulated in law.

Limitations

Internal price referencing is a rather static method that does not fully exploit the efficiency potential of lower-priced medicines. It would, therefore, be important to accompany the pricing policy with further measures that target the volume with a view to increasing generic uptake. Lower prices will only be able to reduce the pharmaceutical bill of public payers if lower-priced medicines are utilized. Demand-side measures such as prescribing by International Non-Proprietary Name and generic substitution can support the effectiveness of internal price referencing (Kaplan et al., 2016). An exploratory study of a few medicines in European countries showed that differences between originator and generic prices were higher in countries that had implemented competitive pricing policies in combination with demand-side measures to enhance generic uptake compared to countries with more static methods such as a generic price link (Vogler, 2012).

Differential Pricing

In differential pricing, the relevant criterion for consideration is the income of countries. Differential pricing, also called tiered pricing, is based on the idea of having different prices for different purchasers (in the case of medicines, they are public purchasers representing countries of different income levels).

Sometimes, differential pricing is also referred to as "price discrimination" or "Ramsey pricing". These terms relate to situations in which pharmaceutical companies achieve optimal pricing (from a business perspective) by differentiating markets according to purchaser demand elasticity. Ramsey pricing is thus a commercial strategy used by marketing authorization holders and not a government policy. As government action, differential pricing describes a cross-country policy of setting the price of a medicine in accordance with the ability-to-pay and/or economic situation of different countries involved, based on coordinated decisions taken by national governments or by international organizations. Alternative names for such differential pricing approaches are equity pricing (Rovira, 2013) and minimum-level pricing (Mossialos and Dukes, 2000).

Use

Differential pricing has mainly been used in LMIC. It tends to be limited to a few therapeutic areas (e.g. HIV/AIDS, malaria, and tuberculosis) or specific products (vaccines). Apart from these medicine groups, differential pricing has not been widely used for other essential medicines. Purchasers are frequently international organizations such as United Nations (UN) agencies (e.g. UNICEF, PAHO, and UNFPA) and programs as well as initiatives such as the Global Alliance for Vaccines and Immunization (GAVI) or the International Drug Purchasing Facility UNITAID. In a few cases, particularly related to middle-income countries, national governments have been involved in differential pricing (Babar and Atif, 2014). More recently, differential pricing has been implemented to increase access to medicines for noncommunicable diseases, mainly as part of public–private partnerships to improve access (Access and Affordability Initiative, 2018).

Benefits

This policy has sometimes been effective in ensuring patient access. For instance, there were indications that for some least-developed countries access improved in situations in which medicines would otherwise have been unaffordable (Babar and Atif, 2014; Moon et al., 2011; Yadav, 2010).

Limitations

Differential pricing is not an appropriate policy to lower medicine prices since its major aim is to improve access. Studies showed that generic competition was more effective in reducing prices than differential pricing (Moon et al., 2011; Waning et al., 2009).

Further limitations of this pricing policy relate to its methodology: differential pricing (if it were applied as a collaborative approach of governments) requires from the involved countries an agreement of principles, mechanisms, and rules. Common understanding of the procedure (e.g. the extent of markdowns or markups to reflect different ability-to-pay levels of countries) has to be reached. In addition, the issue of how to set the starting price needs to be settled.

Given high price tags of some medicines in recent years, it has been discussed whether, or not, high-income countries could also use differential pricing. A study (Vogler et al., 2016a) exploring the feasibility of introducing differential pricing as a collaborative policy of EU Member States concluded that, though commonly mentioned limitations (existence of EPR and parallel trade) could be addressed, differential pricing appears to be an unrealistic option in the EU for political reasons since it would require high political commitment from all 28 Member States to agree on principles.

Cost-Plus Pricing

Cost-plus pricing is a policy that determines a medicine price by taking into account production costs, promotional expenses, investments into research and development (R&D), administration costs, overheads, and profits. Prices are based on information on the costs incurred provided by the marketing authorization holder plus a profit margin considered "reasonable".

Use

Use of cost-plus pricing is known from several countries all over the world. It is predominantly applied in LMIC. Cost-plus pricing is used, for instance, in Vietnam, China, Sri Lanka, Bangladesh, Iran, and Pakistan. The number of countries using cost-plus pricing; however, has been decreasing as some countries (e.g. India, Colombia) have discontinued applying this pricing policy (Nguyen et al., 2014; WHO, 2013). In the European region, some countries (e.g. Cyprus—for locally produced generics, France, Greece, Spain, Slovakia, and Turkey) used cost-plus in their pricing decisions two decades ago (Kanavos, 1999; Vogler et al., 2008; Vural, 2015), but as of today (2018) no EU Member State applies cost-plus pricing.

Benefits

While there is a lack of analytic studies on the impacts of this pricing policy, no evidence has been identified to support use of cost-plus pricing (WHO, 2013).

Limitations

The WHO Guideline on Country Pharmaceutical Pricing Policies advices not to use cost-plus as an overall pharmaceutical pricing policy (WHO, 2013). As a major limitation, public authorities depend on the pharmaceutical company's information about their costs. This could incentivize marketing authorization holders to engage in the "manipulation of costing data" (WHO, 2013) and could lead to higher prices. Obtaining independent information is very difficult and practically impossible for many governments.

Value-Based Pricing

Value-based pricing (VBP) describes an approach in which the "value" that a medicine offers determines the price. But a clear and generally agreed definition of the VBP policy is missing (Garner et al., 2018). In a narrow interpretation (in the context of the English National Health Service/NHS), VBP has been defined as "(the price) that ensures that the expected health benefits [of a new technology] exceed the health predicted to be displaced elsewhere in the NHS, due to their additional cost" (Claxton, 2007). Applying a broader approach of understanding, any policy linking the price of a medicine to its added therapeutic benefit could be considered to fall into the VBP category. The assessment of the value of new medicines can account for different dimensions: improvements in length and quality of life, comfort of use, cost savings in other parts of the health system, and gains in labor productivity for patients and carers. It can be focused on the health care system or be applied to a broader societal approach (Paris and Belloni, 2013).

To assess "value", pharmacoeconomic evaluations and health technology assessments (HTAs) are performed. A key pharmacoeconomic method in this respect is the cost-effectiveness analysis (CEA) in which an incremental cost-effectiveness ratio (ICER) is determined. Usually, the quality-adjusted life years (QALY) approach is applied to assess the benefits of a health care intervention (including medicines). In general, an intervention is considered cost-effective if the ICER (e.g. price per QALY) is below a predetermined threshold.

In the European context, HTA is defined as "a multidisciplinary process that summarizes information about the medical, social, economic and ethical issues related to the use of a health technology in a systematic, transparent, unbiased, and robust manner. Its aim is to inform the formulation of safe, effective, health policies that are patient focused and seek to achieve best value" (EUnetHTA, 2018). It has been stressed that HTA is a tool to support pricing and reimbursement policies, but it is not a policy. HTA offers evidence to support prioritization, but it is up to policy makers to appraise the findings from HTA (Patera and Wild, 2014). In contrast to the concise definition of HTA in Europe, a broader understanding of HTA is found in other regions of the world, especially related to LMIC where HTA is understood as "a systematic approach to evaluate the properties, effects, and impacts of health technologies or interventions" (World Health Organization, 2015).

Use

Countries in which pharmacoeconomics play a major role in setting medicine prices are Australia, New Zealand, Canada, Sweden, and the UK. Australia was the first country to require pharmaceutical companies to provide economic data in their application for inclusion of new medicines in the Pharmaceutical Benefits Scheme (PBS); the first set of formal pharmacoeconomic guidelines was published in 1992 (Henry, 1992; Langley, 1993). In 1993, the Pharmaceutical Management Agency (PHARMAC) in New Zealand and the Canadian Agency for Drugs and Technologies in Health (CADTH) published pharmacoeconomic guidelines for their processes (Davis, 1993; Detsky, 1993). Sweden introduced a VBP system (in the narrower sense) in 2002: with pricing and reimbursement processes being completely integrated, eligibility for reimbursement is assessed against three criteria: the human value principle to guard against discrimination of individuals, the need and solidarity principle that gives priority to those in greatest need and the cost-effectiveness principle (Pontén et al., 2017). England has been applying pharmacoeconomic principles for years. It wanted to move to a full-fledged VBP scheme in 2014 (Claxton et al., 2011) but this plan was eventually not implemented (Rafferty, 2014). Still, England continues applying a value-considering approach in pricing and reimbursement (value-based assessments). Many further European countries also consider pharmacoeconomic evaluations and HTA (Paris and Belloni, 2013; WHO Regional Office for Europe, 2015). In some European countries, HTA is applied for all new medicines and in others for medicines with uncertain clinical benefits or expected high budget impacts. At least one HTA institution is in place in many European countries (WHO Regional Office for Europe, 2015).

Benefits

With VBP, the value of new medicines is put into the center. As such, VBP addresses one of the main drawbacks of EPR that has been criticized for not taking into account value considerations.

HTA and pharmacoeconomic evaluations aim to lead to more sound assessments that support policy makers in pricing and reimbursement decisions.

A major element of VBP is the willingness-to-pay (WTP) of public payers. If payers disclose their WTP, this could create an incentive for the development of products that generate increased added value (Bouvy and Vogler, 2013; Godman and Gustafsson, 2013). It has been argued that by signaling their public health priorities (e.g. related to R&D), policy makers and payers could become more active whereas the current pharmaceutical policy framework appeared to be supply-driven (Consultative Expert Working Group on Research and Development, 2016; Franken et al., 2012).

Limitations

Overall, VBP is a resource-intensive pricing policy. To perform HTA and pharmacoeconomic evaluations, extensive capacity-building is required. It has been discussed whether, or not, small countries should establish HTA agencies, or if they could use evidence from other countries and translate it into their settings.

VBP offers opportunities to industry for "gaming", in particular in the choice of the comparators and the threshold (Kanavos et al., 2010). In a VBP system with published cost-effectiveness thresholds, marketing authorization holders are incentivized to price up to the threshold (Hughes, 2011).

In theory, a new medicine with a price above the ICER threshold would not be reimbursed, but in practice policy makers may deviate from the ICER threshold, and have done so in the past, in case of unmet medical need, rarity and severity of the disease treated and public pressure (Paris and Belloni, 2013; Simoens et al., 2013).

This tends to support the position that "a 'value-based' pricing model is not viable in many countries because it does not take into account affordability and total cost" (WHO, 2017b). While the importance of informed decisions based on CEA and HTA has been generally acknowledged, risks of using value-based assessments as the sole basis for pricing have been stressed since this does not take into account need, prevalence and affordability (Garner et al., 2018).

Competitive Pricing (Tendering)

Tendering and tendering-like procedures are mechanisms of competitive pricing which can be applied in settings where competition is possible, with multiple suppliers for same or similar medicines (e.g. therapeutic equivalents). In a tendering procedure, "tenders (offers) are requested, received and evaluated for the procurement of goods, works or services, and as a consequence of which an award is made to the tenderer whose tender/offer is the most advantageous." (WHO Collaborating Centre for Pharmaceutical Pricing and Reimbursement Policies, 2016). In many cases, it is the (lowest) price that makes a bid most advantageous but other criteria, such as supply conditions, payment terms, frequency of delivery, or packaging can also play a role (Vogler et al., 2010).

Use

Tendering is the key procurement method in the public sector in many countries, including many LMIC (Seiter, 2010). In high-income countries, tendering mainly occurs in the hospital sector; it is done by individual hospitals and hospital groups or through pooling of regional hospital procurement at national level by procurement agencies (Vogler et al., 2010). Use of tendering, or tendering-like systems, in the outpatient sector is less frequent. It is in place in the outpatient off-patent sector in some European countries (e.g. Denmark, Germany, the Netherlands, Romania Slovenia) (Dylst et al., 2011; Kanavos, 2012).

Benefits

Tendering is able to achieve lower prices due to competition. The price-reducing effect of competition has been shown, for instance for HIV/AIDS medicines. In Brazil, the price of HIV/AIDS medicines confronted with generic competition was reduced by 82% over 5 years while prices of medicines without generic competitors remained rather stable, falling 9% over the same period of time. In LMIC, generic competition resulted in a decrease of the price of the AIDS triple-therapy from US$10,000 per patient and year to US $350 within 1 year (T'Hoen et al., 2001).

Limitations

The key argument against competitive policies such as tendering is that these practices could contribute to shortages and nonavailability of medicines, as suppliers are driven from the market.

A study (Vogler et al., 2017a) investigated the impacts of tendering for outpatient off-patent medicines in three European countries (Belgium, Denmark, and the Netherlands). While the study confirmed high savings for public payers due to competitive pricing, it did not identify a withdrawal of companies from the market in the three surveyed countries.

Overall, to mitigate the risk of availability limitations, it has been advised to do "strategic procurement" and maintain a naturally balanced competitive situation (Ferrario et al., 2016). In this respect, a "divide-the-pie" strategy may be more appropriate to ensure a "healthy market" even though the "winner-takes-it-all" principle will likely drive prices down to lower levels.

Conditional Pricing

Conditional pricing describes a pricing policy that links the price of a medicine to specific criteria (e.g. health outcomes, minimum purchases). Conditional pricing falls under a variety of terms and taxonomies. "Risk-sharing" and "pay-for-performance" are commonly used terms to describe such pricing and reimbursement policies (Carlson et al., 2010; Garrison et al., 2013). In the European Union, the notion "managed-entry agreement(s)" (MEA) has been established as an umbrella term for these conditional pricing policies (Ferrario and Kanavos, 2013). A MEA is defined as "an arrangement between a [pharmaceutical] manufacturer and payer/provider that enables access to (coverage or reimbursement of) a health technology subject to specific conditions" (Klemp et al., 2011).

Typically, MEA are distinguished into two categories: either financial-based (or nonhealth outcomes-based) schemes or performance-based (or health outcomes-based) schemes. Financial-based MEA include (price or dose dependent) discounts, price or utilization capping or price-volume agreements. Performance-based MEA comprise, among others, variants such as outcome guarantees (i.e. an agreement where the manufacturer provides rebates, refunds, or price adjustments if the product fails to meet the agreed outcome target), coverage with evidence development (i.e. reimbursement where additional data gathered in the context of clinical care would further clarify the impact of the medicine), and patient eligibility linked to patient registries to measure post-marketing clinical outcomes (Ferrario and Kanavos, 2013).

Use

Conditional pricing (application of MEA) is typically used for new medicines with high prices that are not affordable for public payers. Financial-based MEA are more common than performance-based MEA that are more complex in design. Nearly all high-income countries have implemented MEA, and use of conditional pricing and reimbursement arrangements have also been reported from upper–middle income countries and emerging markets (Babar, 2015; Carlson et al., 2010; Ferrario and Kanavos, 2013; Ferrario, 2016; Garrison et al., 2013; Morel et al., 2013; Neumann et al., 2011; Pauwels et al., 2017; WHO Regional Office for Europe, 2015).

In many cases, MEA are add-on arrangements taken after an initial price has been determined based on other pricing methods, usually EPR (cf. Section External Price Referencing). To agree on a price that payers can afford, a lower (reimbursement) price is negotiated, taking the EPR benchmark as a starting point. The arrangements about agreed conditions, including the discounted price, are usually kept confidential. Pharmaceutical industry has an interest to keep officially communicated list prices high as other countries will refer to them in their EPR application (Bouvy and Vogler, 2013).

Benefits

A conditional pricing arrangement is considered to be beneficial for patients as it facilitates access to high-priced medicines that would otherwise be unaffordable. MEA provide earlier accessibility of medicines through the publicly funded health care systems, even if added therapeutic value has not yet been proven while providing fail-safes if the medicine does not deliver. Thus, they allow the public payer to manage some uncertainty (Ferrario and Kanavos, 2013). This is particularly the case for performance-based MEA that, in combination with patient registries, help collect real-life clinical data.

Limitations

A major limitation of MEA is linked to the confidentiality of data. While MEA allow for the agreement of lower prices than those published, the exact difference in these amounts is unknown. Confidentiality, however, weakens the negotiating power of payers since they have no alternative but to trust industry's promise that they "got the best deal" (Vogler and Paterson, 2017). Manufacturers may systematically ask for higher departing prices in expectation of a MEA (Gerkens et al., 2017). It has been argued that by agreeing to MEA public payers implicitly accept high (list) prices (Vogler et al., 2016c).

While confidential discounts have been in place for a long time, formal use of MEA, particularly of performance-based agreements, has been increasingly observed more recently. As a new tool, MEA have been developed through experimenting and learning-by-doing. No standard methodology for MEA has been implemented. Since particularly performance-based MEA are challenging, and data collection and monitoring of the progress can be time-intensive, payers can encounter high administrative and transaction costs (Adamski et al., 2010; Carlson et al., 2010; Gerkens et al., 2017). The implementation of MEA needs to be accompanied by a clear disinvestment strategy when updated data support discontinuation of funding a high-priced medicine under a MEA. Such a disinvestment strategy; however, can be difficult to implement in reality if patient expectations have been created (Vogler et al., 2017b).

Pharmaceutical Pricing Policies in the Supply Chain

As mentioned above in Section Prices, the price will be increased along the supply chain: the add-ons are wholesale and pharmacy markups or other forms of distribution remuneration as well as taxes, duties, and fees.

Distribution Remuneration

Commonly applied distribution remuneration includes add-ons for pharmaceutical wholesale and dispensaries, usually community pharmacies (also for dispensing doctors and hospital pharmacies that dispense to outpatients, for instance). Remuneration of distribution actors may be regulated, or not; if so, regulation can be limited to specific medicines (e.g. prescription-only medicines, publicly subsidized medicines). Regulation of distribution remuneration defines how distributors and dispensaries are rewarded for their services, for example through a markup (i.e. a defined linear or percentage amount is added on to the cost of a good to create a profit), a margin (i.e. the percentage of the selling price that is profit) or a fee, or of a combination of fees, for the services rendered.

The WHO Guideline on Country Pharmaceutical Pricing Policies recommends that "as part of an overall pharmaceutical pricing strategy, countries should consider regulating distribution chain markups (distributors/wholesalers)" as well as "regulating retail chain mark-ups and fees (pharmacies, dispensing doctors, dispensaries)" (WHO, 2013).

To support the development of this WHO Guideline, a review of remuneration for pharmaceutical distributors was produced. The review concluded that regulation of distribution remuneration as part of a comprehensive pricing policy will probably lead to reduced medicine prices (Ball, 2011). The review also pointed to a lack of evidence on distribution remuneration in general, even of descriptive data. Information on the size and extent of distribution remuneration is mainly available for high-income countries. This suggests that regulation of these price components also contributes to improved transparency. Evidence from European countries seems to support this assumption: In some European countries (e.g. Cyprus, Denmark, Finland, the Netherlands, Norway, Sweden, and the UK) wholesale remuneration is not regulated, and medicine prices are set at the wholesale price level. Wholesale margins are negotiated between the manufacturer and the wholesaler, usually on a confidential basis (Vogler and Martikainen, 2015). For these countries, average wholesale margins are usually not known, even not by public authorities, whereas such data have been published for other countries (Vogler et al., 2014).

Many high-income countries (e.g. in Europe) implemented regressive wholesale and pharmacy markup or margin schemes, in which the add-ons for higher-priced medicines gradually decrease (Vogler and Martikainen, 2015). The WHO Guideline on Country Pharmaceutical Pricing Policies recommends regressive markups or margin schemes rather than fixed percentage markups and margins since the latter provide an incentive for higher-priced products to receive a higher net margin (WHO, 2013).

Still, even regressive schemes are linked to the price of a medicine at previous stages. Distribution remuneration can also be designed independently from the price of the medicine: in a fee-for-service system, public payers specify fixed fees for defined services (e.g. dispensing, consultancy, generic substitution, and night service) in a tariff catalog. Such fee-for-service distribution remuneration has been in place in the Netherlands, Switzerland, and the UK for many years, and, more recently, some further European countries combined a fee (e.g. per prescription dispensed) and price-dependent funding elements of markups and margins to remunerate community pharmacies (Vogler et al., 2014).

Taxes

Additionally, indirect taxes can form part of the final prices of medicines. As shown in the presentation of the various price types in the WHO/HAI methodology to measure medicine prices, availability, affordability and price components (cf. Section Concepts and Definitions), sales taxes can be added at any stage in the supply chain (WHO and HAI, 2008).

A WHO/HAI review on sales taxes for medicines (Creese, 2011) noted that LMIC have increasingly used VAT as a common revenue-raising strategy since the early 1990s. The review considered indirect taxes on medicines as inequitable because, with the amount paid on a certain medicine being a percentage of the prices for everyone, the medicine tax will result in a larger share of a

poor person's income than a rich person's. The review also found that taxation on medicines varied between countries, ranging between 2.9% and 34% in LMIC and between 0% and 25% in high-income European countries (Creese, 2011). Furthermore, many European countries apply a VAT rate on medicines that is lower than the standard rate. Some countries (e.g. France, Ireland, Sweden, and the UK) have different VAT rates for different groups of medicines (e.g. reimbursable/prescription-only medicines vs. non-reimbursable/nonprescription medicines) (Vogler and Martikainen, 2015).

The WHO/HAI review discussed the issue of "taxing for the poor" and suggested applying the principle that "unhealthy products and behavior should be taxed while health-promoting actions and goods should be tax-exempt or subsidized" (Creese, 2011). In line with this principle, the WHO/HAI Guideline on Country Pharmaceutical Pricing Policies recommends that countries should consider exempting essential medicines from taxation and should ensure that any reductions or exemptions from taxes on medicines have the effect of reducing costs to the patient/purchaser (WHO, 2013).

Taxes that account for a considerable part of the medicine price constitute a barrier to affordable medicines for patients in settings (e.g. LMIC) where they have to pay fully out-of-pocket (Cameron et al., 2009; Levison and Laing, 2003). This might result in patients refraining from purchasing needed medicines (Creese, 2011). In solidarity-based high-income countries with public coverage of prices of essential medicines, this might be less an issue. Still, interestingly, during the global financial crisis that hit some European countries hard, an increase in VAT rates on medicines was one of the most frequently applied cost-containment measures, probably because this policy can be implemented rather swiftly compared to other policies (Vogler et al., 2016b).

Conclusions

Pharmaceutical pricing policies comprise a variety of measures. When developing pricing policies for medicines, policy makers are recommended to consider some overarching principles.

1. **Mix of policies**
   Some policies are only applicable, or meaningful, for specific price types and certain medicine groups (e.g. if generic equivalents are available, competitive pricing policies can constitute a feasible option, and there is no need for resource-intensive value-based pricing). The choice of pricing policies may also depend on national health priorities and practical issues such as available resources. It is, however, disadvised to focus on one sole price type or a single market segment and disregard the other price components and medicines. Regulation of distribution remuneration without regulation of either the manufacturer or retail prices is unlikely to lower medicine prices (Ball, 2011). In this respect, it should be reminded that pricing is only one area of the pharmaceutical policy toolbox. Thus, in developing the most appropriate "policy mix", other policies (e.g. volume-impacting policies, reimbursement policies) have to be taken into account as well. For instance, any pricing policy that lowers the prices of generics still does not bring economic benefit to patients (in the private sector) or to a public payer (in a reimbursement system) if higher-priced originator medicines continue to be prescribed and dispensed. Further measures might be required to enhance the uptake of lower-priced medicines; possible (nonprice related) interventions could be the improvement of the quality of generics (in case of quality issues) and to build trust and acceptance of generics with patients, doctors and pharmacists (Kaplan et al., 2016).
2. **Enforcement**
   As for any policy, pricing mechanisms are required to be enforced, as also stipulated in the WHO Guideline on Country Pharmaceutical Pricing Policies: "If regulation of pharmaceutical prices is introduced, effective implementation will be required to ensure compliance (e.g. incentives, enforcement, price monitoring system, and fines)" (WHO, 2013). This involves, for instance, building staff capacity of the pricing authorities and, if need be, targeted stakeholders. Resources might also be required to ensure access to price databases for surveying data needed for EPR, to literature and other databases for performing HTA, to establish a unit that validates price data submitted by marketing authorization holders and/or to regularly perform price surveys, for example in accordance with the WHO/HAI methodology (WHO and HAI, 2008).
3. **Evaluations and reviews**
   Similarly, to ensure sustainable effectiveness of pricing (and further) policies, it is important to regularly evaluate whether, or not, the mix of policies is able, and continues to be able, to achieve the intended policy objectives. A policy that yielded expected results in the beginning might "fade" out its effectiveness over time because the circumstances might have changed and stakeholders have learned to "game" the system (Rosian et al., 2001).
   The above-described pricing policies are applied to set the prices of medicines at their market entry. Pricing, however, is not a one-point-in-time intervention but has to be understood as continuous government action, as part of an effective enforcement strategy. Thus, regular price reviews are advised, with the possibility of subsequent price changes if need be. Sufficient resources and capacity should be made available in advance. It is recommended stipulating details of price reviews (e.g. frequency, scope such as 50 top-selling medicines and methodology) in pricing regulation.
4. **Transparency**
   Last but not least, price transparency should be a major principle. Distortions due to confidential price negotiations and secret discounted prices and their impacts have been discussed (cf. Sections External Price Referencing and Conditional Pricing). It is not solely an issue of EPR and MEA but there is need for transparency in any pricing policy and for all price types (e.g. lack of transparency due to the unknown rebates and claw-back systems between supply chain actors). Transparency is not only required with regard to the outcomes (i.e. medicine prices), but also related to processes: thus procedures of how decisions on prices are taken, and upon which criteria, must be clear. Policy makers should aim to attain the highest possible level of transparency.

The chapter has shown that each pricing policy can be designed in different formats. The methodology that is considered as most appropriate for achieving intended policy objectives should be chosen, and, if needed, adapted after evaluation, for each of the policies.

List of Abbreviations

AIDS	Acquired Immune Deficiency Syndrome
ATC	Anatomical Therapeutic Chemical (classification system)
CADTH	Canadian Agency for Drugs and Technologies in Health
CEA	Cost-effectiveness analysis
CIF	Cost, Insurance, Freight
EPR	External price referencing
EU	European Union
GAVI	Global Alliance for Vaccines and Immunization
GST	General sales tax
HIV	Human Immunodeficiency Virus
HTA	Health Technology Assessment
ICER	Incremental Cost-Effectiveness Ratio
LMIC	Low and Middle-Income Countries
MEA	Managed Entry Agreement(s)
MSP	Manufacturer's selling price
MWPP	Manufacturer (price), wholesale (price), pharmacy (retail price net) and pharmacy (retail price gross); alternatively: manufacturer, wholesaler, pharmacy and patient
NHS	National Health Service
OECD	Organisation for Economic Co-operation and Development
PAHO	Pan-American Health Association
PBS	Pharmaceutical Benefits Scheme
PHARMAC	Pharmaceutical Management Agency
QALY	Quality-adjusted life year(s)
R&D	Research and development
RPS	Reference price system
UHC	Universal Health Coverage
UN	United Nations
UNFPA	United Nations Population Fund
UNICEF	United Nations International Children's Emergency Fund
USD	United States Dollar
VAT	Value-added tax
VBP	Value-based pricing
WHO	World Health Organization
WTP	Willingness-to-pay

Glossary

Term and possible synonyms	*Definition*
Price	The value component of expenditure. It may relate to different market segments (e.g. outpatient or inpatient markets, on-patent or off-patent markets, prescription-only medicines or nonprescription medicines) and may be defined for different price types.
Price type	The level (i.e. stage in the supply chain) at which the price of a medicine is set.
Ex-factory price (synonyms: manufacturer price, ex-manufacturer price, manufacturer's selling price)	The price at the level of industry, charged by a pharmaceutical manufacturer.
Wholesale price (synonyms: pharmacy purchase price, pharmacy purchasing price, wholesale selling price)	The price charged by wholesalers to the retailers (usually community pharmacies); it is based on the ex-factory price and additionally includes any remuneration for pharmaceutical wholesale (e.g. in the form of a wholesale mark-up or a wholesale margin).
Pharmacy retail price (synonyms: consumer price, public price)	The price charged by community pharmacies to the general public; it is based on the pharmacy purchasing price and additionally includes any pharmacy remuneration (such as a pharmacy mark-up, a pharmacy margin or dispensing fee). It can be gross (including value-added tax and further sales taxes) or net (excluding taxes).

Reimbursement price	The maximum amount of a medicine price that is covered by a third party payer.
Policies (synonyms: policy options, policy measures)	Instruments, tools and approaches that allow policy makers to achieve defined objectives. Policies are government actions (in contrast to strategies of private sector actors).
Pricing policies	Regulations and processes used by government authorities to set the price of a medicine as part of exercising price control.
Pricing (synonyms: price control, price setting, and price regulation)	Government actions to set, monitor, review and adapt the price of medicines.
Free pricing	Pricing policy where pharmaceutical companies determine the price of the medicine they launch.
External price referencing (synonyms: international price comparison, external reference pricing)	The practice of using the price(s) of a medicine in one or several countries to derive a benchmark or reference price for the purposes of setting or negotiating the price of the product in a given country.
Internal price referencing	The practice of using the price(s) of identical medicines (ATC 5 level) or similar products (ATC 4 level) or even with therapeutic equivalent treatment in a country to derive a benchmark or reference price for the purposes of setting or negotiating the price or reimbursement of the product in a given country.
Anatomical, therapeutic, and chemical classification	A classification system of medicines where the active ingredients are divided into different groups according to the organ or system on which they act and their chemical, pharmacological and therapeutic properties. Medicines are classified on 5 specified levels (ATC 1, ATC 2, ATC 3, ATC 4, and ATC 5) of which the first level divides medicines into 14 main groups. ATC 2 specifies the therapeutic subgroups (e.g. medicines used in diabetes). ATC 3 and 4 indicate the pharmacological and chemical subgroup, respectively (e.g. oral blood glucose lowering medicines and biguanides, respectively) and ATC 5 is the chemical active substance (e.g. metformine). The 2nd, 3rd and 4th levels are often used to identify pharmacological subgroups when that is considered more appropriate than therapeutic or chemical subgroups.
Differential pricing	Cross-country approach of setting the price of medicine in accordance with the ability-to-pay, and/or the economic situation of the involved countries. The pricing decision would be taken in a collaborative approach by the governments of the involved countries or an international organization. There is a difference to "price discrimination" ("market discrimination", "Ramsey pricing") that describes a business strategy of economic actors to segment the market according to the observed demand-elasticity of consumers.
Cost-plus pricing	Pricing policy that determines a medicine price by taking into account production costs, promotional expenses, research and development, administration costs, overheads, and profit.
Value-based pricing	Through this policy authorities set the prices of a new medicine and/or decide on reimbursement based on the therapeutic value that a medicine offers, usually assessed through health technology assessment (HTA) or economic evaluation. In a full-fledged VBP policy, the pricing and reimbursement systems are integrated, and the price and reimbursement decision is taken jointly based on a value assessment.
Health Technology Assessment	A multidisciplinary process that summarizes information about the medical, social, economic, and ethical issues related to the use of a health technology in a systematic, transparent, unbiased, and robust manner. Its aim is to inform the formulation of safe, effective, health policies that are patient focused and seek to achieve best value.
Tendering	Any formal and competitive procurement procedure through which tenders (offers) are requested, received and evaluated for the procurement of goods, works or services, and as a consequence of which an award is made to the tenderer whose tender/offer is the most advantageous.
Conditional pricing	Pricing policy that links the price of a medicine to specific criteria (e.g. health outcomes, minimum purchases). Conditional pricing falls under a variety of terms and taxonomies (e.g. managed-entry agreements, risk-sharing, pay-for-performance).
Managed-entry agreement	An arrangement between a manufacturer and payer/provider that enables access to (coverage/reimbursement of) a health technology subject to specified conditions. These arrangements can use a variety of mechanisms and are usually classified into financial-based and performance-based MEA.
Distribution remuneration	Reward for distribution actors (e.g. wholesalers, community) to pay them for their services. Distribution remuneration can take the form of linear or regressive markups (add-ons) and margins that constitute part of the final pharmacy retail price, and of fee(s) for service not linked to the price.
Markup	A defined (linear or percentage) amount is added on to the cost of a good to create a profit. The wholesale markup is the gross profit of wholesalers, expressed as a fixed or percentage add-on to the ex-factory price. The pharmacy markup is the gross profit of pharmacies expressed as a fixed or percentage add-on to the wholesale price.
Margin	The percentage of the selling price that is profit. The wholesale margin is the gross profit of wholesalers, expressed as a percentage of the wholesale price. The pharmacy margin is the gross profit of pharmacies expressed as a percentage of the pharmacy retail price.
Fee-for-service	Payment to a provider (a pharmacy, for instance) for each act or service rendered.

Development of the Theoretical Concept of Pharmaceuticalization

Kath Ryan, University of Reading, United Kingdom

Introduction

The aim in this chapter is to provide a roughly chronological overview of the development of the behavioral sciences concept of pharmaceuticalization, its evolving and expanding definitions, parameters, insights, and potential future directions while at the same time offering the reader a way into the research and literature encompassed by this line of enquiry.

For over 40 years, annual global sales of prescription medicines have increased dramatically to USD1.35 trillion in 2017, making the multinational pharmaceutical industry a powerful global economic force (IQVIA Institute for Human Data Science, 2018). Pharmaceuticals are an important element in the therapeutic toolbox for improving health and relieving human (and animal) suffering; however, their use must not go without critique.

In spite of a decline in the development of new medicines and therapies, consumption of pharmaceuticals continues to grow (Abraham, 2010; Busfield, 2015). Ageing populations with complex health needs in developed countries and growing populations in developing countries might account for some of the growth but that is not the whole story. So, why are people taking more medicines than they were two or three decades ago?

Scholars and researchers from sociology, anthropology, and related disciplines have been studying pharmaceuticals and the pharmaceutical industry since the mid-1980s (Abraham and Sheppard, 1999; Braithwaite, 1984; Gabe and Bury, 1988; Gabe and Bury, 1996; Medawar and Hardon, 2004; Whyte et al., 2002), and this work eventually developed into the field of study known today as pharmaceuticalization.

Pharmaceuticalization is an explanatory, anthropological/sociological concept advanced in recent years to capture and direct our developing understanding of the place of pharmaceuticals in society and individual lives. It is a dynamic and evolving theoretical concept with fields of enquiry and definitions that are, necessarily, changing and expanding in depth and breadth. Early debate (see Conrad, 2007, for example) revolved around whether it was even a necessary concept or just a component of the concept of medicalization that originated in the 1970s. Medicalization is *defining a problem in medical terms, usually as an illness or disorder, or using a medical intervention to treat it* (Conrad, 2007, pg 3). More recent scholars (Abraham, 2010; Bell and Figert, 2012; de Camargo, 2013; Gabe et al., 2015), however, have argued that it is possible to *have pharmaceuticalisation without any significant degree of medicalization* (Gabe et al., 2015, pg 193) and that pharmaceuticals are now used beyond the realm of clinical medicine and medical authority for lifestyle and enhancement purposes. Abraham stated that there is

> *a need for the concept of 'pharmaceuticalization' because the empirical phenomena to which it refers cannot be adequately captured or explained by recent revision to medicalization theory* (Abraham, 2010, pg 605).

The Pharmaceutical Person

The term "the pharmaceutical person" was first used in a 1967 film entitled *Drugs in Our Culture* and then again by Emily Martin in 2006 to investigate contemporary US culture in relation to the consumption of medicines from the individual micro level where they might be taken to maintain order or even enhance capacity ("a pill for every ill" (Busfield, 2010)) to the societal macro level where potent *precision-engineered molecules* are produced for corporate profit (Martin, 2006, pg 280).

Martin's article was inspired by a 2003 exhibition entitled *Cradle to Grave* at the British Museum (http://www.urban75.org/blog/thousands-of-pills-cradle-to-grave-by-pharmacopoeia-at-the-british-museum/) in which Susie Freeman (a textile artist), David Crtichley (a video artist), and Liz Lee (a GP), exhibiting under the name of Pharmacopoeia, displayed a work knitting together

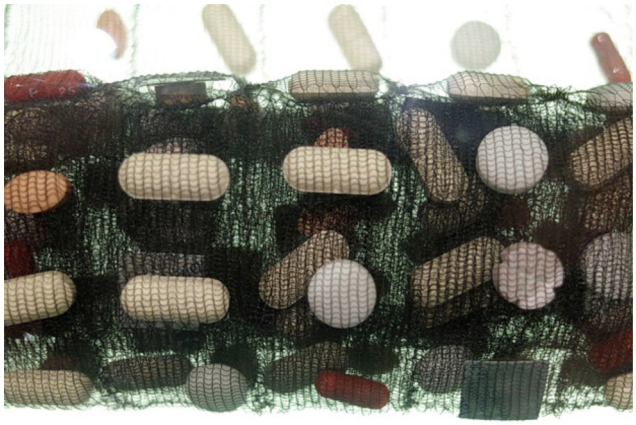

Figure 1 Thousands of pills: Cradle to grave by Pharmacopoeia at the British Museum.

all of the prescribed medicines consumed by a man and a woman in Britain over their lifetimes. Astoundingly, the artists calculated that each person would consume over 14,000 prescribed pills, tablets, and capsules and, if over-the-counter medicines were included, it would be 40,000 (Martin, 2006) (**Fig. 1**).

Martin argued that one way people become pharmaceuticalized (although she did not use that specific term) is when medicines are personified, that is, when individuals use them to produce a new identity, to make them *a better person, an enhanced person or, more precisely, more like the person they really are without the interference* of a particular health condition (Martin, 2006, pg 276). People, she wrote, are now expected to be responsible for reducing their suffering, optimizing their capabilities and maintaining control of their environment. One way they can do this is with the help of doctors, by finding the right combination of medicines to enable that they function in a manner acceptable to society (Rose, 2003).

In addition, Martin argued that companies market medicines in a manner that invests them with personality traits to enhance our connection to them in an attempt to make us better people (*If this drug was a person, what kind of a person would it be?* pg 275). She also suggested that medicines move from being poisons to remedies when their dangers or side effects are minimalized, such as in the use of very fine print or rapid speech of advertisements and the flimsy paper of patient information leaflets. She claimed that the side effects of medicines are *displaced* by being *hidden in plain sight* (pg 283), which enables us to ignore their dangers and make them part of our daily lives (Martin, 2006).

The Pharmaceuticalization of Daily Life

Medicines as part of everyday life, as a concept, was further elaborated upon by Fox and Ward (2008) who picked up on the development and use of "lifestyle" drugs (*profitable medicines for a range of daily activities* pg 856), for, arguably, nonhealth-related complaints such as impotence (e.g., Viagra), hair loss (e.g., Regaine), weight loss (e.g. Xenical), and various other conditions including sleep disturbances, heartburn, and high cholesterol, for example (Fox and Ward, 2008). Pharmaceuticalization of daily life, they suggested, occurs when drugs interact with social and cultural lifestyle factors to normalize daily activities. It involves the domestication of pharmaceutical consumption beyond medical or health professional supervision. Direct to consumer advertising (in the United States and New Zealand) and other marketing activities such as pharmaceutical company detailing and support for patients' groups, access to medicines via the Internet, the ability of pharmaceutical companies to construct knowledge, and the willingness of health systems to fund "lifestyle" drugs are all factors that have driven pharmaceuticalization.

> *Pharmaceuticalisation of daily life is a complex mix of factors that involves the biological effect of a chemical on a human tissue, the legitimacy of a condition as a disease, the willingness of consumers to adopt the technology as a 'solution' to a problem in their lives, and the corporate interests of drug companies* (Fox and Ward, 2008, pg 865).

The Pharmaceuticalization of Society

Moving forward, then, to the end of that decade and John Abraham (2010) wrote about the "pharmaceuticalization of society," a step change metamorphosis from emphasis on the personal to the societal expose of medicines (Abraham, 2010). Drawing on the work of others (Busfield, 2006; Conrad, 2007; Fox and Ward, 2008; Marshall, 2009; Williams et al., 2009) on aspects of disease states and specific medicines, Abraham argued for a theoretical understanding of the concept of pharmaceuticalization, focusing particularly on the prescription drug sector. He defined pharmaceuticalization as

> *the process by which social, behavioural or bodily conditions are treated, or deemed to be in need of treatment, with medical drugs by doctors or patients* (Abraham, 2010, pg 604).

Abraham (2010) proposed five heavily interrelated *biosociological explanatory factors: biomedicalism, medicalization, pharmaceutical industry promotion and marketing, consumerism, and regulatory state ideology or policy* (pg 603). Biomedicalism (the belief that the expansion in drug treatment reflects advances in biomedical science), he stated, partially explains the growth in the use of pharmaceuticals as a consequence of progress in medical science, including research and development within the pharmaceutical industry, increased health needs, and improved diagnostic tools. The relationship between biomedicalism and pharmaceuticalization, however, is not always straightforward because of other interests and drivers. Medicalization [the *process by which nonmedical problems become defined and treated as medical problems* (Conrad, 1992, pg 209, cited by Abraham pg 604)], Abraham argued, is also a big part of the explanation for pharmaceuticalization. Industry activities, such as promotion and advertising of medicines, health professional "expert" endorsement of medicines and the creation of "new" diseases also drive the increased use of pharmaceuticals. Abraham called this the '*medicalization-pharmaceuticalization complex*' (pg 608) and pointed out that until 2010 most sociological debate had revolved around the use of medicines for lifestyle conditions and various social disorders. Consumerism—the transformation of patients into consumers of medicines and their related activities, both adversarial (e.g., citizen and class action related to harm from medicines) and collaborative (e.g., activism around access to medicines, e.g., HIV/AIDS treatments (Epstein, 1996))—explains both growth and (potential) decline in pharmaceuticalization. The final factor to shape pharmaceuticalization, (decreased) state regulation and policy related to medicines as a result of consumer and industry collaboration and lobbying, has made some medicines more quickly available, in spite of doubts about their overall benefits and cost-effectiveness (Abraham, 2010).

Abraham's overall thesis is that pharmaceuticalization has been driven more by medicalization and the activities of the pharmaceutical industry, in collaboration (co-constructed) with consumerism, to expand markets than by improvements in medical science. His summarized his position as follows:

> *. . . pharmaceuticalization in the form of new drugs offering significant therapeutic advance has been* shrinking *in the last 15 years. Expansion in pharmaceuticalization cannot be explained by growth in techno-scientific discoveries of therapeutically significant innovations that meet health needs because no such growth has been forthcoming* (Abraham, 2010, pg 615).

Further to Abraham's realist approach (focus on "real life," facts and scientific methods in the development of knowledge) to the pharmaceuticalization of society, Williams et al expanded the definition of pharmaceuticalization, to cover both the medical and the nonmedical use of drugs, as the

> *translation or transformation of human conditions, capabilities and capacities into opportunities for pharmaceutical intervention* (Williams et al., 2011b, pg 711).

They proposed a framework for analysis of empirical and theoretical work to

> *look at the way that pharmaceutical products are used* outside *the medical domain and explore the broader way in which pharmaceutical* futures *are shaping how we think about innovation, policy and the very meaning of health and illness, therapy and enhancement* (Williams et al., 2011a, pg 730).

Williams et al were the first to coin the phrase *pharmaceutical regime* to capture the complex, evolving, and dynamic nature of the *socio-technical process* of pharmaceuticalization (Williams et al., 2011b, pg 711). They argued for the need to cover all aspects of the process of development, production and consumption of pharmaceuticals, including the networks of people and organizations and their intellectual endeavors, and recent developments in active social resistance to the process from individuals and collectives.

They suggested six areas in which future research might profitably explain why pharmaceuticalization, as a theoretical standpoint, is becoming more and more important:

- *Selling sickness? The redefinition and reconstruction of health problems as having a pharmaceutical solution*
- *Changing forms of governance: globalization and the new role of regulatory agencies in promoting innovation*
- *Mediation: the (re)framing of health problems in the media and popular culture as having a pharmaceutical solution*
- *Patients, consumers, and the life world: the creation of new social identities and the mobilization of patient and consumer groups around drugs*
- *From treatment to enhancement? The use of drugs for nonmedical purposes and the creation on new consumer markets*
- *Pharmaceutical futures in the making: drug innovation and the colonization of health futures* (Williams et al., 2011b, pgs 712–721).

Anthropologists, Bell and Figert, entered the debate around the intersection between medicalization and pharmaceuticalization, seeing them as distinct processes and arguing for a reconceptualization to include *modern and postmodern theories in empirical studies throughout the globe . . .* to address *significant gaps . . . in social science understandings of pharmaceuticalization* (Bell and Figert, 2012, pg 781). In particular, they focused on public health and inequalities in *pharmaceutically mediated health-care delivery* (pg 781) between developed and developing nations. Williams et al responded with a call to develop *a framework that can more fully explain the global complexities and contingencies* of pharmaceuticalization (Williams et al., 2012, pg 2130). They highlighted a number of areas of investigation that are adding to our understanding including resistance to the use of pharmaceuticals by individuals and groups (adversarial consumerism, see the depharmaceuticalization subsection below); the relationship between the medical profession and the pharmaceutical industry; the use of medicines for nonmedical (enhancement) purposes; the economic and innovation challenges facing the pharmaceutical industry; and more equitable global access to medicines and development of drugs for neglected diseases (e.g., pharmaceutical philanthropy as in the work of the Bill and Melinda Gates Foundation).

A one-day symposium entitled *Pharmaceuticals in Society*, at the University of Warwick, UK, in December 2011, enabled leading pharmaceuticalization scholars from a variety of disciplines to *consider the empirical and theoretical questions arising from recent trends in the development, regulation, marketing and use of pharmaceutical products* (Gabe et al., 2015, pg 193), critique previous, and current work and set an agenda for future collaborations. This symposium sparked a series of papers and lively debate culminating in a special edition of the journal *Social Science and Medicine* in 2015.

The special edition contained an eclectic mix of individual studies on specific topics (e.g., drugs, conditions, processes),

> *taking account of both upstream level processes concerning the development, testing and regulation of pharmaceuticals and downstream level processes concerning the meaning and use of pharmaceuticals in medical practice and in everyday life . . . to explore in a sustained way the broad processes of pharmaceuticalization and its consequences for individuals and society* (Gabe et al., 2015, pgs 193-194).

The articles in the special issue (Social Science and Medicine Special Issue Section, 2015) moved pharmaceuticalization theory forward considerably. It is beyond the scope of this chapter to discuss the individual studies (although readers are strongly encouraged to look at them), but the editors provided an overview under five themes (Gabe et al., 2015):

- *Markets for medicines*, for example, over treatment and overuse of medicines (Busfield, 2015) and local and global inequalities in access to medicines (Pollock and Jones, 2015)
- *Regulatory agencies and the state*, for example, globalization and governance on developed world/pharmaceutical industry terms (Sariola et al., 2015), governments as drivers of pharmaceutical innovation, especially in countering bioterrorism and pandemics (Elbe et al., 2015)
- *Patients, consumers, lifestyles*, for example, meanings of medicines in people's lives and identity formation (Dew et al., 2015), consumers as holders of information, consumers as champions and resistors of medicines (Britten et al., 2015)
- *From treatment to enhancement—the use of drugs for nonmedical purposes*, for example, illicit "markets" for prescription medicines (Vrecko, 2015) and the quest for new "diseases" amongst healthy people
- *Pharmaceutical futures in the making*, for example, expectations of pharmaceutical research and development (Brown et al., 2015; Fisher et al., 2015)

This body of work was helpful in enabling us to consider the sociological analyses of the factors contributing to pharmaceuticalization at the societal and individual level, but it hardly dealt with how and why people become pharmaceuticalized or, more recently, possibly depharmaceuticalized.

Living Pharmaceutical Lives

At about the same time that Abraham, Williams, and others were writing about the pharmaceuticalization of society, Ballantyne et al., sticking to the personal, were writing about becoming old as a "pharmaceutical person" in an ethnoculturally diverse community in Toronto, Canada (Ballantyne, 2011). Contrary to the popular perception of the elderly as passive recipients of health care, these researchers showed that older people are active agents who are ambivalent about medicine use, make *thoughtful, reasoned* decisions including nonadherence, and are self-monitoring and responsible for their own health. They suggested that, *the older-person-as-patient needs to be re-conceptualised as a "pharmaceutical person"* (*Ballantyne, 2011, pg 182*).

In a similar vein, research on how medicines are used in the home provided insights into how people see themselves, their personal identities and responsibilities, and their relationships with others including family members and health professionals, all mediated through medicines (Chamberlain et al., 2011; Dew et al., 2014; Hodgetts et al., 2011). The perspective of this team was that:

> *Attitudes change according to why pharmaceuticals are taken and who is taking them, their impacts on social relationships, and different views on the social and natural production of disease, the power of the pharmaceutical industry, and the role of health experts. Pharmaceuticals are tied to our identity, what we want to show of ourselves, and what sort of world we see ourselves living in* (Dew et al., 2015, pg 272).

Dew et al. (2015) concluded that the way people behave around the consumption of medicines could be thought of as a form *pharmaceuticalized governance* (pg 273), with varying responsibilities and moral implications, whether self-imposed or as directed by others.

More recently, Ballantyne et al. (2018) attempted to understand *the formation of the young and middle-aging "pharmaceutical person"* in New Zealand. Investigating medicine use in a prospective, longitudinal birth cohort of children born in 1972/3, they showed that while the proportion of people using medicines did not change from age 26 to 38, the actual quantity of medicines consumed by medicines-users did increase. This led them to speculate about incremental normalization of the use of medicines to mediate life and pose questions about the gradual progression toward polypharmacy in later life. Interpretation of the findings through a pharmaceuticalization lens, they suggested, shows that forces other than therapeutic need and effectiveness are driving increased use of medicines with inherent overtreatment, and even harm, while at the same time blinding users to other means of maintaining health (Ballantyne et al., 2018).

Pharmaceuticalization as a Theorising Concept

Scholars (Ballantyne et al., 2018; Williams et al., 2011b) have argued that one strength of pharmaceuticalization as an *analytical framework for empirical and theoretical research* (Williams et al., 2011b, pg 722) is its value-neutral stance, in contrast to value-laden terms like "disease mongering" (Moynihan, 2002; Moynihan and Mintzes, 2010), which is pejorative, or biomedicalism, which is presumed to be positive and laudable, for example. In actuality, though, these different perspectives simply offer different interpretations of why the consumption of medicines is increasing and the factors that are driving that increase.

Another strength of the pharmaceuticalization thesis is its ability to encompass micro, meso, and macro (downstream, midstream, upstream) level analyses of the places of pharmaceuticals in society (Ballantyne, 2016; Gabe et al., 2015). It enables the development of understandings around which pharmaceuticals are developed, how they are brought to market and promoted, regulated, accessed and consumed and most importantly, why these things happen as they do. It enables investigation of the various actors in a variety of complex networks including asking whose interests are being served. Ultimately, it enables us to explain what is happening, question the status quo, and potentially change what is *disconnected from or even contrary to the well-being of populations* (de Camargo, 2013, pg 845).

Gabe et al. (2015) have pointed out, however, that *the concept does have some limitations* and that *pharmaceuticals are but one part of the contemporary therapeutic landscape* (pg 197). Pharmaceuticals sit alongside and sometimes compete with alternative therapies, traditional healing practices, self-help lifestyle changes, and outright social reform that could relieve human suffering and improve quality of life. Focusing only on pharmaceuticalization dominates scholarship to the detriment of developing understanding in other areas of health and medicine.

Finally, it is worth mentioning Williams et al.'s 2011 plea that scholars not try to *provide some sort of grand theoretical synthesis* but remain open to the multilevel, multidimensional complexities of pharmaceuticalization and maintain *theoretical eclecticism* (Williams et al., 2011b, pg 722). This was more or less reiterated by Gabe et al's 2015 construction of the

> *pharmaceutical regime . . . based on three central features: the close association of medicine with science, the dominance of a science-based pharmaceutical industry with strong links to basic research and the medical profession, and a central role played by government agencies in regulating the process of drug development, production and sale . . . that can be analysed along cognitive, organisation and technological dimensions* (Gabe et al., 2015, pg 197).

Depharmaceuticalization

Depharmaceuticalization can be broadly defined as a decreased use of pharmaceuticals to deal with the problems of living. It might occur at the individual or societal level as a result of resistance to the growth in the use of medicines.

Few if any areas of life once pharmaceuticalized become depharmaceuticalized (Williams et al., 2011a, pg 730), wrote Williams et al. in 2011 but they had already acknowledged that pockets of resistance to pharmaceuticalization, from *the media, government, medicine, patients, and diverse publics*, show that depharmaceuticalization in part might be possible (Williams et al., 2011b, pg 722). They also acknowledged the unevenness in the pharmaceuticalization process that has seen growth and decline over time. Although depharmaceuticalization is rare, it is worth recording here a few possible examples.

Resistance to medicine taking by individuals, framed in biomedical terms as nonadherence, can be thought of in terms of purposeful depharmaceuticalization on an individual level. This includes attempts to minimize intake and cessation of use for various reasons, such as undesirable side effects, social stigma, fears of dependence, and denial of diagnosis (e.g., with antipsychotics and antidepressants) or a general wish to be medicine free (e.g., with many long-term conditions such as asthma and hypertension). These individual depharmaceuticalization decisions are often as a result of complex personal cost/benefit analyses involving experiential knowledge, personal priorities, and social situations (Britten et al., 2010; Pound et al., 2005).

Deprescribing, *the process of tapering, stopping, discontinuing, or withdrawing drugs* (usually in elderly patients), *with the goal of managing polypharmacy and improving outcomes* (Thompson and Farrell, 2013, pg 201), can be thought of as depharmaceuticalization on a professional level.

To balance the power between pharmaceutical industry-sponsored patient support groups, that are able to influence access to medicines and research agendas in line with their own interests (*propharmaceuticalization access-oriented groups*), and the contrasting adversarial consumer activist groups seeking compensation or redress for injury (*depharmaceuticalization injury-oriented groups*), Britten et al. (2015) suggested that the involvement of patients in medicines licensing decisions might address *democratic accountability and citizen-participation in regulatory decision-making* (Britten et al., 2015, pg 295). In a case study, these researchers showed that patients could contribute their own experiential knowledge and critical focus on benefits and risks to the discussion about whether or not to license a medicine. This is a new area for end-user involvement that might add to (de)pharmaceuticalization processes and debates.

Pharmaceuticalized Futures

How pharmaceuticals are used in the future can largely be determined by their use in the past alongside cognizance of current and developing scientific, medical, political, and social trends, so it seems obvious that the technological revolution will play an

important part. Social media, technology-mediated adherence (digital apps and inserted devices to monitor physiological parameters, for example), artificial intelligence, pharmacoprinting (3D manufacture of medicines), (de)regulation, and deprescribing are a few of the influential factors. Pharmacogenetics or personalized medicine is likely to become increasingly important, especially in relation to rare diseases.

One of the main areas to be addressed by scholars and policymakers, however, is the inequality of access to essential medicines and how this might be addressed in the future. As Bell and Figert (2012) noted, pharmaceuticalization *maps onto global patterns of wealth and poverty, and of power and inequality* (Bell and Figert, 2012, pg 779). Will careful theoretical analyses of how this happens provide solutions that aim to alleviate human suffering worldwide not just in wealthy parts of high-income countries?

Another area for attention is the research focus of the pharmaceutical industry and the development of important, as opposed to profitable, medicines to tackle 21st century global problems (Fisher et al., 2015), such as pain, diabetes and communicable diseases including those capable of setting off pandemics, and bioterrorism, for example (Elbe et al., 2015). Governments are playing an increasingly important role in *influencing the development, regulation, sale and consumption of pharmaceuticals designated as "medical countermeasures" to these biological threats* (Gabe et al., 2015, pg 195). Who will set the agenda for the development of new medicines in the future?

Finally, pharmaceuticalization, as a concept, offers a means of understanding people's perspectives on the varied relevance of medicines in their lives. Members of the public will play a more prominent and crucial role in the cessation of the use of ineffective treatments and the development of safer, more efficacious, targeted medicines some of which will be accessed via nonclinical routes. Will social media become a means of reinforcing *existing power relations* (Williams et al., 2011b, pg 716) and further pharmaceuticalization of lives or a channel for increased resistance and public activism or, more likely, both?

> *It is vital . . . to develop a framework that can more fully explain the global complexities and contingencies [by] paying attention to resistance and ambivalence, the ongoing role of the medical-pharmaceutical nexus, the innovation 'crisis' in the industry and the contribution of research in both the global north and south* (Williams et al., 2012, pg 2130).

Conclusion

Pharmaceuticalization is a way of viewing life, health, and our response to illness through medicines. Pharmaceuticals are important in modern therapeutics and human enhancement but their discovery, regulation, production, and use must not go unquestioned. Pharmaceuticalization provides a useful theoretical and analytic framework for the critique of our pharmaceutical futures and how we will choose to live pharmaceuticalized lives.

Technology and Pharmacy: Theory, Practice, and the Future Vision

Darrin Baines*, **Zaheer-Ud-Din Babar**†, *Bournemouth University, Bournemouth, United Kingdom; †University of Huddersfield, Queensgate, Huddersfield, United Kingdom

The purpose of this chapter is to examine the importance of technology to pharmacy practice. We do not discuss this relationship using the everyday, reductionist interpretation of "technology" being manufactured objects (such as laptop computers) or technological processes (such as algorithms). Instead, we emphasize its "performative" nature by focusing on the ways in which human performance can be enhanced technologically. To fully understand this issue, we explore how different philosophies of pharmacy practice (for instance, dispensing and pharmaceutical care) discuss, analyze, and treat technology as an issue. From our exploration, we suggest that the existing philosophies fail to fully represent technology and its wide ranging implications for professional activities. In response, we suggest that there is a need for a supporting conceptual framework to help fill the gaps, which we introduce in summary. We also present a cyclical model of planning, action, and fact-finding based upon the principles of action research that may be used to examine pharmacy-related technologies throughout their lifecycle. Finally, we conclude that pharmacy practice is inseparable from technology and now is the time for the profession to rethink its technological worldview.

To meet the primary aim of this chapter, we perform the following tasks in the sections below. First, we provide an introduction to health technology using the World Health Organization (WHO) definition and discuss its implications for pharmacy. Next, we explain how technology may be viewed as "performative" and introduce the concepts of "intrinsic" and "extrinsic" technologies. In third section, we provide a brief history of the use of technology in pharmacy practice. The fourth section introduces the concepts of General Purpose Technologies (GPTs) and Technology-enabled Pharmacy (TEP). Next, we outline the conceptual framework suggested by Baines and Hale (2005) and discuss the importance of its institutional perspective. The sixth section presents a cyclical model of the technological lifecycle based upon the principles of action research. Finally, we conclude that technology is, and will always be, a vital part of pharmacy practice and it is important that further research and development is performed on this topic.

Introduction

The WHO defines "health technology" as the "application of organized knowledge and skills in the form of devices, medicines, vaccines, procedures, and systems developed to solve a health problem and improve quality of lives." This definition is written from a "performative" perspective because the holders of technical knowledge don't just report what they know as education or narratives, but they must be productive and do it efficiently by maximizing input/output ratios (Lyotard, 1986). Therefore, technologies should be viewed as part of dynamic production processes involving both humans and machines, changing in time, evolving within societal institutions, redefining professional roles, shifting technical and economic boundaries. In other words, health technologies are designed to enhance human performance at improving human health and well-being.

The World Health Assembly (WHA) is the decision-making body of the World Health Organization (WHO). In 2007, the WHA recognized that health technologies are indispensable tools for effective and efficient prevention, diagnosis, treatment, and rehabilitation, as well as the attainment of internationally agreed health-related development goals (WHO, 2007). In its report, the WHA specifies that health technologies are both a technical and an economic challenge to health systems worldwide. The WHA adds that investments in health technologies (particularly medical devices) are inappropriate if they: (1) do not meet

high-priority needs, (2) are incompatible with existing infrastructures, (3) are irrationally or incorrectly used, or (4) do not function efficiently. Used wisely, health technologies have their costs and their benefits. Used inappropriately, they are a potentially damaging waste of resources.

The WHA statement suggests that technologies may be viewed from both a technical and an economic point of view (Freeman, 1994). From the former, the successful adoption of new technologies is an engineering problem, which considers the best means of implementing new technical procedures to deliver specified outcomes. In short, what works best to solve specific problems. From the latter, technology adoption is a question of resource use and redistribution. For instance, do the benefits of novel technologies outweigh their costs? This question is addressed by health economists working within the field of Health Technology Assessment (Dawoud and Baines, 2017). Often, economic evaluation studies find that new technologies that are technically feasible are not economically viable. Therefore, all new technologies funded from cash-limited health-care budgets should not only be effective but should be proven to be cost-effective. In other words, they should also be performative. However, recent evidence on the effectiveness and cost-effectiveness of health technologies used in a pharmacy setting has been relatively poor (Baines et al., 2018b).

Pharmacy Practice and Technology

All pharmacy practice relies on some form of technology or another. Both old and new technologies contribute significantly to the technical operation of pharmacy systems. For instance, computerized ordering systems are often employed to maintain medicines inventories (Awaya et al., 2005). Similarly, pharmaceutical care services frequently use software that records patient details and interventions provided (Rossing et al., 2019). As these examples suggest, most pharmacy practice is "technology-enabled" in the sense that the capabilities and the performance of pharmacy practitioners is enhanced by its use. Sometimes, the technologies utilized are mature and long established (they are "vintage"). Other times, they are novel and previously untried (they are "novel"). In this respect, pharmacy is no different to other professions, industries or retail sectors that rely on old and new technologies to supply goods and services for an identifiable gain.

Given that pharmacy is similar to many other economic sectors in its experience of using technology, should pharmacy technology be a separate topic? We suggest that the answer to this question should be "yes" because three fundamental features combine to make the profession a special case. First, the practice of pharmacy is a "craft" (i.e., performed with human hands). Next, the business of pharmacy is a "trade" (i.e., profits are made from providing goods and services). Finally, the practice and the business of pharmacy are based upon identifiable and replicable "routines" (i.e., fixed working patterns and procedures) not employed elsewhere in health systems (Pavitt, 2002).

Combining these features, we can make three foundational statements about pharmacy and technology. First, pharmacy has a "boundary" in the sense that some technical activities are performed by the profession and others are not. Activities that do not involve pharmacists are usually considered to be outside of current pharmacy practice. For instance, pharmaceuticals supplied by dispensing doctors. Next, the practice of pharmacy is "technology-enabled" in the sense that the routines employed for dispensing, pharmaceutical care, counter sales and other professional activities all involve technology. There are very few working practices that do not involve technology somewhere in their procedures or processes. For instance, face-to-face pharmaceutical consultations are usually supported by Information and Communications Technologies (ICTs) that book appointments, record patient details, claim reimbursement, update medical records, order and cancel drugs (Jawla and Rai, 2018). Finally, the routines that define pharmacy as a separate profession must, to be successful, generate resources and reimbursement from health systems commissioners and payers or patients and members of the public. As an example, pharmacists worldwide could support medication switches to newly emerging smart inhaler technologies (Mohammadi, 2018). As yet, there are no examples of health systems or patients paying pharmacists for this type of input. As this example suggests, technological advance not only depends upon invention and innovation but also on appropriate and timely resourcing for the pharmacy profession.

Exploration of the Foundational Statements, Technology, and Pharmacy Practice

An exploration of the foundational statements outlined above may help illuminate the nature of the relationship between technology and pharmacy practice in three ways. First, changes in technology (such as the adoption of novel technologies and the retirement of vintage technologies) will shift the boundaries of pharmacy practice. For instance, advances in robotics could eventually remove, or radically diminish, pharmacist involvement in the dispensing process (Barrett et al., 2012). Consequently, the boundaries of pharmacy practice may shift inwards like they did when industrial drug manufacturing killed compounding as a professional routine (Baines, 2014). Next, changes in technology will also alter what pharmacists do as a profession. For instance, the Internet of Things (IoT) could revolutionize medicines adherence, creating demand for a new specialism, "medicines adherence pharmacy"(Alex et al., 2016). As a result, new methods, technologies, and procedures could combine to create new working routines within pharmacy's shifting boundaries (Strickland-Hodge et al., 2018). Finally, what is technically feasible may not be affordable. As an example, smaller pharmacies serving deprived areas may be unable to afford large-scale robotic dispensaries. Therefore, pharmacy is likely to evolve in a "second best" technological world where funding arrangements and routines mismatch new technical opportunities and the shifting boundary of the profession. Given this situation, a concern with pharmacy technology should, therefore, be a concern with finding the optimal funding and organizational arrangements for

pharmacy practice. However, policies related to pharmacy profession and practice often lag behind the opportunities available to the profession (Kay and Baines, 2017).

What is Technology?

The term "technology" is commonly used to refer to manufactured objects (such as mobile phones) or technological procedures (such as Artificial Intelligence) used by human beings either for their own personal ends or for the production of goods and services for sale (Feenberg, 1991; Vyas et al., 2018). However, this definition reduces the meaning of the concept to the objects and the procedures themselves, while excluding the wider dynamic surrounding their application. For instance, a novel phone app designed to remind patients to take their medicines may be described as a new technology (Car et al., 2017). In practice, the successful use of this innovation by patients may require pharmacist input into associated working processes (such as setting up, regular communications, reviewing, safety checking, and the like). In its truest sense, technology is not just manufactured objects and technological procedures, but also incorporates human inputs and clearly defined operational processes.

An exploration of the etymology of the term "technology" is helpful in clarifying how the word should be applied in a pharmacy context. Technology derives from the Greek word "techne," which means "art, skill, cunning of hand," but also has the implication of "craftpersonship, craft or art." This definition implies that technology is employed by practitioners who develop niche skills in applying specific working practices (Puech, 2016). For instance, pharmacists are experts in the processes surrounding the use of pharmaceutical objects and procedures. Over time, the acquisition and application of practical competencies and technical knowledge creates identifiable groups of practitioners who organize into "crafts" (i.e., occupations or trades requiring skill with the hands). For instance, the widespread consumption of pharmaceuticals by millions of patients worldwide is handled by the profession (craft) of pharmacy, with its specially educated and trained workforce of medicines technologists commonly referred to as "pharmacists." Using this line of reasoning, it is clearly the case that the practice of pharmacy is a craft-based skill, and the profession is defined by the technologies it employs.

As the history of pharmacy demonstrates, technology is not just manufactured objects or technological procedures, but encompasses the dynamics of human performance within identifiable working processes. Following this logic, Baines et al. (2018a) defines "technology' as the "dynamic clustering of techniques, methods, skills, and processes used in the production of goods or services or in the achievement of outcomes that deliver desired benefits for consumers." This dynamic clustering suggests that the relationship between human behavior and technology is "performative," which implies that the human use of technologies evolves over time and is not fixed, *a priori*, but is ceaselessly shaped in social performances that are not routine or matter of fact. Applying this logic, pharmacists may be seen as working within an evolving dynamic of operational methods that shapes the nature of their professional performance. If technological practices alter, the performance of pharmacy practice changes. As our third fundamental feature suggests, the practice and the business of pharmacy are based upon identifiable and replicable "routines" that will evolve as technology changes. For this reason, understanding the nature of technology is a vital prerequisite to generating insights into the possibilities and opportunities that technological advances can offer the profession.

To help understand how technology could create new possibilities and opportunities for pharmacy practice, the following two concepts are useful:

1. "Intrinsic technologies" are innovations that improve current production processes, without changing the range of outputs produced.
2. "Extrinsic technologies" are innovations that expand the range of outputs that are producible, but do not necessarily improve the efficiency of existing or new production processes.

Throughout their history, pharmacists have adopted both intrinsic and extrinsic technologies. As an example of the former, barcode technologies are designed to improve the productivity of dispensing, which improves performance without changing what most pharmacies do. In relation to the latter, recent technological advances could make medical screening possible in a pharmacy setting, thus expanding the range of services available to patients (Lowres et al., 2015). As these examples suggest, technological advances can enable pharmacists to do what they currently do better, as well as creating new production opportunities for the profession. In the hands of pharmacists, new technologies can be performative, both enhancing efficiencies and shifting professional boundaries.

Technology in the History of Pharmacy

Throughout their recent history, pharmacists have undertaken three key roles: compounders, dispensers, and (in the last two decades) providers of pharmaceutical care services. Within the emergence of the modern pharmaceutical industry, pharmacists lost their role as the compounders and the preparers of medicines. In the post-war era, dispensing became the main activity for the majority of pharmacists, with "counter-sales" being a supplementary task in community pharmacy (Baines, 2014). With the

publication of Hepler and Strand (1990), pharmaceutical care became a new vision for professional practice, which shifted the emphasis of pharmacy practice away from dispensing toward the provision of patient services.

During their early history, the evolutionary predecessors of modern-day pharmacists (apothecaries, then chemists and druggists) were "technologists" in the sense of "being experts in a particular field of technology." From the medieval era onwards, apothecaries were specialists in using transformative techniques for turning herbal and other ingredients into potions, poisons and medicaments (Anderson, 2018). This expertise was based upon the technique of "compounding," which involves combining or processing appropriate ingredients using specific tools or processes to meet the personal needs of patients or customers (Anderson, 2005). Through this method of combining, the earliest makers of medicines were able to produce a wide range of diverse products. Vela Aulesa (2015, p. 132) discusses their working practices:

> What linked the diversity of their products that, in many cases, the apothecaries themselves made in their workshops? The answer is that they all shared the same production techniques: decoction, infusion, distillation, sublimation, maceration, pulverization, dissolution and conservation in sugar or honey. The apparent diversity of uses concealed great technical uniformity: most compounds were obtained from formulae that involved similar techniques to obtain products made in exactly the same way but varied in their uses.

The quote suggests that apothecaries were directly involved in the manufacturing process, shaping the products with their own hands. Also, the class of practitioners referred to as apothecaries were definable as a group because they shared the same production techniques (Hunting, 1998). Finally, a diversity of products was achieved using highly uniform technical processes or techniques, which we refer to as "routines."

During the 19th century, chemists and druggists in countries such as the United Kingdom, America, and Germany were at the forefront in experimenting with innovations in the emerging field of modern chemistry (Marland, 1987). Their work not only created new medicines but also led to major developments in manufacturing processes outside pharmacy (such as new methods in the production of dyes). In other words, chemists and druggists developed intrinsic as well as extrinsic technologies. These practitioners also responded with fervour to the opportunities offered by the introduction of mass-produced glass (Silverman, 1953). For instance, they filled their shops with mirrors, glass-fronted cabinets, bottles, and carboys, as well as investing in expensive plate-glass windows to attract customers inside (Chemist and Druggist, 1915).

During this time, chemists often had a workshop at the rear of their retail premises, but would also compound or mix preparations in front of customers. In the medicines marketplace, more successful producers would sell their concoctions to other retailers and an industry of branded medicines flourished until the introduction of institutional controls on the sales of such goods. This trade was enabled by the development of railway networks connecting important commercial centers. To further serve their trade, chemists and druggists led the way in innovating new means of formulating final products, including inventing machines for making tablets, creating capsules, and packaging powders. During the early-20th century, they were among the first retailers to experiment with moving shop displays that used electric motors to create moving parts to attract the attention of passers-by.

As the involvement of the profession in chemistry diminished, during the 20th century pharmacists positioned themselves at the forefront of the revolution in mass-produced medicines by stocking their shops with a rapidly growing range of branded drugs. Accompanying this revolution was a rejection of glass as the defining feature of the pharmacy premises. Instead, technological advances in paper and plastics led to boxes and blister-packs becoming the key methods of medicines storage and display. Pharmacists evolved by responding rapidly to the opportunities offered by new waves of pharmaceutical and retail technologies. Today, this process can be seen again with the increasing adoption of robotic and barcodes dispensing, as well as digital Dossett boxes and pill dispensers (Furmedge et al., 2018).

Throughout history, the dual focus on technological advancement and successful retailing has been a defining feature of the pharmacy profession (Scott and Walker, 2018). The rapid introduction of a new wave of digital technologies in coming years will again make apparent the importance of the technology–retailer relationship in pharmacy practice. Innovations such as robotic dispensing, adherence monitoring devices, the Internet of things, and the like will revolutionize dispensing and pharmaceutical care (Baines et al., 2018b). Emerging technologies will create novel opportunities for the profession, which may be a catalyst for a renaissance in pharmacy practice and a redefinition of the primary purpose of community pharmacy premises.

Renaissance of Community Pharmacies Based Upon Emerging Health Technologies

As pharmaceutical care focuses on the development of professional knowledge and skills for individual pharmacists, since 2000 pharmacy premises have largely been ignored as an area of professional concern. In response, Baines (2015a) proposes a renaissance of community pharmacies based upon emerging health technologies. He argues that community pharmacies should become the health-care technology hubs of the future. To make his vision of Technology Enabled Pharmacy a reality, Baines suggests five steps:

1. Refit the "front of house" as a technology hub that allows patients to connect with the pharmacy, local doctors, the health-care system, pharmaceutical companies, charities, other patients and the like;
2. Exploit the time that patients wait for their prescriptions by connecting them to a technology-enabled task, such as reporting on their medicines use, watching an interactive educational program, completing a questionnaire, or being expert patients in research studies;

3. Network the pharmacy hub into the wider health-care community, including providers, patient groups, and private companies (by doing so become the port of first call for patients), and coordinate their care through the pharmacy's technology-enabled network;
4. Retrain pharmacists in health-care technology not just medicines optimization;
5. Educate and enable the public to become technology-enabled pharmacy users.

These steps are important because they suggest that (1) pharmacies could become the focus of technology enablement not just pharmacists, (2) extrinsic technologies may be important to the future development of the profession, and (3) dispensing may become a poorly reimbursed task completed solely to attract footfall so that other technology-enabled services may be provided. As these developments suggest, the opportunities and threats created by the digital age may encourage the pharmacy profession to evolve yet again.

GPTs and TEP

With the ongoing advance of digital, it is vital that pharmacists fully understand the nature of innovative technologies and their potential impact on the profession (Karampatakis et al., 2018). Following the lead of economists and other social analysts, pharmacists could classify technologies into two basic classes. On the one hand, "general purpose technologies" (GPTs) are those that affect an entire economy and have the potential to disrupt the economic life of whole societies (Helpman, 1998). Lipsey et al. (2005) report that there have only been 24 GPTs in history, including the steam engine, trains, electricity, computing, the Internet, artificial intelligent, and block chain. In contrast, "enabling technologies" are innovations that are directly designed to improve the capabilities or the performance of specific users not society as a whole. For instance, telehealth technologies are designed to enable long-distance communications between health practitioners and patients. Such advances can revolutionize care provision, particularly in rural areas, but will not have spill over effects elsewhere.

Normally, GPTs will eventually affect all industries in an economy. For instance, it is hard to imagine any industrial sector not using electricity or information technology (IT), which are considered to be the two most important GPTs (Jovanovic and Rousseau, 2005). In a pharmacy context, this implies that professional working practices will eventually be affected by all new GPTs (for instance, block chain). As major innovations sweep through the economy, the question is not whether novel technologies should be adopted, but when and how diffusion will occur? (Rogers, 2010). In response to emerging GPTs, there is an argument for profession-wide action because the widespread adoption of whole economy technologies may achieve better outcomes if all production units are involved. For instance, most pharmacy bodies support the use of the Internet as a means of individual pharmacies or chains communicating with patients. For example, via social media (Benetoli et al., 2015). The regular use of such technologies ensures that the profession does not lag behind technical developments commonly adopted in other industries. In sum, GPTs can be seen as a special case, especially due to their rare occurrence and disruptive effects.

The Concept of "Technology-Enabled Pharmacy"

Baines (2015a) coined the term "technology-enabled pharmacy" (TEP) to describe the use of intrinsic and extrinsic technologies within a pharmacy setting. The concept of TEP is based upon the notion that technology can improve the capabilities of pharmacists to deliver patient services. As a concept, it is based upon "extension theory," which Lawson (2010) reports conceives of technical objects as "some kind of extension of the human organism by way of replicating, amplifying, or supplementing bodily or mental faculties or capabilities." For instance, enabling technologies could enhance the physical and the mental capacities of working pharmacists, which could increase their incomes and benefit patients. Linking this implication to the notion of intrinsic and extrinsic technologies, TEP has the power to innovate current production processes and to expand the range of outputs pharmacists currently produce.

The above discussion suggests that the impact of GPTs and TEP may be either evolutionary or revolutionary. This may be illustrated using Fig. 1, which shows the relationship between production outputs and costs. Within economics, the operational dynamics that transform the physical inputs of capital, labor, and consumables (i.e., the costs of production) into planned outputs are called "production functions." Production functions for dispensing and pharmaceutical care are outlined by Baines et al. (2018a). Production processes consume inputs in the forms of: (1) labor from pharmacists, technicians, and auxiliary staff; (2) capital investment in premises and production technologies such as automated dispensing; and (3) consumables in the forms of the items used during supply (such as medicines packaging) and pharmaceutical care consultations (such as computing support).

In Fig. 1, the vertical axis shows the outputs derived from pharmacy practice activities such as dispensing and pharmaceutical care. On the horizontal axis, the costs of production are shown. As the model assumes diminishing returns, the relationship between costs and outputs is shown by the curved lines that represent various production functions (PFs). Each PF represents a different package of technology and maps a different relationship between costs and outputs. As the Fig. 1 shows, PF2 is an incremental improvement over PF1. For instance, a new software package for stock control may yield only marginal improvements in dispensing efficiency. In contrast, PF3 is a "technology shock" and represents a major improvement in the outputs that can be produced with existing resources. For instance, pharmaceutical care technologies (such as "smart pill" systems) may greatly enhance productivity. In

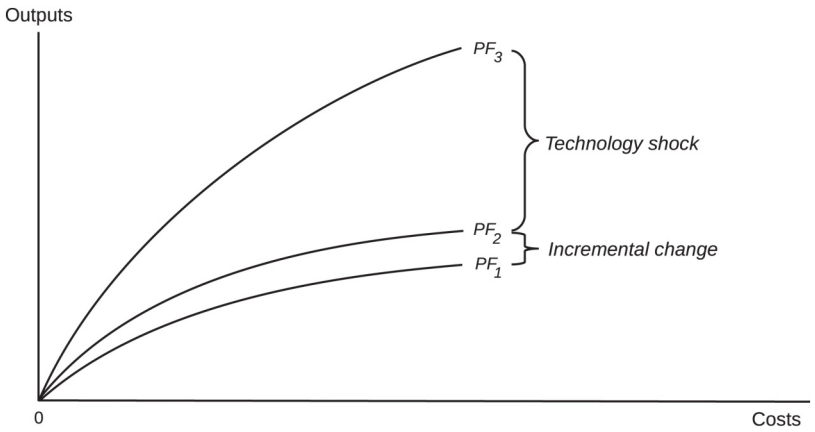

Figure 1 Technology shock verses incremental change.

sum, improvements in productivity are often variable. To secure improvements in performance, pharmacists should pursue small gains that accumulate slowly over time, as well as sudden technology shocks.

Conceptual Framework: Relationship Between Technology and Pharmacy Practice

How the relationship between technology and pharmacy practice is analyzed will often depend upon the conceptual framework adopted. Conceptual frameworks allow researchers to organize ideas about empirical topics. For instance, how should we categorize what we currently know about the monitoring technologies useable in a pharmacy setting? There are several prominent philosophies for analyzing pharmacy practice, notably those for dispensing and pharmaceutical care. Despite their widespread employment, both have limitations in the current context. For instance, the practice philosophy for dispensing focuses primarily on drug supply, while pharmaceutical care was developed in 2000 before the emergence of many new technologies such as the Internet, mobile devices, block chain, and many others. Therefore, pharmacy needs a robust conceptual framework that can truly organize the profession's thinking and knowledge about the ways that technology can and will affect its working practices.

Baines and Hale (2005) outlines a conceptual framework for analyzing how environment, institutions, organizations, and philosophy all influence the ways that pharmacy services are provided. At its core, the framework is based upon a paradigm of thinking developed within economics referred to as "new institutionalism." This approach claims that "history matters" in the sense that current economic opportunities are shaped by the evolutionary paths that economic entities follow. Borrowing a quote from Greif (1998, p.82), the institutional approach suggests that today's pharmacy practice is a product of an "historical process in which past institutional, economic, political, social, and cultural features interact in shaping the nature of contemporary institutions and their evolution." For instance, pharmacists in the United Kingdom became dispensers of medicines (rather than general practitioners) due to a series of unintended events and historical accidents. Because history matters, today's professional arrangements are not based solely upon logical design (Baines, 2015b).

The model in **Fig. 2** represents the conceptual framework suggested by Baines and Hale (2005). Starting at the bottom of the pyramid, environmental factors (such as public funding for pharmacy services and general economic conditions) are the first influence on pharmacy practice. For instance, if governments support technologies that enable pharmacists working in nursing homes, then new roles may be created for the profession. Next, the diagram suggests that pharmacy is governed by a range of "institutions," including laws, regulations, rules, conventions, ethics, and norms governing behavior (Baines and Hale, 2005). Institutions like these limit the innovations deemed suitable for professional use. For instance, the Food & Drug Administration (FDA) regulates the use of novel health technologies, including medicines (Molteni, 2017). Its rules are the

Figure 2 Hierarchy of influences on pharmacy practice.

main institution governing the adoption of digital technologies by pharmacists and other health-care professionals in the United States.

Institutions are important because, as Douglas North (1991) states, they are "the humanly devised constraints that shape human interaction" or, put differently, "the rules of the game in a society." In other words, they are social limits imposed upon technology-enabled individuals. Above institutions in the hierarchy are organizations, which North (1991) defines as "groups of individuals bound by some common purpose to achieve objectives." In order to realize their aims, organizations of individuals must become players of the institutional games governing their activities. For instance, independent and multiple pharmacies may be seen as separate groups of players organized to work for the objective of generating revenue by dispensing drugs within the institutions governing medicines supply. Like most games, technology may be employed to enable players to compete more effectively. For instance, pharmacies could offer coordinated home deliveries using app technologies, which will help them generate more revenue by reaching customers over wider areas than other local pharmacy shops. As rules can be broken, professional and other bodies often police the behavior of players in institutional games. For instance, data protection legislation in many countries imposes penalties on pharmacists who break the rules governing the use of confidential patient information (Gostin et al., 2018).

Although most companies strive to be competitive, they also place limits upon themselves by adopting philosophies that guide their tactics for survival. For instance, most companies now have environmental policies that stop them pursuing profits at any cost. During the 20th century, many pharmacists in the United Kingdom adopted the philosophy of education, professionalism, and fraternity originated by the founder of the Pharmaceutical Society, Jacob Bell. As a result, pharmacy was viewed as a profession not just a trade, which motivated how many pharmacists played the pharmacy game (Holloway, 1991). As time passed, Jacob Bell's practice model evolved, but became less important after the philosophy of pharmaceutical care was launched by Hepler and Strand in 2000. With this change in dominant philosophy came a shift away from dispensing toward patient services as the major concern of pharmacy practice philosophers. In Scotland, this shift led to the emergence of government policy promoting robotic dispensing as a means of freeing community pharmacist time to work with patients (van der Meer et al., 2015). As this example suggests, philosophy of practice is one among a number of key influences that affects pharmacy and its use of technology.

Finally, in the hierarchy, is the practice of pharmacy. This is not the philosophy of practice, but the actions and behaviors of pharmacy practitioners. Because pharmacy is a craft, pharmacists learn by doing, as well as through education and training. In other words, pharmacy practice is a form of "action research." The founder of the approach, Kurt Lewin, describes action research as "comparative research on the conditions and effects of various forms of social action and research leading to social action." In his original paper, he wrote that the method of inquiry follows a "spiral of steps, each of which is composed of a circle of planning, action and fact-finding about the result of the action" (Lewin, 1946). Torbert and William (1981) adds:

> Knowledge is always gained through action and for action. From this starting point, to question the validity of social knowledge is to question, not how to develop a reflective science about action, but how to develop genuinely well-informed action – how to conduct an action science.

As this quote suggests, understanding gained directly from experience may equal or surpass the importance of knowledge learnt from academic education and training. For instance, what practitioners learn from implementing telehealth technologies may be more important than knowledge they can read or be taught (Hebert et al., 2006). In response to this insight, pharmacy practitioners should be guided by a circle of planning, action and fact-finding that illuminates the process of technology adoption, use and decommissioning in their working practices.

Pharmacy Action Research Cycle

As the process of adopting, using, and rejecting specific technologies is dynamic, the pharmacy profession requires a cyclical approach to technological planning, action, and fact-finding. Fig. 3 meets this need by presenting an action research cycle for pharmacy, which embodies the following seven tasks:

1. Scope—The process of technology adoption (or modification) begins with the task of looking for technological advances that could improve or expand production opportunities.
2. Formulate—Next, identified possibilities are expressed as operational blueprints or formulae that include details of how novel technologies may be incorporated into existing (and possibly new) production processes.
3. Experiment—The third task is to test new technological processes under experimental conditions as a means of exploring their performance and safety before widespread dissemination.
4. Reify—Innovations that prove to be promising in controlled experiments may be developed into an actual, concrete procedures useable in practice. These technological processes should have definite forms and functions and be part of identifiable production processes.
5. Implement—Next, reified technological processes are introduced into existing, or innovated, production processes. The ways in which existing production processes are performed may be temporarily modified until new technologies are fully embedded.

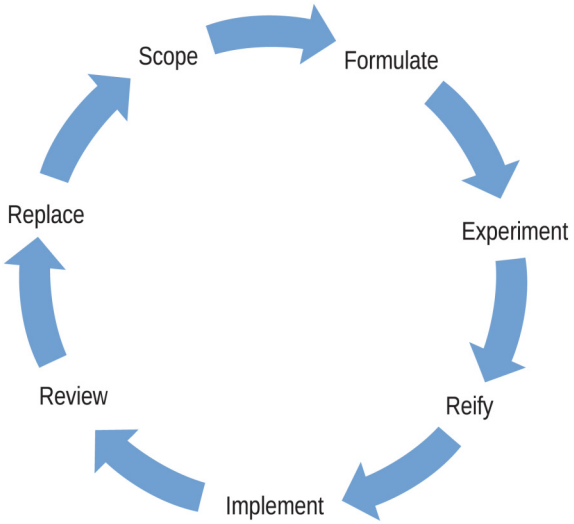

Figure 3 Pharmacy action research cycle.

6. Review—Introduced technologies should be critically evaluated at key stages in their implementation and use. At the beginning, the green light may be given for widespread adoption. At maturity, evidence may suggest that an incumbent technology should be retired.
7. Replace—Finally, technologies that may be replaced with more efficient or superior procedures should be removed from production. However, the need for large-scale capital investment may delay the replacement of some suboptimal technologies.

Together, the above tasks suggest the following: (1) technologies are performative processes that experience complex lifecycles, (2) one-off evaluations like HTA will not capture their true nature, and (3) the use of novel and vintage technologies can be optimized using an action research approach to supporting practitioner learning, evaluation, and choice.

Conclusions

Throughout their history, pharmacists have always been technologists. Their work has led to the development of an untold number of innovations that have benefited the trade of pharmacy and the lives of patients. As well as being inventors, pharmacists have adopted innumerable GPT and TEP technologies developed elsewhere for both general and pharmacy use. With the evolution of the digital age, a new wave of innovations is emerging at a time when the profession is looking for new roles and health systems are seeking to better manage costs. In response, we presented a performative perspective on pharmacy practice and highlighted the importance of taking an institutional approach to analyzing the development of pharmacy-related technologies. After discussing the pertinent issues, we suggested that pharmacists should take an action research approach to understanding the lifecycle of the technologies harnessed by the profession. In sum, we conclude that pharmacy practice is inseparable from technology and now is the time for the profession to rethink its technological worldview.

Public and Patient Engagement

Louise Worswick, NHS England, London, United Kingdom

Introduction

This chapter describes public and patient engagement and involvement in health and social care and summarizes its progress over the last couple of decades. Definitions of terms that are commonly used to describe public and patient engagement are provided and explanations of the processes for engagement and involvement across various areas of health and social care are described. This chapter focuses on public and patient engagement and involvement in the area of healthcare and acknowledges that there is a large body of work around engagement and involvement in social care. Some reference is made to public involvement in social care, usually referred to as service user involvement. Public and patient engagement and involvement are found in healthcare planning, delivery, evaluation, commissioning, teaching and research, as well as in the wider social context. The achievements and milestones for public and patient engagement and involvement are highlighted and the implications for pharmacy practice and research are discussed. Engagement and involvement of the public and patients in health and social care are part of routine practice across the health and social care landscape and this includes pharmacy practice and research.

The Origin of Public Involvement

Early accounts of the origins of public involvement in healthcare describe the development of a social movement (Morrow et al., 2012; Barnes and Cotterell, 2012; Greenhalgh et al., 2011). Williamson (2010) describes the simultaneous occurrences of: shifting social values, some poor quality healthcare, and a movement in critical sociological research as the start of the patient movement some fifty years ago.

From the health service management perspective it was the introduction of clinical governance in the 1990s in the United Kingdom that placed patient and public involvement (PPI) as a core element of quality in healthcare. Clinical governance offered a strategic framework that ensured systems and processes were in place to support high quality care. Clinical governance was structured in seven pillars including clinical audit, risk management, clinical effectiveness, and PPI (Scally and Donaldson, 1998). Healthcare organizations developed strategies for delivering PPI and healthcare staff were encouraged to involve patients in planning, delivering, and evaluating healthcare (Department of Health, 1999, 2002). The commitment to involving patients and the public across the health sector to effect change was needed because "change will only happen if services are shaped by the people who rely on them" (Glynn et al., 2008, p. 7).

The increase in promoting public involvement sits alongside the drive for professional accountability. Health and social care providers, academic institutions, and research funders have routinely involved public members in service delivery, planning and evaluation, and in policy development and priority setting for well over a decade (Nilsen et al., 2006; Smith et al., 2006; Oliver et al., 2004; Crawford et al., 2002; Boote et al., 2002). Social attitudes have changed and there is not just acceptance but expectation for public involvement in health services.

Parallel activities have taken place in social care and in higher education institutions in the planning and delivery of education and research and in research funding organizations and charities.

The concept of consumerism in health and general welfare was probably the consequence of a political shift with policy makers showing more interest in consumer choice (Beresford and Wallcraft, 1997). As public services developed their consumerist approach, it became usual practice to engage people in the development of services as well as in the delivery and evaluation of these services. This occurred in social care and healthcare delivery but also in education and research organizations and there is now a large body of work demonstrating the growth and potential impact of public involvement in the work programs of health, education, and research organizations. The Evidence Bibliography produced by INVOLVE, an on-line library, contains all the reports and articles about the nature and extent, the impact and reflections on public involvement in research (INVOLVE, 2014).

Over subsequent years the importance and significance of PPI has grown to alter the way in which we work in healthcare. Reflecting the changes in the prominence and value placed upon PPI following a public inquiry, Berwick (2013) stated, "Involvement means having the patient voice heard at every level of the service, even when that voice is a whisper."

Healthcare organizations receive support in their attempts to involve the public through the publication of national guidelines (National Institute for Health and Clinical Excellence, 2008) and through local government Healthwatch organizations (see list of relevant web pages). There is also a moral argument that service users should have a voice in research that may have an impact on their health status (Staniszewska et al., 2011; Smith et al., 2008).

In relation to health research the Department of Health for England's five-year strategy (2006) was for a health research system focused on the needs of the patients and the public and followed earlier strategies that claimed to place user involvement center stage (Ong and Hooper, 2003). It was known that engaging with patients and the public would make research more relevant to peoples' needs and make it more likely for the research recommendations to be put into practice (Frankham, 2009).

There is now an international journal, Research Involvement and Engagement, launched in 2015 that is coproduced by an involved and engaged patient and carer and a researcher (Stephens and Staniszewska, 2017). A reflective paper in 2017 after two years of publication contemplated the impact of their publication as having stimulated wider interest in research about public involvement and shared decision-making, on a global scale. Recent published research has explored the extent of public involvement in systematic reviews (Pollock et al., 2017), in ethics committee reviews (Staley and Szmukler, 2016), in reducing health and care research waste (Minogue et al., 2018) and in mapping health literacy interventions (Howard Wilsher et al., 2017). There are also emerging developments involving young people in research such as research around children and young people with neurodisability (Allard et al., 2014; McAnuff et al., 2016).

Legal Requirements for Public Involvement

In the UK, the requirement to involve patients and the public in the planning, development, and delivery of health services became enshrined in law in 2012 in Section 14Z2 of the NHS Act 2006, as amended by the Health and Social Care Act 2012—public involvement and consultation by clinical commissioning groups (NHS England, 2017).

Key regulations set out the essential standards of quality and safety that people who use health and adult social care services have a right to expect and the regulator provides guidance for providers of services about how to meet the regulations (Care Quality Commission, 2015). Public and patient experience and engagement policies complement the delivery of the essential quality and safety standards (Ocloo et al., 2017).

Definitions for Public Involvement

There are many different terms used in different ways by people from different sectors to describe PPI that can lead to confusion unless definitions are made clear.

Whatever term is used, the principles remain similar and are about trying to ensure that the patient perspective is included in discussions and decisions about healthcare. This might be at an individual level where patients are involved in shared decision-making with healthcare professionals about the care they wish to receive. Or it might be where patients, or patient representatives are involved in corporate decision-making about delivery of care or services from an organizational perspective.

Some of the terms used to describe patient involvement are: public and patient involvement, public and patient engagement, public and patient participation, patient experience, service user involvement and engagement, stakeholder engagement, and several others. In pharmacy practice the term Public and Patient Involvement Engagement and Participation (PPIEP) is often used. We will use the term "public involvement" in this chapter as a broad term to encompass all types of involvement and engagement.

In addition to the activities of involvement and engagement it is also helpful to try to understand the area of practice, discipline, sector, or domain in which the involvement is being undertaken. The area of public involvement that might be of interest to a specific individual or group or organization might include: healthcare planning, healthcare delivery, healthcare evaluation, healthcare commissioning, public health, health research, or health education. Any of these areas could relate to primary or secondary care or other service areas including pharmacy practice.

Drawing on the definitions used by INVOLVE (see list of relevant web pages) below are a few examples of the ways in which members of the public and patients might be involved in the work of health researchers and which can readily transfer to the health service setting including pharmacy practice.

Involvement

The activity referred to as public involvement is where patients or members of the public contribute to the development, delivery, or dissemination of a research study or in fact any activity throughout the research cycle. This might include:

- Joining advisory groups such as those making decisions about prioritization of research, funding research, or those providing oversight to a research study.
- Providing advice about structure and content for material to be used by participants of research such as leaflets, posters, and participant information sheets.
- Assisting in a researcher role (user or carer researcher) with data collection such as interviews or data analysis.
- Supporting the research team in the role as coapplicant on a research funding application.

Engagement

The activity described as engagement in research is when researchers, or others such as patient representatives, communicate their research findings or information about the impact of their research. This activity aims to spread information to the wider research community and beyond and might be specifically targeted at certain groups. It can take a number of different approaches such as: presentations, articles in newsletters, websites, social media, blogs, television, and radio to promote the research and raise awareness, open days at higher education institutions and in hospital settings, science festivals, and research clubs.

Participation

In relation to research, participation refers to the role of people in research as participants where the research team collects data from or about the participants to contribute to the research data collection and therefore influences the research findings. Participation is when people are recruited into a trial or when people provide research data through interviews or questionnaires.

When It Isn't Clear

There are sometimes scenarios where an activity called public involvement can be challenged by others who think it is a research activity, therefore illustrating that there might be overlap in the definitions of involvement and participation. For example, if patients are involved in a focus group as part of a research study the research team might call this public involvement. Some might call this participation because the members of the public are involved in the research itself. There is usually one straightforward way to clarify this. If research data are collected, for future analysis, from the members of the public, then they are participating in research. If the data that are collected are not research data then it is likely they are involved members of the public rather than participants in a research project. Taking the example of a focus group, if members of the public are being asked for their opinions on an intervention from the patient perspective this is probably a research study that is collecting research data from the members of the public as participants in the research. If a research study runs a focus group of patients with asthma to ask their opinions in designing a patient information sheet for a forthcoming trial, this is patient involvement, not participation.

Support for Public Involvement

INVOLVE (see list of relevant websites) describes its purpose as supporting "active public involvement in UK National Health Service (NHS), public health and social care research." INVOLVE uses the term "public involvement" to describe involvement of patients, potential patients, carers, and people who use health and social care services as well as people from organizations that represent people who use services.

While INVOLVE's remit is around health research, the principles and approach are broadly similar to those used for public involvement in healthcare. The INVOLVE website (see list of relevant websites) contains useful definitions about what is meant by public involvement and also what is not. In summary, INVOLVE describes public involvement in research as, "research being carried out 'with' or 'by' members of the public rather than 'to', 'about' or 'for' them." (© NIHR INVOLVE).

Examples of involvement in research might see members of the public working with research funding bodies to assist in prioritizing research, public members on a research project steering group in an advisory capacity, or helping to design research tools such as questionnaires and participant information leaflets.

People in Research

There are occasions when researchers might find it difficult trying to find suitable members of the public to support them in their research. People in Research is a website (see list of relevant websites) which advertises involvement opportunities in UK NHS research and also uses Twitter to promote their research and help researchers find members of the public to get actively involved in their work by enabling them to advertise their opportunities. The website also allows patients and members of the public to find research they might like to become involved with through searching the database.

What Is Required for Public Involvement to Work?

Being prepared to embrace public involvement requires a shift in thinking and in ways of working. Practitioners no longer view the patient as a recipient of services but as someone with whom they can work in partnership. This resembles a shift in power and therefore requires a different kind of relationship, in which healthcare professionals work in partnership with patients and the public (Parston and Kippin, 2010). Public involvement therefore brings about a shift in power from professionals to a more equal partnership (General Social Care Council, 2012). Power sharing can contribute to the achievement of the goals of a research project and can influence attitudinal change (Boote et al., 2011; Renedo and Marston, 2011; Lindenmeyer et al., 2007; Tritter and McCallum, 2006; Coulter, 2006).

This cultural change helps to drive quality improvement and such changes were seen when healthcare providers included a focus on the measures of patient experience as well as those of clinical care in their monitoring and regulation activities. A significant development in this area has been the introduction of patient reported outcome measures, known as PROMs where data about patient experience are included in measuring success in clinical outcomes. Patients were involved in the development of the patient reported outcomes to determine the appropriate methods and processes for reporting such outcomes in cancer research (Wilson, 2018).

There are now changed beliefs and attitudes toward public involvement as a result of working with patients and the public in research and service development (Mockford et al., 2012). Other changes that have occurred are seen in the NHS Constitution in relation to patient involvement in research (Purvis, 2012), changes to the standards of training in the Health and Care Professions Council (2012), and the recruitment of Patient Research Ambassadors (National Institute for Health Research, 2012).

Each patient or public member brings their individual beliefs, values, and everyday experiences (Fotaki, 2011) and their experiential knowledge is a source of advice that cannot be substituted by professional knowledge, which makes their contribution relevant (Lehoux et al., 2012).

Research involving the public makes the research more relevant to the people for whom it is designed (INVOLVE, 2013; Staniszewska et al., 2011; Research Council UK, 2010). As public involvement is becoming more embedded in the culture of health services and health research members of the public are becoming more experienced and more interested in how they can shape services in the future.

A movement that started in the voluntary sector, promoting patients as leaders, has been gaining momentum in healthcare. It describes the qualities of a patient leader as being similar to a strategic leader with a capacity for self-leadership, the ability to focus on solutions and having a willingness to value and work with others (Doughty and Gilbert, 2012). We now see patient leaders working alongside healthcare leaders to create service improvement through coproduction (King's Fund, 2013).

Standards for Public Involvement

The UK national standards for PPI in research were launched in March 2018 across a small number of test bed organizations. From April 2018 to April 2019, the next stage in developing the standards is to make sure that they work in practice as part of a pilot scheme. The aim of the standards is to improve the quality and consistency of public involvement in research. There are six national

standards, each with supporting indicators, resources, and downloadable documents in different formats. The standards were developed following consultation carried out in 2017 across the devolved administrations in the UK.

Each standard is a statement of good practice that describes one of six core elements in public involvement in research. For each standard there is an indicator, which is a statement of good practice that describes what is needed to demonstrate meeting the standard. Examples are provided on the website for NIHR PPI standards.

Standards for Public Involvement in Pharmacy Practice

Research is being undertaken at the University of Aberdeen about PPI in developing quality improvement standards, indicators and measures for the community pharmacy-based management of acute consultations. The aim of this research is to define, measure, and improve existing practice. There is further information on the Health Services Research Unit at the University of Aberdeen on their website.

Methods for Public Involvement

Public involvement is possible at almost every stage and every level of health service planning, commissioning, delivery, and evaluation and in health education and health research. It is recommended that we consider what is appropriate, when, and how, in terms of public involvement in what we do. For example, we might decide to seek feedback from patients on their experience of accessing a new service by means of a survey and then use a focus group of patient volunteers to contribute to discussions about how to use the survey results to improve the services. Below is a list of some of the methods used for involving the public and patients in healthcare.

- Surveys, questionnaires, focus groups
- Advocacy, facilitation
- Events, open days, science cafés
- Community meetings, consultation, collaboration, listening events
- Newsletters, feedback, social media
- Partnerships, networks
- Social movements, communities of interest, citizen's panels, patient representatives, patient groups, patient ambassadors
- Action research, participatory research
- Power sharing, coproduction
- Campaigns, lobbying
  NHS England guidance for commissioners (2017)

The academic literature holds numerous examples of different methods and approaches for public involvement: participatory research (Cook et al., 2017), community engaged research (Lowrie and Tyrrell-Smith, 2017), participatory learning and action research (De Brun et al., 2017), and participatory theme elicitation (Best et al., 2017) which involved young people in data analysis and other recruitment strategies for public involvement (Vat et al., 2017).

An important consideration is about the support that is going to be provided for the public members who are to be involved and to make sure that carefully tailored training and support for public involvement is available (Caldon et al., 2010; Morrow et al., 2012).

The process of recruiting patients or members of the public has been shown to reflect significantly upon their subsequent involvement experience. Providing the right information and support is part of a well-managed recruitment approach. Early negotiation about roles gives way for mutual respect and an active relationship, and establishes the process of two-way communication (Caldon et al., 2010; Boote et al., 2002). An example about how to recruit patients and the public to work collaboratively on a public panel for a microbiology research study is described by Grier et al. (2018).

With regard to the inclusion of information about public involvement when studies are published there has been much criticism of authors for failing to provide sufficient detail about the public involvement component of a study. This is important, as it is necessary to know of the detail about public involvement, especially when claims are being made about the impact of public involvement. The development of guidelines for reporting public involvement in research has addressed this issue. The GRIPP2 reporting checklists provide authors with a step-by-step approach to including all the details that are required about public involvement in a study and this has the wider impact of adding to the evidence base of public involvement in research.

The GRIPP2 reporting checklist has been developed as evidence-based consensus guidance on reporting PPI in research. It reiterates the importance of providing information on context, process, and impact of public involvement. Staniszewska et al. (2017) introduced the idea of a short form and long form for reporting PPI. GRIPP2 is the first international, evidence-based community consensus informed guidelines for reporting of PPI in research.

One of the approaches used for public involvement is experience-based codesign. The principle of engaging service users in the design of services using the model of experience-based codesign (Bate and Robert, 2006) brings a deeper more rewarding experience and results which are more sustainable (King's Fund, 2013). Another approach is coproduction.

Coproduction

Public involvement can break down barriers, lead to shared experiences, build understanding and seek diversity of knowledge from a range of settings, individuals and organizations and this has the potential to create the setting for coproduction to occur (Boyle and Harris, 2010). Coproduction is the process where members of the public work alongside professionals as partners in the delivery of services (Boyle et al., 2006). Coproduction draws upon the diversity of what public members and health professionals or researchers can bring and they become coproducers of knowledge that can influence health policy and practice (Gillard et al., 2012). Coproduction is seen as a goal of public involvement because it is where knowledge is produced across disciplines.

Good practice in quality improvement in clinical communities to establish shared norms of conduct occurs where members of the community become united by a common purpose to learn or share knowledge and take responsibility for achieving their aims (Aveling et al., 2012; Dawda et al., 2010; Baxter et al., 2001; Lave and Wenger, 1998).

Engaging service users in partnership with professionals creates one of the essential components of reform (Boyle and Harris, 2010). In the context of coproduction, instead of just being consulted, service users become equal partners and cocreators of service change (Social Care Institute for Excellence, 2012). An example of coproduction in creating, delivering, and evaluating a lay assessor training program has been described by Horobin et al. (2017).

The Coalition for Collaborative Care, NHS England describes coproduction as "a way of working that involves people who use health and care services, carers and communities in equal partnership; and which engages groups of people at the earliest stages of service design, development and evaluation" (see diagram below). Coproduction acknowledges that people with lived experience of a particular condition are often best placed to advise on what support and services will make a positive difference to their lives. Done well, coproduction helps to ground discussions in reality, and to maintain a person-centered perspective. Coproduction is part of a range of approaches that includes citizen involvement, participation, engagement, and consultation.

Values and behaviors that are exhibited by those working in a coproductive manner are described by the Coalition for Collaborative Care Action for Long Term Conditions in their coproduction model. See **Figs. 1 and 2**.

http://coalitionforcollaborativecare.org.uk/a-co-production-model/

Guidance on Coproducing a Research Project

INVOLVE has an ongoing work theme around coproduction and in February 2018 produced a guidance document for coproducing a research project (see list of relevant websites). It describes the key principles and key features of coproduction.

Key principles of coproduction are: sharing of power, including all perspectives and skills, respecting and valuing the knowledge of all those working together on the research, reciprocity, and building and maintaining relationships.

Key features of coproduction are: establishing ground rules, ongoing dialogue, joint ownership of key decisions, a commitment to relationship building, opportunities for personal growth and development, flexibility, continuous reflection, and valuing and evaluating the impact of coproducing research.

Organizational Perspectives on Public Involvement

NHS England

The commissioning body for healthcare in England explains the important role of public involvement,

> "Patient and public participation is important because it helps us to improve all aspects of health care, including patient safety, patient experience and health outcomes – giving people the power to live healthier lives."
>
> NHS England website March 2018

Figure 1 Five values and behaviors of coproduction. *Reproduced with kind permission from the Coalition for Collaborative Care.*

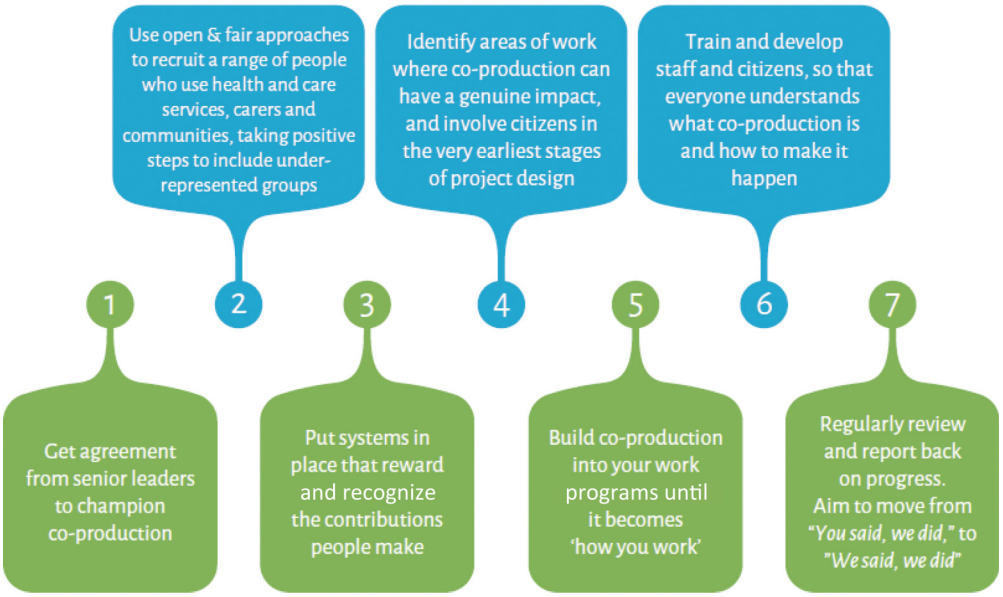

Figure 2 Seven steps to make coproduction happen. *Reproduced with kind permission from the Coalition for Collaborative Care.*

Healthwatch England

Healthwatch England is the independent consumer champion for health and social care and aims to, "have a society in which people's health and social care needs are heard, understood and met." They aim to make sure that people shape and influence health and social care delivery and the services they receive.

NHS England and Healthwatch England have an agreement to work together "to support a shared purpose of improving health and wellbeing outcomes for consumers, including patients, carers, families and communities" (NHS England and Healthwatch England, 2015).

Clinical Commissioning

Public involvement in commissioning is about enabling people to voice their views, needs and wishes, and to contribute to plans, proposals, and decisions about services. Health service commissioners aim to involve anyone who uses services or may do so in the future, including carers and families. The term "involvement" is used interchangeably with "engagement," "participation," "consultation," and "patient or public voice." Different approaches will be appropriate, depending on the nature of the commissioning activity and the needs of different groups of people.

Primary care commissioning managers and those working on national policy and programs affecting how primary care is commissioned consider involvement and participation as an integral part of commissioning, i.e., at all stages of the commissioning cycle. In planning policy, programs, and services, commissioners have to show they are aware of their legal duty to involve the public in this area of work, and take action as appropriate. Commissioners work to a set of key principles aimed at changing the way they embed public involvement in their work. These key principles, outlined in the Framework for patient and public participation in primary care commissioning (NHS England, 2016) are:

1. Reach out to people rather than expecting them to come to you and ask them how they want to be involved, avoiding assumptions.
2. Promote equality and diversity and encourage and respect different beliefs and opinions.
3. Proactively seek participation from people who experience health inequalities and poor health outcomes.
4. Value people's lived experience and use all the strengths and talents that people bring to the table, working toward shared goals and aiming for constructive and productive conversations.
5. Provide clear and easy to understand information and seek to facilitate involvement by all, recognizing that everyone has different needs. This includes working with advocacy services and other partners where necessary.
6. Take time to plan and budget for participation and start involving people as early as possible.
7. Be open, honest, and transparent in the way you work; tell people about the evidence base for decisions, and be clear about resource limitations and other relevant constraints. Where information has to be kept confidential, explain why.
8. Invest in partnerships, have an on-going dialogue and avoid tokenism; provide information, support, training, and the right kind of leadership so everyone can work, learn, and improve together.
9. Review experience (positive and negative) and learn from it to continuously improve how people are involved.

10. Recognize, record, and celebrate people's contributions and give feedback on the results of involvement; show people how they are valued.
(NHS England, 2017)

Public Involvement in Research—A Broader Perspective

This section introduces some broader views and approaches to public involvement and shows how the movement has progressed across continents.

The United Kingdom is said to be a leader in its approach to formalization of public involvement at an organizational level (Spencer et al., 2011) and its progress in spreading public involvement, especially across the public sector cannot be disputed.

In the United Kingdom a blog in the British Medical Journal was used to promote the involvement of patients and the public in research and turn this into a global "social movement" (http://blogs.bmj.com/bmj/2017/11/30/tessa-richards-patient-and-public-involvement-in-research-goes-global/).

In the United States, this work is being led by the Patient-Centered Outcomes Research Institute (PCORI) whose mission is to help people "make informed healthcare decisions, and improve healthcare delivery and outcomes, by producing and promoting high-integrity, evidence-based information that comes from research guided by patients, caregivers, and the broader healthcare community" (PCORI website March 2018).

In Canada, where the term patient engagement in research is used, the work is led by Canada's Strategy for Patient-Oriented Research (SPOR) and their review of the literature found only two studies that engaged patients in the research process (Adesanoye and Guirguis, 2017).

The Consumer and Community Research Network at the University of Western Australia describes their public involvement in research as, "the active involvement of consumers, community members and researchers working together to make decisions about health research priorities, policy and practice" (Consumer and Community Research Network September 2018).

They have developed an Involving People in Research website:
http://www.involvingpeopleinresearch.org.au/

Patients Included

Patients Included is an initiative that endorses public involvement practice. Patients Included charters are provided to organizations, courses, journals, and any function associated with healthcare that is shown be committed to, "incorporating the experience and insight of patients into their organizations by ensuring that they are neither excluded nor exploited." Charters have been provided for conferences, journals, and patient information resources with many other initiatives awaiting endorsement such as; clinical trials, continuing professional development courses, funding bodies, pharmaceutical companies, and healthcare organizations. See list of relevant websites.

Public Involvement in Higher Education

Professional bodies and government policy in the UK have made it a requirement for higher education institutions to demonstrate involvement of service users and carers in education and training for social workers and for health professionals (Department of Health, 2002).

In 2003 when the educational requirements for a social work qualification changed from a diploma to a three-year degree course there was also a requirement for higher education institutions offering the degree to involve service users and carers in the design and delivery of the program. This is illustrated by their involvement in recruitment and selection of students for the social work degree program, involvement in teaching programs and in the assessment of learning. It is now usual practice for service users and carers to be involved by helping to design the interview process and they might also be involved in undertaking the interviews for social work degree placements (Department of Health, 2002; General Social Care Council, 2005).

Methods for the involvement of service users and carers in social work teaching might take place through sharing their personal stories as case studies or they might be presented in the form of video recordings.

Drivers for service user involvement in social work education programs are similar to those in the health sector—that is, demands from service user-led organizations and regulatory requirements (Robinson and Webber, 2013). The increase in service user involvement in research in higher education institutions over the last two decades has been driven largely by service users themselves, the professional bodies and government policy (Chambers and Hickey, 2012). The Department of Health Education Commissioning for Quality document (2009) includes guidance on user involvement in the design and delivery of education and the Nursing and Midwifery Council requires evidence of involvement in program development and delivery (Nursing and Midwifery Council, 2015; Rhodes and Nyawata, 2010). The Health and Care Professions Council (2012) has developed Standards of Education and Training (SETs) for service user involvement in the design and delivery of their regulated education and training programs. Methods of involving service users in the education of health professionals includes their involvement in course design, student assessment, and teaching in the classroom (Cooper and Spencer-Dawe, 2006; Repper and Breeze, 2007; Haeney et al., 2007; Thomson and Hilton, 2011).

Public Involvement in Pharmacy Teaching

There are examples in the public domain, on websites giving examples of public involvement in pharmacy teaching.
http://www.uclan.ac.uk/about_us/case_studies/pharmacy_patient_public_involvement.php

A lecturer and a teacher practitioner at the University of Central Lancashire invited patients to an event scheduled for fourth year pharmacy students in the cancer module. They hosted chat show style interviews with patients who talked about how pharmacists had helped them with their conditions. Both students and teaching staff had found the session very positive (Becket et al., 2014).

National Coordinating Centre for Public Engagement (NCCPE)

https://www.publicengagement.ac.uk/

The UK NCCPE supports higher education institutions in their public engagement in research. They define public engagement as:

- the myriad of ways in which the activity and benefits of higher education and research can be shared with the public;
- a two-way process, involving interaction and listening, with the goal of generating mutual benefit.

The NCCPE provides training, resources, and holds an annual conference for engagement professionals across the higher education sector.

Resources for Public Involvement

See Table 1.

Conclusion

This chapter has aimed to give a broad overview of where, why, and how public involvement is occurring across the health landscape and offer examples of good practice and resources for others to replicate.

We are moving toward health services, research, and education, which are enhanced through public involvement and where the benefits improve peoples' health encounters, experiences, and outcomes.

Involving the public in planning of healthcare can lead to more accessible and acceptable health services whereas involving the public in research can lead to research that is of better quality, more relevant to patients, and of benefit to the end users.

Because the general public knows more and understands more about healthcare, and because reliable information is now so much easier to access, members of the public are even better placed than before to take up their positions as leaders. The leadership potential for patients and the public in influencing healthcare has gained momentum. The roles of healthcare professionals and patients as leaders are being redefined. As healthcare professionals are starting to think differently about the way they practice and the way they communicate, patients too are shifting in their thinking about their partnership role in the transformation that is happening in healthcare.

Pharmacy practice and pharmacy practice research are part of the transformation that is occurring through public involvement. This chapter has brought together some of the many examples of PPI, Engagement and Participation from the research literature and across the health community which provide the evidence base for this exciting transformation.

Relevant Web Pages

INVOLVE

www.involve.nihr.ac.uk

The INVOLVE website is one of the most comprehensive websites for supporting researchers and practitioners in their public involvement in NHS, public health and social care research activity. Although focused on research, much of the guidance provided by INVOLVE is transferable to the practice setting. Key guidance documents are:

- Briefing notes for researchers
  http://www.invo.org.uk/resource-centre/resource-for-researchers/
- Guidance on payment for and recognition for public involvement
  http://www.invo.org.uk/resource-centre/payment-and-recognition-for-public-involvement/
- Budgeting for Involvement including an Involvement Cost Calculator
  http://www.invo.org.uk/wp-content/uploads/2014/11/10002-INVOLVE-Budgeting-Tool-Publication-WEB.pdf
- PPI Standards
  http://www.invo.org.uk/current-work/standards/

People in Research

www.peopleinresearch.org

This website helps researchers find suitable members of the public with an interest in getting involved in research. Likewise it helps members of the public find research that they might be interested in helping with. There is a link to this website from the INVOLVE website in the Resources section.

GRIPP2 Reporting Checklists for PPI

GRIPP2 reporting checklists: tools to improve reporting of patient and public involvement in research.
https://www.ncbi.nlm.nih.gov/pmc/articles/PMC5539518/

University of Central Lancashire

http://www.uclan.ac.uk/about_us/case_studies/pharmacy_patient_public_involvement.php

The Pharmaceutical Journal

https://www.pharmaceutical-journal.com/research/perspective-article/involving-patients-and-the-public-in-the-delivery-of-pharmacy-education/11138731.article

Grimes et al. (2013) describe the advantages and the challenges of involving patients and the public in pharmacy education and give several practical examples for public involvement.

Healthwatch

https://www.healthwatch.co.uk

There are local Healthwatch organizations across England and their role is to champion things that matter to patients and lobby for improvements to services. A national Healthwatch body has oversight of national issues and reports to government on its activity.

The Royal Pharmaceutical Society in Great Britain

The Royal Pharmaceutical Society in Great Britain provides a Patient Engagement Hub on the resources section of its website: https://www.rpharms.com/resources/ultimate-guides-and-hubs/patient-engagement-hub. It contains a list of useful resources including leaflets, posters, and videos for patients to help them understand how pharmacy can help them with their condition.

Patients Included

https://patientsincluded.org/

NIHR PPI Annual Reports

https://www.nihr.ac.uk/about-us/how-we-are-managed/managing-centres/nihr-central-commissioning-facility/ccf-ppi/ppie-annual-reports.htm

NIHR infrastructure organizations such as Biomedical Research Centres, Collaborations for Leadership in Applied Health Research and Care, and Clinical Research Facilities have their annual patient and public involvement reports published on the NIHR website. These contain many examples of good practice in public involvement and most of them contain links to the organizations' websites and project pages.

Acknowledgments

Thanks to INVOLVE for permission to cite their resources and especially to Gill Wren for making this happen.

Thank you to the Coalition for Collaborative Care, NHS England, for permission to use their model for Coproduction and especially to Samantha Stewart for making this happen.

Sociology for Pharmacists

Janine M. Traulsen*, Paul Bissell†, Kath Ryan‡, *University of Copenhagen Copenhagen Ø, Denmark; †University of Huddersfield, Huddersfield, United Kingdom; ‡University of Reading, Reading, United Kingdom

Historical Development

Traditionally, pharmacy education has been based on knowledge of pharmacology, biochemistry, chemistry, physics, and physiology. This knowledge served pharmacists well when they were considered artisans and craftsmen who could know and utilize all the available knowledge. In the post-antibiotic era with its pursuit of the "magic bullet" and the subsequent growth of the pharmaceutical industry, more and more medicines came to market and the increased specialization in the health-care sector created an increasingly fragmented and complex system. The time had come for pharmacy practice to become reflective and forward thinking, which required taking stock, that is, to control, intervene, and implement change in the delivery of services and pharmacy management.

Organization and research skills were needed if pharmacies and pharmacists were to develop and maintain a key position in health care. This created a need for input from the organizational, behavioral, and social sciences. Sociology was one of the first social sciences to contribute to the field of pharmacy practice research (PPR). As far back as the 1960s, the role of the pharmacist was a much studied topic, and sociological theories of the professions provided a framework for this research (Lau and Traulsen, 2017). Since the 1980s, sociologists and other social and behavioral scientists began to play an important role in the education and research of and for pharmacy.

In 1994, one of the founding academic centers of pharmacy practice research in the United Kingdom asked Nick Mays (a social scientist working in health services research) to conduct a critical review of the existing PPR literature. He concluded that PPR had reached a point where it needed to work with and include other disciplines. He argued for greater utilization of sociological theory as one way to enhance the explanatory capacity and sophistication of pharmacy practice research (Mays, 1994). Through their theories and methods, sociologists provided conceptual and research tools to identify, analyze, and explain the social context of pharmacy and patients and health-care professionals use of pharmaceuticals. This included organizational systems and patient behavior—essential elements in the practice of pharmacy and the extended role of the pharmacist.

In general, sociology accentuates society rather than the individual by viewing individuals within the context of their environment and larger social processes. In this way, sociology differs from psychology, which emphasizes individual behavior often divorced from the social context. Medical sociology studies how people manage issues of health and illness, disease and disorders, how work effects health, how families deal with illness, the socio-economic determinants on health and health care, as well as the care and services for the sick as well as the healthy.

Sociology has enriched PPR by introducing concepts and theories such as social capital (the collective value of all social networks), social inequality (differences in health status), social status (the relative rank of an individual in society), and the organization of health-care organizations, to name but a few (Harding et al., 1990).

Sociology has not always been the preferred collaborator in PPR. Health professionals have often seen sociology as overly critical in its approach, given that it is usually challenging the status quo. For this reason, it has been seen by many in PPR as confrontational, i.e., concerned more with identifying, analyzing, and understanding problems rather than seeking solutions. One reason could be because sociological-oriented research is explicitly concerned with power; however, one might like to define power. A PPR example could be to ask what impact the power and authority exercised by health-care professionals has on patient compliance. In relation to medicine, a sociologist would look at the consequences of expecting patients to comply with a therapeutic regimen that has been shown to be unpleasant, complex, and difficult to live with (Bissell and Traulsen, 2005).

Another example would be to study the power of the powerless, that is, how patients from various social groups challenge, circumvent, and adopt therapeutic regimens.

One of the earliest contributions to medical sociology was made by the American sociologist Talcott Parsons (1951). Parsons theorized and coined the concept of the "sick role"—an approach to understanding the responsibilities and rights of patients in their interaction with doctors. According to Parsons, the sick role maintains order and to this end he attributed the following four components:

1. Ill people are exempt from their normal social responsibilities such as work or domestic labor.
2. Ill people are not held responsible for their condition and cannot be expected to recover by an act of will.
3. Ill people must want to try to get well or they can be accused of malingering.
4. Ill people are obliged to seek and cooperate with medical practitioners to help make themselves well again (Bissell and Traulsen, 2005).

Concepts and topics of particular interest to the field of PPR include adherence, compliance, concordance, the patient perspective, pharmaceutical policy, organization, and evaluation studies.

Whereas sociology was contributing to and becoming visible in PPR, clinical pharmacy research allied itself with health services research and the broad spectrum of methods in that subdiscipline, with relatively little crossover to sociology. Clinical pharmacy research is interested in real-world settings, that is, how well medications work on specific human patients once they have been approved. It is concerned with evidence-based outcomes research and draws on the knowledge of medicine and disease as taught within the framework of basic science and then relates this knowledge directly to the clinical requirements of patients (Harding et al., 1990).

Sociological Contributions to PPR

Sociology has provided PPR with a "toolbox" of study designs, theories, and research methods, including arguing for different approaches to how to design a project, a questionnaire, and concepts used (understood). One especially useful contribution has been the introduction of qualitative methods (Kaae and Traulsen, 2015), such as interviews, focus group interviews, various types of observation, document analysis, and more recently netnography (Kaae and Traulsen, 2015).

Beliefs About Health and Illness

Beliefs about health, illness, and medicines have been one area of PPR. Sociology has contributed a theoretical understanding of the causes of disease and illness, as well as the reasons for seeking various types of medical care (Conrad, 2008). Sociology has also contributed methods and theory for researching patient compliance and noncompliance with medical regimens and adherence issues—the extent to which a person's medicine-taking behavior corresponds to the advice from health-care providers. A further development in the attempt to understand the extent to which a patient's behavior aligns with medical advice has been the introduction of the concept of concordance. Concordance refers to the nature of the interaction between clinician and patient on medication taking, about whether, how, and when medical treatment will be used (Gabe et al., 2004). Whereas Parsons' depiction of patient–professional relationships referred to the "institutionalized superiority of the professional's role," the concordance model describes treatment choices as the "negotiation between equals" (Bissell and Traulsen, 2005).

Sociological studies have contributed to the service user's perspective, providing pharmacists with insight into and vital information about their patients in order to understand where they are coming from and what informs their views on health and medicine. This knowledge is essential for understanding and developing communication skills—a must for pharmacy practice.

Researching Risks

Whereas prior to the scientific revolution, issues of life, death, health, and illness were discussed in terms of fate, chance, personal destiny, and the will of God, today research on risk has become a major approach to assessing public health risks (Gabe et al., 2004). Theories of risk, methods to measure risk, and regulating risk have become ubiquitous features in research concerning the effects and side effects of medicine treatment. Since the late 1970s and early 1980s, the discourse about risk and research on risk has exploded in the clinical and social sciences. Whereas psychologists have been concerned with questions of "how risk is perceived," sociologists have been concerned with "how risks are negotiated" (Bissell and Traulsen, 2005). German sociologist Ulrich Beck and British sociologist Anthony Giddens were two of the most influential proponents in developing the theories of risk and society that laid the foundation for many studies of health services and medicine treatment. A major theme in this literature has been the discrepancy between lay and expert perspectives of risk, which some have explained as the result of competing or alternative rationalities (Bissell and Traulsen, 2005). There is research evidence that experts and patients sometimes conceptualize and perceive risks differently. This complicates the need to manage risks, distancing the expert from the patient and creating a need for "intermediary links"—a common ground where they can work together on risk management. In the world of medicine, the pharmacy has been identified as

this "intermediary link." The risk discourse and the resulting theories of risk have contributed much to health services research as well as PPR; for example, studies of the perceived risk of future drugs; clinical studies that have developed measurement tools; and research on risk communication (especially between pharmacist and patient). As long as pharmaceuticals continue to have side effects, be they physical, social, psychological, economic, or ethical, there is a basis for researching the risk perceptions of patients and various approaches to risk communication and risk management (Bissell and Traulsen, 2005).

The contribution of risk research to the realization that there is a gap between experts and patients in terms of treatment options brings us to one of the major contributions of sociology to PPR—theories and methods for researching the patient perspective. The patient perspective refers to the ideas, perspectives, and sources of knowledge people use to interpret the experiences of health and illness in their everyday lives.

PPR has contributed to and expanded this approach by introducing the patient perspective in a societal context, for example, by emphasizing the role of contextual factors in health beliefs and practices. Sociologically informed research has studied social inequalities and health, effects of gender and ethnicity on health, and use of health services. Most significant has been the wealth of research done on social class and health and the evidence of how social class inequalities correlate with inequalities in health status (Harding et al., 1990).

Pharmaceutical Policy

In the new century, a major area of interest has been patient perspectives and involvement in pharmaceutical policy. Almost every national and supranational health policy document accords high importance to the need to listen to and "empower" patients. This field of research includes studies that look at lay attitudes toward pharmaceutical policy, lay experiences of drug therapy and how it affects their daily lives, patient and public involvement (PPI), the problem of identifying lay representatives, the relationship between industry and consumers, and the effect of the media on medicine users and pharmaceutical policy itself (Traulsen and Almardóttir, 2005a). Topics of concern for PPR have been pharmaceutical policy in relation to the rational use of drugs (Almarsdóttir and Traulsen, 2005a), cost-containment (Almarsdóttir and Traulsen, 2005b), the role of the lay public (Traulsen and Almardóttir, 2005a); and the role of the pharmacy profession (Traulsen and Almarsdóttir, 2005b).

Theories of the Professions

Research accounts of the struggle of professions to attain and maintain a monopoly, strategies of exclusion and usurpation, have formed an interesting and fruitful area of sociological research. Theories of the professions have been a useful framework for studies concerning the future of the pharmacy profession including professional identity, and for decades have been a popular and recurring theme in professional journals and at international pharmacy conferences (Traulsen and Druedahl, 2018).

The work tasks of pharmacists, the environment they work in and the overall status of the pharmacy profession have been fruitful areas of research in sociology (Traulsen and Almarsdóttir, 1999; Traulsen and Bissell, 2004; Traulsen and Druedahl, 2018). For example, sociological studies on the labor market for pharmacists have addressed issues such as gender, wages, and salaries; part-time versus full-time work (Carvajal and Popovici, 2016); labor supply functions; and the consequences of pharmacist shortages (Carvajal et al., 2012). Studies on the working conditions and work environment have addressed concerns among community pharmacists that patient safety is being compromised due to high-pressure working conditions in combination with long working hours without breaks (Gidman et al., 2007). Theories of power and labor market analysis found in sociology can be useful when exploring labor market trends and what they mean for pharmacists. For example, cases where pharmacists report that they are being pressured to focus on providing services that generate extra sales and fees that are reimbursed by third-party payers.

Another field of sociologically informed research deals with demographic shifts in the composition of the pharmacy work force. These include gender, cultural diversity, and ethnicity (Carvajal et al., 2014).

Rising social and economic pressures on health-care systems have made understanding the role of organizational structures and processes in health-care facilities, including pharmacies, an immediate concern in ensuring quality of care. Generally speaking, organizations are stable elements of social life, the basic structures within which the state establishes regulatory policy, business is conducted, and people work. They intersect and interact with political, economics, and labor institutions. Organizations have been and still are a central component of sociology. The increasing complexity of health-care organizations has presented challenges for policymakers, health-care workers, and decision makers, making research into the organization of care delivery a top priority. One goal of these endeavors has been to identify ways of improving care by improving the organizations that provide this care. Sociology has numerous theories and methods that address research in this field.

Of particular concern for pharmacy practice are the challenges of transitional care. Transitional care is the term used to refer to the coordination and continuity of health-care services between health-care practitioners when patients are moved from one health-care facility to another or, in many cases, home. Community and hospital pharmacies are key actors and important service providers in ensuring the quality of this service, and sociology has a history of conceptualizing and theorizing questions and problems pertaining to organizations and management in this field and in health care in particular. More recently, attempts have been made to develop theories of care transition (Bury and Taylor, 2008) in the hopes of contributing to a solution to this problem.

Evaluation Research

Evaluation research aims at providing useful feedback on the impact of social and medical interventions. There is broad consensus that the major goal of evaluation is to influence decision making or policy formulation through the provision of empirically driven feedback. Sociology has contributed much to the field of program evaluation, conceptualizing various forms of evaluation research and developing useful methods for conducting various types of evaluation studies, including need assessments and monitoring studies. Sociological treatment of qualitative research and evaluation methods has influenced many studies of health-care services (Patton, 2002).

Pharmaceuticalization

Pharmaceuticalization, the process by which lives are mediated through pharmaceuticals, is a theoretical concept developed to guide research and understanding of the discovery, production, regulation, distribution, and consumption of medicines at both societal and individual levels. It has evolved from many disciplines, including sociology and anthropology, and it is presented in a separate chapter. It is a fruitful area of enquiry for PPR focusing as it does on all aspects of the development and use of pharmaceuticals.

A Bit of Crystal Ball Gazing

Futurology is a field of research to which sociology has contributed theories and methods. Future studies (as they are sometimes called) provide fertile ground for PPR for those interested in long-term planning and providing visions for the future of pharmacy. Futurology is the study of postulating potential, probable, and preferable futures. Futures studies design can be descriptive as well as prescriptive. The former, also known as the exploratory method, attempts to objectively describe how the future can or could be. The so-called prescriptive method attempts to help people clarify their values and preferences so that they can develop visions of desirable futures.

Futures research is useful in helping people to better understand future possibilities and provide policymakers (including professional groups) with various scenarios from which to make decisions and plan for the future. When successful, it provides critical thinking concerning long-term developments. Gazing into the future is always a risky and uncertain endeavor, but we can extrapolate based on current knowledge about the role of pharmacists and pharmacy practice, as well as predictions for new and revolutionary therapies. Although we will never be able to predict the future, we can identify some of the major trends and challenges known to us today. Realistic and viable visions for the future of the pharmacy and the pharmacy profession require an ongoing analysis of the outside world—especially societal, economic, and workforce trends. Sociology can contribute to insights into the current labor market and world of pharmaceuticals using labor market and work organization theories (Traulsen and Druedahl, 2018). There is general consensus that multiple methods are needed to design these studies, such as the Delphi method, trend assessment, and future scenarios.

The following is a list of some of the most pressing issues that will be affecting the pharmacy sector:

New Technology. Globally the labor market (including pharmacies) is faced with the unprecedented rapid increase in technology and automation often referred to as the "Fourth Revolution." According to a recent report by the World Economic Forum (2016), more than one-third (35%) of the skills considered important in today's workforce will change. By the year 2020, the Fourth Revolution will have introduced more robots, advanced artificial intelligence, biotechnology and genomics, all of which will transform the pharmaceutical industry as well as the work and careers of pharmacists (Traulsen and Druedahl, 2018).

New methods of organizing work. The skills that are foreseen to be important in the future include complex problem solving, critical thinking, people management, and the ability to coordinate others. A World Economic Forum report points out that negotiation skills and flexibility, which were skills high on the list in 2015, will be taken over by machines able to process masses of data (World Economic Forum 2016).

Evolving therapies. Many of the evolving therapies will not only affect but in some cases replace pharmaceuticals as we know them today. These therapies include gene therapy—the therapeutic delivery of nucleic acid into a patient's cells to treat disease; cell therapy—injecting intact, living cells into a patient; and regeneration therapy—the process of replacing, engineering or regenerating human cells, tissues or organs to restore or establish normal functions. Some of the research questions for PPR include: will this therapy replace existing medicine therapy? Will there be a need for coexisting or supplementary pharmaceuticals? What role will the pharmacy and the pharmacist play in this therapy?

Parallel to the search for new therapies is the activity of repurposing medicines, or teaching old medicines new tricks, as it is sometimes called. This endeavor involves finding uses for drugs in the freezers of the pharmaceutical industry, which were tested on humans (safe), but not useful for the purpose originally designed. The job of repurposing medicines, an evolving development, will most certainly require the input of pharmacists and potentially a new role for pharmacies. This development poses a unique opportunity for PPR to be proactive by studying the pros and cons of this development and providing valuable information on which to develop strategies and recommendations that include pharmacy practice expertise.

Sociology and PPR—Looking Forward

Sociologists' working together with pharmacists have been a fruitful collaboration, even if sociology is not the first social science discipline pharmacists reach out to when starting a research project. Sociology is not an exact science and is criticized for being diffuse, jargon-ridden, and lacking a specific coherent subject. In addition, sociology's emphasis on initiating a critical approach to any and all research topics is seen by many as subversive. Being trained as natural scientists and often taking a problem-solving approach to their research, pharmacists tend to shy away from sociology, which is heavy on theory and critical in its approach. However, pharmacy needs to know more about—and more importantly be able to track changes—in society, and here sociology has much to offer PPR.

Essential for communication with patients, pharmacy needs to understand where their patients are coming from and what and how their views are informed. A sociological approach can help pharmacy practice focus their attention on the practical and policy-making implications of the changes currently transforming the field. For example, new therapies, changes in medicine production, and new methods of marketing are already radically changing how pharmaceuticals will look in the future and are destined to change the role of pharmacies and pharmacists. Sociological theories that help explain the scope and breadth of these societal changes, methods that can generate empirical studies of the workplace, the products and the patient can contribute to PPR and help prepare pharmacy practice for this uncertain future.

On the microlevel, sociology can reveal perceptions of health risks and their management as well as risk acceptability of medical interventions. On the macrolevel, sociology can contribute to the study and understanding of social movements, patient organizations, public health risks, and the policy process, as well as the social construction of health risks and their regulation.

The question is always—can sociologists orient themselves better than anyone else with common sense? The answer is yes. Sociology as a discipline is characterized by its rigorous search for interconnections among different societal spheres and its systematic use of comparisons. It is anti-utopian in its claims and anti-fatalistic in its orientation and distinguishes "generalized" knowledge from localized common sense knowledge. Sociology goes further than common sense: sociologists are better at orienting themselves, because they are constantly developing and refining concepts, theories, and research methods. Developing concepts is an ongoing endeavor in sociology—which can help PPR to track, identify, and understand current pharmacy practice problems as well as help plan for the long-term future.

PPR often tries to align itself with mainstream service/practice issues, thus marginalizing sociology. This direction has been fuelled by the fact that the focus of pharmacy practice has become more commercial over the years, with the result that PPR has bonded with social sciences that promise practitioners the reward of being able to change patients' behavior and/or initiate new money-saving organizational changes. This explains the increase in the number of pharmacy practice studies driven by health services research and applied psychology, and positivist policy-oriented sciences moving into health economics, service improvement, and patient safety. This approach has been useful for studying and changing internal and day-to-day pharmacy practices. However, if pharmacy practice and research trained pharmacists are to thrive and maintain a key role in health care and services, it is necessary to plan for the immediate and long-term future. This means to momentarily look away from the micro-world of the pharmacy and the systemization of daily work and consider the implications of global mega trends that are affecting the entire field of pharmaceuticals. From R&D to patient care, sociology has the theories and methods necessary for PPR to do just that.

Glossary

Sociology Sociology is the "science" of society. It is difficult to define its boundaries as a discipline, because sociology overlaps with many other social science disciplines—economics, political science, anthropology, psychology, cultural studies, and human geography. Sociology deals with real-world issues (i.e., research on and with people), and these issues are forever in transition and change. As an academic discipline, sociology takes into account the related disciplines mentioned above. Sociological discourses are ongoing and contemporary, constantly being influenced by lay society, policy, and popular culture. On one hand, sociology seeks to understand how the thoughts, actions, and behavior of individuals are influenced by broader society. On the other hand, sociology seeks to understand how individuals actively create that society through individual and collective actions.

Pharmacy practice research (PPR) Pharmacy practice research (PPR) is a specialty field within the wider area of health services research, focusing on studies of how and why people access pharmacy services, the cost of care and services, and what happens to patients as a result of this care. PPR is often regarded as an applied field of research, in that a large part seeks to intervene, control, and implement changes in the delivery of services and pharmacy management.

Transitional care Transitional care is the term used to refer to the coordination and continuity of health-care services between health-care practitioners when patients are moved from one health-care facility to another or, in many cases, home. Community and hospital pharmacies are key actors.

Future Studies Future studies provide a knowledge base for exercises in long-term planning and developing visions for the future. Futures studies is the study of postulating potential, probable, and preferable futures, these studies can be designed as descriptive as well as prescriptive. The former, also known as the exploratory method, attempts to objectively describe how the future can or could be. The so-called prescriptive method attempts to help people clarify their values and preferences so that they can develop visions of desirable futures.

Essential Medicine List, Policies, and the World Health Organization

Muhammad Atif*, Iram Malik*, Dalia Dawoud†, Anwar Gilani‡, Naseer Ahmed‡, Zaheer-Ud-Din Babar§, *Department of Pharmacy, The Islamia University of Bahawalpur, Bahawalpur, Pakistan; †Clinical and Pharmaceutical Sciences Department, School of Life and Medical Sciences, University of Hertfordshire, Hatfield, United Kingdom; ‡The Aga Khan University, Karachi, Pakistan; §University of Huddersfield, Huddersfield, United Kingdom

Overview

- Essential medicines have public health relevance as they satisfy the priority healthcare needs of the population and have evidence on efficacy, safety, and comparative cost-effectiveness.
- In 1963, Cuba was the first country to launch a list of basic medicines. This was followed by the introduction of national lists in Tanzania (1970) and Peru (1972). In 1977, World Health Organization (WHO) published the first WHO Model List of 212 essential medicines.
- A WHO Expert Committee on the Selection and Use of Essential Medicines is responsible for the development and the revision of Essential Medicines List (EML) every 2 years.
- The Nairobi Conference on the Rational Use of Drugs, held in 1985, was the first international conference on essential medicines policies. The development and implementation of Essential Medicines Policies (EMPs) evolved in three periods, that is, 1st era from 1970s to 1990s, 2nd era from 1990s to 2010s and 3rd era from 2010 to present.
- Standard elements of an EMP are procurement, supply, prescribing and dispensing of medicines, financing, and rational use of medicine.
- WHO has devised a framework to guide policy makers for collective action on improved access to essential medicines for Universal Health Coverage (UHC) by 2030. The framework is in line with the Sustainable Development Goals (SGDs) and includes elements such as rational selection and use of essential medicines, their affordability and availability, sustainable financing, and reliable health and supply of quality products.
- Over the years, WHO has widely supported most low- and middle-income countries (LMICs) in the development and subsequent implementation of national EMP. By 2013, most of the LMICs (>90%) had a list of essential medicines.
- The latest (20th) WHO model EML (containing 433 drugs) was published in 2017.
- Implementation of the EMP has resulted in easy availability, better affordability, and improved quality use of essential medicines in LMICs.
- Hospitals and healthcare organizations in high-income countries also use essential medicines concept to allocate funding resources.

Introduction

History and Development of Essential Medicines Policies

What are Essential Medicines?

Essential medicines have been defined by WHO as "those that satisfy the priority healthcare needs of the population. They are selected because of their public health relevance, evidence on efficacy and safety, and comparative cost-effectiveness. Essential medicines are intended to be available within the context of functioning health systems at all times in adequate amounts, in the appropriate dosage forms, with assured quality and adequate information and at a price which the individual and the community can afford" (World Health Organization, 2003).

Evolution of essential medicine concept

The concept of "essential medicines" was evolved from military tradition in which medicaments (such as antibiotics) were very important to be carried by soldiers into the battle zones (Greene, 2011). Before the involvement of WHO in the essential medicine concept, governments were worried about the circumstances for years, and a few had started to take measures to satisfy the therapeutic needs of their residents by providing them with the essential medicines (Mirza, 2008). In 1963, Cuba was possibly the first country to launch a list of basic medicines (Wirtz et al., 2017). First international checklist of basic medicines was given in Maurice King's revolutionary book in 1966 (King, 1966). This was pursued by the introduction of national lists in Tanzania (1970) (Wirtz et al., 2017) and Peru (1972) (Wirtz et al., 2017). In 1977, WHO published the first WHO Model List of essential medicines, including 212 medicines (World Health Organization, 1977). In 1978, The Declaration of Alma Ata (1978) incorporated the provision of essential medicines as an element of primary healthcare (World Health Organization, 1978), and essential medicines were considered fundamental for preventing and treating diseases, which affect millions of individuals throughout the globe (Pillon, 2016).

Rationale for Essential Medicines

Both demand and supply perspectives are linked to the concept of essential medicines. From the demand side, medicine needs of people from low socio-economic strata are fulfilled marginally by the public healthcare facilities. From the supply point of view, a medicine innovation involving discovery, manufacturing, and delivery is mainly market driven (Pammolli et al., 2006). Influenced by return-on-investment, the pharmaceutical manufactures and private pharmacies stock these medicines so that they could can bring extra profit and concentrate on those consumers who can purchase costly medicines. In this context, essential medicines are not the part of supply and demand cycle and remain unavailable (Hardman and Limbird, 2001; Mirza, 2008).

The rationale behind the essential medicines is that while there are numerous medicinal products registered and accessible in the market, it is vital to be selective considering the medical needs of the majority of the citizens and also to guarantee the safety, efficacy, and cost-effectiveness. Essential medicines approach is reasonable, well organized, and based on sound ethics and economics (Mirza, 2008). It also supports national policies concerning the use and availability of medicines, and encourages the goals of primary healthcare (Hutchings et al., 2010; Management Sciences for Health, 2012).

Steps for the Development of EML

While developing an EML, the WHO expert committee on the Selection and Use of Essential Medicines meets and decides which medicines should be included in the list (Laing et al., 2003). The committee members (generally 8–12 in number) are from appropriate background and have experience in procurement, supply, and/or use of medicines (Foster et al., 2006; World Health Organization, 2011). The WHO has suggested inclusion of the following healthcare professionals in the Expert Committee on the Selection and Use of Essential Medicines (**Box 1**) (World Health Organization, 2011).

Applications for addition, deletion, or change of a medicine in the list are submitted (through concerned departments in WHO) to the secretary of the WHO Expert Committee at least 4 months before the meeting (Murray, 2015).

Box 1 Representatives of the Expert Committee on the Selection and Use of Essential Medicines.

- Representative of the Ministry of Health including employees from the medicines procurement department
- Professional organizations
- National and local health facilities
- ≥ 1 clinical pharmacologists
- Physicians and surgeons
- Child specialist
- ≥ 1 hospital and district pharmacist
- Director of hospital
- Additional specialists as required
- Members of disease control programs, for example, tuberculosis, malaria, and AIDs programs can be designated to attend meetings

Source: World Health Organization, Agenda item for the 18th Expert Committee on the Selection and Use of Essential Medicines: Draft for consultation, 2011.

The steps involved in the selection of essential medicines include efficacy, quality, and safety of medicines followed by their relevance with the current standard treatment guidelines (STGs) (World Health Organization, 2002). A transparent scientific and evidence based process for creating and updating the EML is followed by the Expert Committee. Selection of essential medicines is done on the basis of relevance to the disease pattern, proven efficacy and safety, adequate quality, desirable pharmacokinetic properties, cost-effectiveness, local pharmaceutical manufacturing, and the availability of medicine as a single compound.

These medicines are recognized by the International Non-proprietary Names (INN), or generic name (World Health Organization, 2002; Management Sciences for Health, 2012; World Health Organization, 2011). Resulting essential medicines list is made widely accessible to all healthcare providers and in all healthcare facilities in both electronic and printed form (World Health Organization, 2002). In the WHO, medicines in the model EML are classified into two categories: (1) core medicines that are defined as "efficacious, safe, and cost-effective medicines for priority conditions" and (2) complementary medicines that are defined as "medicines for priority diseases that are efficacious, safe, and cost-effective but not necessarily affordable, or for which specialized health care facilities or services may be needed" (World Health Organization, 2003). A nationally adapted EML based on STGs can help countries spend their scarce resources on the essential and affordable medicines (Van den Ham et al., 2011).

Essential Medicines Policies

The Nairobi Conference on the Rational Use of Drugs, held in 1985, was the first international conference on EMPs. Three decades after Nairobi Conference, essential medicines became a widely acknowledged public health policy concept (Greene, 2011; Wirtz et al., 2017). According to the Lancet Commission on Essential Medicines Policies, the development and subsequent implementation of EMPs can be classified into three time eras (Wirtz et al., 2017) (**Fig. 1**).

Standard elements of an EMP are procurement, supply, prescribing and dispensing of medicines, financing and incentive policies, and rational use of medicine (World Health Organization, 2001; Seiter, 2010; Greene, 2011). WHO has devised a framework to help policy makers improve access to essential medicines for Universal Health Coverage (UHC) by 2030. This is in line with the Sustainable Development Goals (SGDs) and includes the following four elements (World Health Organization, 2017a):

- **Rational selection and use of essential medicines**: It is linked to the development of national standard treatment guidelines and national EML.
- **Affordability and availability**: It is an inevitable factor in access to essential medicines that must be persuaded through multiple mechanisms including use of unbiased available price information, allowing price competition, supporting bulk procurement, implementing generics policies, negotiating fair pricing or abolition of duties, tariffs and taxes, and promoting local production of quality medicines.
- **Sustainable financing**: It can be guaranteed through various mechanisms including reduction in out-of-pocket expenditures, increased public funding, expansion of health insurance schemes, and exploration of external funding and financing mechanisms.

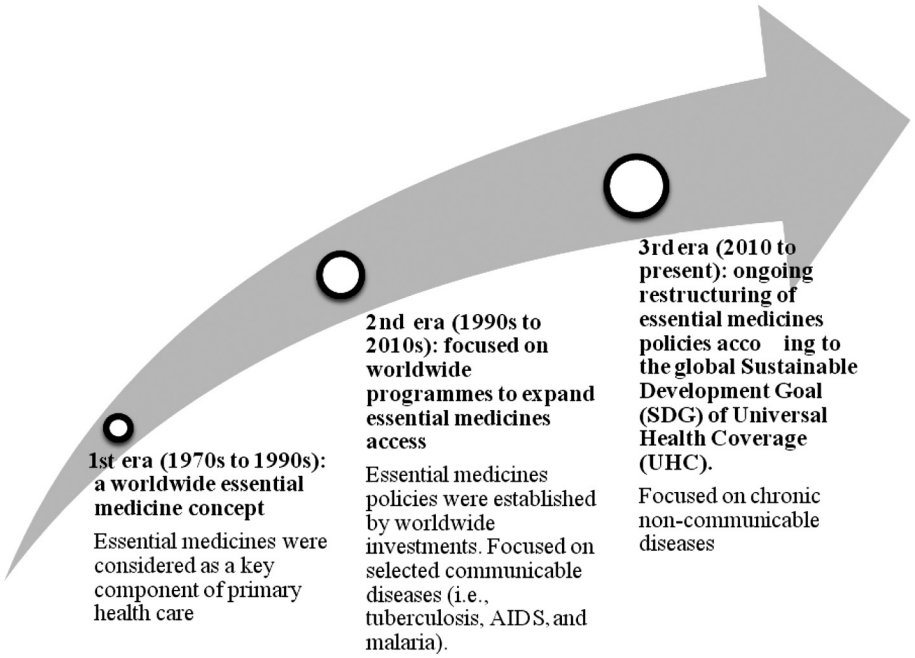

Figure 1 Evolution of essential medicines policies.

Table 1 History and development of EMLs and essential drug policies in few LMICs

Low and middle income country	*History and development of EML and essential drug policy (EDP)*
Bangladesh	• The Ministry of Health of the Government of Bangladesh in 1982 created an eight-member professional taskforce to develop National Drug Policy draft (Islam, 1984). • In 2011, the Government of Bangladesh adopted a new national health policy for the provision of essential medicines for non-communicable diseases (Das and Horton, 2013). • Current EML was published in 2016 (World Health Organization, 2016a).
Nigeria	• Nigeria embraces WHO-promoted essential drugs initiative in 1987 (Adikwu and Osondu, 1991). • Nigeria adopted the Bamako Initiative (BI) program in 1988 to confirm a stable supply chain for essential medicines (Uzochukwu et al., 2002, Chukwuani et al., 2006). • The Nigerian government started two plans to improve access to essential medicines that is the Essential Medicines Scale-up Plan in 2011 and the Save One Million Lives (SOML) in 2012. • Most recent edition of EML was published in 2016 (World Health Organization, 2016b).
India	• The first ever Indian National Essential Medicine List was developed in 1996 (Sharma et al., 2010, 2011). • Government of India in 2011 has announced a policy designed to increase the availability of EMs (Bandameedi et al., 2016). • Current NEML of India was published in 2015 and comprised of 376 medicines (World Health Organization, 2015).
Brazil	• The concept of essential medicines is a focus of the Brazilian National Medicines Policy since 1964. Brazil has had an EML, and from the year 2000 to 2010, the list has been periodically updated 5 times, working as a guide to quality medicine use (Osorio-de-Castro et al., 2018).
Mexico	• Health reform in 2000 introduced the people's health insurance (SPS) in Mexico and the government has implemented policies and reformed to guarantee equitable access to health care (Knaul et al., 2015). • In 2005, the MOH created the background document to serve as a basis for a national pharmaceutical policy (Moïse and Docteur, 2007; Gasman, 2008; Wirtz et al., 2008). • The current Mexican Formulary List (MEX-LIST) was published in 2014 (Roth et al., 2018).
Ethiopia	• The EML was first introduced in 1980 and revised regularly in 1989, 1996, 2002, 2007, and 2010. The sixth edition addressed three levels of health care (Food, 2010, Food, 2014).
Malaysia	• The Minister of Health announced on February 17, 1995 to implement a NEML (Haque, 2017). But it was first established in 2006 (Ministry of Health, 2013). • Last EML was published in 2014 and contained 321 medicines (World Health Organization, 2014a).
South Africa	• The EM initiative of South Africa was built as the National Drug Policy, which was instigated in 1996 since the instatement of the country's new democratic government in 1994 (Department of Health, in press, South African National Department of Health, 1996). • Since 1996, STG/EML has been revised 13 times. Latest edition EML was published in 2018 (Perumal-Pillay and Suleman, 2017, Health Department: Health Republic of South Africa, 2018).
Pakistan	• A National Medicines Policy (NMP) exists in official documentation form and was last modified in 1997 (World Health Organization, 2014b). • The NEML of Pakistan was first published in 1994. The list was revised in 1995, 2000, 2003, 2007, and 2013 by the MOH. The current NEML published in 2018 encompasses 428 molecules (30 categories and 78 sub-categories) (Government of Pakistan, 2018).

- **Reliable health and supply of quality products**: It is vital in sustaining access to essential medicines. Factors that support effective health and supply system include health sector development, efficient public-private-NGO mix, regulatory control, efficient procurement system, and the inclusion of traditional and complementary medicines.

The term "essential" has different interpretations and understanding in different nations, depending on the disease patterns, resources, medical traditions, and the result of pharmacoeconomic evaluation to select medicines. History and development of EML and essential drug policy in LMICs are summarized in **Table 1**.

Challenges Related to Essential Medicines

Over the years, the global health community has attempted to tackle the challenges related to essential medicines policies. The challenges include inadequate financing, improving affordability, quality and safety, improving medicines use, and developing new essential medicines. These challenges for the policies on essential medicines are not new (Wirtz et al., 2017) (**Fig. 2**). The Lancet Commission on EMPs has presented a comprehensive summary of the interventions shown to improve quality use of medicines. Collaborative efforts of the governments, policy makers, healthcare providers, the pharmaceutical industry, donors as well as civil society organizations and international agencies must address these challenges (Wirtz et al., 2017).

Figure 2 Core challenges for essential medicines policies.

Box 2 Highlights of 20th WHO Essential Medicine List

- Antibiotics categorized as access, watch and reserve along with recommendations to promote rational use.
- New drugs added to treat HIV, hepatitis C, tuberculosis and leukemia, including two oral cancer medicines (dasatinib and nilotinib) and first combination therapy added (sofosbuvir and velpatasvir) to treat all six types of hepatitis.
- Addition of two new fixed-dose combinations for malaria (dihydroartemisinin + piperaquine and artesunate + pyronaridine).
- Deletion of streptomycin as a first-line tuberculosis treatment from the core EML list.
- Expert committee strongly emphasized development of essential diagnostic list (EDL) for evidence-based clinical guidance.

The Role of World Health Organization

In May 1975, WHO strongly emphasized the formulation of national pharmaceutical policies based on quality, affordability and availability of medicines (World Health Organization, 1975). A resolution was tabled, and global public health vocabulary was introduced with the concepts of "essential drugs" and "national drug policy" (World Health Assembly, 1975; Quick et al., 2002). The first meeting of the Expert Committee on Selection and Use of Essential Drugs was held in 1976 (Helling-Borda, 2003); in 1977, WHO adopted the first Model List of Essential Drugs (World Health Organization, 1977). In 2007, the World Health Assembly Resolution (WHA60.20) on Better Medicines for Children emphasized the need to formulate child-specific dosage forms of many essential medicines (World Health Organization, 2007a).

As a result, first Model List of Essential Medicines for Children was published in 2007 (World Health Organization, 2007b). Over the years, the WHO has widely supported most LMICs in the development and subsequent implementation of national EMPs. By 2013, most of (>90%) LMICs had a list of essential medicines, and it was published in their national medicines policy document (Kanji et al., 1992).

The WHO Model List of Essential Medicines is updated and revised in every 2 years by the WHO Expert Committee on Selection and the Use of Medicines. The latest (20th) EML was published in June 2017; it contains 433 drugs (30 new medicines for adults and 25 new medicines for children) that meet priority health needs globally. Highlights of the 20th WHO Essential Medicine List are shown in **Box 2** (World Health Organization, 2017b).

Core Functions of WHO Essential Medicines Policies

Core functions of EMP include articulating and advocating policy options, working in partnership with the United Nation (UN) agencies, helping policy-makers through guidelines and tools for executing the elements of a national drug policy, developing norms and standards as a base for effective control, regulation, manufacture, and sale of drugs. The agenda also includes stimulating strategic and operational research; develop human resources and collection, and dissemination of information on medicines issues (World Health Organization, 2000).

Multiple Stakeholders Involvement in Formulating Essential Medicines Policies

Essential medicines strategies are developed and finalized in consultation and coordination with the range of stakeholders including governments, legislative bodies of the member states, WHO collaborating centers, WHO Expert Committees, the broader UN family, NGOs, and other global organizations (Shao et al., 2015). According to researchers, the present essential medicine system requires collaboration of stakeholders, and it would have positive impact if majority of its stakeholders contribute toward essential medicines operating system (Hui, 2011).

Stakeholders concerned with the essential medicine operating system are categorized on the basis of three key traits: power, legitimacy, and urgency. The "power" is the aptitude to instigate societal and political forces. The "legitimacy" is assembled by both normative legitimacy (having a fairness based on moral responsibility) and derivative legitimacy (stakeholders whose actions could influence normatively legitimate stakeholders) (Philips, 2003). The "urgency" is comprised of sensitivity (extent to which administrative delay is objectionable when dealing with the claims) and criticality (the significance of the claims to the

Figure 3 Classification of stakeholders involved in essential medicines policy.

stakeholder). On the basis of these three key traits, stakeholders could be categorized as dominant stakeholder, definitive stakeholders, dependent stakeholders, dormant stakeholders, dangerous stakeholders, or discretionary stakeholders (Mitchell et al., 1997; Shao et al., 2015) (**Fig. 3**).

Pharmaceutical Industry and Distribution Enterprises

Pharmaceutical manufacturers and distributors are dangerous stakeholders in the system, and are possible threats not only for the reason that they lack legitimacy but also because the medicine policies reduce their profits. It is also considered that the benefits of EMP are uncertain for them; however, they can earn profits by supplying medicines. However, industry can negatively impact EMP, if it started working against it (Management Sciences for Health, 2012; Shao et al., 2015).

The Role of Government

According to the Lancet Commission, government can take actions to ensure access, affordability, quality and safety, improved use, and availability of essential medicines. Access to medicines can be ensured through provision of adequate finance and addition of

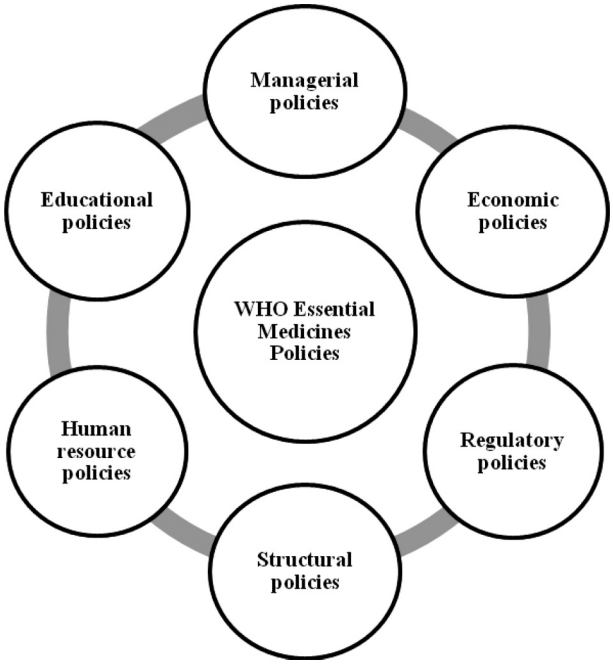

Figure 4 WHO essential medicines policies.

essential medicines in health insurance schemes. The quality and safety is ensured by adopting good procurement practices. The government can develop self-governing pharmaceutical analytics units that work in collaboration with other stakeholders to encourage quality use of medicines. Government also needs to give priority to policy framework for global research and development (R&D) of missing essential medicines, including its financing mechanisms (Wirtz et al., 2017).

Impact in a Globalized World

Access to basic medicines is the fundamental human right (Haque, 2017). However, there are millions of people who cannot access medicines (Lozano et al., 2012; Murray et al., 2012). Almost 10 million deaths globally [4 million in Southeast Asia and Africa alone (Zarocostas, 2007)] can be avoided every year, if access to essential medicines is improved (Guan et al., 2018); however, ensuring access to essential medicines is challenging in LMICs (Kaplan and Mathers, 2011). The HAI and WHO consider 80% availability of medicines as satisfactory in any given country (Kotwani, 2013).

Currently, four out of five countries globally have their own national EML (World Health Organization, 2016). Implementation of EMPs is known to save lives, promote rationale use of medicine as well as improve prescribing (Chao et al., 2018). It also improves detection of adverse drug reactions (ADRs), treatment compliance and reduction in antimicrobial resistance, and lowers prices through effective procurement policies (World Health Organization, 2000; Management Sciences for Health, 2012; Bandameedi et al., 2016).

In 2014, a 54-developing and transitional country analysis revealed overall six domains (**Fig. 4**) of EMPs associated with the better quality use of medicines. These include educational policies (initiation of undergraduate training and continual medical education of doctors and other health care professionals), managerial policies (revision of national EML and STGs, and implementation of generic prescribing and substitution), and economic policies (public health insurance, free supply of essential medicines to patients at all levels of healthcare).

This also includes regulatory policies (restriction on the availability of over-the-counter antibiotics and injections, active ADRs monitoring, and regulation of pharmaceutical marketing), structural policies (drug and therapeutics committees, and presence of national drug information center) as well as human resource policies (no prescribing by untrained staff). These policies were associated with the better use of medicines (Holloway and Henry, 2014). Among these, undergraduate training of doctors and nurses in STGs, unrestricted supply of free medicines to patients, and promotion of rational use of medicines through the MOH based regulatory unit were linked to the quality use of medicines (QUM). (Holloway and Henry, 2014).

Impact of Essential Medicines Policies in Low- and Middle-Income Countries

After the successful implementation of EML in LMICs, availability of essential medicines is a priority. According to a global report, EMPs have been successfully implemented in many low- and lower-middle income countries (Bazargani et al., 2014).

Implementation of the EMPs has resulted in easy availability, better affordability, and quality use of essential medicines in LMICs, but still, there are gaps in regulating medicines prices and improving their affordability.

Among Asian LIMCs, Bangladesh was very successful in launching and implementing an essential drug list in 1980s; however, it slowly deteriorated (Government of Bangladesh and United Nations Country Team, 2005; Islam, 2008; Ahmed and Islam, 2012; Akter et al., 2012; Islam et al., 2017).

A recent Indian study highlighted the need for revision of pricing policies to improve availability (Sarangi et al., 2018). Implementation of national EML also improved prescribing patterns and use of medicines in Malaysia (Saleh and Ibrahim, 2006). However, it was observed that effective price control is needed to control the high drug prices in the country (Babar et al., 2007; Ahmad and Islahudin, 2018).

Before 1993, medicine supply chain system in Pakistan was non uniform (Atif et al., 2017). Introduction of EML concept in the country made an impact and as a result the availability of essential medicines in public healthcare centers improved (Atif et al., 2016a,b). Though there are challenges related to high prices, affordability, and use of medicines (Saleem et al., 2016; Atif et al., 2016a, Saqib et al., 2018) as well as prioritization of research, including in-depth surveillance, promotion of rational prescribing practices, and a rationale pricing policy to promote access and use of medicine in the country (Zaidi et al., 2013; Atif et al., 2017).

In Nigeria, the overall prescribing pattern, utilization, and availability of essential medicines have improved after the introduction of essential medicine concept (Adebayo and Hussain, 2010; Oyeyemi and Ogunleye, 2013; Bazargani et al., 2014; Abdu-Aguye et al., 2016). According to recent reports, access to essential medicines was high in healthcare facilities and the prescribers had satisfactory awareness. However, prescribing practices were poor indicating gaps in the policy implementation (Hassan et al., 2018; Oghuvwu et al., 2018).

In Ethiopia, introduction of EML led to increased medicine availability and improved prescribing practices; however, medicines affordability did not improve (Lindtjorn, 1987; Carasso et al., 2009; Sado and Sufa, 2016). A recent Ethiopian study revealed lower availability and affordability, and high price for essential medicines (Abrha et al., 2018). In South Africa, cautious selection of a limited number of essential medicines and better medicine management resulted in improving quality of healthcare (Perumal-Pillay and Suleman, 2016).

In Mexico, EML is no longer evidence based; there are no uniform guidelines on the selection of essential medicines. Instead, economic and political interests influence the policy (Rivas, 2011; Lopez, 2018).

In Brazil, compromised quality, high prices, and inadequate availability of essential medicines represent flaws and inefficiencies of the national medicine policy (Naves Jde and Silver, 2005; Nogueira et al., 2011; Magarinos-Torres et al., 2017; Osorio-de-Castro et al., 2018).

The Use in High-Income Countries

Healthcare systems in high-income countries (HICs) also utilize selective medicines (from WHO's essential drugs) for effective allocation of resources (Gustafsson et al., 2011), though this is a concept intended essentially for resource-limited nations (Wirtz et al., 2017).

Managing EML is quite easy in high-income countries owing to their better healthcare systems and health insurance schemes (Cameron et al., 2009; Wagner et al., 2011). High-income countries implement health technology assessment (HTA) to evaluate cost-effectiveness of medicines. This is in turn useful for reimbursement and funding decisions in regard to medicines (Lexchin and Mintzes, 2008; Clement et al., 2009). Examples of these organizations are Pharmaceutical Management Agency of New Zealand (Pharmac), the Pharmaceutical Benefits Advisory Committee (PBAC) in Australia, the Scottish Intercollegiate Guidelines Network (SIGN) in Scotland, and the National Institute for Health and Care Excellence (NICE) in the United Kingdom (Duong et al., 2015).

In 2000, the National Medicines Policy was introduced in Australia with emphasis on the "quality use of medicines." The NMP has been successful in improving the healthcare needs of the population (Yoongthong et al., 2012).

The introduction of essential medicine concept in Saudi Arabia has reduced the cost of medicines and improved prescribing practices (Al-Mazrou et al., 1990; Almalki et al., 2011). A Canadian study has estimated 28% reduction ($4.27 billion savings per year) in expenditure from universal public coverage of essential medicines (Morgan et al., 2017). In Europe, implementation of EMP resulted in rational use of antibiotics (Mölstad et al., 2008; Huttner et al., 2010).

Implementation of Change in Pharmacy Practice

Michael J. Rouse[*], **Arijana Meštrović**[†], [*]International Services Accreditation Council for Pharmacy Education (ACPE), Chicago, IL, United States; [†]Pharma Expert Consultancy and Education, Zagreb, Croatia

Change Management

Change management is the process that guides how we prepare, equip, and support individuals to successfully adopt change to drive organizational success and outcomes. It is the systematic approach and application of knowledge, tools, and resources to deal with change effectively and in accordance with the desired timeline (Society for Human Resource Management, 2018).

Change is defined as a modification to a previous situation (Grand dictionnaire terminologique), and it could occur on an individual, organizational, institutional, national, regional, or global level in different aspects of pharmacy practice, regulation, and education.

Change management is extensively described in the literature and in various publications. In PubMed, change management is mentioned in more than 100,000 publications (Pubmed, 2018), but fewer than 3000 publications are related to the pharmacy profession, including changes mostly in industry, technology design, protocols in collaborative practice, chronic disease management, clinical services, and education. One recent publication presented 16 authors as a source of reference in the field of change management. This review provided a brief theory statement, description of models, and possible methodology of changes that could be adopted (Guérin et al., 2015).

In all publications, key elements described are communication processes, strategy, goal setting, organizational culture, leadership, conflict resolution, as well as barriers and facilitators of the change process in general. It is evident that change is influenced by the vision of the leaders and stakeholders as well as human resource management. As a dynamic entity, change management is seen as a tool to be used to achieve the goal set in the vision of an individual, organization, or nation.

When change is attempted in any organization or system, there are four distinct possibilities in terms of the outcome: it never gets off the ground; it occurs but undershoots the level originally planned for (suboptimal); it achieves focused "pockets of excellence" but no more; and it achieves pervasive and sustained change at the desired level (Vlasses, 2012). Another way to consider the typology of change is the depth and pervasiveness of change achieved. This is depicted in **Fig. 1** (adapted from Eckel et al., 2001).

In this chapter, some of the aspects of change management will be described in a format that is intended to be useful in implementing change in the pharmacy profession.

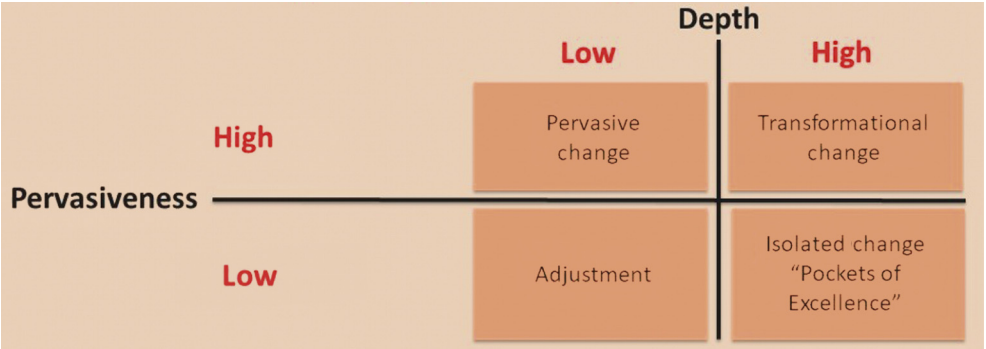

Figure 1 Typology of change.

Perception of Change Management in Pharmacy Practice

The change process in the pharmacy profession is usually observed and perceived as a slow, long, and complex process, involving different barriers and challenges. (Tsuyuki and Schindel, 2008) Different factors influence change in pharmacy practice, such as environmental, contextual, and personal/psychological aspects of change. Strong traditions in the profession, as well as strict regulatory frameworks, influence the dynamics of change, frequently resulting in long discussions and procrastination in the change process.

Many pharmacists will declare the need and desire for change to happen, but not so many are ready to change their habits in learning, practising, and approaching the issues in the pharmacy profession (Bellanger and Shank, 2010). Even if new opportunities, such as new services and roles, are occurring, resistance will often come from within the profession, as well as outside it. More complexity is added considering the fact that many different stakeholders are interested and involved in the change process in pharmacy, advocating for their own perspectives and goals. There are strategies and methods to lead the process of stakeholder involvement and influence the change process (Roberts et al., 2003). Providing support for practice change in a structured and organized way will endorse the process of change and assure the success of the desired vision (Gregory et al., 2017). Leading the change process requires a sensitive approach, strategic planning, leadership skills and dedication, commitment to change, and social intelligence. By knowing and applying some theory behind change management and following some of the available concepts, change in the pharmacy profession should be possible and realistic.

What is Changing in Pharmacy Practice?

Many aspects of pharmacy practice are changing. Products are no longer in the center of pharmacists' attention; they are now seen more as a part of the solution, responding to patients' needs. Cognitive services are developing and emerging as a new way to achieve patient goals and improve the safety and outcomes of medication use, adding value to the pharmacist's role and responsibilities in health-care systems.

Technology advancements are reflecting on pharmacy practice in many ways, from robotic procedures to IT tools and applications for patient use and safety. Data collection, documentation, and interpretation are now part of everyday practice, resulting in growing research and publications in the pharmacy practice field. The communication culture is changing, e-health is available in many regions, providing new opportunities to share and use health-related information in fast and effective ways.

Screening tests, point-of care services, various risk assessment methods, prevention programs, and public health campaigns are changing the face of pharmacy practice, in hospital and community pharmacy, and other practice settings. New services, such as seasonal immunization, pharmacogenomics, home and annual medication review, visits to pharmacies are requiring new knowledge, skills, and attitudes, as well as new approaches to education and training of pharmacy practitioners, including pharmacists and pharmacy support personnel.

Changes in pharmacy education are emerging in many different countries, led by professional organizations, academic institutions, and innovative leaders. New strategies and goals have been set on a global level to build capacity and foster and promote changes in educational activities and methods to achieve the desired competencies of pharmacy practitioners (FIP, 2017).

The pharmacoeconomic aspect of practice is playing a bigger part in health politics and strategies, with great impact on financial savings in health care. Collaboration with other health-care professionals is growing, including joint services with medical doctors, nurses, nutritionists, physiotherapists, and others. Often, changes in regulation are slower than changes in practice, which causes procedural gaps and lack of unity in the profession (Bader et al., 2017).

Who is Involved Into the Process of Change?

Stakeholders are people or organizations with a direct or indirect interest in the process and outcomes of the exercise or project, whether positive or negative. A stakeholder should also be thought of as any individual or group who can affect or is affected by the actions, decisions, policies, practices, or goals of the project. Stakeholders involved in pharmacy practice are many. While varying in the degree of influence on and support of change, they have an interest to be involved, either to facilitate change and make it successful or to block it. Depending on the nature of the change, sometimes the same stakeholder group might have different roles and levels of support, including opposition. For each stage of the change, it is essential that all key stakeholders are identified and, as appropriate, consulted and given the opportunity to participate (e.g., in discussions, planning and decision-making, in a pilot project, in data collection and interpretation) or, at a minimum, kept fully informed.

Stakeholders will differ in a number of important characteristics: their mission and goals, motives, needs, interests, expertise, resources, and focus can be different. It is important to understand these issues before starting to develop engagement strategies to include them in the change process. Additionally, it is necessary to prioritize efforts to ensure that energy is directed at the most appropriate stakeholders.

Stakeholders' Support

Stakeholders' support of the proposed change can be high, low, unknown, mixed, or even outright oppositional in certain cases. One example of an important stakeholder when considering changes—especially expansion—in pharmacy practice would be medical doctors as a group. If the change is focused, for example, on pharmacists' services to improve patients' adherence, they would probably be supportive and influential in helping to achieve that change. On the other hand, if the change relates to immunization as a new role for pharmacists, they might be less supportive or even actively engaged against the change to happen. What can also be the case is that under one stakeholder group, the level of support may differ on an individual-by-individual basis; for example, some medical doctors might support measuring blood pressure in the pharmacy, some might be against that change, some might be undecided. In this case, different engagement strategies would be needed with each subgroup.

Stakeholders' Power and Influence

Before initiating change, it is very important to recognize who the stakeholders might be, to understand their motives and goals, and try to predict how influential (powerful) they are to facilitate or block/impede the proposed change. It is helpful to be well informed about the scope of their responsibilities, as well as their defined mission, so as not to be surprised during the ongoing process of change, if they need to react, give permission, or postpone the decisions and processes of change. It is also important to understand the hierarchy between them and to identify the paths of the change process in order to be successful and complete the change within the desired timeframe. Additionally, it is essential to be aware of the organizational structure of the institutions, channels, and protocols for communication and the time needed to secure required permissions, documents, etc. This might depend on the frequency of important meetings and/or deadlines and procedures in the institution; recognizing that any request will likely compete with other priorities and urgent situations.

It should not be assumed that all stakeholders who offer to be involved in the change management process are supportive. Some stakeholders will want to maintain the status quo, and they will participate primarily to resist change and ensure that their point of view is heard. This group can come from so-called "opinion leaders," who can be very slow in accepting and embracing the changes in their field, especially if they did not come up with the idea or initiate the change.

In the pharmacy profession and practice, we can identify the following stakeholders who might be involved in the change process (**Table 1**) (Mendelow, 1991; Savage et al., 1991): .

Stakeholder Matrix and Engagement Strategies

Once it is known who the stakeholders are, the next step in the change management process is to map them into a stakeholder matrix, according to their level of support and ability to influence (facilitate or block) the desired change (**Fig. 1**). When those two criteria are combined, it is possible to assign stakeholders into typically one—but sometimes two—of the following four boxes (**Fig. 2**):

The statements allocated under each group of stakeholders indicate the essence of the engagement strategies and action plans to involve stakeholders in the most appropriate way. In more detail, those strategies could include, but are not limited to:

1. *Partnering with stakeholders of high influence and high support* because the connection is natural, goals will be aligned and collaboration should realistically lead to successful change and a win/win outcome. When the stakeholder shows high support, the platform for collaboration is open for inclusive participation, shared responsibilities and resources, and combined expertise as there are no threats in the process. Creative ideas and solutions might be presented and accepted within these partnerships.

Table 1 Stakeholders who might be involved in the change process

Governmental (national/state/provincial) institutions:
- Ministry of Health
- Ministry of Higher Education
- Medicines Agency and other regulatory bodies
- Institutes of public health
- Health insurance organizations
- Accreditation agencies/councils

Professional bodies
- Pharmaceutical Chambers (mandatory membership)
- Pharmaceutical Societies (voluntary membership)
- Institutes for quality improvement

International organizations
- International Pharmaceutical Federation (FIP)
- World Health Organization (WHO)
- Regional professional and educational organizations
- Regional pharmaceutical advocacy/trade groups

Pharmacy practitioners
- Hospital pharmacists
- Community pharmacists
- Clinical pharmacists
- Pharmacy assistants
- Pharmacy technicians
- Preceptors
- Pre-registered practitioners

Other health-care professionals (and their professional organizations)
- Medical doctors in general practice
- Medical doctors in specialty practice
- Nurses
- Engineers of medical biochemistry
- Laboratory practitioners
- Nutritionists
- Physiotherapists
- Other health-care professionals
- Interprofessional organizations

Academia and other providers of education, training and credentialing
- National, regional, or international associations of colleges/faculties of pharmacy
- Professors and faculty members
- Researchers
- College/faculty of pharmacy administration
- Students and students' organizations
- Teacher practitioners/preceptors
- Providers of continuing education/continuing professional development
- Credentialing bodies, for example, specialty certification bodies
- Trainers and coaches in pharmacy practice

Patient organizations
- Organizations for the patients' rights/advocacy
- Organizations of special interest groups of patients

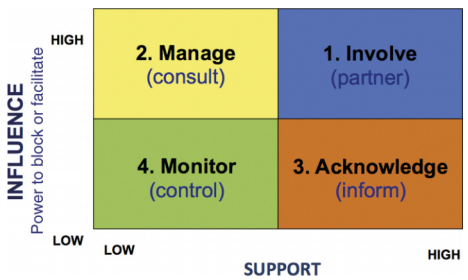

Figure 2 A stakeholder engagement matrix.

High influence will open the opportunities to achieve the results earlier than expected, and efficacy could be high. Also, when leaders of change cooperate with highly influential and highly supportive partners, motivation is high, and engagement is more intensive. That leads to good results to be presented and followed by new actions and procedures. Showing publicly the influential partners' support will change other stakeholders' perceptions of the change. The engagement strategy of active involvement aims to ensure that the support of the stakeholder remains high. Regular meetings with partners must be held to establish implementation project parameters and strategies, define success criteria, identify potential constraints or barriers, review and agree on key issues, and establish a mechanism for early "flagging" of problems.

2. *Managing the stakeholders of high influence, but low support* will take lots of energy and strategic thinking by the leaders of change. The reason for this is that highly influential stakeholders will have power to block the change, delay its realization, or limit its scope. If the stakeholders in this category have low or unknown support, it is essential to include them in the process in a way that they can openly express their concerns, suggest possible solutions, and choose between possible options to maintain their authority and interest. The strategy has to be designed to increase their support and ultimately involve them as partners in the change. These stakeholders need to see that change managers are following their instructions, asking them for guidance and contribution, and creating opportunities for a true partnership. For this stakeholder group, it is important to demonstrate the value of change, either for them directly or for those they represent to achieve more support and engagement. Change might have political implications, such as election results; therefore, it could be part of strategic thinking on a higher level. Once a few influential stakeholders with initial low or unknown support are convinced, other important stakeholders might follow in showing more support.
3. *Acknowledging the stakeholders with high support and low influence*. A high level of support for change is always welcome, but it will not necessarily lead to realization and sustainability in practice. Many stakeholders who can contribute to the success of change could come from this group (e.g., students, practitioners, patients, and educators), but if the change process is too slow and not promising, the stakeholders might lose interest and slow down their engagement activities and support. Change leaders must clearly communicate to these stakeholders the nature of and rationale for the change and regularly inform them of progress and results.
   It is very important to acknowledge the support and contribution of these stakeholders, not just at the time of their engagement, but also in later stages, when first results are starting to be visible. Once the change is achieved, it is appropriate to keep this group engaged, visible and recognized, as their influence might be crucial in other projects and changes in the future. The essence of the engagement strategy is to ensure that their support remains high. If the level of support drops, there is a risk that the "influence" of this group can increase indirectly through their advocacy efforts with those who hold real power to block or limit change.
4. *Monitor the stakeholders with low support and low influence.* The contribution to the change process of this group of stakeholders might be underestimated, as they might not have the power to stop or block change, but they could slow down the process of change and bring confusion to the active partners on the process of change. If not "controlled" this group of stakeholders can become a distraction and consume valuable time and effort. It is, therefore, good to monitor their activities carefully to ensure that they do not become a distraction for the change management team. The engagement strategy is to find ways to increase their level of support and involvement if possible because, as with Group 3, there is a risk that their "influence" can increase indirectly through their advocacy efforts with those who hold real power to block or limit change.

Some authors have suggested a more detailed approach to stakeholder engagement, implying that change initiatives can be evaluated using six factors (Peltokorpi et al., 2008):

- the effect of the planned intervention on stakeholders' actions and position;
- stakeholders' capability to influence the project's implementation;
- motivation to participate;
- capability to change;
- change complexity; and
- management capability

Traditional methods of sociodynamic profiling are also found to be useful as an analytical management approach to manage stakeholders in projects that are likely to experience high resistance to change. Stakeholder engagement mechanisms can cause some projects to fail or succeed, depending on the acceptance of the stakeholders' approach, but improved stakeholder communication methods can create a better understanding of resistance to or acceptance of change (Walley, 2013).

Practical Application of a Stakeholder Engagement Matrix

In summary, when a major change or project is envisioned, a stakeholder engagement matrix can serve as a simple but useful tool for the change management team, by following these steps:

1. Identify *all* stakeholders who are important to the change/project.
2. Assign each stakeholder to one or more of the groups described above (1. Involve; 2. Manage; 3. Acknowledge; and 4. Monitor) remembering that individuals of a particular stakeholder group (such as physicians) may have different levels of support and, therefore, could be assigned to different groups.

3. Develop engagement strategies based on the level of influence and support, with priority attention for early action being given to the key stakeholders in Groups 1 and 2.

The Eight Step Process of Successful Change

One of the most successful and popular approaches to change management is the theory of change published by John Koetter (Koetter and Rathgerber, 2006).

This approach can be applied in eight stages, as follows:

Set the Stage

1. Create a Sense of Urgency
   This first step to achieve the desired change needs to be strategically planned and prepared to ensure that the message is communicated in the right way, in the right place, and to the right people. The aim of this step is to help others see the need for change and the importance of acting immediately, or as soon as possible. When it comes to change, it's human nature to procrastinate and wait until circumstances are "ideal." Communications should be affirmative, informative, and carefully articulated, to be heard and clearly understood. A sense of urgency can be strengthened by adding important statistical or financial facts, showing the trends and projections of the unwanted scenario; for example, what will happen if there is no change? What are the consequences? Sources for such facts should be reliable and well checked, preferably endorsed by important and influential health-related organizations, such as, the World Health Organization (WHO) or important, well-recognized recent publications. The communications should be reinforced through the use of multiple methods and media formats at the same time (news, leaflets, social networks, etc.). Those messages could be a part of ongoing, well-timed public health campaigns, government initiatives, national, regional, or international strategic plans to immediately assure strong and well-recognized partners to reduce costs and multiply results.
2. Pull Together the Guiding Team
   The leader of the change needs to ensure that there is a powerful group guiding the change—one with enthusiasm, leadership skills, resilience, credibility, assertive communications, strong authority, good analytical skills, and a sense of urgency. The guiding team should be carefully selected, to assure a smooth process of change initiation, including affirmative atmosphere, inclusive approach, and participatory leadership. Responsibilities should be well-defined and shared, timelines set, and goals clearly visible to all members of the team. Communication should be carefully planned until the plan is ready to be announced.

Decide What to Do

3. Develop the Change Vision and Strategy
   The most important part of this stage of the process is to clarify how the future will be different from the past, and how that future could become a reality. Building the mind-map is one of the strongest accelerators to acceptance of the change in the mind of the target group. This is when marketing strategies and project planning will take place, including economic, clinical, and humanistic aspects of the change. In particular, possible benefits and results should be announced and accepted. Strategies to be adopted should demonstrate win-win situations to include and engage important stakeholders, especially targeting patient safety and outcomes, which can lead to financial savings in the health-care system, more efficient operational procedures, and sustainability.

Make It Happen

4. Communicate for Understanding and Buy-In
   In the third phase, which is connected to realization, it is important to make sure that as many others as possible understand and accept the vision and the strategy for the desired change. It is crucially important to design communication strategies to avoid any misunderstanding in this early implementation phase. Communication here includes stakeholders (with different strategies to engage them) and a process of announcements in the health-care system. Benefits for each stakeholder group and/or their constituents as well as the health system as a whole should be clearly described. In addition, the different roles and valuable contributions that specific stakeholders can make during implementation should be highlighted. Authors and deliverers of these messages should be well prepared to address all possible concerns and questions with evidence-based facts and published resources.
5. Empower Others to Act
   In this phase, it is important to remove as many barriers as possible so that those who want to make the vision a reality can do so. Education and training activities are essential here, including toolkits for application and evaluation of the

change process. All questions and concerns should be answered in this stage, building capacity and leading to the first results.

6. Produce Short-Term Wins
   In the change process, some visible, unambiguous successes should be assured as soon as possible. Establishing simple projects and objectives ("low hanging fruit") and collecting early evidence of success will assure a firm start and solid foundation and encourage and motivate stakeholders, leading to further success. On the other hand, setting unrealistic and over ambitious objectives may result in failure to achieve the desired results, lead to discouragement and demotivation of stakeholders, and provide an opportunity for cynics and naysayers to denounce the change. If possible, the success should be celebrated, champions recognized, and results published to advocate for the further developments and visibility of change. In this stage, some stakeholders can increase their level of support and join the efforts to bring the project to a higher level. It is important to communicate with them the further steps and strategies and to find a place where they can contribute to the process of change.
7. Don't Let Up
   Many good initiatives end after the first successes (e.g., adoption by "early adopters" or champions) or even earlier. This does not necessarily mean that there was a problem with the idea behind the initiative. After the early successes, there is a "gulf" (see later discussion in this chapter) when leaders of change should press harder and be relentless with implementing the change until the vision is a reality. It is crucially important not to disappoint the leading team and to not allow the initiative to "die" after the first promises have been fulfilled. There are many strategies to be used in this stage of the change process, such as, fostering publications, panel discussions, announcements of national projects, organizing educational programs, and meetings to inspire others to act and be a part of success.

Make It Stick

8. Create a New Culture
   This is the time to hold on to the new culture and new ways of behaving and make sure they succeed until they become strong enough to replace old traditions. New regulations can help here, if it is possible to change requirements and demand implementation of new services, new principles, and new standard operating procedures. The new culture should be promoted and visible, as well as set as a new standard to follow. This empowerment can be organized at institutional and organizational levels, to assure the clarity of standards and to avoid improvisations and failure.

Pilot Project to Manage the Change

A *pilot project*, *pilot test*, or *pilot experiment* is a small-scale preliminary project conducted to evaluate sustainability, feasibility, resources and materials, timeline, costs, and possible outcomes of the project that will introduce the change. The main purpose of piloting the project is to identify gaps and barriers of implementation, to improve the study design and/or appropriateness of materials and resources prior to full implementation of the change. Some stakeholders might like to wait until a pilot project has shown preliminary results to be fully engaged, which is also one strategy to consider when selecting partners for the project. The pilot project also needs to be properly designed, strategically planned, and include different aspects of implementation. If possible, indicators of successful implementation should be in place to allow improvements and check points (Billé, 2010).

Individual Response to the Change Process

Every change will have an impact on the individual level, for all participants included in the change process. The impact of change in different organizations or at the national level might have different responses from different groups of people. Research indicates that individuals find it difficult to engage with change in a meaningful manner as stress, fear, and anxiety prevail; therefore, a strong strategy in change management is required to assure change implementation and sustainability. Leadership must help individuals to accept the change and to adjust it in everyday practice with visible meaning and reasoning about the benefits of the change. The eternal question "Why do we need the change now? Why should it affect me?" should be addressed by well-organized strategy and planning, to avoid negative individual contributions (Vakola, 2014)

Rogers' Innovation Adoption Curve

One of the most cited and used models in explaining innovation adoption is Rogers' innovation curve, which portrays different group of people in their responses to the proposed change. Researchers have studied why some innovations spread more rapidly than others and which are slow in implementation. If the perception is that the innovation will be advantageous, compatible with existing values, beliefs, and experiences, relatively easy to comprehend and adapt to, observable or tangible, and divisible for trial, it is more likely to be adopted (Rogers, 2003).

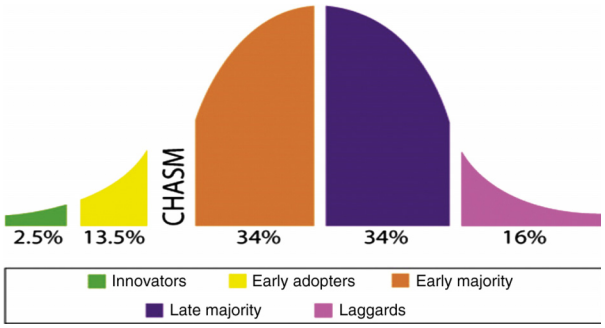

Figure 3 Rogers' innovation adoption curve.

Rate of adoption is described as the relative speed with which members of a social system will adopt an innovation. It is measured by the length of time required for a certain percentage to adopt an innovation and change. The dynamic is slow until the change adoption reaches the so-called "tipping point," at which time/point an innovation reaches critical mass and turns into a self-sustaining process to make change stable, effective, and visible (Fig. 3).

Innovators are people who will adopt change first; they could even invent and suggest change, bearing the need to describe the outcome and impact of innovation. They comprise 2.5% of a typical population. Considering pharmacy practice, they will need to adjust innovations to the existing law-frameworks and pharmacists' scope of practice, usually trying to fit into existing practice models. They are creative, affirmative individuals or groups, who will always investigate options and opportunities to improve practice and advance the roles of pharmacy practitioners. Usually, they belong to younger generations and highest social class, have the closest contact to scientific sources, and interaction with other innovators in their field. They are willing to take risks and initiate the change process under any circumstances.

The second fastest category of individuals who adopt an innovation is *early adopters* (13.5% of a population). They are easy to include in the process of change. Even though they didn't suggest or initiate the change, it will be easy to persuade them. They have the highest degree of opinion leadership, higher social status, advanced level of education, and willingness to try.

The next category would adopt an innovation after a varying degree of time. The time of adoption is significantly longer than with the innovators and early adopters. This group represents the *early majority* (34% of a population). These individuals seldom hold positions of opinion leadership, but they are of above average social status. To include them in the process of change, it would be helpful to introduce incentives and to explain clearly how the change will benefit them. They like to see large numbers of stakeholders supporting the change to be more convinced that change is important, realistic, and needed.

The *late majority* (34% of a population) are typically highly skeptical and will not be easily convinced that there is any need to change. They are likely to express that they have some reservations, not being sure that the change will work in real practice. In this group, members will adopt the innovation after they observe that it has been adopted by a majority of the population. Members of this group typically have below average social status and have very little opinion leadership.

The group, which will be the last to adopt an innovation, demonstrates little to no opinion leadership. They are called *Laggards* (16% of the population). They like to stick to tradition and do things in "the good old way." The need for change is something they will typically not see. They will often only change when forced to by their employer or through regulation. They tend to be advanced in age, are very likely to have the lowest social status, and have a poor network of experts they can rely on and consult in certain situations. Their resistance to change in general could be applied directly and personally on the innovators and agents of change and cause conflicts and distraction to the change management process.

There are two important points in the rate of adoption. The first is positioned between the early adopters and the early majority. It is described as a "chasm" or "gap" to signify the difficulty of making further progress in the change process after the innovators and early adopters. It is also a warning to change managers to persevere in the process and apply more effort and resources. This is an important stage to maintain the process of change at the desired level and not to allow the change to be compromized and prolonged. If this point is not recognized, there will be delays in the change process, which can cause loss of motivation and engagement of the innovators and early adopters and may ultimately lead to a breakdown of the change process.

The second point is positioned between the early majority and the late majority. When 50% of the population has adopted the change, the dynamic of the change process alters and change happens by itself. This point is graphically portrayed as the top of the curve and it is named the "tipping point" for change. After that point, the change process should be irreversible, maybe even facilitated by regulation or other forms of requirement and standard procedures.

Managers of change should use existing tools to navigate the process of change in a structured, strategic, and efficient way, avoiding delays and obstacles. Other skills that are helpful in achieving the desired implementation of change include time management, organizational skills, strategic planning, assertive and motivational communication, risk management, marketing skills, public speaking, presentation skills, and IT literacy.

Barriers and Facilitators of Change in Scope of Pharmacy Practice

Innovation in pharmacy services is growing and shaping pharmacy future in a patient-outcome oriented way. According to the Good Pharmacy Practice (GPP) guidelines, pharmacists in community and hospital settings, as well as nursing homes and other tertiary care positions, should introduce new services in collaboration with other health-care professionals, to meet societal needs and embrace new roles and responsibilities (Joint FIP/WHO Guidelines on Good Pharmacy Practice, 2011).

All these changes are on the agenda of many professional organizations, regulators, and private initiatives, confronting the change management process with many internal and external challenges. In many countries, regulation is not clear about the competency level of pharmacists needed to provide new services, and there are inconsistencies between countries and regions in this regard. There is a critical question about credentials and privileges of different groups of pharmacists to assure that services are introduced in safe and standardized ways to patients. Levels of clinical experience and skills of pharmacists differ across the globe, including the generational differences due to various curricular changes and clinical aspects of educational programs offered over the last 20 years. All these aspects should be observed through change management aspects, ensuring many stakeholders are included in the process of implementation of new services and roles of pharmacists in practice.

It is important to understand that every practicing pharmacist has developed clinical reasoning and judgment to a certain extent, and that there is a requirement for all pharmacists to perform on a certain clinical level. Pharmacists who are specialized in some clinical areas (such as ambulatory care, pediatric care, oncology, etc.) will be able to introduce services on a different level but that does not mean that all pharmacists cannot embrace new roles and responsibilities.

Besides pharmacists' traditional roles to prepare, procure, store, secure, distribute, and dispense medicines and medical products, there is a new demand to provide rational pharmacotherapy. Based on GPP guidelines, that means that pharmacists should assess the health status and needs of the patient, manage medicine therapy processes, monitor the outcomes of the treatment and progression of the patient, and provide information on medications and treatment procedures to patient and carers.

It is also required that pharmacists in all settings should achieve excellence and continuous improvement in their knowledge, skills, attitudes, and values by planning and implementing continuing professional development to achieve new competencies.

There is also requirement to contribute to effective functioning of the health system and public health activities by informing and educating patients about medicines, prevention, and health through active involvement in prevention and treatment outcome procedures. All actions need to be in line with the national context, guidelines, and legislation, providing active support and promotion of national strategies that aim for good outcomes of treatment and patient safety (FIP/WHO Guidelines on Good Pharmacy Practice, 2011).

Cognitive Services and the Change Process for Their Implementation

Innovative cognitive services are needed in rationalization of medicine therapy and patient education. Cognitive pharmaceutical services can be defined as professional services provided by pharmacists, who use their skills and knowledge to take an active role in patient health improvement, through effective interaction with both patients and other health professionals. There is growing evidence of the effectiveness of implementation strategies that ensure that changes in this aspect of pharmacy practice are successful.

To foster the success of the change management process, it is important to recognize the usual barriers and facilitators of change and to account for them in the strategic planning and implementation process.

Services that should be introduced in the process of change should be based on an *interprofessional, integrated approach to the patient* and include collaborative practice. To facilitate change, the main stakeholders, such as medical doctors, should be not just informed but invited to partner in the change management process. If that is not the case, and pharmacists try to work in isolation they will become one of the biggest barriers of service implementation.

Furthermore, the *selection of services* to be implemented in pharmacy practice should be based on public health, patient education, adherence, and patient safety, care systems. They belong to the specific expertise of pharmacists, not interfering with other health-care professional services but contributing to efforts to achieve safe and effective use of medication. It is also important to choose a service based on the real and carefully examined *needs of patients* through interviews, surveys, and expert panels, alongside considering *patient satisfaction* with the services provided in the health-care system. Seasonal immunization, as one example, was successfully implemented in more than 40% of EU countries, based on the real need and satisfaction of patients. If the implementation of a new service changes the perspectives of patients, thereby increasing the expectations and demand for the service, that is a very strong facilitator of change, and it is important to continue with the change process. *Communication with and counseling of patients* can be a strong facilitator for service implementation, using the principles of motivational interviewing and active listening skills. Proper selection of a new service obviously can facilitate the change, as the need to implement it is easily recognized and welcomed in the health-care system.

One of the most important facilitators to implement a new service is *well-organized team work and shared responsibility* of the pharmacy team, utilizing their competencies and specializations in certain aspects of pharmacy practice. For full-service implementation, it is recommended to include *external experts* with skills and knowledge that are needed to facilitate the process of change. Those could be experts such as educators, consultants, designers, project developers, IT managers, lawyers, and marketing experts. One of the biggest barriers to change implementation is the perception that members of the pharmacy team can manage all these

aspects of implementation themselves. It usually takes much more time, costs are higher at the end of the process, and the result is not always on the level of excellence.

Clearly defined *standards and quality control* of service provision can facilitate change; therefore, it is important to ensure that the legal framework and regulatory issues are ready before implementation starts. Pilot projects are always recommended and needed and, as regulation processes sometimes can be slow, it is good to start with collecting evidence that a new service is effective, needed, and well received by patients. For these aspects of implementation, *IT tools and applications for data collection* and processing can facilitate the change but also be barriers to implementation, as many pharmacists will still prefer to collect data in traditional ways.

A solid and sustainable financial base for a new service implementation can also be a strong facilitator, as the benefits of the implementation will be assured and visible quickly. It could be perceived that providing services for free can be a facilitator for implementation success, and payment for services can be seen as a barrier but much evidence shows that in real-life situations that is not the case. Patients are ready to pay for services when they see and respect the value of the service. If the service is provided for free, it might not be perceived as so valuable by the patient. Pharmacists wondering why they have to provide extra work for no financial gain can be a strong barrier to embracing new roles and changes in practice.

Marketing tools are important facilitators for change management. Marketing activities directly involve inviting messages, calls for participation in new services, and making the change more visible and desirable in society. Messages and signs in the pharmacy windows and/or dispensing area, together with reallocation of service provision (to the consultation room for example), as well as space designation are strong facilitators of change. They help both providers and customers to see the difference between old and new systems and realize the benefits that new services can provide. Visualization of change is helpful to maintain momentum, especially when the early majority starts to buy into a new concept of care.

Referring back to Rogers' innovation adoption curve shows that it is important to understand that one of the most important facilitators of change is the *development and visibility of internal "champions" and accelerators of changes* within any system that is introducing change. Those individuals are important in the process and serve as positive role-models for other colleagues. They provide examples in real-life situations that changes are possible. Generative systems, open to change, will always recognize and invest in the development of those champions as part of the change management process. It is important to celebrate success and excellence in accepting new roles and responsibilities and then set new standards for the pharmacy organization and all its departments. Achieving impact on patient outcomes and safety is probably the strongest facilitator of change, as it fosters pharmacists' motivation and professional satisfaction, which results in more change in practice (Roberts et al., 2008).

All barriers can be analyzed on multiple levels within a system and externally. A systematic analysis of internal barriers can include, but is not limited to: current organizational culture of the pharmacy, lack of an internal implementation champion, lack of priorities and goals, inappropriate layout (including the lack of a counseling room), lack of appropriate technology and resources, and lack of bibliographic resources and medicines-information support/assistance. At the pharmacy staff level, lack of leadership, lack of staff awareness about the relevance of the service, lack of priority to implement the service, inadequate workflow, and lack of staff training to provide the service are identified as the major barriers (Garcia-Cardenas et al., 2016).

If new services are oriented toward models of collaboration with other health-care professionals, such as nurses, general practitioners, specialists, there is evidence that demonstrates what is successful when integrating changes into an existing primary care team. After the determination of the needs and priorities of the team and its patients, it is recommended to clearly communicate and explain new roles to the health-care professionals and to develop new and updated pharmacist job descriptions. Then, it is necessary to train and educate the team about the new roles and collaboration, including all members of the team. It is also important to ensure that clinic infrastructure supports the new pharmacist's role and to ensure that pharmacists' skills are strongly developed and their knowledge is up to date, so they can provide proactive care and take responsibility for patient outcomes. In the process, it is highly recommended to regularly seek feedback from the team, as well as developing and maintaining professional relationships with other team members in the health-care system (Jorgenson et al., 2013).

The change in pharmacy practice should be considered as an essential part of the quality improvement and advancement. It is necessary and possible. Despite many obstacles, there are tools and paths to be used to achieve the desired change, and change management is a competency of the pharmacists that should be developed and nurtured providing new knowledge, new skills, especially new attitudes, and values. All stakeholders in pharmacy practice, education, and regulation have shared responsibility to maintain the good collaboration and mutual support in this noble task, rather than working in isolation. Innovation is a category we have to consider essential to provide better care and assure best possible outcomes for our patients.

Professional Boundaries

Mohamed Hassan Elnaem*, Noha Alaa Hamdy†, *International Islamic University Malaysia, Kuantan, Pahang, Malaysia; †Pharos University in Alexandria, Alexandria, Egypt

Introduction

Professionalism is considered by the American College of Clinical Pharmacy as one of the six competencies of practitioner pharmacists that can be described by the maintenance of the highest standards of integrity and honesty in the pharmacists' relationship with their patients (Saseen et al., 2017). In addition, the credibility and trustworthy interactions of the pharmacist with students, trainees, colleagues, and other professionals represent another perspective of professionalism. These interactions should exhibit the values and behaviors of a standard professional practice. To maintain the highest standards of professional practice, it is necessary to define professional boundaries to prevent the intentional or unintentional breaching of these professional standards.

Understanding the professional use of the term "boundary" is paramount in clinical practice. Boundaries in professional relationships have been highly dynamic throughout the years. It has been reported that professional boundaries between the healthcare workforce components dynamically recognize the unavoidable interrelationships to achieve the goals of medical care (Nancarrow and Borthwick, 2005). Moreover, it is well established that health-care professionals should be trained to practice therapeutic relationships that enable them to utilize their knowledge, abilities and experiences to meet the patient's care needs (National Council of State Boards of Nursing, 2018). The challenge in the practice of therapeutic relationships that insufficient patient's involvement because of too rigid professional boundaries may potentially lead to disengagement and lack of patient's trust (Smythe et al., 2018). While exceeding the limits of these therapeutic relationships may lead to violations in the professional boundary (Manfrin-Ledet et al., 2015). Historically, the professional boundaries have been developed over time from no well-defined boundaries (the Apothecary model) to strict boundaries (the product-oriented practice) until reaching the era of the patient-centred care whose boundaries are dynamic to support therapeutic relationships that meet the patient's care requirements. The expansion of the pharmacist's role and evolution in the disciplines of pharmacy practice have shifted some boundaries by identifying new domains of work or by adopting roles usually carried out by other providers (Bidwell and Thompson, 2015; Nancarrow and Borthwick, 2005). Among health-care providers, the pharmacy profession has experienced remarkable growth and development (Pearson, 2007). Overall, it can be said that professional boundaries in the health-care system have been moving on a sliding scale (Hart, 2017) from no boundaries to strict boundaries, and then, opening doors, finding new roles, and switching responsibilities from day-to-day (**Fig. 1**).

By the early 1990s, Helper and Strand had introduced the concept of pharmaceutical care: "The responsible provision of drug therapy to achieve definite outcomes that improve a patient's quality of life." Consequently, pharmacists are recognized as drug experts, whose role is to act collaboratively with patients, physicians, and other health-care professionals to optimize the use of medications and health outcomes (Helper and Strand, 1990). The widespread increase in chronic diseases and their complications in parallel with the increase in life expectancy and the demand for a better quality of life place a burden on the overall health-care system (King et al., 2015). Furthermore, increasing health costs and rates of drug-related morbidity and mortality have led to a need to shift boundaries and change the scope of practice of health-care providers, including pharmacists (Macleod-glover, 2011). In addition, the emergence of a considerable number of drugs places a professional and ethical responsibility on the pharmacist to contribute effectively to the health-care system in terms of promoting the efficient and safe use of drug therapy (Bains, 2009).

In a Canadian study aimed to assess the perceptions of pharmacists, pharmacy students and the public toward the pharmacy expanded scope of practice, it was found that transition to patient-centred practice has raised public expectations and impose greater responsibility on pharmacists to collaborate effectively with other healthcare members (Schindel et al., 2017). Therefore, the dynamics of pharmacy professional boundaries have been changed to accommodate the different shaping of public expectations and the introduction of new responsibilities including medication reconciliation, medication therapy management, pharmacoeconomic studies and policy making.

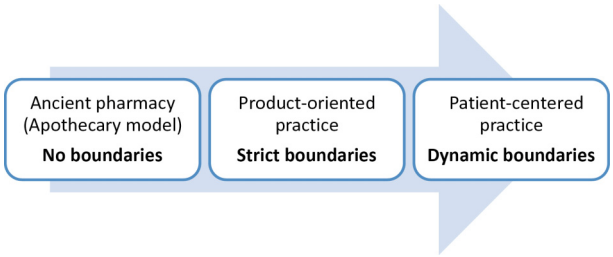

Figure 1 Professional boundaries progress in pharmacy profession.

The World Health Organization (WHO) and the International Pharmaceutical Federation (FIP) have framed new boundaries and expanded the roles of pharmacists to improve patient care and drug therapy outcomes (FIP and WHO, 2011). Moreover, collaborative prescribing by pharmacists has resulted in another shift in professional boundaries. Pharmacists, as prescribers, are empowered by a good professional relationship and mutual trust with doctors and other health-care providers (Lloyd and Hughes, 2007). The prescribing pharmacist's role is associated with many opportunities and responsibilities (Makowsky et al., 2013). These opportunities include improving patients' compliance and disease control, fewer drug interactions, better allocation of resources, reduction in patient waiting time, and increasing patients' access to medicines (Emmerton et al., 2005; Kay and Brien, 2004). The responsibilities are related more to the required additional and role-specific training such as physical examination and patient counseling (Dawoud et al., 2004). In summary, it is noticeable that the changing or evolving roles of pharmacists have contributed to a change in the dynamics of professional boundaries.

Patient-Related Professional Boundaries

The professional boundary with patients denotes the respect for the patient's psychological and physical integrity (Glass, 2003). Boundary violations can be defined as those actions that improperly disrespect patient's boundaries. These actions range from breaching the patient's privacy (e.g., disclosure of patients' information to unauthorized persons without their prior consent) to the extreme level where gross sexual exploitation is involved (Glass, 2015). Although this crossing of professional boundaries has been typically reported by patients against health-care providers as malpractice claims, it has also been reported by health-care givers as incidents against some of their patients (Bird, 2009).

The ethics that govern the pharmacist–patient relationship constitute the fundamental part of the ethical framework of the pharmacy practice. According to the code of ethics of the American Society of Health-system Pharmacists (ASHP), relationships with patients should be controlled by three main ethical principles in relation to the moral obligations, caring responsibilities, and respect of every patient's autonomy and dignity (ASHP, 2012). Moreover, the Australian Pharmaceutical Society (APS) has published a code of ethics that has been divided further according to the pharmacist's focus area such as patients, professionals, business, or community. A summary of the ethical principles relevant to the relationship between pharmacists and their patients from both the American and Australian codes of ethics are presented in **Table 1**.

Typically, the code of ethics provides general outlines that need to be abided by all practitioners. Nevertheless, many situations can be challenging for practitioners from an ethical perspective. At the beginning of a caring relationship with a patient, there are many views on identifying the proper ethical approach in accepting a gift from a patient who wants to show gratitude or even the initiative to help some cases through discounted service fees. It has been observed that accepting any form of informal relationship such as gifts, or making any sort of exception to a particular patient with regard to waiting time or service fees, is regarded as an early warning sign for the crossing of professional boundaries (Galletly, 2004). Therefore, a violation of professional practice ethics may occur if the practitioner is unable to identify the early warning signs of the crossing of professional boundaries. It can be argued that a

Table 1 Summary of the code of ethics relevant to the pharmacist–patient relationship

American Society of Health-system Pharmacists (ASHP) Ethical Principles
A pharmacist respects the covenantal relationship between the patient and pharmacist.
A pharmacist promotes the good of every patient in a caring, compassionate, and confidential manner.
A pharmacist respects the autonomy and dignity of each patient.
Pharmaceutical Society of Australia (APS) Ethical Principles
Pharmacists recognize the health and well-being of the consumer as their first priority.
Pharmacists pay due respect for the autonomy and rights of consumers and encourage consumers to participate in decision-making actively.

proper balance between expressing care, compassion, integrity, and trustworthiness on the one hand, and maintaining limits and boundaries on the other hand, is crucial for relationships with patients.

Furthermore, in a Tanzanian study designed to explore the views and experiences of pharmacy workers in providing treatment services related to sexually transmitted diseases among homosexual men, the phenomenon of stretching the boundaries was observed (Larsson et al., 2016). This study highlighted the concept of "Stretching Boundaries for Pharmaceutical Responsibilities" to describe the dynamic process of changing workers' experiences from limited to regular engagement with providing services to this population. Emotional motivation and financial interests were found to have effects on the dynamic change of professional boundaries. Furthermore, another work in the same setting was conducted to qualitatively explore the perceptions and experiences of this group of care seekers toward pharmacy services (Agardh et al., 2017). The findings underpinned the perceived barriers to accessing pharmacy care services as low. However, further initiatives to improve the knowledge of care seekers and pharmacy workers are needed.

A Romanian study also assessed the dissatisfaction of patients with regard to the professionalism of their medical staff (Popa et al., 2017). Two main domains were the cause of dissatisfaction in patients: the first domain related to the lack of a proper explanation regarding the treatment choices, procedures, and duration, which might affect the patient's sense of security. The second domain was linked to the poor communication skills of medical staff in that they usually do not introduce themselves. Some patients perceived this lack of good communication skills as a sign of disrespect. These findings highlighted that shortcomings in the professional capabilities of health-care practitioners create unnecessary boundaries with patients. Consequently, it should perhaps be recommended that all health-care institutions reassess the professionalism of their health-care practitioners in terms of their attitude and practices in facing the challenge of unnecessary boundaries due to a lack of professionalism.

Any health education program should have a process known as professional socialization, which includes some components that contribute toward equipping future practitioners with professionalism (Arndt et al., 2009). Schools of pharmacy should have a strategy to imbue their students with professional qualities such as honesty and integrity, responsibility, commitment to excellence, respect for others, and care with compassion. In a pharmacy school in the United States, the positive impact of the implementation of a co-curricular professional development program on the promotion of the professional identity of the students was investigated (Hoffman et al., 2017). This program can be a role model for other schools of pharmacy to design customized contents to instill a professional character in future practitioners.

Despite the development and testing of instruments to assess the behavioral professionalism of pharmacy students (Hammer et al., 2000), it is worth highlighting that the evaluation of professionalism is still a challenge because of the multifaceted concept of professionalism that relies on idealized traits. An evaluation of these traits should take into consideration their important values in professional practice to assure applicable and fair evaluation outcomes. It has been suggested that a more practical and explicit method of implementing the theory of a value-based practice would be to include its three pillars, namely, education, regulation, and teamwork, in the professionalism assessment (Ahmadi and Hasan, 2017). Nevertheless, it has been highlighted that professionalism should not be limited to certain defined behaviors, attitudes, or values but should go beyond these traits toward a holistic approach that focuses on the formation of a professional identity through experiential learning and the alignment of the curriculum with work practices (Mylrea et al., 2015).

Patient Preferences as the Focus of Professional Boundaries

Professional boundaries with patients refer to the apparent separation between professional behavior that meets the patients' health needs and the pharmacist's views and feelings (Pharmacy Board of Australia, 2012). Shifting the pharmacist's role to a patient-centered model enables them to spend more time with patients. Pharmacists interview and assess patients, make specific therapeutic recommendations, monitor responses to drug therapy, and provide drug information (Tietze, 2012). Therefore, in a patient-focused health service, the patients' preferences should be taken into consideration (Gerard et al., 2012).

Patients and pharmacists may have different views about the latter's role in the patient/practitioner relationship. Researchers have examined the opinions of patients and pharmacists about their relationships. They both share the concept that clear information increases a patient's trust in the pharmacist (McCullough et al., 2016; Worley et al., 2007). The patients' expectations include consistent patient care services, greater pharmacist participation, and a sense of being patient centered (Schommer and Gaither, 2014; Worley-Louis et al., 2003). Also, the patients' trust is affected by the type of experience they have had previously with pharmaceutical services, where a positive experience increases trust (Patterson et al., 2013). Moreover, the lack of acknowledgment of the pharmacist's role might affect their motivation level in performing their professional duty (Schommer and Gaither, 2014). In addition, it may be necessary to revisit the scope of the roles, responsibilities, and practices of pharmacists so as to adapt it to the existing opportunities for making better use of pharmacists in direct patient care (Schindel et al., 2017).

Another issue in research involving patients is that pharmacists should respect the right of patients to withdraw from a study without judgment and without compromising the pharmacist–patient relationship or the care of the patient (Pharmacy Board of Australia, 2012). Professional boundaries must be maintained at all times; if these are crossed, patients may lose trust and confidence in pharmacists (General Pharmaceutical Council, 2012). Patients have the right to be treated with dignity and respect by helping them to make their own choices through a shared decision (Duggan et al., 2006). This can be accomplished through effective communication using professional knowledge, skills, behaviors, with honesty, integrity, and respect for the confidentiality of patients (General Pharmaceutical Council, 2016). The attributes of pharmaceutical care services should guarantee the quality of

the professional–patient relationship and indeed, the continuity of care (Gerard et al., 2012). Policymakers should develop clear objectives for the quality of the provided services.

Boundaries with Health-care Professionals (Interprofessional Boundaries)

Professions are engaged in an ongoing and dynamic process involving the appraisal and adaptation of organizational, skills, and knowledge bases (Nancarrow and Borthwick, 2005). Each health profession has a predefined role that relies on other related professions in different degrees to facilitate a patient care process (Frank et al., 2015). Highly elastic boundaries induce overlap in the scope of practice among different health-care providers that might give rise to friction among team members and initiate disputes of health-care role boundaries among professionals (King et al., 2015; McNeil et al., 2013). It has been reported that those professionals who have had more experience and interaction with pharmacists have better perceptions regarding potential professional disputes (King and Ross, 2004; McNeil et al., 2013). Consequently, they are more likely to be engaged in a collaborative relationship, where the members are willing to delegate and share responsibilities (Doucette et al., 2005; MacNaughton et al., 2013). Furthermore, the key elements for a powerful collaboration, such as interdependence, perceptions, skills, and interests, have a significant impact on the boundary dynamics (Bardet et al., 2015).

It is thought that a further elaboration of the scope of practice and health policies of pharmacists can help to enable healthy team-based interactions. Also, policymakers are expected to support flexibility in the professional role and provide innovations in the provision of health care derived from the health needs of the society (King et al., 2015; Nancarrow and Borthwick, 2005; Schindel et al., 2017). This will consequently ensure a mutually effective, respectful, and clear communication, and an acknowledgement of the contribution of each practitioner involved in the care of the patient (Pharmacy Board of Australia, 2012). Therefore, immovable professional boundaries should be dynamically shifted based on health policies and in the light of patient-centered care (King et al., 2015). In this regard, interprofessional professionalism is a model linked to professionalism and teamwork that precisely emphasises an individual health-care professional's ability to practice collaboratively with other health-care professionals (Hammer et al., 2012).

It is a well-established fact that patient care is an all-inclusive process that requires collaboration with all health-care providers, including physicians, pharmacists, nurses, and other allied health-care professionals. The findings of a recent UK study showed that effective communication and cooperation between physicians and pharmacists can potentially increase the optimization of medications and improve patient safety in primary health-care settings (Bradley et al., 2018). The interactive relationship between many health-care providers from different backgrounds both facilitates and obstructs the achievement of a productive collaborative relationship. It facilitates in the sense that health-care providers are interested in collaboration, are aiming to improve the quality of patient care, and are making use of opportunities to identify potentially new professional roles. By contrast, the barriers to a productive collaborative relationship are the lack of awareness among health-care providers of each other's professional competencies, their concerns about confidentiality when sharing information, inadequate efforts toward setting a team-based mentality, and the planning of interprofessional training (Supper et al., 2014). According to the results of a qualitative study of the perceptions toward interprofessional collaboration between general practitioners and community pharmacists, shared trust and appreciation were identified as important influences on the quality of interprofessional interaction (Löffler et al., 2017). The findings highlighted that pharmacists are focused on their need for a well-defined and clear pathway for professional communication with physicians, while physicians value the potential professional contribution of pharmacists in the challenge of providing care to an increasing population of elderly patients and patients with chronic diseases.

Interestingly, the introduction of an interprofessional collaboration model that concentrates on predefined outcomes has had a positive impact on ensuring successful collaboration, while maintaining professional boundaries (Rathbone et al., 2016). Moreover, the determinants of a successful collaborative practice include trust, interdependence, awareness, and expectations with regard to the other health-care professionals, curiosity for a collaborative practice, role description, and communication (Bardet et al., 2015). These determinants can be the framework for any initiative aimed at maintaining good control of interprofessional boundaries in clinical practice. Furthermore, it is worth highlighting the significant association between the extent of collaboration between health-care professionals and the possibility of implementing the recommendations of a medication review process (Kwint et al., 2013). This finding is fundamental in assessing the potential impact of collaborative practice on the quality of patient care. Therefore, efforts and initiatives should be directed at facilitating interprofessional collaboration by addressing commonly perceived barriers and professional boundaries. **Table 2** presents a summary of the interprofessional boundaries with their relevant facilitating suggestions.

Professional Boundaries with Students with a Focus on the Emerging Role of Social Media

Social media has been utilized widely by pharmacy students, faculty members, and practitioner pharmacists in relation to facilitating pharmacy education and practice (Benetoli et al., 2014). However, there are reported cases where open use of social media could adversely affect professionalism such as describing opinions, feelings or attitudes toward patients, colleagues or faculty members even if they were kept anonymous. Therefore, the concept of e-professionalism has emerged to define a set of behaviors and attitudes that refer to the paradigm of professionalism through digital media networks (Cain and Romanelli, 2009).

Facebook provides an informal learning environment for expanding the learning content to involve current topics in the context of optional professional participation (Cain and Policastri, 2011). Moreover, the use of Facebook in pharmacy education shows

Table 2 Summary of interprofessional boundaries with its relevant facilitating suggestions

Concerns related to interprofessional boundaries	*Suggestions to overcome concerns of interprofessional boundaries*
Lack of awareness of one another's professional competencies	Early introduction of interprofessional education involving all health-care students.
Inadequate professional responsibility (sharing information & confidentiality).	Clear job description for each professional role with its relevant roles and responsibilities. Revisiting the pharmacist's roles, and responsibilities.
Lack of mutual trust and appreciation.	Health-care institutions should focus on initiatives that foster interprofessional trust and appreciation between all health-care providers in daily clinical practice.
Poorly defined communication framework between physicians and pharmacists.	Health-care policy makers should take initiatives to regulate professional communication between physicians and pharmacists.
The need for setting team-based mentality and planning the interprofessional training.	Future medical and pharmacy training curricula should be directed toward a comprehensive interprofessional interaction at early stages within professionals' education, training, and career.

potential benefits in terms of facilitating the pharmacotherapy course-related discussion between students and faculty members (Divall and Kirwin, 2012). The popular use of Facebook has made the issues of privacy, identity protection, and e-professionalism the focus of discussions related to professional and organizational impacts (Mattingly et al., 2010), particularly in the context of lacking robust evidence that regulates the proper interaction between social media use and pharmacy professional boundaries (Hammer et al., 2003).

In a study conducted by Hall et al. to explore the views and use of social networks among the UK pharmacy students, it was found that the wide use of social networks is associated with potentially inappropriate professional attitudes. The same study highlighted that male students seem to be less concerned about professional issues related to their use of social networks and have a less comprehensive view of professionalism than female students (Hall et al., 2013). Furthermore, the evaluation of social interactions between faculty members and students or residents has shown that the students, especially at a public university, were more concerned that "friending" on Facebook represented a violation of professional boundaries. In addition, the students reported that they had to be cautious as to what content to share if it could be seen by faculty members (Bongartz et al., 2011).

From the perspective of faculty members regarding the professional way of interacting with their students on social networks, there is no clear consensus about professional boundaries in this regard. It was reported in a US study that the majority of faculty members agreed that they should not initiate friendships with current students on social networks, but they varied in their acceptance rate and response to friendship requests sent by students (Schneider et al., 2011). Most faculty members considered that social media connections with current students could compromise the boundary of lecturer–student relationship (Cain et al., 2013). It is essential for faculty members to investigate further the proper context for the use of social media for educational, professional, and networking purposes (Cain et al., 2013). Overall, all social interactions involving students and their mentors or faculty members should be kept professional to overcome potentially inappropriate attitudes and behaviors that constitute threats to maintaining professional boundaries (Bongartz et al., 2011). In conclusion, it should be noted that the framework regulating the professional aspect of social interactions involving pharmacy students, pharmacists, and faculty staff members is not clear, and further explicit working definitions of professional boundaries in this context are needed.

Conclusion

Professionalism in pharmacy practice and education is affected by the ability to recognize the different types of professional boundaries while dealing with patients, health-care professionals, trainees, and students. The promotion of knowledge concerning professional boundaries, important warning signs, behaviors, and attitudes should be considered as early as during the health-care education of undergraduates. It is the responsibility of educational institutions, management of health-care facilities, and policymakers to exert continuous efforts and initiatives to maintain professional boundaries and facilitate a professional identity in daily practice.

Drug Misuse and Dependence: The Role of Community Pharmacy

Jane Lois Sheridan*, **Suzanne Nielsen**†, **Rhys Ponton***, *School of Pharmacy, Faculty of Medical and Health Sciences, University of Auckland, Auckland, New Zealand; †Monash Addiction Research Centre, Monash University, Melbourne, VIC, Australia

Introduction

The use of psychoactive drugs for pleasure and ritual purposes is not a new phenomenon, and the use of psychoactive substances obtained from plants based materials such as betel, khat, tobacco, and coca have a long history (Sullivan and Hagen, 2002). The notions of addiction and dependence (see Section "Misuse, Addiction and Dependence—A Brief Review of Concepts and Terminologies") are a modern framing of substance use, which sees the use of most psychoactive substances (excluding alcohol and nicotine) as deviant and problematic and, in many cases, an illegal activity as a result of international treaties and conventions. Health professionals tend to frame substance misuse and dependence in a medico-legal context, but may also see it as deviant.

This chapter will describe a predominantly 20th and 21st century role for community pharmacists in the treatment of drug dependence, as well as describing community pharmacy's role in a harm reduction approach to substance misuse. In doing so, the chapter will focus mainly on developed countries, using European (mainly United Kingdom), Australasian and the North American evidence. A brief description of concepts and terminologies will be followed by a description of the changing role of community pharmacy, using the UK as a case study, from the late 19th century through to the mid-1980s. The major paradigm shift towards harm reduction in the post HIV/AIDS era will then be described, followed by a more detailed exploration of pharmacy's role in newer initiatives in treatment and harm reduction, followed by brief crystal-ball gazing into the future. The chapter does not specifically focus on the pharmacist's role in the management of risky alcohol consumption, nor on smoking cessation.

Misuse, Addiction and Dependence—A Brief Review of Concepts and Terminologies

As with any area of medicine, shared terminology is critical in supporting effective communication. The importance of language has been highlighted in a number of recent commentaries in the field (Botticelli and Koh, 2016; Kelly et al., 2016). These reflect concerns about how stigmatising the language of health professionals can be, and the negative impact this can have on patient care. For example, two separate studies of commonly used terms identified that when a patient was referred to as a 'substance abuser' they

were more likely to be considered to be deserving of punishment, or a greater social threat compared to when the words 'person with a substance use disorder' (SUD) were used (Kelly et al., 2010; Kelly and Westerhoff, 2010).

The term 'abuse' and 'abuser' are no longer used by the World Health Organization, and SUD is now the term used in the fifth edition of the Diagnostic and Statistical Manual of Mental Disorders (DSM) (O'Brien, 2011). Similarly, when urine samples containing substances are referred to as 'dirty' this can also imply a value judgement, and conversely, a person being described as 'clean' when they are not using any substances may also imply that a person who is using a drug is 'dirty. The term 'addict' is also considered pejorative, labelling a person by their substance use. In the following section we provide definitions of three key terms in the addiction field: misuse, dependence, and addiction.

Misuse

The World Health Organization defines misuse as the 'Use of a substance for a purpose not consistent with legal or medical guidelines, as in the non-medical use of prescription medications' (https://www.who.int/substance_abuse/terminology/abuse/en/).

Dependence

The International Classification of Disease (ICD-10) definition of dependence is a cluster of physiological, behavioural, and cognitive symptoms, whereby the substance takes on a much higher priority in a person's daily life. Where a drug takes prominence in someone's life, this can also be referred to as 'salience'. Further characteristics of dependence include strong desires to take the substance, sometimes referred to as 'craving'. There are psychological aspects of dependence, which centre on the loss of the control over the use of a substance and cravings for the substance. Physical aspects of dependence include 'tolerance', where more of a substance is required to produce the same effect, and 'withdrawal' where a group of symptoms emerge on cessation of the use of the substance. For substances such as opioids when used in the context of treating pain, the development of physical neuroadaptation is expected with long-term use, and this alone is not considered 'dependence' in the absence of psychological aspects such as loss of control over use, salience or craving.

Addiction

The term 'addiction' has fallen in and out of favour over time, though the term is broadly understood by the public, and is often used interchangeably with 'dependence'. The term 'addiction' is not currently used to define problems with substance use in the widely used ICD-10 or DSM. The term addiction is often preferred in the pain field to avoid confusion with the term 'dependence', which is used to refer to physical dependence in the absence of the psychological or behavioural aspects of substance use disorders.

Sociological Constructs of Addiction/Dependence

Drug misuse and dependence are very emotive subjects and they form a common theme of political and sociological discussion. How society should, and does, address drug use depends on a multitude of factors including the society in question, the drug, and historical views of the use of the drug. At times, certain drugs have been vilified in 'moral panics'.

In general, the use of alcohol and tobacco is legal. In Western society, alcohol use is both legal and socially acceptable, and in some ways positively encouraged, particularly in social settings. The use of most other 'drugs' is largely deemed socially unacceptable, in line with legislation prohibiting their sale and use. Alcohol and tobacco (nicotine) are largely ignored as drugs, even though that is what they are. As will be explored further in this chapter, the social rules and legislation that Western society has drawn up in respect to drug use are not always firmly rooted in scientific evidence.

Legislation has formed over centuries in response to experience and sometimes to aforementioned panics, which have been artificially created (most classically illustrated by the 1936 film, 'Reefer Madness') and may bear little relation to the harm posed by each individual drug. In 2010, a seminal paper by Nutt et al. (2010) described the harms of drugs (as assessed by a group of experts) and found that these were not reflected in the legal approaches to each drug in the UK.

Earlier in the chapter, the term addiction was defined from the medical/scientific point of view. However, another aspect is the perception of dependence by those who are using a drug, and society at large. The medicalisation of dependence is challenged by many. They argue that SUDs are associated with a combination of personal and sociological issues, where the drug alleviates or ameliorates negative emotions that an individual is experiencing. This was demonstrated in a series of experiments during the 1970s, which have been colloquially termed 'rat park' (Alexander et al., 1978). These suggested that rats caged alone experienced negative psychological effects, which were not experienced when rats were housed with other rats in a community. The rats that were caged alone drank a morphine solution in preference to water, which did not occur in the social 'park'. Studies of United States soldiers returning from the Vietnam conflict found that, in the same way that solo rats used drugs to cope with stressors, the soldiers in Vietnam had used the easily obtainable opioids there to deal with the stress of witnessing death and destruction, along with the risk of death they faced on a daily basis. Upon returning to their homes in the United States at the end of their tour of duty, most troops ceased opioid use, indicating the use was linked to their situation, rather than the individual or the drug (Hall and Weier, 2017; Leshner, 1997; Robins et al., 1974).

However, in healthcare, it is generally accepted that a SUD is a chronic, relapsing medical condition. It is sometimes referred to as a chronic 'disease' (Volkow et al., 2016). Pharmacists involved in the care of individuals with SUD need to be aware of its relapsing nature and to support the individuals when necessary. Substance use affects not only the person who uses a drug, but other people, both friends and family, as well as the wider community. Direct harm from the drug or complications from use (to the individual using the drug) are obvious consequences of drug use. Effects on those close to the individual are also clearly witnessed and may include worry, frustration and sadness over the individual's drug use, to physical harm for example from drug or alcohol induced violence or aggression. However, individuals not known personally to those with a substance use disorder may also suffer through events such as being the victim of a vehicle accident caused by an intoxicated driver, or being a victim of an acquisitive crime committed to fund drug use.

A Historical View of Pharmacy and Addictive Drugs—The British Experience

Contemporary pharmacy manages substance use and addiction within a framework of the legal regulation of psychoactive substances. This is in line with international conventions on narcotic drugs and psychoactive substances, and classifies drugs into legal groupings, which describe their manufacture, distribution, possession, use, prescribing, and dispensing. The most tightly controlled substances (e.g. lysergic acid diethylamide (LSD); 3,4-methylenedioxymethamphetamine (MDMA) commonly known as ecstasy) are deemed to have no recognised medical use. Other substances may be prescribed only by authorised doctors, whilst other substances may be prescribed more widely according to specific regulations. Many countries control access to potentially addictive substances through laws such as the Controlled Substance Act in the United States (1971), The Misuse of Drugs Act (the United Kingdom, 1971), The Narcotic Drugs Act (Australia, 1967), and The Misuse of Drugs Act (New Zealand, 1975). However, this has not always been so and the following brief description of the history of British drug laws serves as a case study.

In formulating this following section, we acknowledge the BMA Board of Science "Drugs of Dependence: The Role of Medical Professionals" report (2013). In the 1800s, there was unrestricted access, for example to opium, and there was an estimation of opium consumption at 6.5 people per million in Britain in 1894 although this fell to 4.9 per million by 1903 (Berridge, 1999). Products containing opium, such as laudanum, could be freely obtained from pharmacies with no restriction. However, concerns about consumption led to the first attempt in the UK to control access through the Pharmacy Act 1868 (BMA Board of Science, 2013). The Act changed access to these substances from pharmacies only, and pharmacists were required to keep records of sales and supplies, although there was little restriction on the quantity that could be supplied. In the early 1900s, a subsequent Act also controlled morphine and cocaine. It was not until World War I, when concerns were raised about troops using cocaine, that for the first time, a prescription was required for the supply of cocaine, and the subsequent Defence of the Realm Act 1914 meant that "it was an offence for anyone except physicians, pharmacists and vets to be in possession of, or to sell or give cocaine" (BMA Board of Science, 2013, p. 88).

In 1920, as a result of it being a signatory to the 1912 International Opium Convention, the UK government enacted the Dangerous Drugs Act, which expanded control over drugs such as morphine, cocaine and heroin, and also allowed doctors to prescribe these drugs. Lack of clarity over whether prescribing to people dependent on these drugs was a legitimate medical activity led to the convening of the Rolleston Committee which, in its Report (Ministry of Health, 1926), confirmed that doctors could prescribe opioids to people dependent on opioids for the treatment of addiction. This was the beginning of what has become known as the "British System", which saw a "balance of a medical approach within a penal framework" (BMA Board of Science, 2013, p. 89). This situation, with a small number of patients being prescribed heroin long term, remained unchanged until the 1960s when concerns were raised about younger people becoming dependent on heroin. In 1965, the Brain Committee ruled that prescribing of heroin should be by licenced doctors only and saw the setting up of specialist drug clinics (Ministry of Health and Scottish Home and Health Department, 1965). This resulted in a decline in the prescribing of diamorphine (pharmaceutical heroin) with replacement by methadone—a longer acting, orally bioavailable opioid agonist, which had emerged from the USA. It is interesting to note that the "British System" was at odds with the American approach, which had prevented doctors prescribing for addiction.

One of the biggest changes to the way pharmacists could supply addictive drugs to patients came in 1971 with the introduction of the Misuse of Drugs Act (1971), which classified drugs into schedules laid out by the UN 1961 Single Convention on Narcotic Drugs. These schedules defined restrictions on manufacture, prescribing, supply, possession and use. For pharmacists, this meant becoming familiar with a whole new set of regulations and legal requirements on the storage and dispensing of such drugs.

In the 1980s, in the UK and many other countries, there was a rapid increase in the number of people using illicit 'street' heroin. In the UK, the government released its strategic policy "Tackling drug misuse" (Home Office, 1985), which included the wider use of doctors beyond specialists to prescribe methadone for addiction and thus a greater number of prescriptions being presented at community pharmacies. However, the biggest change to the role of pharmacy and indeed to the way in which substance misuse and dependence were framed did not really occur until the recognition of the HIV/AIDS epidemic in the 1980s, and the acknowledgement that the HIV virus was blood borne and could be transmitted from one individual to another through the use of shared injecting equipment, as well as through unprotected sex. The UK Governments' Advisory Council on the Misuse of Drugs (ACMD) produced its first report "AIDS and drug misuse", which contained the highly influential statement that: "The spread of HIV is a greater threat to individual and public health than drug misuse" (Advisory Council on the Misuse of Drugs, 1988) and led policy-makers to embrace a different approach to the management of drug misuse and dependence—a harm reduction approach.

HIV/AIDS and the Emergence of a "Harm Reduction" Approach

Harm reduction has many definitions, but the basic premise in the 1980s was a pragmatic approach to preventing the spread of HIV. The approach accepted that people would continue to inject drugs, and set in motion a number of interventions, which were designed to reduce the HIV transmission, without the aim of reducing use of drugs *per se*. The two main harm reduction interventions which impacted on community pharmacy practice were the introduction of needle exchanges, and the expansion of OAT from mainly detoxification regimes to maintenance treatment, with the aim of reducing drug injecting.

Needle exchanges (often known as needle syringe exchanges), were set up to supply sterile needles and syringes to people who injected drugs and also offered a means of safely disposing of used injecting equipment. Research indicates that in cities with needle exchange schemes, HIV seroprevalence reduced in comparison with cities with no needle exchange (Hurley et al., 1997). It was recognised that another avenue for the supply of sterile injecting equipment was through community pharmacies. At the same time, there was a rapid expansion of oral methadone prescribing through primary care in the context of methadone maintenance (also known as opioid agonist treatment (OAT)), designed to reduce injecting, as opposed to being primarily directed at detoxification and abstinence. By the late 1980s, a national survey of community pharmacies in England and Wales, indicated that 3% of pharmacies were involved in a needle exchange scheme and 23% were involved in the provision of methadone to people who inject drugs (Glanz et al., 1989). Almost a decade later, 19% and 51% respectively were providing these services (Sheridan et al., 1996).

Pharmacy needle exchange services were not standardised, and evolved according to local need, with a range of methods for financing the scheme, and the range of equipment provided free of charge to pharmacies for distribution at no cost to people who inject drugs, also varied (Sheridan et al., 2000). Provision of needle exchange services was not without problems, with pharmacists reporting issues such as shoplifting; however, concerns about violence appear to have been unfounded with pharmacists generally positive about providing the service (McVeigh et al., 2017; Sheridan et al., 2000, 2005). Even in the USA in the late 1980s, where regulations made it difficult for pharmacists to sell sterile injecting equipment, a study in Maryland found a considerable level for support for needle exchange schemes (Gleghorn et al., 1998).

The prescribing of oral opioid substitutes as maintenance treatment, also increased around this time and in the period between 1998 and 1995 the proportion of community pharmacies in England and Wales dispensing prescriptions for controlled drugs such as methadone, for the management of drug misuse, increased from 23% to 51% (Sheridan et al., 1996). Since that time this role has expanded to providing supervised dosing of methadone and buprenorphine, in monitoring patients to identify where they may need clinical review, and providing support to patients to achieve their treatment goals (Chaar et al., 2011). The early adoption of these harm reduction services by community pharmacies was not universal, and research indicates that motivating factors include awareness of local need, and wanting to reduce the spread of HIV (Matheson and Bond, 1999). It has been suggested that overt support from government agencies, professional bodies and pharmacy professional associations may have had a positive impact on participation (Matheson and Bond, 1999; Myers et al., 1996).

The 1990s and 2000s saw a proliferation of research interest in this field, with studies being carried out on service development and implementation, service delivery, and pharmacist attitudes towards HIV and drug misuse. Research on attitudes towards the provision of needle exchange and OAT found a proportion of pharmacists with very positive attitudes, and a relationship between positive attitudes and service provision (Matheson et al., 1999; Sheridan et al., 1997). However, a small proportion of community pharmacists were not comfortable providing the services, indicating it was not their role.

Pharmacists also had concerns about the impact that providing these services might have on their business (Matheson et al., 1999; Sheridan et al., 1997, 2007). However, a study of public perspectives of pharmacy harm reduction interventions indicated generally positive support, although with a preference for these services to be provided in a private area (Lawrie et al., 2004).

Importantly, the opinions of people who use drugs on the role of pharmacists in harm reduction have also been explored. Both qualitative and quantitative research with people who inject drugs revealed a number of key themes, one of the most significant being that of stigma. People who inject drugs reported feeling stigmatised (Matheson, 1998), and if they are too embarrassed to access pharmacy services this could have a negative impact on harm reduction interventions (Simmonds and Coomber, 2009). Stigma has also been a theme in research exploring clients' perspectives on OAT (Anstice et al., 2009) and there have been reports of negative treatment by staff (Matheson, 1998). However, OAT clients find that community pharmacies are accessible, and note the importance of positive and supportive attitudes of pharmacists and their staff (Laird et al., 2016; Matheson, 1998).

Harm Reduction Beyond HIV/AIDS—Take Home Naloxone

Harm reduction as a concept has expanded beyond the prevention of the spread of HIV/AIDS to embrace a broader perspective of harm. One of the harms associated with substance misuse is drug overdose. Opioid overdose is a significant issue. If a person overdoses on opioids they experience respiratory depression which can ultimately be fatal. Opioid overdose deaths can be prevented through the timely use of opioid antagonists such as naloxone.

Naloxone is a competitive opioid antagonist with a relatively fast onset of action, usually within a few minutes depending on the route of administration (Dowling et al., 2008). When naloxone is given to a person who has been administered (or taken) an opioid agonist it displaces the opioid agonist from the opioid receptor, effectively reversing the effects of the opioid agonist. Naloxone is an

effective antagonist for most prescribed and illicit opioids (e.g. heroin), though higher doses are thought to be required with partial agonists such as buprenorphine, and high potency opioids such as fentanyl and its analogues (Dahan, 2006).

Naloxone has can be administered via a range of routes including intramuscular, intravenous, subcutaneous, and intranasal. Since it was discovered, it has been in routine use paramedic and hospital settings. In these settings has been shown to be safe, reliable and effective. More recently naloxone has been supplied to trained laypeople who may witness an opioid overdose, enabling earlier naloxone administration. This is often referred to as 'take-home naloxone'.

Take-Home Naloxone Programmes

Take-home naloxone programmes have been recommended by the World Health Organization in response to rising opioid-related mortality (World Health Organization, 2014). Systematic reviews have confirmed that community naloxone supply is an effective way to reduce overdose mortality, with few serious side effects and no abuse liability (European Monitoring Centre for Drugs and Drug Addiction, 2015; McDonald and Strang, 2016; Olsen et al., 2016). Most overdoses are witnessed, so there is an important opportunity for naloxone to be administered if a trained bystander is present (Strang et al., 1999).

Over the past decade in the United States, a trebling in opioid overdose mortality has led to a recommendation for a rapid expansion of naloxone distribution (Rudd et al., 2016; Straus et al., 2013). By 2010 over 50,000 take-home naloxone kits had been distributed, and more than 10,000 successful overdose reversals were reported. There are now naloxone programmes in many countries including the United Kingdom, Australia and Canada.

Naloxone in Community Pharmacy

In 2016, naloxone was downscheduled to a pharmacist only medicine in Australia, making Australia one of the first countries with naloxone widely available without a prescription. In the United States and the United Kingdom, different supply strategies have also been devised to remove the need for a prescription, including the use of standing orders in many US pharmacies, and patient group directives to enable supply within the UK healthcare system (Nielsen and Van Hout, 2016). These supply mechanisms mean that pharmacists have an increasingly important role in the supply of naloxone. Community pharmacies have wide geographic distribution and long hours of operation. This means that take-home naloxone can be accessed widely in the community, particularly in rural and regional communities and outside opening hours of many drug treatment services.

Community pharmacy is a key primary health care hub, and most people at risk of opioid overdose and other opioid related harms are already in contact with community pharmacists, either through the supply of opioid agonist treatments such as methadone and buprenorphine or through receiving pharmaceutical opioids for the treatment of pain. Research has demonstrated that interventions in healthcare settings can significantly reduce opioid overdose risk compared to standard care (Bohnert et al., 2016), and that training laypeople to administration naloxone is an effective way to reduce overdose mortality (European Monitoring Centre for Drugs and Drug Addiction, 2015; McDonald and Strang, 2016). As skilled health professionals, pharmacist can combine these two effective strategies of overdose risk education and naloxone supply.

Challenges with Expansion of Naloxone Supply

Expansion of naloxone availability in community pharmacy is not without challenges. Research in Australian pharmacies has indicated that pharmacists have low confidence in identifying who to supply naloxone to, and how to train people about its use (Nielsen et al., 2016). Research in the United States and Canada has confirmed that not all health professionals are confident to supply naloxone (Edwards et al., 2017). A recent study of Canadian pharmacies found one in four had naloxone available, with less than one in five anticipating that they could supply it within a week (Cressman et al., 2017).

Additional barriers to naloxone supply have traditionally been the need for a prescription, though rescheduling, standing orders and other supply channels have gone some way towards addressing this. A further significant barrier to naloxone supply is cost. Where naloxone is not covered through government programmes or insurance the cost to the individual can be considerable, with wholesaler prices of USD$75 for an intranasal dose and exceeding USD$450 for autoinjector devices (Gufford et al., 2017).

Naloxone in the Future: New Formulations

Traditionally, take-home naloxone programmes provide naloxone through either ampoules or prefilled syringes for intramuscular injection, or prefilled syringes with atomisers for intranasal administration. The use of injectable products can be a barrier for those not familiar with administering injections (particularly for family members or carers) and in criminal justice settings. In some settings the carrying of injecting equipment may be illegal, adding an additional concern with injectable formulations.

New intranasal formulations address this barrier, but raise new queries about the ideal dose of naloxone. The dose of naloxone in intranasal formulations was determined through healthy volunteer studies aiming for comparable pharmacokinetics to intramuscular doses, though ideally this will be supported by experience in the field with use of these products to reverse overdoses. With expanded use of high potency opioids such as fentanyl and carfentanyl, it is possible that higher doses of naloxone may be required to reverse an overdose, although the onset of respiratory depression may be so fast, and the depression so severe that naloxone may be ineffective.

Consumer Education with Naloxone Supply

When providing naloxone to those who may witness and overdose, it is critical to firstly provide education on the signs of an opioid overdose so that the need to administer naloxone can be established.

A first step when supplying naloxone in pharmacy settings, is for the pharmacist to establish what is known about recognising and responding to a potential opioid overdose. Many people who are likely to witness an overdose may have already attended formal training on overdose management, and/or have previously administered naloxone. Conversely, concerned family members or carers, and those prescribed opioids for chronic pain may have had little exposure to opioid overdose, and may not be familiar with the signs of opioid overdose to look for. Open ended questions to establish baseline knowledge may help to target information more based on the patients existing knowledge.

In addition, information on naloxone administration and where naloxone fits into broader overdose management, including the importance of calling an ambulance, are key counselling points.

Other Overdose Risk Factors

Pharmacists may be ideally placed to identify other known contributors to opioid overdose risk. In addition to naloxone supply, pharmacists can advise patients on potential drug interactions when combining sedatives such as alcohol and benzodiazepines with opioids, and can identify those pain patients on higher opioid doses that are associated with increased overdose risk (doses of 50 mg oral morphine equivalents [OME] have been shown to increase the risk of overdose 4-fold, and doses of 100 mg OME have been shown to increase the risk of overdose 9 fold compared to people receiving doses of 1–20 mg OME per day) (Dunn et al., 2010). Patients who report using of multiple central nervous system depressant substances, and those with other mental health comorbidities, may also be at increased overdose risk (Park et al., 2016).

Medicinal Cannabis and Pharmacy

The medicinal use of cannabis has occurred for millennia, with recorded use for over at least 4000 years. Historically, the drug has been used for an array of conditions. The absence of proven effective medical use for cannabis resulted in it being placed within the strictest levels of control in the legislation introduced in the early 1970s. However, for certain medical conditions, effective treatments still do not exist and demand for cannabis products persists to this day, and there is limited evidence of efficacy for some conditions. In a form of a vicious circle, the tight controls placed upon it have hindered any research into possible medical use.

In 1996, the people of the state of California in the US voted to introduce the 'Medical Marijuana Initiative'. This would enable the use of cannabis for a range of medical conditions for which cannabis 'provides relief'. Subsequently, many States have introduced similar legislation with others having also legalised it for recreational use (National Conference of State Legislatures, 2017). In the States in the US where it is approved, medicinal cannabis is available as a range of products for use including smokeable matter, capsules/tablets, edible forms (such as cookies), and tinctures. Some States prohibit some forms; for example, New York does not permit forms for smoking or edibles (New York State Department of Health, 2017).

The pharmaceutical industry has attempted to develop cannabis over a number decades. One of the first products to be launched was the synthetic cannabinoid, nabilone, which was primarily used for nausea and vomiting in patients undergoing chemotherapy. In 2005, a product, Sativex™, a standardised formulation of cannabis extract containing delta-9-tetrahydrocannabinol (THC) and cannabidiol (CBD), was approved for use in Canada. The manufacturer claimed "the world's first prescription cannabis medicine" (GW Pharmaceuticals, 2010).

The use of cannabis for medical purposes remains controversial, most crucially because evidence of efficacy for most indications is still lacking. However, cannabinoids are currently an area of significant research and interest; therefore, further data on safety and efficacy are expected in the near future.

Pharmacy Distribution of Cannabis

Medicinal grade cannabis has been available on prescription through community pharmacies in the Netherlands since 2003 (Hazekamp, 2006). More recently, in late 2013, Uruguay legalised access to cannabis for both recreational and medical reasons. It introduced changes that allowed the growing of plants and the purchase of limited quantities of the drug. An important deviation from that of all other jurisdictions is that Uruguay chose for the sales of cannabis to be made from pharmacies (Walsh and Ramsey, 2016). The new law was explicit in its aim to improve public health, and therefore the distribution from a healthcare setting appears a logical choice. Furthermore, in Australia, in 2016, the federal government legislated to allow medicinal cannabis (TGA). State-based legislation and guidelines have been introduced which will allow patients to obtain a prescription from a doctor and have their prescription dispensed at a pharmacy. This new role for pharmacists is likely to require additional training and education. Very little research to date exists on pharmacist knowledge and attitudes towards medicinal cannabis.

From Illegal to Legal—The Growing Problem of Prescription Drug Misuse

Over time there has become less of a distinction between illicit and legal substances. Traditionally illicit substances such as cannabis are being intensively studied for therapeutic use. Widely used 'illicit' opioids such as heroin (also known as diacetylmorphine) have historically been used for medical treatment. Diacetylmorphine is still used as an analgesic in some clinical settings, in addition to its provision as Heroin Assisted Treatment (HAT) for addiction in countries including the Netherlands, the United Kingdom, Switzerland Spain, Germany and Canada (Strang et al., 2015). Over the past two decades there has been increasing non-medical use of over-the-counter and prescription opioid medicines. The rising mortality associated with prescription drugs has placed a sharp focus on their supply, misuse and associated harms. As such, there is an increasing role in pharmacy practice to prevent, identify and respond to the non-medical use of pharmaceutical drugs.

Pharmaceutical Opioids

Large increases in opioid prescribing have been observed in Australia, North America, and Europe (Berterame et al., 2016). These increases have largely been due to the increasing use of opioids for acute and chronic pain. This increase in therapeutic use has been associated with dramatic increases in harms including dependence, morbidity, and mortality (Bohnert et al., 2011; Fischer et al., 2013, 2016; Roxburgh et al., 2011). The non-medical use of prescription opioids is well established, though problems also emerge in the context of therapeutic use. Studies in Australia and the United States have found that between 10% and 35% of people using long-term opioids for chronic pain are estimated to meet criteria for opioid dependence or opioid use disorders (Boscarino et al., 2015; Degenhardt et al., 2015).

There in an international trend for mortality from prescription drugs to exceed mortality from illicit drugs (Martins et al., 2015). The increase in mortality has paralleled increased in use of prescribed opioids for pain (Martins et al., 2015). This highlights the need for interventions that address overdose risk in medical settings.

Other Prescription Medicines

Benzodiazepines have been widely available since the 1960s and were thought to have a lower dependence liability (Wick, 2013). In recent decades the risks of dependence have become clear. On their own, benzodiazepines are unlikely to cause death with overdose; however, benzodiazepines are commonly implicated in mortality statistics when taken in combination with opioids, alcohol or other sedatives (Bachhuber et al., 2016).

Emerging concerns have been identified with the non-medical use of the gabapentinoids pregabalin and gabapentin (Schifano, 2014). Descriptions of misuse have emerged in case reports (Bonnet and Scherbaum, 2017), and gabapentinoids have also been implicated in increasing numbers of opioid-related deaths (Gomes et al., 2017). The risk for dependence is thought to be greater in those with a history of substance use disorder (Bonnet and Scherbaum, 2017), suggesting care should be taken when gabapentinoids are prescribed for this patient group.

Whilst the misuse of antipsychotics is not new, an emerging body of cases reports and case-series describe the misuse of atypical antipsychotics, with quetiapine the most commonly identified drug (Montebello and Brett, 2017). Misuse is described in a range of contexts and settings, for example in correctional settings (e.g. prisons) where other substances may be less available (Montebello and Brett, 2017). Reasons for non-medical use of atypical antipsychotics commonly centre on their sedative effects (Malekshahi et al., 2015). Atypical antipsychotics are also used off-label as to treat anxiety and insomnia, though evidence to support this practice is lacking (Thompson et al., 2016).

Stimulants such as dextroamphetamine or methylphenidate are indicated for the treatment of attention-deficit/hyperactivity disorder. Misuse of stimulants is most commonly described among adolescents and student populations, with an estimated 5–9% school aged children and 5–35% of US college aged students reporting past year non-medical use (Wilens et al., 2008). Use of pharmaceutical stimulants by this group is described primarily to assist in studying, and medications commonly supplied to peers (i.e. shared or sold between students) (Benson et al., 2015).

Anabolic–androgenic steroid steroids such as testosterone and its synthetic derivatives are indicated for conditions such as muscle wasting with HIV or hypogonadism. These drugs are used by professional athletes to build muscle mass and improve performance; however, much misuse is thought to occur among recreational sportspeople (Sagoe et al., 2014). While not considered to be psychoactive, there are concerns with dependence with steroid use.

The Pharmacists' Role in Management of Prescription Drug Dependence

The community pharmacist has a key role in prevention and management of prescribed medication misuse. Many patients have low awareness that the consumption of widely used medications such as opioids and benzodiazepines may result in dependence. A discussion between the pharmacist and patient about the potential for medications to lead to physical tolerance and psychological dependence may be warranted. Treatment contracts between patients and healthcare providers are a useful way of managing and documenting these risks, in addition to other structural approaches to treatment that can minimise misuse. For example, community pharmacy interventions include supervised dosing, facilitating daily or weekly medication collection and monitoring for signs of escalating dose or non-medical medication use. With the increasing availability of prescription

monitoring programses, pharmacists have the potential to be central in identifying problematic use and providing responses to reduce harms (Lynas, 2013).

Where medications are known to have a significant dependence liability, care should be taken in populations with known vulnerabilities to SUD. This includes those with histories of trauma, mental health co-morbidity and family histories of substance use. These risk-factors do not preclude the use of effective medications where clinically indicated, but additional precautions actioned by pharmacists such as discussing the risks prior to commencing a medication, only dispensing the amount required or dispensing smaller amounts more frequently and monitoring for early requests for further supplies and signs of loss of control can all increase patient safety.

There is a paucity of research into pharmacist perspectives on prescription drug misuse and even less into prevention and treatment interventions. In a study in New Zealand on issues for primary care, both general practitioners and community pharmacists reported problems with managing inappropriate requests and dealing with aggressive behaviours (Sheridan and Butler, 2011). In the same study it emerged that participants tended to take a binary view of prescription drug misuse, classifying people into those who purposely misuse drugs and those who had become addicted through no fault of their own, with the latter being seen more sympathetically, and more likely to be offered support. However, such support for this group was hard to access (Butler and Sheridan, 2010).

The Future

There are clear roles for community pharmacy in harm reduction, prevention and treatment of SUD that go far beyond medication supply. For example, pharmacist prescribing of OAT has become standard practice in some services in the United Kingdom (Hill et al., 2014) and is being considered in other countries. Proactive identification of opioid overdose risk and naloxone supply is another example of extending pharmacist roles to provide life-saving interventions. There may be a broader role in the routine screening for SUD in the future.

If drug laws continue to change as in the case of Uruguay, supply of psychoactive drugs from pharmacies, possibly dedicated specialist pharmacies, may become a standard. The concept of distribution of drugs for recreational purposes from pharmacies is not new. In 2009, the Transform Drug Policy Foundation released "After the War on Drugs: Blueprint for Regulation" (Transform Drug Policy Foundation, 2009) and the legal supply of drugs through the community pharmacy was proposed as one prospective route of supply. Indeed, in 2012, The Foundation joined the experts advising the regulation model in Uruguay; the pharmacy supply model was launched in July 2017 and will be the first test of this model anywhere worldwide. The issue of supply of recreational drugs through pharmacies was also proposed in early 2013 (All-Party Parliamentary Group for Drug Policy Reform, 2013). It was argued that some recreational drugs, such as ecstasy (MDMA), could be supplied in a purified form from community pharmacies to reduce harms from the illicit supply chain. The idea was rebutted in a response from the President of the Royal Pharmaceutical Society stating that "The role of a health professional is to improve health, which seems completely incompatible with selling cigarettes and any other substance for recreational use which we know causes harm without any health benefit" (Royal Pharmaceutical Society (News Team), 2013). However, in a world of ongoing change with regard community pharmacy, this is a possible future role.

Whatever the future holds, there will always be a role for community pharmacists to play in managing substance use and addiction given their role in the supply and control of these substances. Pharmacists need to be well prepared for such roles and pharmacy curricula should embrace this and ensure they provide appropriate education and training.

Corporatization of Community Pharmacy

Sue Burton, NomaChina Kubashe, Nelson Mandela University, Port Elizabeth, South Africa

Introduction

Traditionally, reimbursement in community pharmacies has principally been linked to medicine distribution or the sale of medicines, where the medicine, for the most part, is considered a commodity of retail exchange rather than a health service. Consequently, community pharmacists have always lived with the tension of providing a healthcare service within a retail business environment. Being retail enterprises, community pharmacies can only continue operating if they are financially viable, and consequently one of the primary focus areas of any pharmacy owner or manager, has to be profitability. Therefore, within a retail business environment, the commercial interests and the need for profit generation constantly compete with the altruistic motives of providing a healthcare service. This issue—the tension between the commercial interests and the altruistic provision of a healthcare service—has been central to pharmacy's age-old struggle to claim its role and status as a profession (Bush et al., 2009; Denzin and Mettlin, 1968).

Over the past few decades, the practice of pharmacy has progressed through many phases, mirroring periods of constraint and expansion in the role of the pharmacist, relative to their relationship with society and patients. More specifically, the phases are aligned with changes in role orientation between what can be described as a business, commercial or product orientation and a professional, service or patient orientation. Consequently, the phases also reflect fluctuations in the professional status of pharmacy (Daughton and Ruhoy, 2009).

Within recent years, this tension or the dilemma for role definition and professional status of pharmacists has become exacerbated by the deregulation of pharmacy ownership laws to allow for open ownership and the "corporatization" of community pharmacy. Corporatization of community pharmacy refers to the shift in ownership type of community pharmacies from independent, pharmacist owned private pharmacies to small, medium, and large pharmacy chains owned by corporate organizations.

Corporatization of community pharmacy worldwide has largely been permitted, and even encouraged, as a means to increase access, availability, affordability, and quality of medicines and pharmaceutical services. The consequences, however, of open ownership on the professional status have to be questioned. In this chapter, we will explore the rationale for deregulation of pharmacy law worldwide, which has led to open ownership and corporatization, the state of pharmacy ownership, and the consequences on the profession. We will conclude by discussing the implications for the future of community pharmacy.

Corporatization of Community Pharmacy

Because of a public interest in healthcare delivery and the need to deliver quality pharmaceutical services to society, community pharmacy worldwide has evolved within a milieu of wide-ranging regulations and operational standards. By placing restrictions on key issues governing the ownership, establishment and operation of community pharmacies, these regulations and standards have

essentially created a controlled and restricted environment within which community pharmacy has been practiced. The primary focus of these restrictive laws has been on:

- market entry and the establishment of new pharmacies, together with geographic and demographic criteria to open a new pharmacy;
- ownership, including restrictions on who may own a pharmacy and the number of pharmacies that may be owned by an individual or group;
- operating or opening hours;
- pricing regulations relating to the sale of medicines; and
- competition.

Within this controlled and restricted environment, and with the growth of the pharmaceutical industry and the entry of increasing numbers of new medicines onto the market, community pharmacies were able to capitalize and "build profitable enclaves with limited competition" (Strong, 2015). By the 1980s, the pharmacy retail business worldwide was dominated by relatively small-sized independently owned businesses, with comparable management and organizational structures, all offering relatively similar products and service provision, and generating analogous fiscal results. Employing comparable organizational and operational strategies meant that pharmacies largely competed with one another based on location and convenience. For the most part, costs and productivity became a secondary focus even though market growth and the development of the chronic medicine industry resulted in greater dispensing volumes and contributed to the stability and profitability of independent pharmacies (Strong, 2015).

Until the 1980s, in many parts of the United States (US) and in the United Kingdom (UK) where ownership laws were less restrictive, the development of corporate and chain pharmacies remained mostly contained or regional. By the early 2000s, the less restrictive regulations and relatively free market nature of pharmacy in the US and UK resulted in an extensive entry of corporates, including supermarkets and discount stores, into the pharmacy and over-the-counter (OTC) medicines market.

Even though regulations governing pharmacy practice within a country or state are relatively stable, there has been a developing global trend toward a more liberal approach to pharmacy regulation. The move toward liberalization of pharmacy regulations, particularly relating to pharmacy ownership, is often termed "deregulation" of pharmacy ownership. The term deregulation is used to describe varying degrees of relaxation of the regulations regarding pharmacy ownership, and can refer to anything, from a reduction of restrictions in some countries, to a complete abolition of restrictions in other countries. An important result of the deregulation of ownership laws has been the opportunity for corporatization of the community pharmacy sector.

Rationale for Deregulation of Pharmacy Ownership

The global trend of deregulation toward open ownership and corporatization has been driven by various motivations. The primary intention is often cited as the creation of a free market environment, which encourages competition. Central to the creation of competition within a retail market are low barriers of entry—creating the opportunity for multiple potential competitors to enter the market. Therefore, pro-competitive policies, often driven by competition authorities, play a pivotal role in driving deregulation (Anell, 2005; Helen Suzman Foundation, 2016; Lluch and Kanavos, 2010; Pharmaceutical Society of New Zealand, 2017).

Primary arguments for increased competition and allowing new entrants into the community pharmacy market center on four main issues: access, affordability, consumer choice, and quality of services.

Access to Medicines and Pharmaceutical Services

Arguments and motives for deregulation of pharmacy ownership laws have often focused on the role of competition in creating greater access to medicines and pharmaceutical services, particularly in previously underserviced and rural areas (Helen Suzman Foundation, 2016; Lluch and Kanavos, 2010; Vogler et al., 2014). Availability of medicines and pharmaceutical services can be described in terms of greater or lesser access to pharmacies due to increased or decreased numbers of pharmacies, shorter or greater distances between pharmacies and longer or shorter operating hours.

In South Africa, changes to the Pharmacy Act in 1997, allowing for open ownership, were based on the understanding that prospective entrepreneurs and businesses would be enabled to open pharmacies in underserved areas and provide highly needed pharmaceutical services (Helen Suzman Foundation, 2016). Liberalization of ownership laws in Sweden in 2009 was also based on the rationale that open ownership would increase availability of pharmacies and consumers' access to medicines (Wisell et al., 2015).

In North Dakota, proponents for deregulation of ownership laws have argued that it would increase access to medicines and pharmaceutical services in rural areas, where it is ordinarily difficult to attract pharmacists to work (Haarsager, 2010). Similarly, the Ministry of Health in New Zealand is pushing for deregulation of ownership rules, with the expectation that this will result in an increase in the overall number of pharmacies and longer operating hours, particularly in underserved or rural areas (Pharmaceutical Society of New Zealand, 2017).

Affordability of Medicines to the Consumer

Since pharmaceuticals, comprise a large share of healthcare expenditure, in the international context of a constrained financial environment, there is intensifying pressure to contain medicine costs. Consumer access to affordable medicines is an imperative for all governments. Competition is believed to stimulate efficiency, and particularly when corporate chains enter the market, economies of scale, enhanced buying power and lower distribution costs are anticipated to result in lower prices and more affordable medicines for consumers (Helen Suzman Foundation, 2016).

The promotion of competition and the lowering of medicine expenditure and consumer costs has been cited as the rationale for deregulation by many governments, including Iceland, Norway, Portugal, South Africa, and Sweden (Anell, 2005; Martins and Queirós, 2015). The Office for Fair Trading—a UK government department tasked with ensuring markets function favorably for consumers—in its 2003 report, "The control of entry regulations and retail pharmacy services in the UK," suggested that removing the control of entry regulations into the prescription medicine market could result in consumer savings in two ways:

- entry of corporate discount pharmacies and supermarket chains into the market could promote the availability of low prices to consumers and
- promoting price competition between pharmacies, would result in lower medicine prices in all types of pharmacies.

Increase Consumer Choice and Quality of Service

In a competitive market, the need to keep up with rivals is believed to stimulate the range and quality of products and services provided. Competition is also believed to drive innovation to deliver better services, and more integrated patient-focused services (Lluch and Kanavos, 2010; Pharmaceutical Society of New Zealand, 2017). In arguing for deregulation of pharmacy ownership laws, the New Zealand Ministry of Health states that ownership restrictions are not necessary for ensuring safe and rational medicines use, and that there is no direct link between the percentage shareholding of a pharmacy by a pharmacist and the safety of patients. Furthermore, the Ministry contends that restrictive ownership laws, by reducing the scope for competition and investment in community pharmacy, have the effect of hampering rather than promoting innovation. The Ministry further suggests that "more flexible ownership arrangements could assist in achieving the mutual goal of the pharmacy profession and the Government of helping the sector move toward better, integrated and consumer centered care" (Pharmaceutical Society of New Zealand, 2017).

Despite the existence of some common arguments for deregulation of ownership laws and increased market competition, there is considerable diversity in community pharmacy systems across the world because of differences in prevailing legal, political, and healthcare structures. Consequently, there is a multiplicity of ownership rules worldwide.

Pharmacy Ownership Types

Pharmacy ownership rules lie on a continuum between the more restrictive forms on one end, where pharmacy ownership is the exclusive right of pharmacists, and the less restrictive, deregulated forms on the other end, where open ownership of pharmacies is permitted and encouraged.

Along the ownership continuum, various types of pharmacy ownership exist. Although the exact nature and details of these vary from country to country, in general the following types can be identified.

Pharmacist-only Ownership

These are pharmacies, which are owned solely by pharmacists, either individually or in groups. Examples of countries with regulated pharmacy systems and pharmacist-owned pharmacies include Australia, Denmark, Finland, Germany, Greece, Luxemburg, and Turkey (Danish Medicines Agency, 2014; Employed Community Pharmacists in Europe (EPhEU), 2017; Government of Western Australia Department of Health, 2017; The Association of Finnish Pharmacists, 2014; Vogler et al., 2014). In many low-income countries, including India, Nigeria, Côte d'Ivoire, Vietnam, Cameroon, and Lebanon, ownership is restricted to pharmacists (Lowe and Montagu, 2009).

In highly regulated pharmacy systems, where ownership of a pharmacy is the sole domain of pharmacists, there are often restrictions placed on the number of pharmacies each pharmacist may own. In Germany for example, a pharmacist may own a maximum of three pharmacies with the proviso that they are located in the same or adjacent district, and each pharmacy must have a pharmacist in place as branch manager. In Finland, pharmacists are restricted to ownership of one pharmacy, while in Greece, a pharmacist may own one pharmacy and have a minor share-holding in a second (EPhEU, 2017; The Association of Finnish Pharmacists, 2014). In Australia, the restriction on the number of pharmacies owned by one pharmacist varies from territory to territory. For example, there is no restriction in the Australian Capital and Northern Territories, while Tasmania and Western Australia have a restriction of four pharmacies, New South Wales, Queensland, and Victoria a restriction of five, and South Australia a restriction of six (Government of Western Australia Department of Health, 2017). Limitations on multiple ownership, except for a limited number of branch pharmacies, prevent the formation of chain pharmacies. The establishment or entry of new pharmacies into the market is also often tightly controlled by the need for a state concession or a license, and by geo-demographic criteria, including population quotas per pharmacy and distance from existing pharmacies. Although terminology varies, when

ownership is restricted to one or more pharmacists, and they own five or fewer pharmacies, the pharmacies are generally termed independent pharmacies.

Mixed Ownership

Partial deregulation in many countries has resulted in mixed ownership types. These comprise pharmacy systems where ownership of a pharmacy must include shareholding by a pharmacist but may include non-pharmacists or corporate entities as shareholders. The extent of shareholding required by a pharmacist or group of pharmacists varies considerably from country to country. In some systems, pharmacists must be the majority shareholders, for example, in Austria, Cyprus, and Latvia, a pharmacist or pharmacists must own at least 51% of the business, while in Lithuania and Spain, pharmacist shareholding must be at least 75%. Furthermore, in many of these countries it is a requirement that the pharmacist who holds the pharmacy license must have the exclusive power of management and representation (EPhEU, 2017). In New Zealand, current legislation specifies that a registered pharmacist or a company with the majority share capital held by a pharmacist or pharmacists must have at least 51% ownership. There is also a restriction on prescribers holding any interest in pharmacies (Pharmaceutical Society of New Zealand, 2017).

North Dakota, the US state with the most stringent pharmacy ownership laws, requires 51% of the ownership interest of every pharmacy in the State, to be held by a pharmacist licensed in the State. Furthermore, the laws in North Dakota require that the pharmacists with the controlling interest in the pharmacy are actively employed in the pharmacy and have managerial control over the pharmacy. Although there is no ban on corporates entering the market, this law has effectively discouraged corporatization and the formation of chains within the State of North Dakota, since large-scale retailers are statutorily restricted to entering the pharmacy market as minority shareholders (Haarsager, 2010).

The only other US state with restrictive ownership laws is Michigan, which requires that a pharmacist or pharmacists have at least a 25% shareholding in a pharmacy. Michigan, however, has no corresponding requirement that the pharmacist owner has managerial or operational control over the pharmacy (Legislative Council - State of Michigan, 2017). Haarsager (2010) makes the point that, despite comparable ownership laws, corporate "retail giants" have penetrated the retail pharmacy market in Michigan but not in North Dakota, suggesting that corporates are not willing to own pharmacies in which they are not the majority, controlling shareholder.

Open Ownership

On the more liberal end of the ownership continuum, pharmacy ownership rules have been deregulated and there are few or no establishment rules for the entry of new pharmacies into the market and almost no restrictions on who may own a pharmacy. Examples of such countries include Belgium, Bulgaria, England, Iceland, Ireland, Italy, the Netherlands, Norway, Portugal, Romania, Slovakia, South Africa, Sweden, Switzerland, most US states, and some Canadian provinces (Helen Suzman Foundation, 2016; Lovells, 2017; Pharmine, 2016; Vogler et al., 2014). Within an open ownership system, there are frequently some common but minor exceptions to ownership, for example, a limitation on ownership by prescribers or manufacturers of medicines (Vogler et al., 2014).

Globally, corporatization has been a major trend in the retail industry and the pharmacy retail industry is no exception. It is within these deregulated environments where open ownership is permitted, that corporations have entered the retail pharmacy market, resulting in the corporatization of community pharmacy. In deregulated countries chain pharmacies are now the norm, for example, approximately 96% of pharmacies in Norway, 86% in Sweden, 64% in the US, and 61% in the UK, are owned by corporate chains (National Community Pharmacists Association, 2017; Sukhar, 2016; Vogler et al., 2014).

In some countries, the establishment of pharmacy chains is limited by restrictions on the number of pharmacies that any person or business entity may own. This has resulted in wide variations in the extent of corporate penetration into the market and has given rise to various levels of chain pharmacies, including small, large, and multiple chain stores. Entry of supermarket retailers into the market in countries such as the UK, US, and South Africa has also resulted in the creation of supermarket chain pharmacies. In more regulated countries where, the establishment of chain stores is limited, franchising or branding is used to develop and create de facto chains (Helen Suzman Foundation, 2016; Lowe and Montagu, 2009). Franchising or branding is a business relationship in which the franchiser or owner permits another party—the franchisee to use their brand, products, or business systems, and in return, the franchisee pays an upfront fee and ongoing royalties. In many European countries, and in both Australia and New Zealand, where ownership is restricted to pharmacist-only or mixed ownership types, franchising is effectively leading to chains or networks of privately owned pharmacies. Franchising enables an individual pharmacy owner the opportunities and efficiencies of operating as part of a larger group while retaining independence and professional autonomy (Pharmaceutical Society of New Zealand, 2017).

Impact of Deregulation of Ownership Laws on the Community Pharmacy Market

In this section, we will review the evidence and experience of the reduction or removal of restrictive pharmacy ownership regulations. The intention of deregulation in many countries was the creation of a more competitive pharmacy market, with the anticipation of a consequent improvement in accessibility to affordable medicines, increased consumer choice and improved quality of services.

Although we will consider the impact of deregulation on each of these aspects, we will also review the influence of deregulation on levels of competition within the market, and on issues of professionalism and the practice of pharmacy.

Unbalanced Increase in Accessibility

In countries with deregulated pharmacy markets, there is normally a general increase in accessibility of medicines because of the entry of new players into the market and the establishment of new pharmacies, resulting in an overall decrease in the number of inhabitants per pharmacy. Deregulation, however, tends to favor the more densely populated and affluent areas, most of which already had good accessibility to medicines and pharmaceutical services (Vogler, 2014).

In a study to evaluate the impact of deregulation in community pharmacy ownership on accessibility of medicines, Vogler et al. (2014) compared community pharmacy systems in five deregulated countries (England, Ireland, the Netherlands, Norway, and Sweden) with four regulated countries (Austria, Denmark, Finland, and Spain). Vogler et al. (2014) concluded that deregulation of pharmacy ownership laws was associated with opening of new pharmacies, an increase in the number of pharmacies, and a corresponding decrease in the number of inhabitants per community pharmacy. New pharmacies, however, were clustered in established urban areas and there was no apparent increase in the number of pharmacies in rural and previously under-served areas, or in the accessibility of medicines in these areas. Furthermore, they suggested that the opening of new pharmacies appears to be a short-term trend or phenomenon in the early years following deregulation but diminishes with time and the increased competition that is created can ultimately lead to pharmacy closures.

Examination of the evidence by Anell (2005), following deregulation of the pharmacy market in Iceland and Norway, showed similar trends to those described by Vogler et al. (2014). The relaxation of restrictive ownership laws in Iceland in 1996 stimulated an initial increase in the number of pharmacies. The increases, however, were largely focused on the more densely populated and urban areas, such as Reykjavik, which experienced positive benefits. The benefits sometimes came at the expense of parallel closures of pharmacies in the more rural areas. With the opening of new pharmacies came the formation of strong chains, and by 2004 two pharmacy chains controlled 85% of the market. Pharmacies in these two chains, however, were only available in Reykjavik and in Akureyri, the two largest cities in Iceland, creating a major difference in access between the urban and rural areas. Similar changes in the Norwegian pharmacy market were evidenced following deregulation in 2001. Within a three year period (2001–2004) there was a 32% increase in the number of pharmacies. The majority of these new pharmacies, however, opened in city centers and shopping malls, close to existing pharmacies with high sales volumes. With only a few exceptions, the changes in policy did little to stimulate the availability of pharmacies in rural areas.

Proponents of the deregulation of pharmacy ownership laws in North Dakota have used the potential for greater access to medicines in the more rural areas as a large component of their argument. A comparison of North Dakota with its neighboring deregulated state, South Dakota, provides insight into the strength of this argument. There are, geographically, more local pharmacies in North Dakota, spread evenly throughout the State, while in South Dakota; pharmacies are mostly located in large cities and high population areas. In North Dakota, 53% of rural census tracts have pharmacies, compared to only 35% in South Dakota (Haarsager, 2010; LaVecchia and Mitchell, 2014).

Based on the Portuguese experience, Martins and Queirós (2015) purport that deregulatory changes can lead to an unbalanced distribution of pharmacy services which favors already well serviced, more affluent urban markets. The concentration of chain and supermarket pharmacies in more affluent areas has also been described in the UK. Bush et al. (2009) suggested that in the UK, independent pharmacies tend to be located centrally within communities and were easily accessible to those without transport while supermarket pharmacies were found on the peripheries in retail parks and were more difficult to access without transport—in other words by those who are generally also the socioeconomically disadvantaged (Bush et al., 2009).

In an effort to improve access in the UK, through longer operating hours, an exemption from a licensing requirement to prove new pharmacies were "necessary and desirable" was introduced in 2005, and granted to all new pharmacies which opened for "100 hours" per week. Although this exemption saw a tenfold increase in the number of new licenses being issued, these were mainly to large multiples protecting their high street and retail park businesses and to new supermarkets entering the market. This exemption law was withdrawn in 2012 as it was viewed by the Pharmaceutical Services Negotiating Committee as creating "clustering of additional pharmacies that bring about little improvement in access." Regulations that are more restrictive were reintroduced, requiring new entrants to the market to pass a new market entry test centered on a pharmaceutical needs assessment (Pharmaceutical Journal News Team, 2012).

In South Africa, permitting of open ownership was specifically intended to increase access and provide medicine in underserved areas. Therefore, at the time of the amendments to legislation, it was widely understood that the establishment of new pharmacies under lay ownership would be focused in previously underserved areas. In addition, the general understanding of the pharmacy profession was that the issuing of new pharmacy licenses would be preceded by the distribution of a notice of intent to existing pharmacies in the area, giving them an opportunity to provide reasonable objections (Helen Suzman Foundation, 2016). No geographical restrictions, however, have been applied and the entry of corporates and the formation of chains have been largely facilitated by what Lowe and Montagu (2009) describe as "the existence of an urban middle-class market." This has resulted in a two-tier community pharmacy market, where rural areas are underserviced and the majority of pharmaceutical services are provided in suburban areas and city nodes (Adams, 2011).

Despite a global trend toward deregulation and corporatization, in some Eastern European countries, for example, Estonia and Hungary, a lack of increased access to medicines following a period of open ownership has actually resulted in the reintroduction of

stricter regulatory control of pharmacy ownership, often referred to as "reregulation" (Gross and Volmer, 2016; Helen Suzman Foundation, 2016). Estonia, a country with liberal pharmaceutical policies and ownership laws introduced in the 1990s, has re-introduced legislation which from 2020, will again restrict ownership of community pharmacies to the pharmacy profession. This is because liberal ownership laws, which were related to economic factors and not improved patient care, resulted in an uneven geographical distribution of community pharmacies and vertical integration between community pharmacies and wholesalers. Following deregulation in the 1990s, there was a significant increase in the number of community pharmacies. The majority of the new pharmacies, owned by corporate chains, operated in larger towns. The legislative changes being introduced to reregulate pharmacy ownership have been a consequence of the perceived threat to the viability of small community pharmacies in rural areas and the potential this has to limit access to medicines and community pharmacy services in the future (Gross and Volmer, 2016). Similar changes resulting in reregulation of pharmacy ownership laws have also taken place in Hungary. In 2010, the Hungarian government legislated that at least 51% of shares in community pharmacies must be held by Hungarian pharmacists. This decision was based, in part, on a lack of improvement in the supply of medicines in rural and economically disadvantaged regions, despite an overall increase in the number of pharmacies post-deregulation.

Affordability of Medicines and Pharmaceutical Services in Deregulated Community Pharmacy Environments

As discussed previously, pro-competitive moves toward deregulation of ownership laws are often aimed at increasing the affordability of medicines and pharmaceutical services. Experience has, however, demonstrated that anticipated financial savings on medicine costs are not generally realized for either the patient or the government (Vogler et al., 2014). Basing their conclusions on both their study to evaluate the impact of deregulation of community pharmacy ownership on European countries, and an extensive literature review, Vogler et al. (2014) concluded that there was "no indication for an association between the extent of regulation and the amount of total, or public, pharmaceutical expenditure." Furthermore, they suggested that there was a range of policies and factors affecting pharmaceutical expenditure and the cost of dispensing medicines was only one aspect.

Although, as Strong (2015) argued, deregulation and consequent corporatization has generally been associated with a fall in prices, prices tend to fall faster than costs, and margins have been negatively impacted. In the context of the pharmacy environment where core dispensary reimbursements, ordinarily paid by governments and third-party agents such as pharmacy benefit management companies (PBMs), are being constantly reduced, this trend is putting pharmacies, especially independents, under severe economic strain.

Corporates, with their economies of scale and widespread geographical reach are viewed as having sufficient financial muscle to negotiate with governments and third-party agents. For example, community pharmacists in the UK believe that corporate pharmacy chains are well positioned to attract disproportionate financing through the National Health System (NHS) commissioning processes (Bush et al., 2009). Similarly, in South Africa, medical schemes, medical benefit, and insurance companies enter into agreements with pharmacies to provide their members with medicines, in an effort to contain costs. Through a system of designated service providers (DSPs), these third party agents then negotiate reduced dispensing fees. To be appointed as a DSP, the pharmacy has to enter into a contract that sets the dispensing fee payable for the supply of medicines at a lower price than the upper limit set by government. Thus, for the advantage of becoming a preferred provider, an agreed level of price reduction or incentive is provided to the third party agent. Although such agreements are in principle open to all pharmacies, in reality, the chain nature of corporate pharmacies, their geographical coverage, together with the economies of scale that they are able to offer, makes the negotiation of such contracts easier and simpler for them, and smaller independent pharmacies are therefore largely excluded from such negotiations (Helen Suzman Foundation, 2016).

With the global movement toward open ownership, there has been an accompanying trend toward both horizontal and vertical integration in the pharmaceutical distribution chain. Vertical integration is the merging or fusion of business entities with complementary business interests, and a vertically integrated company participates at multiple levels of an industry's distribution or value chain. Open ownership has led to the merger of pharmacies at the retail and wholesale levels, and more specifically in the UK, US, and several European countries, to large pharmaceutical wholesalers merging with or owning pharmacy chains. Within three years of deregulation in Norway, horizontal integration had resulted in 97% of all community pharmacies being aligned with the three major pharmacy chains (Apotek 1, Alliance Unichem, and Vitusapotek), all of whom had formed vertical alliances with the three main wholesalers in Europe (Phoenix, Alliance Unichem, and Celesio). In the US, vertical integration between pharmacy chains and PBMs has also become common place (Barlas, 2018). Horizontal integration, the fusion of business entities conducting the same line of business, such as the merging of multiple community pharmacies, has also resulted in the creation of powerful corporate chains (Anell, 2005; Kanavos et al., 2011; Vogler et al., 2014).

The current financial climate has also seen an unprecedented increase in vertical integration between corporate pharmacy chains and PBMs in the US. A reduction in drug prices, aimed at assisting consumers to manage costs while improving health outcomes, is cited as the prime motivating factor behind these mergers. Barlas (2018) argued, however, that although there were some small indications of point of sale discounts, these cost reductions were for the most part not being passed on to consumers. Agency theory suggests that the primary goal of a corporate business is to increase profit (Dobson and Perepelkin, 2011). Therefore, since logically the prime reason for the existence of a corporate organization is to fulfill its responsibility to its shareholders by making a profit, it is not surprising that deregulation of ownership has little effect on the sale price of pharmaceuticals and that financial savings are not passed onto the consumers.

In the context of a drive for profit maximization, when price savings in the dispensing and selling of medicines in corporate pharmacies are passed on to the consumer, they are viewed as a "loss leader" and a means of drawing customers through the stores. Within corporate chains, dispensary operations are frequently not considered to be a significant contributor to profits; as Strong (2015) stated the role of dispensaries is shifting from being a "profit-driver to a traffic driver." Honeysett, a former CEO of the Clicks Group, the largest retail pharmacy chain in South Africa, summed this up when he said: "dispensaries ensure greater footfall in Clicks stores, thus increasing sales volumes across the brand" (Trevor Honeysett, Former CEO—Clicks Group, cited by Bolin, 2005).

Experience of deregulation in many countries has demonstrated that corporate ownership of pharmacies has led to the development of oligopolies where a small number of organizations become dominant and hold the majority of the market share. In the US, two corporates—CVS Health Corporation and Walgreens Boots Alliance—hold approximately 40% of the prescription medicines market share between them (Statista, 2017). Walgreens Boots Alliance is the world's largest pharmacy operator and the owner of the UK-based Boots pharmacy chain. In the UK, 12 large multiple corporate chains own approximately 50% of the community pharmacy market, with the largest of these, Boots, owning approximately 17% (Sukhar, 2016). In Ireland, Norway and Sweden, the three largest community pharmacy chains respectively own approximately 79%, 81%, and 68% of the market share. In fifteen years, since the deregulation of pharmacy ownership laws in South Africa in 2003, two companies, Clicks and Dis-Chem, have captured nearly 45% of the retail pharmacy market.

The development of oligopolies within the community pharmacy market has, in many deregulated countries, given rise to a substantial reduction in competition, and could even result in higher prices for consumers. Furthermore, within a market characterized by oligopolies, consumer choice becomes more limited.

Implications of Deregulation on Consumer Choice and Quality of Services Provided

As Strong (2015) contended, within a regulated community pharmacy environment, small independent pharmacies, all offer similar products and services and consumer choice is limited. Community pharmacy patronage decisions within these restricted markets are largely based on location and convenience. Consequently, the intentions of deregulation to create increased competition and resultant consumer choice are generally realized fairly soon after new competitors enter the market. New entrants enter the market with fresh strategies, frequently targeted at specific customer segments; for example, low-price, volume driven corporates and supermarkets often target the more cost-conscious consumer. With time, however, vertical and horizontal integration and the development of oligopolies leads to reduced consumer choice, especially when small-scale independent pharmacies are being placed under severe pressure and sometimes squeezed out of the market. Although consumer choice of a pharmacy is most frequently driven by location and convenience, range and quality of professional services is increasingly becoming a factor (Strong, 2015).

Bush et al. (2009) investigated the implications of corporatization on community pharmacy in the UK, focusing on service provision, public health function and professional status. Although the researchers reported no relationship between the pharmacy type and the provision of essential services such as health promotion and the collection of waste medicines, they did identify an association between the provision of enhanced services and pharmacy type. The decreased levels of provision of services such as domiciliary visits, palliative care, out-of-hours, and home delivery services—none of which offer any immediate, short-term financial benefits—by large chain and supermarket pharmacies were notable. There was also a tendency for supermarket chains to limit the services they provide to those which might be considered socially acceptable or less controversial such as the supply of emergency hormonal contraception (EHC) to persons younger than sixteen years without a prescription. A high proportion of supermarket and multiple chain pharmacies, however, did offer medicines use reviews (MURs). These findings with regard to MURs confirmed the outcomes of a 2008 study by Bradley and colleagues, which identified ownership type as the most significant determinant in the uptake of MURs by community pharmacies in England (Bradley et al., 2008). These findings need to be viewed in the context of MURs being classified as a Tier Two, advanced service, in the national contractual framework for pharmacies in England and as such attract reimbursement from the NHS per MUR conducted. Bradley et al. (2008) demonstrated that MUR provision by multiple pharmacy chains was almost twice that of independent pharmacies. The results of their study also highlighted a difference in the manner in which multiple chains and independent pharmacies approached MURs. Interviews with five pharmacists employed in multiple chain pharmacies reported being pressured by the chain management to achieve MUR targets, often to the detriment of quality. When the work of pharmacists is measured by the achievement of targets, the purpose and quality of their work becomes compromised. For example, MURs serve the purpose of optimizing medicine use, but when under pressure to achieve targets, pharmacists may opt to perform MURs for patients with fewer medicines or simpler medicine regimens rather than for patients with more complex regimens with multiple medicines (Latif et al., 2011).

The case of MURs in the UK highlights an important issue concerning the professional autonomy given to employee pharmacists within corporate environments and the impact of corporatization on professionalism. This is an issue not unique to the UK and has been noted in many other countries including the US, Canada, South Africa, Norway, and Sweden (Canadian Pharmacists Association, 2016; Gaither et al., 2008; Vogler et al., 2014).

Professional Implications of Deregulation

Changing models of pharmacy practice require greater levels of professional autonomy, increased service-orientation, increased patient focus, and greater emphasis on clinical skills. Corporatization is often associated with a loss of the pharmacists' autonomy,

decision-making abilities, and level of control, due in part to the more inflexible and fixed structures of these organizations, the focus on profit, and the resultant commoditization of pharmacy services (Perepelkin, 2008; Sukhar, 2013).

In considering an appeal for greater liberalization of ownership rules in Italy and Germany, the European Court of Justice drew attention to the unique nature of medicinal products, stating that the therapeutic effects of medicinal products "distinguish them substantially from other goods." For this reason, because the unnecessary or incorrect consumption of medicinal products poses a very real public health risk, the Court stated that medicinal products were best sold by a pharmacist. In addition, the ruling alluded to the notion that the safe sale of medicinal products is most probable when a pharmacist has "genuine professional independence" and any breach of laws governing the sale of medicines would both threaten his/her professional existence and financial investment. The Court ruled that although the restriction of pharmacy ownership to pharmacists constituted "a restriction on the freedom of establishment and the free movement of capital" it was justifiable as necessary for the reliable provision of good quality medicinal products (Commission of the European Communities, 2009).

Irrespective of the type of ownership, at an operational level, the presence of a licensed or registered pharmacist is required in almost all countries for the operation of a dispensary. Licensure or registration as a pharmacist carries with it professional responsibilities and obligations and compliance with laws and regulations, the goal of which is to optimize medicine related health outcomes and safety. A full appreciation and knowledge of the legal and ethical issues related to medicines and their supply are essential requirements of competency, registration, and practice as a pharmacist. In a corporate pharmacy environment, however, pharmacists are not only bound to pharmaceutical regulations but also corporate institutional policy decisions, which are often centralized and removed from the operational level (Dobson and Perepelkin, 2011; Perepelkin, 2008; Pharmaceutical Society of New Zealand, 2017). As the Helen Suzman Foundation (2016) report suggests, in a corporately owned pharmacy "there is a separation between principal and agent." While the organization or principal may be tempted to comprise on professional standards, it is the pharmacist—the agent, carrying out the functions of the organization—who has to carry the primary concern of maintaining professional and ethical standards. In an independent pharmacy, the pharmacist generally understands that upholding professional standards is a means of protecting their investment; however, when employed by a corporate organization, the cost of maintaining professional standards, especially if it involves opposing the employer, is much more personal in nature (Helen Suzman Foundation, 2016).

Within corporate pharmacy businesses, pharmacists are often viewed as a necessary but costly human capital expense; this results in corporations trying to either economize or maximize on the expenditure on pharmacists (Dobson and Perepelkin, 2011). Maximizing involves seeking to gain the maximum benefit from employee pharmacists and results in increased workloads and work pressure for pharmacists. As a further means of maximizing, pharmacy chains are increasingly employing non-pharmacists as store managers. This is viewed as a means of freeing pharmacists from non-pharmaceutical related managerial tasks and allowing them to focus on providing pharmacy services. Many pharmacists, when forced to work with a non-pharmacy manager, feel that their authority is undermined and they are uncomfortable with the lack of clarity over responsibilities (Elvey, 2011). The other tendency in corporate environments is to try to economize on the services of pharmacists by employing fewer pharmacists and more pharmacy support personnel, such as pharmacist assistants and technicians. Attempts to either maximize or economize on the services of pharmacists have the potential to compromise the quality of pharmaceutical services provided and might ultimately pose a threat to patient safety. Furthermore, non-pharmacist owners and managers are likely to be more focused on production efficiency rather than the professional objectives related to patient outcomes and safety (Dobson and Perepelkin, 2011). Consequently, in many countries, corporate ownership of pharmacies has been associated with increased workloads and a more stressful work environment for pharmacists. Excessive workloads and constant challenges to their professional status by non-pharmacist managers, often leave employee pharmacists in corporate pharmacies feeling "jaded" (Kubashe, 2017).

The Changing Community Pharmacy Landscape and the Way Forward

Challenged with the tension of providing a healthcare service within a retail business environment, community pharmacy exists within complex economic and social structures. Consequently, the international movement of the retail industry toward corporatization has not escaped community pharmacy. Corporatization has and is undoubtedly changing the community pharmacy landscape with pharmacy chains of varying sizes and supermarket pharmacies now the norm in many countries.

We have seen that international evidence and experience does not support a claim to superiority of any of the ownership types. As Lluch and Kanavos (2010) contended, there are useful lessons to learn from all types. Countries with liberal or deregulated pharmacy systems could learn from the policies applied in more strictly regulated countries, which increase the equity and professional status of community pharmacies, while highly regulated countries could consider some of the policies from liberal countries to increase efficiency in the pharmacy system.

A final word of warning may be apposite, however, based on the work of an American sociologist, George Ritzer, Harding and Taylor (2000) referred to corporatization as the "McDonaldization" of community pharmacy. Harding and Taylor explained how the four dimensions described by Ritzer, as characterizing the working practices of large corporations in rationalizing products and services are similarly apparent in corporate pharmacies. The four rationalizations are:

- *Efficiency*—the carrying out of tasks in the most optimal and rational manner, with no freedom for individualization, is achieved through the routine following of standard operating procedures (SOPs).

- *Calculability*—relates to the commodification of medicines and services, where they become a unit of supply and a cost item, rather than a unit of therapy and healing.
- *Predictability*—refers to the standardization of experience in any outlet within a chain, regardless of geographic location. It is achieved by the standardization of store layout and service, uniformity of products and the implementation of centrally driven company policies, protocols, and procedures.
- *Control*—achieved through the minimization of skilled activities by staff and the use of automation and technology wherever possible.

These rationalizations in the pharmacy domain have resulted in the formation of pharmacy chains or "McPharmacies" in which the standardization of policies, procedures, and processes become routinized, and, thus, products and services standardized. Even the store layout and fittings are uniform in design. Through in-house training programs, all staff, including pharmacists and managers, are socialized into the corporate ethos and way of providing services and even interacting with clients. Essentially, throughout a corporate chain of pharmacies, the consumer experience becomes uniform and standardized (Harding and Taylor, 2000; Taylor and Harding, 2003).

Within the context of this standardized corporate milieu, where the pharmacist's work becomes measured by "speed and efficiency" and pharmacists become "McPharmacists," there is little space for individualized, patient-centered care. Taylor and Harding (2003) asked searching questions about the challenges this raises for the future of the pharmacy profession. They contended that the changes brought about by the "McDonaldization" of pharmacy have implications for all levels of the pharmacy profession, including practitioners, professional bodies, researchers, and educators. The pharmacy profession has to capitalize on the rationalization and routinization of practice to create greater opportunities to "extend and promote their professional activities" (Taylor and Harding, 2003). Even within corporate environments, this could mean striving for greater community and patient focus through increased pharmacist availability, development of their advisory and health promotion roles, provision of pharmaceutical care services, medicines management activities, and pharmacist prescribing. All community pharmacists need to be fully integrated into primary care and resourced to deliver value-for-money, efficient, individualized, and patient-centered healthcare. Their role needs to be supported by supportive and proactive professional bodies and by pharmacy educators focused on developing critical thinking, decision-making pharmacists, who are willing to exercise autonomous professional judgment, albeit as employee, manager or owner pharmacists (Taylor and Harding, 2003).

Glossary

Chain pharmacy: A retail or community pharmacy, belonging to a group of more than five pharmacy outlets, co-owned by a pharmacist, multiple pharmacists, and/or non-pharmacists, business entities or corporations.
Community pharmacy: A business or for-profit organization providing pharmaceutical and primary healthcare services and products to a community.
Community: A group of people living within a specific geographic area, sharing both similar or different characteristics and needs.
Corporate pharmacy: A retail pharmacy forming part of a corporation-owned small, large, multiple, or supermarket pharmacy chain, having more than five pharmacy outlets centrally managed.
Corporation: An organizational form typically found in business, characterized by clearly articulated corporate objectives, centrally managed, with a separation between senior management and operations.
Corporatization: Although generally referring to the process of bringing businesses under the control of a corporation, in this chapter it will be a reference to the shift in community pharmacy ownership, from private independent pharmacies to chain pharmacies.
Deregulation: The revision, reduction, or removal of laws and regulations that hinder free competition in the supply of products or services.
Horizontal integration: The merging or fusion of business entities conducting the same line of business. In the pharmaceutical distribution chain, this usually refers to the fusion between wholesalers or the fusion between retail or community pharmacies to create chains.
Independent pharmacy: A retail or community pharmacy owned by a pharmacist or multiple pharmacists, who have five or fewer pharmacy outlets.
Large chain pharmacy: A pharmacy forming part of a group of more than 20 but fewer than 200 pharmacy outlets, co-owned by a pharmacist, multiple pharmacists, and/or non-pharmacists or business entities.
Mixed ownership: Ownership form of a community or retail pharmacy or chain that requires a pharmacist or pharmacists to be co-owners.
Multiple chain pharmacy: A pharmacy forming part of a group of 200 or more pharmacy outlets, co-owned by a pharmacist, multiple pharmacists, and/or non-pharmacists or business entities.
Oligopoly: A market structure in which a small number of organizations hold the majority market share and become dominant.

Open ownership: Ownership form of a community or retail pharmacy or chain that does not require a pharmacist as a co-owner.
Pharmacy-only ownership: Ownership form of a community or retail pharmacy or chain that restricts ownership to licensed or registered pharmacists only.
Reregulation: The process of reinstating laws and regulations that restrict free competition in the supply of products or services.
Retail pharmacy: A business or for-profit organization selling medicines, in quantities intended for personal use, direct to the consumer.
Small chain pharmacy: A pharmacy forming part of a group of more than five but fewer than 20 pharmacy outlets, co-owned by a pharmacist, multiple pharmacists, and/or non-pharmacists or business entities.
Supermarket pharmacy: A pharmacy outlet within a supermarket chain.
Vertical integration: The merging or fusion of business entities with complementary business interests. In the pharmaceutical distribution chain, this usually refers to the fusion between wholesaler and retailer, or manufacturer, wholesaler and retailer.

Stigma Surrounding Medicine Use—HIV Exemplar

Irmina Wlodarczyk*, Shane Scahill†, *ViiV Healthcare, Middlesex, United Kingdom; †Massey University, Auckland, New Zealand

Introduction

This chapter explores the notion of stigma surrounding medicines use and utilizes as its example human immunodeficiency virus (HIV). HIV is a significant social and public health issue and by the end of 2016, there were 36.7 million people in the world living with HIV; 1.0 million of whom died in 2016 through infection and corelated illnesses (WHO, 2017). HIV is the precursor condition to acquired immune deficiency syndrome (AIDS) and The World Health Organisation (WHO) plans to end the public threat that is caused by the AIDS epidemic by 2030 (Rintamaki et al., 2006).

The HIV pandemic which started in the 1980s, brought to society a new type of stigma, associated with this relatively unknown and significantly lethal disease. The origin and the epidemic characteristics of the disease were not publicly known at that time, therefore, people living with HIV (PLHIV) were perceived by society in a largely negative way. Since the WHO launched the Special Programme on AIDS in 1982, a radical increase in the number of patients covered by antiretroviral therapy (ART) has been observed. Nevertheless, there is still a number of common challenges related to HIV/AIDS and stigma experienced by PLHIV certainly remains as one of the considerable social issues they deal with (Rintamaki et al., 2006).

The definition of stigma is a reaction, negative in its nature, to a discrediting or undesirable trait of an individual in a social setting. Stigma occurs when one group of people hold a biased/prejudicial opinion against another group, who happen to be identified with a mutual attribute (Martinez et al., 2018). Stigma can manifest in several ways. In addition to stigma in its most common understanding (discrimination by society), stigma can also occur as "anticipated stigma," where an HIV-positive person expects negative reactions from people who may learn about their serostatus, or as internalized stigma, where a person living with HIV assumes that their personal and societal worth is in some way compromised by their disease. This thinking can lead to self-destructive health behaviors and has a negative impact on the quality of life for PLHIV's (Helms et al., 2017). The Social Cognitive Model is a popular theory related to HIV stigma; the theory outlines the process of development of HIV stigma in an individual who becomes aware of negative perceptions of HIV/AIDS and therefore is able to accept them as valid and truthful. For that reason, when the individual becomes HIV-positive, they perceive their serostatus as meaning they are now part of the discriminated group, which perpetuates the negative beliefs further (Travaglini et al., 2018).

What is more, discrimination and stigmatization which may correlate with access to anti-HIV treatment, is significantly dependent on such factors as gender and age, geography and belonging to key populations (WHO, 2016b). These key populations, as identified by The Joint United Nations Programme on HIV and AIDS (UNAIDS), include sex workers, men who have sex with men (MSM), transgender people, intravenous drug users (IDUs), and prison inmates (UNAIDS, 2016b, 2018). These populations have been socially marginalized throughout history, even before the negative connotation related to HIV emerged (Vanable et al., 2006). These key populations experience multifaceted issues related to discrimination and stigma, which may negatively influence these peoples' adherence to medication regimens (WHO, 2016a). In some regions, such as Sub-Saharan

Africa and the Middle East, there is still a lack of tools available for effective measurement of stigma in those populations (Fitzgerald-Husek et al., 2017).

HIV infection has been associated with the increased likelihood of mood disorders, substance abuse, and addiction, posttraumatic stress disorder (e.g., related to their HIV diagnosis) and serious mental health issues such as schizophrenia (Travaglini et al., 2018). It has also been proven that HIV stigma can be associated with bidirectionally maladaptive coping behaviors such as hazardous drinking. A "self-medication" alcohol consumption model (i.e., drinking to relieve stress) has been observed among people living with HIV. This type of alcohol consumption tends to cause more alcohol-related negative consequences than other forms of excessive drinking, e.g., binge drinking in social situations (Wardell et al., 2018).

Overview of HIV Medication Stigma

It has been established, that for ART to be successful, medicines adherence in an HIV-positive person must be 95% or higher (Martinez et al., 2018). Otherwise, anti-HIV medications will not be sufficiently effective in terms of increasing CD4 counts and lowering viral load (Dlamini et al., 2009). It has been proven that HIV stigma can make PLHIV three times more likely to be nonadherent to their therapy recommendations, compared to PLHIV not experiencing such concerns (Martinez et al., 2018).

Nonadherence may be a nondirect consequence of, for example, mental instability caused by stigma. A study in South Africa suggested that internalized stigma, which led to cognitive-affective depression, consequently caused nonadherence (Bhatti et al., 2016). Poor medication adherence may cause the antiretroviral therapy to be unsuccessful, but also has a wider impact on public health, giving rise to drug-resistant HIV strains (Rao et al., 2007). Consequently, the resistant virus strains might be transferred to other individuals, and limit their options in terms of effective anti-HIV therapy (Rintamaki et al., 2006). Another stigma-associated factor that negatively impacts the HIV epidemiology is avoidance of HIV testing by people with anticipated HIV stigma. That can lead to a delay in starting treatment and the virus to be transmitted to, for example, sexual partners of the HIV-positive person. Moreover, the fear of being stigmatized might, in fact, lead to risky sexual behaviors such as not using a condom; PLHIV with anticipated stigma might worry that initiating a discussion on safe sex hints that the person has a sexually transmissible disease (STD) (Vanable et al., 2006).

In 2006 a study found that people who struggle with HIV stigma are less likely to be adherent to their medications as well as correctly interpreting their CD4 counts (Rintamaki et al., 2006). PLHIV also tend to hide their status from their acquaintances which may lead to lapses in medication adherence. Being seen taking medications or with medication bottles related to HIV might induce questions and consequently force them to reveal their disease (Vanable et al., 2006). It has also been theorized that stigma might be related to poor social support and psychological status of HIV-positive individuals and therefore impact on medication adherence (Vanable et al., 2006). One study suggested that stigma is commonly associated with "attachment-related anxiety." This type of anxiety can impact medicines adherence due to anticipated stigma and fear of being negatively judged by a close person when they witness the person living with HIV, taking their medications (Helms et al., 2017). Another example of nondesirable behaviors of HIV-positive patients who want to conceal their antiretroviral medication intake was reported in South Africa—patients ground their medicines into powder, which caused a risk of inconsistent dosing (Mills, 2006). The effect of different types of stigma (e.g., anticipated vs. experienced) on adherence should be further analyzed in this context (Helms et al., 2017).

Moreover, some anti-HIV medications might be stigmatizing due to their side-effects. For example, atazanavir can cause clinical jaundice, which although not causing a clinical threat to the patient, can be potentially stigmatizing (WHO, 2016a). A study in Thailand found that women who gained weight due to anti-HIV medication were concerned about their looks and the potential for associated discrimination (Liamputtong et al., 2015).

Apart from the multidrug combinations that are designed for HIV-positive patients, it is important to remember that antiretroviral therapies include those that are intended to prevent the infection. Oral preexposure prophylaxis (PrEP) is a prevention tool for individuals exposed to substantial risk of HIV infection. It has been proven that PrEP is highly effective where adherence is satisfactory. Unfortunately, even in the case of PrEP, stigma might cause insufficient adherence. WHO guidelines on the use of HIV drugs outline that if PrEP recommendations reach beyond specific populations such as MSM and if PrEP is properly implemented within health care systems, the associated stigma might be reduced, while general access to the therapy can be increased (WHO, 2016a).

HIV stigma is not only associated with inadequate adherence but also lack of HIV testing and implementation of HIV prevention as appropriate (Quinn et al., 2017). Being infected with HIV can also cause patients to be wary of treating other diseases as this would require them to disclose their serostatus (Madhombiro et al., 2018). Therefore, it is crucial that all data collected from HIV patients needs to remain confidential, not only to respect their privacy but also to prevent any stigmatization (WHO, 2016a). As an example, a study on alcohol use associated with HIV treatment showed that HIV stigma can be a barrier for people to seek help for alcohol-related addiction (Madhombiro et al., 2018).

Even people who are in stable romantic relationships with HIV positive people can face stigma when they disclose their partners' serostatus. The so-called "courtesy" stigma can be experienced by people in serodiscordant relationships due to their friends and family who might, for example, not appreciate and stigmatize their partners (Siegel et al., 2018).

Review of HIV Stigma in Key Populations

MSM and Transgender

MSM accounted for 12% of new known HIV infections worldwide as of 2015 (UNAIDS, 2017). Sexual minorities suffer from all types of stigma, including enacted stigma such as verbal harassment, discrimination, or physical assault. It has been proven that enacted stigma can be associated with a higher occurrence of risk-related sexual behaviors, e.g., anal intercourse without the use of a condom (Balaji et al., 2017).

PrEP has been recognized as a means for reducing HIV susceptibility among MSM. HIV stigma and antigay prejudice have been identified as important factors discouraging MSM to consider PrEP for HIV prevention in two cities in the United States. Another important barrier was presented by lack of trust for health professionals, especially widespread in the black MSM community (Cahill et al., 2017). A New York based qualitative study conducted in 2017 on 37 MSM showed that participation in the PrEP regime can trigger stigmatizing behaviors. The study participants reported that when people saw them taking antiretroviral medications they assumed that the cause for that was being HIV-positive or the PrEP users' promiscuity and willingness to have unprotected sex. They also experienced anticipated stigma which led them to hide their medications from their sexual partners (Franks et al., 2018). Another study on African American MSM found that the use of PrEP can make people wary of other people's undesired presumptions such as participants' homosexuality, promiscuity, or having AIDS (Weathers et al., 2017). A study on young MSM and transgender women showed that PrEP stigma is more common in areas with high concentration of racial minorities, while lower stigma was observed among people with prior knowledge about PrEP, as well as among white and nonmale participants (Mustanski et al., 2018).

A study of young black MSM suggested that some specific aspects of stigma might have more influence on their health outcomes than others, whereas total stigma did not impact their adherence. What is more, the study demonstrated that anticipated stigma can be associated with a higher likelihood of optimum adherence (Quinn et al., 2017). Another study on a similar population suggested that stigma and hostile environments might serve as a "daily reminder" for people to take their medications (Radcliffe et al., 2010). Both studies showed that MSM who experience a high level of stigma are more likely to participate in high-risk sexual behaviors while intoxicated or under the influence of drugs. One of the reasons to take drugs before having sex among HIV-positive MSM may be to suppress feelings of shame and guilt (Quinn et al., 2017; Radcliffe et al., 2010).

Results of a four-country study conducted in Indonesia, Malaysia, The Philippines, and Timor Leste showed that significantly more transgender people experience stigma and discrimination by health care providers compared to MSM. The most common form of stigma was verbal discrimination, however, over 18% of the questioned transsexual people had experienced being refused access to health care services (Cortes, 2017).

Women

In 2016, worldwide there were 17.8 million HIV-positive women (aged 15+) (UNAIDS, 2017). HIV positive women tend to have insufficient coping strategies and less social support when compared to male PLHIV (Martinez et al., 2018). Barriers to adherence that women face can be gender specific, such as family obligations and physical abuse (Roberson et al., 2009). A study of American adolescent females aged 15–24 did not show a direct relationship between stigma and adherence. It suggested, however, that when there was a low satisfaction level related to health care, stigma might have decreased adherence. If patients found their experiences with health care highly satisfactory, the impact of stigma was lower. Also, various coping strategies such as spiritual coping or seeking support from family helped participants to maintain better adherence, despite enduring stigma. The study failed to demonstrate a direct relationship between depression and stigma (Martinez et al., 2018).

Mother-to-child-transmission (MTCT) is the main reason for HIV infections in children. Nevertheless, as of 2017, only 62% of pregnant women living in low and middle-income priority countries were covered by prevention of MTCT services (McMahon et al., 2017). A research study conducted in Tanzania in 2017 showed that stigma was the main barrier to obtaining HIV-related health services for women, affecting, therefore, the number of infant infections. Study participants felt especially vulnerable when they were subject to stigma as well as having to face health care facility limitations at the same time. It was suggested that peer support networks and "mother-2-mother" groups could be effective forms of intervention for HIV-positive mothers to encourage them to become engaged in prevention of MTCT (McMahon et al., 2017).

HIV burden among Black women is an example of race-related disproportions in HIV epidemics. It has been forecast that in the US, 1 out of every 48 Black women will be diagnosed HIV positive. In the case of US White women, the prevalence for HIV diagnosis is 1 out of 880 (Lambert et al., 2018). In a study of 220 Black women, anticipated HIV stigma was correlated with fear of disclosure of their serostatus as well as increased likelihood of mental health symptoms, and use of dysfunctional/negative coping strategies (Travaglini et al., 2018). Twenty African American women, who participated in a study in 2003, experienced HIV stigma as "being marked by the disease"; it also caused social isolation and was an important barrier to medicines adherence (Edwards, 2006).

Children and Youth

As of 2016, there were an estimated 2.1 million children (<15 years old) living with HIV globally (UNAIDS, 2017). Great progress has been made in regard to the survival of children, who were infected through HIV vertical transmission, into adolescence. Their

survival, however, also implicates complex challenges related to access to medications and adherence for this group of patients. Their situation is unique, since they often face the perspective of taking medications for the rest of their lives, from their early childhood and never having lived without the illness (Bernays et al., 2017). What is more, HIV-positive adolescents, especially those belonging to key populations, experience stigma and discrimination in high levels (WHO, 2016a).

In a study involving 25 young PLHIV, over 90% of the patients acknowledged the fact that their health condition could get worse unless they follow their therapy recommendations. That contradicted the popular opinion that young people feel invulnerable and therefore tend to be reckless with regard to their health. Stigma was identified as the reason for poor medication adherence for half of this young age group, which was caused by fear that the medicines could disclose their serostatus to their relatives and friends (Martinez et al., 2018).

Young people require a friendly environment in places where health services are provided, which should also reinforce the importance of ART adherence (WHO, 2016a). A study from 2017, however, showed that clinics, where the highest pressure was put on adherence (which was presented, for example, as a young patients' moral duty), could also create a stigmatizing environment. A group of young PLHIV, who participated in one study, when asked about their reaction to their own nonadherence talked about their deep shame and feeling of failure. This feeling created a barrier for them to seek support from clinicians when they missed their doses (Bernays et al., 2017).

Disclosure to children of their HIV positive status is an additional challenge that parents and caregivers face. According to WHO, children at school age should be informed about their disease which, as defined in the WHO guidelines, means that a child that has "cognitive skills and emotional maturity of a normally developing child of 6–12 years" (WHO, 2011). Caregivers must also face their concerns and fears related to HIV stigma. A study in China revealed that parents and caregivers of young patients sometimes did not disclose the disease status with the child or forbade the child from talking about their medications with their friends and playmates. One child in the study confessed that she was asked about her medications numerous times at school and once her HIV status was disclosed, she felt separated from others (DeSilva et al., 2018). Children and young people might benefit from the provision of accessible and culturally aware mental health counseling in conjunction with their classical ART (Quinn et al., 2017).

Prison Inmates

Around 3.8% of inmates worldwide are estimated to be HIV-positive, however, it varies significantly between regions (AVERT, 2018). In the United States, in 2010 there were around 20,000 HIV-positive prison inmates, and a high racial disproportion was observed (e.g., male African Americans were five times more likely to be diagnosed with HIV compared to white men) (CDC, 2018). A study in the United States of 17 former male inmates showed that there is a need for better education on HIV stigma in jails, which should cover both incarcerated people and staff. Inmates might avoid HIV testing due to HIV/AIDS stigma and related stereotypical views on PLHIV. One participant of a study admitted that even though other inmates were aware of the existence of antiretroviral drugs, the inmates did not believe these medicines could prevent the death of an HIV positive person who should be taking them. In the same study, it was also noted that incarcerated people often do not distinguish between being HIV positive and having AIDS (Derlega et al., 2010).

As of 2015, more than 700,000 women and girls were imprisoned throughout the world, including more than 200,000 in the United States. The population of female inmates has grown since the new millennium by around 50% (ICPR, 2015). It has been proven that female inmates, in general, have their HIV status diagnosed later after being infected compared to incarcerated men. Women also tend to hide their serostatus more often than men (Roberson et al., 2009). A plethora of incarcerated women have been victims of psychological, sexual, and physical abuse, experienced drug and alcohol addiction or have been infected with STDs. Their complex and unmet health and psychological needs impact the general health status of the population, including HIV epidemics (Sprague et al., 2017). Incarcerated women experience many barriers to adherence to antiretroviral drugs, one of the main ones being stigma. A study of 12 HIV-positive female inmates showed that the other important barrier is the lack of privacy in jail. Participants of the study complained that they often had to wait for long periods in queues to have their medications prescribed, which could potentially aid in disclosing their serostatus to other inmates if they were taking a lot of medications (Roberson et al., 2009). In an interview series with 25 previously incarcerated HIV-positive women, which took place in the US in 2015, the interviewees shared stories of being separated from other inmates, experiencing discrimination from prison staff and breaches of confidentiality regarding their serostatus (Sprague et al., 2017).

The "HIV prison paradox" has been defined in the United States as a situation where HIV-positive inmates-to-be increase their chance of being covered by ART by entering prison—an environment widely recognized as unhealthy (Sprague et al., 2017). Moreover, a study from 2009 showed the routine of living in jail can facilitate their adherence to ART (Roberson et al., 2009).

Drug Users

Out of 13 million people estimated to inject drugs worldwide, 1.7 million are expected to be HIV-positive (WHO, 2018). A series of qualitative interviews with 52 HIV-positive drug users in 2007 found that they had experienced stigma resulting in a feeling of loneliness and marginalization, which was further exacerbated by drug use (Ware et al., 2006). A study of 40 former and current drug users living in Bali showed that stigmatization was one of the main barriers to HIV testing, while 15% were concerned about the confidentiality of the testing process (Ford et al., 2004).

A 2010 study conducted in Ukraine, a country with one of the highest HIV epidemics in Europe, showed that among IDUs stigma was one the most significant barriers to medicine adherence (including stigma experienced from interaction with health care providers), along with discrimination by police and ART side effects. Discrimination and harassment by police, the barrier which was most commonly discussed by the studied patients, was related to possession of anti-HIV medication. It was noted that police officers misidentified people's medications as narcotics and confiscated them from HIV-positive individuals (Mimiaga et al., 2010).

Estonia and Russia have some of the highest rates of HIV outside of Sub-Saharan Africa and many of those PLHIV are IDUs. Participants of a study on HIV-positive IDUs living in Kohtla-Järve, Estonia and St. Petersburg, Russia, reported that they experienced simultaneously high levels or four types of stigma: internalized HIV stigma, anticipated HIV stigma, internalized drug stigma, and anticipated drug stigma. In Estonia, however, due to better developed harm reduction programs, stigma was less associated with poor health outcomes (Burke et al., 2015).

Sex Workers

Prevalence of HIV among sex workers can be very high in some regions such as Southern Africa where prevalence rates of 50%–70% have been reported (UNAIDS, 2016b). Sex workers are a highly stigmatized key population, suffering from such forms of discrimination and abuse as police repression, physical and sexual violence, and insufficient access to health care and even detention. This group is often not sufficiently protected by law and state policies, as their occupation is criminalized in many countries (Decker et al., 2014). Low uptake of ART has been observed in those HIV-positive women who are sex workers and also inject illicit drugs. This group is also at high risk of HIV infection due to having multiple partners who do not always use condoms. A study on 159 female sex-workers in Vancouver showed that these participants had to face not only a high risk of HIV infection (and other infectious diseases), but also unstable living conditions, discrimination, and poverty. Only 9% of the participants were taking anti-HIV medications at the time of the study, however, high levels of injection/noninjection drug use were observed (Shannon et al., 2005).

Sex workers' fears of being stigmatized are a critical barrier to adherence to anti-HIV therapies. What is more, sex workers might fear that if they start taking anti-HIV medications, it could disclose their serostatus to their clients and therefore reduce their own income (Decker et al., 2014). The stigma might also reduce adherence to PrEP among sex workers, as they might be required to take medications after coitus and therefore in the presence of their clients (Mutua et al., 2012).

There are around seven million sex workers in China, even though sex work is officially prohibited there. A study on 517 sex workers (of different genders) in China revealed experiences of various forms of discrimination, and some participants reported an increase in their HIV infection vulnerability, e.g., confiscation of condoms by the police (Shen and Csete, 2017; Decker et al., 2014). Participants of a study in South Africa, among whom there were sex workers, expressed that they often felt blamed and discriminated by health workers who were supposed to provide them with help (Duby et al., 2018). In a study in Zimbabwe, female sex workers living with HIV reported that they more often felt stigmatized because of the sex work than being HIV positive. They were also more likely to be refused help from health professionals because of their occupation rather than their HIV serostatus (Hargreaves et al., 2017).

Review of HIV Medication Stigma in Selected Regions

Africa

Close to two-thirds (64%) of new HIV infections globally are reported to occur in Sub-Saharan Africa (UNAIDS, 2017). Botswana is a country with one of the highest HIV infection rates in the world (with the prevalence rate of 21.9% for adults aged 15–49 as of 2016) (UNAIDS, 2016a). In a study involving over 100 patients and 60 health care providers in Botswana, stigma was identified as one of the most important barriers to medicines adherence. This study also recognized other implications of HIV stigma in Botswana, such as keeping HIV infected people's status confidential from patients' families and the community. Patients who felt that their adherence was compromised by stigma did not feel that they could take their medications at home or at work. They also did not feel comfortable about getting medication refills in clinics, being wary of other people learning of their disease status (Weiser et al., 2003).

A study on 158 Tanzanian PLHIV showed that involuntary disclosure of their serostatus was related with higher perceived stigma. Also, the participants who voluntarily disclosed that they were HIV positive, experienced a lower level of self-stigma. Lower adherence to ART was observed among patients who were in denial of their serostatus and/or had higher alcohol intake (Lyimo et al., 2014).

In a study involving over 1000 HIV-positive women and men living in Cape Town, South Africa, an anonymous survey found that 40% of the studied population had been discriminated against due to their disease. More than one in three individuals experienced self-induced stigma, caused by shame, guilt, or feeling "dirty" (Simbayi et al., 2007).

South, East, and Southeast Asia

In China, a high prevalence of HIV is observed in key populations (Shen and Csete, 2017). Family honor in China is cherished by the culture, which creates a barrier to disclose one's serostatus (DeSilva et al., 2018). Similarly, in India, a country where there were

2.1 million PLHIV in 2016 (UNAIDS, 2016c), being HIV-positive can be seen as a dishonor for the family (Nyamathi et al., 2018). A study in India with 60 PLHIV showed that the main barriers to adherence included stigma, cost savings, and perceived benefits of nonadherence to medicines (e.g., lack of side effects or even death). Over one-fifth of the participants did not disclose their serostatus to their relatives, which might have made taking medications more difficult for them (Kumarasamy et al., 2005).

Almost 40% of HIV positive people in India were female as of 2016 (Nyamathi et al., 2018). A study which included 400 HIV-positive women and their children living in a rural state of India (Andhra Pradesh) showed that the women experienced lack of social support as well internalized stigma and a generally low quality of life (Bagley et al., 2017). In a study with health care staff in India, over 80% of nurses and doctors admitted that if they had to face a situation that would expose them to body fluids, they would not treat HIV positive patients equally (Nyamathi et al., 2018).

Thai HIV-positive women, who participated in a 2014 study, presented a very optimistic view of antiretroviral medications. According to them, ART helped to reduce stigma and fear in society and made others more compassionate about the disease. They still did not feel comfortable enough, however, to take their medicines openly. The women reported that in order to take them, they would hide, e.g., in a bathroom or lied that the medicines were related to some other "socially acceptable" disease (Liamputtong et al., 2015).

Middle East

Prevalence of HIV in the Middle East and North Africa (MENA) remains relatively low; in 2016, there were around 230,000 PLHIV in MENA. PLHIV, however, are highly stigmatized and discriminated against in that region (Gökengin et al., 2016; UNAIDS, 2017). Sexual transmission seems to be the main way by which people are infected in MENA; however, this remains understudied for various reasons specific to the region. The main issue being that sex between men is generally unaccepted and penalized (Gökengin et al., 2016).

A study on 162 male college students from Saudi Arabia showed that HIV/AIDS shame was the most significant predictor in that population in relation to HIV stigma (Badahdah, 2010). Another study conducted also among students (in the United Arab Emirates), showed that 53% of them believed that PLHIV should be separated from society, while only 27% considered HIV-positive children as being able to attend school (Ganczak et al., 2007). Over half of Yemeni students who participated in a study in 2010, confessed that in their opinion "people with AIDS should be ashamed of themselves" and that they would be humiliated if someone from their family suffered from AIDS. Over 40% of the students felt anger and lack of sympathy toward PLHIV (Badahdah and Sayem, 2010).

Iran has been recognized as the HIV prevention pioneer in the Middle East, thanks to its needle-exchange program. HIV related stigma and discrimination, however, are still present there (Oskouie et al., 2017). A study of 25 HIV-positive women living in Iran showed that they had experienced frustration, fear, shame, and rejection. One of the women was afraid to disclose to her own daughter that the medication she was taking was for HIV, because she believed the daughter would reject her own parents. Some of the study participants also expressed that people surrounding them did not have sufficient knowledge about HIV and, therefore, avoided contact with PLHIV based on misconceptions. One participant admitted that the fear of stigmatization affected their medicines adherence as they did not want to be seen taking their medication. Stigma was also recognized as the main reason to withdraw from therapy follow-up visits and for instituting self-medication or trying alternative medicines (Oskouie et al., 2017). A similar study was conducted in Kerman, Iran. The participants experienced both internal (shame, isolation, nondisclosure of the serostatus) and external (from their family and health care professionals) stigma. One woman admitted to lying to her family members that she had cancer and therefore had to take medications (Karamouzian et al., 2015).

Parallels With Stigma Associated With Other Diseases

Prejudice and stigma are observed in many diseases other than HIV/AIDS, such as tuberculosis (Yan et al., 2018), mental illnesses (Corrigan and Al-Khouja, 2018), leprosy (Susanti et al., 2018), obesity (Brewis et al., 2018), and STDs (Ross et al., 2017). Stigma is also experienced by patients with opioid use disorder who are treated with medications (Bagley et al., 2017) even though there is evidence that methadone/buprenorphine therapy reduces the risk of death due to overdose and relapse of use of opioids. In the case of opioid addiction, additional stigma is the consequence of the illness being perceived as the addict's choice, alongside HIV where it is sometimes treated as the result of PLHIV's life decisions (Wakeman and Rich, 2018).

As with HIV, stigma in key populations or regions can be even more challenging to tackle. For example, it was found that in Saudi Arabia a high number of hospital staff working in King Abdulaziz Hospital had a stigmatizing attitude toward patients with mental illnesses (Sewilam et al., 2018). Military service members tend to avoid mental health services, wary that it might cause stigma, harm their career and reduce the trust of their superiors (Hernandez et al., 2017). MSM who participated in a study in Tanzania reported that when they were suffering from STD symptoms, health care professionals were not polite in response to the majority of symptoms (Ross et al., 2017).

A 2016 analysis suggested that encouragement of uniformed and civilian leaders of military service members should help them overcome stigma related to the use of mental health services. Military leadership should emphasize the value of these services in the overall health and encourage preparedness of military service members (Hernandez et al., 2017). A study in Indonesia showed that early diagnosis of leprosy and support of self-care groups can help with increasing adherence and motivation for healing (Susanti

et al., 2018). A case study from 2018 suggested that stigma associated with opioid agonist treatment among young adults can be tackled by increasing access to the treatment, through implementing public education campaigns, educating health professionals, changing stigmatizing language, and involving the media in campaigns (Hadland et al., 2018).

Discussion and Way Forward

Changes in legislation and public health policy as well as media initiatives should be utilized to help eradicate the stigma associated with HIV positivity and treatment. Effective strategies for tackling stigma in different regions of the world should be advanced (Vanable et al., 2006). WHO suggests that integration of services tackling various HIV-related issues, which includes provision of those services in the same location (e.g., the same clinic), might positively impact stigma over time. Moreover, an involvement of HIV-positive people in the training of health workers, or providing support to other patients can have a positive impact on overall stigma (WHO, 2016a). A study, which showed that internalized stigma can be associated with suboptimal medicines adherence, suggests that confronting interpersonal challenges that PLHIV face (such as low self-esteem and fear of being seen while taking medications) through Cognitive Behavioral Therapy (CBT) techniques can empower people to believe they can challenge stigma if they ever face it (Helms et al., 2017). A study in Ghana found that HIV-positive MSM are mainly motivated to engage in anti-HIV therapy by their fear of mortality, social support, and better knowledge of the treatment options available (Ogunbajo et al., 2018).

To really challenge multidimensional stigma among key HIV populations, it is crucial to understand other aspects of social hostility these people face in their daily lives, such as transphobia, homophobia, racism (Quinn et al., 2017), and sexism (Logie et al., 2011). A study of 135 older HIV-positive gay and bisexual men showed that participants were subject to internalized sexual minority stigma and enacted sexual minority stigma in health care settings, which was associated with increased likelihood of high-risk sex behaviors and less frequent presentation to health care facilities (Emlet et al., 2017). Furthermore, HIV-positive MSM who are also illicit substance abusers experience more limited access to anti-HIV therapy in comparison to nonsubstance abusers (Shoptaw, 2017).

Cultural awareness has to be applied, especially when approaching highly stigmatized communities such as Black MSM, who should be covered by HIV-education and stimulated to have open discussions on HIV that would encourage nonrisky sexual behaviors and the use of appropriate prevention (Weathers et al., 2017). A study in China showed that HIV-positive MSM believed that developing an HIV cure would significantly reduce all types of HIV stigma (anticipated, internal, enacted). This group, however, also did not believe this would meaningfully impact stigma against MSM, as its roots reach well into societal beliefs of MSM's levels of promiscuity and high rates of STD (Wu et al., 2017).

One study of male sex workers in Vietnam demonstrated that a population that suffers complex stigma (in this case related to sex work, their sexuality, and HIV status) can be positively influenced by health promotion interventions that would increase their knowledge on sexual health, sexual diversity, stigma management, and so forth. The authors expressed their belief that interventions promoting health knowledge might benefit even the most stigmatized and difficult to reach groups (Goldsamt et al., 2017).

Stigma can also be worse in patients suffering from comorbidities such as Hepatitis C coinfection, however, mental health problems are still the most common comorbidities that PLHIV suffer. A study published in 2016 tried to trace how mental health problems associated with HIV positive people living in London evolved during the decade 2004–14. The data showed that despite the significantly more effective anti-HIV therapy, PLHIV continued to experience significant mental health issues (Adams et al., 2016).

Reduction of HIV stigma in the health care setting should be treated as a priority. Health care providers should be aware of the existence of stigma and benefits that can be achieved by its reduction, such as better adherence to antiretroviral medication (Nyblade et al., 2009). In South Africa, results of a three-year research project suggested that collaboration between traditional healers and health care professionals could have a positive influence on global HIV health outcomes (Maleke et al., 2017). It has been proven in many studies that an effective social support network significantly improves HIV-positive patients' health and adherence to medications (Nyamathi et al., 2018). Self-stigma, of an HIV-positive person, can also be significantly reduced by loving support in a relationship (Yang et al., 2017). A randomized controlled trial in Kenya showed that HIV patients benefit from open communication and a feeling of being treated with compassion which helps to deal with stigma (Lowther et al., 2018).

Injectable long-acting anti-HIV medicines might be a promising alternative for people who struggle with HIV stigma. Taking medication less frequently not only improves the overall quality of life of patients but also has been reported, in one US and Spanish study, as more "discrete" and as reducing internalized stigma due to not having pills that serve as a daily reminder of the disease (Kerrigan et al., 2018).

New prevention technologies (NPT), such as PrEP, vaginal rings containing antiretroviral medications, rectal microbicides (compounds used to prevent infection), and HIV vaccination might bring positive change to highly vulnerable populations (the last three of these are still in development). Concerns have arisen, however, in regard to expected adherence to these prevention tools. A study in South Africa showed that participants were initially enthusiastic about using NPT. They felt that it would help them not only in the situations where they fail to negotiate using a condom during sexual intercourse but also in the event of rape, which is especially relevant for women and MSM. NPT also has the potential to empower women to make their own decisions in societies where they experience gender inequality and assist in protecting themselves against infections without seeking their partners' permission. The participants of this study, however, were mainly concerned about long waiting times and the stigmatizing approach

of clinic staff where they would receive NPT (Atujuna et al., 2018). What is more, PrEP stigma is still observed which negatively effects already disadvantaged populations in significant ways (Golub, 2018).

Web and mobile-based communities are increasingly common with support groups that can be easily accessed by people who are challenged by HIV stigma. Posts that were analyzed in a study on PositiveLinks, a mobile health intervention, showed that the community helped each other to cope with stigma by sharing their stories, and talking about companionship, positive thinking, finding hope in one's religious beliefs and so forth. Participants expressed that PositiveLinks helped to look at HIV/AIDS in a "hopeful light" and to increase HIV positive people's self-worth through positive affirmations (Flickinger et al., 2018).

Summary

Stigma related to HIV remains one of the most significant and challenging problems related to HIV infection and management with ART. Various research studies have proven that ART, even though currently highly effective and with a good risk-benefit ratio, might cause distress for patients who tend to hide the real cause for their taking of medications and who are constantly worried that the medicines might disclose their HIV serostatus. Stigma related to ART is unambiguously related to HIV/AIDS stigma and interlinked with the discrimination of various key populations. Some of those vulnerable populations might overlap (e.g., transsexual sex workers) and therefore their members experience even more complicated and severe stigma.

HIV stigma in some populations remains understudied, which might be the reason why some study results contradict each other when, for instance, trying to measure the correlation between stigma and adherence to medicines. Continuing studies are required to understand how different aspects of stigma affect various populations and how they relate to the lives of people living with HIV.

Stigma might negatively impact not only the mental health status of people living with HIV, but also their physical well-being, either through inadequate access/adherence to ART or discrimination by health workers, and even physical violence. For that reason, it is crucial that policies and programs in every region of the world should protect key populations and reinforce public education about HIV/AIDS, especially among health care professionals. It is of the utmost importance that there is greater access to programs dedicated to increasing access to harm-reduction services, reduction of high-risk sexual practices, and learning about active coping strategies.

New biomedical prevention technologies give hope that the most vulnerable populations, such as women, men who have sex with men, and IDUs will be able to defend themselves against HIV infection without being stigmatized. Similarly, new technologies and web-based communities should serve as a source of information and support for people living with HIV, a large number of whom suffer from stigma.

Glossary

AIDS	Acquired immune deficiency syndrome
ART	Antiretroviral therapy
HIV	Human immunodeficiency virus
IDUs	Intravenous drug users
MENA	Middle East and North Africa
MTCT	Mother-to-child-transmission
NPT	New prevention technologies
PLHIV	People living with HIV
PrEP	Preexposure prophylaxis
STD	Sexually transmissible disease
UNAIDS	The Joint United Nations Programme on HIV and AIDS
WHO	The World Health Organisation

External Reference Pricing and Medicines

Amna Saeed[*,†,‡,¶], **Zongjie Li**[*,†,‡,¶], **John Alimamy Kabba**[*,†,‡,¶], **Caijun Yang**[*,†,‡,¶], **Yu Fang**[*,†,‡,¶], [*]Xi'an Jiaotong University, Xi'an, Shaanxi, China; [†]Center for Drug Safety and Policy Research, Xi'an Jiaotong University, Xi'an, Shaanxi, China; [‡]The Global Health Institute, Xi'an Jiaotong University, Shaanxi, China; [¶]Shaanxi Centre for Health Reform and Development Research, Shaanxi, China

Introduction

The increasing price of medicines and growing pharmaceutical expenditure are becoming a major concern for governments, policy makers, and health insurers worldwide (Espin et al., 2011). These high prices can make essential medicines inaccessible and unaffordable hence compromising one of the Millennium Development Goals (MDGs) of United Nation (UN), i.e., "access to essential medicines" (Sachs and McArthur, 2005). Different price regulation policies are adopted by countries to contain medicine prices specially of the new medicine products, which are protected by some exclusive market rights, such as patents and external reference pricing (ERP) is one such cost containment strategy (Espin et al., 2011).

Currently, many countries (HICs) (Nguyen et al., 2014; Rémuzat et al., 2015) are using the ERP or International Reference Pricing (IRP). The ERP uses benchmarking or taking the price of a medicinal product as reference from one or more other countries to set or negotiate the local price of that product (Espin et al., 2011). Besides being feasible for adaptation by many high-income countries, this system can also be conveniently applied with limited technical resources, thereby justifying its use by small countries. There is a scarcity of evidence about its actual impact, limitations and scope, especially from LMICs, but some objective information is available regarding its use and implications from Europe and OECD countries (Espin et al., 2011). It may, however, pose some negative impacts as well, such as delayed launch of products, deceptive published prices, and higher priced generic products (WHO, 2015).

This chapter gives practical understanding of the concept of ERP together with prerequisites for adopting the ERP system in detail. The potential impact of employing ERP on local prices of medicines in different countries and on the pharmaceutical manufacturing firms has also been discussed.

Need for Pharmaceutical Pricing Policies

One of the main goals of a sustainable health policy in any country is the provision of cost-effective, accessible, and affordable pharmaceutical care services, as a vital component of the health-care system (Borowitz, 2010). Medicines account for a large portion of health-care expenditures across the globe, e.g., 20%–60% in LMICs and around 20% in the HICs (Acosta et al., 2014; WHO, 2015). The HICs have the major share in the pharmaceutical market. The LMICs have 84%, and HICs have 16% of the world's population, but global pharmaceutical expenditure by LMICs is 22% compared to 79% for HICs (Lu et al., 2011). This results in significant differences in per capita expenditures ranging from US$7.61 in LMICs to US$431.60 in HICs (Acosta et al., 2014). The increasing prices of medicines are becoming a major reason for unaffordability and inequitable access to medicines, making it necessary to include some price regulation strategies into the overall health policies. The purpose of pharmaceutical pricing policies is to determine the prices of drugs, which are suitable for both manufacturers and users of drugs, and to ultimately ensure the equitable access to medicines (Acosta et al., 2014).

Medicine Price Regulation: Policies and Strategies

Setting the maximum price of drugs that is fair and appropriate is of great concern for every country, no matter which mechanism of pricing is used (Rietveld and Haaijer-Ruskamp, 2003). There are different definitions of maximum price of drugs among all countries. It largely depends on their demography, pharmaceutical needs, share of the pharmaceutical industry in the national economy, and prescribing trends (Mossialos et al., 2006).

A fair price regulatory system should comprise certain features. Relevance to the particular health system and policy objectives, financial sustainability, affordability, and promotion of quality assured pharmaceutical products are probably the most important components of price regulation (Espin et al., 2011). WHO recommends the use of a mix of pricing policies such as cost-plus pricing, profit ceiling, price negotiations, internal and ERP, which cater for the individual needs of the countries and address both demand and supply issues. Such policies should be aimed at promotion of affordable medicines and should consist of a proper legislative framework and implementation, which must be reviewed on a regular basis. The transparency of pricing policies and international collaborations to promote the exchange of information regarding policies' impact is also endorsed by WHO (WHO, 2015).

When improving affordability is the sole target, prices are directed to lower than the prevailing prices but if a country has other targets such as promotion of research, innovation, new drugs development, availability, and local production, then a different set of policies will be required (Espin et al., 2011). Research and development may not be a main concern for many of the developing countries as they usually do not contribute much in this area but for developed countries this is of great importance. For research and development, drug prices serve as the main incentive for manufacturers especially when market competition is poor. The lowered prices of drugs will lead to lack of interest in manufacturing or importing essential drugs by many countries. So, patients might be deprived of many life-saving drugs, leaving a negative impact on their health. Hence, access to medicines will be compromised. This explains the significance of customizing the pricing policies according to country-specific needs (Espin et al., 2011). So, different countries use varying sets of pricing policies based on their particular objectives.

External Reference Pricing

ERP is also known as International Reference Pricing or External Price Benchmarking. It has been defined as "the practice of comparing pharmaceutical prices across countries" and "there are various methods applied and different country baskets used" (OECD, 2008). The OECD definition has been adopted by many pricing policy reports. The World Health Organization (WHO) defines ERP as, "the practice of using the price of a pharmaceutical product (generally ex-manufacturer price, or other common point within the distribution chain) in one or several countries to derive a benchmark or reference price for the purpose of setting or negotiating the price of the product in a given country". It is also indicated that, "Reference may be made to single-source or multisource supply products" (WHO, 2015). Under ERP, the manufacturer is guided by the country to set a product charge according to the price of the same product in selected foreign countries. The set of selected foreign counties is termed as that country's reference basket (Geng and Saggi, 2017).

It is noteworthy that another term called as "internal reference pricing" is a different type of reference pricing and shall not be confused with ERP. Under internal reference pricing, the price of a drug is set by taking the prices of other domestic drugs that are its therapeutic equivalents, as a reference. This system is usually used for pricing new drugs that already have their therapeutic equivalents in the local market. If the new drug has proven superior therapeutic advantage over the already existing therapies then it is given the benefit of a percentage increase in the price. Internal reference pricing can also be used for pricing generic medicines by setting lower prices than for brand medicines. This method is mostly used when adding medicines to the reimbursement list (Vogler et al., 2008).

In the past, different cost containment strategies such as cost-plus methods or internal reference pricing have been used by the majority of countries but recently ERP is being considered as a major price control mechanism by many countries across the globe. In the 1990s, when many new drugs (with superior therapeutic value) were introduced into different countries, ERP became an important instrument in setting fair prices of individual drug products rather than setting average price levels of drugs (Persson and Jönsson, 2016). Over time, ERP has been adopted by many countries because it is uncomplicated compared to other pricing models that need data on profits, costs, and cost effectiveness, that is, pharmacoeconomic evaluation, etc. (Geng and Saggi, 2017).

The purpose of ERP is to facilitate pricing by regulatory bodies by providing them with a reference price or a benchmark to set or negotiate the price of the drug in a domestic market. García Mariñoso et al. (2011) stated that "External referencing (ER) imposes a price cap for pharmaceuticals, based on prices of identical products in foreign countries," which they contrast with "directly negotiating the drug's price with the firm" (Garcia Mariñoso et al., 2011).

Requirements for Implementation of ERP

WHO states that the following factors must be considered when adopting ERP policy (see **Fig. 1**)

- Justified criteria for selection of countries in a reference basket.
- Availability of true data for prices rather than a falsified price.

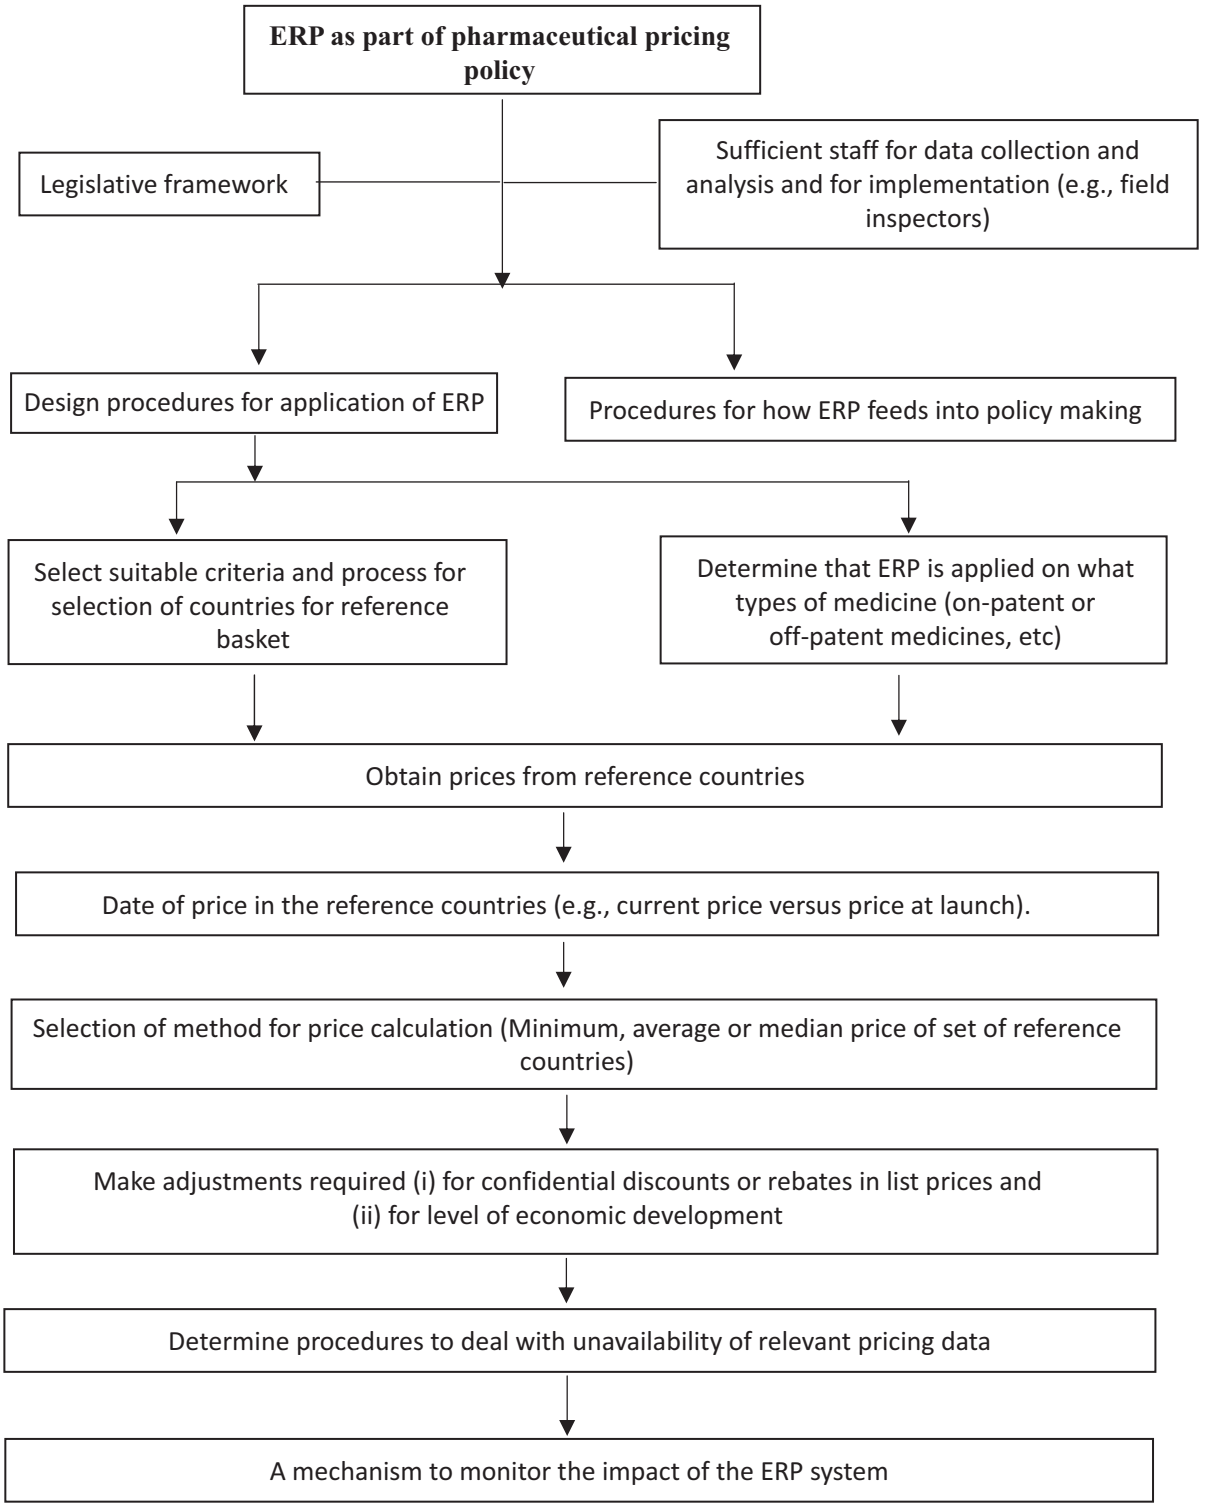

Figure 1 Process to implement the external reference pricing system. *Source: Adapted from the WHO guidelines on country pharmaceutical pricing policies. Geneva. (World Health Organization 2015).*

- Scope of ERP policy: selection of the type of drugs on which ERP will be applied (e.g., new drugs) and the level at which ERP will be applied (e.g., ex-factory price, procurement price, or manufacturer's price).
- Determination of method of calculating the ERPs, such as lowest price in that particular drug group, average price of all products, or median price of all products.
- Predefined procedures for application of ERP and regular monitoring of medicines prices backed by legislative framework.
- Management of database and data analysis.
- Making adjustments according to the current currency exchange rate with the reference country, and also considering the level of economic development (WHO, 2015).

Potential Benefits, Harms, and Risks of Using ERP

The potential benefits of using ERP as a pricing strategy are as follows:

- It is easily applied compared to other systems, such as economic evaluations.
- Lesser technical skills are required to manage its implementation (Nguyen et al., 2014).
- It provides quick evidence to policy makers even with limited availability of resources.
- It allows for international comparisons (Espin et al., 2011; WHO, 2015).
- It can develop a sense of security and satisfaction in the general public that they are not paying more than other countries to get the medicines (Persson and Jönsson, 2016).

Potential risks and harms of using ERP are as follows:

- The inappropriate selection of countries in a reference basket can lead to increased drug prices.
- Manufacturers and payers can falsify or hide true prices on the official list of medicines prices, so it can become hard to sustain the ERP in a true sense (Geng and Saggi, 2017; Persson and Jönsson, 2016).
- Patients in LMICs might experience limited or delayed launch of new drugs because the manufacturers will aim to launch the drugs first in high-income countries where they can charge higher prices to consumers (Espin et al., 2011; Geng and Saggi, 2017; Nguyen et al., 2014; WHO, 2015).
- Data sources for price comparison might be dubious (WHO, 2015).
- Consumers from high-income countries might not be able to pay in accordance with their buying power and their wish to contribute to the research and development of innovative drugs (Persson and Jönsson, 2016).

Implications of ERP Use in High-income Countries

As most of the countries from Europe (EU) are high-income countries, it is noteworthy that approximately 23 out of 27 of these are using ERP as the main drug pricing strategy (Rémuzat et al., 2015). European countries observed a 76% rise in pharmaceutical expenditure in the outpatient sector from 2000 to 2009 (Vogler et al., 2011). To deal with this situation and also under pressure from the global financial crisis of 2008, many price containment strategies were employed such as price reduction, changes in medicines value added tax (VAT), and in co-payments. Among the other pricing methods ERP was also widely applied in EU member states. The United Kingdom is important in the world's ERP system as it is taken as a reference country by many other countries, irrespective of their regions, because in the UK drug prices have been reported to be relatively low (Espin et al., 2011; Rémuzat et al., 2015; Ruggeri and Nolte, 2013). Many non-EU high-income countries such as Canada, Australia, Japan, and Norway have also applied ERP and are including EU countries in their reference basket (Leopold et al., 2012; Ruggeri and Nolte, 2013). The majority of the European countries are using the ERP system, which is backed by a legislative framework (Rémuzat et al., 2015). Other pricing mechanisms, such as direct price control, that is fixed maximum prices, profit ceiling, and internal reference pricing are also being used for different types of drug products by EU member countries. The less common methodology is "free pricing," which is being used mainly by Germany and the UK for specific products such as patented medicines (Mrazek and Mossialos, 2004). Most of the high-income countries use ERP to control the prices of medicines with patent protection or other intellectual property rights (pricing monopoly). Among the EU countries, some are using ERP for off-patent drug products, including Slovenia, Austria, Slovakia, Croatia, Poland, Czech Republic, the Netherlands, Iceland, Italy, Lithuania, and Latvia. ERP is used mostly for drugs that are reimbursed by the government in the European countries. Among EU members, France, the United Kingdom, and Germany are the top three most referenced countries. Japan has a different strategy compared to other high-income countries, as it uses ERP either to increase or decrease the local prices of medicines according to an adopted formula (Espin et al., 2011). The reference price used to calculate the external reference price varies among high-income countries but the majority use ex-factory prices. Drug prices are reevaluated regularly in the majority of countries. Among the EU member states, reevaluation ranges from every 3 months (Greece) to every 5 years (France) (Rémuzat et al., 2015).

There is scarcity of evidence on the impact of ERP (Kaiser et al., 2014; Ruggeri and Nolte, 2013). It is reported by two studies, conducted in both EU and non-EU countries that substantial decreases in drug prices has not yet been observed (Kyle et al., 2008; Leopold et al., 2013). With the widespread use of ERP by high-income countries, pharmaceutical manufacturers are developing strategies to counter any negative impact on them, such as reduced drug prices. So, many countries are facing delayed launch of

new drug products into the market. For example, Belgium faced delayed dossier submission by manufacturers because Belgian prices are usually not among the highest prices in EU member countries (Konijn, 2007). Another study reported that in Germany and New Zealand, the prices of some medicines (e.g., ACE inhibitors and atorvastatin) were deliberately kept high because manufacturers knew that these countries would be used later as reference countries (Kyle et al., 2008; Richter, 2008). This behavior can compromise the main purpose of ERP, which is to reduce prices and make medicines more affordable. Counter strategies by manufacturers put a big question mark on the sustainability of the ERP system. Price convergence, reported to be another result of ERP based systems, has led to reduction in funding of research and development of new products due to decreased revenues (Rémuzat et al., 2015). It has also been revealed that changes in prices in one country (i.e., a reference country) can result in changes in prices in other countries. It is estimated that if medicine prices are reduced by EUR1 in Germany, it can cause a decrease of EUR0.15–0.36 in 15 other European countries using the ERP system (Stargardt and Schreyögg, 2006). This evidence also puts emphasis on the importance of the selection of countries in the reference basket. So, if a country's aim is to reduce drug prices, then it should select a reference country that has low prices and is at the same level of economy. If the purpose is to promote research and development, however, then the choice should be made accordingly. Use of the ERP system by five high-income countries has been summarized in **Table 1**.

Implications of ERP use in Low- and Middle-Income Countries

In view of increasing global pharmaceutical expenditure, almost all high-income countries (except the United States) have adopted different pricing and procurement policies to reduce medicines' prices to cope with this situation (Critchley, 2006; Rietveld and Haaijer-Ruskamp, 2003). The situation has become worse for the LMICs, however, due to the lack of a regulated system, that is, stringent pricing, purchase, and reimbursement policies, which is making these countries "price acceptors" and increasing out of pocket expenditures (Sengupta et al., 2008). It has been reported that 61%–77% (per capita) of total pharmaceutical expenditure is private expenditure in LMICs (Lu et al., 2011). Health-care information systems are also lacking in the LMICs, making designing and the application of policies difficult compared to high-income countries (Nolen et al., 2005). Despite all of this, the situation is changing, as some LMICs are adopting different approaches to deal with increasing pharmaceutical expenditures. Some LMICs are now using one or more of the techniques (ERP, cost plus, internal reference pricing, profit controls, economic evaluation, and direct fixation, etc.) to set fair maximum prices for drug products (Vogler et al., 2008). The widespread use of ERP by high-income countries and its comparatively easy application is leading to its use by many LMICs. The applicability of ERP is due to lesser technical and analytical requirements compared to other methods of pricing such as cost plus or pharmacoeconomic analysis (Espin et al., 2011). In the ERP system, the selection of countries in the reference basket should ideally be from the countries with similar economies and within the same region, but lack of pricing data from these countries is a big obstacle for LMICs. So, in the absence of price information from reference countries, while implementing the ERP system, these countries also rely on international medicine pricing from the latest International Medical Products price guide produced by Management Sciences for Health (MSH, 2015).

There is very limited literature available on pricing policies and hence the use of ERP in LMICs. WHO and Health Action International (HAI) started reviewing the policies in 2011 under their broader project on prices and availability of medicines. Thirteen LMICs were selected for review. It was observed that the procedures for design and implementation of ERP varied among all the selected countries. For price referencing, average or minimum costs were reported as selected by the majority of these countries. Many European countries were observed to be taking reference countries from the same region. Slovakia takes eight European countries in its reference basket and the price regulator demands that the product's manufacturer provide information about its price in the other European countries and in the product's country of origin. The price setting commission of Iran uses ERP for ex-factor and wholesale prices of only on-patent and imported medicines taking Turkey, Spain, Greece, and the country of origin as reference (Espin et al., 2011). Pakistan is using the ERP system for setting a fair price for new molecules, taking India and Bangladesh as reference countries (DRAP, 2015). The Czech Republic takes an average of ex-factory prices in all EU countries to set prices of drugs in the government's reimbursement list of medicines (Espin et al., 2011). Indonesia adopted ERP along with other pricing strategies such as cost-plus pricing in 2010, for setting the prices of generic medicines. A price reduction in LPGs of about of more than 2000% for some drugs but not for the branded drugs was observed because of the lack of such policies for originator brands (Rida and Ibrahim, 2018). Turkey had also adopted ERP system (revised in 2011) and was used for all medicines. A decrease in the pharmaceutical expenditure (as a part of total health-care expenditure) was observed to be from 36% in 2004 and 27% in 2011 (Rida and Ibrahim, 2018). This decrease in prices both in Indonesia and Turkey can be linked to the ERP implementation up to some extent, but there is no objective evidence about it in the literature and there could be many other contributing factors leading to such results.

The increasing uptake of the ERP system by the LMICs serves as an index to its ease of use and applicability (Espin et al., 2011; Persson and Jönsson, 2016). It is hard to analyze the direct impact of pricing policies on drug prices in these countries because LMICs lack monitoring reports and relevant studies (Espin et al., 2011). Two Cochrane reviews were conducted which aimed to measure the impact of reference pricing on the health outcomes and medicine prices in 2006 and 2014 but none of these reviews included any LMICs (Acosta et al., 2014; Aaserud et al., 2006). Although the use of ERP seems justified for LMICs due to its comparatively easy application, still there is a dire need for these countries to strengthen their legal framework for better regulation of pharmaceutical prices, followed by sustainable monitoring and reporting systems (Nguyen et al., 2014). Use of the ERP system by five LMICs has been summarized in **Table 1**.

Table 1 Use of External Reference Pricing System in five high-income countries and five low- and middle-income countries

	World bank high-income countries					*World bank low- and middle-income countries*

ERP and Pharmaceutical Manufacturers

The pricing of pharmaceuticals is a complex process that involves expertise and is influenced by the dynamics of demand (consumers) and supply (manufacturers). How well these market forces harness the institutional policies of government or private sector (e.g., health insurers) will determine access, availability, and affordability of medicines to consumers. It is worth emphasizing that the primary objective of manufacturers is maximizing profit by marketing their drugs at the highest cost possible (Babar, 2016). ERP is an excellent tool that has been shown to reduce end user and public-sector health expenditure cost (Espin et al., 2014; Babar, 2016; Miraldo, 2009). The effectiveness of this pricing practice, however, depends on how well market monopoly is discouraged, the transparency of the negotiated price (Miraldo, 2009), and the country in which manufacturers first launch their products.

The market dynamism for pharmaceutical products differs from other consumers goods. Mostly, buyers are not the end users, but institutions are given the responsibility to provide for the population. Two scenarios come into play in this instance: protecting manufacturers' business from external referrers and cutting health expenditure. Countries tend to achieve the former by offering a relatively high ex-factory price to manufacturers or fail to publish the actual transaction price and letting the manufacturer determine the product price (Leopold et al., 2012; Espin et al., 2014). The latter is achieved by providing a platform for companies to compete, which prevents exploitation of the payers (Leopold et al., 2012).

Nonetheless, ERP does not prevent pharmaceutical companies from price manipulation. Leopold et al. used the term *"gaming"* to explain the pattern used by manufacturers to launch their product, targeting high-income countries where there will possibly achieve a higher price for their product (Leopold et al., 2012). This explains why the majority of countries using ERP are high-income countries because countries tend to reference countries with the same economic status (Espin et al., 2014). Furthermore, companies can get to the point of withdrawing their product from countries referencing the lowest possible price to avoid decline in revenues (Remuzat et al., 2015) or refuse to sell their product abroad if the domestic market is lucrative (Geng and Saggi, 2017).

Generally, ERP is a working pricing system that ensures health system sustainable by lowering overall cost; however, since it is a complex process it must be implemented with caution to protect the interests of both pharmaceutical companies and patients. Thus, there is a need for expertise in its implementation.

Future of ERP

The ERP system is becoming a popular cost containment policy in both HICs and LMICs because of its relative simplicity and its consequent assurance to the general public that they are paying the same prices for drugs as people in other countries (Persson and Jönsson, 2016). A huge benefit of using this model is its potential to bring down the prices of drugs, especially those that are protected by patents and other intellectual property rights, which can lead to obvious cost savings at least in the short run (Espin et al., 2011). Although the main aim of ERP is to reduce drug prices, it must also align with the objectives of health policy. For many countries, especially high-income countries, the goal of health policy is not only to reduce pharmaceutical expenditure but also to bring about improvement in research and new drug development (Rémuzat et al., 2015). In that case, the ERP system might play a negative role by decreasing drug prices and hence profits to the companies, ultimately causing reduced investment in the development of new drugs (Geng and Saggi, 2017).

ERP is also seen as a threat to market competition and price discrimination. If LMICs keep taking high-income countries into their reference basket (may be due to lack of pricing data from other LMICs), one price will be seen in all the markets and companies will not be able to discriminate according to the buying capacity of countries at different levels of economy. This will also decrease revenue to manufacturers that could have been more by discriminating (selling products at high prices to the high-income countries and at low prices to low-income countries). Manufacturers can respond to such a situation in two ways: first, by selling high priced drugs to high- and middle-income countries and ignoring low-income countries and, second, by launching new drugs in two waves, that is, first in high- and middle-income countries at high prices (thereby accumulating profit for some years) and then launching the drug in low-income countries. In the first case, high- and middle-income countries will have to pay high prices (Geng and Saggi, 2017; Persson and Jönsson, 2016). In both cases, low-income countries will either have no or delayed access to new drugs. This places a big question mark on the existence of the ERP system.

In view of the potential benefits and harms of the ERP system, it becomes very important to evaluate the true impact of ERP on medicines prices (especially in the LMICs). Besides this, the LMICs should focus on strengthening their legislative work and databases for medicines pricing to make comparisons at the same level of economy possible and to get the best out of the ERP system.

Glossary

External Reference Pricing The World Health Organization (WHO) defines ERP as "the practice of using the price of a pharmaceutical product (generally ex-manufacturer price, or other common point within the distribution chain) in one or several countries to derive a benchmark or reference price for the purpose of setting or negotiating the price of the product in a given country". It is also indicated that "Reference may be made to single-source or multisource supply products" (WHO, 2015).
Cost Plus Pricing A negotiated additional cost besides the costs for drug manufacture and research & development is decided with the manufacturer using the "cost plus" pricing method. The fixed mark-up usually includes this added cost (e.g., cost for drug promotion, stability testing, and workers' profit, etc.) (Nguyen et al., 2014).
Profit Ceiling This usually involves periodic negotiations with the pharmaceutical manufacturing companies to set the profit, which they can achieve by selling their products. The profitability of the company as a whole is taken into account as compared to setting margins for individual drug products (Rietveld and Haaijer-Ruskamp, 2003).
Price Negotiations This system includes negotiations, usually between government's price regulatory bodies and the manufacturers, over setting fair drug prices.

Pharmacy Workforce Development: A Global Pathway to Gender and Health Equity

Lina R. Bader*, Claire Anderson†, *International Pharmaceutical Federation, The Hague, The Netherlands; †Division of Pharmacy Practice and Policy, School of Pharmacy, University of Nottingham, Nottingham, United Kingdom

Pharmacy Workforce Development: A Global Imperative

The intersection of health, access, and equity lies at the heart of global health and the collective to achieve universal health coverage (UHC). Social pharmacy provides a lens through which the development of the pharmacy workforce can directly improve health, expand access to services, and advance equity (both in terms of [1] health equity and access to services and [2] equity within the workforce itself). This paper presents the global Pharmaceutical Workforce Development Goals (PWDGs) as a means to achieving UHC and the global health agenda and examines, in particular, the 10th Goal on gender equity and diversity balances as a priority area for development, and catalyst for better health everywhere.

Developing the Pharmacy Workforce for Universal Health Coverage

Access to quality essential health services and safe and effective medicines and vaccines is fundamental to achieving UHC by 2030, as part of the United Nations (UN) Sustainable Development Goals (SDGs)—especially SDG 3: "Ensure healthy lives and promote well-being for all at all ages" (United Nations, 2015). Health service delivery, health workforce, and access to essential medicines are three of six World Health Organization (WHO) health system building blocks (World Health Organization, 2010). As medicines experts, the pharmacy or the pharmaceutical workforce plays a key role in improving health outcomes through responsible use of medicines and in optimizing effective choice and use. Pharmacy workforce refers to the whole of the pharmacy-related workforce (e.g., registered pharmacist practitioners, pharmaceutical scientists, pharmacy technicians, and other pharmacy support workforce cadres, preservice students/trainees) working in diverse settings (e.g., community, hospital, general practice, research and development, industry, military, regulatory, academia, and other sectors) with diverse scope of practice. Investing in the development of an adaptable, flexible, competent, and well-distributed pharmacy workforce contributes toward achieving UHC, SDGs, and strengthening health systems.

Medicines are vital in the prevention, diagnosis, treatment, and cure of disease. Access to effective and safe medicines is an essential human right and a central foundation of any healthcare system. Medicines and drug development, medicines management, and the responsible use of medicines are vital components in improving the health of nations. As medicines experts, the pharmacy workforce is an integral part of the healthcare team that plays a key role in bettering health outcomes through optimizing patients' use and understanding of medicines (Nkansah et al., 2010). In many countries, pharmacists are the most accessible of all healthcare workers and as such are at the forefront of healthcare service delivery (Anderson et al., 2010). However, the capacity to meet these expectations, including delivering these pharmacy services, depends on having an assured, competent workforce and an integrated academic workforce to train sufficient numbers of new pharmacists and other support staff at both foundation and advanced levels. This, in part, explains why pharmacists have been recognized in the UN indicator for the achievement of the health target 3.c focusing on health workforce:

> 3.c Substantially increase health financing and the recruitment, development, training and retention of the health workforce in developing countries, especially in least developed countries and small island developing states.

The measurement will include the density of pharmacists per population (in addition to physicians, nursing personnel, midwifery personnel, and dentists) (United Nations, 2017).

Despite pharmacists being at the forefront of healthcare delivery, the global pharmacy workforce faces many challenges. The 2012 Global Pharmacy Workforce Report by the International Pharmaceutical Federation (FIP) described a number of problems

facing pharmacy human resources around the world, mirroring the challenges faced by the wider global health workforce (International Pharmaceutical Federation, 2012). Access to pharmacy services in developing countries and regions, such as Africa, is hindered by the insufficient supply of well-trained pharmacists. This carries implications for global inequalities in access to medicines and medicines expertise. The 2015 Global Pharmacy Workforce Intelligence Trends Report illustrates that, while the past decade witnessed a general increase in workforce numbers around the world, some low-income regions and countries still have a disproportionately low number of pharmacists and a low capacity for delivering pharmacy services (International Pharmaceutical Federation, 2015).

The Pharmaceutical Workforce Development Goals

Transforming the global pharmacy workforce requires a global vision with clear and consensus-based objectives consistent with global health strategies. The FIP is the global professional leadership body representing over 4 million pharmacists and pharmaceutical scientists around the world. FIP has developed a transformative workforce road map adopted at the Global Conference on Pharmacy and Pharmaceutical Sciences Education held in Nanjing, China, on November 7–8, 2016. The workforce road map sets out the desired milestones for education and workforce development of pharmacists and pharmaceutical scientists, clearly linked with a global vision for transforming pharmacy and pharmaceutical sciences education (International Pharmaceutical Federation, 2017). After an extensive consensus-based consultation process, the following three milestone documents were presented and adopted at the Global Conference:

1. A Global Vision for Education and Workforce that provides a description of the future directions of pharmacy profession and how education can support the progression of medicines science and practice.
2. A set of PWDGs that aim to facilitate national implementation of the global vision and road map through a series of measurable, feasible, and tangible goals.
3. A set of Statements on Pharmacy and Pharmaceutical Sciences Education (the Nanjing Statements) that describe an envisioned future for progressive professional education to enable further enhancement of pharmaceutical education standards worldwide.

The PWDGs (Fig. 1 and Table 1) have been developed as a measurable, feasible, and tangible means to activate and give purpose to the Global Vision. These 13 goals were the product of extensive external and internal consultation processes and adopted by consensus. The goals will provide action-oriented workforce planning and ways of monitoring progress toward global achievement

Figure 1 The FIP pharmaceutical workforce development goals.

Table 1 The pharmaceutical workforce development goals: description, rationale, drivers, and potential indicators

Cluster	*PWDG*	*PWDG general description. Countries/territories and member organizations should have:*	*Rationale, drivers, and potential indicators*
Academy Focus on schools, universities, and education providers	 1. **Academic capacity**	Engagement with pharmaceutical higher education development policies and ready access to leaders in pharmaceutical science and clinical practice in order to support supply-side workforce development agendas	• Increase the capacity to provide a competent pharmaceutical workforce by developing initial education and training programs that are fit for the purpose, according to national health resource needs (clinical practice, pharmaceutical science areas, and stakeholders across all cadres) • Develop new and innovative ways to attract young pharmacists into all areas of pharmaceutical practice and science (e.g., encourage young pharmacists to consider careers in clinical academia, as preceptors/trainers, in industrial pharmacy, regulatory sciences, nuclear and veterinary pharmacy, among others) • Capacity building should include the ability to meet minimum national standards of facilities, educators, and student support in order to ensure access to quality education for all students • Enhance interprofessional education and collaboration with key stakeholders, including governments, national and international pharmacy/pharmaceutical organizations, and patient advocacy groups to achieve sustainable solutions for capacity development • The clinical academic educator workforce needs more attention to training, career development, and capacity building, which must, importantly, include research capacity enhancement
	 2. **Foundation training and early career development**	Foundation training infrastructures in place for the early post-registration (post-licensing) years of the pharmaceutical workforce as a basis for consolidating initial education and training and progressing the novice workforce toward advanced practice	• Create clear and purposeful education and training pathways/programs to support post-registration (postgraduation) foundation training (clinical practice and pharmaceutical science areas) • Develop early career maps and frameworks to support a seamless transition into early career practice and toward advanced practice • Develop structured approaches to early career mentoring systems to support novice practitioners to engage with peers and preceptors (in clinical practice and pharmaceutical science areas across the pharmaceutical workforce)
	 3. **Quality assurance**	Transparent, contemporary, and innovative processes for the quality assurance of needs-based education and training systems	• Ensure the quality of the workforce by quality assuring the continuous development and the delivery of adequate and appropriate education and training; quality assurance needs to address academic and institutional infrastructure in order to deliver the required needs and competency-based education and training • Establish standards-based global guidance for quality assurance of pharmacy and pharmaceutical science education in the context of local needs and practice • Implement fair, effective, and transparent policies and procedures for quality assurance of pharmacy and pharmaceutical science education and training • Define critical stakeholder input on development of adequate education and training and fair and effective policies, including necessary student input

(*Continued*)

Table 1 The pharmaceutical workforce development goals: description, rationale, drivers, and potential indicators (*cont.*)

Cluster	*PWDG*	*PWDG general description. Countries/territories and member organizations should have:*	*Rationale, drivers, and potential indicators*
Professional development Focus on the pharmaceutical workforce	 4. **Advanced and specialist expert development**	Education and training infrastructures in place for the recognized advancement of the pharmaceutical workforce as a basis for enhancing patient care and health system deliverables	• Need for a common and shared understanding of what is meant by "specialization" and "advanced practice" in the context of scope of practice and the responsible use of medicines • Ensure competency and capability of an advanced and expert pharmacist in all sectors (including specializations extending into industry and administration settings) for greater optimization of complex pharmaceutical patient care. This may now include prescribing roles within a recognized scope of practice • Systematic use of professional recognition programs/systems as markers for advancement and specialization across the workforce, including advanced pharmaceutical scientists
	 5. **Competency development**	Clear and accessible developmental frameworks describing competencies and scope of practice for all stages of professional careers. This should include leadership development frameworks for the pharmaceutical workforce	• Use of evidence-based developmental frameworks to support the translation of pharmaceutical science within scope of practice, across all settings and according to local/national needs • Support professional career development by using tools such as competency frameworks, describing competencies, and behaviors across all settings • Evidence of clear policy that links leadership development (from early years) with competence attainment for the advancement of practice activities
	 6. **Leadership development**	Strategies and programs in place that develop professional leadership skills (including clinical and executive leadership) for all stages of career development, including pharmaceutical sciences and initial education and training	• Creation of programs/strategies for the development of leadership skills (including tools and mentoring systems), to support pharmacists and pharmaceutical scientists through their careers • Advocacy for leadership development in healthcare teams, linked to collaborative working activities (e.g., promotion of team-based approaches to healthcare service delivery) • Ideally, this should be linked with competency and foundation and early year career development activities
	 7. **Service provision and workforce education and training**	A patient-centered and integrated health services foundation for workforce development, relevant to social determinants of health and needs-based approaches to workforce development	• Systematic development of education and training activities based on local healthcare systems, their capacity, and funding • Evidence of systematic development policies and strategies for the strengthening and transforming pharmaceutical workforce education and the systematic training of trainers/educators • Education providers must ensure, by the provision of evidence-based approaches, that lecturers/teachers/trainers are themselves appropriately trained for capability and competency • Enable the pharmaceutical workforce and key stakeholders to promote health equity through actions related to social determinants of health
	 8. **Working with others in the healthcare team**	Clearly identifiable elements of collaborative working and interprofessional education and training which should be a feature of all workforce development programs and policies	• Evidence of policy formation to demonstrate how healthcare professionals can develop and engage in partnerships to achieve better health outcomes • Develop education and training strategies/programs to ensure collaboration within the pharmaceutical workforce and training on medicines for other healthcare professionals • Ideally, this should be linked with formal professional development activities

Table 1 The pharmaceutical workforce development goals: description, rationale, drivers, and potential indicators (*cont.*)

Cluster	*PWDG*	*PWDG general description. Countries/territories and member organizations should have:*	*Rationale, drivers, and potential indicators*
Systems Focus on policy development, governmental strategy and planning, and monitoring systems	 9. **Continuing professional development strategies**	All professional development activity clearly linked with needs-based health policy initiatives and pharmaceutical career development pathways	• Evidence of an effective continuing professional development strategy according to national and local needs • Development of programs to support professional development across all settings of practice and all stages of a pharmacist's career • Ideally, this should be linked with all professional development activities across the workforce • Education in continuing professional development strategies and self-directed behaviors should be initiated at the student level
	 10. **Pharmaceutical workforce gender and diversity balances**	Clear strategies for addressing gender and diversity inequalities in pharmaceutical workforce development, continued education and training, and career progression opportunities	• Demonstration of strategies to address the gender and diversity inequalities across all pharmaceutical workforce and career development opportunities • Ensure full and effective participation and equal opportunities for leadership at all levels of decision-making in pharmaceutical environments; avoidable barriers to participation for all social categories are identified and addressed • Engagement and adoption of workforce development policies and enforceable legislation for the promotion of gender and diversity equality, policies and cultures for the empowerment of all without bias • This should be applicable to academic capacity and leadership development activities
	 11. **Workforce impact and effect on health improvement**	Evidence of the impact of the pharmaceutical workforce within health systems and health improvement	• Engagement with systems to measure the impact of the pharmaceutical workforce on health improvement and healthcare outcomes. Links with needs-based education, training, and workforce planning • Gather continuous data points to monitor the performance of the pharmaceutical workforce • Ideally, this should be linked with strategies to enhance workforce intelligence
	 12. **Workforce intelligence**	A national strategy and corresponding actions to collate and share workforce data and workforce planning activities (skill mixes, advanced and specialist practice, and capacity). Without workforce intelligence data there can be no strategic workforce development	• FIP should aim to have a global workforce compendium of case studies developed by 2019 • Develop monitoring systems to identify workforce trends to enable decision-making on deployment and supply of pharmaceutical workforce, noting that time lags are often present in these activities • Ideally, this should be linked with stewardship and leadership for professional leadership bodies
	 13. **Workforce policy formation**	Clear and manageable strategies to implement comprehensive needs-based development of the pharmaceutical workforce from initial education and training through to advanced practice	• Adopt and strengthen sound policies and enforceable legislation for holistic needs-based approaches to professional development across all settings and stages • Develop strategies where pharmaceutical science and professional services are the driving forces for this activity

of the workforce vision. Crucially, they will provide a consistent structure for coherent and comprehensive national workforce development actions.

The 13 PWDGs are gathered into three groups:

- Academy: Focus on schools, universities, and education providers
- Professional development: Focus on the pharmacy workforce
- Systems: Focus on policy development, governmental strategy and planning, and monitoring systems

Progressing the Goals to Progress Gender and Health Equity

Gender and Diversity Balances in the Workforce

PWDG 10: "Gender and diversity balances in the workforce" calls for countries around the world to develop clear strategies for addressing gender and diversity inequalities in pharmacy development, continued education and training, and career progression opportunities. Progress toward this goal can be measured through the demonstration of strategies to address the gender and diversity inequalities across all pharmacy workforce and career development opportunities. It includes ensuring full and effective participation and equal opportunities for leadership at all levels of decision-making in pharmaceutical environments; avoidable barriers to participation for all social categories are identified and addressed. The engagement and adoption of workforce development policies and enforceable legislation for the promotion of gender and diversity equality, as well as policies and cultures for the empowerment of all without bias, are needed to progress PWDG 10. These policies and strategies should be implemented across all sectors and at all levels of the workforce starting from education.

PWDG 10 links directly not only to the UN SDG 3 on health but also particularly on SDG 5: "Achieve gender equality and empower all women and girls" and its targets with an emphasis on Target 5.1: End all forms of discrimination against all women and girls everywhere and Target 5.5: Ensure women's full and effective participation and equal opportunities for leadership at all levels of decision-making in political, economic, and public life.

Gender equity is the process of being fair to men and women. To ensure fairness, measures must often be put in place to compensate for the historical and social disadvantages that prevent women and men from operating on a level playing field. Equity is a means. Equality is the result. Gender inequity has contributed to unemployment and underemployment, low education and health achievements, and overall poverty. Sustainable development will depend on better gender equality. Yet, while in the developed world progress has been made, the International Labour Organization (ILO) states that African women continue to face persistent challenges to get decent jobs (International Labour Organization, 2016). Any change requires a continental effort and proactive action. The UN Development Programme's flagship 2016 report on development in Africa focuses on gender equality and women's empowerment (United Nations Development Programme, 2016). The report describes a continent limited in its potential by serious problems; it finds that gender discrimination leads to a loss of an average of $95 billion every year. The UN High-Level Commission on Health Employment and Economic Growth acknowledges that the health sector can greatly contribute to gender equality by being one of the biggest and fastest growing employment sectors for women (International Labour Organization, 2017) recommended to "Maximize women's economic participation and foster their empowerment through institutionalizing their leadership, addressing gender biases and inequities in education and the health labour market, and tackling gender concerns in health reform processes" (World Health Organization, 2016).

Science, technology, and innovation have been identified as the key driver of economic progress and sustainable development, which, for Africa, will depend largely on the use of its human and natural resources. All recent African declarations agree on this question. UNESCO's vision for sustainable socioeconomic development in Africa has translated this into action in four key projects, making science education accessible to women involving women in science. UNESCO also has had a number of projects promoting science, technology, engineering, and maths (STEM) careers to girls at school (United Nations Educational, Scientific and Cultural Organization, 2017). If we take Kenya as an example, two in five students in higher education are women and one-third of the students studying STEM subjects are women. The gender gap is narrowing in pharmacy education; there are 822 male and 690 female students.

A recent *Lancet* editorial promotes gender equity in science as both a moral and necessary imperative (The Lancet, 2018). A US national survey has identified STEM workplaces as "deeply misogynistic" (Parker and Funk, 2018). In the United Kingdom and Australia, schemes, such as Athena SWAN, show that STEM workplaces cannot be gender inclusive without institutional commitment to removing unconscious bias. Gender balance is not reflected at the leadership level, too.

Paving the Pathway to Equity

Seven out of ten health and social workers are women, and unpaid care work represents half of women's contribution to global wealth. Women health workers deliver care to around 5 billion people. WHO predicts a shortage of health workers (18 million), especially in low- and middle-income countries (LMICs) to achieve UHC. Resilient health systems and UHC cannot be progressed without consideration of the gendered aspects of the workforce.

Without this consideration, we will not be able to achieve the SDGs. Addressing gender biases and inequities in the health and social workforce is not only essential to achieving SDG 3 (health and well-being), but also SDG 4 (quality education), SDG 5 (gender equality), and SDG 8 (decent work and inclusive economic growth).

The ILO–OECD–WHO five-year action plan on health identified the (1) development of gender-transformative global policy guidance and (2) support to build implementation capacity to overcome gender biases and inequities in the education and health labor market as two key deliverables to maximize women's economic participation and empowerment.

Global Pharmacy Workforce

The recent 2018 FIP report on workforce intelligence trends describes the global capacity trends observed in the pharmaceutical workforce from 2006 to 2016, including gender distribution (International Pharmaceutical Federation, 2018). The proportion of women in the pharmacy workforce between 2009 and 2016 shows a steady increase at a percentage rate of around 7.5% every decade. The Southeast Asia region showed the highest proportional increase in the sample period. The results indicate that the average female proportion of the total global pharmacy workforce will continue to increase to around 72% by 2030, mirroring the proportions of the global health workforce.

Countries across each WHO region and income level category are experiencing an increase in the proportion of female pharmacists in the last decade as identified by the FIP report. This acceleration of female participation in the pharmacy workforce indicates a strong and positive attraction among females for entering the profession globally. Similar trends are found in medicine; all economic national categories have experienced increases in female participation in education, training, and entry to the medical workforce. In higher-income countries such as the United States, females now represent 50% of medical school graduates—an increase of 7% in the last 50 years (Pelley et al., 2016). In Canada, this increase is more marked with only 8.5% of female medical students in the 1970s increasing to 50% in the 1990s and currently sitting at around 57% of all medical students (Weizblit et al., 2009). The current UK proportion is approximately 60% (Moberly, 2018).

One major impact of having a high percentage of female pharmacists is the decrease in the overall contribution to the workforce. Various studies have highlighted that globally female pharmacists are more likely to take career breaks and work part time in comparison to male pharmacists, most commonly associated with child and family care (Carvajal, 2018).

Current research on gender equity in the health and social care workforce is focused on quantitative analysis of data (World Health Organization, 2018). While sex-disaggregation data shed light on the realities of gender equity such as the wage gap, quantitative research alone does not provide insight into the barriers and facilitators identified through the lived experiences of women in the workforce. Qualitative research is needed to ensure policy changes are attuned to the contextual realities of gender challenges. A high proportion of the literature identified in the recent WHO review (International Pharmaceutical Federation, 2017) points to inequities in the health workforce. The link between gender-transformative policies at the academic level and their positive impact on gender equities in the health workforce affecting both students and faculty improves the distribution, extent, and skill mix of the workforce. For example, segregation often starts at enrolment and more evidence examining this link and its impact on gender-based outcomes in the workforce is needed to influence higher education policy.

Job and Career Satisfaction as an Equity Issue

Female pharmacists in higher-income countries have consistently reported higher levels of job satisfaction than male colleagues, while the latter indicate greater intentions to leave the profession. In the United States, female pharmacists reported higher overall satisfaction levels including a higher satisfaction with pay, even though average statistics indicate reduced remuneration rates of up to $11,000 less than males (Carvajal et al., 2018). In Taiwan (a high-income country), one study indicated that more male pharmacists wanted to leave the profession (across all sectors) compared with female colleagues, which was reported as due to insufficient professional challenge (Lin et al., 2007). In Lebanon (an upper-middle-income country), female pharmacists reported greater satisfaction with the profession than male pharmacists (Salameh and Hamdan, 2007). Similar results have been reported in the United Kingdom, with females being more satisfied, in particular with career aspects such as working hours, social engagement, and patient interaction (Seston et al., 2009).

That these reports consistently suggest greater job satisfaction in the profession seems a generalizable trend and clearly linked with social roles. With association between satisfaction, gender, and the social interactivity of modern pharmaceutical roles, this would seem to suggest that the quantitative forward projections of an increasingly female-majority workforce have an underlying basis in gender identity. The global challenge is in ensuring that pharmaceutical workplace environments and pharmaceutical employment policies are contemporary and flexible enough to support this global trend.

Conclusion

This paper has shown how social pharmacy provides a lens, focusing on gender and diversity equality and health equity, through which the development of the pharmacy workforce can directly improve health, access to services, and advance equity (both in terms of [1] health equity and access to services and [2] equity within the workforce itself). We have presented the global PWDGs as a means to achieving UHC and the global health agenda and examined, in particular, the 10th Goal on gender equity and diversity

balances as a priority area for development, and catalyst for better health everywhere. Further research is needed to provide insight into the barriers and facilitators and the lived experience of women in the workforce.

Role of Pharmacists in Responding to Humanitarian Crisis

Huma Rasheed*, Hafiz Awais Nawaz*, Alia Zafar Rao†, Syed Khalid Saeed Bukhari‡, *Institute of Pharmaceutical Sciences, University of Veterinary and Animal Sciences, Lahore, Pakistan; †World Health Organization, Chak-Shehzad, Islamabad, Pakistan; ‡United States Pharmacopoeia Commission, U.S. Pharmacopeial Convention, Rockville, MD, United States

Learning Objectives

- Introduction to the concepts of humanitarian aid and types of humanitarian crisis.
- Identification of the role of the pharmacists in responding to humanitarian crisis.
- Understanding responsibilities of pharmacists toward handling of medicines during crisis.
- Learning from good and bad cases of donation of medicines.
- Understanding the role of technology in the development of pharmacist's role in provision of professional services in emergency condition.

Take Home Lessons/What Needs to be Done

1. Pharmacist is an essential component of the humanitarian aid team and must be involved in all segments of its planning and execution.
2. The donation supply and management needs to be an ongoing process of learning and need to be evidence based.
3. Supply chain management is an integral part of the pharmacist's role during health emergencies.
4. Rationality and ensuring responsible use of medicine must be at the core of the planning of pharmacy services.
5. Awareness and training regarding disaster management is needed for health-care professionals.

Background

Medical and pharmaceutical responses are crucial for saving precious lives during any humanitarian crisis. These responses include provision of both supplies as well as skilled human resource. Increasing number of humanitarian crisis situations are happening due to natural (owing to global warming, climatic change, and natural geographic processes) as well as global sociopolitical scenario with rising number of unresolved conflicts, economic turmoils, and international disputes (The World Economic Forum, 2019). Hence, health professional's response to humanitarian crisis have evolved as a permanent feature of the global health-care scene.

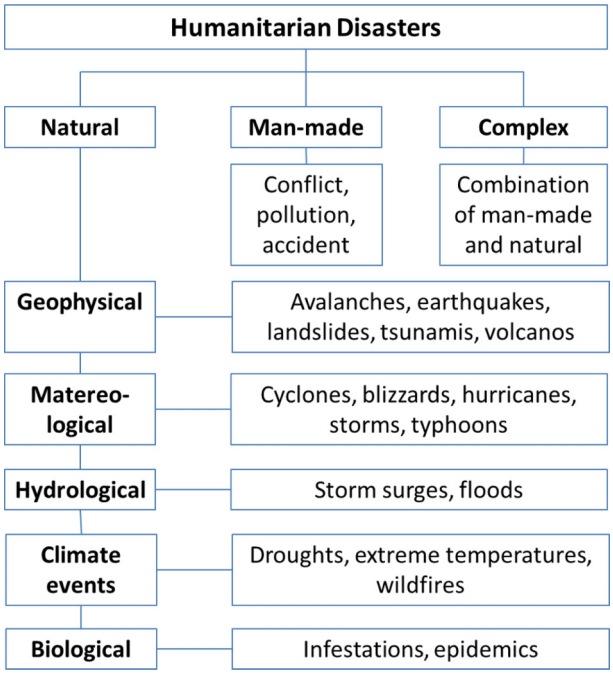

Figure 1 Classes of human disasters.

Pharmacists as the essential member of health-care team, are incorporated in the health system network globally, also including their presence in the emergency conditions. The role of pharmacist is transforming globally to patient-centered approach. Similarly, in emergency medicine, pharmacists have not only struggled to advance their role in the logistic management but also focussed on rationality and safety, in accordance with the needs of the population.

Types of Humanitarian Crisis

The events that result in threatening situations toward safety, health, and well-being of single person or community are identified as humanitarian crisis. Such events influence the community's capacity to cope with physical, environmental, or economic damages that arise due to these events.

Centre for research on the epidemiology of disasters (CRED) and the international disaster database (EM-DAT) have categorized the human disasters as in Fig. 1.

These crises can also be classified on the basis of resource needs, operational challenges, and overall requirements (1). This includes

1. Small-scale injury/illness events: tornado, small level disease breakout, bus crash.
2. Large-scale natural disasters: tsunamis, hurricanes, flooding, moderate earthquake.
3. Complex events: terrorism activity (multiple shooting of bombing), mass burn events, limited outbreak of infectious disease such as severe acute respiratory syndrome (SARS), and Avian Influenza.
4. Catastrophic health events: major earthquake, bioterrorism, pandemic, or nuclear detonation.

Health-Care System During Crisis Conditions

Implementation of emergency response emphasizes the importance of sustaining the resources of primary health-care system and reflecting these services into primary health-care strategies, policies, and services (Swathi et al., 2017). For instance, a number of health policies have been implemented by the United Nations and International Federation of Red Cross (with Non-Governmental Organizations) in collaboration with the local governments. The essential components of primary health-care system have been adopted to devise these policies. Reduction in events of disaster associated chances of morbidities and mortalities have also augmented the importance of implementing these policies. Moreover, standalone emergency response (trauma care, management of chronic situations, immunization, psychological support) has been recognized as an essential component of primary health-care system (Swathi et al., 2017).

The need of a design and implementation of an integrated health-care system for humanitarian crisis management framework was felt due to the lack of framework, competency in disaster management, and appropriate skills. Despite understanding of levels of disasters and their types (Fig. 1), meager efforts have been made to invest on strategies to cope and treat the aftermaths of such threatening events. The available policies do not train health-care professional students (physicians, pharmacists, nurses, and so on) to directly excel in disaster management competencies. Disaster management has classically not been part of the core curricula in health systems and mostly opted as an additional course delivered by the international or regional humanitarian aid organizations. The limited web-based programs and conferences only target the professional health-care workers and not the students.

An iconic disaster management system is envisioned of preparedness and rescue, which is regionalized, tiered, adaptive, and resilient. It can cope with all the different types and levels of humanitarian crisis. This system should be based upon networks of disaster management health-care centers and community-based resilience. Long-lasting success of this system is based on the alliance of three major components, that is, a resilient community, specialized disaster management hospitals/centers, and network of skillful health-care professionals (Toner et al., 2018).

The Phases of Response to Humanitarian Crisis and the Health-Care Professionals

The phases of crisis have been studied under prevention, incident preparation, response generation, and recovery efforts. A more comprehensive scheme includes six stages including warning, risk assessment, response, management, resolution, and recovery. The nature and severity and type of needs may vary tremendously in the initial phase of the emergency. The initial acute phase of 24 h needs can be further split into the immediate needs (0–2 h) and the extended phase (12–24 h) (Hurd and Mount, 2008).

Preparedness

Crisis is declared when the health-care needs exceed the capacity of the available infrastructure. The scale, intensity, and the short time in which these demands arise warrant the need of prior preparedness of the health system to deal with any emergency. Following key components of the emergency preparedness are identified in the literature (Hurd and Mount, 2008)

Planning

Anticipation of the role of health-care providers and identifying the types of disasters needed to be covered in planning are of important national and organizational concerns. The key health-care providers identified for responding to crisis are also called first responders. In the United States, pharmacists have been identified as part of the planning team for the crisis management since 1960s. Disaster preparedness is part of the requirement for accreditation of hospitals by the Joint Commission on Accreditation of Health Organization. According to a national survey in the United States, all hospitals have plans for responding to natural disasters, whereas most hospitals also have plans for chemical, biological, explosive, or nuclear/radiological events.

A diverse range of professionals are involved in response to the disasters. The personnel coming in first contact are termed first responders and include police, security, or other law enforcement personnel, firefighters, rescue personnel and paramedics, and ambulance attendants. Evacuation helpers, drivers, air lifters, and divers may also be engaged in depending upon the nature of emergency. Professional health-care personnel are mostly involved at second level, in the health-care facility or clinic whether permanent or in a make shift capacity. A good number of volunteers and public works personnel are also involved (Hurd and Mount, 2008).

Emergency department (ED) pharmacist has a key role in planning and responding to intentional (man-made) or unintentional (natural) disastrous events. ED pharmacist should be connected to regional and national emergency networks and should be involved in planning and policy-making decisions. Selection of pharmaceuticals and associated provisions for emergency inventories can be decided by involving ED pharmacist in disaster planning committees. The competence of ED pharmacist can help developing the guidelines for the treatment of disaster victims, postexposure symptoms, prophylaxis, patient isolation, and the provision of antidote in all emergency-related health-care centers. Another important role for ED pharmacist is to rationalize the procedures to obtain antidote from national stock in case of insufficient supplies available in the local emergency centers. ED pharmacist can provide antidote in case of bioterrorism event and can effectively participate in actions concerned with prophylaxis, treatment, and counseling. The pharmacist can also help in the provision of mass supply of appropriate medications and advise to physicians for rational prescribing.

Rescue

Search and rescue (SAR) is one of the most important and dynamic operation in disaster management. To do so, there are some principle methods, which can be applied. Security and safety should be always fully considered for both staff and victims. Generally, the initial SAR phase could last for hours or days after the crisis. However, a prompt response is required to save the lives from imminent danger. This phase usually passes in few days and actions turn toward providing support to the affected people.

The personnel engaged should be familiar with the role of rescue services in work on-scene, incident command structure, and international standards for rescue missions. In the crisis of Hurricane Katrina in 2005, SAR phase extended to 4 weeks. People remained trapped in their houses with limited food availability. Houses were surrounded by flood and most shared the emergency

supplied foods with neighbors until disaster teams rescued them. It was only possible with the collaborative effort of health-care professionals and local authorities. Immediate rescue concerns in emergencies that are more focused on health issues may warrant the need of arrangement of immediate medical supplies, which may be followed by setting up a temporary structure for pharmacy (bus or trailer or mobile van) rather than establishing a permanent structure.

Rehabilitation

The rescue and respond activities are followed by recovery, reconstruction, and rehabilitation. This is the most challenging phase of the disaster cycle and covers a wide range of actions. Perhaps the most demanding element is to review and evaluate the disaster management process to see whether it could have been managed better in preparation for possible future disasters. This phase may include spatial planning, developing infrastructure, communication, water, hygiene, and sanitation, housing, livelihoods, social security, transport, agriculture, and evaluation. This transition phase from the temporary and ad hoc structures to permanent ones may call for exceptional service designs from the health-care professionals. Like temporary relaxation of pharmacy dispensing procedures to ensure that health coverage is not compromised among masses following the crisis situation (Hurd and Mount, 2008).

Role of Pharmacists

Pharmacy professionals can deliver various roles in disasters, emergency situations, conflicts, wars, and disease out breaks as a part of the humanitarian aid organizations or being a part of the health facilities of the affected region. These include

1. Planning and purchasing of pharmaceuticals and related supplies
2. Monitoring and evaluation of the stocks received
3. Establishing drug supply system
4. Carrying out pharmacovigilance activities and monitoring the supply chain for any infiltration of substandard and falsified medicines
5. Ensuring rational use of medicines
6. Preventing antimicrobial resistance
7. Counseling and ensuring medication adherence
8. Preventing wastage of medicine
9. Controlling and preventing misuse and abuse of medicines
10. Minimizing communication barrier between affected community and pharmacy professionals to ensure proper counseling and understanding of the social and cultural preferences.

Policy and legal framework, drug supply management, and management support are three main levels of pharmacist's role in health facilities (WHO Regional Office for Africa, 2004).

Pharmacists can play the role of a health-care volunteer, a regulator, a team member. He can help development of indigenous guidelines drug donations to cater the needs of the local population specially in settings that are particularly vulnerable to disaster or crisis. Once donations are received at the relief camps pharmacy professionals are responsible to ensure that the supply is utilized in a rational and safe manner.

Delivering Pharmacy Services According to the Sociobehavioral and Cultural Needs of People

Health-care services of societies are closely aligned with the cultural, social, and religious beliefs of the people. It is important for the pharmacists to ensure this in its planning, procurement, and service design activities. The sensitive scenario of humanitarian crisis where many lives are at stake and people are already facing trauma, loss, and insecurity careful analysis of their social needs enable the pharmacist to implement its role in an effective manner.

The humanistic needs of the aid provision are important component. Pharmacists in humanitarian aid organizations can also be involved in managing advocacy campaigns or working. To understand the actual needs of the community, it is important for some of the professional members to work in field projects. Understanding patients' behavior and psychology is inevitable to ensure the proper delivery of pharmaceutical services to the population.

Preventing Antimicrobial Resistance and Disease Outbreaks

Epidemics and infectious diseases are an identified threat during any manmade or natural disaster situation. Scarcity of clean water and proper toilets pose problems of water borne diseases such as diarrhea, cholera, and gastroenteritis. The situation can become an urgent threat to the lives of population, which may be practically cutoff from the regular supplies or food and medicine. Cholera outbreaks were reported in the past in many natural and man-made disasters including the civil war in Sierra Leone (Dyer, 1995), floods (Tordrup et al., 2013), and post-earthquake (Bukhari et al., 2010) in Pakistan.

Apart from cholera malaria, tuberculosis and skin infections including scabies were also reported in such situations, due to people living in confined settings where they have poor sanitation, poor ventilation, and no sunlight. Apart from drug supply shortages, poor quality of pharmaceuticals has also been identified as the one of the problems encountered. Substandard antimalarial was found to be the cause of poor prognosis and emergence of multidrug-resistant malaria in an Afghan refugee camp in Pakistan (Leslie et al., 2009). Hence, adoption of a concrete policy for the quality assurance of the supplies is warranted in the disaster management programs. WHO prequalification system has been used as an effective tool in this regard (Bukhari et al., 2010). Rational use of medicines and efficient inventory management ensure the availability of antimicrobials as well as their safe and effective use. The shortage of trained staff in such situations are compensated using predesigned and standardized dosing protocols as used by relief and rescue organizations such as Medicines Sans Francis.

In order to develop a cautious approach to the public health issues regarding infectious diseases and their outbreaks, pharmacists must be equipped with the skills to understand and effectively use the epidemiological tools such as World Health Organization's (WHO) Disease Early Warning System (DEWS) for estimation and planning of pharmaceutical supplies in need. WHO established DEWS for early detection of diseases in the war-stricken regions of Iraq, Sudan, Serbia, and Afghanistan in early 2000s (World Health Organization, 2019). The key components of this system include infectious disease monitoring, outbreak investigation, disease control coordination, logistical support, and quality control (U.S. Agency for Internatioanl Development, 2013).

Irrational supplies, poor-quality medicines, absence of trained health professionals, and lack of prescribing protocols for safe and rational use of antimicrobials need to be preoactively addressed to prevent emergence of resistant pathogens in the resource constraints environment such as refugee camps.

A specialized logistic system needs to be established that entails the responsibility of safe use of pharmaceutical in the circumstances where affected people are more vulnerable to damage than in normal circumstances.

Antibiotic needs of the population are likely to be different in emergency situation than during peacetime (World Health Organization, 2011). AMR guidelines (antibiotic choices, doses, duration of treatment) for emergency situations must be evaluated. It is challenging to decide on a single appropriate guideline in such situation due to difference in nature of each type of hazard (i.e., trauma, flooding, earthquake, blasts, or volcanic eruptions) as each produce different medical problems and infections. Hence, no single approach can be adopted as a guiding principle.

Absence of laboratory support is also an important area that demands an alternate strategy for supporting diagnosis for use during the crisis situations. However, adopting AMR as a priority in the response planning may present a difficult task due to different priorities of the crisis management settings (World Health Organization, 2011).

Good Donation Practices

Initially introduced in 1996 (World Health Organization, 1999), the guidelines for medicines donation by WHO were revised in 2010 to interagency guidelines (World Health Organization, 2010). The document incorporates experiences of major international humanitarian agencies. It provides lessons from medicines donations carried out around the globe during the last decade. These Interagency Guidelines for Drug Donations are developed and endorsed by Caritas Internationalis, Churches Action for Health of the World Council of Churches, International Committee of the Red Cross, International Federation of Red Cross and Red Crescent Societies, International Pharmaceutical Federation, Medicines Sans Frontieres (MSF), Oxfam, Pharmaciens Sans Frontieres, The Joint United Nations Commission on HIV and AIDS (UNAIDS), United Nations Development Programme (UNDP), United Nations Population Fund (UNFPA), the United Nations High Commission for Refugees (UNHCR), United Nations International Children's Emergency Fund (UNICEF), World Bank, and WHO.

The guidelines describe medicine donation problems by using the examples from the earthquake in Gujarat, India (2001), the Tsunami in Srilanka (2004), and the inconsistent and insufficient supply of medicines in Tanzania.

Administration of veterinary eyedrops to women in Lithuania (1993) causing temporary eyesight loss, supply of large quantities of useless items (contact lenses) in Sudan (1990), donations of thousands of tonnes of poor-quality pharmaceuticals to Bosnia and Herzegovina during 1992–96, and inappropriate quantities of unsorted items delivered to Armenia (1998) are the historical examples quoted in the guidelines documents to enable the understanding of the recipient countries to be aware of rationalizing the donation process (World Health Organization, 1999, 2010).

In addition to the type, packaging, labeling, and quality issues, several other ethical issues are also identified regarding medicines donations. These include donation of returned, expired, or short expiry drugs, and so on. Hence, not being able to foresee the hazards of receiving uncontrolled donations may result in a bigger financial and ethical liability then controlling the damage caused by medicine shortage (World Health Organization, 2010).

Core principles of guidelines for drug donations according to interagency guidelines issued by WHO (World Health Organization, 1999, 2010).

1. Donations should be aimed at the benefit of the recipient
2. Recipient has the right to exercise its authority and wish in choosing the nature and quantities of the donations
3. Care should be taken to watch against double standards in quality (supply of medicines not registered in the donating country or banned in donor country, near expiry, or expired drugs donation, compromised or damaged stock or returned or controversial, doubtful stocks)
4. Effective communication between donor and recipients is needed

Examples of Bad Medicines Donation

Banda Aceh province in Indonesia was hit by Tsunami in December 2004. WHO has funded a study to evaluate the drug donation situation and its handling following the disaster. Pharmaciens Sans Frontières Comité International carried out this comprehensive study that provides the factual analysis of the situation.

The report is an excellent source to help humanitarian aid workers, organizations, and governmental organizations, who have a stern stance on donation policies during humanitarian crisis. The report states that nearly 60% of donated medicines were not listed in the national List of Essential Drugs and 10% had expired before reaching the destination. Thirty percent of donated medicines had just 6 months or less shelf life, also they had missing expiry dates. This was a result of accepting the unasked donations of 4000 tonnes for a population of 2 million people (Pharmaciens Sans Frontières Comité International, 2005).

Similarly, in 2004, during the Tsunami crisis in Srilanka, a large bulk of medicines was donated by 278 donors, including 150 International organizations and 30 foreign governments. Medicines were labeled in more than 16 foreign languages. In 2005, the use of poorly stored spinal anesthesia from these stocks led to the growth of Aspergillus sp., resulting in meningitis in three pregnant women. It also resulted in Health Ministry in Srilanka paying for the huge costs not only for the storage, shipment, and handling of donations but also for the cost of the medicine disposal (Benaragamama and Fernandopulle, 2007).

Case Stories Pharmacists Serving in Humanitarian Crisis Globally

FIP and Capacity Building of Pharmacist Working in Humanitarian Crisis

The International Federation of Pharmaceuticals combines the role of emergency pharmacist and the military services under the umbrella of military and emergency pharmacists (MEPS) since 1994 (International Pharmaceutical Federation (FIP), 2019). The organization provides extensive framework of activities including the meeting of the MEPS colleagues during annual congress of FIP, webinars, newsletters, and special projects including the FIP pictogram project and development of guidelines for emergency preparedness of pharmacists during disaster situation.

In Chronic Disease Management

As global political conflicts continue to increase, more and more refugees are facing urgent challenges such as the unavailability of proper medical care. Many of the Syrian refugees now living in Jordan (the entire group accounts for one-tenth of that country's population) are struggling with at least one chronic disease, placing tremendous strain on existing health and humanitarian resources as a result.

A 3-month long-single blinded randomized study was carried out in three cities of Jordan with the majority Syrian refugee population. The total number of patients recruited was 109. Treatment-related problems (TRPs) were identified and resolved using the pharmacist-delivered Home Medication Management Review (HMMR) service based on the Australian HMMR protocol. Significant differences were observed between the intervention and control groups with the percentage of TRPs resolved/improved in the intervention group being 66.8% in comparison to 1.5% in the control group. The postintervention evaluation showed that only 19.7% of the TRPs remained unresolved in the group receiving medication review by the pharmacists (**Fig. 2**). The study demonstrates that pharmacists can play a vital role in closing treatment gaps for managing chronic health conditions among this underserved population. The interventions were received positively by the physicians as well as by the patients, and the authors recommend that this service can be of vital significance in designing effective refugee health programs (Al Alawneh et al., 2018).

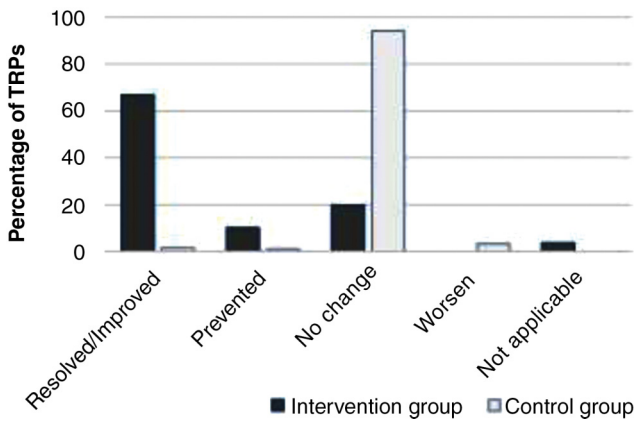

Figure 2 Outcome on TRPs observed in the Syrian refugee population undertaking pharmacist led Home Medication Management Review in Jordanian cities.

Ensuring the Adequate Supply of Quality Essential Medicines in a Country with Poor Access to Essential Medicines (2005–2013)

In 2005, earthquakes hit the northern regions of Pakistan, and the federal capital and the task of essential medicines availability were closely managed by a team of pharmacists that grew from few pharmacists to an expanded team working in nation-wide disaster management offices under World Health Organization (Bukhari et al., 2010).

For a country where pharmacist was still to be recognized as an essential health-care team member, the pharmacists managed to provide essential medicines to the far flung regions in the country. WHO acted as a hub for receiving and rationalizing the donations for many donor agencies, and this centralized framework was the main reason for a low pharmaceutical waste documented during this humanitarian operation.

Emergency pharmacists were trained along with the establishment of central warehouse and satellite facilities. Apart from logistic supplies, it was ensured that the medicines were provided with the training of paramedics delivering the services of catering the remote facilities. Storage, dispensing, and prescribing protocols were developed, and the huge number of pharmacists and paramedics were trained to work in close collaboration with the public health experts and epidemiologist to enhance the effectiveness of emergency response.

The concept of health-care kit supplies was used to ensure rational and complete provision of the treatment needs. The whole process was aided with the development of an ungraded software (LSS upgradation to Pharmacy Information System (PIMS)) that linked the central warehouse with the regional units. Two types of customized kits were designed to cater different types of health-care needs and speed up the delivery and demand process (Bukhari et al., 2010).

Advances in Management of Humanitarian Crisis—Use of Technology and Involvement of Multidisciplinary Approach

The use of information technology can aid the pharmaceutical need in humanitarian crisis by making the processes more efficient and cost-effective by minimizing the wastage. Along with the classical use of logistic software such as Logistic Support Service by WHO, use of online access to dosing protocols, the of use of pictogram-based software has also been used to promote health literacy and to improve patient counseling.

In 2004, the International Pharmaceutical! Federation (FIP) in collaboration with its Military and Emergency Pharmacy Section (MEPS) with the Children Hospital of East Ontario (CHEO) started the Pictograms Project. The project is designed to provide easy to understand pictograms to provide information on the proper and safe use of medicines for use in illiterate patients or patients with language barriers as seen with immigrants and during the humanitarian aid projects. The project has wide application and was tested for its use during the Syrian refugee crisis when a number of immigrants who were non-English speaking women, children, and elderly reached Europe. The software is called PictoRx and the Arabic version was added to the software in 2015 to help the refugees. The previously available languages included English, French, Spanish, Dutch, Maori, German, Chinese, and Polish. PictoRx software is used to aid local pharmacists in routine dispensing by ensuring that patients receiving the medicines are provided with the proper counseling using pictograms and printed labels. It has been tested in several communities across the globe, including Germany, the recipient of largest number of Syrian refugees. The project has been granted WHO Grant on Patient Safety in 2010 and the 2009 Canada Post Community Literacy Award. An improved version of the software is developed by Applied Research and Innovation at the Algonquin College, O Ottawa, Canada. The software is available as online or offline version from the home page (www.fip.org/pictograms, https://www.fip.org/pictogramsoftware). The software provides printable material and labels for use as the counseling aids to the patient. Various modalities are provided in the software to provide comprehensive medicine information to the patient in the form of an information sheet as well as prescription calendar, which incorporates several medicines for a patient at one place (Vaillancourt et al., 2012).

Technological advances and their usage in humanitarian crises have led to the transformation of the aid process and added a greater diversity to its needs and resources attached. The modern plan of aiding in humanitarian crisis shifts from giving aid in kind to cash, collecting data for development purposes, private sector partnerships, use of blockchain, keeping the recipients right as priority, use of unmanned aerial vehicles, tracking and identifying aids including 2D-bar code, and Radio Frequency Identification tags and labels.

Simple and cost-effective aids are also in use along with the universal adoption of Track and Trace systems for tracking and identification of authenticity of pharmaceutical supplies in order to prevent the influx of substandard and falsified medicines in the supply chain (Rasheed et al., 2018).

Strengthening Health Systems in Low and Middle-Income Countries Through Evaluating Cancer Medicine Prices, Availability and Affordability: A Case Study and Proposal

Zaheer-Ud-Din Babar*, Fatima Suleman†, Syed S. Hasan*, *Department of Pharmacy, University of Huddersfield, Queensgate, Huddersfield, United Kingdom; †Discipline of Pharmaceutical Sciences, UKZN, South Africa

Background

Nearly 1 in 6 deaths globally is due to cancer and almost 70% of these deaths occur are in low- and middle-income countries (LMICs) (World Health Organization Facts Sheet, 2018). The median survivals have improved as a result of chemotherapy (NIH, 2015). Among patients with metastatic breast cancer, the average life expectancy has increased over time by 13.2 months, however the lifetime medical costs have increased by USD 72,200/person (Howard et al., 2016). Given that low and middle-income countries (LMICs) account for the largest proportion of cancer deaths (Kanavos, 2006), the ever-increasing cost of cancer medicines is an important field to explore (Farmer et al., 2010). Cancer-related treatment services are available in more than 90% of high-income countries compared to less than 30% of low-income countries (World Health Organization Facts Sheet, 2018). In LMICs, only less than a third who develops cancer survive whereas in high-income countries the cancer survival rate is high (Gelband et al., 2016).

High priced chemotherapeutic agents are one of the major reasons leading to differences in survival rates in LMICs (Gelband et al., 2016). High prices of new cancer medicines impact on patients' access to medicines, however, the prices of the same medicines vary greatly between high-income countries (Howard et al., 2016). Vogler et al. (2016) surveyed the prices of 31 cancer medicines in 18 high-income countries. The results showed that the prices of cancer medicines varied, from 388 for high priced country to 28% for a low priced country (Vogler et al., 2016). Goldstein et al. (2017) systematically measured the differences in prices of eight cancer medicines between high-income countries (Australia, Israel, the United Kingdom, and the United States) and LMICs (China, India, and South Africa). The prices showed great variations and were lower in high-income countries than in LMICs (Goldstein et al., 2017). For instance, the 4-weekly prices of bevacizumab ranged from USD 543 to 6827 among high-income countries and USD 4364 to 19006 among LMICs.

Preliminary research in LMICs suggests that there are variations in cancer medicine prices impacting on affordability and medicine-buying capacity of patients and funders. However, these studies have methodological challenges, they have obtained pricing data from published resources and the empirical data is scarce on the issue (Salmasi et al., 2017; Goldstein et al., 2017; Sarwar et al., 2018). Also, no consideration of discounts and rebate or add-ons like taxes and distribution fees were taken into account. In this context, the prices reported in these studies may not reflect what actually patients and governments were paying for these medicines. The WHO/HAI methodology differs to the extent that it collects actual patient prices through a tested and validated methodology. The methodology has been used to collect data on other non-communicable (Mendis et al., 2007) and infectious diseases (Cameron et al., 2009), however, very little data has been collected on cancer medicine prices.

The growing number of expensive innovative cancer drugs impact on cancer care budget and patient access to innovative cancer drugs has become challenging. The economic impact of cancer is increasing as total annual economic costs of cancer in 2010 were estimated at USD 1.16 trillion (World Cancer Report, 2014). After including the long-term costs to patients and their families, the annual global cost of cancer is around USD 2.5 trillion (World Cancer Report, 2014). Generally, cancer treatment is expensive and is

either paid by the patients themselves, insurers or the government reimbursement and funding agencies (Howard et al., 2016). Due to absence of any special access schemes and government reimbursements in LMICs, many patients, have to bear the cost of the treatment. Naturally, with poor socio-economic condition most of the newer cancer drugs are out of reach for large vulnerable and neglected populations in LMICs and even the older cytotoxic agents remain only affordable to a minority of patients.

Measuring cancer medicines prices fits into the global agenda of making cancer drugs accessible and affordable. This is directly in line with the United Nations' Sustainable Development Goal of ensuring healthy lives and promoting well-being (UN, 2018). World Health Organization has also highlighted the need to measure cancer drugs pricing and affordability and this has been considered as a key priority area to explore. This proposal can advance knowledge regarding pricing and availability of medicines across a spectrum of LMICs. Availability of more accurate data on cancer prices would improve affordability and quality of life of the cancer patients. The project can aid in policy and decision-making related to drug affordability and accessibility, funding, and reimbursement of medicines.

Aims and Objectives of the Proposal

According to Global Initiative for Cancer Registries (GICR), only one in five LMICs have the necessary data to drive cancer policy (GICR, 2018). People living with cancer are often frail and vulnerable and their survival depends on factors including availability, affordability, and accessibility to treatment (WHO, 2018). The proposed study aims to gather data on prices, availability, and affordability data of cancer medicines using WHO/HAI methods (WHO/HAI, 2008). The long-term aim of this project is to form a global database on cancer drug prices. A model or tool would be developed by using test data from one country.

Proposed Research Design and Methods

Stage 1: Piloting of Study Methods

Sampling Plan

The proposed study methods are planned to be tested in one of the LMICs. The World Health Organization/Health Action International (WHO/HAI) methodology will be used to collect data on medicine prices, availability, and affordability (WHO/HAI, 2008). A systematic sampling method will be used to collect data across two sectors (public and private sectors) in at least six geographical regions of the country. The Area 1 will be a federal territory. Areas 2–6 will be within 400 km (one-day traveling) from the federal territory (including other major cities). These regions will be fairly representative of the whole country. In each area, one major city and four peripheral cities will be chosen. Data will be collected from public hospitals, and private specialist cancer clinics. In each area, the main government hospital in the major city and four other government hospitals in peripheral cities will be included. A private hospital and a private specialty clinic will be randomly chosen within a 5 km radius of the indexed government hospital. A list of public, private hospitals, and cancer clinics will be obtained from central authority.

Prices of Cancer Medicines

A sample of at least 40 cancer medicines will be evaluated. For each medicine, pricing and availability data will be collected on originator brand (sold by the company originally holding the original intellectual property) and lowest price generic (LPG, locally or internationally produced generic version) medicines. Public sector procurement prices will be collected centrally and from public facilities, while availability will be assessed only at the facility level. The medicines will be selected based on the following criteria: (1) medicines with high consumption rate in LMICs, (2) availability of international reference price (IRPs) for the selected medicine, and (3) authorized for oncology indications by relevant agency.

For each selected medicine, one presentation of the medicine will be determined (defined as a medicine in a specific pharmaceutical form, strength, and pack size (example—name: Cisplatin; brand: Cisplasol (Pfizer); strength: 50 mg; pack size: 1; dosage form: injection). A prerequisite for the inclusion will be availability of selected presentation in the same pharmaceutical form and the same strength in the selected LMICs. Either monthly or total treatment cost and daily dose of a tablet, or monthly vial for injection (or weight-based 2–4 weekly injections) will be used to compare results in this study. The total medicine dose required for 2–4 weeks of treatment will be calculated using average weight and a body surface area based on average height and weight in selected countries. The Workbook software calculated the median price ratio (MPR) for each medicine type in each sector only if the medicine will be available in at least six facilities. The MPR is the comparison of the local median unit price of the medicine with the median unit price in the Management Sciences for Health Price Indicator Guide (International Drug Price Indicator Guide, 2014).

Affordability of Cancer Medicines

The data on affordability of 40 cancer medicines will be collected. In this study, affordability will be assessed using both the impoverishing payment method and WHO/HAI methods (WHO/HAI, 2008; Niens et al., 2010). The impoverishing effect of a medicine is defined in terms of the percentage of the population that would be pushed below an income level of poverty lines when having to purchase the medicine. The most recent and widely recognized poverty indicator of USD1.90 per day by the World Bank will be used (WBG, 2018). This suggests that if the pre-payment income is above the USD1.90 poverty line and the post-payment

income falls below these lines, then purchasing the medicine impoverishes people. The impoverishment rates denote the percentage of the population that would become impoverished (Niens et al., 2010). The affordability of a medicine then refers to the percentage of the population that either already is or would remain above the poverty line when having to procure the medicine (Niens et al., 2010).

Qualitative Study

The qualitative interviews (the occurrence of saturation will dictate the final number) will be conducted with the key stakeholders (e.g., healthcare providers, policy makers, etc.) and the people living with cancer based on several visits. The point indicates the occurrence of saturation where the new information obtained from any further interview does not provide further insight into the issue. Semi-structured interview guide will be developed with a variety of open-ended questions. Theoretical sampling, which is a process of sampling individuals that can contribute to build the open and axial coding of the theory, will be used to select participants of the qualitative study.

Suitability of the Approaches and Methodologies

The WHO/HAI methodology on measuring medicines pricing, availability and affordability has been tested in over 50 countries (WHO/HAI, 2008). This methodology became a validated and internationally accepted means of collecting reliable evidence on medicine prices and availability and the work is published in *Lancet*, *PLoS Medicine*, and in the *Bulletin of World Health Organization*. The strength of qualitative research is its ability to provide complex textual descriptions of how people experience a given research issue (QRM, 2018). In-depth interview is one of the three most commonly used qualitative methods. In-depth interviews are optimal for collecting data on individuals' personal histories, perspectives, and experiences, particularly when sensitive topics are being explored. Pricing strategies and interventions are sensitive issues particularly in LMICs. Thus, qualitative approach (interviews) is a suitable method to achieve above objective. The proposed research will provide a strong foundation for the health systems in the target LMICs to build upon in their effort to ensure access to cancer medicines for all patients in a fair and equitable way.

Stage 2: Developing Global Pricing Database

In long term, the data collection tool developed will be used to collect data from over 100 LMICs. These countries will be selected based on the Global, Regional, and National Cancer Incidence, Mortality report (1990–2015) (GBDCC, 2017), as well as on the basis of cancer incidence and inclusion in the OECD Development Assistance Committee (DAC) list. The collection of large medicine prices and affordability data on yearly basis from LMICs would allow tracking the changes in pricing strategies and to plan interventions to promote availability and affordability of cancer medicines. Besides medical and health sciences, the project would attract researchers from public health, health economics, and social sciences with multidisciplinary approaches. There is a scope of involving data scientist and/or data analyst to extract and interpret the data, which requires both tools and methods from statistics and machine learning. This would help investigators and partners in LMICs to make better decisions about data sharing and technology enhanced models for capacity building in LMICs.

Research Impact

The proposed project has very high significance to create real change in LMICs. The project will have impact at several levels. The actual data on medicine prices in LMICs will help governments and funders negotiate better prices with drug companies to improve the affordability of cancer medicines. It will also support the decision makers and reimbursement and funding bodies to formulate policies to promote access, affordability, availability, and to ensure the transparent and efficient distribution of funds. Cancer medicines pricing is complex and using WHO/HAI methods would initiate and pave the way for larger and bigger cancer medicines pricing studies in this area. The project will improve the quality as well as the quantity of the LMICs data related to cancer medicine prices. Performing interviews with stakeholders as well as information from cancer pricing data will be helpful to build a data collection tool to capture information, which is otherwise not available just alone with pricing data. Academic papers, technical reports, evidence summaries, conference posters, and papers will be produced. Successful completion of this project will provide the basis for expanding the research work to over 100 LMICs. The open access database developed will be a valuable resource for LMICs, making available much-needed information for these countries, which suffer from inherent lack of accurate data relating to cancer treatment. This research will strengthen LMICs' health systems' ability to plan and deliver cancer treatment in an affordable and equitable way. It will also strengthen health systems negotiating strategies, thus, ensuring fair pricing and, consequently, improving access to affordable cancer medicines for patients in LMICs.

This research will strengthen the exiting collaboration with partners in the LMICs involved, through close working and exchange of ideas. LMIC partners will be included based on their expertise and relevant research work in the area of pharmaceutical pricing and policy. Ideally, co-applicants representing LMICs should be experienced researchers and the ones who understand the issues surrounding cancer medicine prices and affordability in LMICs.

Introduction

Prescription Drugs

Prescription drugs are used to treat, maintain, or prevent symptoms of a medical disease or condition. All drugs available for use in humans have been deemed as "safe"; however, safety is a relative term. A safe drug is not one that is without risks, rather the known risks associated with that drug are deemed acceptable (Strom, 2013b). The likelihood of harm increases if a prescription drug is taken against clinical advice such as failing to complete the prescribed drug regimen; excessive use, that is, taking the medication at a higher dose, more frequently or for a longer duration than prescribed; medication error; taking a drug prescribed for another person; or, concomitant use with other prescription drugs, over-the-counter (OTC) products, illicit drugs, or alcohol.

At the time of prescribing, the health professional must consider the risk/benefit profile of any prescribed drug, according to the patient's unique clinical profile, including their likelihood of benefiting from prescription drug therapy. The prescriber must inform each patient of the potential risks associated with prescription drug use so the patient can make an informed decision about their health care. The evidence regarding the risk/benefit profile of a drug is generated from clinical trials, pharmacovigilance/pharmacoepidemiology activities or reporting systems once the drug is approved for prescription (or use as an over-the-counter drug) to the general public by a regulatory agency [e.g., US Food and Drug Administration (FDA) or the European Medicines Agency (EMA)].

In order for a drug to be approved for use in the general population, the drug developer must demonstrate the drug is both safe and effective in humans via clinical trials. Clinical trials enroll participants according to strict criteria to ensure the population is similar (homogenous) and to test the drug's safety and efficacy in a controlled environment to ensure consistency, including drug dose, patient adherence, and all effects the drug has on the patient. This is important as the human response to a prescription drug varies based on multiple factors which include (but are not limited to): age, sex, weight, genetic profile, ethnicity, diet and exercise. Consequently, enrolling a sample of homogeneous people will reduce the variability of the drug response to determine safety and efficacy. However, if the drug is approved for use in the community, the general population is likely to be diverse according to these factors in addition to their clinical profile, comorbid conditions, other prescription or illicit drug use, and alcohol consumption. Due to these diverse patient populations other side effects or adverse events may occur that were absent during the clinical trials (Box 1). The disciplines of pharmacovigilance and pharmacoepidemiology focus on identifying the risks, and potential benefits, associated with prescription drug use during clinical trial phases and in the real-world setting.

Box 1 Importance of patient population

Example demonstrating variation in patient response

A clinical trial demonstrated the response of 215 patients to a statin. The majority had a reduction in LDL cholesterol levels, which is the expected affect a statin should have on cholesterol. However, a small proportion of patients had an increase in their LDL levels. This example demonstrates the need for pharmacovigilance and pharmacoepidemiology surveillance, as we need to be aware of the range of responses a drug can elicit and recognize patient factors that may lead to a poor response to reduce, and ideally prevent, future ADEs.

What is the Process for a Prescription Drug to be Approved for Use in Humans?

In order for a drug to be prescribed to humans, its safety and efficacy needs to be proven for the symptom/condition of interest in preclinical phases such as testing in a laboratory through drug discovery and using animal models (Fig. 1). The preclinical phases may take several years to complete. If the drug progresses past the preclinical phase, it will be assessed in three clinical trial phases (Australian Government National Health and Medical Research Council Department of Industry Innovation and Science, 2015). Currently, the cost of developing a drug from preclinical phase to market is estimated between $1.3 and $1.7 billion (Strom, 2013a). Consequently, there needs to be strong evidence from preclinical phases that the drug has the potential to go to market and be profitable for the drug company.

There is ample evidence that describes and critiques the methodology, strengths and limitations of clinical trial phases. This section briefly summarizes the purpose, population size and duration of each clinical trial phase to demonstrate how pharmacovigilance and pharmacoepidemiology methods can complement clinical trial data. The population size and duration of each phase described in this chapter are a guide only, these factors will vary between trials based on the drug and population size of the disease/condition of interest.

Phase I—Determine Safety

Purpose: test the safety of a drug by documenting the frequency of adverse effects or adverse drug events (ADEs) occurring during the trial period (Box 2). Drug dose may be varied to determine whether higher doses are associated with adverse effects.

Population size: 20–80 healthy controls (persons that do not have the symptom/condition of interest).

Duration: few weeks.

Box 2

What about patient safety in clinical trials?

Clinical trials are often double-blinded to reduce the possibility of biasing the results. To ensure a drug is safe, and the patients in the intervention group are not harmed by a drug, a safety monitoring committee, (members are not involved in the clinical trial), will review any reported adverse event as they emerge to determine if the ADE occurs more frequently in the intervention group. Clinical trials may be abandoned early due to drug safety concerns.

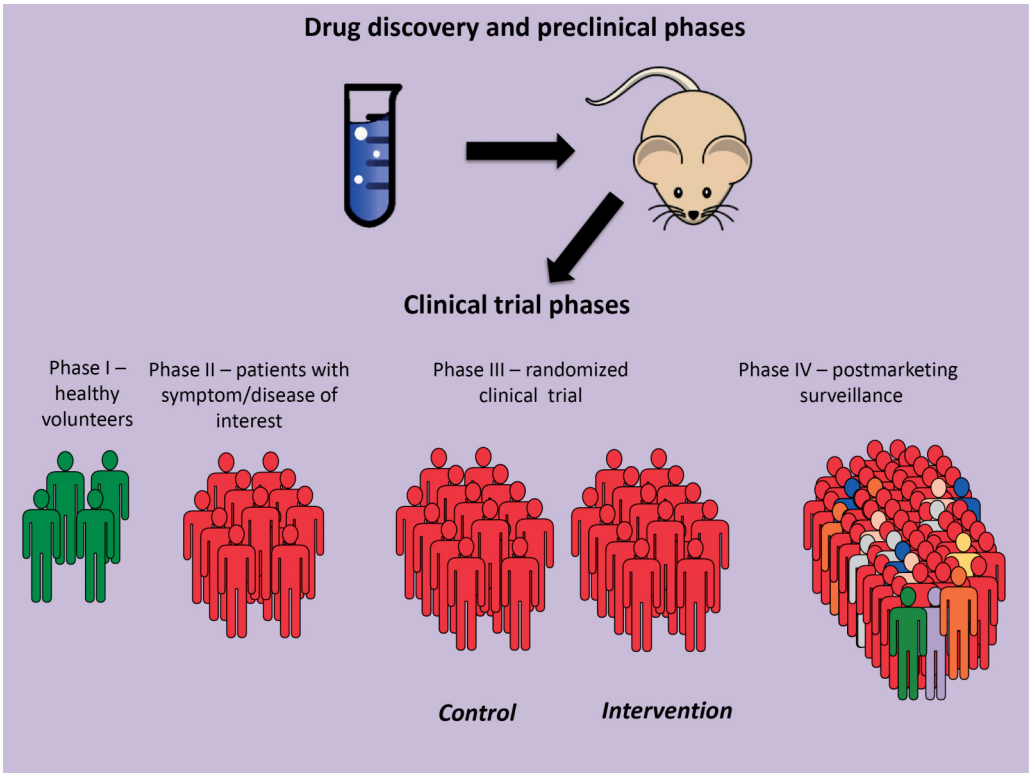

Figure 1 Summary of the process for a drug to be approved for use in the community.

Of note, some drugs (e.g., cytotoxic drugs) are not tested in healthy individuals as they may cause long term adverse health outcomes. Consequently, these drugs are tested directly on patients who require these drugs (e.g., cancer patients).

Phase II—Determine Efficacy

Purpose: test the efficacy of the drug, that is, whether the drug achieves its intended purpose in a clinical trial setting. For example, does an opioid analgesic reduce pain severity or symptoms? This phase continues to evaluate the drug's safety in patients with the symptom/condition of interest. Doses may vary to examine the therapeutic range and determine efficacy at higher and lower dosages.

Population: ≥100 people with the symptom/condition of interest.

Duration: few months.

Phase III—Demonstrate Drugs Superiority to Standard Care/Control Condition

Purpose: to demonstrate the superiority of the new drug or regimen (intervention) against standard care (control). Patients with the condition of interest are randomly allocated to the intervention or control group. The randomised allocation of patients to the different clinial trial conditions (intervention or control), is the primary strength of clinical trial methodology as it ensures both patient groups are similar, and any confounders, either known or unknown, will be comparable between the two groups. Clinical trials are generally double-blinded meaning neither the researchers nor the patients know whom is receiving the intervention versus the control, to minimize the risk of bias when recording results (Box 2). This phase continues to build upon evidence (from Phases I and II) regarding the frequency of adverse events and benefits. In order for a drug to be approved for use in humans (in the community, not only in a clinical trial) a drug must have five positive clinical trial results (a positive

result is when patients in the intervention group have a superior outcome compared to patients in the control condition). Although clinical trial evidence is regarded as compelling due their strict methodology, there have been instances where clinical trial findings have been misrepresented which was discovered after a drug was approved for use in the community. As a deterrent for this potentially fraudulent practice, drug companies have paid large fines and may be required to withdraw the drug from the market (Box 3).

Box 3

Clinical trial evidence controversy

There have been multiple controversies surrounding clinical trial evidence, A well-known example is from the UK in 2012 where GlaxoSmithKline was ordered to pay £1.9 billion in fines because they knowingly deceived the public to prescribe an antidepressant (Paxil; paroxetine] to children, despite their clinical trial data clearly showing paroxetine was ineffective for adolescent depression and increased suicidal ideation. An investigation was launched after a number of completed suicides were associated with paroxetine use. To ensure drug companies do not only report favourable outcome measures, all clinical trials must be registered prior to enrolling patients. During the clinical trial registration process, researchers must define all outcomes of interest including how each outcome will be defined and the time period of assessment. This increases the transparency of clinical trial findings, and ensures the outcome measures are objective, and not determined after data collection or analysis.

Population: ≥1000 people with the medical condition/symptom of interest.
Duration: few years.

Phase IV—Postmarketing Surveillance Studies

Purpose: to continue monitoring drug safety in the community after the drug is available for use (via prescription or over-the-counter). It is increasingly common for regulatory agencies to mandate additional drug safety data be collected during routine use in the community. This practice may eventually be part of the drug approval process across jurisdictions.

Population: general population with the symptom/condition of interest; size ranges from hundreds to millions of patients.
Duration: indefinite; potentially the life of the drug on the market.

What is the Point of Pharmacovigilance and Pharmacoepidemiology?

The utility of pharmacovigilance and pharmacoepidemiology have been demonstrated on a number of occasions where prescription drug use was associated with adverse drug events (ADEs) after it was approved for community use. The most infamous example is thalidomide. Thalidomide was developed in the 1950s by a West German pharmaceutical company, it was marketed as an anticonvulsive drug. It also made people feel tired and relaxed. In Germany in 1956, thalidomide was available as an over-the-counter drug (not requiring a health care professional to write a prescription) to reduce morning sickness in pregnant women. In the 1960s, doctors were concerned about the possible side effects of thalidomide including nerve damage in limbs associated with long-term use. There was also an increase in children born with phocomelia (a rare medical condition characterized by malformation of the limbs) and other effects included deformed eyes, heart, alimentary, and urinary tract; blindness; and deafness. The link between thalidomide and phocomelia was discovered, and thalidomide was withdrawn from the market.

Interestingly, in 1964, a health professional noticed thalidomide reduced leprosy symptoms. This association was proven in 1967 in a clinical trial conducted by the World Health Organization. Today, thalidomide is used to reduce the symptoms of leprosy, AIDS, and some cancers.

The thalidomide example demonstrates the dual nature of pharmacovigilance and pharmacoepidemiology, to examine the negative, and potentially positive, impact of prescription drug use for patients.

What is Pharmacovigilance?

Pharmacovigilance Definition

There is no one accepted definition of pharmacovigilance. The World Health Organization defines pharmacovigilance as:

> "the science and activities relating to the detection, assessment, understanding and prevention of adverse effects or any other drug-related problem. . .. The aims of pharmacovigilance are to enhance patient care and patient safety in relation to the use of medicines; and to support public health programmers by providing reliable, balanced information for the effective assessment of the risk-benefits profile of medicines." (World Health Organization, 2017)

In short, pharmacovigilance monitors the frequency of adverse events that may be a consequence of prescription drug use. If the number of cases (patients) experiencing a common adverse event after using the same prescription drug is higher than expected, the relationship between drug use and the adverse outcome will be examined. Pharmacovigilance also includes the collection,

reporting, analysis, and dissemination of information regarding ADEs including off-label use, abuse, misuse, occupational exposure, or medication errors (Van Puijenbroek and Harmark, 2017).

The primary challenge of pharmacovigilance is the under-reporting of adverse drug events (ADEs). This underreporting occurs when a health professional suspects an adverse event is connected to prescription drug use, but does not report it to a pharmacovigilance monitoring system. In fact, under-reporting may be as high as 94%, meaning only 6% of ADEs are reported, which makes it difficult to examine the strength of the relationship between an ADE and prescription drug use (Hazell and Shakir, 2005).

Furthermore, there is considerable variation in the quality and detail of the reports made by health professionals (Carleton, 2017). Reports may be duplicates, where multiple health professionals report the same ADE or overreported where the frequency of a known ADE is more commonly reported than unknown adverse events, particularly if an adverse event has been reported in the media.

Another challenge of pharmacovigilance is knowing how to effectively communicate the risk of prescription drug use once an ADE has been discovered to both the general population and health professionals. For example, a clinician reads a letter stating there is an incidence of 0.09% of a particular adverse outcome occurring in patients taking that drug (Carleton, 2017). This is not meaningful to the clinician as there is a very small chance any of their patients will actually experience this outcome (9/10,000 people taking the drug). Clinicians are more interested in the individual patient's risk rather than the population risk. If the letter provided patient-specific risk information, such as an increased risk in the elderly, the clinician may alter their prescribing patterns or alert the patient to the risk of harm. It is believed that if clinicians benefit from the clinical impact of reporting ADEs then both the number and quality of reports would increase.

What is Pharmacoepidemiology?

There is no consensus on the definition of pharmacoepidemiology, it applies the methods of epidemiology to the content area of clinical pharmacology (study of prescription drug use in humans) (Strom, 2013a). The World Health Organization defines *epidemiology* as:

> "the study of the distribution and determinants of health-related states and events in the population, and the application of this study to control health problems." (World Health Organization, 2003)

Pharmacoepidemiology is a specific branch of epidemiology. The World Health Organization defines *pharmacoepidemiology* as:

> "applying epidemiological methods to studies of the clinical use of drugs in populations. A modern definition .... is the study of the use and (side) effects of drugs in large numbers of people with the purpose of supporting the rational and cost-effective use of drugs in the population thereby improving health outcomes." (World Health Organization, 2003)

The case of thalidomide discussed previously is only one example of a prescription drug causing harm once it has been released on the market. Recently, multiple studies investigated the number of drugs withdrawn from the marketplace due to safety concerns (Food and Drug Administration; La Rochelle et al., 2016; McNaughton et al., 2014; Onakpoya et al., 2016; Procon.Org, 2014; Siramshetty et al., 2016). The frequency of prescription drug use and their associated harms led to the development of the discipline of pharmacoepidemiology (Strom, 2013a).

Adverse Drug Events: The Burden to Patients and Society

From the definitions of pharmacovigilance and pharmacoepidemiology, it is clear that these disciplines focus on prescription drug safety, and frequency of potential harms for patients. This section will focus on the impact of the harms called ADEs, from patient and health care system perspectives.

An ADE is a "harmful or unpleasant reaction resulting from an intervention related to the use of a medicinal product, which predicts hazard from future [use] and warrants prevention of specific treatment, alteration of the dosage regimen, or withdrawal of the product" (Edwards and Aronson, 2000). There are six types of ADEs:

1. **Dose-related:** the event occurs from a particular dose threshold.
2. **Nondose related:** the event occurs regardless of the drug dosage.
3. **Time-related:** the event occurs after taking the prescription drug for a specific time period.
4. **Dose-related and time-related:** the event occurs after taking the drug at a particular dosage for a specific time period.
5. **Withdrawal:** the event occurs after a patient has stopped taking the prescription drug.
6. **Failure of therapy:** the event occurs but does not effect the medical condition or symptom it was intended to treat.

Historically, drug companies and clinicians have reported ADEs. In practice, clinicians rarely believe ADE reporting is one of their primary duties (Carleton, 2017), consequently many ADEs are underreported, despite patients presenting to a health professional as a consequence of an ADE. It is mandatory for drug companies to report all ADEs.

Burden of Adverse Drug Events

ADEs are recognized as a leading cause of morbidity and mortality globally. The incidence of ADEs range from 0.2% to 65% depending on the population and jurisdiction of interest. ADEs cost the health care system $77 billion annually (Johnson and Bootman, 1995). The drugs most commonly associated with ADEs include: anticoagulants, systemically administered antibiotics, diabetes agents, opioid analgesics, antiplatelets, renin-angiotensin system inhibitors, antineoplastic agents, and sedative/hypnotic agents (Shehab et al., 2016).

Despite the frequency of ADEs, it is estimated 20%–70% may be preventable (Strom, 2013a), that is the drug dose/administration route was inappropriate for the medical condition/symptom; standard laboratory tests were not performed; medication error; excessive amount taken; or known drug–drug interaction or allergy (Classen et al., 1997). The action required to treat an ADE varies from no intervention (ADE will resolve spontaneously) through to requiring other medication(s), emergency department presentation or hospitalization; however, some ADEs are fatal.

Few studies have quantified the burden of ADEs in the outpatient setting (Bouvy et al., 2015). However, it is reasonable to assume that because ADEs are the most common form of iatrogenic harm, the cost to the outpatient system would be considerable.

The frequency of ADEs resulting in an emergency department presentation is increasing. Over 8 years, the number of presentations increased 87% (5.2–9.7/1000 persons); of these, 27% resulted in a hospitalization (Meier et al., 2015). Of note, 62% of emergency department presentations for ADEs were preventable (Meier et al., 2015).

Of the $77 billion ADEs cost the health care system annually, $2.6–$47.4 billion are due to hospitalizations (Bates et al., 1995, 1997; Hafner et al., 2002; Johnson and Bootman, 1995). Annually, up to 3.5% of hospitalizations are due to ADEs and 10% of hospital inpatients experience an ADE (Bouvy et al., 2015). An ADE hospitalization is associated with a significantly prolonged length of in-hospital stay, increased economic burden and increased risk of death (Classen et al., 1997). Annually in Europe, 84 million patients are hospitalized due to an ADE. In the US, ADEs account for >32 million hospital visits annually (Classen et al., 1997).

The potential savings to the health care system in reducing the number of preventable ADEs was recently demonstrated in Germany. The cost of ADE-related hospitalizations was €2.3 billion annually (Meier et al., 2015). However, this cost could be reduced by €1.3 billion if preventable admissions were avoided.

It is difficult to quantify the number of deaths which may be attributed to ADEs. In relation to inhospital deaths due to ADEs, in Europe, the rate ranges from 0.05% to 0.5%; equating to 42,000–419,000 deaths annually (Bouvy et al., 2015). The crude mortality rate for ADEs during a hospitalization is 3.5% (Classen et al., 1997). Patients who develop an ADE inhospital are almost twice as likely to die compared to patients who do not develop an ADE (Classen et al., 1997).

This section has demonstrated the frequency and burden of ADEs on patients and the health care system. Consequently, a better understanding of the relationship between prescription drug use and adverse drug reactions is now an urgent goal of the public health system.

Common Pharmacovigilance and Pharmacoepidemiology Data, Methods and Study Design

The most important stage of any research study is the planning stage, where you develop the research question, identify the appropriate data, (and its limitations), study design, outcome measure(s) of interest, define outcome measures, consider the impact of any explanatory or confounding variables (especially if they are not measured in the data source), determine how to interpret the results accurately and the potential limitations of study findings. The methods for pharmacovigilance and pharmacoepidemiology overlap considerably, so the data, methods, and study designs for both disciplines will be presented together.

Data

Preclinical Study Data

Data from preclinical studies investigate whether a drug has major organ toxicity, chronic toxicity, carcinogenicity, mutagenicity (capable of inducing genetic mutations), and teratogenicity (capable of producing physical defects in an embryo) (Waller, 2010). These data generally determine whether the drug will have extreme adverse events in humans, they do not necessarily demonstrate safety. Generally, for a drug to progress to use in humans, they will not induce any of these outcomes. In rare circumstances, some adverse outcomes may be acceptable based on the intended patient population. For example, a drug with teratogenicity properties may be deemed safe for use if the prescription drug is intended for use exclusively in men.

Clinical Trial Data

Clinical trial data may be analyzed to examine the frequency of particular adverse events. Data from Phase III clinical trials may be used to determine whether adverse events occur more frequently for the new intervention drug against its comparators. However, these data will not detect adverse events that: are rare, develop after prolonged use of the drug, occur in particular populations (e.g., elderly and pregnant women) or the consequence of inappropriate use of the medication, such as drug nonadherence or taking greater than anticipated doses, or combining use with other prescription or illicit drugs, or alcohol. **Table 1** describes summary of the strengths and limitations of the clinical trial methodology.

Table 1 Clinical trials methodology: strengths and limitations

Strengths	*Limitations*
Randomized patient allocation	Short-time period of assessment
Specific predefined outcome measures	Artificial conditions (i.e., increased patient monitoring and adherence) which may bias results
Strict inclusion criteria	Homogenous patient sample reduces generalizability of results
Double-blinded	Drug may not be tested against other available drug treatments
Multiple phases to examine safety, efficacy, and/or superiority to standard care	

Postmarketing Surveillance Data

Postmarketing surveillance data focus on prescription drug use after it is available for use in the community. The cornerstone of pharmacovigilance and pharmacoepidemiological research are postmarketing surveillance data as they demonstrate whether a patient has been exposed to the drug, and adverse health effects that required a health care interaction. These data are generally de-identified which means they contain basic patient information such as date of birth, sex, limited socioeconomic information; and content data for drug databases including drug name, quantity dispensed, and prescribed daily dose (i.e. the amount of the prescribed per day by the clinician). However, content data for each health dataset varies between jurisdictions and health care systems.

The ability to examine a drug's safety profile depends on the rate of uptake. If a drug has a slow uptake then it may take years to examine the safety profile and potential adverse events. Alternatively, if there is rapid uptake, and the drug induces an adverse effect, then many people may experience ADEs while the safety of the drug is being investigated. These data may include: prescription data, pharmaceutical claims data, or electronic health records.

Prescription data are generated by general practitioner clinics, where patients present with a symptom/condition and a health care professional prescribes a drug to resolve the issue. However, these data generally overestimate the number of people taking prescription drugs as not all patients prescribed a drug will get the prescription filled at a pharmacy. A patient may decide not to take the drug or symptoms may resolve without taking the drug.

Pharmaceutical claims data are generated by pharmacies, where patients have filled their prescription. These data are more accurate than prescription data; a filled prescription is commonly used as a proxy for drug exposure, as it is assumed if a person pays for a prescription to be filled they are likely to take the drug.

Electronic health care records are data that combine health records from multiple sources, which may include prescription, pharmaceutical claims, disease registries, and outcomes data (discussed below), depending on the jurisdiction (Black et al., 2015). These data are increasingly used to detect adverse drug reactions (Black et al., 2015).

Outcomes Data

Outcomes research may be defined as the "study of the end results of health services. . .intended to provide scientific evidence relating to decisions made by all who participate in health care" (Roger, 2011). Examples of outcomes data include hospitalization, emergency department, health practitioner consultations, mortality data, or disease/drug registry. Apart from registry data, all other datasets are routinely collected meaning they are collected for a purpose other than research such as for reimbursement. These data include limited patient demographics and content data relevant to reimbursement arrangements. For example, hospitalization data include all diagnoses for which a patient is treated for during their episode of care as the hospital is only reimbursed for provided treatment. The record will not contain a diagnosis for a medical condition if it was not treated during the hospitalization. Similar to pharmaceutical data, the particular variables contained in each dataset described in this chapter vary across jurisdictions.

Data Limitations

These datasets have varying degrees of completeness, based on the health care system and jurisdiction. For example, in the US health insurance is provided by employment and health insurance is generally required to receive in-hospital treatment. Consequently, hospitalization data are limited to persons who are employed or can afford health insurance and is not representative of the entire US population. In contrast, Australia has a universal health care system which means all residents/citizens have access to treatment, regardless of health insurance status.Prior to using any health dataset, it is important to familiarize yourself with the features of the health system and limitations.

Methods

Levels of Evidence

To determine the safety, or risk, of using a prescription drug, study findings (referred to as evidence) are reviewed by clinicians and researchers. However, different studies can present contradictory findings. For example, one study may find that drinking red wine

Figure 2 Levels of evidence.

reduces the risk of coronary disease, whereas another study may find any alcohol consumption increases the risk of cancer. In order to determine which study findings are more robust, we judge the study based on levels of evidence (Fig. 2).

The World Health Organization categorized the various methods and study designs for pharmacovigilance studies (World Health Organization, 2007). The themes and study designs included in this chapter are based on the WHO framework and include:

- Passive surveillance: spontaneous adverse reports, case reports, and case series.
- Active surveillance: sentinel sites, medicine event monitoring, and registries.
- Comparative observational studies: cross-sectional study, case–control study, and cohort study.
- Descriptive studies: natural history of disease and drug utilization study.

Passive Surveillance

Spontaneous Adverse Reports

The World Health Organization defines a spontaneous report as

> "an unsolicited communication by healthcare professionals or consumers to a company, regulatory authority or other organization that describes one or more adverse drug reactions in a patient who was given one or more medicinal products which was not derived from a study or organized data collection scheme." (World Health Organization, 2007)

The purpose of this system is to generate a safety signal to determine whether there is a relationship between a drug and an adverse reaction, which was previously unknown or incompletely documented (Breckenridge, 2015). These reports can also provide information regarding at-risk groups, risk factors and clinical features of known serious ADEs (World Health Organization, 2007). The rate of which spontaneous reports are reported depend on multiple factors including time since the launch of the medicine, pharmacovigilance-related regulatory activity, media attention, and the indication for the drug (Group, 2001; Heimann, 1980; Sondheimer, 1988; Weaver et al., 1991).

Case Reports

A case report describes a series of events that happened to a single patient after being exposed to a particular prescription drug, and usually includes the patient's outcome(s) and any clinically relevant details.

The purpose of such reports are to increase the awareness of a potential ADE, including drug interactions, as well as describe the treatment a patient received and the outcome to guide other clinicians who encounter a similar case.

However, as these reports usually focus on a single patient, they should not be the sole source of information to make decisions about drug safety. Rather these reports can be the first piece of evidence for a specific ADE, which will then be tested in a rigorous study design with a larger number of patients. However, there are two scenarios in which more rigorous testing may not be required. Firstly, if the outcome is rare and consistent with the drug profile effect or known side effects of that prescription drug. Secondly, when the disease course is well established and the treatment causes an unexpected change in the disease trajectory, including if the patient returns to their previously treated state after the drug is withdrawn and treatment can be repeated without any side effects. For example, if a patient overdoses on methadone and naloxone is administered the patient will regain consciousness with no side effects, and if they overdose again, naloxone may be administered again.

Case Series

Case series either describe patients with the same drug exposure and their clinical outcomes are reported; or, the antecedent exposure will be described for a group of patients with the same clinical outcome. The evidence for a case series is stronger than case reports; however, any findings of case series should also be tested in a rigorously designed study with many patients.

Active Surveillance

Sentinel Sites

Surveillance at a sentinel site involves reviewing all medical records or interviewing patients and/or physicians at key sites to obtain data on any adverse event (World Health Organization, 2007).

The purpose of this methodology is to target key sites to ascertain complete information regarding patient prescription drug use, any adverse event or side effect, detailed patient demographics and the nature of prescription drug use at the time of the adverse event. These data are examined more systematically than spontaneous reports. The limitations of this approach are: it is based on patients who present to a key site (selection bias), includes a small number of patients and increased costs.

Medicine Event Monitoring

This method is cohort-based, prospective and observational. Patients are identified from any prescription data source including electronic or health insurance claims. A single prescription or series may be collected over the period of monitoring. A follow-up questionnaire is then sent to each prescribing physician and/or patient at predetermined time intervals to obtain outcome information. The information derived from the questionnaire complements the data obtained via the data source, such as indication for treatment, dosage regimen and duration, reasons for discontinuation, and medical history.

Registry

Registry data are organized around a specific drug, drug class, or medical condition (see Section "Outcomes Data" for information regarding registry data). Generally the drug or condition of interest is quite rare. These data are invaluable to determine whether an ADE occurs in one of these specific populations. Data are collected via standardized questionnaires prospectively. However, as these data are not routinely collected, data quality may vary across patients, particularly if there are multiple enrolment sites. Registries may opt-in and as a consequence may not be representative of the entire population. However, studies have demonstrated the representativeness of patient demographics and outcomes for a registry cohort may differ from the entire patient population diagnosed with that disease or using a prescription drug. If the two populations (registry and general community) characteristics are disparate, the generalizability of study findings is unclear (Catalano et al., 2013; Curtis et al., 2009; Gomez et al., 2015; Knapstad et al., 2016; Reeves et al., 2012; Zhang et al., 2017).

Comparative Observational Studies

Cross-sectional Study

A cross-sectional study involves collecting data on a group of people at a single time point (or a specified time period), regardless of exposure, or disease status. This is often referred to as a "snapshot" to see what is happening at a given moment of time. This method is predominantly used to gather data for surveys or ecological analyses to determine the prevalence of disease or examine trends over time. Studies are also used to examine crude associations between exposure and outcome in ecological analyses.

Ecological studies examine trends in an exposure and/or drug-related outcome. For example, I wrote an ecological paper examining Australian prescription opioid utilization and number of opioid-related hospitalizations and deaths (Blanch et al., 2014). This paper clearly demonstrated that as prescription opioid utilization increased, so too did the number of opioid-related hospitalizations and deaths. However, as these data are aggregated, it is unclear whether the patients prescribed opioid analgesics are those experiencing the opioid-related adverse outcome. These studies may provide evidence and generate questions that are then examined using person-level, linked, pharmaceutical drug and outcomes data. Secular trends can be compared across multiple regions within one jurisdiction; longitudinally; and/or across jurisdictions.

Case–Control Study

A case–control study includes persons who have been exposed to the drug (cases) and those who have not (controls). In general, the purpose of a case–control study is to compare the frequency of an outcome between these two groups to determine whether persons taking a prescription drug have a higher or lower chance of that outcome than persons not taking the drug, or taking a different drug in the same therapeutic drug class.

Cohort Study

A cohort study involves enrolling/identifying a group of people defined by a specific characteristic who are followed over time. Cohort studies generally compare exposed patients to unexposed patients, but they can also compare one exposure to another. An association is identified when the outcome occurs more frequently in the exposed than the unexposed group. Comparators can be persons not exposed to the drug, or taking a drug from the same therapeutic class. Yet, due to the nonrandom assignment of groups, increased attention must be given to the selection of appropriate comparators.

Routinely collected pharmaceutical data may be used to identify a cohort of persons all exposed to the same drug, who may then be observed for years to examine the long-term side effects of that prescription drug use. If these data include all drug dispensings, researchers use other prescription drug use as a proxy for comorbidities to calculate the risk of a specific outcome occurring based on the presence of disease.

Descriptive Studies

Descriptive studies are primarily used to obtain the background rate of outcome events and/or establish the prevalence of prescription drug use.

Natural History of Disease

Epidemiology originally focused on the natural history of disease, including characterizing the patient population for a specific disease; determining the distribution of disease in particular populations; and, population prevalence and incidence rates of outcomes of interest. These studies often include a description of adverse events which provide a context to interpret the occurrence of events described in spontaneous reports.

Drug Utilization Study

These studies describe how a drug is marketed, prescribed and used in a population and may also examine how these factors influence patients' clinical, social, and economic outcomes. These studies may stratify the cohort based on important characteristics such as age (elderly, children); presence of disease (diabetes, cardiovascular disease); sex, or concomitant drug use. These studies also consider the effect of drug policy changes, media attention, or regulatory action on utilization; adherence to guidelines; investigate potential for inappropriate use of drug; burden of disease; and economic analyses.

Limitations of Pharmacovigilance and Pharmacoepidemiological Studies

The primary concern of all pharmacovigilance or pharmacoepidemiological studies is identifying an association between prescription drug use and an adverse outcome, when no such relationship exists (Strom, 2013b). Another concern is providing false reassurances about a drug's safety. These risks are minimized by appropriate study designs based on the limitations of the original dataset, and appropriate and responsible interpretation of the results obtained (Strom, 2013b). The limitations of all study designs covered in this chapter are summarized in **Table 2**.

Challenges in Pharmacovigilance and Pharmacoepidemiology Studies

Signals

The primary challenge of pharmacovigilance and pharmacoepidemiology is to determine whether there is a clear signal demonstrating a previously unknown (beneficial or adverse) relationship between prescription drug use and an outcome.

A signal is defined as "information that arises from one or multiple sources which suggests a new potentially causal association or new aspect of a known association between an intervention and an event or set of related events, either adverse or beneficial, which would command regulatory, societal or clinical attention and is judged to be of sufficient likelihood to justify verificatory and, when necessary, remedial actions" (Hauben and Aronson, 2009).

There are no clear guidelines on how to act once a signal has been established. A few factors contribute to deciding what action to take: the seriousness of the suspected ADE; condition being treated; and, alternative drugs available for treatment. Each jurisdiction may respond uniquely to signal information and enforce different outcomes. For example, one country may withdraw a drug from use, another country may issue a black box safety warning.

Future Directions for Pharmacovigilance and Pharmacoepidemiology

As described previously, pharmacovigilance and pharmacoepidemiology rely on data to make associations between drug use and outcomes, yet underreporting increases the challenge of making these associations. To overcome this issue, the utility of other data sources and datasets to complement more traditional methods are being explored.

Social Media

The Internet has proven to be an effective method for patients, and caregivers, to research medical conditions and adverse events associated with prescription drug use indications and side effects. It has also connected many patients and caregivers via health social networks. A recent survey by the Pew Research Centre indicated that 34% of caregivers and 20% of patients either read or watch someone else's commentary or experiences online. Also, 11% of caregivers and 6% of patients share their experiences and post questions online (Fox, 2011). Social media analyses are becoming more common to investigate ADEs, and has been used by popular pharmacovigilance resources including the FDAs adverse event reporting system (Sarker et al., 2015). In recent years, pharmacovigilance and pharmacoepidemiological research activity has focused on how to best utilize social media posts to better understand prescription drug use and ADEs.

There are many strengths associated with this emerging methodology. Firstly, posts are read in real-time, so may identify disease outbreaks quicker than more traditional surveillance methods (Sarker et al., 2015). Secondly, given the ease of Internet access,

Table 2 Pharmacoepidemiological and pharmacovigilance study methods (World Health Organization structure)

Study design	*Strength(s)*	*Limitation(s)*
Passive surveillance		
Spontaneous reports	• Establish a signal for a previously unknown association between prescription drug use and an adverse outcome.	• Limited information regarding patient demographics and nature of prescription drug use at time of event. • Extremely small sample size ($n = 1$).
Case series	• Patients are typical of those with the exposure or disease. • Quantifying incidence of an adverse reaction. • Increase awareness of ADEs that may not have been apparent during clinical trial phases.	• Difficult to determine if the description of the patients are unique to the exposure or outcome.
Active surveillance		
Sentinel sites	• Efficient for drugs used mainly in institutional settings such as hospitals and nursing homes. • Helpful in identifying risks among patients taking orphan drugs.	• Selection bias – only includes persons presenting for treatment at that site. • Small sample size. • High costs associated with employing staff to complete data abstraction or interviews.
Medicine event monitoring	• Potentially includes entire population in country or region. • Information from patient and prescriber perspectives. • Incidence rates available to allow for precise calculation of risk factors.	• Poor physician/patient response rates for questionnaire.
Registries	• Large sample size of patients with a rare disease or prescription drug use. • Questionnaires provide opportunity to collect detailed clinical and disease history.	• Quality of self-report data may vary by individual and enrolment site. • Opt-in registries may not be representative of the entire patient population.
Comparative observational studies		
Cross-sectional study	• Relatively quick study design to examine trends between the exposure and outcome(s) of interest.	• Temporal relationship between exposure and outcome cannot be assessed.
Case–control study	• Study multiple causes of a single disease, as the same cases and controls can be used to examine multiple exposures and potential risk factors. • Studying relatively rare diseases, as it requires a sufficient number of cases with the disease. • Study rare diseases with a smaller sample size than required for a cohort study.	• Information obtained retrospectively. • Past exposure information is self-report and generated by abstracting medical records, administering questionnaires or interviews. • Validity of self-report data are unclear. • Difficult to appropriately select controls and may lead to selection bias, which may lead to incorrect conclusions.
Cohort study	• Provide evidence when a randomized clinical trial is unethical or unfeasible. • Representative study population. • Relatively cheap and cost-effective compared to other study designs. • Examine multiple potential outcomes from a single exposure.	• May require large sample sizes to study uncommon outcomes. • Prospective cohort drug studies may include a prolonged time period to study delayed drug effects. • Unmeasured confounding may impact on results/interpretation.
Descriptive studies		
Natural history of disease	• Quantify the disease course, particularly important for rare diseases. • Examine the impact of therapy on patient population over time.	• Long observation period.
Drug utilization study	• Examine trends over an extended time period. • Determine prevalence of prescription drug use. • Examine frequency of adverse events (to accurately interpret spontaneous reports).	• Lack of clinical outcomes data for patients using drug.
Analyses of secular trends	• Provide evidence for or against a specific hypothesis.	• Studies use aggregated data, so minimal information on patients are provided. • Unable to control for confounding factors. • Unclear if patients took the medication as instructed. • Unclear if same patients who were prescribed the medication are the people experiencing adverse outcomes.

affordability and the prevalence of use, social media analyses may include data from people that are unable to access health care through formal channels (Velasco et al., 2014). Also, these data are global, not confined to a specific region. Further, it may include experiences of patients who are typically excluded from clinical trials such as those with rare diseases, pregnant/lactating women, geriatrics or patients with comorbidities (Stricker and Psaty, 2004). Thirdly, social media posts can be used to validate or reject signals that have arisen in other reporting systems (Sarker et al., 2015).

The limitations of social media include the issues of credibility, recency, uniqueness, frequency, preciseness, and salience of these data (Abbasi et al., 2014). For example, Twitter is one of the most utilized social media platforms, yet due to the 140-character text limit information regarding ADEs will be superficial and may be vague, so if someone says they are sleepless using a sedative, is it an ADE or the reason for the sedative use? (Nikfarjam et al., 2015; Sarker et al., 2015). In the fields of pharmacovigilance, natural language processing analyses free-text fields, generally created by health care professionals, to ask important health care questions. Challenges for this methodology include the source data being free-text and entered by multiple people, information varies between entries; misspellings; and, nonmedical, descriptive terms may be used to discuss health issues; these issues are exacerbated when the general public enter these data (Sarker et al., 2015). For example, current natural language processing techniques are less effective in identifying relevant concepts in shorter texts, such as tweets. Consequently, this method is being refined for the purpose of applying it to social media entries such as Twitter or Facebook (Owoputi et al., 2013). See a review by Luo for further information (Luo et al., 2017). A recent systematic review found many studies use data that are not publically available so attempting to compare methodologies to identify ADEs are not possible (Sarker et al., 2015). Also, evaluation and development of systems have progressed in different directions without the development of any standard evaluation criteria (Sarker et al., 2015).

Patient-Reported Adverse Drug Events

Historically, drug companies and health professionals report ADEs. Reporting is mandatory for drug companies and voluntary for health professionals (Sarker et al., 2015). However, patient reporting systems are becoming increasingly popular across jurisdictions and may assist in combatting under-reporting as it would take the onus away from health professionals. In the European Union, after introducing patient reporting systems the number of recorded ADEs increased 30% (Inácio et al., 2017).

Spontaneous reports from patients are more detailed than clinician reports and include temporal facts; reports about different drugs and system organ classes (such as the central nervous system, general disorders, and administration site conditions) (Alves et al., 2013; Avery et al., 2011; Harmark and Van Grootheest, 2008; Hazell et al., 2013; Pal et al., 2013; Silverman, 2009; Van Hunsel et al., 2011). The patient perspective also describes the impact and severity of ADEs on daily life, including quality of life (Inácio et al., 2017; Van Balveren-Slingerland et al., 2015). Despite the unique utility of this information it is an underused resource as patient reporting of ADEs is rare in most countries.

Of note, there were no qualitative differences in information provided by patients and health care providers (Inácio et al., 2017). As expected, media attention led to a spike in patient reports received by the pharmacovigilance authority (Inácio et al., 2017). The opportunity to report ADEs online also increased the reporting rate in patients (Inácio et al., 2017). However, the tolerability and seriousness of ADEs may vary based on the perspective of the reporter. For example, many ADEs would be regarded as nonserious according to internationally agreed professional criteria, while nevertheless being intolerable, considered serious and causing severe problems for patients (De Langen et al., 2008; Frankenfeld, 2004). The evidence from these studies demonstrate that allowing patients to report ADEs adds new information which complements existing data from pharmacovigilance systems. This information can contribute to improved decision-making processes in regulatory activities.

The main limitation to patient-reported ADEs is the lack of patient awareness that these pharmacovigilance systems exist and they can contribute valuable information. For example, a patient spontaneous reporting system has been in operation in the UK since 2005, yet only 9% of patients are aware they could report an adverse event (Inácio et al., 2017). The longer a system has been in place, the higher the level of patient awareness and engagement (Inácio et al., 2017). There could also be potential participation bias, meaning the patients that report ADEs may not be representative of the entire population taking that drug. There is also a limit to the ADEs a patient can report, that is patients cannot report ADEs that require a medical test to confirm. Similarly, patient reported ADEs are not confirmed medically, so the pharmacovigilance system may need to introduce an addition system to follow up these reports.

Conclusions

This chapter introduced the key components, definitions, and principles of the disciplines of pharmacovigilance and pharmacoepidemiology, which should be considered whether embarking on a new research study or reviewing previous studies in this field. The most important aspects of pharmacovigilance and pharmacoepidemiology is understanding the data used to assess the association between prescription drug use and an outcome, whether adverse or beneficial; and, understanding the limitations of the study design chosen to answer the research question. It is important to realize all prescription drug use is associated with harms, but an independent body has reviewed the evidence and deemed the known harms to be acceptable. It is important to investigate if any new harms emerge after the drug is approved for used in the community, to ensure we minimize the risk of avoidable adverse drug events.

Glossary[1]

Adverse drug event (ADE) an untoward outcome occurring during or following clinical use of a drug.
Case–cohort study a study design that compares cases (persons with the relevant medical condition/exposure of interest) to controls (persons without condition or exposure). These studies may examine different exposures to disease, or quantify the risk of a particular outcome.
Case report describes a patient's experience after prescription drug use. Case reports may be the first piece of evidence indicating an association between drug exposure and an ADE.
Cohort study a study design that identifies a defined population and follows them forward in time, examining their frequencies (e.g., incidence rate) of disease.
Confounding variable a variable, other than the risk factor and outcome measures, that is independently related to both the risk factor and the outcome and may create or mask an association.
Cross-sectional study examines exposure and outcomes in a population at one time point.
Descriptive studies describe drug utilization or outcomes in a population.
Drug any administered substance that originates outside the human body (exogenous) and exerts a physiologic effect.
Drug effectiveness a study examining whether, in a clinical setting, a drug has the intended effect upon prescribing it.
Drug efficacy a study examining whether, in a clinical trial setting, a drug has the intended effect upon administration.
Drug utilization examining the "marketing, distribution, prescription, and use of drugs in a society, with special emphasis on the resulting medical, social and economic consequences" (definition from World Health Organization).
Drug utilization (study) studies quantifying the use of a drug including current use, trends, and the time course of drug use at national, regional, local, or institutional levels.
Ecological study examine trends in prescription drug use or disease events over time and/or across jurisdictions and correlate them with an expected outcome.
Exposure use of a prescription drug.
Generalizability of results whether a study cohort is representative of the entire population; if so, then study findings can be used to describe use/outcome(s) for the entire population. Factors that impact on the generalizability of results may include patient sex, age range, socioeconomic status, other comorbid conditions, etc.
Incidence rate measure the frequency of how often a medical condition occurs. The formula to calculate the incidence rate is: number of new cases of disease in a particular time period and population, divided by the number of people in that population.
Observational studies researcher examines (observes) real world prescription drug treatment and outcomes using data that reflect actual treatment patterns.
Over-the-counter drug drug available from a pharmacy that does not require a prescription from a health professional.
Pharmacoepidemiology the study of drug use and its effects in the community.
Pharmacovigilance the identification and evaluation of drug effects in the clinical trial and community settings.
Population-based database or study an identifiable group of people whose medical care (e.g., prescription drug dispensings) are included in a database. This allows one to determine incidence rates of diseases and quantify health care interactions in a population. Population-based studies are a representative sample of all patients using a prescription drug in the real world, particularly compared to clinical trials.
Post-marketing surveillance study of drug use and effects after it is released onto the market (available for use in the general community).
Prospective study studies that enroll patients and examine an event of interest (e.g., prescription drug use or outcomes) that will occur in the future (i.e., event may not have occurred at time of study enrolment).
Retrospective study studies that enroll patients after the event of interest (prescription drug use or an outcome) has occurred.
Spontaneous reporting systems collect unsolicited clinical observations regarding prescription drug use and outcomes that originate outside of a formal research study.

[1] Please note: all glossary terms are defined in relation to the fields of pharmacovigilance and/or pharmacoepidemiology. However, many of these terms will describe terms that are used in other disciplines and may have a slightly different focus.

Introduction

Medicines have a major role in the management of many conditions and illnesses. However, in order to achieve their desired outcomes, medicines must be used safely and appropriately in a manner that is consistent with best available evidence. In practice, there is often wide variation in medicine prescribing and use between prescribers, health services, practice settings, jurisdictions/provinces, countries, and regions. Although medicines can have many benefits, when used inappropriately, the negative outcomes associated with medicines use can have considerable health and economic consequences. This is a global issue of concern as worldwide, it is estimated that more than 50% of all medicines are prescribed, dispensed, or sold inappropriately, while 50% of patients fail to take them correctly (World Health Organization, 2002).

The World Health Organization (WHO) first defined the concept of rational medicines use in 1985 as "patients need to receive medications appropriate to their clinical needs, in doses that meet their own individual requirements, for an adequate period of time, and at the lowest cost to them and their community" (World Health Organization, 1985). Many countries have subsequently adopted this principle in their own versions of policies on medicines use. For example, one of the central objectives of Australia's National Medicines Policy is Quality Use of Medicines (or QUM). This refers to the judicious, appropriate, safe, and efficacious use of all medicines (Department of Health and Aging, 1999) with appropriate use referring to use in a manner that avoids misuse, abuse, underuse, and overuse (Spinewine et al., 2007).

Medicine or drug utilization studies, as they most often referred, aim to increase our understanding of how medicines are being used in clinical practice, and ensuring that they are used safely and effectively, in a rational manner. Given the extent of medicines use in society, drug utilization research represents an extremely important and large research field. There are a number of approaches to undertaking drug utilization research studies, which have evolved in complexity. This chapter provides an introduction to the key concepts central to understanding drug utilization studies and highlights the scope of this field of research.

What are Drug Utilization Studies?

The importance of undertaking drug utilization studies was first highlighted in the mid–late 1960s following the pioneering work of researchers in Europe and the United Kingdom (World Health Organization, 2003a). Arthur Engel and Pieter Siderius' seminal work

Table 1 The medical, social and economic aspects of drug utilization research proposed by Baksaas and Lunde (Baksaas and Lunde, 1986; Wettermark et al., 2016)

Medical	• Benefits: efficacy/effectiveness of drugs in preventing, relieving and eliminating diseases or their symptoms and complications. • Risks: short-term and long-term adverse effects, special risk factors associated with genetics, disease and environment, nutrition, age, sex, pregnancy, lactation, etc. • Benefit/risk ratio: to which extent may inappropriate prescription (indication, choice, dosage, duration) and use (compliance) reduce benefits and increase risks?
Social	• Drug and health attitudes and their causes, current trends in the culture regarding pharmacotherapy use vs alternative therapies. • Drug misuse, abuse and dependence. • Disuse of drugs (noncompliance, nonjustified drugs for the purpose). • Discrimination and social injustice (unavailability of important drugs). • Effect of informative and regulatory measures or interventions.
Economic	• Drug/product price and cost, imports vs local production. • Drug cost-effectiveness and safety in relation to purpose and alternative measures. • Current and future allocation of national resources (money, human resources, and facilities) to the drug and health budget.

in this field demonstrated marked variations in the sales of antibiotics across six countries in Europe, prompting recognition of the need to assess and compare the use of medicines between different countries and regions (Engel and Siderius, 1968). The WHO subsequently held its first meeting in drug consumption in Oslo in 1969, resulting in the formation of the WHO European Drug Utilization Research Group (DURG) (World Health Organization, 1970). It was then acknowledged that in addition to assessing overall patterns of drug use, there was a need to understand factors related to the safe and effective use of medicines at an individual level. The scope of the field therefore needed to be extended to be able to answer the following types of questions (World Health Organization, 2003a):

- Why are medicines prescribed?
- Who are the prescribers?
- For whom do the prescribers prescribe?
- Are patients taking their medicines correctly?
- What the benefits and risks of these medicines?

In 1977, the WHO formally defined *drug utilization research* as the "marketing, distribution, prescription, and use of medicines in a society, with special emphasis on the resulting medical, social, and economic consequences" (World Health Organization, 2003a). The medical, social, and economic consequences of drug utilization are outlined in further detail in **Table 1**. In summary, medical consequences relate to establishing the benefits and risks of medicines use; the social consequences address aspects of inappropriate use and the overall culture of medicines; while the economic consequences concern the cost-effectiveness of medicines and the impact of drug costs and health budgets.

Although the main objective of drug utilization research is to provide insights into the patterns, quality, determinants, and outcomes of medicines use (World Health Organization, 2003a), over the years, there has been an increased emphasis on the methods used to undertake this work. Consequently, the definition of *drug utilization research* has evolved to be "an eclectic collection of descriptive and analytical methods for the quantification, the understanding and the evaluation of the processes of prescribing, dispensing and consumption of medicines, and for the testing of interventions to enhance the quality of these processes" (Lee and U, 2012).

As a field, drug utilization research intersects with many other disciplines, and is often considered to bridge the gap between health services research and pharmacoepidemiology (Wettermark et al., 2016). Although the terms pharmacoepidemiology and drug utilization research are sometimes used interchangeably, there are clear distinctions between the two disciplines. *Pharmacoepidemiology* is the "study of the use and effects of drugs in large numbers of people" (Strom, 2012a), with a key emphasis on undertaking population-based studies to examine the outcomes of medicine(s) use (Bergman, 2001). Although drug utilization studies often make use of population-based data sources on medicines sales or utilization, they are generally focused on the quantity and quality of medicines use and understanding the key drivers behind the patterns observed, rather than an emphasis on establishing an association between use and an outcome (Wettermark et al., 2016). Nonetheless, many core methodological principles of pharmacoepidemiology also apply to drug utilization research.

Descriptive vs. Analytical Studies of Medicines Use

Studies of medicines use are broadly divided into two categories—descriptive and analytical (World Health Organization, 2003a). *Descriptive studies* describe patterns of medicines use and identify issues for further investigation. In contrast, *analytical studies* investigate the link between medicines use and outcome measures. Data about medicines use can be *qualitative* or *quantitative*, and obtained at a number of levels including national, regional, local health facilities, households, or from an individual (World Health Organization, 2003a). In the context of research regarding patterns of medicines use, qualitative studies explore issues related

to the quality or rational use of medicines, often assessing the appropriateness of use (World Health Organization, 2003a). Meanwhile, quantitative studies aim to describe the current trends and patterns in medicines use, and also prescribing practices at various levels of the health care system (World Health Organization, 2003a). These data are often derived from prescription or registry data or from surveys (World Health Organization, 2003a). For example, national household surveys collecting data on self-reported use of a variety of prescription medicines and recreational drugs.

Types of Drug Utilization Studies

Drug utilization studies are often focused on examining one of the key stages in the medicines-use chain, such as (World Health Organization, 2003a):

- *the systems and structures regarding medicines use* (e.g., how medicines are ordered, delivered, and administered in a hospital or health care facility).
- *the processes of medicines use* (e.g., what medicines are used and the manner of use, including whether use is consistent with relevant criteria, guidelines, or restrictions).
- *the outcomes of medicines use* (e.g., determining the short-term and long-term effectiveness, benefits and harms of use, as well as utilization of resources such as pathology tests and health care utilization).

These studies can be either cross-sectional or longitudinal in nature. *Cross-sectional studies* provide a snapshot or representation of drug use at a particular point in time (e.g., on a specific day, or over a month or year) (World Health Organization, 2003a). They are especially useful for making comparisons of the patterns observed across other settings or regions, or to collect data before and after an intervention to examine the impact of a change in policy or intervention (World Health Organization, 2003a). *Longitudinal studies*, or cohort studies, consist of the collection of multiple measurements of a group of individuals over time (Greenland, 1998). These studies include cohort data from repeated cross-sectional surveys or continuous data derived from administrative datasets. Longitudinal studies are necessary for evaluating the long-term trends in medicines use and the impact on health outcomes.

Methodological Considerations When Designing Quantitative Drug Utilization Studies

Considerable planning is required prior to commencing a drug utilization study. Development of a detailed written plan for the drug utilization study, also referred to as a study protocol, with input from relevant stakeholders, is advised prior to study commencement (Gamble, 2014; Public Policy Committee International Society of Pharmacoepidemiology, 2016). Depending on the setting and data source that will be utilized, it may be necessary to obtain formal ethical approval from an independent human research ethics committee prior to study commencement. Factors such as identifying the aim of the drug utilization study and most appropriate study design, discerning between the use of a secondary data source or undertaking primary data collection, deciding how medicines use will be defined, and determining the most appropriate way to manage, analyze, and present the data are important steps in the planning and execution of quantitative drug utilization studies (**Table 2**).

Study Design

It is essential to formulate a clear research question and identify the exact exposure(s) and outcome(s) of interest prior to study commencement. In pharmacoepidemiological studies, the use of a certain medicine can be classified as either an exposure or an outcome, depending on the research question under study. Quantitative drug utilization and descriptive studies often report use of specific medicine(s) as the main outcome measure. Quantifying the exact reason for the study and the exposures and outcomes of interest will inform the study design and assist with selection of the most appropriate data (e.g., primary data collection or a secondary data source) in order to address the research question of interest.

Selecting a Data Source for the Drug Utilization Study

Data about medicines use can also be collected prospectively or retrospectively, and is largely dependent on the availability of sources of medicines use. Sources also differ between countries, dependent on the structure of individual health care systems, and requirements for the routine collection, analysis and reporting of data about medicines use. A range of different data sources may be suitable for conducting drug utilization studies. A data source which is valid and reliable, with complete capture of all medicine(s) of interest and medicines supplied across all necessary settings (e.g., hospital inpatient, community, residential aged care, or long-term care facilities) is desirable to avoid bias.

The most frequently used sources of information include manual collection of data about prescribing, dispensing or administration of medicines directly from individuals or their medical records, or accessing information from registries, administrative health claims datasets or electronic health records. It is important to be aware of the strengths and limitations of each potential

Table 2 Factors to consider when planning a quantitative drug utilization study (Bain et al., 1997; Birnbaum et al., 1999; Crystal et al., 2007; Gillum and Johnston, 2003; Kornegay and Segal, 2013; McGlynn et al., 1998; Mitchell et al., 1994; Motheral and Fairman, 1997; Petrie and Sabin, 2009; Sluggett, 2014; Sørensen et al., 1996)

Study design
- What is the research question and aims/objectives of the drug utilization study?
- What are the exposure(s) and outcome(s) of interest?
- What sample size is necessary for the proposed analyses?

Ethical considerations
- Have the necessary approvals been sought from data custodians?
- Is human research ethics approval required prior to study commencement?
- Where will the data be stored and who will have access to the data?
- What strategies will be used to maintain patient confidentiality?

Selecting a data source
- What data will used for the study (e.g., primary or secondary data source)?
- Is the data source valid and reliable?
- If an existing (secondary) data source is proposed for the drug utilization study, how representative is the population captured within the data source?
- Does the data source capture information about all medicines of interest and medicines use across all desired settings?
- If necessary, are there sufficient data available for follow-up?

Data management
- If data entry is necessary, how will data entry errors be minimized or identified?
- How complete are the data? Are there any missing data or outliers and if so, how will these be handled?

Defining and interpreting medicines exposure
- How will medicines of interest be identified and extracted from the data source?
- Is the indication for use, dose and duration of use for all medicines of interest available?
- What time period will be used to ascertain medicines use for the drug utilization study? Will incident and/or prevalent medicines use be assessed?
- Were there any changes in medicines subsidies, coding, patient eligibility, or relevant guideline recommendations during the study period?

Data analysis and presentation of results
- What software package will be used for statistical analyses?
- What is the best way to summarize the data?
- What is the best way to present the results?

data source, and whether there are aggregate or individual-level data available when determining between potential data sources for a drug utilization study.

Primary data collection involves the study investigator(s) collecting information about medicines use directly from subjects via interview or survey, or through auditing medical records (Kornegay and Segal, 2013). The term "medical record review" may be used to describe a drug utilization study that uses prerecorded, patient-focused data as the primary source of information (Worster and Haines, 2004). Primary data collection methods can elicit more comprehensive information about nonprescription medicines use than other data sources. In addition to information about medicines use, detailed demographic and clinical information can also be determined, enabling a more in-depth analysis at the individual level. However, primary data collection is often resource intensive and it can be difficult to obtain a sufficiently-sized sample. Self-reported medicine use may not reflect prescribed use, and there is potential for recall bias when medicines use data are self-reported (Hafferty et al., 2018). As with any data source, data collected must be both reproducible and valid (Boyd et al., 1979).

Aggregate data can be defined as "data that are tracked across time, across organizations, across patient populations, or across some other variable," but are not individual-level data (Ryan and Thompson, 2002). Aggregate data sources for drug utilization studies may include medicines procurement records, medicines sales and purchasing data, and summary records of medication errors or adverse drug events (World Health Organization, 2003a). These data are often used to compare the utilization of similar medicines for a specific indication in large populations, or compare utilization in different populations or countries (World Health Organization, 2003a).

Clinical registries are organized systems which collect prespecified data on a defined population for monitoring safety or for quality improvement purposes (Gliklich et al., 2010). Clinical registries may be developed to collect details of individuals with a specific medical condition or the use of specific treatments or medicines (Dreyer and Velentgas, 2012; Gliklich et al., 2010). Clinical registries often include comprehensive acute care data and reflect "real-life" practices and patient outcomes. It is important to discern how medicines information is captured (e.g., self-report, data linkage) when using clinical registry data to investigate drug utilization.

Administrative health claims datasets contain longitudinal records of medical and pharmaceutical claims submitted to a central body for payment (Sluggett, 2014), and often provide access to a large number of prescription records over many years. Population coverage, quality and completeness of data, and information about drug utilization may vary between databases (Schneeweiss and Avorn, 2005; Strom, 2012b). Administrative health claims datasets can be used to examine drug utilization among large populations

efficiently and cost-effectively. However, clinical data and information about nonprescription medicines are often not recorded in administrative health claims databases, and medicines dispensed in hospitals or long-term care facilities may not be captured (Furu et al., 2010; Stricker and Stijnen, 2010).

Medical record databases and electronic health systems are used by health professionals to record information such as health conditions, prescribed medicines, pathology results, and other clinical information for their patients (Ogdie et al., 2012). De-identified datasets extracted from medical record databases or electronic health systems are sometimes made available for research purposes (Ogdie et al., 2012). Information about the indication, dose and intended duration of a prescribed medicine is often available from these data sources; however, it may not be possible to determine if the medicine was dispensed or administered. There may be variation in the quality of data entry and quantity of free text entries, and loss to follow-up can occur if a patient switches to a different health care provider (Sluggett, 2014).

Linked health databases are commonly used to conduct drug utilization studies. Availability of unique personal identifiers may enable linkage between national administrative health claims datasets and registries. Data linkage, the process of connecting records for the same person across datasets to obtain longitudinal records for each individual and improve the utility of individual datasets (Kornegay and Segal, 2013), may also be undertaken by study investigators. Records can be linked based on the exact match of one or more unique identifiers available from each dataset (deterministic matching), or by using specific software to match records based on pattern recognition and probabilities (probabilistic methods) (Clark, 2004).

When using a secondary data source, it is essential to understand the coverage of the data source and the underlying rules and regulations that underpin the prescribing, purchasing or administration of medicines in the particular setting or health care system involved. These factors will impact decision rules and the analysis plan for the study.

Medicines Exposure in Drug Utilization Studies

Because drug utilization studies generally focus on the prescribing, purchasing, or administration of certain medicines, defining medicine exposure in an accurate manner is essential to ensure the validity of the study (ENCePP, 2013).

Incident and Prevalent Medicines Use

The concept of prevalent or incident medicines use is important to consider when planning or interpreting findings from a drug utilization study. Prevalent use considers all users of the medicine of interest, regardless of when the medicine was started. Drug utilization studies which consider incident (or "new-user") use of a medicine consider only those individuals who commenced use of a medicine within a defined period (Ray, 2003).

Incident user definitions of medicine exposure can reduce certain types of bias. This is because prevalent users of a medicine are essentially "survivors" of the early period of medicines use, meaning they have tolerated the medicine and not experienced significant adverse events, and may have had a positive response to treatment (Ray, 2003). However, incident user definitions are not without biases and it is still common for some drug utilization studies to define medicine exposure based on prevalent use (World Health Organization, 2003a).

It is possible to define an incident medicine user from a secondary data source such as administrative health claims data or electronic medical records using a "washout" period or window without any evidence of medicine use. However, there is no consensus on the most appropriate definition or duration of the washout window when undertaking a pharmacoepidemiological study (Johnson et al., 2012). It is important to minimize the risk of the *prevalent pool effect*, which can occur when prevalent users are misclassified as incident users, leading to an overestimation of the true number of incident medicine users during the first few years of a dataset (Brameld et al., 2003).

It is important to consider both the research question and the strengths and limitations associated with each strategy when deciding whether a prevalent or incident user study design is necessary. Certain research questions will not require incident use; for example, it may not be necessary to restrict to new medicine users when undertaking a drug utilization study to determine the percentage of patients treated with an antiplatelet after hospitalization for acute myocardial infarction. However, for a study investigating the likelihood of an adverse event when taking a medicine of interest, and the adverse event may occur soon after the medicine is initiated, then restricting the study population to incident users is advised.

International Classification Systems used in Drug Utilization Research

To ensure consistency and standardization in the presentation of data on drug utilization, and to enable cross-national comparisons in medicine use statistics, it is important to have a universal medicine classification system and unit of measurement to represent utilization. The Anatomical Therapeutic Chemical (ATC) classification system and the Defined Daily Dose (DDD) metric were originally developed in Norway in the early 1970s, and are now the gold standard for international drug utilization monitoring and statistics (WHO, 2018a). The WHO Collaborating Centre for Drug Statistics Methodology is responsible for maintaining and updating the system, which can be found online at: https://www.whocc.no/atc_ddd_index/.

Structure of the Anatomical Therapeutic Chemical Classification System

Each medicine included in the ATC classification system is classified within a hierarchy consisting of five levels (WHO, 2018b). The 1st level comprises of 14 main anatomical/pharmacological groups. Each ATC main group is then divided into 2nd levels which are either pharmacological or therapeutic groups. The 3rd and 4th levels are chemical, pharmacological, or therapeutic subgroups and

the 5th level is the medicine/chemical substance. The 2nd, 3rd and 4th levels are often used to identify pharmacological subgroups when that is considered more appropriate than therapeutic or chemical subgroups. The structure of the ATC classification system is illustrated below using metformin (ATC code A10BA02) as an example (WHO, 2018b):

A	Alimentary tract and metabolism (1st level, anatomical main group)
A10	Drugs used in diabetes (2nd level, therapeutic subgroup)
A10B	Blood glucose lowering drugs, excluding insulins (3rd level, pharmacological subgroup)
A10BA	Biguanides (4th level, chemical subgroup)
A10BA02	Metformin (5th level, chemical substance)

There is one seven-digit ATC code for each medicine/chemical substance, which usually represents its main therapeutic use (WHO, 2018b). However, there are exceptions when a medicines/substance can have multiple indications (WHO, 2018b). For example, calcium channel blockers are classified according to the pharmacological group C08 Calcium Channel Blockers, avoiding specifying whether the main indication is coronary heart disease or hypertension (WHO, 2018b). Similarly, a medicine may be assigned multiple ATC codes depending on the indication for use. For example, the ATC codes for aspirin (acetylsalicylic acid) are A01AD05 (agents for local oral treatment), B01AC06 (platelet aggregation inhibitors excl. heparin) and N02BA01 (salicylic acid and derivatives, under the 3rd level subgroup other analgesics and antipyretics). It is important to note that combination products are generally assigned separate ATC codes to the individual medicines.

Defined Daily Doses

The DDD metric provides a fixed unit of measurement independent of price, currencies, pack size and strength, enabling trends in drug utilization to be assessed and compared between population group (WHO, 2018a). A DDD is defined as "the assumed average maintenance dose per day for a drug used for its main indication in adults" (WHO, 2018a). Only one DDD is assigned per ATC code and route of administration (e.g., oral, transdermal, parenteral formulations). As the DDD is a unit of measurement to allow data from drug utilization studies to be standardized across countries and settings, the DDD for a given medicine does not always align with the doses recommended in clinical practice, nor does it take into account variations in dose recommendations for different clinical indications or treatment purposes (e.g., acute, maintenance, or prophylactic therapies) (WHO, 2018a). Moreover, DDDs also do not take into account individual characteristics or factors that can influence treatment responses such as age, weight, ethnic differences, type, and severity of disease (WHO, 2018a). Consequently, when interpreting drug utilization data that are presented in DDDs, it is important to be aware that these data provide an overall estimate of utilization, and may not represent actual trends in use.

Oral Morphine Equivalents

The potential limitations of DDDs to overestimate or underestimate drug utilization has been most recently highlighted in the context of undertaking studies of opioid analgesic utilization (Nielsen et al., 2016; Svendsen et al., 2011). Opioids generally require highly individualized dosing which is titrated to pain responses, rather than having standard therapeutic dose ranges, and there is significant variation in the opioid doses used to treat acute and chronic pain. Among a representative cohort of people prescribed strong opioids for the treatment of chronic pain in Australia, DDDs were found to be 0.6–7.1 times the median opioid doses used by the cohort (Nielsen et al., 2017). Given that there are significant differences in the actual doses used in clinical practice and the DDDs proposed by the WHO, researchers have proposed an alternative metric to quantify opioid utilization: oral morphine equivalents (OMEs) (Nielsen et al., 2017; Svendsen et al., 2011). OMEs are based on the idea that different doses of different opioids (with varying potency) may produce a similar analgesic effect. This metric has the added advantage of being able to take into account the use of multiple opioids, as is common in contemporary clinical practice. The use of OMEs is becoming increasingly common across a range of various research studies (Degenhardt et al., 2016; Karanges et al., 2018; Lalic et al., 2018).

Defining and Interpreting Medicines Exposure

Exposure to a medicine of interest can be defined in a number of different ways. Medicines exposure is often classified as a binary variable (e.g., yes/no) when undertaking a drug utilization study (Gamble, 2014). Exposure can also be classified according to the number of medicines of interest an individual is exposed to (e.g., 0, 1, ≥2 medicines) or the dose received (e.g., in mg, DDDs or OMEs (Nielsen et al., 2016)). The drug utilization studies described in **Table 3** have used a range of different approaches to define medicines exposure. The time period to determine whether an individual is exposed to a medicine of interest, or to ascertain the duration of medicines exposure or the cumulative dose an individual receives, must be considered carefully and may vary depending on the research question and data source.

Table 3 Examples of approaches used to assess medicines exposure in drug utilization studies

Reference	*Country*	*Summary*	*Approach used to report exposure to medicine(s) of interest*
Sluggett et al. (2015)	Australia	Administrative health claims data were used to determine prevalence of use of medicines to reduce secondary stroke risk after hospitalization for transient ischemic attack or stroke.	Medicine use was stratified by diagnosis, medicine class and age group. The number of participants receiving 0, 1, 2, and 3 guideline-recommended medicines, and clinical and demographic factors associated with use of all three recommended medicine classes were reported.
Nishtala and Soo (2015)	New Zealand	A repeated cross-sectional study was undertaken to assess utilization of proton pump inhibitors (PPIs) between 2005 and 2013 among people aged ≥65 years using a national population-level prescription claims dataset.	The number of defined daily doses (DDDs) of PPIs per 1000 people per day were determined. Utilization trends were further stratified by PPI type, age group, sex, ethnicity, and region of residence.
Degenhardt et al. (2016)	Australia	This study assessed utilization of strong prescription opioids, other prescription opioids or over-the-counter opioids in Australia in 2013 using national sales data.	Opioid utilization was estimated in three different ways: (1) the number of packs of opioids sold, (2) the number of milligrams of each opioid sold, and (3) the total oral morphine equivalent milligrams (OME mg). Utilization was mapped according to geographical location of supply for comparison.
Bell et al. (2010)	Finland	Medicines data collected by nurses for 2052 residents of long-term care wards over a 2-week period were assessed to determine exposure to sedative and psychotropic medicines as part of this cross-sectional study.	Exposure to individual medicines and medicine classes of interest were reported. Sedative load was calculated for each participant to determine cumulative exposure.
Gnjidic et al. (2012)	Finland	A cross-sectional study which assessed exposure to anticholinergic and sedative medicines and functional outcomes among 700 community-dwelling older people.	Exposure to anticholinergic and sedative medicines was determined using the Drug Burden Index.

An understanding of local medicine supply policies, coding of pharmaceutical claims, and changes to the availability of subsidized medicines is important when conducting a drug utilization study using pharmaceutical claims data, particularly when comparing medicines use across countries or examining changes in medicines use over time (Sluggett, 2014). There may have been changes to the ATC codes or the DDD assigned to the medicine of interest (WHOCCDSM, 2018), or release of new combination formulations with different ATC codes. Other factors, such as changes to treatment recommendations in clinical guidelines, medicines shortages and product withdrawals may also contribute to variation in the utilization of the medicine(s) of interest. Seasonality may also be important when interpreting the results of drug utilization studies assessing use of medicines such as vaccines or antibiotics indicated for respiratory infections (Antonova et al., 2014; Suda et al., 2014). Careful inspection of medicines use at regular intervals during the data analysis process is advised to identify unanticipated variability in medicines exposure.

Data Analysis and Presentation of Results

Statistical software packages are commonly used to analyze data for drug utilization studies. Descriptive statistics, such as percentages, rates, and measures of location (e.g., mean, median) and spread (e.g., standard deviation, interquartile range) are commonly used to summarize findings. Statistical tests may be used to determine any differences in demographic, clinical and health provider factors for those who received the medicine(s) of interest in comparison to those who were not exposed to the medicine(s) of interest during the study period. For example, statistical tests such as *t*-tests or Wilcoxon rank sum tests are sometimes used to compare continuous measures (e.g., age in years) depending on the distribution of the two populations. Statistical tests such as chi-square tests and Fisher's exact tests are commonly used to compare dichotomous variables (e.g., sex) in a contingency table, with selection of the most appropriate test depending on factors such as sample sizes within the cells of contingency tables. Outcome measures are often further stratified by demographic and clinical variables of interest such as patient age, geographical area, year, medicine/drug class or treatment indication. Multivariable regression models are often used to estimate measures of associations (e.g., odds ratios, relative risk) between demographic, clinical, and health provider factors and the prescribing, dispensing or utilization of the medicine(s) of interest in a drug utilization study.

Results of drug utilization studies are generally summarized within the text and presented within tables or diagrams. For example, for a drug utilization study examining the frequency of use of "pro re nata" (PRN or when required) medicines by residents of aged care services, the frequency of prescribing and administration of all PRN medicines were stratified according to the WHO ATC classification system and results were presented graphically (Stasinopoulos et al., 2018). Backward stepwise multivariate logistic regression was undertaken to determine resident characteristics associated with administration of PRN medicines among residents who were charted at least one PRN medicine and the unadjusted and adjusted odds ratios, 95% confidence intervals and *P*-values were presented in a table (Stasinopoulos et al., 2018).

As with any research study, it is important to follow good practices in the presentation and reporting of results and findings. There are several published standards and guidelines that are useful for reporting drug utilization studies, including: American Society of Health-System Pharmacists (ASHP) Guidelines on Medication Use Evaluation (American Society of Health-System Pharmacists, 1996); the International Society of Pharmacoepidemiology Guidelines for Good Pharmacoepidemiology Practice (GPP) (Public Policy Committee International Society of Pharmacoepidemiology, 2016); the European Network of Centres for Pharmacoepidemiology and Pharmacovigilance (ENCePP) Guide on Methodological Standards in Pharmacoepidemiology (ENCePP, 2010); the STrengthening the Reporting of OBservational studies in Epidemiology (STROBE) (von Elm et al., 2008); and REporting of studies Conducted using Observational Routinely-collected health Data (RECORD) statement (Benchimol et al., 2015).

Applications of Drug Utilization Studies

As described throughout this chapter, drug utilization studies can address many different aspects of medicines use. There are an endless number of applications and examples of drug utilization studies in the literature, ranging from cross-sectional drug utilization evaluations to more complex longitudinal evaluations of health and policy interventions. Some selected examples of applications of drug utilization studies are presented below.

Evaluating the Rational Use of Medicines

One of the primary purposes for undertaking drug utilization research is to ensure that medicines are used rationally with an emphasis on maximizing benefits while reducing harm (World Health Organization, 1985). As such, a simple search of any literature database using the terms "rational medicines use" or "inappropriate medication use" will return many examples of studies and methods for assessing the rational use of medicines. By far, one of the most common applications of drug utilization studies is the conduct of *drug use evaluations (DUEs)*, *drug utilization reviews (DURs) or medication-use evaluations (MUEs)*. Undertaking DUEs is an essential process in order to evaluate the rational use of medicines and to optimize pharmacotherapy, even in low- and middle-income countries where resources for more sophisticated studies are limited.

Although drug utilization studies using aggregated data can identify whether medicines are being over- or underused, individual-level data is needed to determine whether medicines are used appropriately, and to identify the nature of any irrational use (e.g., incorrect medicine choice, incorrect dose, contraindications and any drug–drug interactions) (World Health Organization, 2003b). Therefore, DUEs provide a system for an ongoing, systematic and criteria-based evaluation of drug use to ensure that medicines are used appropriately at the individual patient level (World Health Organization, 2003b). A DUE can be drug or disease specific and be structured to assess any of the processes related to the prescribing, dispensing or administration of a drug (World Health Organization, 2003b). The term DUE is often used synonymously with the term drug utilization review (DUR). In addition to the overall goal of DUEs to optimize medicines use, MUEs also aim to improve patient outcomes and quality of life (American Society of Health-System Pharmacists, 1996; World Health Organization, 2003b). As such, MUEs also measure clinical outcomes, for example, number of infections cured, and whether blood pressure or lipid level targets have been met.

A systematic review of drug utilization studies in the WHO South-East Asia region identified that DUEs are the most common type of drug utilization study conducted, and that most studies used hospital-based patient records to assess the rational use of medicines (Bachhav and Kshirsagar, 2015). However, this is not reflective of the extent of drug utilization studies in more developed parts of the world where studies are often conducted across a range of settings (including the general community and in residential aged care facilities) and for many other purposes, including the evaluation of policy and health interventions.

Many countries have organizations or formal committees (often referred to as Drug and Therapeutics Committees) to coordinate ongoing programs of work to evaluate the manner in which medicines are being used in different settings, such as in individual hospitals or in the general community. For example, one of the core roles of Australia's Drug Utilization Sub-Committee is to advise the Pharmaceutical Benefits Advisory Committee on changes in national drug utilization patterns that have occurred as a consequence of changes in drug availability or restrictions on drug use, and to review the utilization of drugs or general therapeutic classes (Australian Institute of Health and Welfare, unknown). More information and past reports can be found online: http://www.pbs.gov.au/info/industry/listing/participants/drug-utilisation-subcommittee.

Cross-national Studies of Drug Utilization

As summarized earlier, a major factor contributing to the development of the ATC/DDD classification systems was to enable cross-country comparisons in drug use statistics. The increasing availability of administrative datasets, including dispensing registers and other pharmaceutical claims databases, have been instrumental in facilitating cross-national drug utilization studies, and more recently, in the development of multinational cohort studies, particularly in the Nordic region (comprising Denmark, Finland, Iceland, Norway, and Sweden) (Furu et al., 2010). To date, many of these studies have focused on various aspects of psychotropic medicines use including: population-based cohorts of Nordic residents examining the use of medicines to treat attention-deficit/hyperactivity disorder in children (Furu et al., 2017) and adults (Karlstad et al., 2016), and cross-national comparative studies assessing patterns of antipsychotic medicines use across 16–17 counties worldwide (Bachmann et al., 2017;

Hálfdánarson et al., 2017). Other examples include global studies of the use of and barriers to access opioid analgesics (Berterame et al., 2016) and an evaluation of the impact of *WHO Essential Medicines* policies on inappropriate use of antibiotics (Holloway et al., 2016).

Informing Pharmacovigilance

Drug utilization studies are often incorporated into post-marketing surveillance of newly registered medicines and in assessing the long-term benefits and risks of medicines. Traditional approaches to pharmacovigilance (defined as the detection, assessment, understanding and prevention of adverse effects or any other drug-related problem (WHO, 2018c)) have focused on detecting safety signals from spontaneous adverse drug reaction (ADR) reporting systems (Coste, 2017). However, this method is limited by extensive under-reporting and limited generalizability, warranting the need for alternative pharmacovigilance approaches. One example is the use of prescription sequence symmetry analysis (PSSA) to detect ADRs using pharmaceutical claims data (Hallas, 1996; Pratt et al., 2014; Wahab et al., 2013). This method has been validated against known ADRs reported in randomized controlled trials (Wahab et al., 2013), and has shown consistency in estimates for identifying ADRs across five countries in the Asia-Pacific region (Australia, Hong Kong, Japan, Korea, and Taiwan) (Pratt et al., 2015). Other examples where PSSA has been used to investigate potential ADRs include studies assessing potential relationships between: proton pump inhibitor use and the risk of dementia (Park et al., 2018), hypothyroidism induced by antiepileptic use (Lai et al., 2013), urinary tract infections and angiotensin-converting enzyme inhibitors (Pouwels et al., 2013), stroke and nonsteroidal anti-inflammatories (Caughey et al., 2011), and depression and cardiovascular drugs (Hallas, 1996).

Informing the Design and Evaluation of Health Policy and Educational Interventions to Optimize Medicines Use

When used appropriately, medicines can improve health and wellbeing; however, medicines are not always used as intended. Inappropriate medicine use can lead to considerable economic costs for health systems and consumers, along with poor health outcomes such as adverse drug events, hospitalizations and mortality (Chiatti et al., 2012; Hyttinen et al., 2016). Once a potential medicines-related problem has been identified, for example through a drug utilization study, strategies to optimize the use of that medicine may be deemed necessary. Furthermore, new medicines are increasingly costly and health funders may implement policies or procedures to support judicious use of high cost therapies (World Health Organization, 2015). Drug utilization studies play a key role in the planning, implementation and evaluation phases of interventions to optimize medicines use.

Interventions to support medicines to be used safely, efficaciously, and cost-effectively may be funded and/or implemented by individual health care providers or organizations, research organizations, health care payers, regulatory bodies, or policy makers (Grimshaw et al., 2012). The target population for interventions to improve medicines use may include consumers and carers, clinicians, health care organizations such as hospitals or aged care providers, and other stakeholders. Examples of interventions which are commonly used to optimize medicines use include changes to health policies, formulary or medicines reimbursement restrictions, audit and feedback, written educational materials, educational meetings and academic detailing (Grimshaw et al., 2012). Multifaceted interventions are those which utilize more than one strategy to promote behavior change leading to improved medicines use (Squires et al., 2014). Health policy and educational interventions to optimize medicines use require considerable planning, stakeholder engagement and a comprehensive understanding of factors which may impact on the uptake, delivery and sustainability of an intervention. Consideration of relevant behavior change theories throughout this process is advised to increase the likelihood of success and support sustained change leading to improved medicines use.

After implementing a change or strategy to optimize medicines use, those responsible will be interested in monitoring the impact of the intervention on medicines use and health outcomes, and determining if the initiative was effective or if changes are necessary. Interventions to optimize medicines use may be investigated as part of a controlled trial; however, policy changes are often unable to be trialed within a controlled trial environment and randomization may not be possible for health policy and educational interventions that are implemented across an entire population (Bärnighausen et al., 2017). Quasi experimental designs such as interrupted time series and regression discontinuity studies may be used to investigate the impact of interventions to optimize medicines use. Examples are discussed in **Table 4**. Interrupted times series studies are increasingly used in drug utilization research and, in the absence of a controlled trial, are the most robust design to investigate the effects of an intervention to optimize medicines use (Briesacher et al., 2013; Jandoc et al., 2015; Wagner et al., 2002). This method enables assessment of changes in the use of a medicine of interest after one or more interventions, meaning the cumulative effects on medicines use over time can be determined (Pratt et al., 2017; Wagner et al., 2002). Detailed information regarding the design and interpretation of interrupted time series studies using pharmaceutical claims data is available elsewhere (Kemp et al., 2011; Wagner et al., 2002).

Finally, it is important to note that quantitative drug utilization studies may be undertaken in as part of a wider evaluation which may incorporate qualitative approaches to understand factors which impacted on the implementation of a policy change or educational intervention, or cost effectiveness analyses.

Finally, it is important to note that quantitative drug utilization studies may be undertaken in as part of a wider evaluation which may incorporate qualitative approaches to understand factors which impacted on the implementation of a policy change or educational intervention, or cost effectiveness analyses.

Table 4 Examples of studies examining the effect of health policy and educational interventions to optimize medicines use

Reference	*Country*	*Summary*
Pratt et al. (2017)	Australia	The combined impact of five national multi-faceted quality improvement interventions targeting clinicians and consumers to improve the use of proton pump inhibitors was evaluated using interrupted time series.
Komen et al. (2017)	Sweden	Study using interrupted time series to assess the impact of national and international guideline recommendations, local drug and therapeutics committee recommendations, and medication reimbursement decisions on the initiation of direct-acting oral anticoagulants among people with atrial fibrillation.
Judge et al. (2015)	United Kingdom	Study using interrupted time series to assess the changes in the prescribing of disease modifying anti-rheumatic drugs within the first 12 months of diagnosis of rheumatoid arthritis following release of national rheumatology guidelines.
Zuckerman et al. (2006)	United States	The impact of an educational intervention targeting potentially inappropriate use of short acting β2 agonist inhalers among children who received Medicaid-subsidized health services was assessed. Study findings obtained from a regression-discontinuity analysis were compared to results of an uncontrolled before–after analysis.

Conclusion

As evidenced throughout this chapter, drug utilization studies are a necessary part of increasing our knowledge and understanding of the manner in which medicines are used in the community, with the ultimate goal of ensuring that medicines are used safely and appropriately. As with any field of research, there are many study approaches and methodological aspects to consider when designing robust drug utilization studies. Understanding and applying the fundamental principles underlying these studies is especially important as the field continues to evolve in scope and complexity.

Glossary

Anatomical Therapeutic Chemical (ATC) Classification System a standardized classification system used to assign drugs to pharmacological groups according to a five-level hierarchy.
Defined Daily Dose (DDD) a standardized metric used in drug utilization research. The DDD represents the assumed average daily maintenance dose of a medicine for its main indication in adults.

Case-Control Studies

Caroline Sirois, Université Laval, Quebec, QC, Canada; Centre of Excellence on Aging of Quebec, Quebec, QC, Canada; National Institute of Public Health of Quebec, Quebec, QC, Canada

Introduction

Evidence-based data guide shape pharmacists' clinical practice. Randomized clinical trials, for example, provide the foundation for rational choices of treatments, establishing the conditions for which a medication will provide the greatest benefits to individuals. Nonetheless, clinical trial data have limitations. Clinical trials are usually performed among groups of people with homogeneous characteristics that poorly reflect the diversity of individuals seen in clinical practice. Older adults, multimorbid individuals, and those with renal or hepatic failure, for example, are often excluded from clinical trials. Ethical considerations also limit inclusions of pregnant women and children in many clinical trials. Moreover, limited follow-up and the fact that clinical trials include small numbers of individuals make it difficult to identify rare side effects.

Observational data, generated in real-world practice, are therefore equally useful for the health professionals including pharmacists. These data can be employed in studies to evaluate the actual effectiveness of drugs, investigate common or rare adverse events associated with their use, or simply describe the quality of medication use according to different norms or standards. Pharmacists can thus exploit the information gathered in such observational studies to inform their own practice.

Case-control studies are useful observational studies to evaluate the impact of medications on different health outcomes. Because of their particular design, case-control studies are especially useful for examining rare events and multiple exposures at the same time. These situations pose a particular problem when conducting research: to ensure sufficient power (i.e., an appropriate number of cases), many individuals would have to be followed up over long term. Studies requiring large number of individuals and/or long follow-up are often not possible or feasible to perform. Case-control studies thus provide valuable help in dealing with such situations.

The chapter proposes a review of the fundamentals of case-control studies. Of note, many elements that are addressed in this chapter are similar to the ones pertaining to observational cohort studies. Moreover, case-control studies are increasingly embedded in cohort studies.

Defining and Designing Case-Control Studies

By definition, case-control studies are analytic studies where cases who experienced the outcome under investigation are compared to controls who did not. Controls are chosen to represent the population that gave rise to the cases. As for study outcomes, they may be of various natures, either diseases or events such as mortality, hospitalizations, or fractures, for example. The case-control study therefore addresses the following question: did the exposure differ between cases and controls? In other words, were the cases more likely to be exposed to a particular risk factor or drug than the controls (or vice-versa)?

Case-control studies can be seen as the opposite study design of cohort studies. In cohort studies, exposed and unexposed individuals are followed up over time until the disease or event is observed (e.g., until the person dies, is lost to follow-up, or until the end of the study). In case-control studies, the outcomes are already known: the individuals who have experienced the disease or event under study are identified as the cases. The controls are individuals who did not experience the outcome of interest. Contrary to the cohort studies, the researchers in case-control studies must identify if the cases and controls were exposed to the risk factors or drugs. Fig. 1 illustrates schematically the procedures in a case-control study. Starting from the population, cases and controls are identified by the presence or absence of the outcome of interest. The following step is to determine whether or not the individuals were exposed to the risk factor(s) or the drug(s) studied. Fig. 2 depicts the nested case-control study, a specific type of case-control design that is embedded in a cohort study, which helps understand the contrast with cohort studies.

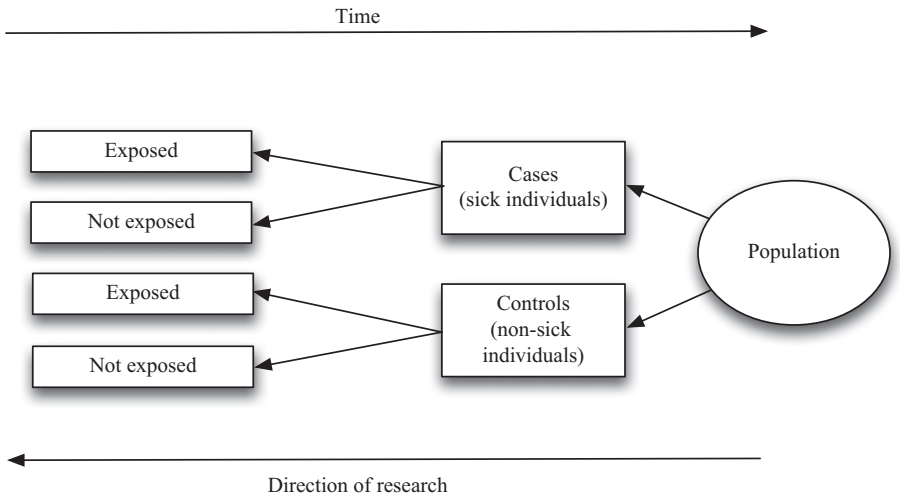

Figure 1 Design of case-control study.

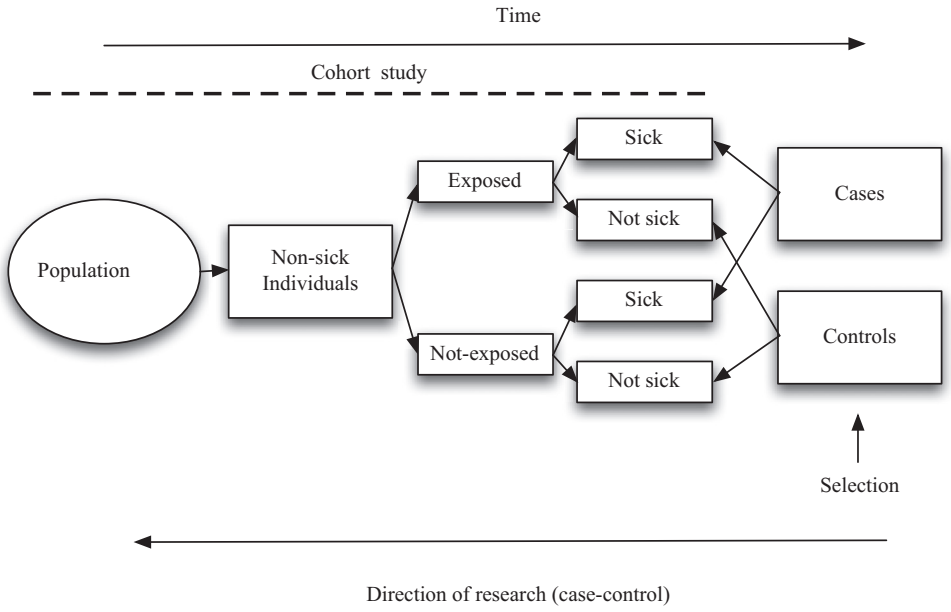

Figure 2 Design of nested case-control study.

As such, a case-control study can be viewed as an efficient cohort study because only a fragment of the total population is studied. The individuals who would have experienced the outcome under a cohort study are identified and compared only to a certain number of controls who would not have experienced the outcomes in a cohort study. The step of selecting cases and controls offers greater efficiency and less costly procedures.

Origin of Case-Control Studies and Examples of Case-Control Studies Studying Medications

The first case-control study in pharmacoepidemiology is believed to be one examining clear-cell adenocarcinoma of the vagina in young women: The hypotheses tested by the investigators were that exposure to either radiation or a drug caused the condition. They compared eight women with adenocarcinoma of the vagina (cases) to 32 controls, girls born at a similar date to the cases in the same hospital. Exposure to diethylstilbestrol (DES) was revealed to be associated with a great increase in risk: the odds for a baby girl exposed to DES in utero to suffer from a carcinoma was 132 times the odds of a baby not exposed. The strength of the association gave a clear indication that there was a strong link between the exposure to DES and cancer occurrence.

Other well-known examples of case-control studies involving drugs are those establishing the link between acetyl-salicylic acid (ASA) and Reye syndrome, and the relation between eosinophilia-myalgia syndrome with the food supplement L-tryptophan. In 1984, researchers in the United States conducted a case-control study with 30 patients with Reye's syndrome. After matching those cases with 145 controls for age, race, and type of antecedent illness, it appeared that the cases were significantly more exposed to ASA, with an odds ratio (OR) of 16.1. Similarly, a case-control study permitted to explicit that the origin of an outbreak of eosinophilia-myalgia syndrome in 1989 was associated with the manufacturing conditions of L-tryptophan by one specific company. The odds of developing the syndrome among individuals exposed to the contaminated product was 19.3 times the one of unexposed people. These case-control studies paved the way for dramatic changes in the way medications were used. But performing case-control studies entails following strict methodological founding principles; otherwise they are prone to bias and their conclusions may not be valid.

Selection of Cases and Controls

Appropriate selection of cases and, above all, controls, is fundamental in conducting case-control studies. Cases are selected according to inclusion and exclusion criteria and must be selected such that they are representative of the population, otherwise the results may be biased.

The major challenge of a case-control study is to select appropriate controls for the cases. As noted earlier, the controls must be representative of the population where the cases come from. Conceptually, this population is made up of all the individuals who would have been identified as a case if they had experienced the outcome. It is critical to select control by means of procedures that are independent of the exposure (i.e., of the studied medication in pharmacoepidemiology). The overarching goal of control selection is to determine the relative numbers of people exposed and not exposed to the medication in the source population. If controls are selected in a way that is related to the exposure, the estimate of the risk will thus be biased. This situation may lead to a selection bias that will confound the appropriate association between the use of the medication and the outcome. This problem will be further described in the section "Dealing With Bias".

Different techniques exist to select appropriate controls. In classical case-control studies, controls can be selected among the cases' neighbors (by applying systematic selection algorithms, for example). This allows for geographical representativeness and the control of socioeconomic status, which may be important confounding factors. Recruiting cases' friends is also an alternative sometimes used to identify potential controls. Yet, as friends often share similar interests—and hence exposures—care must be exerted to ensure that the exposure is truly representative of the source population. In hospital studies, cases may be individuals hospitalized in one or more departments or hospitals. Controls can thus be selected from among those hospitalized in the same hospitals. It is of utmost importance however to ensure that the reasons for hospitalization are not related to the studied exposure. Finally, when the outcome of interest is death (so cases are deceased persons), deceased controls can also be chosen to ensure better comparability of information. Regardless of the chosen technique, it is important to remember that it must be free of selection bias, which will be discussed later in this chapter.

Control selection methods may be somewhat different when studies are nested in larger cohorts. In pharmacoepidemiology, administrative data are often used to create large cohorts of individuals who may or may not be exposed to drugs. Individuals are defined as cases if they had an event during a specific period of time. Selection of controls can then be carried out retrospectively; the probability of being selected as a control will be proportional to the time the individual is at risk of becoming a case, which is known as incidence density sampling. An individual could therefore be chosen as a control and become a case later on in the follow-up.

Each case can be matched to one or more controls in the analysis. Matching provides the opportunity to control for potential confounding factors, that is, characteristics that both a case and his/her control(s) will share. For example, case X who is a women of 40 years of age, will be compared to a control Y who is also a women of 40 years of age. Matching a case to 3–4 controls will increase precision and power. Enhancing the ratio to greater than 4 will not result in much gain in precision and may increase study costs. Yet, nowadays the use of large administrative databases allows for the selection of many controls, without such restrictive monetary considerations; it is relatively common to see matching involving more than 4 controls, which will improve power.

Defining Exposure

Another challenge in case-control studies is to define the exposure appropriately. This is of particular issue in pharmacoepidemiological studies using the case-control design. In order to study the effect of a drug, it is fundamental to explore its pharmacology: its mechanism of action, the possible drug-drug interactions that may be involved, the way the product is eliminated. This information will help determine which elements are essential for defining exposure. It will also be necessary to question the effect of the dose, the duration of exposure, the frequency with which the individual receives the medication. In addition, exposure must be defined according to the event of interest. Does the individual need to be exposed immediately before the event? Should exposure be studied over a month, six months, one year, or ten years? The pathophysiology of the disease must also be taken into account when defining exposure. The hypothesis regarding the relationship between the exposure and the disease or event needs to be clarified before the start of the study. It will then be possible to determine the relevant exposure in terms of dose, duration, and temporal relationship regarding the occurrence of the outcome. For example, a myocardial infarction could not be attributed to taking a statin if an individual swallowed the first dose in the previous hour. Exposure may need to be maintained for a period of time for the individual to experience the effect of the drug. Therefore, the individual may not be considered exposed until a predefined length of exposure has been reached.

Several examples can be retrieved in the literature for defining exposure in case-control studies. For example, it can be categorized into classes, such as: current user of the medication at the date of the event (index date, for cases and similar date for the control), recent user, past user, or never user. Cumulative exposure can be described as a combination of length of exposure and mean dose received. Yet another consideration when assessing the effect of drug use on health outcomes, is to determine whether the effect of the drug will persist for a long time after the individual stops taking it. A drug that accumulates in the body, shows a long half-life, or causes irreversible effects on a tissue or organ could induce benefits or side effects well after the treatment is ceased. In this situation, it would be appropriate to consider the individual exposed to the drug even if, in fact, he or she did not use the product recently.

The conceptualization of exposure will also determine which data sources are the most appropriate. For example, it would be unrealistic to ask individuals to report their exposure to all the medications they have consumed in the last ten years. This measurement can, however, be done in large databases. On the other hand, one could easily recover the information by asking a person if the exposure was defined as use of a medication in the previous days. The data sources thus present strengths and limitations. Data reported by individuals may be prone to recall bias: it may be difficult to remember exactly what drug use was in a defined period of time. This bias may also be of a differential nature: a person who has experienced the event (a case) may better remember their exposure than the control. This can lead to problems in the interpretation of results, as will be discussed in the section "Dealing With Bias". In administrative data, the information available comes from purchased drugs. The actual use of the medication is not known, nor are the reasons for which the individual was or not prescribed the drug. This can lead to different issues, such as confounding by indication, as described again in the section "Dealing With Bias".

Calculating and Interpreting Odds Ratios

Odds ratios (ORs) are the measure of association in case-control studies. The odds ratios refer to the probability that an event will happen divided by the probability that it will not happen. To fully understand how this measure is calculated, one can construct a 2×2 table like the one presented in Table 1. The OR will compare the odds of being exposed between cases and controls. The proportion $a/(a + c)$ represents in a way the probability for a case of having been exposed and $c/(a + c)$ that of not having been exposed. The ratio $a/(a + c)/c/(a + c)$ reflects the relative chance of being exposed, which can be simplified by a/c. The ratio a/c measures the odds in favor of exposure vs. non-exposure. For example, if the odds is 2, the probability of being exposed is twice as high as that of not having been exposed.

Similarly, the odds for the controls are equal to b/d. The interpretation remains similar to the one previously stated for the cases.

Using the ratio $a/c \div b/d$, we can compare the odds of exposure between the cases and the controls. The OR can be written:

$$\mathrm{OR} = \frac{a/c}{b/d} = \frac{ad}{bc}$$

Table 1 2×2 table used to calculate odds ratio in an unmatched case-control study

	Case	*Control*	*Total*
Exposed	a	b	$a + b$
Not exposed	c	d	$c + d$
Total	$a + c$	$b + d$	$a + b + c + d$

Odd of exposure (cases) = Number of cases exposed/Number of cases not exposed = a/c
Odds of exposure (controls) = Number of controls exposed/Number of controls not exposed = b/d
Odds ratio = Odds of exposure (cases)/Odds of exposure (controls) = ad/bc

Table 2 Example of an odds ratio calculation in an unmatched case-control study

	Cases	*Controls*	*Total*
Exposed	15	7	22
Not exposed	30	38	68
Total	45	45	90

Odd of exposure (cases) = Number of cases exposed/Number of case not exposed = 15/30
Odds of exposure (controls) = Number of controls exposed/Number of controls not exposed = 7/38
Odds ratio = Odds of exposure (cases)/Odds of exposure (controls) = (15 × 38)/(7 × 30) = 2.71

The OR allows to estimate the relative risk between the exposure and the health outcome. If there is no association between the outcome and the exposure (e.g., drug) studied, the odds of the two groups will be similar, leading to an OR of 1. If there is a positive association between the exposure studied and the outcome, the odds will be higher in the cases than in the controls, so that the OR will be greater than 1. If the OR is <1, then the exposure to the drug under study prevents the health outcome. In Table 2, the OR is 2.7. The exposure is thus associated with the outcome. The odds of exposure among cases is 2.7 times the one seen in controls.

While it can be concluded that the OR estimates the relative risk between the exposure and the outcome, the estimate will be more or less close to the true relative risk depending on the type of case-control design and the prevalence of the outcome. In general, the OR overestimates the true relative risk. For example, if the OR = 2.3, the true relative risk may be 1.9. Similarly, if an OR demonstrates a protective effect, such as an OR of 0.6, the real relative risk will be less protective in reality, with a value of 0.8, for example. The rarer the event (prevalence <10%), the closer the OR will be to the relative risk. Some case-control designs allow for a more accurate estimation of the RRs. More information is available in the section presenting the different designs.

Interpreting an OR should also involve the evaluation of the confidence intervals (CI) surrounding this measure. The CI includes a range of values that may contain the true measure of association (the true OR in this case). For a 95% CI, if we were to repeat the same study a hundred times, 95 of the different CIs would contain the true value of the OR. The CI helps us examine two elements: the precision of the measurement and the fact that the observed association is more or less likely to be due to chance. A CI whose values are very widely spread will signify that the true OR could take a large range of possible values. The conclusion would be that the accuracy is low: it is possible that one or the other of the extreme values could be the real OR. The CI will also help establish the statistical significance of the result. A CI that includes a value of 1 means that there is a possibility that the exposure odds are the same for both cases and controls. In this event, there would be no association between the exposure and the occurrence of the event. Therefore, a CI that includes the value of 1 means that the difference observed in the study may be due to chance: the result will not be statistically significant.

Dealing With Bias

There are several biases that may affect the OR of a case-control study. As with other study designs, selection, information, and confounding bias can invalidate the measures of association in a case-control study. They must obviously be avoided so as not to affect the OR and the conclusions that will be drawn from the study.

Selection Bias

Selection bias relates to how individuals are recruited and how they are retained in a study. Selection bias occurs when a preferential selection of the individuals to be included in the study leads to a distortion of the results. In case-control studies, a selection bias will be present if the recruitment of cases or controls is related to the presence of exposure to the factor (e.g., drug) being studied.

To understand how this bias alters the results, we can analyze the distribution of case and control exposures from the total population and compare it with the study population (Table 3a). We should obtain a distribution of exposures in the study population that respects the same proportions as in the source population. Any imbalance in one portion of the table (e.g., a portion of individuals might have a lower probability of being included in the study) will lead to a potential bias. In the example of Table 3b, the OR in the population (the real OR) would be 2.7. However, the approach taken to recruit the controls was faulty, so that the estimated OR in the study is 1. There is therefore a significant disparity between the two results. The estimated OR from the study underestimates the true measure.

There are several types of selection biases that can influence the conclusions of case-control studies. Some of them are discussed below.

Survival Bias and Depletion of Individuals at Risk

If the selection of cases in a study rests upon the inclusion of prevalent cases, asymptomatic individuals and those with a fatal and short-lived episode are less likely to be included. For example, if individuals exposed to a drug are more likely to die than those who are not, the study of prevalent cases will lead to the inclusion of a group of individuals who will be more likely to not have been exposed to the drug. There will be overrepresentation of the cases that lived the longest, that is, the unexposed cases. This will bias OR estimates.

Table 3a From source population to studied sample

	Source population			*Studied sample*	
	Cases	*Controls*		*Cases*	*Controls*
Exposed	A	B	Exposed	a	b
Not-exposed	C	D	Not-exposed	c	d

In an unbiased study, the proportion of individuals included in each cell of the tables will be concordant between the source population and the studied sample. This is represented by the full line. When there is a disparity between one or more cells, as represented by the dotted line, the calculation of the odds ratio will be biased and thus spurious association will be found.

Table 3b Example of a selection bias due to improper selection of controls

	Source population			*Studied sample*	
	Cases	*Controls*		*Cases*	*Controls*
Exposed	100	1500	Exposed	10	80
Not-exposed	50	2000	Not-exposed	5	40

The selection of exposed controls was incorrect in the study, as it was not representative of the source population. This situation leads to an imbalance in the ratio of exposed/not-exposed controls: the ratio is 0.75 (1500/2000) in the source population and 2 (80/40) in the studied sample. Accordingly, the estimated odds ratio is incorrect. While the true odds ratio is 2.7 in the source population $[(100 \times 2000)/(1500 \times 50)]$, the estimated odds ratio is 1 in the study $[(10 \times 40)/(80 \times 5)]$. The true association is therefore underestimated: while there is no apparent association between exposure and the health outcome in the study, there is a 2.7 increased risk for those exposed to the drug in the source population.

For example, if a medication causes a gastro-intestinal intolerance shortly after individuals start the therapy, patients who do not withstand this effect will stop using the medication. This may result in a cohort of "survivors" who are much more likely to tolerate the product well and benefit from it. If the study includes only these "survivors," the results will be biased. Hence, the selection of prevalent cases rather than incident cases may cause problems in the evaluating the risk. Moride and Abenhaim highlighted the presence of this bias in a case-control study assessing the occurrence of gastrointestinal bleeding related to NSAID use. The relative risk estimate for individuals who had used an NSAID in the previous 3 years was 3.0 (95% CI 1.9–4.7), whereas for new users it was 22.7 (95% CI: 2.8–200.0). These results suggested a depletion of susceptible individuals; the individuals who continued the treatment were therefore those who could tolerate it better, while the others were excluded from the population at risk. To avoid such bias, it is preferable to include only incident users, that is, individuals starting the therapy.

Detection Bias

Detection bias occurs when the exposure to the medication of interest directly influences the detection of the disease or outcome under study (e.g., using the medication contributes to the diagnosis process). For example, if an oral contraceptive is known to increase the risk of venous thrombosis, more tests could be ordered in individuals using it. There is thus a higher probability of detection due to increased medical monitoring. Since more cases will be detected in users of the specific oral contraceptive, the association between oral contraceptive use and the outcome will be artificially inflated.

Admission Bias (Berkson's Bias)

This bias occurs when the comparison groups are hospitalized patients. The bias arises when the probability of being admitted to the hospital differs depending on whether or not the individual is exposed to the factor being studied. For example, exposed cases may be more likely to be admitted to the hospital or controls may be hospitalized because of the presence of the medication. The following hypothetical scenario illustrates this situation. The use of ACE inhibitors is believed to increase the risk of liver cancer. The researchers identify 200 cases of liver cancer recorded in a national registry. To calculate the risk associated with the use of ACE inhibitors, the researchers select 200 individuals admitted for any reason other than cancer to the hospital where they work. If there is no association between the exposure and the outcome, the distribution of ACE inhibitor users and non-users would be the same for cases and controls (and the OR would be 1). However, ACE inhibitors are used in a variety of conditions that may increase the risk of hospitalization, such as diabetes, coronary heart disease, or heart failure. Since diabetes and heart conditions represent very common causes of hospitalization, the sample of hospitalized controls will be more likely than the general population to be using ACE

inhibitors. Consequently, the ratio of exposed/not exposed among controls will be higher than expected, and the OR will be lower than 1. The observed protective effect will be spurious.

Information Bias

Information bias refers to the systematic errors related to how information about variables (exposure, outcomes, confounding, or modifying covariates) are measured during the study. For example, information bias could occur due to misclassification of exposure (unexposed individuals are considered exposed, and vice versa) or outcome (sick individuals are considered non-sick, and vice versa). This is called a misclassification bias. This type of error can occur in both cohort and case-control studies.

Recall Bias

Recall bias is particularly important to consider in case-control studies. Individuals who have experienced an outcome (cases) may be more prone to remember their behaviors and activities than those who did not experience it. A case-control study in which the cases know their status and the relationship being studied, and in which the exposure is of a socially sensitive nature could also be susceptible to information bias.

When using administrative databases, the definition of exposure will not be subject to recall bias. Information can be retrieved over a long period of time, even if exposure has been characterized by sporadic medication-taking. The use of administrative databases is therefore considered as one of the best methods for determining drug exposure. Nonetheless, data come from dispensed medications: patients may not have actually taken the medications, which may overestimate actual use and still lead to an information bias.

Protopathic Bias

In pharmacoepidemiology, it is possible to define the protopathic bias as a situation when a drug is prescribed for an early manifestation of a disease that has not yet been diagnosed, and that this drug appears to be the cause of the disease that is ultimately diagnosed. For example, an individual consulted a physician for exercise dyspnea. The physician prescribes a cardiovascular drug such as a nitrate. However, a pulmonary fibrosis is diagnosed a few months later. The cardiovascular drug may appear to have caused the fibrosis, but in fact, it was prescribed for the first symptoms of dyspnea associated with the fibrosis.

To decrease the possibility of spurious associations due to protopathic bias, it is suggested to use a lag period in the definition of exposure. This period includes a time interval, prior to the date of diagnosis, that is excluded from the definition of exposure. There is no pre-defined duration in the literature for the latency period. It must be defined according to the drug and the outcome studied. The control of protopathic bias, therefore, requires a good understanding of the pathophysiological mechanisms of the diseases studied and behaviors related to the use of drugs.

Confounding Bias

Confounding arises when the relationship between the exposure and the outcome can be explained in part or totally be the effect of another variable. This variable is related to both exposure and outcome, without being in the causal chain between the exposure and the outcome. Confounding variables may be responsible for some or all of the observed effect, may reverse the true effect or cancel it out.

As with other observational study design types, adjusting for potential confounding factors can be done using multivariate regression models. The effect of each variable included in the model is then taken into account. As stated previously, the case-control study design also provides another method for controlling potential confusion bias: matching. One can thus decide to compare each chosen case to controls who possess one or more characteristics similar to the case. These factors could be age, sex, and socioeconomic status, for example. Comparing the cases with controls who share these same characteristics allows for taking into account the potential influence of the selected confounding factors. Several confounding biases may occur in observational studies. Some biases that are relevant to medication exposure in particular are presented below.

Indication Bias

Indication bias is a true chameleon: it is also referred to as severity bias, channeling bias, confounding by severity, or treatment selection bias. An indication bias occurs when the medication is preferentially prescribed to individuals with a lower or higher risk of presenting the outcome of interest. There is always a reason that justifies a prescription, and this reason is often associated with the outcome being studied. If these relationships are overlooked, the association between treatment exposure and the outcome will be spurious.

A concrete example will help explain the importance and potential amplitude of indication bias. In a study performed in 1983, the use of warfarin was associated with an increased risk of thromboembolic events—the risk for those using warfarin was 27 times the one for those not using it. This result is quite inconsistent with the expected effect of warfarin, which prevents thromboembolic events. In fact, this paradoxical result is due to the indication bias: only patients at high risk of experiencing a thromboembolic event or those who already had the symptoms (potential protopathic bias!) were prescribed the therapy. Even after adjustment for several variables available in the records and related to the reason for the prescription, the bias persisted. (The adjusted risk remained 4 times higher in warfarin users.)

It is indeed very difficult to eliminate indication bias. There are many limits encountered in trying to avoid this bias, because the motives that lead a physician to prescribe a drug to one patient rather than another are often complex and beyond the scope of the pathology per se.

Adherence Bias

In 1980, the authors of the Coronary Drug Project in the United States were confronted with a surprising result: the individuals who had been assigned to placebo and who adhered to it experienced a 5-year mortality risk of 15%, whereas individuals who did not adhere to the assigned placebo had a risk of death of 28%. The hypothesis put forward to explain these facts was that the patients adhering to the treatment were also adhering to other interventions (e.g., other drugs, diet, physical activity). This example is not an isolated case. A meta-analysis of 21 randomized clinical trials has shown that people who adhere to placebo have lower mortality rates than non-adherents. Adherence to treatment could therefore be a marker of a healthy lifestyle. The tendency of healthier individuals to initiate and adhere to preventive therapies has led to the terms "healthy user effect," "health user adherent bias," "healthy adherence effect," "adherence bias," or "compliance bias."

When it is possible to measure health-related behavior or the use of health services, biases can be reduced or eliminated using statistical modeling. Other approaches can be used, notably with the assistance of designs themselves. For example, in case-control studies, the case-crossover and case-control-time designs could be appropriate alternatives for controlling such characteristics as the individuals are compared to themselves, as explained in the next section.

Types of Case-Control Designs

Other than the traditional case-control studies where prevalent cases are compared to selected controls, there is a variety of different designs that can be used to perform case-control analyses. Some of the designs are presented here with their strengths and limits. A summary of the different characteristics is also presented in Table 4.

Traditional Case-Control Design (Case/Non-Case)

In this type of case-control study, the controls are chosen from the unaffected or healthy individuals (non-cases) at the end of the follow-up. In this (formerly classical) study design, it must be assumed that the event is rare for the OR to be approximately equal to the relative risk.

Nested Case-Control Studies

Nested case-control studies are embedded in a cohort study. This study design is becoming more popular. Nested case-control studies are conducted both in administrative databases and in cohorts of patients from prospective studies and randomized clinical trials.

Table 4 Comparison of case-control study designs

Design	*Characteristics*
Traditional case-control (case-non case)	• Controls are chosen from the individuals who did not experience the outcome • Also known as epidemic or cumulative design • In this (formerly classic) study design, the event must be rare for the OR $\approx$ RR
Nested case-control studies	• Case-control study embedded in a defined cohort; Individuals who experience the outcomes are cases • Production of a risk set for each case, comprising individuals at risk of experiencing the event at the moment the case had the outcome • With incidence-density sampling and matching: OR $\approx$ HR • Efficient design: less demanding in terms of computer power than time-dependent definition of exposure, as would be required in a cohort study
Case-cohort	• Nested study in a cohort in which cases are compared to a representative sample of the cohort at the onset of follow-up (random selection of pre-defined number of individuals from the whole cohort) • In this study design, OR $\approx$ RR (if conditions are met) • The sub-cohort can form the control group for several types of cases • Simple situation if there are no losses to follow-up or competitive risks • Preferable to a comprehensive cohort study when additional information is required, because only a fraction of the cohort will have to be questioned • Can be seen either as a reduced cohort study where all the cases are added/a nested case-control study with non-matched controls
Case-crossover	• Built on the same paradigm that randomized clinical trials with cross-over for medication with short-term effect • Contains only cases; cases are their own controls; Individuals are exposed and non-exposed during certain periods • Appropriate design for the study of modifiable exposure with a temporary effect • Allows to control all the stable characteristics of the subject—not applicable if there are trends in medication exposure (use case-time-control design instead) • Conditions required: (1) Outcome must be the immediate consequence of medication use; (2) Drug effect period must be well-defined; (3) Exposure data must be valid and known for a long period of time

To perform a nested case-control study, one must identify a cohort of individuals that is followed up until they experience the outcome of interest (or the end of the study). Then, instead of analyzing the entire cohort, one chooses the cases that are matched to only a sample of selected controls. This design is much less complex than a regular cohort study when many thousands of individuals are followed for a long time and when they exhibit complex and changing drug exposure over time.

The following four steps must be followed to perform a nested case-control study:

1. Cohort definition: This step includes a good definition of the time of entry into the study ("time zero" or "index date") and inclusion and exclusion criteria as strict as in a usual cohort study.
2. Follow-up of individuals until outcome of interest (to select all cohort cases) or end of study (those are non-case individuals who have not experienced the outcome of interest).
3. Formation of a "risk set" for each case, comprising the case and his/her corresponding controls (controls are individuals without the outcome of interest who survived until the same moment as the case). One case could be a control of another case and an individual could be the control of more than one case.
4. Random selection of one or more controls for each case. Cases may be matched to controls according to different characteristics (e.g., age, sex, reference year).

Fig. 3 illustrates the creation of a case-control study, and particularly the formation of risk sets. All individuals are included in the cohort, and may enter at different points in time. The moment when an individual becomes a case is represented by the black circle. For each case, all possible controls must be identified. The risk sets of individuals 2 and 7 are shown in Fig. 3. Note that Individual 2 is a potential control of Case 7. In fact, the risk set for each case is formed by all members of the cohort who are at risk of undergoing the outcome of interest (i.e., did not suffer the outcome and are members of the cohort at that time). This risk set is defined at the moment the case undergoes his/her outcome. Thus, individual 3 cannot be a control for individuals 2 or 7 since he/she is not a member of the cohort at the moment when these individuals become cases. When the whole risk set is well identified, one can then choose randomly one or more controls. These controls can be matched according to other variables (age, sex, ...).

The method used to identify controls is called Incidence Density Sampling. If the sampling process and matching procedures are well conducted, the ORs obtained in such nested case-control study will be an unbiased estimate of the hazard ratio (HR) obtained in a standard cohort study. However, the OR will show a greater variability than the HR resulting from a full cohort analysis because there are fewer individuals included.

Exposure to the medication in a nested case-control study will be evaluated at the time the case became a case (index date). The exposure variable will therefore reflect the current use of the medication. Different options exist to define the exposure, depending on the agent involved and the outcome studied. For example, use could be defined as taking the drug in the last 60 days before the index date or the day before.

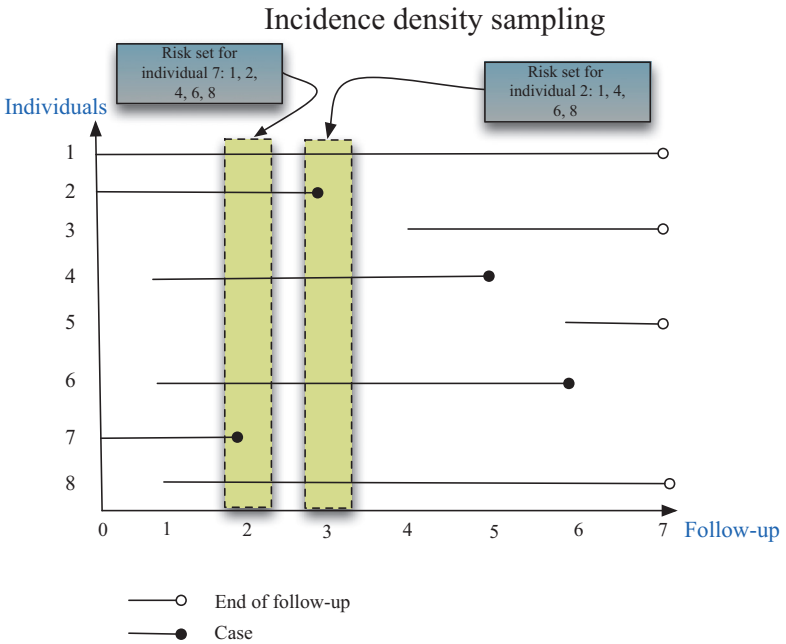

Figure 3 Incidence density sampling in a nested case-control study. In a nested case-control study, the incidence density sampling allows for the selection of a risk set for each case, from which controls can be randomly selected. For the individual 7 who became a case at time 2, five individuals are included in the risk set: 1, 2, 4, 6, and 8. Those individuals were at risk at the time individual 7 became a case. Of note, individual 2 himself/herself became a case at time 3. A case can therefore be a control before becoming a case.

Case-Cohort

In the case-cohort study, all cohort cases are identified (Step 1). Then, a random sample of predetermined size is selected from all individuals in the cohort (regardless of whether or not these individuals experienced the outcome of interest) (Step 2).

Among drawbacks of this design, one must cite that information-gathering on exposure and covariates must be carried out for the entire duration of the follow-up (whereas for the nested case-control study, this data collection may be carried out only during the period of the risk set). However, one of the interesting applications of case-cohort studies is the opportunity to assess the impact of potential confounding factors. In administrative databases, for example, several confounding factors are not available. It would be long, expensive, and difficult to investigate all the individuals included in a cohort. By collecting the required information from all the cases and a random sample of all the individuals included in the cohort, the problems are thus limited. Since the cohort sample is representative of the cohort, the distribution of confounders should be similar in the cohort.

Case-Crossover

The case-crossover design was developed in the late 1980s. As its name suggests, this is a study where cases will be their own controls. In some circumstances, it becomes imperative that a case be its own control since all other control groups would be too vulnerable to selection and information bias.

By definition, in this type of study, all individuals will experience the event of interest since there are only cases included. In pharmacoepidemiology studies, subjects will therefore be successively exposed and not exposed to the drug of interest for certain periods until the outcome occurs. It is then necessary to determine, when the case arises, whether the person was exposed to the drug in the pre-determined period before the occurrence of the outcome.

To carry out a crossover study in pharmacoepidemiology, three conditions must be fulfilled:

1. The outcome studied should be the result of a brief effect of the medication. (Medications that are characterized by chronic and stable use over time would not be good candidates for such studies.)
2. The period when the effect of the drug is expected (the window of the effect) must be precisely determined. (A poor definition of the window will greatly distort the risk estimate.)
3. Data on the use of the product must be valid and known over a long period of time.

Recall that, by definition, all individuals included in these studies undergo the outcome of interest (they are all cases). In addition, individuals will have varied exposure to the medication (they will be successively exposed and not exposed to the study medication until the outcome occurs). For the analysis, one can build a 2×2 table for each individual in the study. It will show whether the individual has been exposed to the drug at the time of the outcome of interest, and the number of times he/she has been exposed and unexposed without experiencing the outcome.

This type of analysis is particularly advantageous when it involves a transient effect of a medication used in a non-regular way. As each individual is matched to himself/herself, it allows for control of potential confounding biases that do not change over time. However, if certain confounding factors are time-dependent, they will not be taken into account. Time-dependent analyzes can be performed to correct time-varying confounding bias, but this complicates the analysis. Moreover, one of the limitations of this design is that it assumes that the prevalence of drug exposure does not follow a time-dependent trend. If this is the case, then the case-time-control study must be used.

In summary, the nested case-control and case-cohort studies answer the question: "Why them," i.e.: "Why did these individuals become cases when the other did not become cases?" (Although some controls will become cases, the designs assume that most controls will not.) The case-crossover answers the question: "Why now," i.e.: "Why did these individuals become cases this day rather than the days before."

Strengths and Limits of Case-Control Designs

The case-control design serves several uses in studying the relationships between drug exposure and health outcomes and can help identify rare side effects of drugs and risk factors for different health outcomes. Also, because case-control designs identify cases, that is individuals who have experienced the outcome, they do not require follow-up for the event of interest to occur, which may be useful in contexts where rapid responses are needed. In case of poisoning, for example, one might discover that a specific batch of a drug is of concern by conducting a case-control study. The impact of clinical practice itself could be evaluated by using case-control studies. For example, one could assess whether populations with higher influenza epidemics are those where pharmacists do not vaccinate. Hence, case-control studies are useful in many instances for research in pharmacy to inform clinical practice. Nonetheless, although the case-control design has several strengths, limitations must also be taken into account in interpreting the results. Table 5 summarizes these main elements.

Finally, an important point to stress is that, due to the observational design, case-control studies cannot be used to measure causal effects of drugs. The fact that there is an association does not imply that the relation is causal.

Table 5 Strengths and limitations of case-control designs

Strengths	*Limitations*
Provide power for rare outcomes (needs less data to measure the association between exposure and outcome than a cohort study would require)	Susceptibility to selection bias (cases or controls (especially) not representative of the source population)
Efficient in time and can be conducted with limited resources	Information bias possible in some circumstances (recall bias, which is not true with most pharmacoepidemiologic studies using large administrative databases)
Allow the study of multiple exposures	Inefficiency for studying rare exposures
Can study conditions with long latency periods	Inability to directly calculate incidence rates (although some designs allow the OR to approximate the HR)
Time-varying nature of drug exposures are more easily dealt with than with a cohort study	Complex design to understand for uninitiated people
Design allows for the control of confounding factors (e.g., matching, case-crossover)	Odds ratios can be difficult to interpret for uninitiated people
	Exposure definitions more limited than in cohort studies

Conclusion

Case-control studies can be very useful in determining the association between drug exposure and health outcomes. This study design is particularly efficient if the event being studied is rare, since only a portion of the study population will be included in the analysis. As with all observational studies, however, it must be ensured that the results are not affected by biases that invalidate the conclusions. The selection of controls in these studies is particularly sensitive to bias. It is necessary to ensure that the controls are representative of the population giving rise to the cases in order to respect the norms of conducting these studies. While case-control were long considered of lower methodological quality than cohort studies, the progresses in statistical and epidemiological methods have repositioned this design favorably in the hierarchy of studies. Moreover, they are often conducted within cohort and randomized control studies to inform on specific study questions that are best answered with the methodology of case-control designs. Hence, when performed according to stringent methodology, the case-control studies represent an important study design in pharmacoepidemiology.

Cohort Studies—A Brief Overview

Ashley I. Martinez*, Daniela C. Moga*,†,‡, *Department of Pharmacy Practice and Science, College of Pharmacy, University of Kentucky, Lexington, KY, United States; †Sanders-Brown Center on Aging, Department of Epidemiology, College of Public Health, University of Kentucky, Lexington, KY, United States; ‡Institute for Pharmaceutical Outcomes and Policy, Lexington, KY, United States

Introduction

In this chapter, we will discuss the history of cohort studies and their use in pharmacoepidemiology, as well as their importance in clinical practice. Clinicians, including pharmacists need to understand cohort studies and other observational designs, their strengths and limitations, as well as the appropriate statistical analyses and the accurate interpretation of their results (Draugalis and Plaza, 2006; Lee et al., 2004).

We will review the details of cohort study designs and the various data sources that can be used. We will conclude with a discussion of best practices when conducting and evaluating cohort studies in pharmacoepidemiology.

A Brief History of Cohort Studies in Pharmacoepidemiology

The cohort design in research spans centuries. In the 18th century, James Lindt conducted what many consider to be the first (pharmaco)epidemiologic cohort study to analyze differences in scurvy development amongst sailors based on diet—ultimately determining that citrus fruits can effectively treat this serious ailment. Perhaps the earliest popularized use of cohort studies in North America came from the insurance industry. The actuarial Society of America published a report in 1903 detailing data derived from policyholders in the United States (US) and Canada from 1870 to 1899 (Actuarial Society of America, 1903). Using existing data, the authors could accurately determine premiums, and employers also attempted to project risk of death based on the data. Cohort studies were also used extensively during the tuberculosis epidemic at the turn-of-the-century, and saw advances in both methodology and analysis. By the late 1940s, large cohort study designs were being conducted throughout the world to address public health concerns. While larger cohort studies continued to be performed through the 1960s and 1970s, interest in improving drug safety and assessing adverse reactions was growing, and the first mention of "pharmaceutical epidemiology" was published in 1974 (Venulet, 1974). As a result, cohort studies investigating drug safety and adverse reactions were being conducted (Jick et al., 1979; Mann et al., 1975; Skegg and Doll, 1977). In 1968, the Medicines Act established the Committee on the Safety of

Medicines in the United Kingdom (UK), but by 1983 researchers continued to be dissatisfied with the available methods. A series of meetings held by the Centre for Medicines Research in 1984 led to the formal recognition of pharmacoepidemiology as a new discipline and set a goal to create an automated database in Britain linking all prescriptions filled with hospital diagnoses (Lawson, 1984). The National Institutes of Health in the United States (established in 1887) had a pivotal role throughout the years by funding large prospective cohort studies, such as the Framingham Heart Study and the Nurses' Health Study (NHS) (Brigham and Women's Hospital et al., 2016; National Heart, Lung, and Blood Institute and Boston University, 2018), and continues to conduct multi-center prospective cohort studies. In an era of "big data", the ability to link records from multiple sources has enhanced our ability to design and conduct pharmacoepidemiologic cohort studies.

Over the years, cohort study methodology and analysis has continued to evolve, enhancing our ability as researchers to use cohort studies to establish causal relationships and allowing observational designs to have broad impacts on both the clinical and regulatory landscape of drug therapy. For instance, the work by Ray et al. (2002) using existing data, related to Vioxx (rofecoxib) demonstrates the potential role of a well-design pharmacoepidemiologic cohort study in impacting the drug market. Approved in 1999 by the US Food and Drug Administration (FDA) for the treatment of arthritis, rofecoxib was touted as a safer alternative to other nonsteroidal anti-inflammatory drugs (NSAIDs) because of its decreased incidence of gastrointestinal adverse events. However, early postmarketing pharmacoepidemiologic studies began to highlight a possible concern for increased risk of acute myocardial infarction and other serious coronary heart diseases (CHD) among rofecoxib users. In fact, researchers from Vanderbilt University were able to use a retrospective cohort study design with data from the Tennessee Medicaid program (i.e., medical and pharmacy claims) to identify the increased risk of serious CHD in rofecoxib users more than 2 years before its official withdrawal from the market in the United States (Ray et al., 2002). By the time Vioxx was officially withdrawn from the market in 2004, an estimated 88,000 American Vioxx users experienced heart attacks, with nearly half of these patients dying (Resnik, 2007). Because signals of this increased risk were detected by researchers well before the results of any clinical trials could show them, it became evident that active postmarketing surveillance of approved drugs should include pharmacoepidemiologic studies. In 2007, the US Congress mandated the FDA to create an active surveillance system (Food and Drug Administration Amendments Act, 2007). Both the Sentinel Program and the Observational Medical Outcomes Partnership (OMOP) were results of this initiative (Platt et al., 2009; Stang et al., 2010). A similar project called the EU-ADR was established in Europe (Coloma et al., 2011).

Description: Defining and Designing Cohort Studies

In the case of the cohort study, groups are identified based on exposure status (Fig. 1). Designing a cohort study often starts with defining the population of interest. Subsequently, those without the outcome of interest (defined through inclusion and exclusion criteria) are selected, and exposure status is assessed. Exposed and unexposed individuals are followed over time to investigate whether any differences exist in the development of an outcome between groups. Exposure groups may be defined as exposed and unexposed, or groups composed of members with different exposures may be compared (e.g., comparative effectiveness studies).

In general, the purpose of a cohort study is to describe an exposure (or multiple exposures in the same population), and investigate the (causal) association with one or multiple outcomes of interest. In pharmacoepidemiology, the exposure is usually drug use, and the most common outcomes studied are effectiveness or safety of that drug therapy.

Study Design

Study Purpose

As with any research study design, the aim of a cohort study will vary based on the type of research question being investigated. Designs can aim to generate new hypotheses, test potential hypotheses, or strengthen the evidence on current hypotheses. The urgency of the answer to the research question can also impact the design of a cohort study.

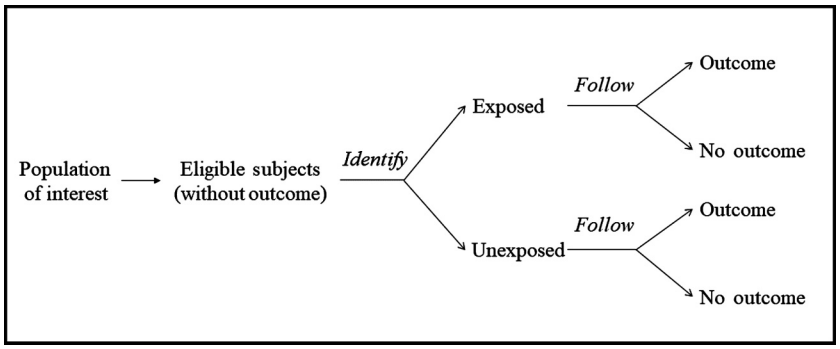

Figure 1 Cohort study design.

Depending on the study aim and context, cohort studies can be divided into two domains. The first domain includes studies whose goal is to assess prescribing trends and medication use in the general patient population, or in specific subpopulations; these studies are often known as drug utilization studies. They contain questions related to diagnosis or disease staging, comorbidities, other medications use, discontinuation of treatment, or other patient characteristics predicting treatment. Often, studies with these aims are more exploratory and hypothesis-generating in nature. For example, investigators in the United Kingdom conducted a population-based cohort study using a primary care database, the Clinical Practice Research Datalink (CPRD) to investigate the prescribing trends among centenarians between 1990 and 2013 (Hazra et al., 2016). They found that 73% of subjects had received at least one prescription, and the sample had a median of seven prescription items per subject. In another study, investigators used Medicaid data from a US state to quantify the use of antipsychotics and anticonvulsants during pregnancy (Epstein et al., 2013). Results such as these can be used to inform prescribing practices and highlight problems that would otherwise go undetected.

The second domain includes cohort studies addressing research questions about effectiveness, efficacy, safety, or studies investigating causal associations based on a priori stated hypothesis. These studies add important information to existing evidence resulting from clinical trials by accounting for patients' or providers' actual behavior under uncontrolled situations. Cohort studies attempting to establish causal associations must use adequate methodology to reduce confounding and the inherent bias threatening observational studies. These methods will be discussed in more depth later in this chapter. Some of these studies may be performed with the aim of investigating the potential for causal association (either a beneficial, or harmful) that is otherwise unfeasible or unethical to perform using an experimental design. For this reason, retrospective cohort studies can be useful to study drug effects during pregnancy, for instance. For example, statins are categorized as a pregnancy risk factor "X" in the United States, indicating that they are contraindicated in pregnancy. Despite this risk, however, some women do inadvertently take statins during the first trimester of pregnancy. To determine whether there was a difference in pregnancy loss between women taking statins shortly before pregnancy and those who did not take a statin, investigators conducted a retrospective cohort study using CPRD in the United Kingdom (McGrogan et al., 2017). Because the database includes medical records, investigators were able to identify the start and end dates of pregnancy and whether a statin prescription was recorded during or in the 3 months prior to the start of pregnancy. Those exposed to statins had a higher risk of spontaneous pregnancy loss. Using a cohort design to investigate these important clinical questions is critical because assigning anyone to use statins during pregnancy would be unethical.

Other cohort studies aim to evaluate whether a certain drug causes an adverse drug event (ADE), sometimes based on hypotheses raised by preclinical or small clinical studies. The occurrence of Reye Syndrome with the use of aspirin in pediatrics is one example of a rare, but serious, ADE that was identified using observational data long after the drug was initially marketed (Halpin et al., 1982).

While evidence about medications is often gathered for officially approved indications, studying the effects of off-label drug use is equally important. In addition to investigating whether a proposed hypothetical indication might be effective, cohort studies can also be used to examine current off-label prescribing trends. For instance, many drugs are not approved for use in children due to lack of evidence from clinical trials, but are used in this population nevertheless. A retrospective cohort study using administrative claims data from Medicaid programs in four US states reported on the off-label use of antidepressants in children and adolescents (Burcu et al., 2017). This study ultimately found an association between Type 2 diabetes mellitus (T2DM) and certain antidepressants, which is important to clinicians who are considering the off-label use of these agents in this population.

Recognizing the need for more research into the safety profiles of older drugs, the Agency for Healthcare Research and Quality (AHRQ) in the US funded the Centers for Education and Research in Therapeutics (CERTs) to improve how drugs are used in the general population. Because of this new initiative more safety concerns are being recognized. Studies suggest that over half of the existing drugs have a postmarketing label change due to major safety issues, and about 20% of drugs get black box warnings after initial marketing (Strom, 2006). Anywhere between 3% and 4% of drugs approved in the United States are ultimately withdrawn from the market for safety reasons—largely due to evidence gained from cohort and other pharmacoepidemiologic studies.

Cohort Study Classification

Cohort studies are classified by the timing of data collection relative to the time when the investigator designs the study (Grimes and Schulz, 2002), as seen in **Fig. 2**.

In prospective cohort studies, the investigator conducts the research by first identifying the population of interest and then classifying subjects as either exposed or unexposed. The investigator follows these subjects in time, recording the development of the outcome of interest. Because the investigator is following the subjects in real-time, these types of studies tend to take the longest to complete. A key element of defining a prospective cohort study is that, at the time the investigators begin enrolment and baseline data collection, study participants are disease-free (i.e., have not yet experienced the outcome(s) of interest). For example, the Framingham Heart Study (National Heart, Lung, and Blood Institute and Boston University, 2018) was designed as a prospective cohort study. Starting in 1948, investigators recruited about 5000 men and women from Framingham, Massachusetts to participate in the study with the objective of identifying risk factors for cardiovascular disease (CVD). Because CVD was their outcome of interest, only subjects without a history of cardiovascular disease were chosen to participate. Every 2 years, subjects' exposure to a variety of lifestyle and medical factors is assessed while investigators document the occurrence of any CVD. The study continues to this day.

In retrospective cohort studies, the investigator uses data that has already been collected to identify exposure groups and outcome occurrence. Because the data has already been collected, the investigators do not need to wait for outcomes to occur, and thus spend a relatively short amount of time identifying exposure and outcome status. A key element of defining a retrospective cohort study is that at the time the investigators design the study, the follow-up data is complete and (some) subjects already experienced the

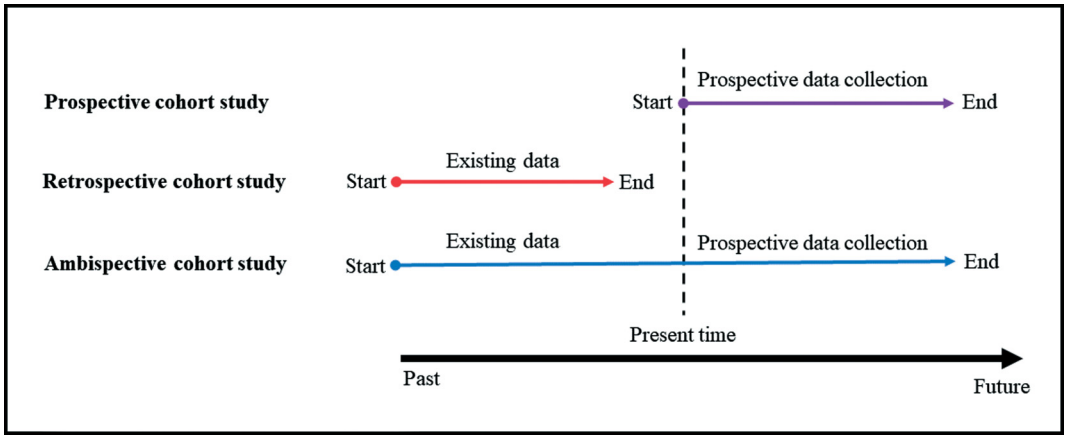

Figure 2 Cohort study classification. *Start*, Beginning of follow-up for study participants; *End*, Follow-up ends for study participants. *Source: Figure based on Grimes and Schulz, 2002.*

outcome(s) of interest. Even though information on exposure and outcome(s) is already available, study design procedures, in particular defining inclusion and exclusion criteria, should be planned without consideration of outcome(s) occurring during follow-up. A study conducted in 2015 utilized this design to investigate whether the risk of T2DM in children and adolescents was higher amongst users of atypical antipsychotics (Sohn et al., 2015). The investigators used data from health and pharmacy insurance claims between 2007 and 2009 to ascertain whether subjects were exposed to atypical antipsychotics. After defining the exposure date, they looked forward through the data and recorded any instance of the outcome, a diagnosis for T2DM. Because the subjects' exposures and outcomes occurred prior to the investigator's study onset, this is considered a retrospective cohort design. As a note, data collected prospectively in cohort studies or research-related longitudinal clinical evaluations can be used to later design retrospective cohort studies to address other research questions than those the original studies were designed to address. For example, a recent retrospective cohort study evaluated the association between bladder antimuscarinics and cognitive decline using data from the National Alzheimer's Coordinating Center (NACC) (Moga et al., 2017). NACC was established in 1999 to further research into Alzheimer's disease and related dementias and has since recruited nearly 40,000 subjects with and without dementia from centers around the United States (Beekly et al., 2004). Although NACC data collection was not designed to specifically investigate the association between bladder antimuscarinics and cognitive decline, the investigators could design the study with existing data from NACC.

Ambispective (or retrospective-prospective) cohort studies combine aspects of both retrospective and prospective study designs. In these studies, the investigator uses data that has been collected in the past to determine exposure status, but then continues to follow those subjects in real-time for outcome occurrence. One example is a study investigating the effectiveness of systemic chemotherapy (SC) alone versus SC plus a gastrectomy for patients with gastric cancer and liver metastasis (Liu et al., 2015). Investigators used retrospectively collected data on which treatment subjects received, and then beginning in 2012 followed subjects for synchronous metastases. Because investigators used data from the past to obtain exposure status, then followed subjects in real-time for outcome occurrence, this study qualifies as an ambispective design.

Defining Exposure and Outcome(s) in Cohort Studies

Depending on the study classification (see above), to quantify exposure(s), outcome(s), and other variables of interest (i.e., confounders, effect modifiers), the investigator has to either plan for data collection, or to rely on the existing data. Primary data collection as part of prospective cohorts gives researchers the ability to use validated definitions; exposures and outcomes, as well as other important variables are usually assessed through interviews, self-completed questionnaires, objective measurements, or laboratory tests. Retrospective studies rely on existing data collected from surveys, clinical records, or insurance claims; although the investigator has no control over the way data are collected, they still need to carefully consider how to effectively use existing information in defining variables of interest to minimize misclassification. Whenever available, investigators should consider validated definitions that compare the sensitivity, specificity, or predictive value of existing data to more accurate data sources (e.g., insurance claims compared to medical records).

Data Sources and Types of Data

In designing cohort studies, especially those retrospective in nature, important considerations should be given to selecting the data source. The choice of data can have important ramifications for the study design, data analysis, and generalizability of cohort studies. Thus, it is important that astute readers understand the nuances of different data sources available. Ideally, the data source of choice is large, stable, representative, and verifiable (Lao et al., 2016). When deciding between data sources, investigators need to consider the relative size, cost, and speed of accessing the data, in addition to generalizability.

While some data used in pharmacoepidemiologic cohort studies are available to the public (including some data provided by the Centers for Medicare and Medicaid Services [CMS] in the United States), other data sources are highly restricted. For instance, if protected health information exists in the data that can be traced back to individual subjects, the project requires review by an ethics committee, like the Institutional Review Board (IRB) or its equivalents. Furthermore, if data are the property of, or managed by an organization, investigators will be required to agree to specific terms specified in a Data Use Agreement (DUA) which clearly states the extent to which data can be used, the approved users, and the duration for use.

Datasets used in cohort studies may contain information on only a few hundred subjects, or may contain tens of millions of subjects. Small sample sizes may call into question the power of the study to detect a difference between exposure groups, while studies using large datasets (e.g., administrative data) may be "overpowered" and detect statistical differences that may not be clinically relevant.

It is also important to note that because the design of cohort studies involves selecting groups based on exposure (not outcome) status, investigating rare outcomes often requires substantially larger sample sizes than would be necessary for a case–control study. In order to detect a relative risk of an outcome that occurs in about 1% of the unexposed subjects, an investigator would need to include about 3000 subjects in each group to achieve 90% power. However, if the prevalence of the outcome was only 0.001%, over 300,000 subjects would be required in each group to achieve the same power.

Investigators should also consider the validity of both exposure and outcome identification. If either is incorrectly specified, any results and interpretation may not be generalizable to a population outside of the study sample. Specifically, misclassification of exposure and/or outcome can lead to spurious results. The goal specificity and sensitivity of measures for exposure and outcome depend on the purpose of the study. If one must choose between the two, maximizing the specificity of the outcome definition and maximizing the sensitivity of the exposure definition will help minimize bias (Brouwer et al., 2015a). When using claims data to define exposures and outcomes, the better algorithm to use can include a combination of diagnosis and medication codes to lower misclassification rates (Rector et al., 2004).

Investigators interested in conducting cohort studies have a plethora of options from which to select the best data. Available data sources for conducting cohort studies include databases of spontaneous ADE reporting or active surveillance, hospital records, health insurance enrollment data, medical claims data (either from outpatient or inpatient settings), or prescription claims data. While these data sources are described in detail in a different chapter, we will briefly discuss them as related to the design and conduct of cohort studies in pharmacoepidemiology.

Administrative Data

Administrative data sources have become more common in pharmacoepidemiology in recent years. Generally speaking, these data sources only contain medical information that would be relevant for billing purposes, which may limit the study questions that can be answered using them (Schneeweiss and Avorn, 2005). Because of their large size, these data sources often require investigators to have advanced computer programming and statistical knowledge as well (Brouwer et al., 2015b). Furthermore, while administrative data sources with pharmacy information contain records of each time a subject fills a prescription, few contain important clinical characteristics such as smoking status, alcohol use, and body mass index. Many different sources of administrative data exist in the United States and throughout the world. For example, in the Ontario province in Canada, administrative databases contain enrollment, pharmacy, outpatient, and inpatient data on all Canadians who utilize the health system in this province (Cadarette and Wong, 2015). In the US, large administrative databases are available from CMS, as well as from a variety of private insurance companies. The National Health Insurance Research Database in Taiwan contains insurance claims for 99.9% of Taiwan's population due to its single-payer system (Cheng et al., 2011).

Clinical Data

Cohort studies might also utilize data that were collected for routine clinical use and/or patient monitoring. Studies have shown that using automated health records collected for clinical purposes to conduct cohort studies can be an effective method of data collection (Hashikata et al., 2011).

In the United Kingdom, one of the largest sources of electronic health records used for research is the CPRD, which has been used in conducting several retrospective cohort studies. One example is a study that aimed to confirm whether corticosteroid treatment was associated with an increased fracture risk (van Staa et al., 2001). In fact, literature reviews have found that, among epidemiological studies, the most frequently used data source was the CPRD, formally known as General Practice Research Database, which accounts for about 20% of the studies using large existing data. Of these, 40% used a cohort design (Perrio et al., 2007).

Kaiser Permanente (founded in 1945) is one of the largest health plans in the US, serving approximately 11.7 million members (Kaiser Permanente, 2018). In addition to providing care, its Division of Research conducts and publishes health services and outcomes research (including pharmacoepidemiologic cohort studies). Using electronic health records obtained from Kaiser Permanente, investigators were able to determine that there was no increase in the risk of recurrent breast cancer in subjects taking paroxetine concurrently with tamoxifen, despite widespread controversy about this drug combination (Haque et al., 2016).

Studies using clinical data might also aim to answer questions about the effectiveness of emerging therapies for which guidelines have not yet been established. The Clinical Data Analysis and Reporting System (CDARS) of the Hong Kong Hospital Authority (the only publicly funded health care provider in Hong Kong) provides electronic health records for research. When investigators were concerned about the growing trend of using gastro-protective agents to prevent gastrointestinal bleeds (GIB) in patients using the

anticoagulant dabigatran, they were able to construct a cohort study using data from CDARS to examine this relationship. With dabigatran dispensing records identifying exposure status and diagnosis records for GIB to determine outcomes, the investigators used Poisson regression controlling for baseline comorbidities and medication use to demonstrate that that patients who used gastro-protective agents with dabigatran had a 48% decrease in risk of GIB compared to those who used dabigatran alone (Chan et al., 2015).

Other Sources of Data

Spontaneous reporting systems were established after the public health disaster of thalidomide and the causal relationship between the drug and birth defects was determined. Between 1961 and 1965, 10 countries began their own reporting systems. In 1968, the World Health Organization (WHO) formed the WHO Programme for International Drug Monitoring (PIDM). As of January 2016, 123 countries report ADEs to the PIDM, which registered over 10 million reports in 2014 (World Health Organization, 2018). In the US, using the FDA's Adverse Event Reporting System (FAERS), health professionals, consumers, and pharmaceutical manufacturers are able to voluntarily submit reports of suspected ADEs. These systems are a cost-effective way to detect rare and serious ADEs that clinical trials do not discover. However, given the difficulties to determine the denominator for reporting rates of events (i.e., total number of individuals using a certain drug), their utility lies in generating hypotheses (also known as signals) of potential problems that require further investigation. Conducting cohort studies using data from spontaneous reporting systems can be fraught with concerns of validity, as nearly anyone can submit a report with very little evidence. In one study comparing the opinions of clinical pharmacists and physicians, the pharmacists agreed only 50% of the time as to whether a drug caused a hospitalization, and disagreed with physicians approximately one-third of the time (Karch et al., 1976). Whether an ADE is actually reported to the system is also a concern, as estimates suggest that less than 5% of nonserious reactions are reported to British and American spontaneous reporting systems (Rawlins, 1995; Scott et al., 1987).

Prescription event monitoring provides another source of data from which to conduct cohort studies. In the United Kingdom, the Drug Safety Research Unit (DSRU) receives individual-level longitudinal prescription information for every drug currently being monitored. After a few months, the DSRU sends prescribers a questionnaire seeking information about possible ADEs. Because the studies conducted by the DSRU (and by investigators using its data) are non-interventional and national, this data source is largely representative of current prescribing practices in the United Kingdom, though currently information is only collected on general practice prescribers.

Combining Data Sources

Considering the limitations of different data sources either in terms of the available information, as well as in terms of the specific population included, several initiatives are currently underway to develop methods to combine data from multiple sources. In the United States these include OMOP, the Sentinel Initiative, as well as the Health Maintenance Organizations Research Network, while Canada has the Canadian Network for Observational Drug Effect Studies (CNODES), Europe has the EU-ADR Alliance and the Innovative Medicines Initiative-Pharmacoepidemiological Research on Outcomes of Therapeutics (IMI-PROTECT), and in Asia the Asian Pharmacoepidemiology Network (AsPEN) has been established.

A 2015 literature review analyzed 22 pharmacoepidemiologic studies that used multiple databases, ranging from 2% to 17. 82% of these used a cohort study design, and claimed that the use of multiple data sources was motivated by improving power (Bazelier et al., 2015).

Data Analysis and Interpretation

The results of a cohort study give the investigator information on the relative risk and attributable risk of the outcome based on exposure status.

Estimates

The most commonly used estimates in cohort studies along with calculations for each of these can be found in Fig. 3.

The cumulative incidence, or risk, in either the exposed or unexposed group is the probability of the outcome occurring in that group. When a ratio of risks in the exposed and unexposed groups is constructed, this is known as a risk ratio or relative risk (RR). The attributable risk, also known as the excess risk, is the arithmetic difference between the incidence (either calculated as risk or rate) in the exposed and unexposed groups. Calculating the attributable risk implies an established causal association and it is important for considering the impact of that association in the exposed population (Walter, 2000).

The rate ratio is a ratio of the incidence rates of the outcome in the exposed and unexposed groups, or incidence density that takes into account follow-up for each group. A rate or risk ratio larger than one means that the exposed group is at a greater risk for the outcome than the unexposed group. A risk ratio less than one means that the exposure appears to protect against the disease (i.e., outcome). If the risk ratio is at or near one, it means that the exposed group is at a similar risk of the outcome as the unexposed group, and that there does not appear to be an association between the exposure and disease. Similarly, risk (rate) differences are interpreted in comparison to the null value of 0 (Fig. 4).

While the risk ratio does not consider the differences in follow-up for different participants, the rate ratio and the hazard provide instantaneous measurements at different time points.

	Outcome	No Outcome	Total	Total follow-up time
Exposed	a	b	a + b	PY_e
Unexposed	c	d	c + d	PY_0

Estimate	Calculation
Incidence density (Rate of disease)	Exposed: $ID_e = \frac{a}{PY_e}$; Unexposed: $ID_0 = \frac{c}{PY_0}$
Cumulative incidence (Risk of disease)	Exposed: $CI_e = \frac{a}{a+b}$; Unexposed: $CI_0 = \frac{c}{c+d}$
Incidence density (Rate) Ratio	$RR = \frac{ID_e}{ID_0} = \frac{a/PYe}{c/PY_0}$
Risk ratio (Relative Risk)	$RR = \frac{CI_e}{CI_0} = \frac{a/(a+b)}{c/(c+d)}$
Attributable risk	$\frac{a}{a+b} - \frac{c}{c+d}$ or $\frac{a}{PY_e} - \frac{c}{PY_0}$

Statistical Methods

While this section is not intended as a comprehensive description of statistical methods, we are presenting information that might be relevant and help the reader understand the available options for analysis in cohort studies.

Linear regression is used to analyze outcomes that are measured as continuous variables. Such examples include blood pressure measured in millimeters of mercury, adherence measures, and scores. One such example is a cohort study analyzing data from the population-based Norwegian Mother and Child Cohort Study (MoBa), which has collected questionnaire data as well as biological

material on approximately 110,000 women who gave birth between 1999 and 2010 in Norway (Magnus et al., 2006). Using MoBa data, researchers investigated whether prenatal antidepressant use is associated with behavioral problems in children (Brandlistuen et al., 2017). The outcome was measured as a score calculated from the mother-reported Child Behavior Checklist and multivariable linear regression adjusted for confounding factors was used to evaluate the association between prenatal antidepressant use and the behavior score measured in children.

More commonly, however, outcomes in cohort studies are measured as binary variables and analyzed using logistic regression (Levy and Stolte, 2000) that generates odds ratios (OR) (Bender, 2009). When the absolute risk of an outcome is small, the OR approximates the RR, but for more common outcomes the ORs are often larger than the risk ratio. In the earlier example of the cohort study evaluating the association between antimuscarinic use and cognitive decline using data from NACC, the outcome was measured as a binary variable: cognitive decline from baseline (yes/no). Exposure to antimuscarinics was determined based on the subject's responses during study visits. Using logistic regression adjusted for confounding factors, investigators reported an OR of 1.4: the odds of cognitive decline were 40% higher among bladder antimuscarinic users compared to nonusers (Moga et al., 2017) when measured using the Mini-Mental State Examination.

Cox proportional hazard regression (used in survival or time to event analysis) is commonly used in cohort studies and takes into account variable observation times, either because participants entered the study at different times, or because they left the study prior to study completion. In these analyses the outcome is measured as time until that outcome occurs. Cox proportional hazard regression models produce the hazard ratio (HR), which is interpreted in a very similar way to the other relative measures, like the risk ratio, but represents the instantaneous risk over a defined time instead of a cumulative risk over the entire study. In studies that utilize Cox models, descriptive results can be reported using Kaplan–Meier curves that allow one to determine the proportion of each exposure group that has experienced the outcome of interest at each point in time. Cox models were used in one cohort study that used data from the Framingham Heart Study. At the time of investigation, the 2013 American College of Cardiology/American Heart Association (ACC/AHA) had just released their cholesterol management guidelines, which changed the eligibility criteria for statin therapy compared to the National Cholesterol Education Program's (NCEP) 2004 Guideline (Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults, 2001; Stone et al., 2014). Investigators set out to determine whether the ACC/AHA guidelines improved the identification of subjects at risk for cardiovascular events compared to the NCEP guidelines (Pursnani et al., 2015). In this study, exposed subjects were those whose statin eligibility was determined by the ACC/AHA guidelines, whereas the unexposed subjects' statin eligibility was determined by NCEP guidelines. The main outcome of interest was time to CVD. Investigators found that subjects whose statin eligibility was determined by ACC/AHA (exposed subjects) had a hazard ratio for cardiovascular disease of 6.8. Interpreting this HR, one can say that at any time, 6.8 times as many subjects in the ACC/AHA eligibility group experienced an event compared to subjects in the NECP eligibility group. This meant that the ACC/AHA guidelines more accurately identified high-risk subjects. This cohort study was important in validating the use of these new guidelines in clinical practice.

In contrast, if the investigator is instead interested in the number of outcomes (frequency or rate) of a rare event in a set period, Poisson regression would be the more appropriate statistical technique. Both Poisson regression and Cox regression are often used in time to event analysis, but when the outcome of interest is a frequency or rate of an event per unit time, the appropriate model would be Poisson regression. The ability to identify the correct model use in the data analysis section of a cohort study is important and can determine the validity of that study's results.

Cohort Studies and Causal Inference

The discordance in results among observational studies, and between observational studies and randomized experiments has led to an undermining and devaluing of pharmacoepidemiologic studies by many clinical practitioners and researchers. To surmount this growing problem, guidelines such the **ST**rengthening the **R**eporting of **OB**servational studies in **E**pidemiology (STROBE) or the **RE**porting of studies **C**onducted using **O**bservational **R**outinely-collected health **D**ata in **P**harmaco**E**pidemiology (RECORD-PE), have been developed (Benchimol et al., 2015; von Elm et al., 2007). These guidelines clearly specify key study design, data analysis, and result interpretation techniques for the different types of observational studies. Following the STROBE, RECORD-PE guidelines will help ensure that a cohort study has been rigorously designed and analyzed in a way that reduces potential bias.

By adhering to these guidelines and rigorously choosing methods that reduce the risk of bias, investigators can increase the validity of their results and use them to further determine a causal association. While selection bias and confounding factors can be addressed in the study design and/or data analysis, it is most important to understand the threat of bias (e.g., selection bias) or the types of confounding in cohort studies and how they can impact study results.

Establishing Causality

In general, there are three types of associations a cohort study must exclude to convincingly draw a causal conclusion. One of the most important prerequisites to conducting a cohort study is to establish biological plausibility for the hypothesis. As the health-care research sector moves more toward large data investigations, this step is especially important. Indeed, statistical significance can be found for any factors if the data are large enough by the very definition of most common statistical significance tests.

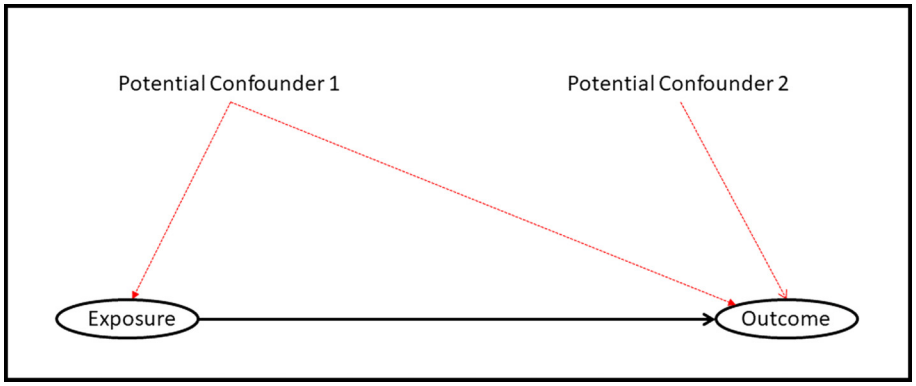

Figure 5 Directed acyclic graph illustration.

When assessing the strength of the causal association purported by a cohort study, it is useful to use five criteria which were established in the first Surgeon General's Report on Smoking and Health (Terry, 1964). First, the association should cohere with existing information and have a biological plausibility, as discussed above. The association should be consistent and specific, and have a clearly established time sequence. Finally, there should be some strength of the association which can be established quantitatively or via a clear dose–response relationship.

Investigators might also consider using structural equation modeling as a framework for causal inference, either through equations or diagrams (e.g., directed acyclic graphs [DAGs]) to assess the relationships between exposure and outcome while including all other known and unknown potential confounding factors. A DAG is illustrated in Fig. 5 demonstrating the causal inference framework for an association between one exposure and an outcome of interest. Using solid arrows to represent the relationship between an exposure and outcome and dashed arrows to represent confounding relationships, investigators can narrow down all confounding effects to determine the true causative nature of an association. Potential confounders might directly affect the exposure, the outcome, or both. DAGs are particularly useful for visualizing potential confounders that cannot be measured to assess their role as true confounders and the potential for residual confounding. Fig. 5 depicts a simple example of an exposure–outcome relationship. Based on the DAG, potential confounder 1 is a true confounder, thus important to measure and include in the analysis. However, potential confounder 2 is not a true confounder, thus the investigator need not to worry about being able to measure it.

Having a thorough understanding of all of the potential relationships between the exposure and the outcome allows investigators to accurately design studies and models while accounting for true confounders and avoiding introducing bias, like collider bias (Fig. 6). For example, using the relationship between vitamin use in pregnancy (exposure) and infant birth defects (outcome), Hernan et al. investigated the minimum necessary set to include in the analysis to account for confounding without introducing bias (Hernán et al., 2002). In this scenario, maternal age (potential cofounder 1), genetic factors (potential confounder 2), and maternal weight gain (potential confounder 3) were all considered as potential confounders. However, upon drawing a DAG, it was determined that maternal weight gain was a collider, as both maternal age and genetic factors determine maternal weight gain. Therefore, none of these factors need to be adjusted for in the analysis, as the collider closes this noncausal pathway.

Beyond a strong theoretical basis for undertaking the study, it is important to reduce the possibility of artifactual (spurious) and indirect (confounded) associations. Spurious associations can arise either due to chance or bias. Chance is unsystematic variation that can be protected against using strong statistical tests and thoroughly establishing a biological hypothesis for the association. Bias

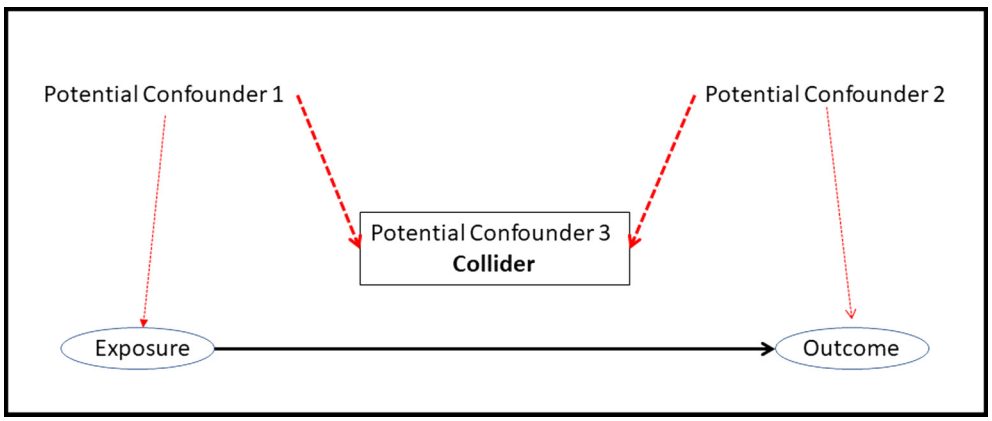

Figure 6 Directed acyclic graph with collider.

is a systematic variation in the data that, once present, cannot be corrected. Protecting against bias in cohort studies is accomplished by rigorously designing the study. Confounded associations can be controlled through random allocation, subject selection (exclusion criteria and matching), and data analysis (stratification, mathematical modeling).

However, the investigator should always remember that even the best methods to adjust for bias are only as good as the theoretical foundation of the research. If important confounders are not measured or are misclassified any adjustment will be inadequate. The student reading research should approach all observational research with a healthy dose of skepticism, and realize that "because human judgment and subject-matter knowledge are fallible, causal inference from observational data is also fallible in ways that causal inference from ideal randomized experiments is not" (Hernán, 2015).

Types of Bias

One of the most common threats to validity in cohort studies is confounding, in which an external variable is 'mixed' with the exposure such that it confounds the effect of the exposure on the outcome of interest. As described in the previous section, in order to be considered a confounder, a variable must be associated with both the exposure and the outcome, but cannot be an effect of the exposure. As an example, consider a cohort study that aims to establish whether an association exists between selective serotonin reuptake inhibitors (SSRIs) and T2DM. To determine whether a subject's weight should be controlled for, the investigator must first determine whether it is associated with the exposure. Indeed, SSRIs have been known to cause weight gain. However, weight gain also has an association with the outcome because T2DM is more common in those with a higher weight. Based on only these two considerations, the investigator might choose to control for weight in this cohort study. However, doing so would actually eliminate the detection of any possible real association between SSRIs and T2DM if the mechanism for that association occurs via an increase in weight. Because the variable of weight gain is an effect of the exposure (SSRI use), it should not be controlled for as a confounder in this hypothetical cohort study. If the investigator is concerned that weight gain is an important factor in this relationship, bias can be reduced by stratifying on different weight categories at baseline, or by adjusting for weight gain using multivariable methods.

As seen in the example above, comorbidities are often important confounders in a cohort study. Thus, it is important to be able to accurately identify and characterize these comorbidities. Measures of comorbidities should be carefully evaluated from the available literature before being used in a cohort study, as improper measures can leave substantial residual confounding (Jackson et al., 2011). Numerous studies have shown that using diagnosis codes to identify comorbidities, especially in the inpatient setting, can lack sensitivity for certain conditions (Fisher et al., 1992; Iezzoni et al., 1992; Powell et al., 2001; Quan et al., 2002). In these cases, a composite weight score (such as the Charlson Comorbidity Index) may be a better measure to use when resolving confounding due to comorbid conditions (Charlson et al., 1987).

Information bias can arise when the information about the exposure or the outcome is not accurate. It can occur during questionnaires if a subject cannot remember information about a drug. Information bias can also be introduced if an interviewer is not blinded to the subject's exposure group. If a prospective cohort study were being conducted to determine the effects of pediatric vaccines on the development of autism and the interviewer believed there was an association, questions could be asked in such a way as to bias those women who the interviewer knew had exposed their children to vaccinations. Interviewers might overstate or understate certain questions based on their personal bias toward the exposure group, even unknowingly. Blinding is the best way to remove this sort of bias.

A related bias occurs if a specific outcome is preferentially diagnosed in an exposed group, which is known as detection bias. For example, suppose a cohort study was designed to compare the incidence of migraines between users and nonusers of a contraceptive. If a physician is aware that a patient is a user of the medication of interest, he or she might be more tempted to diagnose the patient as having the outcome because of detection bias. To avoid this bias, blinding, when possible, plays an important role. In cohort studies using existing data, blinding can be seen through the rigorous design of the study to "ignore" outcome detection until after exposure groups and follow-up are determined.

Protopathic bias, also known as reverse causality bias, arises when an exposure is used to treat an adverse effect that is related to the outcome. Suppose a study was investigating in whether aspirin use in pediatrics causes Reye's Syndrome. As seen in Fig. 7, the relationship in which the investigator is interested is labeled "A." However, Reye's Syndrome can cause a fever which might be treated with aspirin (relationship "B" in Fig. 7). Thus, there is no way for the investigator to determine whether aspirin use is directly causing Reye's Syndrome, or if those with Reye's Syndrome are more likely to be treated with

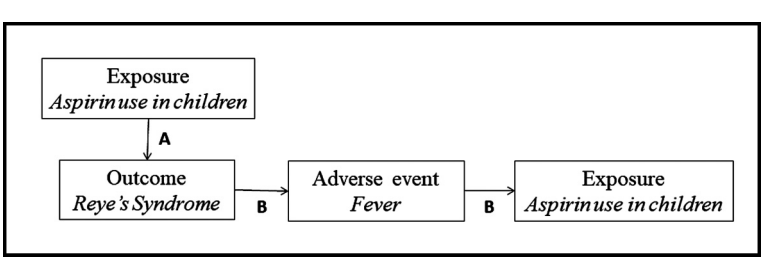

Figure 7 Protopathic bias.

aspirin. In order to reduce this bias, it is important to define the exposure in such a way that its use does not correspond with the outcome. In the example of aspirin and Reye's Syndrome, the investigator could exclude subjects who experience the outcome prior to receiving aspirin.

One type of bias that is specific to retrospective cohort studies is known as immortal person-time (Rothman et al., 2008). This bias arises when inclusion criteria prevent the outcome from occurring for the included subjects. For example, consider a study investigating the incidence of rhabdomyolysis with statin use. The inclusion criteria require subjects to take any statin for at least 3 months to be included in the exposed group. While this type of design may seem useful in that it reduces the possibility of exposure misclassification, it also introduces immortal time bias depending on when follow-up starts. The study is designed in such a way that it excludes anyone who experienced the outcome of interest (rhabdomyolysis in this example) and discontinued the medication prior to 3 months of use. The included exposed subjects are thus "immortal" during the first 3 months of statin use, if these 3 months are included in the follow-up; in addition, only subjects less likely to experience the outcome of interest are being selected for inclusion in the exposed group if the outcome can occur after shorter exposures.

Selection bias can occur when prevalent users are studied instead of new users. This type of selection bias is actually a form of immortal time bias, in which the only subjects included in the exposed group are those who have continued to be exposed long enough to be identified. As an example of the effect this form of selection bias can have on the results of a cohort study, we can consider that several observational studies seemed to suggest that statins improved survival in cancer patients. A study conducted in 2017 set out to emulate a randomized clinical trial (RCT) of statin initiators and nonusers to determine the true relationship between statin use and mortality in cancer patients. After appropriate methods were undertaken to reduce selection and immortal time bias (including requiring users to be incident, and stopping follow-up when drug treatment ceased), the study found no significant mortality benefit with statin use (Emilsson et al., 2017). These results demonstrate that the spurious association identified by previous studies was likely due to immortal time and selection bias, because cancer patients who were taking statins were likely healthy enough to be concerned about their chronic health conditions, and thus more likely to have a longer survival time. Having a clear definition of "time-zero" and syncing treatment assignment with eligibility determination is an important component when designing cohort studies to emulate RCTs and remove bias (García-Albéniz et al., 2017). Ensuring that the start of follow-up and exposure coincide in a cohort study is important to reduce bias, and is another reason new users of a drug are often chosen instead of prevalent users (Lajous et al., 2015).

The healthy patient (or healthy user) bias arises when the health status of a subject influences the likelihood of the outcome. Often, if exposure is defined based on the use of a drug, then the exposed subjects are more likely to be health-conscious and may be less likely to experience an outcome tied to poor health. One rather prominent demonstration of the healthy user bias was in the observational studies investigating the link between estrogen use and breast cancer. Whereas the Women's Health Initiative (WHI) demonstrated a clear increased risk of breast cancer with estrogen use, observational studies failed to identify this link due to the healthy user bias.

Channeling bias, also known as confounding by indication, occurs when a potential association between an exposure and outcome is affected by disease severity. For example, if a drug is prescribed to patients who are already at a higher risk of a particular outcome, the results of a cohort study might indicate that the drug increases the risk for the outcome (Emery and Grahame, 1982). One recent study investigated the associated between inhaled corticosteroids (ICS) and hospitalizations in a group of subjects from an administrative claims database (Filion et al., 2016). The results of this cohort study demonstrated that new users of ICS had higher rates hospitalizations than nonusers. However, after an examination of the data, investigators determined that the ICS of interest had become restricted on the insurance formulary, resulting in only subjects with more severe disease being prescribed. Because those taking the medication were also more likely to experience the outcome independent of their exposure, a channeling bias was introduced. To avoid confounding by indication, an active comparator consisting in a drug recommended for the same indication, or even disease severity, would be preferable over a nonuser group.

Exposure misclassification bias occurs when a subject is incorrectly identified as being exposed or unexposed. This type of bias is especially important when using administrative databases as a data source for a retrospective cohort study. Because the only information on exposure status is gained from claims submitted to a payer, investigators must be aware that there will be a group of subjects who are actually exposed, but because their medication was not billed to payer, are classified as unexposed for the purposes of the study. This can occur as a result of low-cost generic programs that incentive subjects to pay for their medications out-of-pocket, medication claims being submitted to a supplemental payer, or the subject receiving samples of the medication from a provider (Brown et al., 2017; Pauly et al., 2016). If the concern for exposure misclassification is high, the investigator should adjust accordingly in the analysis and result interpretation.

Methods for Reducing Bias

Keeping in mind the many sources of bias in observational research, investigators using cohort study designs have many options to reduce bias and confounding in their studies. Both measured and unmeasured confounders can be addressed through study design as well as in data analysis.

For reducing bias due to known and measured confounders, the cohort study design can match exposed to unexposed subjects. In addition, the investigator can identify potential sources of bias and increase levels of restriction in the design to mimic high and low risk groups, similar to those identified in RCTs (Schneeweiss et al., 2007). When cohort studies are designed to replicate RCTs, the results are closer to those achieved through randomized experiments design (Hernán et al., 2008).

The association between postmenopausal hormone replacement therapy (HRT) and CHD has been controversial. Initially, large observational studies found a reduced risk of CHD among HRT users (Grodstein et al., 2000, 1996), but then the WHI—a large RCT—found that HRT users actually had, a higher risk of CHD than nonusers (The Women's Health Initiative Study Group, 1998), researchers went back to these observational studies and found flaws in methodology that had led to the erroneous conclusions. In one such study, investigators used data from the NHS and attempted to mimic the design of an RCT in every way possible, including the intention-to-treat principle (Hernán et al., 2008). As mentioned in the introduction to this chapter, the NHS is one of the largest cohort studies in women investigating risk factors for chronic disease. Beginning in the United States in 1976 with approximately 120,000 female nurses aged from 30 to 55 years, the study is currently on its third iteration and has nearly 280,000 participants (Brigham and Women's Hospital et al., 2016). Participants receive a questionnaire every 2 years and provide answers about lifestyle, diet, medication use, and diseases.

In this reanalysis of the NHS data, subjects were considered exposed if they reported taking HRT (estrogens and/or progestins) on a questionnaire and were categorized as HRT initiators or noninitiators. The main outcome of interest was the first occurrence of a CHD diagnosis. The investigators' findings suggested that the discrepancies between the WHI and NHS could be explained by differences in follow-up time and time since menopause.

In addition to establishing a causal framework and designing the cohort study as close to an RCT as possible, there are also statistical techniques that can be used to reduce the effects of confounding and bias. These include incorporating propensity scores in analyses with measurable confounders and using instrumental variable analysis in studies with known but unmeasurable confounders. Propensity scores are constructed to model the likelihood that each subject in the study would receive treatment based on theoretically derived baseline conditions. Then, investigators can use this "score" to match subjects, weight observations, or stratify by the propensity to receive treatment (Austin, 2011). Instrumental variable analysis becomes important when investigators know that a certain factor is a confounder but are unable to measure its influence (Baiocchi et al., 2014). In this case, investigators might choose to identify an "instrument" that can represent this unmeasured confounder and explain differences in exposure status. The instrument must affect the exposure directly, only affect the outcome through its relationship on the exposure, and cannot be caused by the exposure. As an example, one study aimed to investigate the association between gastrointestinal complications and the use of nonselective versus selective NSAIDs (Brookhart et al., 2006). However, there were many unmeasured confounders that could obscure this relationship such as aspirin use, smoking status, and alcohol consumption. To reduce bias caused by these unmeasured confounder, investigators used the physician NSAID preference as an instrument and were able to more closely estimate the true effect of NSAID use on gastrointestinal complications.

Strengths and Limitation of Cohort Studies—Comparison with Other Designs

When considering the strength of a particular research design, the classical hierarchy of evidence can aid in an initial assessment, but it is by no means all-inclusive. The original hierarchy of evidence is seen as a pyramid that has case reports providing the least evidence, and systematic reviews and meta-analyses of RCTs as providing the strongest evidence (Guyatt et al., 1995). Cohort studies are positioned higher compared to any other observational study designs, but below interventional studies of any type. However, health professionals analyzing the strength of a research study should be aware that any given level of evidence can be downgraded or upgraded for a variety of reasons. It is important to remember when evaluating research that the best decision-making is informed by a body of evidence, rather than any one piece of evidence (Lapeyre-Mestre et al., 2013). In some areas of research, an RCT may not be ethically or logistically feasible, therefore a well-designed cohort study may provide the best of quality evidence. In other cases, cohort studies may spark an interest or concern and lead to the design of an RCT. In any case, the astute reader will consider all available evidence and make appropriate judgements as to the quality of each piece based on its own merits. Several initiatives provide guidance on such assessment. As mentioned earlier, STROBE was developed to help improve the reporting and design of observational studies in general, and provides specific checklists for each type of study, including cohort studies (Vandenbroucke et al., 2007). More recently, the RECORD-PE statement was developed to address the design and reporting of observational studies, including cohort studies using existing data (Benchimol et al., 2015).

Cohort Studies and Experimental Designs

RCTs continue to hold their place as the most convincing design for establishing causal relationships. This is largely due to the fact that it is the only study design that is accepted to control for both unknown and unmeasurable potential confounders. However, RCTs tend to be expensive and ethical considerations may prevent their use entirely. Additionally, the small sample size, selective population, and short duration of follow-up do not generally lend RCTs to the study of ADEs or other harmful drug-related effects. Thus, researchers must consider other study designs. After RCTs, cohort studies are often considered to be the next most convincing study design (Friis and Sellers, 2004). They allow for evaluation of multiple exposures as well as the causal association with multiple outcomes of interest, while being less expensive and time-consuming compared to RCTs.

The lack of randomization at baseline in cohort studies impacts their ability to control for confounding as compared to RCTs and other experimental designs. However, when methodology is carefully chosen and appropriate statistical techniques are utilized, studies have shown that results similar to large RCTs can be obtained (Benson and Hartz, 2000; Concato et al., 2000) with observational data. For example, finding a good instrument for the instrumental variable approach in cohort studies using existing data can balance both measured and unmeasured confounders, thus providing a similar framework to an RCT. In the absence of a

good instrument, other approaches are available to counteract the potential threats to validity with observational data and provide rigorous methodology for causal inference (Hernán et al., 2008; Ray, 2003; Rohrer, 2018).

Another benefit of cohort studies is that the studied population more closely resembles patients that clinicians might actually encounter. For instance, many RCTs have demonstrated the immense benefits of statin medications. While the results of these studies are important, and can help clinicians make decisions, it was the cohort study that determined that despite these benefits, adherence to statins was extremely low. Without this information, outcomes for patients would have been spuriously low. However, considering the information gained from the cohort study, one can see that indeed benefits demonstrated by RCTs remain. This cohort study was both a public health and a clinical call to action (Jackevicius et al., 2002). An RCT that was large enough to assess adherence would probably be difficult to conduct because of the extreme financial cost associated with administering RCTs. In this sense, cohort studies often serve as a less expensive study design that may provide convincing evidence to later perform an RCT.

In a clinical trial, investigators are certain when subjects begin taking a medication because they assign, and often administer, the drugs of interest. However, in cohort studies it can be difficult to ascertain what is commonly known as "time zero." Thus, the question has arisen whether it is appropriate when assigning user and non-user groups in a cohort study to consider whether users are prevalent or incident. The incident user design has improved the reliability and decreased the bias president and cohort studies (Johnson et al., 2013; Ray, 2003).

In the US, preclinical drug testing usually only involves 500–3000 patients. Based on this sample size, only adverse events that occur in 1 out of 100 patients can be reliably detected (Strom, 2005). Thus, even if an ADE is severe, if it occurs in 1 in 1000 patients or less, it will not be detected using clinical data. In fact, a drug's safety profile at the time it is approved for use on the market is often incomplete. Postmarketing safety surveillance is therefore, essential and has been in place in the United States since the 1950s (Russo et al., 2014).

Cohort Studies and Other Observational Designs

Compared to other observational designs such as case–control studies, selection bias related to the outcome is better controlled in a cohort study because all participants begin follow-up as disease-free (i.e., without the outcome). This also enables cohort studies to evaluate the incidence as opposed to the prevalence of the outcome of interest, making them particularly useful tools in post-marketing surveillance of approved drug products. Furthermore, because participants are selected based on exposure status, a temporal relationship between exposure and outcome can be more convincingly established. Allocation based on exposure status also means that cohort studies are more suited to investigate uncommon exposures, and have the ability to assess multiple outcomes as well as multiple exposures. Historically, cohort studies (i.e., prospective cohort studies) required years to complete resulting in substantially higher costs compared to other observational study designs. In addition, prospective cohort studies were considered less suitable for investigating the occurrence of rare outcomes, which were often investigated through case–control studies, or the newer study designs, such as the nested case–control study and the case-cohort study, both as adaptations of the classical cohort study. In nested case–control studies, subjects are selected from a previously established cohort, but group allocation is based on outcome. Case-cohort studies also allocate groups based on outcome presence, but randomly select controls from the entire cohort (Kelsey et al., 1996). With the wide availability of existing administrative data that allow for establishing large cohorts providing adequate sample size, the relative advantages of case–control designs over cohort design are not as relevant.

Conclusion

In this chapter, we discussed cohort studies and their importance in pharmacoepidemiology. With the increasing availability of existing data and the advancements in methodology, cohort studies are a great tool to investigate the effects of medication use, allowing for assessment of a potential causal relationship between one or multiple exposures with one or multiple outcomes. When using rigorous designs as those implemented in RCTs, cohort studies can build evidence in areas where RCTs are not feasible or pose ethical concerns.

Methodological Challenges in Epidemiological Studies

Jenni Ilomaki*, Anna-Maija Tolppanen†, *Centre of Medicine Use and Safety, Monash University, Melbourne, VIC, Australia; †School of Pharmacy, University of Eastern Finland, Kuopio, Finland

Introduction

It takes several steps to establish a causal association between an exposure and an outcome. The process starts with a well-defined, answerable, study question. The process also involves finding an appropriate data source that have all sufficient data that are required to answer the study question including the exposure, the outcome, and any potential confounders. Selection of an appropriate data source is based on questions such as Are the data representative of the group of interest? Are all important variables appropriately measured or are there possible errors a measurement? Once the data are assessed to be of sufficient quality, it is time to design the study so that it can answer the study question. This includes, in addition to choosing the actual study design such as cross-sectional or cohort study, the definition of the exposure (medication), the outcome, other variables that will be required to adjust the association (confounders) and timing of the measurement (considering the biological plausibility). All of the above are the core of any epidemiological study.

Data Sources

Data sources are discussed elsewhere in this work, but the strengths and challenges utilizing secondary and primary data sources in relation to epidemiological studies are briefly described below.

Utilizing Existing Data Sources

Pharmacoepidemiological studies are most often based on existing data sources (secondary data sources). This means that the data have been collected for other purposes previously, and data are analyzed afterward to answer a specific research question. The most typical existing data sources used are administrative health data (routinely collected data) or data collected for research purposes previously (e.g., large cohort studies or surveys). All these data sources have strengths and challenges that need to be acknowledged.

There are several strengths that make the use of existing data sources attractive for researchers (Table 1), particularly recently when large, routinely collected data sources in different countries have become available for researcher to use. One of the main strengths of utilizing existing data sources is that it is usually far less expensive than primary data collection. The only costs involved in utilizing existing data are data acquisition cost, in some cases, cost of data storage and analysis platform and cost of data analysis.

Utilizing existing data sources also saves time particularly when conducting longitudinal studies. This is particularly important if there is a suspicion that recently approved medication may increase the risk of adverse events that were not detected in premarketing studies due to their lack of power in detecting rare adverse events. Furthermore, existing data sources are often the only data sources with sufficiently large sample sizes to detect rare events, or perform drug–drug comparisons. This applies particularly to routinely collected data because they often cover large regions, or sometimes the whole country. Finally, existing data sources often enable multinational comparison, if comparable data exists across countries.

Table 1 Strengths and challenges of utilizing existing data vs. collecting primary data

	Use of existing data	*Primary data collection*
Strengths	• Cost-effective • Large sample size • Ethical procedures can be simpler	• Can be designed for particular study questions
Challenges	• Limited to existing variables • Data may not have been collected for research purposes • Permissions for data use from data custodians	• Costly • Time consuming • Ethical considerations • Difficulties if recruitment

The benefits of pooled analysis of administrative claims data are illustrated by Furu et al. (2015) who pooled data from all five Nordic countries to investigate whether the use of selective serotonin reuptake inhibitors and venlafaxine in early pregnancy was associated with risk of birth defects. Both antidepressant exposure during pregnancy and birth defects are rare, and without pooling, the data the study would have been underpowered to detect an association to this clinically important question.

Limitations of routinely collected data are that researchers are limited to the variables and time frames available in the data source. This means that one database may not be suitable to a specified research question and that researchers may need to combine several data sources and develop algorithms for deriving variables of interest from different data sources. Routinely collected data are collected for other purposes than research. This means that the data may not be readily usable. It is important that researchers have a good understanding from where the data comes from, how it has been collected, and what was the purpose of data collection. For example, routinely collected hospital data have been used initially for administrative and resource allocation purposes. For example, claims data for insurance purposes include only those eligible for the scheme. People may move in and out of the database based on their eligibility at different points in time. Other challenges are obtaining permission from the data custodians particularly for the use of routinely collected data and linking these datasets to other data sources. These processes change across databases and countries they are held at.

Primary Data Collection

If there are no suitable or accessible data sources available for a particular study question, an alternative is for the research group to collect new data to answer the question. This is called primary data collection. Typical methods for primary data collection are surveys, interviews, or observations. These may involve, for example, self-reports of demographic data and disease history, participant or interview-filled questionnaires using standardized tools (e.g., SF-36 Quality of life instrument, Katz Activities of daily living), or measurement of clinical data such as blood pressure, blood glucose levels, or brain imaging. To collect primary data requires careful planning. Often it is recommended that pilot data will be collected to make sure that you are getting all the data in a correct format in the actual big data collection. Once the data collection is underway, any chances are very difficult to make. One example of primary data collection with a pilot phase is the Australian Life Histories and Health (LHH) Survey (Kendig et al., 2014). LHH was a substudy of the bigger 45 and Up Study of >260,000 participants from the state of New South Wales, Australia. The LHH pilot was conducted among 100 participants, and in total, 2800 participants were invited to the actual LHH survey.

There are some typical challenges of primary data collection. One challenge is the longer duration of primary data collection, particularly if the aim is to recruit a large sample size with multiple data collection points for longitudinal follow-up. Primary data collection usually involves high costs due to requirement of staff, staff training, and other resources. Data that rely on self-report are prone to recall error as people would not always recall their past exposures or medical conditions. One of the big challenges is nonparticipation, including refusal to participate at baseline and attrition during the follow-up. Large nonparticipation rates increase the risk of biased sampling and consecutively biased results. Detecting study outcomes by linking the study cohort to, for example, hospitalization data will help avoid attrition, because outcome will be available for everyone from routinely collected data. However, in most countries or jurisdictions, this would require consent from each study participant. Finally, there are ethical considerations related to collecting sensitive health and medical information from participants and involving participants to attend research sites and collecting clinical data (e.g., blood samples).

Strengths and Weaknesses of Different Study Designs

The choice of optimal study design depends on the purpose of the study, as well as the outcome and exposure. For example, it is not feasible to apply the same design to assess whether a commonly used drug is related to a rare outcome with long latency period, and whether a drug for rare condition has acute toxicity. Brief summary of strengths and weaknesses of different observational study designs is provided in Table 2.

Table 2 Strengths and weaknesses of different study designs

Study design	*Strengths*	*Weaknesses*
Cross-sectional study	• Simple and quick data collection	• Cannot assess incidence • Impossible to disentangle temporal relationship • Cannot control unmeasured confounding
Case–control study	• Feasible for rare outcomes and outcomes with long latency time • Can investigate multiple exposures	• Prone to recall bias (depending on exposure data sources) • Reverse causality can occur • Cannot control unmeasured confounding
Cohort study	• Temporal relationship easier to assess • Can assess rare exposures • Can investigate multiple exposures (and outcomes)	• Cannot control unmeasured confounding • Often not feasible for rare outcomes, or outcomes with long latency period
Self-controlled studies	• Feasible for rare outcomes • Controls for unmeasured fixed confounders	• Must know the latency time for outcome; not the optimal design for outcomes with long latency time

Cross-Sectional Studies

Cross-sectional studies provide a snapshot of the chosen population at a given timepoint. Because they, by definition, have no follow-up and require data collection only once, they are easier and cheaper to conduct than cohort or case–control studies. As the exposure and outcome are measured at the same timepoint, it is impossible to differentiate the cause and effect. Thus, cross-sectional studies cannot be used for assessing causality. Further, depending on the applied data collection method, they may be prone to recall bias. Another limitation is that they cannot assess incidence.

Cross-sectional studies are useful for investigating the prevalence of drug use (or another phenomenon). Thus, they can be used for assessing the burden of disease and prevalence of drug use and for consequent planning and allocating health-care resources. Therefore, although they cannot assess causality, they can still provide valuable information.

For example, a study on older patients' compliance with drug storage recommendations showed that 51.2% of older patients complied with them (Vlieland et al., 2018). In another study, conducted on the patterns of direct anticoagulant (DOAC) prescriptions in 2010–13, the researchers observed that although certain prescription guidelines were followed well, for 58% of patients receiving DOACs, the guidelines were not followed (Diaz et al., 2018). This latter study also illustrates an important fact: the data of a cross-sectional study may well span over (several) years. Therefore, the study design cannot always be inferred from the study period.

Cross-sectional studies can also be serial, which means that the data collected during a longer time period is analyzed in shorter intervals. This kind of studies can be used for comparing the prescription rate of a given drug after changes in policy, or drug availability. For example, the impact of changing availability of tamper-deterrent and nontamper-deterrent oxycodone on prescribing patterns of controlled-release oxycodone was investigated in a Canadian study spanning from 2007 to 2016 (Gomes et al., 2018).

Case–Control Studies

Case–control studies are defined by outcome, and data on exposure are gathered retrospectively. This retrospective nature may introduce information bias (specifically, recall bias) if the cases recall their exposure differently to controls. Another possible source of recall bias is the inclusion of prevalent cases (i.e., those who have had their condition for a longer time). Thus, it is preferable to restrict a case–control study to incident cases as this will avoid several other issues such as different survival (Hill et al., 2003). Selection of appropriate controls is also important, as control selection may introduce selection bias. The controls should ideally be a random sample from the population where the cases were obtained from. For example, studies on congenital malformation are often restricted to live births. This introduces selection bias because the cases and controls are not sampled from the same population as the fetuses/babies with the most severe malformations were removed from the dataset by miscarriages or stillbirths (Suarez et al., 2018). A further limitation of case–control studies is that they provide data on the prevalence of exposure among cases and controls but cannot be used for assessing incidence of the outcome among exposed and unexposed.

Because case–control studies do not require follow-up, they are useful for assessing rare outcomes or outcomes with long latency period. However, especially for conditions with long onset time, it is important to consider protopathic bias (as illustrated with the proton pump inhibitor example in the Assessing the Causality of Results section of this chapter) and the length of the lag time. The same case–control study can be used for assessing several exposures.

Cohort Studies

As opposed to case-control studies, cohort studies are generally prospective (i.e., exposure is measured before the outcome). This means that traditional cohort studies (in which no one has experienced the outcome at the beginning) are not feasible for outcomes with long latency period, as follow-up is costly, and loss to follow-up likely to occur. For the same reason, they are not efficient for

rare outcomes. Further, if the follow-up is long, there may be changes in treatment and diagnostic procedures. This means that the distribution of exposure and outcome may vary temporally. Further, in traditional studies, some selection bias may occur, as persons participating in cohort study tend to differ from the general population. This can affect the generalizability of results. In addition, as the participation in a cohort study can be time consuming, and require ability to return questionnaires, or attend follow-up visits, it can be difficult to engage certain population groups, such as persons with dementia, in participation.

Many of the abovementioned problems can be solved by applying administrative databases. They can be used for obtaining exposure (such as drug use) and outcome (such as dementia or death) data for an existing cohort, or the entire study can be conducted with administrative databases. For example, Gray et al. used computerized pharmacy records to ascertain the exposure to benzodiazepines in an already existing population-based cohort study to assess the association between benzodiazepine use and dementia (Gray et al., 2016). This enabled the authors to retrospectively collect exposure data from the entire follow-up period, which would have otherwise been challenging, biased or impossible as dementia and its undiagnosed prodromal phase would likely affect the individual's ability to accurately report drug use.

In another, entirely register-based study, data from the Finnish national health-care registers were applied to assess whether antipsychotic use is related to a higher risk of hip fracture among persons with Alzheimer's disease (Koponen et al., 2017). This study was based entirely on registers. First, all community-dwelling persons with incident diagnosis of Alzheimer's disease were identified from a national reimbursement register. Data on their antipsychotic use, as well as hip fractures and other comorbidities, were then extracted from other national registers. This enabled the researchers to assess the safety of these drugs in a population group that is frequently prescribed them, but often excluded from randomized controlled studies.

Self-Controlled Studies

Self-controlled designs, such as case-crossover study and self-controlled case series, are attractive as they implicitly control for fixed, unmeasured confounders (Maclure, 1991; Maclure and Mittleman, 2000; Whitaker et al., 2006). In both of these designs, only persons who experienced the outcome of interest are included.

In *self-controlled case series* (Whitaker et al., 2006), the risk of outcome during periods of exposure and nonexposure is compared. Thus, the exposure must be time-varying. Other assumptions are that there is variation in the timing of the outcome, and the exposure is not affected by the outcome, although this can, to some extent be accounted for in the analysis. If recurrent outcomes are analyzed, their occurrence should be independent of each other. It should also be noted that self-controlled case series can measure relative, but not absolute incidence. A worked-up example of application is provided in an accessible tutorial by Whitaker et al. (2006).

The example assessed whether MMR vaccination was related to viral meningitis. In the original study, the investigators obtained data on cases diagnosed with viral meningitis and linked these data to vaccination records. Observation period (i.e., the time during which outcome and exposure were assessed) was the second year of life. Based on previous data, the exposure period was defined to contain days 15–35 after the MMR vaccination. Then the risk of nonviral meningitis during exposed and nonexposed periods was compared. Self-controlled case series has most commonly been applied in vaccine epidemiology, but it is applicable to those exposures with multiple exposure periods (such as other drugs). Further, although the method works best for acute outcomes, it can be used for nonacute outcomes with longer latency time, but then the design is more prone to confounding between age and exposure effects. Further, the likelihood of unmeasured time-varying confounding is larger with longer latency time.

In *case-crossover design* (Maclure, 1991; Maclure and Mittleman, 2000), the exposure frequency during a period immediately before outcome onset is compared with exposure frequencies during control times. The design shares many limitations with self-controlled case series: it works best for acute events and nonrecurrent events. Likewise, the outcome should not impact exposure (or control period(s) should occur before the hazard period). There should be variation (aka crossover) in exposure over time, as only these exposure-discordant persons are informative in the analysis. Further, the probability of exposure should be stable. This assumption is often violated when a new drug comes into market. Therefore, this design cannot be directly applied to such situations (Wang et al., 2014). Selection of hazard and control periods is important as it can affect the results as demonstrated in a screening study of candidate drugs related to higher risk of hip fracture (Tolppanen et al., 2017). In that study, three different scenarios were used to test the sensitivity of results to period definition: (1) hazard period 0–30 and control period 31–61 days before hip fracture, (2) hazard period 0–30 and control period 336–366 days before hip fracture, and (3) hazard period 0–14 and control period 16–30 days before hip fracture. The results were highly dependent on the applied hazard and control periods as 9, 44 and 5 drugs were identified with higher, and 8, 23 and 4 with lower risk of hip fracture in different scenarios. The overlap between drugs identified with different scenarios was small.

Finding the Exposed Participants

There are specific considerations when investigating medications as an exposure in epidemiological studies. Exposure in pharmacoepidemiological studies in more detail is discussed in other chapters of this work. In brief, the following issues need to be considered when using medication as an exposure in epidemiological studies: (1) use of a single ingredient or a medication class, (2) dose of the medication, (3) when the medication use was initiated, and (4) duration of the medication use. Depending on the data

source, it depends whether information is available for all of the four points. It comes down to the research question whether and how important all these points are.

Indeed, one of the main challenges is to find a suitable data source for the study question. Each data source has its strengths and challenges. The strengths of utilizing existing data sources such as dispensing or prescribing data are that (1) data are systematically captured and (2) it allows longitudinal detention on medication exposure. However, exposure on certain medication use may be missed. For example, medication dispensing data often come from medication claims. If medication is not eligible for reimbursement, it may not appear in the claims data. Furthermore, dispensing and prescribing data does not provide information on actual use of medication. Primary data collection on medication exposure often relies on either self-report or view of medication containers or prescriptions. Self-report gives more detailed information on actual use of medications, however, may be prone to recall error and data provided is subjective. Using containers or prescriptions as additional data source alongside self-report reduces recall error. However, it is still unclear whether some information may have been missed.

Another major challenge is to identify exposed and unexposed participants that are comparable, or accounting for possible differences in the analysis. The comparison of people exposed and not exposed to a medication often means that the groups are very different in terms of diseases and severity of diseases, which means that *confounding by indication* will be evident. Confounding by indication is explained later in this chapter.

Selecting the Outcome

Selection of the outcome variable requires the thinking of the study question and what is it that needs to be measured. If the study aims to answer a question on how the use of osteoporosis medication prevents from osteoporotic fractures, then data specifically on osteoporotic fractures need to be identified.

Health outcomes can be crudely divided into two types: surrogate outcomes and hard outcomes. Surrogate (or intermediate) outcomes occur before the hard outcome and are the cause of the hard outcome (Fig. 1). For example, blood pressure or cholesterol level can both be used as surrogate outcomes for cardiovascular disease events, because they both affect the incidence of cardiovascular disease. The advantage of the use of surrogate outcomes is that they usually occur sooner than the actual event, there are more events occurring which means that you may need less participants to detect the outcome, or the outcome is possible to measure as a continuous variable. However, using surrogate outcomes, drawing conclusion of the benefits of treatment will be more challenging. In the example in Fig. 1, the effect of statin use in thought to occur via its effects on LDL-cholesterol. The reduction of LDL cholesterol is, indeed, a good marker of stroke risk reduction (Silverman et al., 2016). However, statins may reduce stroke via other mechanism as well (pleiotropic effects), which would not be captured measuring only the reduction in LDL cholesterol (Oesterle et al., 2017).

Hard outcomes are the "real" outcomes such as mortality, incidence of disease (e.g., stroke, myocardial infarction, and cancer), or hospitalization for a disease. These are the incidences that the treatment is attempting to prevent or delay. These are also the outcomes that people often consider more important. As mentioned earlier, hard outcomes occur later and less frequently than surrogate outcomes, which makes them more challenging to measure. One way of increasing the frequency of hard outcomes is to use composite outcomes. Fig. 2 gives an example of a composite outcome.

In addition to the direct health outcomes such as the previously mentioned surrogate and hard outcomes, soft outcomes can be used. These include, for example, quality of life measures, activities of daily living, or pain level. Soft outcomes are usually subjectively measured, while surrogate and hard outcomes can be measured objectively.

Figure 1 The temporal relationship been exposure variable, surrogate outcome, and the outcome event.

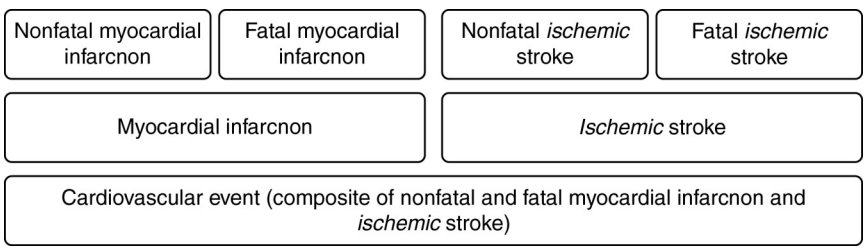

Figure 2 An example of a composite outcome of a cardiovascular event.

One of the biggest challenges in deciding on the outcome is how to ascertain the sensitivity and specificity of the outcome measure. Hospital discharge data is one of the most common data sources used to capture study outcomes. However, relying on hospital discharge data to capture outcomes means that only the most severe cases of events will be captured. For example, investigating falls as an outcome means that only falls leading to hospital admission will be captured. Any falls that lead to an emergency department or general practitioner visit only will not be captured, unless all these databases are linked using a person identifier.

Another example is bleeds. Minor bleeds may not lead to hospital admissions. Another challenge in hospital discharge data is how well medical conditions are coded in the hospital. A Canadian study compared the coding of obesity in hospital discharge database to the Alberta Provincial Project for Outcomes Assessment in Coronary Heart Disease (APPROACH) database which had Body Mass Index measured (Martin et al., 2014). Obesity was defined as BMI ≥30 in the APPROACH database and as ICD-10 codes of E65–E68 in the hospital discharge data. The study found that in people who have undergone cardiac catheterization, the sensitivity of obesity coding in the hospital discharge data was only 7.8%, while the specificity was 99%. Negative predictive value was 81% and positive predictive value 66%. See more on how misclassification of outcomes may lead to bias later in this chapter.

An overall challenge in the outcome measure ascertainment is to find true incident cases. Finding incident cases is important to determine causal association between the exposure and outcome (described in more detail in the following paragraph). Incident case means that the person experiences the event for the first time, for example, having the first stroke. If a person has had a stroke at some point in time in the past, is no longer experiencing and incident or first stroke. There is no data source where you can confidently detect person's first stroke and some assumptions have to be made. For example, not having a stroke recorded in a hospital discharge data for the past 5 years could be a good assumption for detecting first strokes. A study conducted using the New South Wales (Australia) hospital separation data reported that using a 1-year look-back period to determine incident strokes, 11% had actually had a stroke previously (Worthington et al., 2017). However, extending the look-back period to 5 years, this misclassification reduces to 4.4% and to further 1% when using a 10-year look-back period.

Finally, time taken to the outcome to occur is crucial to determine as biologically plausible. If the follow-up time from the exposure to the outcome is too short, it means that the true causal association will not be detected. In contrast, if the follow-up time is too long, the extra time may dilute the outcome occurrence as the effect size is probably bigger earlier in the follow-up period than during the later time periods. Examples of outcomes that usually take a long time to develop are dementia (Wilson et al., 2011) and mesothelioma (Nurminen et al., 2003). Determining the ideal follow-up time, both the exposure and the outcome need to be considered. Please refer to the next paragraph for more details on causal assessment.

Assessing the Causality of Results

When interpreting the results of a study, it is important to ask two questions: "Is it real?" and "Does it matter?" This is crucial when one is interpreting the results of his/her own study, but equally relevant when reading or reviewing a scientific article.

The association between drug exposure and outcome can be explained by (1) chance, (2) confounding, (3) bias, or (4) reverse causality. The first one is often assessed with *P*-value (or significance level) (Wasserstein, (edited on behalf of the American Statistical Association Board of Directors) 2016). However, it is important to acknowledge that the *P*-value does not measure the probability that the data were produced by random chance alone (Wasserstein, (edited on behalf of the American Statistical Association Board of Directors) 2016). Rather, *P*-value measures the strength of evidence against the null hypothesis (i.e., no association between the drug and outcome), but importantly, it is not, and it should not be, interpreted as a statement of the importance or causality of the finding and the traditional cutoff (or any other cutoffs) should not be used (Greenland et al., 2016; Sterne and Davey Smith, 2001; Wasserstein, edited on behalf of the American Statistical Association Board of Directors) 2016). The *P*-value does not exclude the other possible explanations for association. Thus, an association with small *P*-value may still be produced by bias or reverse causality.

When assessing whether the results are due to confounding, it is important to consider how confounding may occur in each design. Confounding can be controlled by both study design and analysis methods. If a randomized controlled study was conducted, the key question is whether the random allocation was indeed random so that there was no association between the confounders and exposure? If an observational study was carried out, was confounding adequately controlled by statistical methods such as propensity scores, matching, or adjusting? Were all relevant confounders measured, and how well the measured confounders captured the reality? If there are unmeasured or under measured confounders, is the residual confounding due to these factors large enough to explain the results? In a self-controlled design (see section Self-Controlled Studies of this chapter), it is important to consider whether there were time-variant unmeasured confounders, which may affect the results. Further, it is important to acknowledge that it is not feasible to adjust for all possible factors, and the possible relationships between possible confounders, exposure, and outcomes should be considered. Sometimes the unnecessary adjustment may distort the true underlying association (Hernan et al., 2002).

Bias means that the results or their inference deviate systematically from the truth (Porta et al., 2008). This can be caused by errors in not only data collection, analysis, or interpretation phase but also from publication or review phase (Last, 2001). It is important to acknowledge that bias can most effectively, or entirely controlled, before the analysis phase. Although it may be possible to use statistical approaches to account for some biases, such as use weighting to correct for selection bias (Haneuse et al., 2009), it is more feasible to spend enough time in planning the data collection (including but not limited to participant recruitment, measurement, and data entry) properly. Importantly, bias can occur in all study designs. In addition to assessing the possibility of bias, it is

necessary to consider whether it occurred differentially among exposed and unexposed or those who experienced the outcome. If the misclassification or error is differential, then the direction of bias should be considered. Different type of bias are shortly summarized in section Typical Biases later in this chapter.

The presence of reverse causality (i.e., whether the outcome "caused" the exposure) can be assessed on the basis of study design. Cross-sectional studies are perhaps the most notorious in this regard, but reverse causality can also occur in case–control or cohort studies. In pharmacoepidemiology, reverse causality is often due to protopathic bias, which means that the drug was started, stopped, or otherwise changed due to the manifestation of the underlying outcome (Feinstein, 1985). Indication bias (confounding by indication) can also cause this phenomenon. Confounding by indication means that the risk of adverse event is related to the indication for drug use, but not to the used drug itself (Csizmadi et al., 2007). For example, proton pump inhibitors have been associated with higher risk of gastric cancer. However, when a lag time was applied, the association was abolished (Tamim et al., 2007). Specifically, a lag time means that drug use occurring during a prespecified time period before the outcome event is not considered because it may reflect use due to prodromal symptoms of the outcome. In this case, proton pump inhibitors were often initiated due to gastric complaints, which were the first manifestations of undiagnosed gastric cancer (Tamim et al., 2007).

Finally, if the researcher, or the reader/reviewer of the scientific article, can rule out the chance, confounding, bias, and reverse causality as possible explanations for the observed association, the next question is whether the observed association is clinically significant, or "does it matter?" Large effect sizes are rare, but smaller effect sizes, or weaker associations between drug exposure and outcome, may be important if the drug is commonly used. However, interpretation of small risk, hazard, or odds ratios can be challenging because they may be easily susceptible to bias (Siontis and Ioannidis, 2011).

Typical Biases

Biases can be classified in several ways, as summarized by Delgado-Rodriguez and Llorca (2004). One possibility is to classify them according to the direction of the change they produce to the estimate (such as the hazard ratio of drug exposure and outcome). Bias toward the null (occasionally the term "negative bias" is also used) occurs when the biased estimate is closer to the null value than the true estimate. Away from the null bias (such as the association between proton pump inhibitor use and gastric cancer illustrated by Tamim et al. (2007)) occurs when the observed association is further away from the null value than the true association. Although the definition of bias often includes the term "systematic" (Porta et al., 2008), it is important to acknowledge that also nonsystematic misclassification (or random measurement error or nondifferential misclassification) can lead to bias toward the null (Hutcheon et al., 2010).

Alternatively, the biases can be classified into three groups as follows: selection bias, information bias, and confounding (Kleinbaum et al., 1982). Here, we briefly introduce the most typical biases according to this classification. More extensive listing of specific biases is available from several other textbooks (such as (Csizmadi et al., 2007; Feinstein, 1985; Kleinbaum et al., 1982), and an excellent summary with unrestricted access is provided by Delgado-Rodriguez and Llorca, 2004).

Selection bias occurs when the study population does not represent the target population. If this is nondifferential (i.e., occurs similarly among the exposed and unexposed), it will impact the generalizability of the results. For example, several population groups such as older persons, those with more comorbidities or concomitant drugs alongside the trial drug are often excluded from randomized controlled trials. Thus, the results of randomized controlled trials may have limited external validity or generalizability to a wider patient population (Kennedy-Martin et al., 2015). If the selection bias occurs only or more strongly among one exposure group, or is differential between outcomes, it can lead to an underestimation or overestimation of the association. For example, studies on drug safety during pregnancy are often restricted to live births only. When the drug is actually associated with higher risk of adverse fetal outcome, the observed association in a study restricted to live births is an underestimation, with the degree on underestimation depending on the rate of competing risks (i.e., stillbirth and miscarriage), and the presence of unmeasured confounders and their association with exposure, outcome and competing risks (Khoury et al., 1989; Suarez et al., 2018; Svensson et al., 2014). As data on fetal deaths is not always easily (or at all) available, and early miscarriages are underreported even if such data are available, one possible approach is to conduct selection bias analyses (Greenland, 1996).

Information bias occurs during data collection. One specific subtype is ecological fallacy, which means that data collected and analyzed on a group level are considered to represent actual association on an individual level. However, this subtype does not occur in studies with individual-level data. Other types of information bias, especially relevant in pharmacoepidemiology, include protopathic bias (as illustrated in the proton pump inhibitor and gastric cancer example by Tamim et al., 2007) and misclassification bias (Delgado-Rodriguez and Llorca, 2004). Misclassification bias can occur not only for exposure and outcome variables but also for confounders. The impact and direction of bias depend on the degree of misclassification and how much it differs between the exposure or outcome variables. Nondifferential misclassification occurs equally in between groups, and it often does not impact the point estimate but widens the confidence intervals, which can lead to interpreting the results erroneously as a null association. However, in specific circumstances, such as categorical variables or continuous exposure, the point estimate may also be affected (Dosemeci et al., 1990; Funk and Landi, 2014; Hutcheon et al., 2010), and the estimate may also be an overestimation (Dosemeci et al., 1990).

In pharmacoepidemiology, one possible mechanism for differential misclassification of outcomes by exposure status is the more active health-care use of those persons who are prescribed certain (or any) drugs. The prescription event itself requires contact with health-care professionals, and persons who are prescribed certain drugs may have different health-seeking behaviors or have more

contact with health-care professionals during their follow-up. Thus, they often have higher probability of being diagnosed. Similarly, in studies conducted with administrative databases, persons who do not have contact with health-care professionals will not have any evidence on their comorbidities. If this occurs similarly between groups, the association is biased toward the unadjusted association, while the impact of nondifferential misclassification depends on the strength of association between the confounder and exposure and outcome variable, as reviewed by Funk and Landi (2014).

Confounding occurs when a covariate is associated with exposure and outcome, but it is not on the causal pathway. Different methods for identifying confounders, including statistical testing (such as automatic or manual variable selection based on certain thresholds) and causal network analysis with directed acyclic graphs have been suggested. Approaches that solely rely on statistical tests have been criticized as they may lead to omission of important covariates, or unnecessary adjustment which may bias the association (Hernan et al., 2002). Using birth defects as an example, Hernan et al. illustrate the importance of a priori knowledge on the relationship between exposure, outcome, and covariable considered as a confounder (Hernan et al., 2002). If the covariable is a common cause of the exposure and outcome, or there is an unmeasured common cause for the exposure and outcome which is captured by the covariable, adjusting is correct and it decreases the bias. However, if the covariable is on the causal pathway, or the confounder and exposure or/and outcome have unmeasured common cause, the adjusted estimate is in fact biased. Thus, it is essential to consider which covariables should be adjusted for. Further, if the measured confounders do not adequately capture the actual confounding, it is important to assess the degree of residual confounding and its impact on the conclusions.

Conclusion

This chapter provided an overview to the main aspects of epidemiological studies, their strengths and challenges. More details on each of these aspects specifically related to pharmacoepidemiology are discussed in detail in several other chapters.

Sources of Data Used in Pharmacoepidemiology and Pharmacovigilance

Prasad S. Nishtala[*], **Sharmin S. Bala**[†], [*]Department of Pharmacy and Pharmacology, University of Bath, Bath, United Kingdom; [†]Department of Preventive and Social Medicine, University of Otago, Dunedin, New Zealand

Introduction

The utilization of automated/computerized databases for pharmacoepidemiological research in North America dates back to 1980, and focuses on capturing claims data for medical services and treatment (Strom, 2012). Nordic countries also have a long-standing history of utilizing aggregate drug utilization data for research, with pioneering studies conducted in the late 1960s and early 1970 (Wettermark et al., 2013). More recently, the Asian Pharmacoepidemiology Network (AsPEN Collaborators et al.) was formed to provide a mechanism to support the conduct of pharmacoepidemiological research in Asian populations (AsPEN Collaborators et al., 2013). Over the past two decades, there has been increased availability of data sources to conduct pharmacoepidemiology research internationally. These databases offer several advantages including large sample size, lower cost, increased generalizability, methodological flexibility, and with no requirement for direct patient recruitment (Harpe, 2009). These databases accrue patient-level health information over a vast period; which is not possible to assimilate through clinical trials that generally acquire specific information for a few thousand patients typically over 12–18 months (Harpe, 2009). Health databases provide an opportunity to examine populations that are often excluded from randomized controlled trials (RCTs), mainly the elderly, children, and women (Torre and Martins, 2012).

Population-based databases often do not necessarily imply the collection of data on a national level. Regional databases, databases capturing populations visiting general practitioners, or claims/insurance databases are also regarded as population-based databases. Solely hospital medical records (such as intensive care unit data) are not considered population-based since there is no underlying registered catchment population (i.e., a record of all the individuals not referred to a hospital). Furthermore, immunization/medication use/disease registries alone are not considered population-based databases if they cannot capture the population not being vaccinated/exposed/diseased. If the vaccination registries capture defined populations from birth to a specific date, including all vaccinated and unvaccinated subjects in that population, then it is considered population-based (Ferrajolo et al., 2012). It is preferable to include the population in the database which is representative of the general population from which it is drawn; however, at times, it may be beneficial to emphasize the more disadvantaged groups that may not have been involved in the premarketing phase studies, such as infants, children, and oldest-old adults.

An ideal database requires that all information can be easily linked through the patient's unique identifier, the records are updated on a regular basis, and that the records are verifiable and reliable; however no single database is ideal (Strom, 2012). A complete database should include records from both inpatient and outpatient care, emergency medical care, results of all laboratory and radiological tests, all prescribed and over-the-counter medications, as well as alternative therapies for each patient (Torre and Martins, 2012). The implementation of studies through databases necessitates a comprehensive understanding of the strengths and weaknesses of pharmacoepidemiology study designs, the procedure of data collection, enrollment and coverage factors, and similar other factors that could have affected data quality and validity. An understanding of the social, cultural, political, and historical settings of the population under study is also crucial. A lack of awareness of the limitations and failure to understand methodological challenges arising with the use of these databases could lead to the selection of inappropriate study designs, which would misinform

the results (Torre and Martins, 2012). In the current chapter, we will introduce these resources, presenting some of the general principles that apply to the databases utilized in pharmacoepidemiology and pharmacovigilance disciplines.

Once the research question and study design are delineated, an appropriate data source must be identified. Pharmacoepidemiology studies may involve data collected prospectively for the study (i.e., primary data), or data collected for some other purpose (i.e., secondary data). When choosing a data source, special deliberation must be given to the relative strengths and weaknesses of the particular data source available, and whether the selected database is appropriate to address the research question (Harpe et al., 2011).

Primary Data Sources

Primary data are data collected prospectively for the particular study (de novo data collection) (Torre and Martins, 2012). This data may be collected through questionnaires, interviews, or chart reviews. Primary data in general offer increased control over the type and amount of information that is available as compared to secondary data. If the information about specific medication-taking behavior is required, for example, for a medication to be taken with meals, the participant in a study that uses the primary data collection can be questioned. This information would most likely not be obtained through secondary data from prescription dispensing data provided by a pharmacy or routine data collections (Harpe et al., 2011). Case-control studies utilizing hospital or community-based primary data collection have evaluated drug-disease associations for rare complex conditions that require a large study population and in-depth assessment by medical practitioners. Typical examples are studies assessing the risk of Primary Pulmonary Hypertension with appetite-suppressant medications, conducted in France (Abenhaim et al., 1996); medications associated with the development of Stevens–Johnson Syndrome or Toxic Epidermal Necrolysis, primary data available from different countries in Europe (Roujeau et al., 1995); and medication etiology of agranulocytosis and aplastic anemia, with the study population from Israel and Europe (Shapiro, 1983). The limitations of primary data are the expenditure and time involved in investigating a progressive increase in sample size (Harpe et al., 2011). National surveys, registries are classified as primary data, and are discussed next.

National Collections and Surveysand

Internationally, a few countries support the use of national health data for research purposes, which can provide extensive information like the prevalence of smoking and other health- related risk factors, obesity among other health ailments, access to health care, etc. (Cox, 2016). In New Zealand (NZ), the Ministry of Health provides data to researchers via the General Medical Subsidy (GMS) Collection, Laboratory Collection, Mortality Collection, National Immunization Register, NZ Cancer Registry (NZCR), National Minimum Dataset (NMDS), National Maternity Collection (NMC), National Non-admitted Patient Collection (NNAP), Primary Health Organization (PHO) Enrolment Collection, National Patient Flow, Programme for the Integration Of Mental Health Datamart (PRIMHD), etc. The NMDS is a national archive of public and private hospital discharge information, which includes coded clinical data for inpatients and day care patients. The NZCR generates the data for incidences of cancer and survival studies, policy formulation, public health research, and for monitoring screening programs. The GMS claim provides information on subsidies paid to decrease consultation cost with general practitioners for children less than 15 years of age or subsidy/community card holders. NZ Medicines and Medical Devices Safety Authority (Medsafe) manage the medication and safety data. The Pharmaceutical Claims Collection maintains the dispensing data on medication claims for prescribed dispensing that are subsidized by PHARMAC. The PHO registers individual data for primary health care. The Laboratory Collection gathers information on laboratory test carried out in individuals. The NNAP maintains a record of non-institutionalized cases in healthcare facilities. The NMC supplies data on maternal deliveries. PRIMHD generates data on the mental health status of those accessing healthcare. Client Claims Processing System (CCPS) provides data which accounts for disability support events in community-dwelling older people (Nishtala et al., 2017). The National Health Interview Survey (NHIS) has monitored the health of the people of United States of America (USA) since 1957. NHIS data on a varied range of health topics are amassed through personal household interviews, the findings of which have been instrumental in providing data to track health status, healthcare access, and progress toward achieving national health objectives. The National Health and Nutrition Examination Survey is a series of studies intended to assess the health and nutritional status of adults and children in the United States, and it combines interviews and physical examinations. Likewise, in Canada, The Canadian Chronic Disease Surveillance System uses linked administrative data sources from every province and territory to estimate the incidence and prevalence of chronic conditions, and, use of health services and health outcomes (Blais et al., 2014). The Canadian Hospitals Injury Reporting and Prevention Program is a computerized information system that gathers and analyzes data on injuries, especially in children (Crain et al., 2016). The information from the Nord-Trøndelag Health Survey are probably the most complete screening data from Norway, and are especially suitable for epidemiologic studies on blood pressure, diabetes, quality of life, tuberculosis, and other lung diseases; along with data on cardiovascular diseases, lifestyle, disablement, work, and the working environment (Holmen et al., 1990). Some of the important national health surveys conducted in Asia are the National Family Health Survey, District Level Household Survey, and the Annual Health Survey (Dandona et al., 2016).

Registries

The National Committee on Vital and Health Statistics of USA describes registries in the field of medicine and public health as "an organized system that utilizes observational study methods to collect uniform data to evaluate specified outcomes for a population defined by a particular disease, condition or exposure, and that serves one or more predetermined clinical, scientific, or policy purposes." The term registry is defined both as the act of recording or registering and as the record or entry itself (Gliklich et al., 2014). In epidemiology, the term "register" is implied to the data concerning all cases of a particular disease or similar health-relevant condition in a defined population such that the cases can be related to a population base. Clinical registries gather a defined minimum dataset from individuals undergoing a particular procedure, diagnosed with a disease or utilizing any healthcare resource, and capture data systematically from existing administrative databases, medical records or directly from clinical staff using data collection forms (Hoque et al., 2016).

Appropriately designed and executed patient registries can provide a real-world view of clinical practice, medication safety practices, patient outcomes, and comparative effectiveness. Registries can be useful data sources, which can be viewed as a collection of patient records on a particular subject (Gliklich et al., 2014). Registries have been observed as complementary resources for the intention of supporting the requirements of risk management plans to systematically collect data from clinical practice (Hoque et al., 2016). Registries should be designed and evaluated according to their planned purposes in terms of patient outcomes as (1) describing the natural history of the disease, (2) determining clinical efficiency and/or cost-effectiveness, (3) assessing medication safety or adverse events, and (4) measuring or improving quality of care (Gliklich et al., 2014).

Disease registries comprise of patients who have or have had a disease or condition of interest. They include the population with a particular disease to be well characterized and establish an adverse event profile for different treatments. A disease registry is a tool used for tracking clinical care and outcomes of a defined patient population (Gliklich et al., 2014). Most disease registries support care management for groups of patients with one or more chronic diseases, such as asthma, diabetes, or coronary artery disease. The Finnish Medication and Alzheimer's disease (MEDALZ) study based on disease registries was utilized to investigate the changes in medication and healthcare service use among individuals with Alzheimer's disease and to evaluate the safety and effectiveness of the medications prescribed (Tolppanen et al., 2016). A retrospective cohort study conducted utilizing data from an ongoing General Practice based register study found a high prevalence of depression in patients diagnosed with Parkinson's disease (Leentjens et al., 2003). A case-control study of incident patients in Scotland using the Scottish Motor Neuron Disease Register was performed to identify risk factors for the subsequent development of motor neuron disease (Chancellor et al., 1993). Disease registries can also provide more flexibility for collecting and reporting data from multiple data sources. Although disease registries vary in the amount of information included about medication use, the data collection can be facilitated either by merging with another data source such as administrative claims data, or by survey or interview methods (Harpe et al., 2011). As many stakeholders have interests in diseases, conditions, and healthcare products and services worldwide, it is not surprising that the interest in global patient registries is growing. Product (drug) registries encompass patients exposed to a healthcare product (drug or device) and facilitate the study of drug utilization patterns, including, for example, off-label use. Pregnancy exposure registries focus on possible exposures during pregnancy and post-partum, and also include effects in the offspring (Gliklich et al., 2014).

When utilizing existing registries in pharmacoepidemiology research, it is important to observe the following factors which affect the value and validity of registries and databases: (1) the comprehensiveness of registration of all individuals under study and the registered data, (2) the size of the data source, (3) the registration period in order to relate the exposure and effect to possible induction and latent periods (induction period is the period required for a specific cause to manifest a disease, the latent period is the delay between the particular exposure and the period of manifestation of the disease), (4) data availability, accessibility, and expenses, (5) data format, and (6) the possibilities of linkage with other data sources (Sørensen et al., 2009). One of the major limitations in utilizing administrative registries for research is the data selection and quality, since the methodology of data collection is not according to the researcher's approach, but is predetermined, and sometimes impossible to validate. The validity may also vary between different settings, and validation studies are therefore essential when using registries as a data source (Sørensen et al., 2009). A study conducted in the Netherlands to validate incidence rates of various coronary syndromes by linkage to the "causes of death registry," and either the "hospital discharge registry" or the "cardiology information system" found incongruity in the data collected from the different sources (Merry et al., 2009). In a study directed to validate the Danish Cancer Registry concerning breast cancer, it was observed that data on the extent of disease and treatment were complete, valid, and reliable, but are too unspecified to be valuable in comparative studies (Jensen et al., 2002).

Registries assist in identification of cases for retrospective studies and clinical trials; improve patient management and record-keeping. Registries assist in evaluation and planning of healthcare services; generate insights into risk factors for adverse outcomes, document the effectiveness of therapies in real-world settings, provide insight into the nature of diseases and benefit of treatments in subgroups of patients, and generate comparative benchmark reports to stakeholders, including hospitals, funders, insurers, clinical staff, patients, and consumers (Hoque et al., 2016).

Clinical quality registries (CQRs), coined initially in Sweden, are described as clinical registries designed to improve the quality and safety of care. CQRs are described in their Health Act as "An automated and structured collection of personal data initiated with the purpose to systematically and continuously develop and safeguard quality of care." A national or regional Quality Registry permits comparisons within healthcare at a national or regional level in which personal data have been collected from several caregivers. CQRs help to identify variation in "best practice" treatments and outcomes across healthcare centers, and provide feedback on performances to stimulate quality improvement processes (Hoque et al., 2016).

Some commonly used registries in NZ include birth, death, marriage registries, maintained by the Ministry of Health. Tumor registries are government-supported agencies that amass complete statistics on the incidence, treatment, and outcome of cancer in defined geographic areas. The NZ Health Information System manages the NZ Cancer Registry. The Health Benefits Limited, administered through the Ministry of Health, was responsible for the procurement and supply-chain data before the introduction of the Pharmaceutical Management Agency Limited (PHARMAC). Death certificate registries can be utilized to follow the mortality of any cohort. Other prominent registries in NZ are the Virtual Diabetes Register, National Immunisation Register, National Cervical Screening Programme Register, and the Australian & NZ Hip Fracture Register (Nishtala et al., 2017).

Some patient registries are a branch of a broader research collaborative that connects individual registries to a more extensive network of registries that collect data for one or more conditions. This network provides a shared infrastructure and standardized data collection across registries. Data collected from each registry may be combined for analysis as researcher-generated or patient-powered research networks. The SEER registries, a collaboration of 19 registries created and supervised by the National Cancer Institute, are an example of a researcher-generated research network. The Genetic Alliance Registry and BioBank, a collaboration of more than 1200 individual disease advocacy organizations, are an example of a patient-generated research network (TA, 2013). The 45 and Up Study is a large-scale Australian cohort study of individuals aged 45 and over, randomly sampled from the Medicare Australia enrolment database, which provides researchers with reliable information on a wide range of exposures and outcomes of public health importance for the ageing population. This study is a valuable resource for the investigation of social and economic determinants of healthy ageing; health effects of obesity; overweight and physical activity; impact of environmental factors on healthy ageing; risk factors for, and the detection and management of cancer, cardiovascular disease and mental health problems; use of health services in relation to ageing, including the determinants of use of residential aged care; and health in people aged 80 years and over (45 and Up Study Collaborators, 2008).

Secondary Data

Secondary data comprise of pre-existing data collected for some other purpose, such as for a previous research question (e.g., clinical trial), or to facilitate some process (e.g., hospital discharge records, or claims). Although data from RCTs are not frequently used in pharmacoepidemiology, data from these studies can be used for secondary analyses. A secondary analysis was conducted by Reid et al. to examine the relationship between Pravastatin and bone fractures from the data of a study of the Long-Term Intervention with Pravastatin in Ischemic Disease (LIPID) trial, and found that there was insufficient evidence to support the hypothesis that statins can be protective against fractures. In the original trial, the patients were not recruited on the basis of being at an increased risk for fracture, since the goal of the LIPID trial was to examine the effects of pravastatin on cardiovascular mortality. The enrolled patients were at a relatively lower risk for osteoporotic fractures. The fact that the original aim of the RCT was not the focus of the secondary analysis is an important consideration when using data from previous RCTs for a new study. Secondary data are utilized to study varied aspects of pharmacoepidemiology and pharmacovigilance, including physician prescribing practices, drug utilization, medication adherence, unintended drug effects, and health policy issues (Harpe et al., 2011). Data gathered on patient encounters with the healthcare system are captured in an automated fashion, often electronically. These automated healthcare databases, or transactional databases, are a source of secondary data (Torre and Martins, 2012). All studies based on secondary data collection should be designed with the same critical approach as with studies based on primary data, i.e., specifying hypotheses, estimating sample size, and aiming at reducing both systematic bias and random errors (Sørensen et al., 2009). The primary limitation of secondary data is that the data are not collected for the specific purpose of answering the research question; thus, there may be specific validity challenges that must be considered (Harpe et al., 2011). Administrative data, claims data, electronic medical records can be grouped as secondary data.

Administrative Database

The provision of health care frequently generates digitalized data such as claims data, hospital-based electronic data, and medication prescription records, collectively termed as "administrative database research" (Nojiri, 2015). From a functional viewpoint, databases may be organized around a disease, a provider, a facility, or a sector of the healthcare system. A substantive orientation relates primarily to the type of information contained in the database, such as financial, demographic, or outcome data (Harpe, 2009). The functioning NZ administrative databases include Aotearoa NZ Health Tracker, EpiSurv records (maintained by the Institute of Environmental Science and Research), and NZ Deprivation (NZDep) dataset. The NZDep index is a composite deprivation score, extracted autonomously from census data, which compares socioeconomic positions of small area mesh-blocks among 60–110 individuals based on their location within a given period (Nishtala et al., 2017). It is essential to understand that administrative databases are fundamentally designed for billing and record-keeping purposes, and not primarily intended for research. Administrative databases generally identify endpoints such as cancer, dementia, myocardial infarction, or fracture, since healthcare provision is becoming increasingly digitized. The patient diagnoses, medical procedures, outcomes of visits to emergency departments, and hospital admissions are documented in hospital databases. Each of these systems leaves a trail of digital information describing a patient's course through a healthcare system (Van Walraven and Austin, 2012; Torre and Martins, 2012). Another major disadvantage of administrative data is the non-permanent residence of the population due to migration, and changes in coverage for specific employees and their family members.

Claims Databases

Claims data provide some of the best data on the prescription of medications in pharmacoepidemiology, and arise from an individual's utilization of the facilities at the healthcare system (Strom, 2012). When a patient visits a pharmacy and a medication is dispensed, the pharmacy charges the insurance carrier the cost of that medication along with complete medication details. Similarly, if a patient visits a hospital or a physician for medical care, the providers of care charge the cost of the treatment to the insurance company, and have to justify the expenses with a diagnosis. One of the frequently used and accurate measurement of exposure to medications is outpatient claims prescription/pharmacy records because the pharmacy has to identify which medications were dispensed and all its attributes (milligrams per tablet, number of tablets, etc.) (Torre and Martins, 2012). If there is a common patient identification number for the claims of the pharmacy and medical care, these elements could be linked and analyzed as a longitudinal medical record. Since the medical claims affect reimbursement, and the filing of an incorrect claim for medications dispensed is fraud, claims are often closely audited, e.g., by Medicaid in the USA. There have also been multiple validity checks on medication data in claims files that proved that the data are of extremely high quality, i.e., confirming that the patient was dispensed the same what the claim showed, according to the pharmacy record (Strom, 2012). In processing these claims, healthcare systems generate and store large amounts of data detailing the services provided and the level of payment for those services. To support the processing of these claims, supplementary information such as medical diagnoses may also be submitted along with claim forms. Also, health plans also maintain the necessary demographic information of individuals. The combined information can serve as a useful tool for research purposes (Harpe, 2009).

The quality of data for diagnosis in claims databases is not perfect. The hospital bills an admitted patient for the therapy and justifies it by assigning the International Classification of Diseases-Tenth Revision-Clinical Modification (ICD-10-CM) codes and a Diagnosis Related Group (DRG). The amount reimbursed by the insurer to the hospital is based on the DRG, so there is no motive to provide incorrect ICD-10-CM codes (Strom, 2012). The ICD-10-CM codes, based primarily on the discharge diagnoses assigned by the patient's attending physician are moderately accurate (Strom, 2012). Trained clinical coders have designated the task to code the diagnosis for reimbursement, and inpatient diagnoses are scrutinized for errors (Strom, 2012). Similar to the diagnosis codes, medications are also assigned codes in secondary databases. There is a clear need for a standardized classification system for medications. Whenever an insured individual switches jobs, migrates to another place, or if the employer modifies health plans in the case of employer-sponsored insurance, claims for that individual (and for others associated with the covered individual) will no longer be captured. To tide over this challenge, eligibility data are used to identify individuals who are continuously eligible for benefits during the course of the study; without which the data may appear as the discontinuation of drugs or the resolution of a medical condition when in reality the individual is no longer covered by the same health plan. In the outpatient departments (OPD), the practitioners themselves affirm outpatient diagnoses. The reimbursement in OPD not only depends on the actual diagnosis but also on the procedures undertaken, and the procedure codes point to the intensity of the services provided. Hence, there is neither any incentive for the practitioner to provide incorrect ICD-10-CM diagnosis codes nor any incentive to be particularly careful about the diagnosis provided. Therefore, the outpatient diagnoses are one of the weakest links in claims databases.

In NZ, the Pharmaceutical Collection is a data warehouse to support the management of pharmaceutical subsidies. It comprises of claims and payment information from pharmacists for subsidized dispensing (Nishtala et al., 2017). Few databases are not composed of actual claims, but are derived from other administrative processes, e.g., data from the US Health Maintenance Organizations. The data are almost similar to those of claims data (Strom, 2012). Claims data include a variety of healthcare services, including OPD visits, inpatient hospitalizations, prescription drug events, and durable medical equipment. It is important to know that different types of claims are not repeated in the same database; e.g., a pharmacy benefits manager may process pharmacy claims separately from the rest of the medical claims (Harpe et al., 2011). A study utilized the data from the Australian Department of Veterans' Affairs claims database to assess if the number of comorbid conditions unrelated to diabetes was associated with a delay in therapeutic progression of treatment of diabetes in Australian veterans (Vitry et al., 2010).

Primary Care Electronic Health and Medical Records

An Electronic Health Record (EHR) (Masnoon et al., 2018) is defined as a longitudinal digital record of patient health information generated by one or more encounters in a healthcare setting. EHRs facilitate a patient-centric design providing a 360-degree view of their health and wellness, and support patient tracking, administration, and scheduling of a range of care-related activities (Deloitte, 2015). The EHR also includes data from patient portals or external laboratories and can be shared beyond the practice site (Murray, 2014). The NZ Ministry of Health is working toward the implementation of a National EHR, which implies that patients wouldn't need to repeat their health history whenever they visited a new clinician, or risk missing out important medical details when being consulted; healthcare providers would have access to information from other health professionals their patients were seeing; policy and service planners would be able to utilize data and information to make investment decisions, target public health initiatives and monitor the effectiveness of programs (Ministry of Health, 2017). Data from EHRs are progressively seen as a crucial aspect to the future of pharmacoepidemiology, pharmacovigilance, and clinical research requiring similar observational clinical data (Murray, 2014). The European research initiative EHR4CR has been instrumental in designing many innovative services to support federated clinical research based on the semantic integration of numerous EHR systems across various organizations and nations (Coorevits et al., 2013). The observation of a systematic review and a meta-analysis is that the use of computerized provider

order entry (CPOE) incorporated in EHRs in hospitals, along with clinical decision support, which alerts clinicians to laboratory and medical errors, significantly reduced adverse drug events and prescription errors (Charles et al., 2014; Nuckols et al., 2014). Lyons et al. observed that the incorporation of the CPOE in EHR was a significant predictor of shorter hospital stay and lower mortality (Lyons et al., 2017).

By contrast, EMR is a digital version of paper charts in a medical practitioner's field of work. The EMR is more specific and narrow in scope, focusing on episodic healthcare events. It is designed to support interactions within a setting (e.g., primary care or hospital) or for a particular type of professional (e.g., pediatric/geriatric specialist). EMRs are medical records that act as a repository of patient information and support resourceful capture and access to information. EMRs provide administration functionality and basic connectivity to enable tracking of patients, exchange of information and assist the delivery of care by providing decision support capabilities (Deloitte, 2015). The data obtained from EMRs is ubiquitous, increasingly used for research in pharmacoepidemiology, and is significantly efficient over manual chart reviews. EMRs offer a higher level of detail compared to administrative claims or patient/provider questionnaires. As the EMR is based on real-time data, there is minimum latency period between the generation of data and its availability for research, which can be compared to the three to six month lag time for most administrative claims-based research data sources or national surveys. One drawback of the EMR is the lack of standardization of these databases, since each EMR vendor may use different formats (Harpe et al., 2011). There may not be entries of laboratory reports, progress notes, quality of life measurements, and information on health beliefs or health behaviors in EMRs (Harpe, 2009). The data contained in EMRs are typically complex, given the longitudinal nature and volume of information included, and can be challenging for conducting statistical analysis. Electronic medical records data are recorded as a procedure of clinical patient care, and not specifically for research purposes. The information from one institution (i.e., a single-site study) can be a limitation. Multisite sources can be advantageous in terms of sample size, but there may be problems with data consistency because documentation practices and implemented functions may vary across the participating sites. Although this may not be significant when analyzing data from one institution, it can be problematic when gathering data from multiple institutions that use different EMR vendors. The coding practices of the providers can also be an important consideration (Harpe et al., 2011). The significant limitations of automated databases are related to the quality of data input and the validity of the diagnostic information contained in the database. Training a future workforce to analyze large electronic databases is critical. While the costs of training and equipping the new cadre of big data analysts will be substantial, the missed opportunity of not doing so will likely incur higher costs (Murray, 2014). Despite their availability, a few practitioners may be reluctant to use these databases because they lack familiarity with database research in general (Harpe, 2009).

Electronic databases are a good source of information to lay the foundation for post-marketing research. A system of cross-linked digital medical records may enable researchers and physicians to monitor post-marketing safety and incorporate monitoring benefits. The same research could also illuminate the net public health effect of regulatory decisions (Herings, 2014). The General Practice Research Database (GPRD) in the UK, considered the world's best database of anonymized longitudinal medical records from primary care, has population-based data with over 15 million patients and has been extensively used for published research in the field of pharmacoepidemiology. Seminal observational studies have been conducted using the GPRD database. The GPRD database was recently used to find the differences in types of pregnancy loss following the potential exposure to a statin just before or early in pregnancy (McGrogan et al., 2017). A case-control study utilizing the GPRD found an association between olanzapine, risperidone, and the probability of incident diabetes (Strom, 2012; Torre and Martins, 2012). The association of pioglitazone with an increased risk of bladder cancer in patients with type 2 diabetes was also found using the GPRD database (Wei et al., 2013).

More recently, the electronic medical record databases are being used on a large scale, often replacing paper medical records as the primary document. This facilitates the large data collection for pharmacoepidemiological studies. The validity of the diagnosis data in these databases is better than that in claims databases, as the data are being used for medical care, and not solely for insurance reimbursement purposes. The database is comprehensive, as different medical practitioners can access the complete medical history of the patients (Torre and Martins, 2012). There is no considerable cost of data collection, other than for those subsets of the population for whom medical records are abstracted and/or interviews are conducted. In addition, electronic databases also enhance the representativeness of research by covering the entire population of a region. Moreover, the large sample size permits the study of prescription patterns of medications that are infrequently used, and lists their uncommon effects. Another advantage of digital databases is that they can demonstrate precise drug dispensing patterns, and there is no opportunity for recall and interviewer bias (as they do not rely on patient recall or interviewers to obtain their data). Also, these databases can potentially be linked to external electronic databases (e.g., birth and mortality records, claims), via a unique identification number to enhance the capabilities and scope of research. These databases are useful: (1) for examining rare outcomes because they offer a large sample size; (2) contain a denominator to calculate incidence rates (Sink et al., 2008); (3) when short -term effects of medications are being studied; (4) when objective, laboratory-driven diagnoses are being studied; (5) when recall or interviewer bias could influence the association; (6) when there is limited time; and (7) restricted budget (Strom, 2012).

One of the prime functions of the United States Food Drug Association (FDA) is to monitor the safety of its regulated products with a view to protect public health. The Sentinel initiative is the FDA's national electronic system which has transformed the way researchers monitor the safety of FDA-regulated medicinal products, including drugs, vaccines, biologics, and medical devices. Sentinel augments monitoring the safety of medicinal products in the pharmacovigilance phase, and complements the existing Adverse Event Reporting System. Through this efficient system, the FDA can rapidly and securely access large resources of electronic healthcare data, such as EHR, insurance claims data and registries, or from a diverse group of data partners. Sentinel utilizes a

distributed data approach which permits the FDA to monitor the safety of regulated medicinal products, while securing and safeguarding patient privacy (FDA, 2018).

Other Transactional and Operational Data

Transactional or operational data refers to data that is collected as a result of activities that support the provision of a service, such as medical care. The administrative claims data previously discussed represent a specific subset of transactional data that arise from the submission of healthcare claims for reimbursement. Information is collected about various "transactions" that occur during healthcare encounters, of which some information, like medication dispensing or laboratory results, may not be required for reimbursement, but could be useful for research purposes. Amassing and consolidating data from separate administrative sources such as pharmacy, laboratory, diagnosis, and patient demographic data, into one data warehouse can be tedious, but is often necessary to conduct meaningful research, clinical decision support, and utilization review. Transactional data can also be found outside of healthcare systems. For example, uninsured patients or patients paying cash are generally not represented in pharmacy claims data, for whom the information on dispensing of prescription medications and sales of medical products could be obtained from a pharmacy or a group of pharmacies in a specific area. Also, sales data have been utilized as a method of syndromic surveillance to predict disease outbreaks (Harpe et al., 2011).

Other Data Sources

There are various other sources of data employed in pharmacoepidemiology that do not correspond to any of the previous categories. Results of laboratory tests contained in laboratory collections may be used as surrogates to monitor the outcome of interest; e.g., a reduction in the low-density lipoprotein cholesterol and glycated haemoglobin (HbA1c) are surrogate measures for effectiveness of high cholesterol treatment and diabetes respectively. The laboratory results are more frequently recorded in electronic medical records, whereas administrative claims data usually only provide information about whether a laboratory test was ordered or not and not typically its results unless both the sources are correctly linked.

Data Structure and Linkage

The process of identifying subjects across databases and consolidating their information is called data linkage; e.g., in different sets of medical charts, and in vital records such as birth and death certificates. Studies linking national health records with health survey data are known as data linkage studies (Torre and Martins, 2012). For example, a data linkage study utilizing the Australian Medicare system linked to the Australian Cancer Database and the National Death Index observed an increased incidence of cancer in children, after CT scan exposure (Mathews et al., 2013). A record-linked dataset of all hospital day cases and inpatient admissions in England was utilized to study the association of Klinefelter's syndrome and autoimmune diseases (Seminog et al., 2015). The Veterans Affairs (VA) Diabetes Epidemiology Cohort, a linked national database of all VA patients, with data from VA medical visits, Medicare claims, pharmacy and laboratory records, and patient surveys were utilized to optimize methods for identifying individuals with diabetes, and to obtain the best estimates of diabetes prevalence in the patients of the Department of Veterans Affairs, USA. Linkage could be conducted among distinct data sources or within a single dataset to identify multiple entries (e.g., re-admissions) for an individual. Studies dependent on linkage data may yield biased findings due to errors in data linkage, which relate to specific characteristics of patients and clinical settings. To overcome this, characteristics of unmatched records and a degree of the quality of linkages, like the rates of false positives and false negatives, need to be regularly measured and reported; potential bias in study results needs to be assessed on a case-by-case basis.

The promise for the significance of real-world evidence using databases in the medical field must be balanced against concerns related to observational inherited limitations for bias and confounding. The risk of biased results can be minimized by providing a robust description of the data tables used, with information on why and how they were created; calculating and reporting the accuracy of diagnostic and procedural codes used, and accounting for any time-dependent nature of variables. The hallmark of good research is meticulously vigilant analysis and interpretation (Nojiri, 2015).

Summary of Data Sources Used in Pharmacoepidemiology and Pharmacovigilance

Primary data	*Secondary data*
National surveys	Administrative database
Registries	Claims database
	Electronic medical records

Conclusion and Future Opportunities

Researchers and medical practitioners have always been intrigued by how the future of databases in pharmacoepidemiology will progress. In the last decade, computerized databases based on administrative claims data, medical records, or disease-based registries have rapidly implemented worldwide. Vast amounts of healthcare data will be generated, including data sourced from electronic decision-support systems.

"Big data" has become a buzz-word in healthcare, where the term mainly refers to the enormous and expanding volumes of automated medical information available in the form of electronic health records, administrative or health claims data, or disease and medication monitoring registries. This type of data has been customarily gathered during administrative processes and clinical practice by different healthcare professionals for a long time without its significance being fully recognized and leveraged. Today, big data has a significant role in healthcare, including in pharmacovigilance, which comprises signal detection, substantiation and validation of medication or vaccine safety signals. The practicality of big data in healthcare is increasingly being recognized and seen as an opportunity to transform huge mounds of routinely collected data into scientific evidence. The progressive use of healthcare database networks has resulted in an expanded range of analytic methodologies to harness the large volumes of heterogeneous data.

The EU-ADR European project includes innovative pharmacovigilance research methods through the application of a web platform for providing advanced medication data exploration and assessment features. Millions of EHRs can be mined for specific drug-events. Advanced distributed computing methods are tailored for coordinating the execution of data-mining and statistical analysis tasks, which allows a ranked drug-event list, eliminating spurious entries and highlighting the relationships with high- risk potential (Oliveira et al., 2013).

In conclusion, the availability of healthcare data from several sources and the increasingly robust statistical tools to analyze such data are an opportunity to study medication utilization and safety on ever wider scales and in greater detail. Frequently used "big data" sources like the medical records, health insurance claims, and linked medication or disease registries should not be considered in isolation, but as part of a more comprehensive data context along with complementary methods and other data sources, such as spontaneous reporting systems and social media. The combined use of the variety of databases in a distributed database network enhances the power and potential of medication utilization and safety studies.

Special Population Studies to Inform Medication Safety—Pediatrics

Minji Sohn, Ferris State University College of Pharmacy, Big Rapids, MI, USA

Introduction

The history of including children in clinical trials is relatively short. Until recently, children were rarely included in the clinical trials mainly due to ethical concerns. More specifically, children are often considered as lacking decision-making ability, and alternatively, their parents or legal guardians represent children's interest. However, subject's autonomy can be potentially threatened when parents give consent while children refuse to participate in the research or vice versa. Meanwhile, there are questions about whether children are capable of comprehending risks and benefits associated with the research and protecting their well-being (Nijhawan et al., 2013). Regardless, research involving children deals with unique challenges to the informed consent process. In addition, the pediatric population represents a wide spectrum of different physiologies, ranging from the preterm newborn infant to the adolescent. During the process of maturation and growth, dynamic changes occur in body proportions and composition, which have a substantial impact on efficacy and toxicity of medicines. Therefore, it is necessary to stratify pediatric patient population into subcategories based on their developmental stage, in order to accurately determine dosage regimens of medicines given to children. As a result, securing the sufficient sample size to preserve statistical power, the lack of age-specific efficacy and safety assessments, and difficulties in identifying clinically feasible end points and appropriate comparators add the complexity of pediatric research (Sampson et al., 2012).

These limitations result in the lack of evidence in pediatric treatments, particularly concerning off-label prescriptions (i.e., unlicensed use of drugs) and suboptimal dosing. Due to challenges in pediatric clinical trials, a number of widely used drugs do not have pediatric labeling. Health-care providers must rely on studies conducted in adults, by extrapolating data from those and applying it to children. In fact, a systematic review study conducted by Cuzzolin et al. showed that 23%–60% of children in different practice settings across different countries are prescribed drugs off-label (Cuzzolin et al., 2006). However, these extrapolations create an environment with a higher risk of drug toxicity and unknown adverse side effects in children. Children are not small adults, and pharmacokinetic profiles of many drugs are not the same between the two populations. Another concern surrounding pediatric medication treatments is related to family self-medication, which is defined as the practice in which a family member (often a parent) selects and administers medicines to their child based on their judgment without consulting health-care professionals. As the World Health Organization (WHO) reported, over-the-counter, traditional and herbal medicines that are readily available are often inappropriately used in children (World Health Organization, 2007). This is in part because medicines are often distributed through unofficial and unregistered routes in many low-income countries. As a result, children may be given medicine without consulting any health-care professionals.

Shirkey, in 1968, used the term, "therapeutic orphans" to describe pediatric patients and the dilemma regarding pediatric drug labeling (Shirkey, 1968). More specifically, it is to reflect the moral and ethical dilemma in which children subjects are excluded from clinical trials to minimize potential harm imposed on them, while this effort will result in the inevitable application of a double standard between adult and child in treatment practice. The standards of drug efficacy and safety cannot be applied equally to both children and adults because they are different with respect to pharmacokinetics and pharmacodynamics. For example, most drugs that are primarily excreted through a renal system are eliminated at a faster rate in children between the ages of 2 and 12 years than adults (age > 18). Moreover, differences in size and perfusion of organs between children and adults influence a drug's behavior in

the body (Ginsberg et al., 2002). For example, levetiracetam, an antiepileptic drug, was shown to have a 30%–40% faster rate of clearance and a shorter half-life in 6–12-year-old patients than in adults. As such, the maintenance dose of levetiracetam in children should be 30%–40% higher than the recommended dose in adults (Pellock et al., 2001).

This chapter provides an overview of regulatory interventions in pediatric research and its impact on pediatric drug use and pharmacovigilance systems. Also, drug safety considerations related to pediatric subpopulations including pregnant women and neonates are summarized. Then, drug categories of antimicrobials and psychotropic medications in the context of prescribing practice and drug safety in pediatrics are reviewed. The chapter will focus on antimicrobials and psychotropic medications because it is reported by the International Society of Pharmacoepidemiology (ISPE) Pediatric Special Interest (PSI) Group that psychiatry/mental health and infectious disease are the areas of the most pressing clinical questions that need to addressed by pediatric pharmacoepidemiology and pharmacovigilance studies (Lasky et al., 2016). Lastly, this chapter discusses current needs in pharmacovigilance methods in pediatrics.

Legislative History of Pediatric Drug Use

Background

Pediatric pharmacovigilance and pharmacoepidemiology have stemmed from public demand for regulatory scrutiny, in response to some of the unexpected adverse side effects that primarily affected children, such as the "thalidomide disaster." During the late 1950s, a number of pregnant women used thalidomide to alleviate their morning sickness and nausea. However, within a few years of the widespread use, it became clear that thalidomide caused birth defects in children of those who used the drug. Australian physician William McBridge wrote to the *Lancet* to report the increased deformities in babies born from thalidomide users at his hospital (Mcbride, 1961). The most common forms of birth defects included phocomelia (i.e., malformations of limbs), congenital heart disease, and other congenital defects affecting the ear and eye (Miller and Strömland, 1999). This tragic incident that affected more than 10,000 babies spurred governments to adopt standards to evaluate the risk of new pharmaceutical agents and regulate commercial advertisements.

Aspirin-induced Reye's syndrome in children is another case that fostered the demand for more regulated assessments and monitoring of adverse drug reactions (ADRs) before and after a drug is marketed. Pharmacoepidemiological studies were conducted to identify adverse side effects that are specific to pediatric patients who use aspirin. Hurwitz et al. conducted a case–control study to assess the possible association between Reye's syndrome and salicylates (Hurwitz et al., 1987). They identified 27 patients with the confirmed diagnosis of Reye's syndrome and matched them with controls based on age, race, and type and timing of onset antecedent illness such as chicken-pox, respiratory illness, or gastrointestinal illness. As a result, a strong association was observed between salicylates and the presence of Reye's syndrome (odds ratio 40, lower 95% confidence limit 5.8).

In the history of regulations specific to pediatric drug use, the Best Pharmaceuticals for Children Act (BPCA) and the Pediatric Research Equity Act (PREA) of the United States (US) in early 2000s, and the Paediatric Regulation of the European Union (EU) in 2007 played an essential role to promote pediatric drug labeling and evidence-based practice in treating children.

The United States

The BPCA intends to improve drug labeling for pediatric population in two pathways. First, for drugs that are still on patent, it provides an incentive for drug manufacturers to conduct pediatric studies by offering an additional 6 months of patent protection and market exclusivity. This 6-month extension is not limited to the drug that was studied in pediatric populations but applied to any of the manufacturer's formulations that have the same active drug ingredient. Second, for drugs that are off-patent, the US National Institutes of Health (NIH) would prioritize therapeutic areas in which on- and off-patent drug products should be further studied in children and fund pediatric clinical trials and pharmacoepidemiological studies in those areas.

Under the PREA, drug manufacturers are required to submit pediatric studies during the new drug approval process if the Food and Drug Administration (FDA) determines that the drug is expected to be used by a number of children and that there is insufficient information available to ensure the safety and effectiveness if used in children.

Europe

Partly inspired by these legislative developments in the United States, the EU enacted the Paediatric Regulation in 2007. The Paediatric Regulation mandates drug manufacturers to establish a pediatric research and development program, the Paediatric Investigation Plan (PIP), for drugs that are on a patent or under the new drug authorization process. Unless a drug is subject to a deferral or waiver, the drug manufacturer is obligated to describe their plan to measure pediatric health outcomes of the drug. As an incentive, if the manufacturer complies with the regulation, they receive a 6-month extension of the patent protection and market exclusivity. On the other hand, if the manufacturer fails to comply with the regulation, the new drug may not be authorized by the European Medicines Agency (EMA) or the respective (adult) marketing authorization may be canceled. For older off-patent drugs, the Paediatric Use Marketing Authorisation (PUMA) was implemented to promote pediatric research in which indications and appropriate formulations of medicines are exclusively developed for use in children.

The Impact of Regulation on Pediatric Medicine

Generally, it is considered that government regulations have made progress in the practice of pediatric medicine. Some of the progress includes better detection of adverse side effects, more appropriate drug dosing and formulations for children, and the development of new treatments for children. For example, in 2003, the drug manufacturer of paroxetine, GlaxoSmithKline, alerted the FDA with a potential risk of suicidal ideation and behavior in paroxetine-treated pediatric patients. Based on that report, the FDA requested several other drug manufacturers of similar antidepressants including selective serotonin reuptake inhibitors (SSRIs) to search for suicide-related adverse events in their antidepressant databases and share patient-level data with the FDA. The FDA derived data from 4582 patients in 24 trials and conducted a meta-analysis to estimate the overall risk of suicidality associated with antidepressants (Hammad et al., 2006). As a result, it was estimated that the overall risk ratio for all antidepressants across all indications was 1.95 (95% Confidence Interval, 95% CI, 1.28–2.98). The overall risk ratio for SSRIs (e.g., paroxetine) was 1.66 (95% CI 1.02–2.68). The overall risk difference for all antidepressants across all indications was 0.02 (95% CI 0.01–0.03). The result indicated a statistically significant and positive association between the use of antidepressants in pediatric patients and a risk of suicidality. In 2004, the FDA issued black box warnings indicating that antidepressants are associated with an increased risk of suicidal thinking and behavior in children. In addition to the ADR of antidepressants, potential ADRs of several other drugs used in children were identified during the postmarketing reviews under regulations; neuropsychiatric symptoms including delirium and confusion associated with oseltamivir; neonatal syndrome associated with SSRI; cardiovascular risks associated with attention-deficit/hyperactivity disorder (ADHD) medicines; and deaths associated with accidental exposure to opioid transdermal system.

Pediatric Subpopulations

Pregnant Women

It has been reported in recent studies that prescription drug use during pregnancy is quite prevalent across different therapeutic categories (Daw et al., 2011; Lupattelli et al., 2014). Moreover, it is anticipated that the rate of drug use during the pregnancy would increase as the number of women having children in older age (childbearing age >35) increases (Mathews and Hamilton, 2014). It is because older women are more likely to have preexisting health problems than younger women. Unintentional exposure to medication may occur when the mother does not realize her pregnancy. Medication use during the pregnancy is an important challenge since it affects both the mother and child. While several drugs were shown to be harmful to the fetus, pharmacotherapy may be necessary in some cases if the mother's untreated acute or chronic illness causes adverse effects on the patient and further affect the child as a result. However, data and evidence to help determine drug and dosage regimen during pregnancy are limited. Only a few studies have assessed the mechanism of drug action and pharmacokinetics pertaining to physiological changes during pregnancy and whether the drug crosses the placenta (Mazer-Amirshahi et al., 2014).

Extensive nausea and vomiting during the pregnancy can decrease the drug absorption substantially. Even though some pregnant women do not have such problems, they still undergo changes in maternal weight, total body fat, total body water, gastric volume, bile content and excretion, and gastrointestinal motility (Abduljalil et al., 2012; Zhao et al., 2014). Liver and kidney are also affected by pregnancy. The activity of some metabolic enzymes such as cytochrome P450 (CYP) 3A4, CYP2D6, and CYP2C9 changes during the pregnancy and alters the rate and extent of drug metabolism in patients (Anderson, 2005; Anderson and Carr, 2009). For example, codeine is metabolized by CYP 2D6, and this enzyme is induced during pregnancy. This increases the rate of codeine metabolism in patients and could result in drug overdose (Lam et al., 2014). Changes in glomerular filtration rate (GFR), creatinine clearance, and renal blood supply during pregnancy may expedite the elimination of drugs that are excreted through the renal system (Hebert et al., 2005). In addition, some individual factors such as gestational age, singleton vs. multiple gestations, the history of alcohol consumption, and tobacco use can affect the pharmacokinetic action of a drug (Zhao et al., 2014).

Another important implication of medication use during pregnancy is related to the differential interaction between a drug and fetal development in each trimester. It is because the physiological changes progress over the course of pregnancy. With the increased maternal and placental blood flow during the third trimester, drugs may transfer across the placenta at a faster rate than the first or second trimester. For example, a recent Danish study involving more than 64,000 children reported that children whose mother took acetaminophen during the second and third trimesters were at a higher risk of ADHD-like behavioral problems or hyperkinetic disorders. However, the risk was not significant for women who used the drug only during the first trimester (Liew et al., 2014). Another example of differential interaction between a drug and fetal development is nonsteroidal anti-inflammatory drugs (NSAIDs) and the risk of miscarriage and malformations. If used in the first trimester, NSAIDs are associated with an increased risk of miscarriage and malformations. Contrarily, if used after 30 weeks' of gestation, they are associated with an increased risk of premature closure of fetal ductus arteriosus and oligohydramnios (Antonucci et al., 2012).

Currently, the most well-known pregnancy risk classification systems are from Sweden, Australia, and the United States. These systems categorize medications to risk groups based on the fetal risk (Schaefer et al., 2015). Although they provide a great value when consulting drug use during pregnancy, pharmacologic effects of many drugs are still unknown. The FDA and EMA recommend pharmaceutical companies to establish pregnancy exposure registries for products that may be used during pregnancy (European Medicines Agency, 2005; Food and Drug Administration, 2002) to promote pregnancy labeling and clinical trials in pregnant women. A pregnancy registry is a program that enrolls a group of pregnant women and collects data on medicine exposure and other factors associated with different pregnancy outcomes (e.g., spontaneous abortions, elective terminations, fetal deaths/stillbirths, and

live births). This type of registry can be very valuable when examining major teratogenicity and detect adverse pregnancy outcomes that warrant further investigation.

Neonates

Neonates are a pediatric subpopulation that places unique challenges to pharmacotherapy. First, it is difficult to appropriately dose medications during the neonatal period, because neonates experience rapid physiological changes that affect pharmacokinetics. Second, due to lack of available dosage forms and drug delivery systems that are specifically designed for neonates, adult formulations are often diluted and administered in small volumes over a period of time. Such practice is prone to administration errors (e.g., errors in dosage calculation and dilution), especially in an intensive care or emergency situation (Rosati and Nahata, 1983). Third, due to the inability of patients to describe a reaction to a medication, some health outcomes may be unintentionally overlooked during the medical decision-making process.

Growth and maturation are the major factors that predict pharmacokinetics and they must be taken into account when determining proper therapeutic dosage for neonates. The levels of growth and maturation are quantified by birth weight, current weight, and age (postnatal, gestational, or postmenstrual age). Disease characteristics, critical illness, specialized therapies, and the expression of organ-specific transporters may further interfer with the variability of maturation in this patient population (Allegaert and van den Anker, 2015; Ku and Smith, 2015).

Currently, insufficient data exist regarding benefits and risks of a pharmacotherapy for neonates. The lack of published drug information and drug labeling resulted in an off-label or unlicensed use of medicine (Allegaert and van den Anker, 2015; Kemper et al., 2011). It was also reported that neonates are commonly exposed to polypharmacy (i.e., multiple medicine use) (Clark et al., 2006). Most likely contributed to such controversial medical practices prevailing in neonatal care, it appears that medical errors and adverse events occur frequently in neonates and infants. In fact, in a cross-sectional study on neonatal intensive care unit (NICU), medical error reports in 54 health-care facilities (n = 1256), approximately 47% of medication errors were due to wrong medication, dose, schedule, or infusion rate (Suresh et al., 2004). Other medical error categories included: error in administration or method of using a treatment (14%); patient misidentification (11%); other system failure (9%); error or delay in diagnosis (7%); and error in the performance of an operation, procedure, or test (4%). Importantly, out of 673 reports in which clinical outcomes of the medical error were reported, 181 (27%) resulted in actual harm. Another study on NICU medication error reports (n = 6749) revealed that approximately 48.2% of all medication error reports were contributed to administering errors (Stavroudis et al., 2010). Other categories included errors involving the transcription phase (18.4%); mistakes in the prescribing phase (14%); mistakes in the dispensing phase (11.9%); and monitoring errors (1.4%). In this study, 4% of reported medication errors resulted in harm.

In the literature, one of the most extensively discussed ADRs in neonatal care is related to the treatment of patent ductus arteriosus (PDA) using NSAIDs. In approximately 70% of preterm infants weighing less than 1000 g and 29 weeks of gestational age, the functional and anatomical closure of the ductus is delayed or does not occur (Bancalari et al., 2005). The PDA can be effectively treated with indomethacin or ibuprofen. Meanwhile, the debate of which NSAID agent is safer goes back to 1970s when indomethacin was initially introduced as the drug of choice for the PDA treatment. Although it was effective for closing ductus arteriosus, neonates who were treated with indomethacin showed severe adverse reactions including a decrease in cerebral blood flow and oxygen consumption (Edwards et al., 1990; McCormick et al., 1993), permanent renal dysfunction (Betkerur et al., 1981), and necrotizing enterocolitis (Cassady et al., 1989). As the alternative to indomethacin, ibuprofen was suggested as it appeared as a safer agent (Van Overmeire et al., 2000). However, other serious adverse side effects associated with ibuprofen were soon reported. These include pulmonary hypertension (Adamska et al., 2005; Gournay et al., 2002) and renal dysfunction (Allegaert et al., 2005). Regarding the treatment of PDA using ibuprofen and indomethacin, Ohlsson et al. published a review in the Cochrane Library in 2008 (Ohlsson et al., 2008). They stated, "In view of the lack of long-term outcome data and potential side effects for both drugs, one drug cannot be recommended over the other as the therapy of choice for a PDA." However, later in the 2010 update of the review (Ohlsson et al., 2010), they found a significant reduction in the risk of necrotizing enterocolitis in the ibuprofen group compared to the indomethacin group. With this finding, they stated, "Based on the currently available information, ibuprofen does appear to confer net benefits over indomethacin for the treatment of a PDA." This conclusion remains in their most recently updated review in 2015 (Ohlsson et al., 2015).

Issues in Pharmacovigilance of Specific Drug Categories

Antimicrobials

Children experience bacterial and viral infections more frequently than adults because the immune system is not fully developed in childhood (Gebel et al., 2008). Also, a growing number of children are exposed to environments in which microorganisms are more easily transmitted from person to person, such as group child care (Bradley and Vandell, 2007). More specifically, sociocultural changes that have occurred internationally over the last several decades have encouraged mothers of young children to work outside of the home. Consequently, demand for out of home child care such as child care facilities has also increased (Holmes et al., 1996). This trend had an important impact on public health by increasing the incidence of infectious disease in young children (Holmes et al., 1996). Children attending group child care are more likely to develop communicable illness including upper respiratory tract infections (URTIs) and common cold (Ball et al., 2002; Nafstad et al., 1999).

Antimicrobials play a major role in the treatment of infectious disease and are one of the most widely prescribed drugs in pediatrics (Buccellato et al., 2015; Chai et al., 2012). However, it has been reported in a number of pharmacoepidemiological studies that antimicrobials are over- or misused in children (Amadeo et al., 2010; McCaig et al., 2003; Nash et al., 2002). For example, excessive use of antimicrobial combinations was observed in 21 European countries (37% of all antimicrobial prescriptions for children) (Amadeo et al., 2010). Also, in the United States, more broad-spectrum antimicrobial agents such as azithromycin and clarithromycin, quinolones, and amoxicillin/clavulanate have been increasingly used among children, raising concerns regarding the development of antimicrobial resistance (McCaig et al., 2003). Uncomplicated URTIs and common colds are often easily self-treated, and the use of antimicrobials is generally not necessary. In fact, antimicrobials do not lead to an improvement of URTI and common cold symptoms, but only increase the risk of adverse side effects (Arroll et al., 2008; Fahey et al., 1998). Nonetheless, a considerable number of antimicrobials are given to children for these conditions. According to the study by Kronman et al., the number of potentially preventable antimicrobial prescriptions for acute respiratory tract infections (ARTIs) in children in the United States is nearly 11.4 million per year (56.9% of ARTI encounters in office-based primary care settings) (Kronman et al., 2014). In addition, with some degree of variability, the use of antimicrobials is prevalent across countries. In a study of pediatric antimicrobial use across 6 countries on 3 continents between 2008 and 2012, it was estimated that South Korea had the highest rate of antimicrobial use (3.41 prescribed courses per child-year for the age group of 0–2 years), followed by Italy (1.6), Spain (1.5), Pedianet, Italy (1.4), United States (1.1), Germany (1.0), and Norway (0.5 courses per child-year for 0–2 years) (Youngster et al., 2017).

Inappropriate and unnecessary prescribing of antimicrobials poses serious public health problems at both individual and population level. It is because such practice not only increases the risk of ADRs to individual patients but also promotes antimicrobial resistance in the entire population. Pharmacoepidemiological studies have associated antimicrobial use during early years of life with several negative health outcomes including imbalances in gut microbiota (dysbiosis) (Vangay et al., 2015), obesity (Bailey et al., 2014; Jess, 2014), allergic disorders (Droste et al., 2000; Ong et al., 2014), and inflammatory bowel diseases (Ng et al., 2013). In addition to this direct harm to the patient, inappropriate antimicrobial consumption could result in the environmental spread of resistant organisms in a community (Bronzwaer et al., 2002; Goossens et al., 2005). After a wide range of bacteria is inhibited or killed by an antibiotic, other organisms begin to proliferate in the space (van der Waaij, 1987). These surviving organisms may acquire antibiotic resistance at various rates (Dancer, 2001; Garau, 2003). Since antimicrobial-resistant organisms are more difficult, or impossible, to eradicate, it is critical to treat the primary infection appropriately during the initial treatment. In fact, in a clinical trial involving 904 adult patients with severe sepsis or early septic shock in North American and Europe, it was shown that inappropriate initial antimicrobial treatment was significantly associated with increased 28-day mortality, after adjusting for differences in patient demographics, vital signs, blood and other microbiological cultures, and measurements of end-organ dysfunction (Harbarth et al., 2003).

Psychotropic Drugs

Psychotropic drugs have long been used for mental disorder treatments in children. While nondrug therapies are available (e.g., behavioral therapy) and generally perceived as less invasive, drug intervention may be necessary depending on the severity of illness and other risk factors associated with each patient. Over the last few decades, the rate of psychotropic medication prescriptions for children has rapidly increased across countries, particularly in the United States (Steinhausen, 2015). More specifically, in the year 2000, the prevalence of all-class psychotropic medication prescriptions in youth was 2.9% in Netherlands and 2.0% in Germany, while it was 6.7% in the United States (Zito et al., 2008). This trend is accompanied by a growing concern that children may be overprescribed with psychotropic medications, especially for the conditions such as ADHD (Sohn et al., 2016; Zito et al., 2008). The elevated acceptance of pharmacotherapy in treating childhood mental disorder is in part contributed to successful discoveries of psychotropic drugs for pediatric use (Domino et al., 2008; Sohn et al., 2016). Also, it was argued that cost containment strategies exercised by managed care have led to the increased demand for psychotropic drugs over alternative therapies (Domino, 2012; Rapoport, 2013). More specifically, to reduce health-care costs, expensive psychiatric care is primarily allocated to medication clinics, and nondrug therapies are provided mainly by nonphysicians including psychologists, social workers, and counselors. As Rapaport speculated, "(I)t is probable, that the increase in medication use results in part from the desire of physicians to be helpful with what they have at hand given their lack of flexibility with respect alternate treatment delivery" (Rapoport, 2013).

Among psychotropic medications that are available for pediatric use, antipsychotics have been subject to a major criticism. Antipsychotic medications are used for the treatment of mental disorders including psychosis, schizophrenia, and bipolar disorder. These medications can be broadly categorized into two classes: (1) first-generation antipsychotics that were discovered in the 1950s and (2) second-generation antipsychotics that were introduced during 1990s. Second-generation antipsychotics were marketed as a safer agent as they showed reducing adverse side effects that were common in the first-generation agents, such as extrapyramidal symptoms. This resulted in the prevalent use of second-generation antipsychotics not only for the licensed indications (e.g., schizophrenia, psychoses) but also for off-label conditions and symptoms (e.g., ADHD). However, several postmarketing clinical trials and pharmacoepidemiological studies evaluated the risk of second-generation antipsychotics and reported that children taking these drugs are at a greater risk of weight gain (Sporn et al., 2007), cardiometabolic syndrome (Correll et al., 2009), and type 2 diabetes (Sohn et al. 2015).

Antidepressant treatment in children has also been extensively discussed. While double-blind clinical trials have shown that SSRIs could be successfully used in children to treat depression (Pine, 2002), the extent of knowledge and understanding about

antidepressant treatment in children is still limited compared to what is known in adults. Great variations in the effect size (Hetrick et al., 2007) and the confirmed risk of suicidality (Hammad et al., 2006) raise a concern whether the benefits of antidepressant treatment would outweigh the risks to children.

Current Needs in Pediatric Pharmacovigilance

Some ADRs can be identified during the drug development process, but knowledge about the drug effectiveness in actual clinical practice and the long-term adverse side effects is limited when the medicine is first introduced in the market. The effectiveness and safety profile of a drug treatment needs to be continuously evaluated throughout the life cycle of the drug.

During the premarketing assessment, investigators should consider targeting pediatric population. The detailed information of the pathology of the disease and the pharmacologic activity and the toxicity profile of a drug will expedite the risk assessment when planning a pharmacotherapy for children. Preclinical studies with juvenile animals may also identify important pointers for a further investigation for potential ADRs in children.

However, the current drug regulatory systems are hampered with a number of weaknesses (Ray and Stein, 2006). Because the authority of drug regulatory agencies is mainly focused on premarketing studies, planned data collection about drug efficacy and safety occurs almost exclusively in clinical trials in which the care environment is highly protocolized and relatively short-term. In addition, potential bias in publications that were funded by drug manufacturers, which is derived from conflicts of interest and the economic motivations of the drug manufacturer, has been demonstrated in the literature (Landefeld, 2004; Ray et al., 1993; Turner et al., 2008). For this reason, postmarketing medicine surveillance is particularly crucial for new pediatric medicines. Furthermore, considering that the off-label or unlicensed use of medicines is prevalent and there are challenges in conducting clinical trials in children, more standardized methods need to be developed to assess physician's prescribing practices as well as to study the treatment effects of a medicine as used in actual practice.

Spontaneous ADR reporting systems are an essential means to detect safety signals or other issues in the postmarketing period, especially in pediatrics. These systems often involve registries that are established by government agencies or health-care organizations, such as the Yellow Card Scheme in the United Kingdom (UK) or the FDA Adverse Events Reporting System (FAERS) in the United States. Although they are useful for capturing early warnings of potential ADRs, it has been recognized that the spontaneous ADR reporting systems have some limitations. First, the reporting of an ADR is voluntary and the reporting rate is low. In an acute hospital setting in the United Kingdom, it was estimated that only 6.3% of potential yellow card cases were reported to the system over a 3-year period (Smith et al., 1996). Obstacles to the spontaneous reporting of ADRs include problems with diagnosis of ADRs (i.e., some health-care professionals do not report unless they are certain about the causality assessment of the ADR.), lack of awareness of pharmacovigilance system, problems with the clinical workload, and problems related to potential conflicts (legal liability) and fear of a breach of confidentiality with patients' data (Vallano et al., 2005). Second, during the reporting process, little information on potential confounding variables is collected, and as a result, the apparent association between an adverse event and a drug may have been confounded. To confirm the independent association between the drug and the observed adverse event, methodologically rigorous studies with a greater statistical power may need to be conducted. Third, identifying a reasonable comparator group is challenging when examining data from the spontaneous ADR reporting system, especially when there is a possibility that the medical condition that the medicine is used for is the cause of the adverse event.

Some countries have developed intensified spontaneous reporting systems in which a list of specific medications is more closely monitored during the early phase of postmarketing surveillance. For example, the EMA publishes a list of medicines under additional monitoring and requires the drug manufacturer of a listed medicine to display a black inverted triangle on their drug package. These medicines include agents that contain new active substances or new biologicals, medicines with the marketing-authorization holder, medicines given conditional approval, and medicines that are identified by the European Commission or the Pharmacovigilance Risk Assessment Committee (PRAC). Another way to apply the intensified ADR reporting system is to target a defined cohort. In this system, the ADR reporting targets specific medicines of interest in a defined group of patients. Ndagije et al. reported on a pilot study of the targeted spontaneous reporting system in Uganda, in which patients with HIV infection in two regional pharmacovigilance centers were closely monitored to investigate the association between tenofovir and renal toxicity (Ndagije et al., 2015).

Further advances in pharmacovigilance can originate from the evaluation of large health care datasets using established study designs in pharmacoepidemiology. Pharmacoepidemiology has been a major contributor to studies of adverse drug events. Furthermore, its scope has also included the study of several other issues related to clinical pharmacology. As seen in the use of antimicrobials and psychotropics in pediatrics, pharmacoepidemiological research is instrumental in assessing physicians' prescribing practices and quantifying the risk of a medicine on potential adverse side events. In addition, it has been suggested that retrospective and prospective monitoring from computerized medical records may be more time-efficient compared to other intensive surveillance systems that demand more efforts and time from healthcare professionals (World Health Organization, 2007).

As the final line of defense, the health-care professionals are primarily responsible for the assessment of drug safety and benefit–risk analysis. When a new medicine is marketed, it is exposed to individuals with different ages, sex, and other genetic factors in addition to different comorbidities. The role of health-care professionals is essential for drug safety monitoring because they are most adequately trained to observe health outcomes in response to a new drug therapy.

Summary

Safe and effective use of medications in children is of great importance as data and information on pediatric pharmacotherapy from clinical trials are limited. Challenges in conducting pediatric clinical trials include ethical issues related to obtaining informed consent, securing the sufficient sample size, lack of information on age-specific efficacy and safety assessments, and difficulties in determining clinically reasonable end-points and comparators. As a result, health-care providers often extrapolate data from studies conducted in adults and apply it to children. These extrapolations increase the risk of drug toxicity and unknown adverse side effects in children because the pharmacokinetics and pharmacodynamics of children are different from that of adults.

After several unexpected adverse side effects that primarily affected children, such as the thalidomide disaster and aspirin-induced Reye's syndrome, regulatory actions were taken by some developed countries. For example, the US and EU implemented legislation that requires drug manufacturers to investigate efficacy and safety of the medicine in the population for which it is aimed and marketed. These regulations resulted in the better detection of adverse side effects, more appropriate dosage regimen and formulations for children, and the development of new treatments for children.

The pediatric population covers a wide spectrum of different physiologies, ranging from the preterm newborn infant to the adolescent. Therefore, special considerations based on the stage of development have to be made in treating subpopulations of children. In particular, a medication treatment in pregnant women can be difficult as it affects both the mother and child. While some drugs cause adverse side effects in the fetus, drug therapy may be still needed if the mother's untreated illness creates a more harmful environment for the fetus. Nonetheless, limited data are available on the pharmacology and pharmacokinetics of many drugs, pertaining to physiological changes in pregnancy and how it affects the fetus. Currently, several countries and pharmaceutical companies make pregnancy exposure registries available to prospectively observe pregnant women regarding their exposure to drugs and other biopharmaceutical products over the course of their pregnancy. Neonates are another important pediatric subpopulation. Neonates go through rapid physiological changes that affect pharmacology and pharmacokinetics of a drug, making it difficult to determine appropriate dosage and dosing schedule. Also, dosage forms and drug delivery systems for neonates are often not available. Therefore, neonates are vulnerable to medication errors in dosage calculation or dilution. In fact, it was reported that medical errors and adverse events occur more frequently in neonates and infants than adults.

Among issues related to specific therapeutic categories, drug safety in the pediatric use of antimicrobials and psychotropic agents are of particular concern. Inappropriate use of antimicrobials in self-managed infections such as URTIs and common colds is prevalent across countries. Such practice is under criticism because it increases the risk of adverse side effects to the individual patient, and it also affects the entire population by spreading antimicrobial resistance. For psychotropic drugs, the rapid increase in psychotropic prescriptions for children has raised concerns that children may be overprescribed with psychotropic medications including second-generation antipsychotics and antidepressants. More specifically, the drug's potential benefits may not be greater than the potential risks in some pediatric patients.

The current drug regulatory systems do not effectively monitor and prevent rare or long-term side effects. It is because structured data collection occurs almost exclusively during the premarketing assessment by the drug manufacturer. Because premarketing clinical trials are not adequate to observe long-term treatment effects of drug use in actual clinical practice, and the off-label prescription occurs frequently in children; postmarketing medicine surveillance is pivotal for pediatric pharmacovigilance. Spontaneous ADR reporting systems are used as an essential tool to collect data on potential adverse side effects. While there are several limitations in the system, it is effective in detecting safety signals that are otherwise unknown. Evaluating large health-care datasets using pharmacoepidemiology can address some of the shortcomings of the spontaneous reporting system. Most importantly, health-care professionals play a key role in identifying potential drug-related adverse events and assessing the benefits and risks of a medication used in children.

Introduction

Internationally, drug approval relies on evidence gained from placebo-controlled randomized clinical trials (RCTs). This type of evidence gives regulators information on the efficacy of the drug compared to a placebo. Generally, efficacy concerns itself with how well a particular treatment works under ideal conditions, such as in the RCTs used in preapproval studies. However, the conditions under which subjects use medications before market approval are certainly dissimilar to those in the normal course of medical practice. It is under these more common circumstances that a drug's effectiveness can be determined. In most therapeutic areas, there are multiple treatment options with limited evidence comparing one treatment to another in the real-world setting. It is this gap in knowledge between efficacy and effectiveness that comparative effectiveness research (CER) seeks to fill.

Colloquially speaking, CER aims to answer the following question: "What treatment works best under which circumstances for whom?" Depending on the target audience of the research, investigators conducting CER can aim to generate scientific evidence to inform individual-level clinical decisions or system-level policy decisions. It is this goal of CER that distinguishes it from the more general field of evidence-based medicine (EBM). While EBM and CER both inform clinical decision-making, EBM primarily focuses on treatment efficacy, while CER's ultimate goal is to inform decisions based on how treatments are used in regular clinical practice (effectiveness). The difference in purpose between EBM and CER influences how researchers regard different study designs, as will be discussed later.

The formal definition of CER has changed throughout the years. In this chapter, we will focus on a definition set forth by the Institute of Medicine in the United States (US) (IOM): "the generation and synthesis of evidence that compares the benefits and harms of alternative methods to prevent, diagnose, treat and monitor a clinical condition, or to improve the delivery of care" (Institute of Medicine, 2009). In general, CER compares two or more treatment strategies, although "standard of care" and "watchful waiting" can also be considered treatments.

Often, CER relies on real-world data (RWD), defined according to the International Society of Pharmacoeconomics and Outcomes Research (ISPOR) as any data obtained outside of an RCT (Berger et al., 2017). ISPOR, working together with the International Society for Pharmacoepidemiology (ISPE), created a task force to standardize recommendations about how to properly conduct studies using RWD. These recommendations will be discussed in further detail in the second section of this chapter.

CER and patient-centered outcomes research (PCOR) are closely intertwined and will be referenced interchangeably often in this chapter. It is important to note, however, that there are nuanced differences between CER and PCOR, namely that while much of PCOR is CER, not all CER is technically PCOR. Throughout the world, CER and PCOR are often considered interchangeable. In the United States in particular, the discussion of CER largely shifted to incorporate PCOR surrounding the passage of the landmark health care reform legislation, the Patient Protection and Affordable Care Act (The Patient Protection and Affordable Care Act, 2010). Though nearly all legislators and the public agreed that there was a need for better quality evidence in the health care decision-making process, much of the American body was wary about the interrelation between CER and cost-effectiveness analysis, which had become equated with health care rationing in the political arena (Leonhardt, 2009). Further, there was recognition that

patients' voices were a key factor in understanding how medications should be studied and used. Thus, much of the discourse shifted from referring to "comparative effectiveness research" to discussing "patient-centered outcomes research" (Rich, 2012). Subsequently, the Patient-Centered Outcomes Research Institute (PCORI) was established as a funding body for research, defining its aim as helping "people and their caregivers communicate and make informed healthcare decisions, allowing their voices to be heard in assessing the value of healthcare options" (Patient-Centered Outcomes Research Institute, 2013). To accomplish this goal, PCORI highlights comparisons and outcomes of medications, medical devices, and health systems while incorporating diverse participants and settings.

It is important to note that while PCORI in the United States is charged with setting national CER priorities and managing CER funding, it is strictly forbidden from basing its recommendations on cost-effectiveness information. This is in contrast to many other parts of the world where cost-effectiveness research is an integral component of CER. While similar methods are often used in both CER and cost-effectiveness research, the latter also considers the cost of the treatments and other health care utilization measures. Many nations throughout the world evaluate cost-effectiveness when determining national medication formularies, including Australia, Canada, the United Kingdom (UK), France, Germany, Italy, New Zealand, Norway, and Switzerland (The Commonwealth Fund, 2013). In this chapter, we will focus only on CER.

CER has been on the rise worldwide for nearly two decades. The UK's National Institute for Health and Clinical Excellence (founded in 1999) pioneered the shift to patient-centered outcomes and with it, the push to perform CER. By 2007, the Congressional Budget Office in the US released a report calling for more CER, followed by an allocation of more than $1 billion to CER as part of the American Recovery and Reinvestment Act in 2009 (American Recovery and Reinvestment Act, 2009; Congressional Budget Office, 2007). In 2010, the US created PCORI as an independent funding organization for CER as part of its health-care reform, as discussed above. More recently, the 21st Century Cures Act was passed in the United States with a goal to "accelerate the discovery, development, and delivery" of new biomedical products (21st Century Cures Act, 2016). This new law requires the US Food and Drug Administration (FDA) to establish a program and guidelines within five years that would determine how real-world evidence (RWE) such as CER should be used not only for new drug approval, but also for new indications for already-approved drugs and to support postapproval requirements. While this law does not change current approval standards, it does enable the use of RWE to obtain information on outcomes that are too costly or otherwise too difficult to obtain from traditional RCTs. Likewise, the GetReal project of the Innovative Medicines Initiative (IMI) in the European Union (EU) was established in 2013 as a public–private consortium with a goal of demonstrating how RWE can be incorporated throughout the drug approval process (Nordon et al., 2016).

In this chapter, we will discuss the study designs that are available to investigators interested in conducting CER, including both interventional and noninterventional study designs. We will follow this with a discussion of important stakeholders in CER and how each works in tandem to push forward the evidence prioritization, generation, and dissemination generated through CER.

Study Designs

As discussed in the introduction, CER operates on a different paradigm than EBM, owing to its focus on impacting health-care decision-making for patients based on clinical practice. Consequently, the hierarchy of evidence sources in CER differs from the one traditionally taught for EBM. Often depicted visually as a pyramid, an inherent assumption is that higher levels provide better quality evidence than lower levels. While there have been many different iterations of the original hierarchy, new modes of categorizing evidence emphasize study design appropriateness to the study question, suggesting that different clinical questions might optimally be answered using different methodological approaches (Concato, 2004). Regardless, most researchers agree that decision-making should rely on the whole body of evidence, rather than the results of one particular study based solely on the study design. In CER, a strength-of-evidence rather than level-of-evidence model is used (Marko and Weil, 2010). The Agency for Healthcare Research and Quality recommends analyzing at least four "domains" to determine strength of evidence, depicted in **Fig. 1** (Owens et al., 2009). Each of these domains receives a score, and the result is a composite score that grades the evidence based on the level of confidence that the evidence reflects a true effect.

With this framework for evidence in mind, CER uses well-known study designs such as systematic reviews, meta-analyses, and both experimental and nonexperimental studies. Randomized, controlled, large simple, and pragmatic trials are examples of experimental, or interventional, study designs used in CER. Noninterventional studies include both retrospective and prospective observational studies wherein the investigator does not assign interventions.

While RCTs have generally been considered the gold-standard in EBM (Guyatt et al., 1995), RCT evidence can be limited due to the strict inclusion criteria required. Traditional RCTs are also known as explanatory trials, as their purpose is to explain the fundamental verification of a biological or physiological hypothesis (Schwartz and Lellouch, 1967). RCTs are certainly important aspects of CER: when the U.S. Congress tasked the Institute of Medicine (IOM) with identifying national priorities for the conduct of CER, they suggested using RCTs in 49 of their top 100 recommendations (Institute of Medicine, 2009). However, other study designs and methodologies are often used in CER that can more readily incorporate RWE. Though explanatory trials offer results with the greatest level of certainty, many CER questions can only be addressed with study designs that inherently produce results with more uncertainty. For example, a hospital's choice of wash cloth for patients in the intensive care unit would probably not warrant the resources required for an RCT, but it is an important question nonetheless.

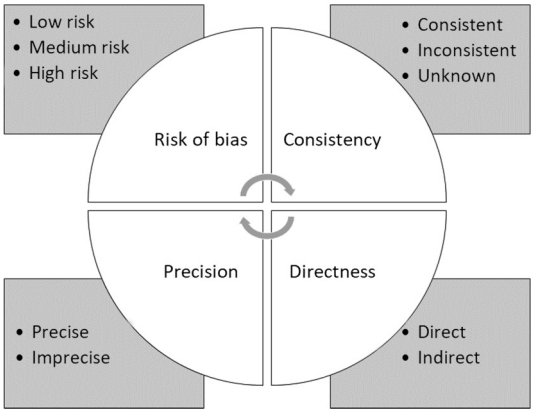

Figure 1 Comparative effectiveness strength of evidence

For all CER study designs, the assumption of clinical and personal equipoise should be maintained. Clinical equipoise is the assumption that one treatment is not better than the other. Personal equipoise is the assumption that the provider does not have a preference of one treatment over the other (Cook and Sheets, 2011).

This section will cover different study designs that produce results with varying degrees of uncertainty—both interventional and noninterventional—that are employed to provide patients, practitioners, and product and policy makers with the answers they seek.

Interventional Research

As discussed in the introduction, many studies involving drugs are designed to maximize their ability to determine efficacy, which is how well the drug performs under ideal circumstances. However, health care professionals realized as early as the 1960s that information gained from these explanatory trials was not always relevant to clinical practice and began to desire study designs that would more closely estimate a drug's effectiveness and inform clinical practice (Fiore and Lavori, 2016).

These designs, known as pragmatic, large simple, or point-of-care trials often aim to keep disturbance to clinical practice at a minimum (Shih et al., 2015). This requires dedicated effort during the study planning phase to balance the clinical relevance of measured outcomes with the feasibility of obtaining those outcomes as part of normal care. These designs would ideally include a population of patients with similar characteristics to those being treated in regular clinical care, a comparison group treated with a common clinical alternative, and meaningful outcome measures. More lenient subject exclusion would result in a more accurate estimate of potential harm, and more realistic conditions (that often result in lower adherence) may be able to determine effectiveness more accurately (Hernán and Hernández-Díaz, 2012; Thorpe et al., 2009). These more realistic study designs have been termed pragmatic clinical trials (PCTs) and have also been known as large simple or point-of-care trials. A comparison of pragmatic and explanatory trials using the standard PICOT framework has been suggested in the literature and is adapted in **Table 1** (Williams et al., 2015).

Designing Interventional Studies in CER

There is no unique tool to determine whether a study design is pragmatic or not, but the Pragmatic Explanatory Continuum Indicator Summary (PRECIS) and the updated PRECIS-2 tools highlight the concept of pragmatism and highlighted specific dimensions of a PCT that should be considered (Loudon et al., 2015; Thorpe et al., 2009). This tool evaluates the level of pragmatism within nine domains of a study design, including the recruitment of investigators and participants, the delivery of the intervention within the trial, and the natures of follow-up and outcomes.

Regarding recruitment into a PCT, investigators should consider the extent to which trial participants are similar to clinical patients, how much effort is required to recruit those subjects outside of normal practice, and how the settings of the trial are different from usual care. These considerations are especially important when studying diseases with a high burden of comorbidity, such as

Table 1 Comparison of pragmatic and explanatory trials

	Pragmatic trial: tests effectiveness	*Explanatory trial: tests efficacy*
Patient	Actual patients in practice	Strictly selected, healthy subjects
Intervention	Flexible, allows changes	Strictly defined, few changes allowed
Comparison	Head-to-head, standard of care	Often placebo; standard of care possible
Outcome	Clinically important	Surrogate or objective
Time	Long follow-up	Short follow-up

Type 2 Diabetes Mellitus (T2DM). Patients with T2DM often have comorbid hypertension, hyperlipidemia, and obesity, yet these patients would normally be excluded from RCTs. This makes health care professionals' decisions on appropriate therapy even more complicated. One example involves patients who are treated with insulin therapy, which has several approved delivery options. Currently on the market are vials of insulin which patients draw into syringes and self-administer, prefilled syringes, and continuous subcutaneous insulin infusions (CSII). When faced with a patient who has uncontrolled blood glucose and T2DM, a practitioner is faced with a conundrum that might be solved with a PCT. One such trial was performed with a CSII device investigating how these different methods of insulin delivery work in clinical practice (Abbott et al., 2017). The study randomized sites to the CSII or standard of care optimization and patients were treated according to routine clinical practice. The primary outcome was change in hemoglobin A1c (HbA1c) from baseline to the end of the study, and investigators found that patients with the CSII had larger drops in HbA1c than those using other methods of insulin delivery. Subjects in this study were recruited through a simple discussion with their provider at a regular clinic appointment and were followed according to routine practice for up to 4 months. Subjects purchased their insulin delivery devices as they had been and had an end-of-study visit that did not impose a schedule of regular visits. In every way possible, regular clinical practice was not interrupted. These data provided RWE about the effectiveness of different insulin delivery devices in treating T2DM.

In addition to considering the recruitment process, investigators should ensure that a PCT allows the same amount of flexibility in how the intervention is delivered and how patients are monitored as in usual care. Many RCTs are labor-intensive for patients, requiring extra visits to providers, and have rigid requirements for treatment delivery. The Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack (ALLHAT) trial was a large, randomized, double-blind pragmatic trial that was conducted in 623 North American practice sites to determine whether incidence of coronary heart disease and myocardial infarction differed among four antihypertensive treatments: chlorthalidone, amlodipine, lisinopril, and doxazosin (ALLHAT Collaborative Research Group, 2002). This trial allowed variation in study drug number and dose based on patient tolerance and clinical judgement, which nonpragmatic trials rarely allow. The study protocol also allowed rechallenges with medications attempted previously, which is common in clinical practice but extremely rare in most RCTs. These aspects allowed the trial to estimate the true effectiveness of these antihypertensives and have ultimately led to substantial changes in practice, including the understanding that many newer and more expensive antihypertensives were no more effective than older diuretics used to treat hypertension (Chrysant, 2003). This shift in clinical framework opened the doors to clinically appropriate and cost-effective hypertension treatment for many patients.

Finally, in a PCT, investigators should consider the extent to which the primary trial outcome is relevant to participants and ensure to include all data. Appropriate outcome measurements are particularly important in pragmatic trials. For example, the Salford Lung Study aimed to evaluate the real-world effectiveness of a new once daily long-acting corticosteroid/long-acting beta agonist dry powdered inhaler for the treatment of asthma and chronic obstructive pulmonary disease (COPD) (Vestbo et al., 2016; Woodcock et al., 2015). Patients were randomized (but not masked) to the new investigative treatment or to the continuation of regular clinical care. Once randomized, patients enrolled in the study received routine care and were followed through their electronic medical record for 12 months. Throughout the study, physicians prescribed treatments as they would in regular practice, and the patients received medications from their own pharmacy. Safety monitoring was conducted throughout the trial through near real-time evaluation of the patients' electronic medical record. Whereas most studies in this field assess only restricted outcomes such as forced expiratory volume, the primary outcome in this study was the Asthma Control Test (ACT) score, which is a clinically relevant measure of overall asthma control. Practitioners could interpret this outcome and apply it to their practice more easily than less clinically relevant outcome measures.

Another important consideration of outcome measurement in PCTs is that long-term follow-up is often labor-intensive for investigators. One way to extend outcome measurement efficiently is for investigators to follow the patients' clinical experience through administrative claims or electronic medical record data. The Salford Lung Study is one PCT that utilized the electronic medical record for study follow-up. The study location was optimal in that patients enrolled were from one metropolitan area in the United Kingdom, and all medical records were linked, which allowed for extensive follow-up. In other fragmented health systems, this may result in methodologic challenges. In the United States, the Dialysis Clinical Outcomes Revisited pragmatic trial compared the effectiveness of sevelamer and calcium-based phosphate binders among patients who were receiving hemodialysis (St Peter et al., 2008). Using administrative claims data for these subjects allowed investigators to more accurately capture baseline comorbidities as well as outcomes, including hospitalization and death date and cause. These relevant outcome measures were particularly important markers of treatment effectiveness in this population. The US federal government has shown that linking clinical and administrative claims data is a priority by investing in a large Multi-Payer Claims Database (Conway and VanLare, 2010). Countries in Europe have also taken an active role in promoting PCTs for the purpose of extending follow-up in clinically relevant patient populations. New EU regulations expected to be implemented in 2019 provide specific guidance to lower some administrative barriers to conducting PCTs (European Parliament and Council, 2014).

Research in Practice

Many PCTs were first designed as quality improvement projects and later produced generalizable results. One such example involved a pragmatic cluster-randomized, crossover, controlled study comparing bathing with chlorhexidine cloths to bathing with non-antimicrobial cloths among critically ill patients (Noto et al., 2015). The authors obtained a waiver of informed consent as a quality improvement step, and patients were not blinded to the intervention due to the difference in appearance between cloths. They found

that the antimicrobial bathing did not improve any of the outcome measures of infection rates. Published results such as these are applicable to other institutions that may be performing this practice without an evidence basis.

Though pragmatic trials attempt to determine real-world effectiveness, there are limitations associated with this approach. The definition of "real-world" often depends on many factors, such as the practice environment. The UK primary care sites recruited from the Salford Lung Study may not be generalizable to populations in other parts of the world, highlighting the potential that the external validity of some PCTs may be a point of concern. An example of geographic differences impacting the results of pragmatic trials is evident in the European Carotid Surgery Trial, which investigated the effectiveness of endarterectomies for carotid stenosis (Masuhr et al., 1998). The differences in clinical practice sites both within and between European countries resulted in different measurements of the outcome, which affected the study's estimation of the treatment effectiveness.

Another potential shortcoming of PCTs is the difficulty of designing a study that meets standard research protocols and also allows patients to experience normal clinical care. An analysis of two simple pragmatic trials conducted in the United Kingdom demonstrates that the approval process for these studies took over three years and that less than 5% of originally interested clinical sites recruited patients for the studies (van Staa et al., 2014). This analysis also brought to light qualitative insights to PCT implementation, such as physician preference that patients with acute illnesses be excluded and that recruitment be as simple as a "flag" during patient consultation.

Furthermore, PCTs may not be able to identify small differences in treatment effectiveness because the populations are designed to be broad and diverse. The large sample sizes and long follow-up time required in PCTs also mean that many are long and labor-intensive. The ALLHAT trial discussed above took nearly 8 years to complete and cost an estimated $130 million (Goldberg et al., 2011).

Regulatory organizations have recognized the need for pragmatic trials as well as their limitations and have responded in suit. In the United States, PCORI has awarded over $350 million as of November 2017 for PCTs studying conditions including cancer, behavioral health, muscular/skeletal system disorders, respiratory, cardiovascular, and digestive system diseases, and many more (Patient-Centered Outcomes Research Institute, 2017). The European Union has also recognized the need to increase the efficiency of these trials, and with regulations set to be enforced in 2019 have defined a new type of clinical trial, the "low-intervention" clinical trial (European Parliament and Council, 2014). Many PCTs may be classified as "low-intervention" trials, thus have fewer administrative barriers.

Noninterventional Research

Whereas the use and design of PCTs are relatively new innovations in CER, most of the evidence generated thus far from CER is noninterventional (observational) in nature. In these studies, investigators do not assign treatment status, but rather observe behavior as it happens in the real-world. This can be done using data that already exist, such as administrative claims data or electronic health records, or investigators can design prospective observational studies that choose participants based on characteristics of interest. "Natural," or ecological experiments occur when treatments are distributed in a population for a reason unrelated to their health status or prognosis. This may occur as a result of formulary changes, or because of geographic differences in innovation or trends.

When a research question requires a large population or long follow-up, observational studies are particularly well-suited to provide evidence more feasibly than the time-consuming and expensive explanatory and pragmatic trials. CER using noninterventional study designs are particularly appropriate to investigate the extent to which RCT results apply to the real-world, extremely rare or poorly studied conditions, current treatment practices, or other situations in which RCTs have not or cannot be conducted. In addition, observational studies are able to capture all types of patients, whereas traditional explanatory interventional studies are generally restricted to healthier individuals. Despite these benefits, because observational CER is not randomized or controlled, there are many opportunities for confounding to influence any potential association that interests investigators, such as confounding by indication and self-selection. Furthermore, because data in most CER retrospective studies are collected for purposes other than answering an investigator's specific research question, investigators must deal with missing data on certain important characteristics.

In the field of CER, like in most EBM, decision makers tend to be more reluctant to implement changes based on information gained from noninterventional studies compared to RCTs. While it is true that observational studies have higher levels of bias and confounding due to nonrandomization, a carefully designed observational study can minimize these effects, and potentially approach the minimal levels of bias observed in RCTs (Danaei et al., 2013). In fact, multiple studies have shown that results from well-designed observational research do not differ systematically from experimental studies if the study question and population are aligned (Benson and Hartz, 2000; Concato et al., 2000; Lipsey and Wilson, 1993).

The ISPOR special joint task force has made seven recommendations regarding good procedural practices for observational studies (Berger et al., 2017). The first recommendation is that researchers are clear as to whether they are performing an exploratory or hypothesis-testing (HETE) study. If performing a HETE study, they should clearly state their a priori hypothesis and publish both a study protocol and analysis plan publicly. Once results are obtained, they should also present the extent to which they deviated from their original study protocol and the reasons for deviations, if any. They should provide enough information in publications for other researchers to replicate their findings, and they should also be able to replicate their own findings in a different data source and population. Finally, the authors should be objective when discussing the weaknesses of their study and be sure to include key stakeholders in design, conducting, and disseminating the results of HETE studies.

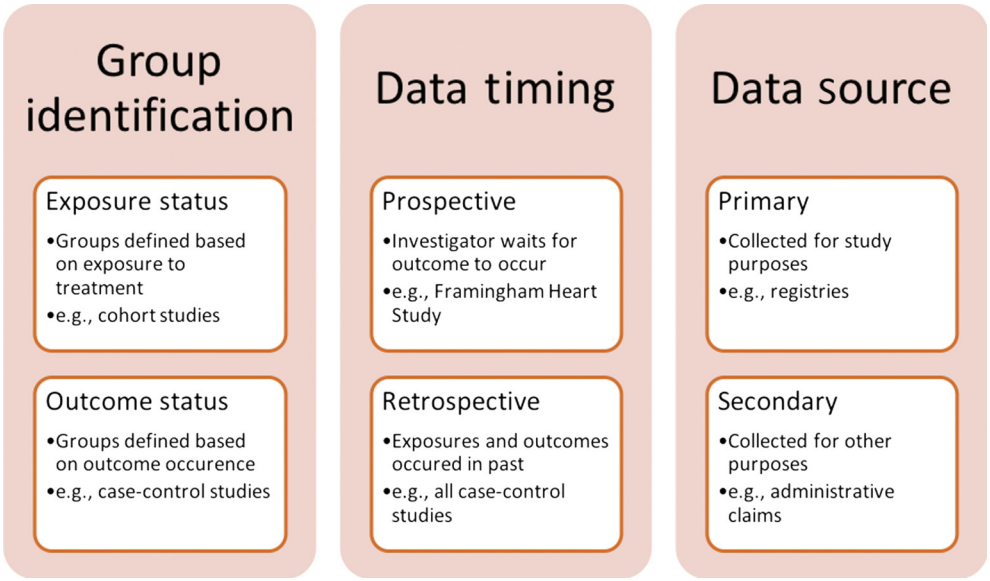

Figure 2 Components of observational CER

Designing Non-Interventional Studies in CER

When CER utilizes observational study designs to answer questions, investigators must consider three main components in order to appropriately design a study, as visualized in Fig. 2: group identification, data timing, and data source. In this section, we will discuss each of these in turn.

Group identification

Of the three main types of noninterventional study designs used in CER, each can be classified based on the characteristic used to identify comparison groups. Studies that define groups based on exposure status are known as cohort studies. In these studies, subjects are divided into groups based on whether or not they use the drug of interest. This is in contrast to identifying groups based on outcome status, as is done in case–control studies. Investigators originally assign subjects to groups based on whether or not they have experienced an outcome of interest, then analyze which subjects in each group were exposed to a particular treatment. Because cross-sectional studies assess both exposure and outcome at the same time, groups are identified based on both characteristics.

Data timing

Another factor that differentiates observational from interventional CER is the ability for researchers to conduct both prospective and retrospective studies. In prospective noninterventional CER, the investigator begins researching subjects before any outcomes of interest occur and follows subjects forward in time. One such example is a prospective cohort study investigating the effect of varenicline versus nicotine replacement therapy (NRT) on smoking abstinence rates (Kotz et al., 2014). Data were gathered from a survey administered to participants in England, and subjects were followed up after 6 months. Investigators found that subjects who used varenicline had greater success in smoking abstinence than those using NRT alone. Because data were collected prospectively, the time required to complete the study was longer than if the researchers had taken a retrospective approach. Other examples of prospectively collected data used in CER are the Framingham Heart Study and the Nurses' Health Study. Retrospective studies in CER are very common because of the advantages they offer over PCTs and prospective observational studies in the time required to conduct research. In retrospective cohort and case–control studies, exposure to treatment and occurrence of the outcome of interest have already occurred in subjects when the investigator begins the study. Looking back in time to establish exposure and outcome (basing groups on either exposure or outcome status in cohort and case–control studies respectively) expedites the study time and reduces costs. Cohort studies can be either prospective or retrospective; however, as case–control studies choose group status based on the occurrence of the outcome, they are necessarily retrospective.

Data source

In CER, observational study designs can rely on either primary or secondary data sources. Primary data arise when the investigator collects information about study participants in order to address a specific research question or hypothesis. Data collected from cross-sectional surveys or prospective cohort studies are considered primary data. These types of data are also generated for observational CER through the use of disease- or exposure-specific registries. In the United States, a large disease-based registry used in CER is the Surveillance, Epidemiology, and End Results (SEER) program (National Cancer Institute, 2018). Beginning in 1973, the SEER program has actively collected data on cancer cases for the purpose of conducting research to reduce the burden of cancer. These registries collect information on patient demographics, tumor site, various cancer markers, first course of treatment,

and patient survival. Because the National Cancer Institute maintains this data, its quality remains high. In addition to this vital information, SEER data can also be linked with administrative claims (a type of secondary data) to provide a more complete patient picture. One study used SEER linked to Medicare claims data to investigate the effectiveness of adding bevacizumab to standard chemotherapy in nonsquamous cell nonsmall cell lung cancer (NSCLC) in older adults (Zhu et al., 2012). A previous RCT had shown a slight survival advantage with this adjuvant therapy, and bevacizumab gained an FDA approval for this indication. However, NSCLC mainly occurs in older adults, and only a small portion of subjects in the RCT were 65 years or older. Investigators in this study were able to analyze outcomes for older patients and did not find a substantial survival advantage over the standard of care. Studies like these highlight the importance of CER in providing information on clinically relevant populations.

If investigators do not collect data for the purposes of their research, but instead use data that have been collected for other purposes, then the research uses secondary data. This type of data can be generated from routine record-keeping processes (such as administrative claims and electronic health records), regulatory processes, or even from repurposed trial data. This last type of secondary data demonstrates that even when data are originally collected for research purposes, an investigator can use it to answer a different question, making it secondary for their purposes. The Fracture Intervention Trial (FIT) was an RCT designed to investigate whether alendronate usage resulted in a lower fracture rate in older women with low bone density (Black et al., 1993). The trial completed subject recruitment in 1993, but later investigators were able to use that same data to answer a slightly different research question. Because alendronate is removed from the body through the kidneys, investigators were interested in determining whether its ability to reduce fracture rate and its potential to cause adverse reactions were augmented by poor renal function in a population of older women with low bone density (Jamal et al., 2007). It was found that alendronate did not perform differently in women with poor renal function, and such women did not experience more adverse effects. Such secondary analyses of existing data provide answers to important clinical questions that health care providers may encounter in their practices.

Research in Practice

While the use of RCTs and PCTs is often preferred in CER, there are certain circumstances in which observational study designs are particularly useful. If an RCT or PCT is impractical due to its potential expense, time required, or ethical considerations, an observational study can provide needed information. Such was the case when investigators were interested in the effectiveness of warfarin for stroke prevention in patients with atrial fibrillation. Large RCTs had shown an overwhelming benefit, but these trials included mainly younger people with few comorbidities. A systematic review comparing RCTs to actual clinical practice showed that patients in RCTs investigating warfarin safety were on average six years younger (range from 3 to 11) with 10% fewer comorbid conditions than the general clinical population (Evans and Kalra, 2001). To strengthen the evidence on using warfarin for this purpose, investigators used data from the Anticoagulation and Risk factors In Atrial fibrillation (ATRIA) study, which included administrative claims data on patients in the Kaiser Permanente health maintenance organization in northern California, United States (Go et al., 1999). Using an observational study, investigators were able to control for many different comorbidities and time-varying factors. Ultimately, they were able to confirm that in this population, warfarin users had a 51% lower risk of thromboembolism compared to nonusers (Go et al., 2003).

Another circumstance in which observational CER may be preferable to interventional trials is when the presence of an association does not have sufficient evidence to warrant a more cumbersome trial. These hypothesis-generating studies are often performed observationally initially. This is especially relevant for research questions pertaining to the way in which specific subpopulations respond to a given treatment. Even if some data exists suggesting that one of three particular treatments reduces hospital length of stay, for example, investigators might be interested in whether those trends hold for a particular minority or group of patients with a particular comorbidity. Although hypothesis-generating studies such as these often need to be followed-up with larger, potentially randomized, trials they nevertheless have their place in CER.

Furthermore, CER uses noninterventional study designs to evaluate prescribing practices in the real-world. One such example exists in treatment guidelines for chronic obstructive pulmonary disease (COPD), which recommend treating flare-ups with low doses of systemic corticosteroids (Global Initiative for Chronic Obstructive Lung Disease, 2017). However, evidence for low-dose treatment was derived from only a few, small RCTs and thus there was concern that physicians were actually prescribing higher dose corticosteroids, which carried much higher risks. Furthermore, there was no consensus about whether intravenous or oral therapy should be used initially. Because the question of whether patient outcomes are better when treated with low- versus high-dose corticosteroids required a very large population, researchers set out to investigate this question using a cohort study design (Lindenauer, 2010). Investigators found that among more than 80,000 patients with COPD exacerbations, low-dose oral corticosteroids worked just as well (and were safer) than high-dose intravenous corticosteroids, but that physicians were more likely to prescribe the latter. In order to achieve enough statistical power to show these results in an RCT, about 30,000 patients would need to be recruited. Policy makers can use information gained from such studies to inform prescribing practices and determine extent to which guidelines are being followed.

Though there are many instances in which this type of CER is warranted, a discussion of observational research design requires a basic understanding of the concepts of bias and confounding. Bias, also known as systematic error, occurs when differences among research subjects occur randomly and can be considered "noise." Both experimental and nonexperimental studies are prone to bias, which can be minimized using randomization to balance out differences between treatment groups. Evidence-based research organizations generally divide bias into four categories as seen in **Table 2**: selection bias, confounding by indication, performance and detection bias, and attrition bias (Higgins and Green, 2011; National Institute for Health and Clinical Excellence, 2012). Many

Table 2 Types of bias in observational studies

Type of bias	*Description*	*Best addressed by*
Selection	The effect of a treatment on an outcome is distorted by the way in which subjects are selected into the study	Rigorous inclusion criteria
Confounding by indication	The indication for a treatment changes based on patient risk/prognosis, thus impacting the outcome	Randomization, controlling for known confounders, matching
Performance or detection	Systematic differences between treatment groups other than the treatment	Blinding
Attrition	Systematic differences in how subjects are lost between treatment groups	Rigorous follow-up

interventional study designs address these biases through randomization, so investigators conducting CER using observational study designs should always identify, measure, and adjust for potential confounding factors in order to provide valid results.

Factors in observational research (such as self-selection instead of randomization) can confound the relationship between a given outcome and treatment of interest. Thus, many different methods are employed in noninterventional CER to address this concern, such as propensity scores, regressions, and instrumental variables. There is no universally accepted standardized method to address such confounding, so CER investigators must demonstrate a thorough understanding of the potential biases and explanation of their choice of adjustment. The lack of standardized guidance for confounder adjustment is a recognized problem in CER, and PCORI is currently in the finishing stages of a project to develop an "observational analysis methodology decision tree (OAMDT) for recommending optimal analysis method(s) for a given data set" (Landsittel, 2018).

Although specific recommendations for reducing confounding in observational CER do not yet exist, international standards have been set to encourage such study designing, including the Strengthening the Reporting of Observational Studies in Epidemiology (STROBE) guidelines, and a report from ISPOR (Berger et al., 2017; von Elm et al., 2007). Furthermore, investigators should follow the Consolidated Standards of Reporting Trials (CONSORT) guidelines as closely as is feasible (Hernán, 2011). Though these guidelines are specifically for RCTs, emulating such designs in observational research reduces confounding. Designing noninterventional CER studies with an RCT in mind would involve correctly identifying "zero-time" for eligibility and baseline characteristics, clearly specifying inclusion and exclusion criteria, adjusting for confounding, and using appropriate statistical techniques (Hernán et al., 2016). One particular area in observational research that has been shown to be troubling is including prevalent users in studies. Whereas most well-designed RCTs always exclude subjects who are already on the treatment of interest (prevalent users)—which allows for the examination of the effect of initiating said treatment—some observational studies often include users who have been taking the drug of interest for some time. Failing to exclude prevalent users from observational studies can result in biased estimates as was shown in some observational studies that investigated the effect of hormone replacement therapy in postmenopausal women on coronary artery disease. Many provided estimates that were in conflict with RCTs examining the same question, but a recent study found that if researchers had excluded prevalent users in observational studies, they would have reached the same conclusions as the RCTs (Danaei et al., 2012).

Interest Groups

There are many stakeholders who might be interested in CER at various stages of its development and implementation. Researchers have divided the classes of interested people into what are known as the "7Ps," which are visualized in **Figure 3** (Concannon et al., 2012). A systematic review of stakeholder engagement between 2003 and 2012 found that engagement was highly variable, but more common in earlier stages of research, often before the research was underway (Concannon et al., 2014). Overall, patients were frequently engaged, followed by clinicians. Other decision makers, including policy makers, payers, and pharmaceutical manufacturers were engaged infrequently.

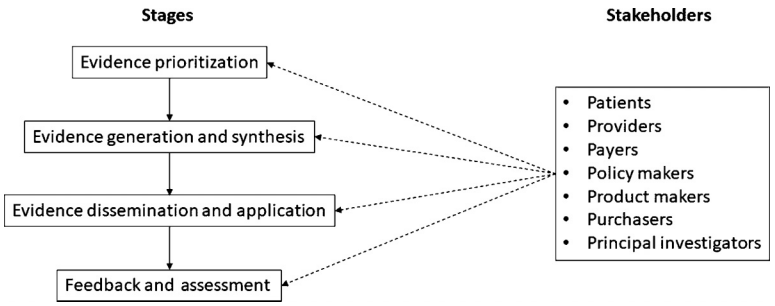

Figure 3 Comparative effectiveness research stages and stakeholders. Source: Concannon, T.W., Fuster, M., Saunders, T., Patel, K., Wong, J.B., Leslie, L.K., Lau, J. A. 2014. Systematic Review of Stakeholder Engagement in Comparative Effectiveness and Patient-Centered Outcomes Research. J. Gen. Intern. Med. 29, 1692–1701.

These "7Ps" in CER can perhaps be broken down into four broad groups: academic researchers, the public, regulatory agencies, and members of the pharmaceutical industry. Each has their own incentives and goals with CER.

Those who conduct most of the CER available today are academic researchers (or principal investigators in Fig. 3). Because they are responsible for most of the evidence generation and synthesis in CER, researchers play a critical role in engaging other stakeholders. As discussed earlier, a key facet of CER that sets it apart from other EBM is its focus on impacting decision-making on an individual and system-level. Whereas in most EBM, researchers can conduct their work with little understanding of the needs of end-users, those working in CER must ensure that research findings are aligned with the needs of those who will be making decisions. In order to do so, it is important that academic researchers involve stakeholders from all areas (the public, regulatory bodies, and the pharmaceutical industry) to properly prioritize, generate, and disseminate comparative effectiveness evidence (Deverka et al., 2012).

Because CER is so often discussed in relation to patient care, it follows that both patients and health-care providers are major stakeholders in the research. Providers have a vested interest in CER because this type of evidence often answers their specific clinical questions whereas placebo-controlled evidence is not often directly relevant. Ultimately, the health of patients is on the line, so their interest is also crucial. In fact, many organizations including the Cochrane Collaboration have raised the issue, and regulatory bodies have also taken note of this. The earliest government funding of CER in the United States occurred in 1972 with the Office of Technology Assessment. Since 1999, the National Health Service in the United Kingdom has had a clear policy directive to involve the public in research, as this involvement has been shown to increase in both relevance and quality of research (Department of Health, 1999). Of course, health-care providers include not only prescribers but also pharmacists. As one of the most accessible health care providers in the health system, pharmacists can play a critical role in encouraging patients to participate in CER and also in applying the results of CER to their own practice. Pharmacists can stand as proponents of CER regardless of their practice site, which will push forward the agenda of including more real-world evidence in health care. When both patients and providers can be active participants, the evidence generated will not only be relevant to their real-world experience, but researchers will be able to more efficiently conduct their research with such input.

As was the case in the United Kingdom, regulatory bodies must occasionally step in to encourage the public's involvement in research. This chapter has discussed the American federal government's interest in patient-centered outcomes research with the establishment of PCORI, as well as the UK's GetReal initiative. However, governments are not the only regulatory bodies involved and interested in CER. The European Medicines Agency (EMA) is a decentralized agency that operates similarly to the US FDA by assessing marketing applications for drugs in Europe, though it does not have all the regulatory authority. The EMA has taken an interest in CER and has developed infrastructure allowing them to monitor postmarketing safety signals and require postauthorization effectiveness studies of manufacturers (The European Commission, 2014). As regulatory bodies become more interested in CER studies, more specific guidance on their conduct is expected, as well as more oversight into postmarketing requirements.

Certainly, pharmaceutical product manufacturers and payers have an interest in CER. If regulatory bodies make drug approval conditional on CER evidence, payers will need to be assured that they will be reimbursed while more evidence is generated. This is especially important in countries such as France, where drug coinsurances vary by effectiveness, ranging from 0% for highly effective drugs to 100% based on therapeutic value (The Commonwealth Fund, 2013). Manufacturers may in fact have a disincentive to supporting CER since results may support their direct competitors. To highlight this concern, we can consider that prior to the funding increase for CER in the United States in 2009, industry lobbyists fought to ensure that three of the 15 members governing the newly created private–public research entity would be occupied by representatives from industry, and while this provision did make it into the Senate Finance Committee's bill, it did not make it into public law (Selker and Wood, 2009).

When all stakeholders work together, researchers will fully understand the questions the public needs answered, regulators will have the appropriate information they need to moderate drug approval, and industry members will be able to contribute to the available evidence base. To ensure this participation, researchers should tailor their work to stakeholders' information needs and be able to demonstrate how their work will impact each stakeholder in the real-world. Unfortunately, even when stakeholders are involved, not all CER is implemented immediately. For example, the results of a RCT demonstrated that initially performing percutaneous coronary interventions (PCIs) in patients with stable coronary artery disease (CAD) did not reduce risk of death or major cardiovascular events compared with optimal therapy using medications alone (Boden et al., 2007). Many thought that this study would result in a sharp decline in the use of PCIs for initial therapy in stable CAD, but this did not occur (Winstein, 2010). Some speculate that this is due to misaligned reimbursement incentives (facilities may receive higher reimbursements for performing surgical procedures), lack of trust in new information due to opaque research practices, or lack of physician engagement in new practices. In fact, one IOM study found that widespread adoption of an intervention takes on average 17 years (Institute of Medicine, 2001). As CER becomes more popularized and methods become more sophisticated, the goal is for uptake of new information to accelerate.

Conclusion

Comparative effectiveness research is a complex area that involves many types of research, including traditional EBM, patient-centered outcomes research, and cost-effectiveness analyses. Within the last two decades, the health care providers, regulatory agencies, industry, and ultimately the public have become invested in conducting of this type of research, and we have seen its use

expand accordingly. As CER continues to evolve in the coming years, everyone involved will see an increase in quality data applicable to real-world situations.

Glossary

Evidence-based medicine The practice of medicine wherein high-quality research is used to formulate guidelines and direct patient care

Explanatory trial A type of clinical trial that is conducted under ideal circumstances with strict inclusion criteria; generally used to determine efficacy, e.g., randomized-controlled trials

Pragmatic trial A type of clinical trial that is conducted under more realistic circumstances with more relaxed inclusion criteria; generally used to determine effectiveness

Real-world data/evidence In general, any data gained outside of a randomized-controlled trial that represents patient characteristics and circumstances found in clinical practice

Economic Evaluation of Pharmaceuticals

Zanfina Ademi, Danny Liew, Monash University, Melbourne, VIC, Australia

Introduction

Overview of Health Economics

Health economics is the branch of economics concerned with the cost, effectiveness, value, and consumption of health care, while *pharmacoeconomics* refers specifically to the health economics of pharmacotherapy. *Health technology assessment* (HTA) is a component of health economics and describes the systematic approach to evaluating the health effects and costs of health-care interventions and the specific determination of their efficiency. HTAs are undertaken as an exercise in scholarship and/or to inform decision-making in health-care practice and policy in the real-world.

HTA addresses the question of *technical efficiency*; that is, whether or not a specific intervention is delivered in the most efficient manner. By contrast, *allocative efficiency* considers the question of how to distribute health-care resources efficiently and takes into account multiple interventions and opportunity costs. This chapter will provide an overview of the economic evaluation of pharmacotherapies and describe the HTA processes used to assess drugs.

The Need for Economic Evaluations

Clinical trials (or meta-analyses of such trials) provide the highest level of evidence regarding the *efficacy* of drugs. The question regarding the efficacy of medicines is "Can drugs work?" The concept of efficacy is distinct from that of *effectiveness*, which refers to the more real-world evidence of the benefit of medicines, taking into account real-world usage (uptake, adverse drug events, compliance, and persistence) (Liew et al., 2002). The relevant question is "Do drugs work?" and measures of effectiveness are drawn from pharmacoepidemiological studies regarding real-world usage. The economic evaluation of medicines seeks to estimate

their *cost-effectiveness*. It extends real-world evidence one step further by addressing the question "Are drugs worth it?" Economic evaluations of medicines combine measures of efficacy and effectiveness with measures of costs. Hence, they are reliant on data from clinical trials, pharmacoepidemiological studies, and costing studies (Haynes, 1999).

There is often a large gap between efficacy and effectiveness because clinical trials are usually undertaken on highly circumscribed populations under tightly controlled study environments. Typically, they have narrow foci in terms of outcomes and are short in duration (up to 5 or so years). Furthermore, in clinical trials of pharmacotherapy, adherence to drug treatment is often greater than would be observed in practice.

There may also be a gap between effectiveness and cost-effectiveness. Highly effective interventions may be so costly that they are not cost-effective, or conversely, cheap interventions may not need to be highly effective in order to be cost-effective. In addition, the funding of health care varies considerably from country to country, and what may be a cost-effective intervention for one country may not be for another. Thresholds for cost-effectiveness are also variable, depending on a country's capacity to afford health care.

Yet, despite all the heterogeneity across different drug markets, a constant fact is that costs and cost-effectiveness are crucial determinants of the feasibility and affordability of pharmacotherapy.

Types of Economic Evaluations

This section describes the different approaches to economic evaluation of pharmacotherapy. There are a number of methods available, with the most common being *cost-effectiveness analysis* (CEA) (**Table 1**), *cost-utility analysis* (CUA) (**Table 2**), and *cost-benefit analysis* (CBA). These differ according to the outcomes being considered, but are common in that they all are tools of HTA; that is, they address the question of the technical efficiency of specific health-care interventions.

In each of CEA, CUA, and CBA, the economic evaluation of the health-care intervention under consideration (the *intervention*) is undertaken in comparison to a relevant reference (the *comparator*). Marginal differences in costs and outcomes between the intervention and the comparator are the outputs of interest.

Cost-Effectiveness Analysis

Cost-effectiveness analysis (CEA) (Drummond, 2005) reports the net cost of a health-care intervention per unit of gain in health outcome of achieved by that health-care intervention. The health outcome is measured in an objective way, and the most common unit of measure is *life years gained* (LYG) (Brazier et al., In Press). However, it can be any clinical outcome, such as deaths prevented, cases successfully treated, symptom-free days, and percentage reductions in biomarkers (e.g., cholesterol level and blood pressure) (Ciani, In Press). The net cost of intervention is calculated by summing the cost of intervention and long-term care and subtracting from this downstream savings (cost offsets) achieved through avoidance of the health outcomes.

The net cost per unit gain in health outcome is the *incremental cost-effectiveness ratio* (ICER) (Drummond, 2005), which is the main output of interest in CEA.

$$\text{ICER} = \frac{\text{Cost}_i - \text{Cost}_c}{\text{Outcome}_i - \text{Outcome}_c}$$

Cost_i = cost of intervention

Cost_c = cost of comparator

Outcome_i = outcome associated with intervention

Outcome_c = outcome associated with comparator

An example of a CEA is provided in **Box 1**.

Box 1

A CEA (Ademi et al., 2016) was undertaken to determine the cost-effectiveness of eplerenone compared with usual care in patients with chronic heart failure and New York Heart Association Class II symptoms. The setting was the Australian healthcare system. It was estimated that over a 10-year time horizon, for each patient compared with usual care, eplerenone would lead to 0.25 LYG at a net cost of AUD $6980. This equated to an ICER of AUD $28,001 per LYG (Table 1).

Table 1 Cost-effectiveness analysis (Ademi et al., 2016) of eplerenone versus usual care

	Years of life lived	*Total costs (AUD)*	*ICER (cost/LYG)*
Usual care	6.07	$4869	
Eplerenone	6.32	$11,849	
Difference	0.25	$6980	$28,001

ICER, Incremental cost-effectiveness ratio; *LYG*, life-year gained.

Box 2

In the same study described in Box (Ademi et al., 2016), a CUA was also undertaken to estimate gains in terms of QALYs. It was estimated that over a 10-year time horizon, for each patient compared with usual care, eplerenone would lead to 0.19 QALYs gained at a net cost of AUD $6980. This equated to an ICER of AUD $37,452 per QALY gained (Table 2).

Table 2 Cost-utility analysis (Ademi et al., 2016) of eplerenone versus usual care

	QALYs lived	*Total costs (AUD)*	*ICER (cost/QALY)*
Usual care	4.39	$4869	
Eplerenone	4.58	$11,849	
Difference	0.19	$6980	$37,452

ICER, Incremental cost-effectiveness ratio; *QALY*, quality-adjusted life year.

Cost-Utility Analysis

A cost-utility analysis (CUA) follows the same principle as a CEA, but the health outcome is measured in terms of *quality adjusted life years* (QALYs), which are discussed in Section 4. Consequently, the ICER is presented in terms of net cost per QALY gained (or lost) (Drummond, 2005).

A distinct advantage of using QALYs as an outcome is that it takes into consideration both the quantity and quality of life in a single summary measure. This is especially useful if multiple health outcomes are relevant to the economic evaluation. For example, the benefits of low-dose aspirin are a reduction in risk of atherothrombotic cardiovascular disease, but its adverse effects include peptic ulceration and bleeding. An example of a CUA is provided in **Box 2**.

For both CEAs and CUAs, a *cost-effectiveness plane* can be used to graphically represent ICERs generated from the evaluation (Fig. 1), with the differences in costs plotted along the vertical axis and differences in health outcomes plotted on the horizontal axis.

Note that the cost-effectiveness plane allows for the fact that the intervention can lead to worse health outcomes (less effectiveness), compared to the comparator. For example, if prescribed to people at very low risk of atherothrombotic cardiovascular disease and very high risk of bleeding, the net effects of low-dose aspirin might be adversarial rather than beneficial (Ademi et al., 2013a). The plane also accounts for the fact that the intervention may lead to net cost savings because the cost offsets are greater than the costs of the intervention. For example, if prescribed to people at very high risk of atherothrombotic cardiovascular disease and very low risk of bleeding, the net effects of low-dose aspirin might be so beneficial such that downstream costs averted from avoidance of atherothrombotic cardiovascular disease would surpass those of aspirin treatment (Ademi et al., 2013a).

For most health-care interventions, net costs and net effects plot in the north-east (upper right) quadrant of the cost-effectiveness plane; that is, they incur net costs (more costly than the comparator) and lead to net health benefits (more effective than the comparator). The ICER associated with an intervention is indicated by a straight line drawn from the origin of the plane to where it

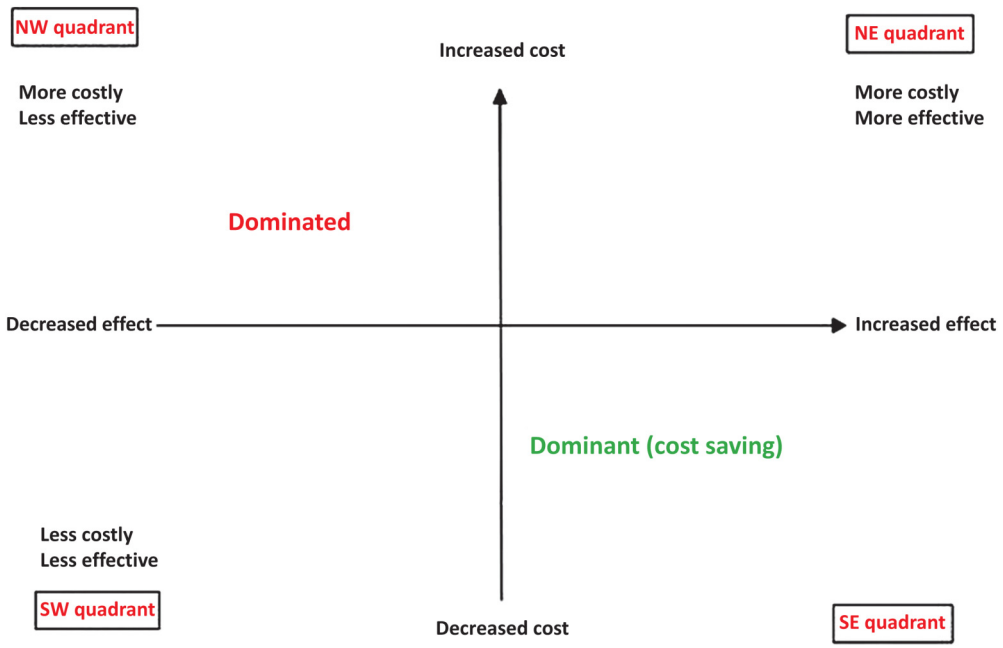

Figure 1 Cost-effectiveness plane utilized to represent ICERs in CEAs and CUAs. *NW*, north-west; *NE*, north-east; *SW*, south-west; *SE*, south-east.

plots in the north-east quadrant. The less steep this line is, implying more effects at lower costs, the lesser the ICER (the more cost-effective it is).

Plotting the net costs and net effects of multiple interventions on a cost-effectiveness plane allows for the comparison of their cost-effectiveness. It should be noted, however, that interventions should be compared only when the settings for the evaluations are equivalent; that is, same time horizon, same health-care system, and ideally, the same comparator.

If relative to the comparator, the intervention is more effective and less costly, then it is considered a *dominant* intervention (south-east quadrant). On the other hand, if the intervention is less effective and more costly, then it is considered a *dominated* intervention (north-west quadrant). For both dominant and dominated interventions, cost-effectiveness ratios are not calculated. This is because there is no need to measure the extent to which an intervention dominates its comparator, or is dominated by its comparator; in either situation, it is clear than one is better than the other.

Cost-Benefit Analysis

The principle of a cost-benefit analysis (CBA) is that all costs and treatment effects (benefits) are measured in equivalent units using only monetary values. That is, only net costs are explicitly expressed. Health outcomes are considered, but measured only in terms of their impact on costs. Costs may be those met by patients, the health-care system, or the general population (Ariyaratne et al., 2013).

The main advantage of CBAs is that they easily allow for budget planning. They can be used to compare treatment interventions that do not have comparable outcome measures and can help with resource allocation. Because only costs are explicitly measured in CBAs, ICERs are not derived.

The main limitation of CBAs is that it is often problematic to attach monetary values to health outcomes. As outlined by Drummond et al. (2005), attaching monetary value to health is commonly reflected by *willingness to pay* (WTP) using a human capital approach. A decision is made regarding how much an individual or society is willing to pay for better outcomes, or how much they are willing to save for poorer ones.

To illustrate a framework of a CBA (in terms of WTP), consider two treatment options (interventions A and B) for hyperkalemia among patients with chronic kidney disease. Intervention A is more effective in reducing serum potassium levels but is more expensive. The total costs over 1 year are $2000 and $1000 for interventions A and B, respectively. Assume that patients are willing to pay a mean cost of $1500 annually for the extra benefit. The net benefit of intervention A versus intervention B is thus $500 ($1500–$1000). The net benefit is thus reported aspositive; the preferred option is intervention A.

Other Types of Economic Evaluations

The principle underpinning a cost-minimization analysis (CMA) is that the interventions being considered have identical effectiveness, and thus the least costly intervention should be favored (Drummond, 2005). CMAs can incorporate the same outcomes measures as other main economic evaluations such as CEAs and CUAs. A common criticism of CMAs is that they are often undertaken on the basis of an observed lack (Briggs and O'Brien, 2001) of statistical significance in superiority studies interventions versus comparators. In clinical trials, lack of superiority does not necessarily imply equivalence or noninferiority between two treatments.

A cost-consequence analysis (CCA) is a form of economic evaluation in which outcomes are reported separately from costs, and there is no specific preference for one outcome measure over another (Drummond, 2005). CCAs typically report a range of outcomes and granular cost information. The intention of this approach is that the reader or decision maker can form their own opinion about the relevance and importance of various health interventions.

Costs

Perspectives

An important aspect of economic evaluations of pharmacotherapy is the *perspective* from which the results are considered; that is, the party paying for the costs. The main perspectives are those of the patient, the health-care system, a third-party payer, and the society as a whole. The perspective adopted determines the costs to be measured (Drummond, 2005), and as costs can vary considerably depending on perspective, the results of economic evaluations can vary across different perspectives. Most economic evaluations adopt either the *health system perspective* or the *societal perspective*, while the patient perspective is rarely adopted. The third-party perspective is mostly undertaken by third-party payers themselves, such as health insurance companies. For the purpose of this chapter, only the health system and societal perspectives will be discussed.

Measuring Costs

Economic evaluations can incorporate a range of costs, which can be grouped into two main types of costs: *direct* and *indirect* (Elliott and Payne, 2005). Direct costs can further be divided into direct medical and direct nonmedical costs.

Direct Medical Costs

Most economic evaluations of health interventions are limited to measurement of direct costs. Direct costs are related specifically to the relevant condition, are mostly borne by the health-care system, and are expressed as either fixed or variable (Drummond, 2005;

Elliott and Payne, 2005). Examples of variable costs include those of the treatments themselves and associated supplies and diagnostic tests, while examples of fixed costs include those of building capital, service infrastructure costs, and other overheads. The latter are largely constant as long as the intervention is being delivered by the same provider.

Direct Nonmedical Costs

Direct nonmedical costs are still directly relevant to the intervention, but not for the intervention itself. Examples include patient and family out-of-pocket expenditure on transportation and accommodation, and costs incurred within the health system for social and other support services.

Indirect Costs

Indirect costs are those consequent to reduced productivity from disease, among both patients and their caregivers. Loss of productivity occurs due to time off work (absenteeism), reduced productivity while at work (presenteeism), and early retirement. This reflects the *human capital approach*.

Indirect costs often make up a significant portion of the total cost of a disease or condition to society but are difficult to measure, and as such, are often not included in economic evaluations of pharmacotherapy. However, guidelines for economic evaluations of pharmacotherapy strongly recommend the inclusion of indirect costs (Drummond, 2005).

The magnitude of indirect costs is dependent on the disease. For example, diabetes and depression affect people of working age, and hence incur significant indirect costs, whereas dementia tends to be limited to older people post working age, and does not incur much productivity loss other than among caregivers. For all economic evaluations, it is also important to determine whose indirect costs are being measured (the patient or the caregiver), and how the activity was costed (i.e., disease episodes, at time of treatment, or after treatment).

Discounting

In economic evaluations, estimates of costs beyond 1 year into the future are usually *discounted* (Claxton et al., 2011; Krahn and Gafni, 1993; Severens and Milne, 2004), because the value of money in the future is less than at the present time (even after taking in considering inflation). This reflects human nature's preference for immediate gratification, and if not immediately, then as soon as possible.

Likewise, health benefits incurred in the future (e.g., years of life or QALYs lived) are also discounted. There are several formulae used for discounting, a common one of which is presented below.

$$\text{Discounted value} = \frac{x}{(1+r)^t}$$

x = undiscounted value of the cost or outcome of interest

r = annual discount rate

t = number of years beyond the first year

In general, the higher the discount rate (Claxton et al., 2011; Krahn and Gafni, 1993) applied to future costs and benefits, the lesser the favorable results of economic evaluations of pharmacotherapy. Hence, failure to appropriately discount future benefits and costs in economic evaluations leads to over-estimation of the cost-effectiveness of pharmacotherapy.

In Australia (Guidelines, 2016), an annual discount rate of 5.0% is usually applied to both future costs and benefits. The United Kingdom (National Institute for Health and Clinical Excellence, 2013), France (Haute Autorité de santé, 2012), Canada (Canadian Agency for Drugs, In Press), and Finland (Application Instructions, In Press) also apply the same annual discount rate for both cost and benefits, but the rates vary between 1.5% and 5.0%. Other countries use differential annual discount rates for costs and benefits. For example, the Netherlands (Guidelines for pharmacoeconomic, In Press) uses a discounting rate of 4.0% for costs and 1.5% for benefits (health outcomes).

Health Effects

The most common measures of the health effects of pharmacotherapy used in economic evaluations are clinical outcomes, *patient reported outcome measures*, LYG, and QALYs gained (or lost) (Brazier et al., In Press; Drummond, 2005).

Clinical Outcomes

Clinical outcomes are measurable changes in health as a result of pharmacotherapy. Important clinical outcomes are usually reported in clinical trials and include morbidity endpoints, such as Myocardial infarction or stroke, and mortality.

Other measures often reported in clinical trials are surrogate (intermediate) outcomes (Fleming and Powers, 2012). A surrogate outcome is defined as "a laboratory measurement or a physical sign used as a substitute for a clinically meaningful outcome that

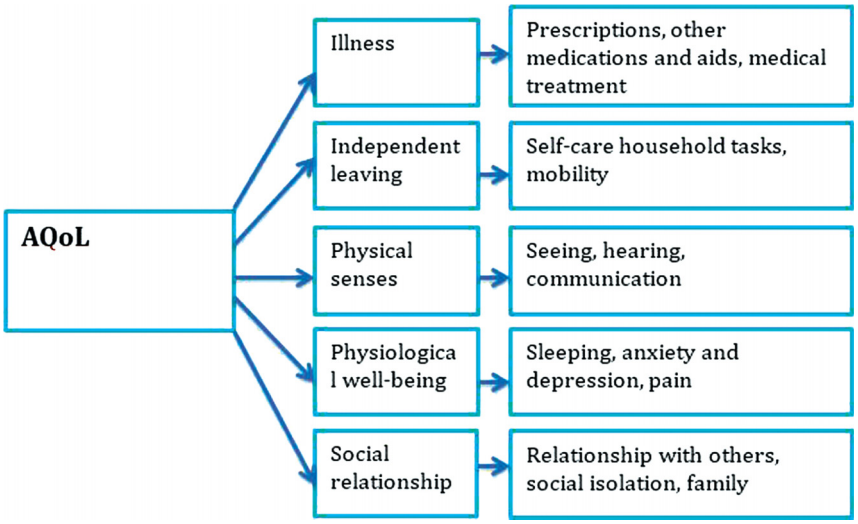

Figure 2 AQoL-assessment of quality of life.

measures directly how a patient feels, functions or survives" (Bucher et al., 1999). Examples include blood pressure as a surrogate for stroke or low-density lipoprotein cholesterol for myocardial infarction or ankle brachial index for peripheral arterial disease.

Patient-Reported Outcome Measures (PROMs)

Patient reported outcome measures (PROMs) are those directly reported by patients to provide a measure of benefit or harm from their own perspective. PROMs are collected using instruments (mostly self-completed questionnaires) that reflect health status, or the different aspects of physical, mental, and social well-being. An example is the assessment of quality of life (AQoL) tool (Hawthorne et al., 1999), illustrated in Fig. 2.

PROMs can be either generic or disease specific. The most commonly used generic PROMs for health-related quality assessment is the EuroQol five-dimension scale (EQ-5D) (Balestroni and Bertolotti, 2012). The five dimensions nominally considered pertain to mobility, pain/discomfort, usual activities, self-care, and anxiety/depression, and these can be measured on either three (EQ-5D-3L) or five (EQ-5D-5L) levels: "no problems," "slight problems," "moderate problems," "severe problems" and "extreme problems," For example, generic PROMs can be used in absolute terms, such as improvement in walking, or can be used to report overall changes perceived from previous pharmacotherapies. Generic PROMs allow for the assessment of a variety of conditions and interventions, whereas a disease-specific instrument better target the assessment of a particular disease, group of patients, or intervention. As such, generic and disease-specific instruments might give different results. Generic instruments are more relatable and useful to decision makers, which disease-specific instruments might be more useful to patients or physicians.

Life Years Gained and Quality-Adjusted Life Years Gained

LYG (or life years lost) and QALYs gained (or lost) are the most widely used measures of health effects in the economic evaluations of pharmacotherapy (Ademi et al., 2013b; Brazier et al., In Press). Both are summary measures, taking into account the potential for drug treatments to both save life or quality-adjusted life (through their beneficial effects), as well as to reduce these (through their adverse effects).

LYG conferred by health intervention is calculated by subtracting the expected years of life lived by patients assigned to the intervention by the expected years of life lived by patients assigned to the comparator. That is, it is the difference in expected years of life lived between the intervention and comparator patients or groups of patients. LYG is usually derived from modeling analyses, which are discussed in Section 6.

QALYs take into account impairment in quality of life as a consequence of disease and "penalise" time lived accordingly. To calculate QALYs, years lived are multiplied by *utilities* (Brazier et al., In press), which are weights used to reflect quality of life, and which range from 0 (zero quality of life) to 1.0 (full quality of life). For example, if the utility associated with moderately severe stroke is 0.70, then a person living 1 year with moderately severe stroke lives 0.70 QALYs. One QALY is the equivalent of 1 year of healthy life lived. The concept of a QALY is illustrated in Fig. 3.

The entire bar represents the total years lived by a person or a group of people. The solid part of the bar represents the years lived in full health (QALYs) and without impairment in quality of life. The hashed part of the bar represents years lived with disability and with impaired quality of life.

Cumulative QALYs lived over a period of time can be estimated by plotting utilities over time and measuring the area under the curve of the plotted line. Cumulative QALYs can then be compared for an intervention versus its comparator. To demonstrate, consider the hypothetical example illustrated in Fig. 4.

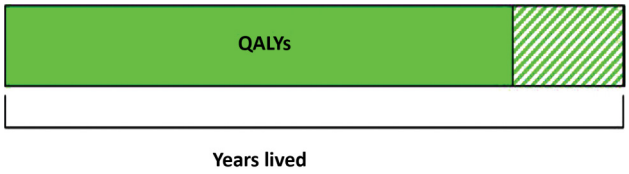

Figure 3 Example of QALYs versus years lived.

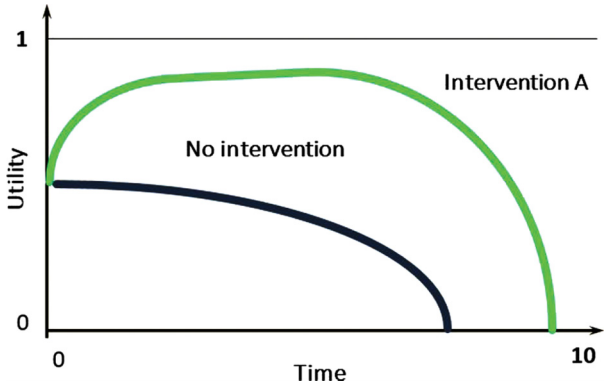

Figure 4 Cumulative quality adjusted life years over time.

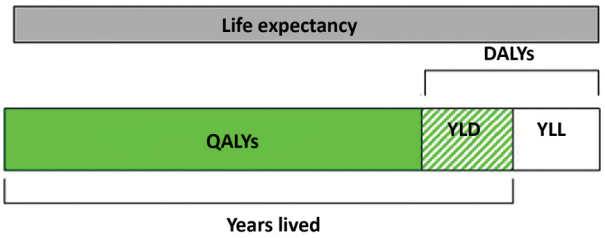

Figure 5 Example of disability adjusted life years versus years lived and quality adjusted life years.

The Figure plots utilities over time for patients after the onset of a disease at time = 0. The gray line represents a scenario without intervention. The utility starts at 0.5 and decreases gradually over time until death. The area under the curve is equivalent to approximately 3.0 QALYs. The green line represents a scenario with an intervention that both improves quality of life and extends it. The utility starts at 0.5, but increases for a little while until it reaches 0.8, then plateaus for a few years, before decreasing until death. The area under the curve is equivalent to approximately 6.0 QALYs.

Measures of the health effects of interventions can also be expressed in terms of *disability-adjusted life years* (DALYs) avoided. DALYs measure burden of disease and take into account both premature mortality due to disease, as well as years lived with disability. Premature mortality is estimated by subtracting the actual years lived by a person or a group of people by the life expectancy of that person or group of people. The concept of DALYs is illustrated in Fig. 5.

The gray bar represents the life expectancy of person or a group of people. The green bar represents the actual years lived by a person or a group of people. The solid part of the green bar represents the years lived in full health (QALYs). The hashed part of the green bar represents *years lived with disability* (YLD), and the white bar represents *years of life lost* (YLL) due to premature mortality from disease. DALYs are the sum of YLD and YLL.

In Fig. 5, the distinction between QALYs and DALYs is made clear. Both take into account the time lived with disability (and consequent reduced quality of life) due to disease. However, QALYs measure quality-adjusted time lived, while DALYs measure quality-adjusted time lost.

Economic Evaluations Alongside Clinical Trials

This section reports on a number of issues that are specifically related to conducting economic evaluations alongside clinical trials. *Trial-based economic evaluations* are designed where possible to estimate the effectiveness of interventions (instead of efficacy) and collect information on health service use and related costs (Ramsey et al., 2015).

Table 3 Analysis plan considerations for trial-based economic evaluations

Quality of life
Follow-up time
Appropriate power/sample calculations
Medical services use
Statistical analysis
Type of analysis
Subgroup analysis
Data collection elements
Presentation of results

This section will deal with issues specific to trial-based economic evaluations of pharmacotherapy: (1) the analysis plan before conducting trial-based economic evaluations; (2) analysis of cost data; and (3) the display of results and uncertainty considerations.

Analysis Plan

An analysis plan describes different data elements and steps that need to be taken before the commencement of trial-based economic evaluations (Glick et al., 2014). **Table 3** lists the key aspects that should be taken into consideration.

A study should define clearly the trial design (e.g., parallel group or crossover study) and its intent, (e.g., superiority or noninferiority) (Brown and Lilford, 2006). The analysis plan should provide a clear set of objectives and hypotheses, incorporate information on the population, intervention, comparator of interest, and define clearly the primary and secondary endpoints. The latter will of course include costs.

As described by Hlatky et al. (2006), the measurement of economic endpoints incorporates two components, namely, the quantity of medical services utilised (collected in the trial) and the unit cost (prices) of these services. The formula to calculate the total costs per patient in clinical trials is as follows:

$$C_a = \sum Q_{ar} P_r$$

C_a = cost per patient

Q_{ar} = quantity of resources r used for patient a

P_r = the unit costs for resource r

Health care resources collected in trial-based evaluations include those of treatments, hospitalizations, personnel, and rehabilitation and home-care services. However, unit costs of these resources are usually collected retrospectively and outside of the clinical trial, as specific unit costs from a single hospital are not regarded as the best source of information (Hlatky et al., 2006) when results are to be represented on a national level. To represent costs nationally, unit costs are usually drawn from national fee schedules.

As highlighted in Section 4, the measurement of health-related quality of life is also important for the assessment of pharmacotherapies in a trial-based economic evaluation. The analysis plan should include the necessary available algorithms required to calculate utilities.

The time horizon for a trial-based evaluation is obviously limited to the duration of the trial, while the appropriate time horizon may well exceed this. For example, the benefits of pharmacotherapy may continue to accrue long after the time duration of a trial, which as mentioned previously, may be short. Regardless, the analysis plan should specify the time horizon as well as the time points at which health effects and costs are measured.

Sample size estimations in clinical trials are usually based on the minimum number of study participants in both groups. However, the number of study participants required for economic assessments of pharmacotherapy can vary from what is needed for the clinical evaluation. That said, in order to minimize potential bias and to be transparent, it is preferable to avoid having clinical trial and economic evaluation sample sizes that are markedly different.

It is also important to capture all relevant health-care utilization during follow-up, particularly those that are expected to differ significantly between the intervention and comparator groups. If only a fraction of health-care utilization is measured, the economic outcomes between groups may be significantly underestimated (Glick et al., 2014). Conversely, collecting a large amount of unnecessary data would pose a practical burden to running the clinical trial. As such, trial-based economic evaluations often focus on estimating only direct medical costs and enroll only a subset of subjects in the clinical trial.

An analysis plan should also highlight the statistical methods utilized to deal with cost data, as well as the type of analysis and subgroup analysis (i.e., where the pharmacotherapy benefit might be more evident in one subgroup of participants) conducted. Furthermore, data collection elements from primary and secondary sources should be described in detail. Some data elements can only be collected prospectively (Glick et al., 2014) through case report forms, electronic medical records, or by providing booklets to patients that serve as a memory aid in follow-up or telephone interviews. Other data elements, such as unit costs and those highlighted above, can be collected retrospectively. Finally, the analysis plan should report on how results will be measured and displayed, in terms of cost per LYG and/or cost per QALY gained.

Analysis of Cost Data

When performing an economic evaluation, it is crucial to test whether there are statistical differences in costs between pharmacotherapies. The first step is to understand and identify the nature and distribution of cost data. Cost data are typically positively skewed, with a relatively low number of patients with high costs and an absence of negative costs (Elliott and Payne, 2005; Glick et al., 2014).

When dealing with skewed data, as per Drummond et al. (2005), the recommendation is to provide a summary of standard descriptive statistics, with histograms to visually represent the distributions of costs in terms of mean, median, and percentiles.

Nowadays, the most common statistical method used to test for differences between treatments in trial-based economic evaluations is based on nonparametric bootstrapping (Glick et al., 2014). Bootstrapping is a statistical technique that was developed by Efron (Efron and Tibshirani, 1994) and is based on resampling, which examines how the value of a statistic (costs) would vary if it was resampled multiple times. To manage this, the resampling of observable data is conducted using computer software such as Stata: data analysis and statistical software, R (programming language), or statistical analysis software (SAS). For example, with a set of observed cost data for 200 people in two treatment groups (A and B), one would repeatedly sample from the observed data. The point estimates of means and differences in means (the point estimates in this case refer to cost) for the 200 people are directly derived from the data set, while the empirical distribution of the difference in means, standard errors, confidence intervals, and *p*-values (Efron and Tibshirani, 1994; Glick et al., 2014) are all derived from the bootstrapping (resampling) of the same data set.

To measure the variability, a sample of size N_a is repeatedly and randomly drawn "with replacement," where N_a is equal to the number of study participants in treatment group A (i.e., $n = 100$). The same process is performed for treatment group B ($n = 100$). In this instance, "replacement" means that when an individual item is drawn it is not removed from the subsequent possible sample pool, such that it can be selected more than once in the same sample. The repetition of this many times over for both treatment group A and B provides with a series of resamples (i.e., bootstraps), where each resample differs from one another.

If resampling was performed without replacement (i.e., no item can be randomly picked twice in the same sample), the resamples (bootstraps) would simply replicate the analysis of the original trial data. As per Efron et al. (Efron and Tibshirani, 1994), it is recommended that to receive a robust result, 1000 resamples should be utilized to estimate bootstrap confidence intervals.

In trial-based economic evaluations, it is preferred to conduct not only a univariate analysis but also a multivariable analysis, as a multivariable model can adjust for the significant number of factors involved, such as subgroups, severity of diseases, and countries. There are a number of multivariable models available, and which to utilize depends upon the sample size and distribution of cost data.

The most common models performed are generalized linear models, using a logarithmic link function with a gamma distribution of errors (Ademi et al., 2010; Glick et al., 2014). Regression models are also common, and such models may be favored over others due to their ease of interpretation (Mihaylova et al., 2011), as the coefficient difference between two treatment groups provides a direct estimate of arithmetic mean of cost. Other models such as zero-inflated negative binomial models are used when there is a presence of a substantial proportion of null values (e.g., hospitalization costs).

Display of Results and Consideration of Uncertainty

As discussed in Section 2, the key output of interest in economic evaluations is the ICER. The differences in effects and costs between a pharmacotherapy and its comparator can also be depicted on the cost-effectiveness plane (as shown in **Fig. 1**). Analyses for trial-based economic evaluations should be performed using an intention-to-treat approach. If the analyses adopt a time horizon of more than one year, costs and effects should be discounted based on rates typically used for the drug market of interest.

As will be discussed more broadly in the next section, it is important to represent the uncertainty of results derived from trial-based economic evaluations. Estimates of costs and health effects are associated with uncertainty, and as a consequence, these need to be expressed.

Lastly, trial-based economic evaluations (as well as modeled economic evaluations) should adhere to established standards for reporting results of health economics of pharmacotherapy, such as the Consolidated Health Economic Evaluation Reporting Standards (CHEERS) checklist, in order to allow for scrutiny of their findings (Husereau et al., 2013).

Economic Evaluations Using Modeling

Section 5 discussed the collection of data regarding health effects and costs required for trial-based economic evaluations. However, the duration of clinical trials is often shorter than the time period over which pharmacotherapy is delivered in practice and almost

always so for chronic diseases. Therefore, the costs and effects of pharmacotherapy often need to be extrapolated beyond the duration for which information is directly available from clinical trials. In these situations, economic evaluations have to be based on modeling.

This section will cover common methods used in *modeled economic evaluations* of pharmacotherapy: *decision analysis*, *Markov modeling,* and *Monte Carlo simulation* to capture uncertainty. There are other approaches to modeled economic evaluations (such as discrete event simulation and neural networks), but these are far less popular, and will not be covered here.

Decision Analysis

Decision analysis (Lilford et al., 1998) is a method commonly used to quantify the downstream consequences of health-care choices, including pharmacotherapy, in order to inform decision-making. In economic evaluations, the consequences of interest are health effects and costs, as discussed in previous sections.

Decision analysis is usually conceptualized as a *decision tree*, which outlines and quantifies the consequences of the two or more options of a decision to be made. Fig. 6 provides a simple, hypothetical example of a decision about whether or not to start drug therapy. Therapy is associated with both potential benefit (decrease in the risk of "disease A") and harm (increase in the risk of "disease B").

The square is the *decision node*, the point where options are defined. In this example, the two choices are "No drug therapy" and "Drug therapy." The circles represent *chance nodes*, from which emanate the possible consequences of each choice. These are called *transition states*. Both options in the example have the same four possible transition states: "Remain in good health," "Develop 'disease A' (but stay alive)," "Develop 'disease B' (but stay alive)," and "Die" (from any cause). The underlying likelihoods of their occurring are indicated below the relevant subbranches and are called *transition probabilities*. The sum of all transition probabilities emanating from a chance node is always one, meaning the transition states are exhaustive (capture all possible consequences) and mutually exclusive (no overlap).

In the example, compared to no drug therapy, drug therapy is associated with a lesser likelihood of developing nonfatal "disease A" (16% vs. 20%) and of dying (9% vs. 10%), but a greater likelihood of developing nonfatal "disease B" (22% vs. 20%). These figures might be based on the findings of a clinical trial of the drug, which showed that compared to placebo, the drug reduced the relative likelihood of "disease A" and death by 20% and 10%, respectively, and increased the relative likelihood of "disease B" and death by 10%. Based on changes to the transition probabilities of "disease A," "disease B," and death, the net change to the transition probability for the transition state "Remain in good health" is increased from 50% to 53%.

The triangles are *terminal nodes*, where the health impact of each consequence, called a *payoff*, is quantified. In economic evaluations, payoffs are direct measures of health effects and costs, which have been discussed in previous chapters. Assume that in the example illustrated in Fig. 6 that the utilities associated with "good health," "disease A," "disease B," and "death" are 1.0, 0.8,

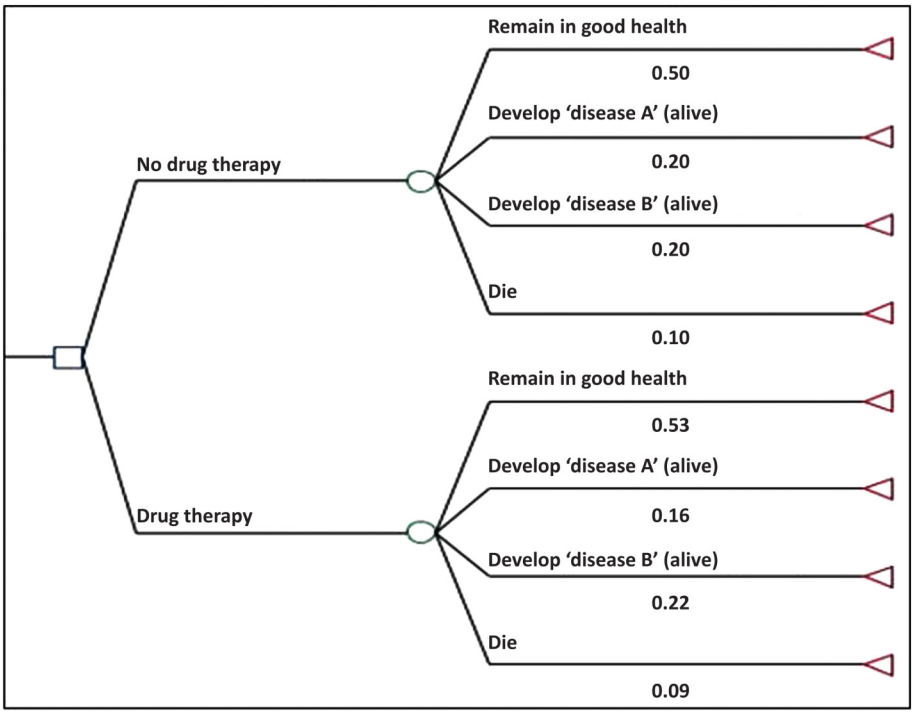

Figure 6 Hypothetical example of a decision tree.

0.6, and 0, respectively. To analyze (evaluate) a decision tree, the "expected value" of each branch is calculated by multiplying the payoff associated with each transition by the probability of it occurring, and then summing these. That is, the expected value of each branch ("No drug therapy" and "Drug therapy") is: Σ (payoff"*transition probability"). In effect, the expected value is a weighted-average payoff associated with the option. In the example, the expected value of "No drug therapy" is 0.78 utility (0.50*1.0 + 0.20*0.8 + 0.20*0.60 + 0.10*0), and the expected value of "Drug therapy" is 0.79 utility (0.53*1.0 + 0.16*0.80 + 0.22*0.60 + 0.09*0). Therefore, on average, drug therapy would provide a (slightly) more favorable health return compared to no drug therapy. Despite that it increases the risk of the more severe "disease B," this is insufficient to offset its beneficial effects on the risk of nonfatal "disease A" and death.

In terms of costs, assume that the costs associated with "good health," "disease A," "disease B," and "death" are $0, $100, $500, and $200, respectively. Analysis of the tree would then lead to expected dollar values of "No drug therapy" and "Drug therapy" being $140 (0.50*$0 + 0.20*$100 + 0.20*$500 + 0.10*$200) and $144 (0.53*$0 + 0.16*$100 + 0.22*$500 + 0.09*$200), respectively. If the cost of drug therapy is assumed to be $300, then the net cost of drug therapy would be $300 + ($144–$140) = $304.

Overall, in the example, on average, if drug therapy was to be delivered, it would increase utility by 0.01 (from 0.78 to 0.79), but cost $304 dollars more.

By itself, decision analysis considers only one sequence of events within one time-frame. This is a limitation if the conditions being simulated have different sequential stages, and/or data inputs (such as transition probabilities or costs) evolve with time. To overcome this inherent limitation of basic decision analysis, Markov modeling (Briggs and Sculpher, 1998) is often employed.

Markov Modeling

Fig. 7 illustrates an extension of the situation depicted in Fig. 6, in which multiple sequential events over multiple, cyclical time periods is considered.

After a subject develops "disease A," that subject may later develop "disease B," and vice versa. Recovery from either diseases is not assumed to be possible (and hence there is no transition back to "healthy"). Any subject is also susceptible to death at any time. To capture all possible events, multiple "health states" need to be incorporated into the model, each with its own set of possible transitions. The exception is death, from which no transitions can be made. Death is considered an absorbing state.

Analysis of Markov decision trees does not involve just a single transition of subjects from left to right across the branches, but rather involves repeated recycling, over discrete time periods called *cycles*, between the terminal nodes (except in the case of absorbing states) and the encircled "M"s, which are called *Markov nodes*. Markov nodes represent the points to which individuals return at the end of each cycle, and are channelled to one of the health states to begin the next cycle, either one previously occupied or another, depending on the transition they just made.

The above process describes Markov modeling (Briggs and Sculpher, 1998), named after the Russian mathematician Andrei Markov (1856–1922).

The key features of a Markov model are as follows:

- That subjects reside in one of a finite set of mutually exclusive *health states*.
- That time is represented by discrete periods called *cycles*, and individuals move between health states via *transition states*, or remain in their current health states, at the end of each cycle.
- That movements are governed by *transition probabilities* that are specific to each health state and each cycle.

Evaluation of a decision tree analysis, which incorporates Markov modeling, is straight-forward: expected values are calculated at the end of each cycle and summed at the end of the simulation.

The main advantage of incorporating Markov modeling into a decision analysis is that is allows for the simulation of more complex consequences of an option, as is illustrated above. Not only can a greater number of possible events be simulated, but they can also be simulated for lengthier periods downstream.

For Markov models with long time horizons, it is important to account for the fact that many data inputs (such as transition probabilities, utilities, and costs) evolve over time. For example, as the age of model subjects increases with repeated cycles, their risks of diseases will increase. Hence, cycle-specific inputs are often needed for Markov models. For some inputs, cycle-specificity is easily estimated, such as age-related changes to risks of disease, but for others, it poses a challenge due to a lack of data, such as age-specificity of disease costs and utilities.

The main limitation of Markov models is that with any cycle, the possible transitions which individuals can make depend only on the state they are in, and not on how they arrived at that state. That is, Markov modeling "lacks memory." For example, in Fig. 7, the health state "Alive with disease A" makes no distinction as to how long subjects have had "disease A." In later cycles of the model, subjects occupying that health state will have only recently arrived, while others may have been there for many cycles. The problem may be overcome by including as many health states as is required to reflect important disease combinations. For example, separate health states could be included that distinguish "disease A" by the time since its onset ("Alive with 'disease A' occurring within the last year," "Alive with 'disease A' occurring within between 1 and 5 years ago," and so on). However, inclusion of too many health states into a Markov model can render it unwieldy. Paradoxically, a complex Markov model that attempts to more accurately reflect multiple related conditions may be subject to more uncertainty because of the need for more data inputs and assumptions to be made about them. A compromise is needed that optimally balances the need to reflect relevant outcomes and reduces uncertainty.

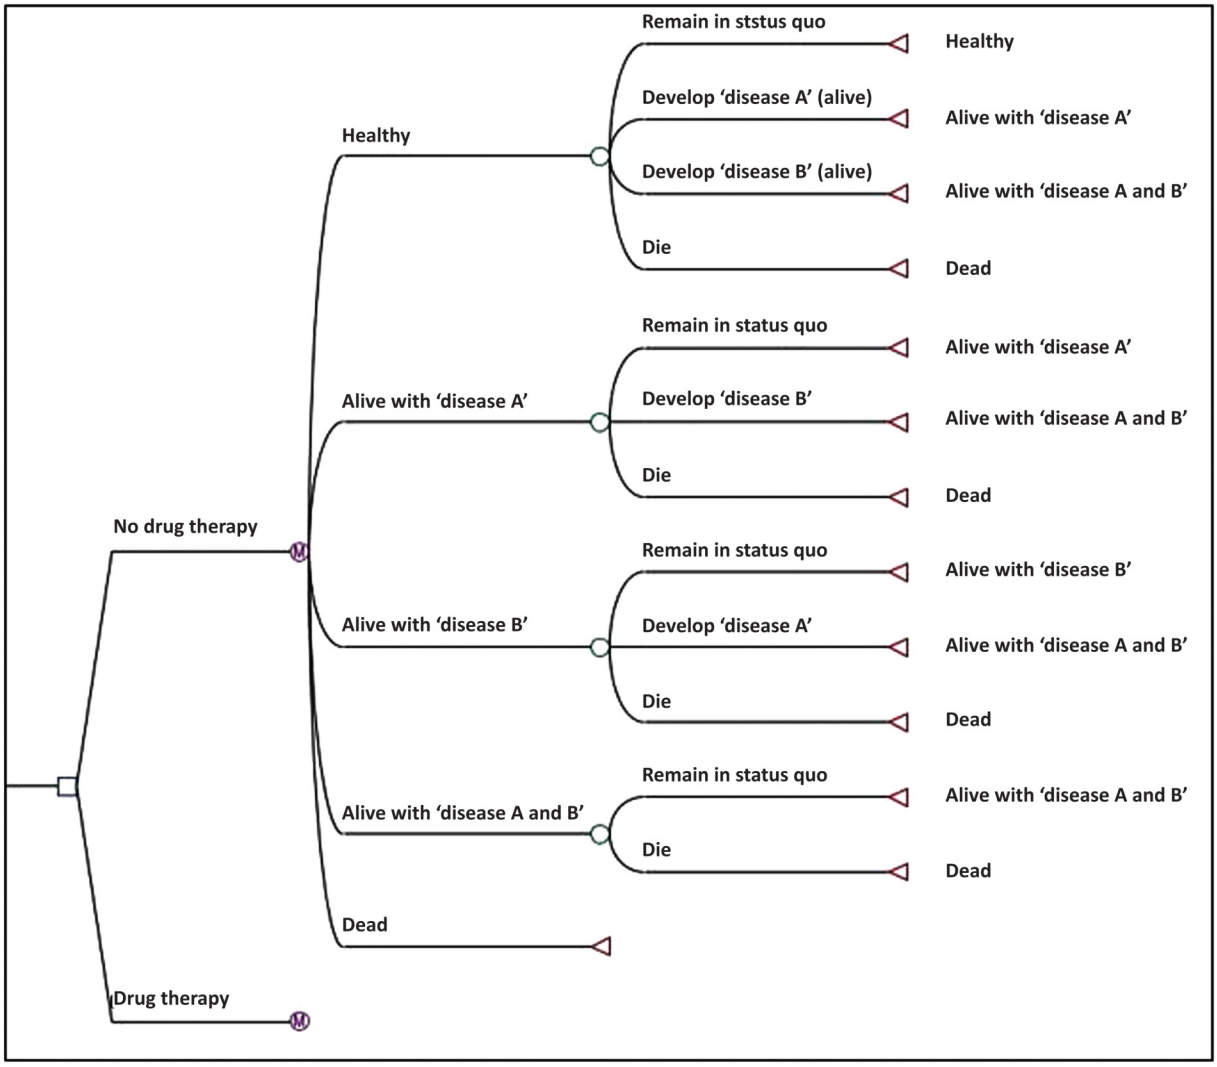

Figure 7 Hypothetical example of a Markov decision tree.

Monte Carlo Simulation

Because modeling is based on conjecture, it is important that uncertainty be expressed in the modeling outputs. Models are vulnerable to uncertainty because they rely on multiple data inputs, and as the number of inputs and modeling steps increase, so too will uncertainty in outputs. In addition, assumptions have to be made in many instances, which serve to increase uncertainty even further.

Monte Carlo simulation (Briggs, 2000) refers to a method of undertaking multiple simulations of a model, each time taking samples from specified uncertainty ranges of the model's inputs (as opposed to point estimates). These uncertainty ranges are most often expressed as probability distributions. Probability distributions describe the range of possible values for a parameter as well as the probability of each value occurring. Common types of probability distributions include "gamma," "uniform," "normal," and "triangular," as illustrated in Fig. 8. Probability distributions that relate to data inputs for a model are often called *input distributions*.

As Monte Carlo simulation involves multiple simulations, it therefore generates multiple outputs, from which probability distributions can also be derived. These are often called *output distributions*. With only a small number of iterations in a Monte Carlo simulation, the output distribution is not well defined. However, as more iterations are run, the output distribution becomes definable and is said to become stable. This phenomenon is known as *convergence*. A sufficient number of iterations must be undertaken in Monte Carlo simulation such that convergence of an output distribution occurs.

Monte Carlo simulation modeling is also known as *stochastic* modeling. This defines a type of modeling in which there is a range of possible outputs that is dependent on the probabilistic nature of inputs. In contrast, models whose outputs are fixed because their inputs do not vary are known as *deterministic* models.

In Monte Carlo simulation, the results of each iteration can also be depicted graphically to demonstrate the range of the uncertainty, as illustrated in Fig. 9. The cluster of results in the north-east quadrant is drawn from multiple analyses. The spread

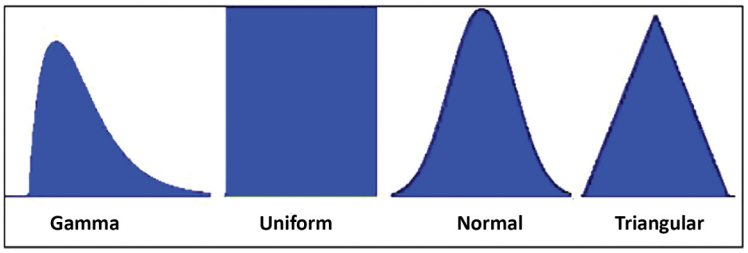

Figure 8 Common types of probability distributions used in uncertainty analyses.

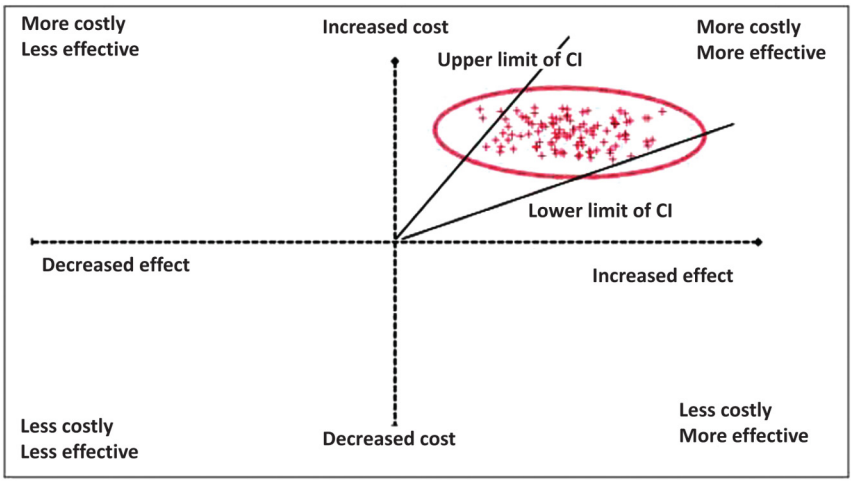

Figure 9 The results of Monte Carlo uncertainty analyses depicted on a cost-effectiveness plane.

of this cluster provides a reflection of the uncertainty in the analyses. In Fig. 9, reference lines representing the lower and upper limit of the range of ICERs are also shown.

Commonly Used Software Packages for Modeled Economic Evaluations

Microsoft Excel (Microsoft Corporation, Redmond, WA) is also widely used to undertake pharmacoeconomic analyses. Being entirely flexible, it can be programmed to simulate decision analysis and Markov modeling. Monte Carlo simulation is enabled in Excel via programming in Visual Basic, or with the use of add-on macros, such as @RISK (Palisade Corporation, Ithaca, NY).

TreeAge (TreeAge Software Inc., Williamstown, MA) is a commonly used software package designed specifically for decision analyses. It is a powerful program that also allows for construction of complex Markov models and incorporates uncertainty analyses via Monte Carlo simulation.

Utilization of Economic Evaluations by Decision Makers

Around the world, health policy decision makers and payers are compelled to ensure delivery of quality health care under ever-tighter budgetary constraints and increasing demand. This situation is fuelled by many factors, chief among which are ageing populations, expensive health technologies, and financial uncertainty. Especially among countries that provide universal health care for their populations, or are striving to it, the process of deciding which health technologies to invest in is a major challenge. Decision-making has to take into account the complex interplay among medical, social, economic, and ethical factors. The way in which health systems are organized is also obviously important. In many countries, such as Australia and Canada, funding for some aspects of health care is provided by the Federal government, but delivered by State or Provincial governments.

Table 4 lists the key countries around the world in which the costs of pharmacotherapies are largely subsidized, and the drug reimbursement authorities in each of these countries that undertake or commission formal HTAs to guide decision-making. Whether or not the findings of HTAs are mandated to be used in decision-making is also noted. The countries listed in Table 4 are among the first to have implemented subsidized pharmacotherapy for their populations (i.e., they are "mature" drug reimbursement markets) and hence are leaders in the science (and art) of pharmacoeconomic evaluations. These countries and their drug reimbursement authorities also have significant global or regional influence because of the size of the markets over which their deliberations have direct or indirect implications.

Table 4 Key countries with "mature" drug reimbursement markets and their major drug-related health technology assessment (HTA) authorities

Country	*Drug-related HTA authority*	*Legislative requirement regarding HTA and decision-making*
Australia	Pharmaceutical benefits Advisory Committee (PBAC)	Results of HTAs have to be considered
Canada	Canadian Agency for Drugs and Technologies in Health (CADTH)	No formal requirement to consider results of HTAs.
Germany	Gemeinsamer Bundesausschuss (G-BA, Federal Joint Committee) and Institute for Quality and Efficiency in Health Care (IQWiG)	Results of HTAs have to be considered
Republic of Korea (South Korea)	National Evidence-Based healthcare Collaborating Agency (NECA)	Results of HTAs have to be considered
Republic of China (Taiwan)	National Health Insurance Administration (NHIA)	Results of HTAs have to be considered
United Kingdom	National Institute for Health and Care Excellence (NICE)	Results of HTAs have to be considered

HTA, Health technology assessment.

There is also cross-referencing among the major reimbursement authorities around the world. For example, decisions made by the UK National Institute for Health and Care Excellence (NICE) are often noted by the Australian Pharmaceutical Benefits Advisory Committee (PBAC), and vice versa.

Given concerns about growing health budgets, more and more countries are adopting HTA to assist with decision-making around pharmacotherapies, or are signaling that they will. For example, Japan introduced a HTA system for evaluating drugs in 2016 (despite that it has funded a universal health-care system since 1961), and there are strong indications that HTA will be used in the future listing, pricing, and reimbursement of drugs at a national level in China.

The Future

As discussed in Section 7, there is growing awareness of the need for HTA in decision-making around the world. This is a driving interest in pharmacoeconomics, both as a science and as a tool to inform health practice and policy. As discussed in Section 4, measures of health effects are also becoming broader, including to incorporate patient-relevant outcomes. Furthermore, new methods for data analysis and advances in data technology are changing the way economic evaluations of pharmacotherapies can be undertaken. In particular, three important, and inter-linked, ongoing developments warrant discussion: *clinical registries*, data technology, and *propensity score analysis* to estimate the efficacy of drugs.

Clinical registries (Wilcox and McNeil, 2016) represent an important method for monitoring the quality of health care. They are essentially longitudinal observational studies that systematically collect data in a uniform manner for populations identified by a specific exposure, disease, or drug. Measures of interest typically include clinical processes and practice, as well as key health outcomes such as death and disease complications. PROMs and costs are also increasingly being incorporated into clinical registries, as these outcomes inform not only the quality but also the "value," of health care. Of the various types of clinical registries, drug registries (Reid, 2015) are perhaps the easiest to mount, because identification of eligible subjects (patients who are prescribed the drug of interest) is relatively straightforward. However, the tracking of outcomes, other than the prescription of other drugs, is generally not easier than for other types of clinical registries (Ariyaratne et al., 2013).

One of the reasons behind the rising popularity of clinical registries is the increasing sophistication in techniques for data collection and analysis. Data linkage, which identifies individuals across different datasets, already offers a convenient way to capture outcomes, including costs, without having to measure these directly "in the field." For example, a drug claims dataset can be linked to a death registry to identify people who were dispensed certain medications and subsequently died, or linked to a hospitalization dataset to identify subsequent hospitalizations for particular conditions, as well as their associated costs. Hence, the downstream health effects of drugs can be estimated, as well as costs. Another advantage of data linkage is that it can be undertaken after outcomes have occurred, meaning that large and mature longitudinal cohorts can be assembled retrospectively. In future, artificial intelligence (machine learning) will also allow for easy analyses of unstructured text (such as free text entries in electronic prescriptions), as well as PROMs. The latter could even be sourced from data contained within "everyday" data sources, such as social media, as long as adequate ethical clearance is obtained. Lastly, ever-evolving improvements in data security, involving both hardware and software platforms, will further facilitate data capture and processing from a broad range of sources. "Big data" and the "internet of things" promise much, but the exchange and use of data need to be properly governed.

Given the increasing ease with which longitudinal observational studies (including drug registries) can be undertaken, it is also important that methods have also evolved to allow for the unbiased assessment of the efficacy of drugs in these studies. Propensity score matching (D'Agostino, 2007) represents a way to assemble two or more groups for comparison so that they appear like they had been randomized to a specific drug or its comparator. In short, the method involves logistic regression analyses to determine the likelihood (propensity) of each person within a cohort being on the drug, and then matching people who were on the drug to those who were not on the basis of propensity scores (Ademi et al., 2013c). Outcomes are then compared between the groups.

On a global scale, economic evaluations of pharmacotherapies is a relatively new field, but it is one which is growing rapidly, especially as more and more countries adopt HTAs to help with decision-making in funding health care, and as new methods an new data technology emerge.

Methodological Considerations in Pharmacoepidemiology and Pharmacovigilance Studies

Marjaana Koponen[*], **Jenni Ilomäki**[†,‡], **Emma Aarnio**[*,§], **Heidi Taipale**[*,¶], [*]University of Eastern Finland, Kuopio, Finland; [†]Centre of Medicine Use and Safety, Monash University, Melbourne, Australia; [‡]Monash University, Melbourne, Australia; [§]Institute of Biomedicine, University of Turku, Turku, Finland; [¶]Karolinska Institutet, Stockholm, Sweden

Introduction

Much of the developments in pharmacoepidemiology are triggered by historical changes in legislation or misadventures related to pharmaceuticals. For example, the United States (US) Food and Drug Administration's (FDA) Food, Drug, and Cosmetic Act in 1938 on medication safety, and the Kefauver-Harris Amendments in 1962 of medication efficacy were introduced to ensure medications marketed in the United States are safe and efficacious (FDA 2012). The latter was prompted by the thalidomide crisis in 1961, where up to 100,000 children were born with congenital anomalies such as phocomelia (FDA 2012). This was also the prompt for the establishment of the World Health Organization's program for International Drug Monitoring in 1968. The thalidomide-related deformities were reported first by Australian obstetrician McBride (McBride, 1961). He reported observing a deformity incidence of 20% in babies of women taking thalidomide when the usual incidence was 1.5% without thalidomide exposure. (McBride, 1961).

Pharmacoepidemiology in based on general epidemiological methods. However, there are some specific differences when medications are assessed as exposure compared with for example environmental, social, and occupational exposures. One benefit in measuring medication exposure compared to other exposures is that it is quite easy to capture very specific exposure in terms of timing and amount depending on the data source used. Despite this, there is a debate among people in the pharmacoepidemiology field on exposure measurement definitions, however, this is natural. For example, results from observational studies are often compared to results from randomized controlled trials where everything happens in a controlled environment.

Being such a young discipline, pharmacoepidemiology has evolved rapidly and new methodologies are applied from other epidemiology disciplines, or new methodologies are developed. Examples of these novel methodologies are discussed in this chapter.

Definition of Medication Exposure

Various data sources for medication exposure have been utilized in pharmacoepidemiological research. Surveys and interviews are common data sources for drug utilization studies; however, automated or electronic databases are more frequently utilized in pharmacoepidemiological research. Most of these databases were primarily founded for administrative purposes, and therefore may lack some important information restricting their potential use.

Strengths and Limitations of Using Different Data Sources in Pharmacoepidemiological Studies

Survey and Interview-Based Data

Information on medication use can be acquired in various questionnaire-based methods, including surveys, interviews, and diaries of used medications. Questionnaires on medication use require a careful design due to complexity of medication use, including the nature of the disease medication is used for, the number of medications available for the same condition, the number of products of the same medication, and complexity of medication regimens which often include more than one concomitant medication for a specific condition. The main strength of surveys and interview-based data is that participants are asked to report their actual medication use (West, 1997). They can be also asked about the regularity of use, dosing, and dose times per day. For medication that are used "as needed," participants may be asked to describe how often they have used these medications. In surveys and interviews, also use of over-the-counter (OTC) medications, nutritional supplements, vitamins, and herbal medications can be assessed, whereas these are rarely included in electronic databases. The reasons for medication use, nonadherence, and other important factors, such as sociodemographic factors, physical functioning, quality of life, and health behavior, may also be assessed in surveys or interviews.

However, survey and interview data on medication exposure are restricted to a certain time point or time period and during this time period medicines use is queried. Questionnaires often ask current medication use, referring to medication use within previous week/month or during a previous episode of the disease (Gama et al., 2009). For this reason, these data sources report primarily cross-sectional medication use. Even in the case of repeated questionnaires, changes in medication use between interviews or surveys may not be documented. Misclassification of medication exposure based on interview data has been found prominent when measuring chronic medication use. For example, in a study on calcium channel blockers, 1.5% of baseline users who were interviewed did not actually use these medications, and 15.5% of baseline nonusers initiated calcium channel blocker during a median of 7.6 years of follow-up with pharmacy dispensing data (Beiderbeck et al., 2004).

One of the concerns in self-reported medication use is recall error. Participants may have problems recalling which medications they have used and underreporting increases if time period in which medication use is assessed is lengthy (West et al., 1995). Persons using medications regularly or for longer duration are more likely to recall the medication they use compared to persons who only have one dispensing. Recall problems are also related to being able to name the medication product, substance, or dose, whereas pictures, availability of medication containers, or a list of medications may enhance recall (Kimmel et al., 2003). Many factors may impact recall. Older age may reduce recall (West et al., 1995), whereas more frequent use of other medications may enhance it (Kimmel et al., 2003). Modes of data collection by questionnaires may impact the results (Bowling, 2005; Choi and Pak, 2005). These include the ways the respondents are contacted, how the questionnaire is delivered, and the way in which questions are phrased. Even minor changes in wording, the order of questions, or response format can lead to differences in the results. One study showed that three different measures resulted in different prevalence of analgesic use: "weekly analgesic use in general," "analgesic use for pain symptoms within the past week," and "giving the name of any analgesic used within the past week" (Ademi et al., 2007). In general, questions involving indication for medication, medication names, pictures, and other memory aids have resulted in higher prevalence of use (Gama et al., 2009).

The utilization of medicines has specific features related to the acute or chronic nature of the diseases and their severity, the number of drugs available for the same condition, the number of medicines including the same active ingredients, and the varying complexity of the treatment regimens, all requiring a careful design of the questionnaires to ensure unbiased evaluations.

The sample size in questionnaires, surveys, and especially interviews is restricted by resources and time allocated in the study. A small sample size reduces generalizability and statistical power of the study. Participation rate may also be low. Low participation rate reduces generalizability of the results as refusal or drop-out from the study may not be random, and may lead to selection bias. Differential participation due to background factors may be called as participation bias. For example, severely ill or persons with disabilities may be more likely to nonparticipation and drop-out (Haapea et al., 2007; Lissner et al., 2003). In addition, nonparticipation has been associated with older age, health behaviors such as smoking and alcohol consumption, and social factors as well as higher mortality. Reporting bias is related to intentional over- or underreporting of medication exposure. Participants may under- or overreport medication use for various reasons. Underreporting may be more likely to be linked with mental health-related medications where the participants may feel stigmatized (Knudsen et al., 2002).

Claims and Dispensing Databases

The main strength in dispensing databases is the identification of medication exposure for large numbers of people, representing a specific population or even a nation, and the ability to follow them up on time. Medication use in these databases is not susceptible to recall, participation, or reporting bias. However, there are challenges in transforming data on dispensing events into periods when medications have been used (See section, Definition of Exposure from Prescription and Dispensing Databases). There is always uncertainty whether, when, and how dispensed medications are actually used. Some dispensing databases include data on dose but most databases include dose only in free text format or lack information on dose altogether (Furu et al. 2010). In addition, dispensing databases lack information of medicines obtained without prescription, particularly OTC medications. OTC medication use may be important for specific research questions, for example, in studies on nonsteroidal anti-inflammatory drugs that are often purchased without prescription.

Databases of various insurance schemes are restricted to medications covered by the specific insurance. For example, some Nordic nationwide or regional databases include only reimbursed medications (Furu et al., 2010). Canadian provincial drug claims

databases are subjected to restrictive drug coverage policies, which refer drugs not reimbursed by the insurance program, or their use is limited by requiring, for example, special authorization (Gamble et al. 2012). Changes in regulations and reimbursement practices in time may impact the usability of these databases for specific research questions. Medication coverage of an insurance may also impact the prevalence of medication use or prescribing (Amadio et al., 2015). Sometimes participants have more than one insurance, or private insurance in addition to public insurance and, thus, databases may lack some of their dispensing due to selective use of insurance (Allin et al., 2013). Medications may also be self-paid and not recorded in the database. Furthermore, medications may also be obtained from other sources, such as a family member, through the Internet, or purchased abroad. Data on medications used in hospitals, aged care services, or prisons may be lacking as some databases are restricted to outpatient medication use. Longitudinal follow-up of people in a database may be complicated by people changing insurance schemes, due to changes in employment or employers changing health plans for employees (Schneeweiss and Avorn, 2005). Instability of the population and lack of continuous enrolment are disadvantages of some insurance-based dispensing databases. In addition, changes may be selective if sick people drop out from their insurance scheme due to loss of job.

Claims and dispensing databases usually lack data on important confounding factors related to lifestyle, such as alcohol consumption and smoking. A limitation may also be that these databases do not include data on hospital care or diagnoses, and thus data on comorbid conditions or diseases severity cannot be obtained. Depending on the country, it may be possible to link claims or dispensing data with hospital care database to obtain diagnoses and possible outcomes of drug use.

Medical Record Databases

Medical record databases collect data on prescriptions from physicians' electronic prescribing and medical record system (Hennessy, 2006). The strengths of medical record databases include detailed data on prescribed medications, often including prescribed doses. Such databases also contain other information relevant for patient care, for example, data on comorbidities, body mass index, alcohol use, and smoking. They may also include data on laboratory test results. As with insurance-based dispensing databases, medical record databases may include unstable patient population which hinders longitudinal follow-up. Such databases include only medications prescribed within these systems and lack prescriptions from other sources (i.e., other clinics or hospitals). For specific patient populations, who are frequently hospitalized, or for specific diseases, which are often treated in specialised settings, this may be an important limitation. In traditional medical records, data may not be in a readily usable format and may require extensive text mining to extract, for example, data on smoking. In addition, information on lifestyle factors may not be recorded for all patients and there is a need to decide how to deal with missing data.

Definition of Exposure from Prescription and Dispensing Databases

Medication exposure from electronic databases includes either prescribed or dispensed medications. Databases consisting of prescribed medications are often called medical record databases as data are derived from physicians' electronic prescription systems. However, terminology may be confusing. For example, Nordic nationwide registers are named as "Prescription" or "Prescribed Drug" registers but actually these databases are based on dispensings from pharmacies. Dispensing databases are based on medications dispensed from pharmacies. This means that they lack data on medications that have been prescribed but never dispensed. Databases based on prescribed medications include also prescriptions that may have never been dispensed from pharmacy (Hennessy, 2006). Some more recent electronic systems combined both prescribed and dispensed drugs.

Prescribed and dispensed data do not readily indicate when a person has been exposed to the medication. However, pharmacoepidemiological research is most often focused on timing and/or duration of exposure. Electronic databases consist of dates of events, when medication has been prescribed or dispensed. Appropriate method for valid definition of exposure depends on various factors, including the research question, study design, the length of follow-up, specific data included in the data source, and whether the assumed association between exposure and outcome is acute or long term.

Correctly defined exposure to medications is crucially important, as misclassification of exposure may lead to biased or spurious results. Cross-sectional measure of exposure is defined at one point in time and is assumed to remain constant during follow-up. For medications used on a "when needed" basis or for symptomatic treatment, baseline users use the medication only on those days when they experience symptoms and baseline nonusers may initiate medication use during follow-up. For example, a previous study showed that baseline benzodiazepine users were exposed to 44.6% of person-days during follow-up as compared to baseline nonusers to 3.7% of days (Ray et al., 2002). This misclassification increased with time. In this study, misclassification led to substantial underestimation of the association between benzodiazepine use and falls risk, compared with exposure status modeled time-dependently on a day-by-day basis (Ray et al., 2002). The changes in who is a "user" and who is a "nonuser" are shown to change in time also for medications meant for long-term regular use (Beiderbeck et al., 2004).

Various methods for deriving medication exposure periods (i.e., when medication use started and ended based on dates of prescriptions or dispensings) have been developed. Applicability of these methods depends on the content in the database. Duration of use may be determined with prescribed doses and prescribed or dispensed amounts of the medication, by dividing the amount with the prescribed dose resulting in the number of treatment days (Lau et al., 1997). Another possibility is the days' supply of medications recorded in each dispensing event in some databases. Recording and validity of the days' supply measure may be supported by a rigorous 30-day refill requirement stated by some insurance plans (Schneeweiss and Avorn, 2005).

If the prescribed dose is not recorded in a separate, readily usable format for research purposes, it may be derived from free text fields included in the prescriptions. This requires enhanced text-mining algorithms and careful consideration of validity of their

results (McTaggart et al., 2018; Shah and Martinez, 2006). However, prescribed doses may include a range of dose and/or frequency of use. In these cases, researcher must choose whether minimum, maximum, or median dose is considered as the "prescribed dose" (Karystianis et al., 2016). Prescribed doses may also include adjustment according to symptoms, for example, extra inhalations of respiratory medications during infections. In addition, not all prescriptions include dosing instructions and researchers must decide how to handle prescriptions such as "use as instructed" and "according to previous instructions." In some databases, a significant proportion (one out of three or four) of exact dosing instructions may be missing from prescriptions (Lum et al., 2017). Similar considerations may apply to measures of days' supply (Gross et al., 2008).

When prescribed doses, free text instructions, or days' supplied are not included in the database, basic methods for deriving medication exposure periods may be categorized into "fixed assumptions" of daily doses and "time window" methods. Time window methods refer to assumptions that a medication is prescribed or dispensed every, for example, 30, 90, or 180 days (Andrade et al., 2006). The dispensing regulations impact on the width of the time window as maximum allowance for medication supply varies between countries, usually from 1–3 months. Waiting time distribution may be described as a form of the time window method. The waiting time estimates how frequently users of a specific medication refill their prescriptions (Pottegård and Hallas, 2013; Stovring et al., 2016). Researchers may choose to use a time window based on the waiting time distribution. One example of this is the number of days when 80% of users have refilled their prescription.

Fixed assumptions of daily doses are frequently used in pharmacoepidemiological research. One of the most commonly used is the assumption that a medication is used as one Defined Daily Dose (DDD). WHO defines DDD as "the assumed average maintenance dose per day for a medication used for its main indication in adults" (WHO, 2018). Even the definition of DDD implies to several disadvantages of this assumption, as medications may be used for multiple indications (possibly with a different dose) and by other than adult users. Another commonly used method is the assumption of "one unit per day," the unit usually referring to tablets. For other formulations than tablets or capsules, such as injections, creams, and patches, this assumption may not be applicable (Tanskanen et al., 2014). These assumptions may be valid for specific medication classes but not for others, even within the same therapeutic area (Rikala et al., 2010). Statins are an example of a medication class that is often used as 1 tablet per day (but almost never as 1 DDD per day) (Romppainen et al., 2014).

All basic methods, especially fixed assumptions of the daily dose, are often accompanied with grace periods (Schneeweiss and Avorn, 2005). Calculated days' supply or duration of use based on a fixed assumption is extended with a grace period which allows some irregularity or nonadherence between refills, or lower than prescribed use. Grace period is needed because in clinical practice, patients may refill their prescription earlier (which results in overlap of two dispensed prescriptions) or later when a gap between two dispensed prescriptions is formed (Gardarsdottir et al., 2010). To balance these irregularities, a grace period (a prespecified gap length) is allowed between dispensing events. The grace period may be a fixed number of days added to the duration of each drug use period, or the calculated duration is multiplied by some fraction (such as 50%). Grace periods are applied to avoid misclassification of use and unrealistically short (1–2 days') breaks between the exposure periods. The length of grace periods may vary from 7 days to 180 days (Andrade et al., 2006; Gardarsdottir et al., 2010).

It is important to note that adding a fixed number of days to each dispensing event disregards the fact that medications may be dispensed in different package sizes, and adding a 30 days' grace period has larger impact when it is added to a 30 days' package than into a 90 days' package. If the grace period is too long, it increases the risk of misclassification of exposure as patients discontinuing use are categorized as users. In contrast, a too short grace period will result in false discontinuation and misclassifies users as nonusers. Gaps can be filled either prospectively (grace period is always added) or retrospectively (grace period is added only if there is a next purchase within the duration of use plus the allowed gap) (Nielsen et al., 2008). This basically means that researchers must decide whether a grace period is always or never added to the last purchase. It has been pointed out that retrospective filling of gaps may lead to biased results (Nielsen et al., 2008). The appropriate length of the grace period depends on the nature of treatment (short-term, intermittent, chronic or episodic), and it should be carefully considered as it will have impact on the results (Gardarsdottir et al., 2010).

Stockpiling of medications means a situation when a patient refills a prescription while there is medication left from the previous dispensing event. Some stockpiling usually happens in each dispensing activity as medications are often dispensed before the last dose has been consumed. Major stockpiling may be introduced due to reimbursement regulations, such as fulfilment of annual limit for medication costs (safety-net), although reimbursement systems usually try to limit stockpiling. Two basic ways to handle stockpiling are ignoring any overlaps or add the overlapped amount to the following dispensing (Mantel-Teeuwisse et al., 2001). Some researchers have also suggested that a part (e.g., 50%) of stockpiling can be assumed (i.e., that a patient uses half of tablets later that were left when the prescription was refilled) (Greevy et al., 2011). Another possibility is to calculate a cumulative stock (assuming that all tablets are used later) during the medication use period. In exposure periods lasting for years, this may not be feasible approach as it is unlikely that large amount of drugs stocked years before would actually be used later.

More recent methods aim to consider individual variation in medication use patterns, such as personal regularity of refilling prescriptions and stockpiling. The estimation of drug coverage (COV) method divides the number of dispensed units by the estimate of averaged dose for each person (Meid et al., 2016). The prescription drug purchases to drug use periods (PRE2DUP) method is based on mathematical modeling of daily doses for each person and each drug (Tanskanen et al., 2015). It takes into account regularity of dispensings, stockpiling of medications, and hospital care periods when medications dispensed from pharmacies are not used. Prescription drug purchases to drug use periods or PRE2DUP does not assume any fixed dose for medications but allows individual variation in dose within limits of normal medication use specific for each medication package.

Individually tailored medication use modeling results in higher accuracy in estimating medication use (Taipale et al., 2016; Tanskanen et al., 2017).

When reading or conducting pharmacoepidemiological studies one must keep in mind the possibility of exposure misclassification and assess whether it may lead to biased results. Especially when the method assumes certain medication use behavior, the researchers and readers of the scientific articles must critically assess whether the actual medication use patterns in the population deviate from the applied assumption. In addition, the coverage of the data sources should be critically evaluated as they may be restricted to a selected population or may not cover all medications. Medications used during hospital care are often not recorded in claims or dispensing databases, which may cause exposure misclassification due to immeasurable time bias (Palmaro et al., 2017; Suissa, 2008). If this unobservable exposure time is not accounted for in the analyses, it may bias the association between exposure and outcome.

Definition of Medication Adherence

The World Health Organization (WHO) has defined adherence as "the extent to which a person's behavior – taking medication, following a diet, and/or executing lifestyle changes, corresponds with agreed recommendations from a health care provider" (Sabate, 2003). When talking about medication adherence, it has been defined as "the extent to which patients take medications as prescribed by their health care providers" (Osterberg and Blaschke, 2005). Medication adherence has been proposed to consist of three components: initiation, implementation, and discontinuation (Vrijens et al., 2012).

Medication adherence can be studied directly or indirectly (Osterberg and Blaschke, 2005). Direct methods (e.g., blood tests, direct observation, or electronic monitoring of medication-taking) are expensive and impractical in large populations. Indirect methods (e.g., data on medication dispensings, participant interviews, pill counts) are more suitable for large adherence studies. Indeed, dispensing databases are often used to study medication adherence (Raebel et al., 2013).

To study primary adherence (i.e., are prescribed medications initiated), data are needed on both prescriptions and dispensings (Raebel et al., 2013). To measure secondary adherence (i.e., adherence to initiated medications) from databases, dates of dispensings and dispensed quantities of the studied medications need to be identified (Peterson et al., 2007). Based on these, it is possible to calculate different metrics to evaluate adherence. Examples of these measures are the medication possession ratio (MPR) and proportion of days covered (PDC). MPR is derived by dividing the number of days of medication supplied with the number of days in the considered interval. PDC is derived by dividing the number of days with medication available with the number of days in the considered interval. Persistence (i.e., time from initiation to discontinuation of medication) can be measured, for example, as days to discontinuation. It is preferable to differentiate between new and prevalent users as adherence estimates most likely differ between these groups (Andrade et al., 2006).

The lack of consistency in the used terminology constitutes a challenge in adherence studies (Raebel et al., 2013). There is also large variability in the applied measures of adherence. Adherence defined as 80% MRP/PDC is often used; however, the clinical meaningfulness of this categorization is not certain (Peterson et al., 2007; Raebel et al., 2013). Adherence studies based on dispensing databases have many limitations, including that the actual consumption of medications is uncertain (Andrade et al., 2006). In addition, information on dosages is not always available leading to the use of assumptions such as fixed dosing to calculate medication availability.

Approaches for Controlling Bias and Confounding in Pharmacoepidemiological Studies

Approaches in Study Design Phase

Restriction of the study population is one commonly used approach in pharmacoepidemiology to reduce both confounding and bias (Schneeweiss et al., 2007). For example, restricting the cohort to new users has several advantages over designs that follow prevalent users (Johnson et al., 2013; Ray, 2003; Schneeweiss, 2010). In the new-user cohort design, follow-up is started from the initiation of medication use and prevalent users are excluded by applying a washout period for previous medication use. Starting the follow-up from initiation of medication use enables studying both the incidence of early and late outcome events and assessing the hazard function over the duration of medication use. If prevalent users were included, the results could be biased as prevalent users often represent "survivors" that are able to tolerate the medication and potentially benefit from the medication use. Therefore, studies that follow prevalent users may ignore outcome events that occur soon after the treatment initiation and result in biased estimate of the risks associated especially with the short-term use of the medicine. In addition, the temporal ordering of events is more explicit in the new-user design and, thus, it enables measuring confounders before the initiation of medication use. This decreases the risk of adjusting for intermediate variables that medication use may already have altered and which may be a part of the causal pathway between the medication exposure and the outcome event.

To be classified as new users, individuals should not have used the medication in question during a washout period (Schneeweiss, 2010). A washout period refers to a predefined time period (e.g., 6 or 12 months) preceding the initiation of medication use that is required to be free from the medication use. The longer the washout period, the higher the certainty that new users are truly treatment naïve. However, longer washout periods reduce the study sample size as higher number of previous users are excluded from the study cohort. Varying the length of the washout period can lead to misclassification of new users and substantial differences in the estimated incidence of medication use as well as impact on the characteristics (e.g., age and sex

distribution) of the included medication users (Gardarsdottir et al., 2006; Riis et al., 2015). Thus, the length of the washout period should be decided by considering the medication and outcome being studied, and it has also been recommended that the effects of different washout periods should be tested in sensitivity analyses.

The new-user design mimics the design of randomized controlled trials (RCTs) (Schneeweiss, 2010). However, in observational studies, the initiation of the study medication is never randomized, and medication users typically differ from nonusers as there is always a reason for initiating the medication (Johnson et al., 2013; Schneeweiss et al., 2007). If the indication for the medication or other characteristics of the patient affect the treatment decision and the same factors affect the risk of outcome, confounding may bias the results. Confounding by indication is especially problematic when studying comparative effectiveness in observational studies because the indication is closely related to the desired effect (Schneeweiss et al., 2007). The comparison group in the new-user design can be nonusers or new users of other medications. Restricting the cohort to new drug users and carefully chosen active comparator may reduce confounding. However, selecting the optimal comparator group is often difficult and confounding by indication may still remain. This is because even medications from the same therapeutic group can have various indications and contraindications, and the factors affecting treatment choices are often unknown.

New-user design with an active comparator group can be used as one approach to reduce the effects of healthy user bias (Schneeweiss et al., 2007). An active comparator could be a drug group with similar indication or another preventive drug group with no known association with the outcome.

Individuals that are adherent to use of preventive drugs (e.g., statins) are often healthier than nonusers of these drugs (Brookhart et al., 2007; Dormuth et al., 2009). It has been reported that individuals who have better adherence to medicines are also more likely to seek preventive treatment, receive vaccinations, attend cancer screenings, follow a healthier lifestyle, and less likely to be frail. Therefore, all or part of the positive effects associated with drug use may not be due to the drug but instead caused by the health seeking behavior. For example, it has been demonstrated that more adherent statin users are less likely to have motor vehicle and work place accidents than less adherent users (Dormuth et al., 2009). These are unlikely related to statins' biological effects. Healthy user bias may cause artificial positive effect, strengthen true positive effect or, on the other hand, diminish negative effects of drugs. In a similar phenomenon, individuals who are frail may be more likely to stop the use of preventive drugs and physicians are also less likely to prescribe preventive drugs for frail individuals near end of life (Glynn et al., 2001). This selective underuse of drugs may also bias results so that drug use may seem to protect from negative outcomes and death.

When studying second-line treatment options, restricting analyses to naïve new users is often not feasible as most patients have switched from the first-line drug to another drug (Schneeweiss, 2010; Suissa et al., 2017). Therefore, it has been suggested that a prevalent new-user cohort design could be applied when comparing the effects of drugs that have newly entered the market with older medications (Suissa et al., 2017). In this modification of the new-user design, the comparator medication user is selected time-dependently so that the history of previous medication use (i.e., time since the first comparator prescription or the number of comparator prescriptions) is similar to the patients who switched to the newer medication. This design has its own limitations and researchers need to consider several methodological issues, such as how to distinguish a switch of a medication from start of a concomitant second medication.

One advantage of using an active comparator is a decreased risk of immortal time bias as follow-up can start from the same time point (i.e., first date of drug use) for both groups (Johnson et al., 2013; Schneeweiss, 2010). When new users are compared with nonusers, researchers need to consider more carefully how to avoid immortal time bias. Immortal time bias refers to a period of follow-up when individual cannot die or experience the outcome event due to the study design that was chosen (Lévesque et al., 2010; Suissa, 2007). For example, if follow-up starts from the diagnosis of a certain disease and exposure status is defined based on the first date of dispensation of the drug after the diagnosis, the time from the diagnosis until the first dispensing is considered immortal time. This is because to be classified as exposed one must survive (i.e., stay alive and without the outcome event) until the first dispensing of the drug. In this situation, immortal time bias may occur if the immortal time is counted as exposed time (misclassification) or if it is excluded (selection) (Lévesque et al., 2010; Suissa, 2007). If immortal time is not properly accounted for, medication users will have apparently better survival. The longer the immortal time, the larger the error. One option to avoid this bias is to conduct the analyses with time-dependent exposure, which is to classify the person-time to exposed and nonexposed time at each day of the follow-up.

Another approach to reduce immortal time bias is to use exposure-matched design where each user is matched (based on, e.g., age, sex, and disease duration) to nonusers and the date of initiation of medication use serves as the index date for the matched nonusers. Applying the new-user design and avoiding immortal time bias are easier in studies that utilize electronic databases as information source for medication exposure (Ray, 2003) than, in for example, cross-sectional interviews.

The new-user design may be conducted with the intention-to-treat (ITT) approach or as-treated or both if one wants to test whether these different approaches lead to different results (Schneeweiss, 2010). In the ITT approach, exposure status is defined at baseline, and all patients are followed for a fixed time period (e.g., 180 days), regardless of changes in drug use over time. In the as-treated approach, follow-up is censored if a patient discontinues medication use or switches to a different medication. The ITT approach may lead to misclassification of exposure time as users may discontinue drug use and nonusers may initiate medication use. The longer the follow-up, the higher the possibility of misclassification bias. On the other hand, the as-treated approach may lead to selection bias if, for example, switching or discontinuation of drug use is due to lack of efficacy or early signs of adverse effects that ultimately would lead to the outcome. In this situation, censoring the follow-up at discontinuation of use underestimates the risk of outcome associated with the drug exposure (i.e., informative censoring). Thus, both ITT and as-treated approaches have their own limitations, and these approaches can be used to complement one another.

A limitation of the new-user design is that it reduces sample size limiting the power of the study (Johnson et al., 2013; Ray, 2003; Schneeweiss, 2010). However, the new-user design has several advantages, and it has been argued that a more valid estimate is better than a more precise but biased estimate. Recently, there has been debate on whether the new-user design should be preferred by default or not in pharmacoepidemiological studies (Brookhart, 2015; Hernán, 2015; Vandenbroucke and Pearce, 2015).

Concerns have been raised that if there is a limited follow-up, this design may decrease the ability to observe outcomes during long-term use and give less information on the risks during cumulative or long-term use (Vandenbroucke and Pearce, 2015). Of course, when choosing or evaluating study designs, we need to consider, for example, what type of effect we are interested in (acute/transient/constant/cumulative) and whether the outcome is rare or has a long latency period. Biases can be avoided or diminished with rigorous selection and application of the most optimal study design and methods for the specific study question. However, the available data source may complicate and limit the choice of appropriate methods. Therefore, all researchers as well as readers must critically evaluate the direction and amount of bias in the results.

Approaches to Confounding Control in Analysis Phase

In addition to controlling confounding by study design, it can be reduced by various statistical approaches in analysis phase (Table 1).

Nowadays, it is common to use propensity score methods to reduce confounding instead of traditional multivariable regression models. Propensity score refers to estimated probability of initiating the drug conditional on patient's baseline characteristics (Glynn et al., 2006). The idea is that conditioning on the propensity scores will balance the distribution of baseline covariates between the drug users and nonusers/comparator drug users. Propensity score can be easily estimated with logistic regression, and it combines all the measured confounders into a single score. Therefore, one important advantage of using propensity score methods against traditional multivariable adjusting is the ability to control vast number of confounders effectively even though the outcome was rare. It is important to plot and compare the distribution of propensity scores for exposed and unexposed individuals (Schneeweiss and Avorn, 2005). The amount of non-overlap of curves for exposed and unexposed on the extreme ends of distribution indicate patients who have a very low probability of treatment (i.e., never treated) and patients who would be expected to always receive treatment. It is also important to check covariate distributions before and after propensity score matching or weighting, for example with standardized differences or other balance diagnostics (Austin, 2008).

Propensity score methods are often considered better in controlling confounding by indication compared with traditional multivariable adjusting (Glynn et al., 2006). However, propensity scores cannot control for unmeasured confounders, and therefore, their applicability and effectiveness at reducing confounding depend on how well important confounders have been identified and measured from the data. As described in Chapter 205 (Methodological challenges in epidemiological studies), the selection of confounding variables should be based on subject matter knowledge. This also applies to covariates included in the calculation of propensity score (Brookhart et al., 2006). True confounders as well as variables that are unrelated to the exposure but related to the outcome should be included in the propensity score model. However, variables that are unrelated to the outcome but related to the exposure increase variance of the effect estimate without decreasing bias.

Table 1 Approaches to control confounding in analyses

Approach	*Considerations*
Standardization	• for example, incidence rates may be standardized by age and sex • difficult to apply otherwise as there are often multiple confounders
Stratification	• the association between drug exposure and outcome can be analyzed separately in different categories of the confounder (e.g., separately among male and female), and these stratified results are then pooled • usefulness is limited as there are often multiple confounders • stratification can be used to investigate effect modification more closely (if an statistical interaction between the exposure and potential effect modifier has been found)
Adjusting in multivariable regression models	• the measured confounders are included into the statistical model • the assumptions of the statistical model must hold • the number of included confounders is limited as there should be enough events per included variable
Propensity score methods	• a measure of likelihood that an individual would have initiated drug use considering the baseline covariates • combines vast number of confounders in a single score • can be used in several ways including adjusting, matching, restriction, stratification or weighting
Disease risk scores	• a measure of likelihood that an individual will have an outcome (disease) by summarizing the predictive information of potential confounders • can be used as a summary confounder in a multivariable statistical model or in stratification

Pharmacovigilance

The WHO defines pharmacovigilance or drug safety as the "science and activities relating to the detection, assessment, understanding, and prevention of adverse effects or any other drug-related problem" (World Health Organization, 2018). Traditionally, pharmacovigilance means almost exclusively spontaneous adverse drug event reporting (ADER). However, recently the availability of near real-time access to large medication claims databases has provided opportunities for postmarketing surveillance with methodologies that can offer quick answers to medication safety questions (Lai et al., 2017).

Most countries maintain their own ADER system via national medicines regulatory authorities. Of these countries, more than 120 submit their ADERs to the Uppsala Monitoring Centre in Sweden as part of the WHO Programme for International Drug Monitoring. To date, over 16 million ADERs have been submitted which now form the "Vigibase" (World Health Organization, 2018).

ADERs is a common source for pharmacovigilance studies. However, utilizing this data requires some considerations on data quality. First, submitted reports may not be complete. If crucial information is missing, the causality assessment between the suspected medication and the adverse drug event (ADE) will be difficult. Tools have been developed to assess the potential causality. These tools include, for example, the Naranjo Algorithm (Naranjo et al., 1981) and the WHO-UMC system (The Uppsala Monitoring Centre, 2018).

Another challenge in analyzing ADERS is the lack of a denominator—the number of people who are at risk of the ADE is not known. New medications are more likely to lead to ADERs as it is mandatory for pharmaceutical companies to report ADEs occurred in clinical trials. Prescribers and pharmacists are also more likely to report unpredictable and largely unknown ADEs, which occur more likely in new medications than in older ones. This means that when comparing ADE rates across two medications or medication classes, the rates will be overrepresented in the newer medication. Another prompts for ADERs are new studies reporting on a possible ADE or any ADE attracting media interest. Overall, ADEs are underreported in any reporting system so the actual rates of the ADEs cannot be detected using ADERs. When conducting a pharmacovigilance study using ADERs, the issues around reporting need to be carefully considered.

There are guidance published on the best practices of summarizing ADERs and determining associations (e.g., European Network of Centres in Pharmacoepidemiology and Pharmacovigilance, 2018). These are important sources when conducting a study utilizing ADERs. FDA provides all their ADE data reported via their Adverse Event Reporting System on their website (https://www.fda.gov/drugs/guidancecomplianceregulatoryinformation/surveillance/adversedrugeffects/ucm082193.htm). These data can be utilized for research purposes with sufficient skills understanding these data and in data management and analysis.

Conclusion

Pharmacoepidemiological studies face methodological challenges; however, the discipline has grown rapidly during the past decades and is still evolving. With robust methodologies and good quality data, real-world evidence on harms and benefits of medications can be produced. This includes pharmacovigilance studies where evidence is created utilizing ADER reports.

Application of Pharmacoepidemiology and Pharmacovigilance Studies

Prasad S. Nishtala*, Sujita Wati Narayan†, *University of Bath, Claverton Down, Bath, United Kingdom; †Medicines Policy Research Unit, Centre for Big Data Research in Health, University of New South Wales, Sydney NSW, Australia

Introduction

Pharmacoepidemiology is the study of use and effects of medicines in large populations, and pharmacovigilance assesses the safety of medications and adverse outcomes related to drug therapy (Strom, 2012). Pharmacoepidemiology has broad applications in research and practice including evaluating patterns and appropriateness of drug utilization, measuring nonadherence, promoting postmarketing surveillance, and has been critical in the evaluation of health interventions to improve drug use and outcomes.

In recent decades, automated datasets have provided a unique platform to follow large populations over a long period to answer key research questions quickly and cost-effectively. Randomized controlled trials (RCTs) often exclude the elderly, pregnant women and children and observational studies utilizing big data have the potential to complement findings from clinical studies by assessing treatment effectiveness in underrepresented groups often encountered in routine clinical practice.

Well-designed studies in pharmacoepidemiology are useful for signal detection and postmarketing surveillance. Disease surveillance and needs analysis can map trends in populations over time and identify prevalent or incident clinical population. Additionally, data from various sources such as hospitalization and medicine claims are useful for identifying health outcomes or estimate economic implications such as costs associated with duration of care provided. Differences in patterns of care in special populations, rare adverse outcomes, or impact of policy implementation can also be measured using pharmacoepidemiology or pharmacovigilance studies.

This chapter outlines the practical applications of pharmacoepidemiology and pharmacovigilance studies in clinical and pharmacy practice, which are related disciplines of the same field of research and focus on improving prescribing and understanding medication safety. In the next section, we focus on studies, such as drug utilization, assessment of medication adherence, and assessment of medication errors that have made a massive impact on improving clinical and pharmacy practice.

First, we describe the impact of drug utilization studies in clinical practice and health services research. The chapter further explains some standardized methods used to measure drug utilization and how to compare results across various health-care studies conducted globally. Drug utilization studies also enhance postmarketing surveillance for the safe and effective use of medicines by monitoring medication adherence and errors, such as prescription or dispensing errors. Second, we discuss the assessment of population-level prescribing by examples of preventive medicines use in specific population and addressing increasing health concerns such as polypharmacy and hyperpolypharmacy in the general population.

Third, we shift the focus to opportunities provided by pharmacoepidemiology studies to monitor the quality use of medicines, assessment of medication adherence, and identification of medication errors.

Finally, we discuss the policy implications of pharmacoepidemiology research how it informs clinical and pharmacy practice. We briefly further deliberate on the advantages of social media platforms to influence policies. The conclusion provides a brief glimpse of future opportunities for pharmacoepidemiology research likely to influence clinical pharmacy and practice.

Pharmacoepidemiology: Impact on Clinical Practice

Drug Utilization Research

In 1977, the World Health Organization defined drug utilization research as the marketing, distribution, prescription, and use of drugs in a society, with particular emphasis on the resulting medical, social, and economic consequences. Drug utilization studies are either descriptive or analytical. Descriptive drug utilization studies using routinely collected automated dispensing or pharmaceutical claims data describe patterns of drug use, estimate under- or overutilization and regulate medicine use.

Drug utilization studies can inform clinical and pharmacy practice by identifying prescribing practices, assessing factors influencing prescribing practices, examining incidence of adverse drug reactions, examining nonadherence to treatment regimens, and cost-effectiveness of drugs. The information derived from drug utilization studies can also inform drug formularies and guidelines.

Monitoring medication use against standard treatment guidelines and evidence-based recommendations provide insight into the evolving prescribing trends. A population-level study (N = 56,026) conducted in the Netherlands found that a significant proportion of women (30%) and men (47%) with hypertension and coexisting cardiovascular disease were undertreated for hypertension as per the guidelines (Klungel et al., 1998). Overall prescribing trends can indicate the appropriateness of medicine use against a backdrop of evolving guidelines (Narayan and Nishtala, 2017). Additionally, drug utilization trends can provide a pathway for regulating the use of controlled medicines or examine the impact of specific quality-driven programs or the impact of interventions. Furthermore, drug utilization trends can be used as a proxy to educate prescribers on the appropriateness of medicines in special populations, for example, elderly with renal or hepatic impairment or geriatric syndromes and with multiple chronic diseases (Hennessy, 2006).

Drug utilization studies have also been employed to understand drug exposure patterns in pregnant women and children. Drug utilization studies done on pregnant women relay vital information on the timing (trimester), dose, and duration of medicine use in pregnancy, which are important variables that influence fetal toxicity.

Drug utilization studies in children have received special attention from both the US Food and Drug Administration and the European Medicines Agency (EMA) in light of growing concerns about the lack of research for the efficacy and safety of medicines use in children. A retrospective cohort study conducted in Europe analyzed primary care data in the Netherlands, the United Kingdom, and Italy to examine prescription patterns in children aged up to 18 years (Sturkenboom et al., 2008). The findings of this study have the potential in informing prioritization of research into the long-term safety of pediatric drugs, as well as inform effectiveness studies in the pediatric population.

Assessment of Medication Adherence

In recent years, there has been increasing use of pharmacy databases including claims and insurance databases to understand medication adherence and persistence in large populations. The findings from these real-world populations present tremendous opportunities to improve patient adherence to chronic medications in pharmacy practice.

Medication nonadherence is high in people living with chronic conditions such as hypertension, diabetes, and hyperlipidemia (Lehmann et al., 2014). Several studies in pharmacoepidemiology have shown high levels of nonadherence to antihypertensive and medications for dyslipidemia contributing to negative health outcomes (Hess et al., 2006; Meddings et al., 2012; Stroupe et al., 2006). Similarly, studies have identified nonadherence to psychotropic medicines such as antidepressants. A large retrospective cohort study (N = 27,865) using the French National Health Insurance reimbursement database found that only 26.9% of patients were adherent to antidepressants as recommended by international guidelines (Braunstein et al., 2017). Another retrospective study conducted using the UK Clinical Practice Research Datalink found patients with gout starting allopurinol were nonadherent to therapy particularly the younger age groups and females. Both studies highlight the importance of training clinical pharmacists to counsel patients on the continuation period for treatments for better health outcomes.

Adherence to medication can be measured using direct or indirect measures such as pill counts, patient reports, questionnaires, interviews, and electronic pill caps (Parker et al., 2007). However, these methods can be very time-consuming. Studies in pharmacoepidemiology employ alternative methods, among which the most commonly used and validated are the proportion of days covered (PDC) and medication possession ratio (MPR) (Karve et al., 2009). There is a considerable body of evidence derived from pharmacoepidemiology showing nonadherence to medications in asthma and chronic pulmonary obstructive disease (COPD). A retrospective cohort study conducted using the prescription database from a network of general practitioner surgeries in Scotland calculated adherence using the MPR and found it was relatively low in this UK population (Covvey et al., 2014). The role of healthcare professionals particularly community pharmacists in improving medication adherence is well established. There is a large body of research conducted in Australia, New Zealand, United Kingdom, and the United States demonstrating that community pharmacists have played a significant role in the improvement of COPD and asthma management via collaborative services and shared decision-making including medicine use services, implementation of asthma management plans, advice on optimal selection and use of pharmacotherapy, and distribution of medicines for asthma.

Given the clinical and economic consequences of nonadherence to chronic medicines, the findings from pharmacoepidemiology can improve pharmacy practice by proposing tailored interventions, such as medication adherence aids, medication management plans, health literacy, and patient education (Brown and Bussell, 2011; Stroupe et al., 2006).

Assessment of Adverse Drug Reactions and Medication Errors

In recent years, there has been increasing use of national pharmacovigilance systems to collate and report patterns of adverse drug events and medication errors. The European Union has legislated reporting of medication errors, and the European Medicines Agency has published guidelines to improve medication error reporting practices.

In Europe, a centralized database, the EudraVigilance, was established for reporting and evaluating suspected adverse reactions of medicines (Postigo et al., 2018). Similarly, National Poison control centers established worldwide are an invaluable surveillance tool for identifying medication errors on a national or regional scale. These centers report medication errors with detailed clinical and biological data, which is particularly relevant to clinical and pharmacy practice. A classic example is the reporting of methotrexate toxicity by national pharmacovigilance and Poison centers (Bebarta et al., 2014; Perregaard et al., 2015). Regulatory agencies can use such surveillance data to improve and update product information. At practice level, pharmacists can follow good dispensing practices to avoid dosing errors, including provision of consumer medication information. Surveillance registers can identify common medicine errors and help implement policies to reduce recurring errors (Antonow et al., 2000).

A retrospective analysis of the FDA Adverse Event Reporting System Database from 2006 to 2014 reported 902,323 serious outcomes including 244,408 deaths, 72,141 disabilities, and 585,774 other serious outcomes (Sonawane et al., 2018). Manufacturers submitted majority (approximately more than 70%) of the expedited reports on serious ADEs. Health professionals (47.3%) followed by consumers (36.1%) and other sources (16.6%) contributed to these reports. Interestingly, there was a bimodal age distribution of ADEs represented by patients aged 45–64 years (40%) and ≥65 years (approximately 33.0%). This is another good example of the contribution made by the field of pharmacoepidemiology in guiding postmarketing surveillance and examining the public health burden of ADEs.

Assessment of Population-level Prescribing

Polypharmacy and Hyperpolypharmacy Trends

The use of multiple medicines increases with the prevalence of chronic diseases and increasing age. Polypharmacy (use of five or more medicines) and hyperpolypharmacy (use of ten or more medicines) are proxy indicators for inappropriate medicine use that lead to adverse clinical outcomes, particularly in the older population (Nishtala and Salahudeen, 2015). Studies that examined the trends of polypharmacy and related clinical outcomes identified that older adults who are prescribed multiple medications may be twice as likely to become frail in a relatively short period (3 years) compared to those who take fewer medications (Saum et al., 2017). The information gathered from these studies serve as a feedback for the development of guidance documents focused specifically on the management rational use of medicines.

A recent position statement from the International Group for Reducing Inappropriate Medication Use and Polypharmacy (IGRIMUP) advocates ten recommendations for action to combat polypharmacy (Mangin et al., 2018). The position statement outlined the global problem of polypharmacy and provided a framework to reduce polypharmacy in the context of multimorbidity.

Evidence of the high prevalence of polypharmacy and potentially inappropriate medicines has also led to the development of medicines optimization services. Medicines optimization services delivered by specialized clinical pharmacists are recognized as a core clinical pharmacy service to address the global challenge of polypharmacy.

Pharmacoepidemiology: Opportunities to Inform Evidence on Prescribing Practices and Medicines Optimization

Inappropriate Prescribing

Pharmacological therapy is necessary to manage acute illness, maintain current health and prevent further deterioration; however, prescribing for populations such as multimorbid individuals or older patients is challenging, and sometimes, medicines can do more harm than good. This also extends to other populations such as children as the WHO estimates that >50% of all medicines prescribed and purchased for children may be inappropriately prescribed (Reidenberg, 2009). In recent decades, drug utilization review tools have been developed to highlight instances of potentially inappropriate prescribing. Among these tools, one of the most widely used, particularly for older people, is the Beers criteria, which were developed in 1991 and had been modified since (American Geriatrics Society Beers Criteria Update Expert, 2012; Beers et al., 1991). International studies and reviews have shown evidence that identifying inappropriate medicines using the Beers' criteria has been associated with adverse health outcomes in community-dwelling middle-aged and older people (Chang et al., 2005; Fick et al., 2008; Jano and Aparasu, 2007; Moriarty et al., 2017).

Similarly, the Screening Tool of Older Persons' potentially inappropriate Prescriptions (STOPP) criteria developed by researchers from Ireland are now increasingly used to screen for inappropriate prescribing on large prescription databases (O'Mahony et al., 2015). Importantly, screening tools such as the STOPP-START have shown utility as decision support tools to reduce inappropriate prescribing and improve patient safety. A recent study validated a computerized application of the STOPP/START criteria to electronic medical record data to assess prescribing for older patients (Nauta et al., 2017). The study highlighted not all domains of the criteria can be applied by means of algorithms. Nevertheless, with rapid development of

technology and advancement of artificial intelligence, it is a matter of time before these tools will have massive implications for changing clinical practice.

In summary, health-care professionals including clinical pharmacists have an opportunity to integrate such decision support tools into their dispensing software and correct inappropriate prescribing where necessary either by initiating a medicine review or a clinical intervention with the prescriber.

Comparative Effectiveness Studies

An important application of pharmacoepidemiology is to conduct comparative effectiveness studies, examining the differences in efficacy demonstrated in RCTs and effectiveness of a medicine when used in large real-world populations. RCTs are considered the "gold standard" for producing evidence relating to the comparative risks and benefits of pharmaceuticals; however, RCTs have their own limitations. First, they lack external validity, since the conditions under which they are conducted may not be reflective of real-world experience. Second, for operational or ethical reasons, it may not be feasible to conduct RCTs over a long enough period to capture all adverse drug events. Moreover, RCTs are not representative of patients prescribed medicines and often exclude vulnerable and multimorbid populations, hence their findings may not be generalizable to these subgroups. Consequently, there is a growing interest in bolstering evidence from RCTs using data from other sources, including population-level data.

Efficacy and Effectiveness

Efficacy is defined as the performance of an intervention under ideal and controlled circumstances, such as during development of a drug therapy, whereas effectiveness is its performance under real-world conditions (Singal et al., 2014). During the drug development process, there is inadequate information on how real-world population will respond to a medicine. In addition, the inclusion of an ideal population in clinical trials does not benefit the increasing number of individuals living with multiple morbidities (Barreto, 2005; Hilmer et al., 2012).

Evidence drawn from comparative effectiveness research is important to patients, physicians, payers, and policymakers in making "real-world" choices among the treatment options that are available. In summary, comparative effectiveness, research can inform evidence base for drug committees and formularies as well as provide the evidence base for pharmacists in applying evidence information at a patient level.

Health Economics and Pharmacoepidemiology

Pharmacoepidemiology provide the evidence on the cost-effectiveness of medicines that could potentially influence policy and decision-making. Additionally, they provide evidence on the costs of inappropriate or suboptimal prescribing on healthcare budgets. A longitudinal study conducted on a large German database measured inappropriate prescribing using the PRISCUS list (Helder et al., 2018). The study included 3,860,842 individuals with no exposure to PIM matched to 508,212 exposed individuals within the same study period. After controlling for confounders, they found that the average effect of one additionally prescribed substance on total health-care costs was increased by an amount of 137 € for individuals exposed to a PIM.

Previous international studies estimating the costs associated with discontinuing a preventive medicine such as statins has yielded positive outcomes and influenced further discontinuation of other medicines hence amplifying these savings (Kutner et al., 2015; Tjia et al., 2014). Furthermore, noticeable findings of a reduction in health-care costs will enable individuals and health-care funders to better allocate their resources.

Pharmacoepidemiology and Medicines Policy

Pharmacoepidemiology research informs and influence policies in improving professional practice and the rational use of medicines (Hogerzeil et al., 1989). Rational use of medicines infers patients receive the appropriate medicines, in doses that meet their requirements, for an adequate period of time, and at the lowest cost both to them and their community (Garattini et al., 2008). Suboptimal prescribing patterns contribute to the high cost of medications for patients as well as the difficulty in providing affordable prescription drug benefit. Studies examining variations from guideline-based prescribing provide real-world evidence on the implications and adverse outcomes related to irrational medicine use to influence policymakers (Fischer and Avorn, 2004; Radley et al., 2006).

Pharmacoepidemiology and Pharmacovigilance in Pharmacy Practice

This chapter discussed the application of pharmacoepidemiology concepts and methodology in clinical and pharmacy practices including drug utilization evaluations, pharmacoeconomics evaluations, comparative effectiveness research, and adverse drug reaction surveillance.

The best drug therapy decisions are based on up-to-date evidence provided by everyday consumers of medicines (Jill and David, 2005). Pharmacoepidemiology provides real-world evidence since assessment of safety of medicines based on clinical trial

data is often inadequate, and big data with larger follow-up periods are essential for signal detection that are often missed during a clinical trial due to small sample sizes, sample selection bias, and limited drug exposure periods. Hence, pharmacoepidemiology delivers a stronger scientific base for making clinically relevant decisions and promoting the rational use of medicines (Chant, 2017; Toklu, 2015). Pharmacovigilance studies employ several methodological designs on big data to detect, analyze, and understand safety signals are also essential to inform clinical and pharmacy practice.

Social Media Platforms

Social media platforms that share health-related information are a potential source for postmarketing surveillance. Data from social media platforms are used to assess smoking cessation patterns, monitor drug abuse, and infectious disease spread (Leaman et al., 2010). A recent study examined Twitter accounts of pregnant women to analyze trends of drug exposure and birth defects during pregnancy (Golder et al., 2018). The study reported a 0.44% rate of birth defects in pregnant women. The authors acknowledge several methodological challenges including difficulty in defining cases and finding matched controls. However, their study highlighted the potential future role of social media platforms in postmarketing surveillance particularly in populations underrepresented (i.e., pregnant women) in clinical trials.

In the current scenario, data extraction from social media platforms is laced with several challenges including limitations of existing tools to mine data accurately and ethical considerations of using private data publicly available. However, in the technological advancement era, the possibility of mining vast amounts of private health data available publicly has the potential to advance pharmacovigilance.

Conclusion and Future Opportunities

Pharmacoepidemiology and pharmacovigilance studies can answer clinically important outcomes; however; the benefits from such observational studies can only be optimized, if they have an impact on clinical practice.

Pharmacoepidemiology provides population-level risk estimates and is useful in understanding adverse drug events and helpful in risk assessment and minimization. The challenge for policymakers is to develop strategies that can be implemented at a practice level in risk minimization.

Pharmacoepidemiology studies have made an immense contribution toward pharmacy practice in a clinical setting and as a health-care discipline, particularly focusing on improving prescribing and understanding medicine safety. The growth in the magnitude, diversity, and availability of electronic patient data has presented unparalleled opportunities for expeditious assessment of drug safety, monitoring pharmaceutical policies, health-care utilization, and decision support relevant to all individuals accessing health care. The opportunity to link patient-level data to hospital admissions, laboratory tests data, and sociodemographic data will facilitate the growth of big health-care data. Research founded on big real-world patient level linked data can produce evidence that is critical to optimizing health-care delivery, health outcomes, and to facilitate better monitoring of pharmaceutical policy.

EDITOR BIOGRAPHIES

Editor-In-Chief

Zaheer-Ud-Din Babar

Zaheer-Ud-Din Babar is Professor in Medicines and Healthcare and the Director of Centre of Pharmaceutical Policy and Practice Research at the University of Huddersfield, United Kingdom. He has worked as an academic in Pakistan, Malaysia, New Zealand, and in the United Kingdom, and understands the health systems and pharmacy globally. He is known for his work in pharmaceutical policy and practice, including quality use of medicines, clinical pharmacy practice, access to medicines, and issues related to pharmacoeconomics. Previously, he was the Head of Pharmacy Practice at the University of Auckland and received Vice Chancellor's Research Excellence Award from the University. He has published in high impact journals, such as *PLoS Medicine* and *Lancet* and has acted as a consultant for World Health Organization, Royal Pharmaceutical Society, Health Action International, International Union Against Tuberculosis and Lung Disease, World Bank, International Pharmaceutical Federation (FIP), and for the Pharmaceutical Management Agency of New Zealand.

His other work includes *Economic Evaluation of Pharmacy Services*, *Pharmaceutical Prices in the 21st Century*, *Pharmaceutical Policies in Countries With Developing Healthcare Systems*, and *Pharmacy Practice Research Methods*. Published by Elsevier and Adis/Springer, the books are used in curriculum design, policy development, and for referral all around the globe. Professor Babar is also the Editor-in-Chief of *BMC Journal of Pharmaceutical Policy and Practice* and can be contacted at z.babar@hud.ac.uk.

Section Editors

Zubin Austin

Zubin Austin BScPhm MBA MISc PhD FCAHS is Professor and Koffler Chair in Management at the Leslie Dan Faculty of Pharmacy and the Institute for Health Policy, Management, and Evaluation—Faculty of Medicine at the University of Toronto. His research focuses on the professional and personal development of the health workforce. He has published over 160 peer-reviewed manuscripts and authored four reference texts. In 2017, he was installed as a Fellow of the Canadian Academy of the Health Sciences, the highest award for health services researchers in Canada. He is the only faculty member of University of Toronto to have ever received both the President's Teaching Award for excellence in education and the President's Research Impact Award for the societal significance of his work. He has also been named undergraduate Professor of the Year by students on 18 separate occasions.

Ahmed Awaisu

Dr. Ahmed Awaisu is an Associate Professor of Clinical Pharmacy and Practice in the College of Pharmacy at Qatar University. He received his Bachelor of Pharmacy degree from Ahmadu Bello University Zaria, Nigeria in 1999, his masters and PhD degrees in Clinical Pharmacy from Universiti Sains Malaysia (USM) in 2004 and 2009, respectively. He is also a licensed pharmacist and has practiced in the hospital setting since 1999. Dr. Awaisu has a unique privilege of past academic experiences in international pharmacy degree programs. He has made substantial and tremendous contributions that impact teaching and learning, research, curriculum design, as well as professional development of students and healthcare practitioners in Qatar and other countries. He received the Qatar University Merit Award for Outstanding Faculty for 2016–17 Academic Year. He is a member of the American College of Clinical Pharmacy (ACCP), and the International Society for Pharmacoeconomics and Outcomes Research (ISPOR), among others.

Professor Awaisu has extensive experience in the conduct of pharmacy practice and clinical research involving various types of study designs including case-control and cohort studies, quantitative surveys, mixed-methods designs, randomized control trials, and systematic reviews mostly on diabetes, cardiovascular diseases, tobacco dependence, and other chronic diseases. He has published over 100 peer-reviewed articles in internationally reputable pharmacy and healthcare journals and 10 book chapters related to the field of pharmacy. He has successfully supervised several postgraduate and undergraduate research projects, including MSc and PhD.

His research interest includes pharmacy practice especially pharmacists' expanded scope of practice, outcome-based research, pharmacoepidemiology and medication safety, and health promotion. Dr. Ahmed Awaisu has conducted training sessions and workshops on research methodology and biostatistics, drugs in sports, developing cognitive pharmacy services, and responding to symptoms in pharmacy practice. He presents regularly at continuing professional development programs for healthcare professionals in Qatar and other countries.

Timothy Chen

Professor Timothy Chen is a registered pharmacist and Professor of Medication Management, School of Pharmacy, The University of Sydney, Australia. Tim is nationally and internationally renowned for his research in medication management review and strategies to reduce medication related harm. Tim's research directly informed the Australian Government funded Home Medicines Review programme (MBS Item 903). Tim is an experienced educator and health services researcher, with experience in both community pharmacy and hospital pharmacy practice. Tim leads a productive research team (>160 peer-reviewed papers) and has completed main supervision of 15 PhDs, amongst other postgraduates. Tim has delivered >70 invited presentations at conferences and meetings across the globe. Tim has received university and national awards (Australian Government) for teaching, is an International Pharmaceutical Federation (FIP) Fellow (2016), and is President of the Social and Administrative Pharmacy Section, FIP.

Louise Curley

Louise Curley is a pharmacist and Senior Lecturer in Pharmacy practice at the School of Pharmacy. Louise's area of research focuses on the effects of recreational drug use in humans. She began her research as an undergraduate by investigating the subjective and electrophysiological effects of the Party Pill drugs using electroencephalography (EEG) and graduated with a PhD in pharmacy in 2012. Her thesis investigated the effects of the main constituents of "Party Pills" benzylpiperazine (BZP) and trifluromethylphenylpiperazine (TFMPP) on executive functioning and reward using functional magnetic resonance imaging (fMRI). Currently, her focus is developing new fMRI paradigms to investigate different aspects of risk, specifically by comparing populations of dependent versus non-dependent participants. Louise also has an interest in pharmacy practice research including innovative methods of teaching undergraduate students using different technologies and evaluating the effects of these innovations. She has recently been awarded the Butland Teaching Award: Innovation in Teaching.

Danijela Gnjidic

Dr. Danijela Gnjidic (BSc PhD MPH) is an NHMRC Dementia Leadership Fellow and Senior Lecturer at the School of Pharmacy, Faculty of Medicine and Health, University of Sydney. Her research expertise is in clinical and geriatric pharmacology, clinical studies on polypharmacy, high risk prescribing, and deprescribing in older people, pharmacoepidemiology, and the quality use of medicines. Danijela's academic track record includes 115 publications, 3-book chapters, with over 2500 citations on Scopus and $4M in research funding. Danijela was awarded the Australasian Society of Clinical and Experimental Pharmacologists and Toxicologists (ASCEPT) Denis Wade Johnson & Johnson New Investigator Award in 2012. Internationally, Danijela's contribution to the filed was recognized with the 2018 American Society of Clinical Pharmacology and Therapeutics William B. Abrams award in Geriatric Clinical Pharmacology. Danijela is an Associate Editor of the *Journal of Alzheimer's Disease* and Academic Editor of the *PloS One Journal*.

Arijana Meštrović

Dr. sc Arijana Meštrović, MPharm, FFIP has been working as a community pharmacist and she was responsible for education, services, and competency development in the biggest pharmacy chain in Croatia. She is now independent consultant and educator in Pharma Expert international agency, providing lectures and workshops in CPD programs for pharmacists, pharmacy technicians, medical representatives, implementing new services in pharmacy chains, and teaching Social Pharmacy and Pharmaceutical Care at universities in Croatia and Cyprus as Assistant Professor. Her Doctor's degree is in biomedical sciences—competency development in pharmacy. Arijana serves as member of the International Services Program Advisory Group the Accreditation Council for Pharmacy Education (ACPE, USA), member of PCNE (Pharmaceutical Care Network of Europe), ExCo member of FIP (Pharmaceutical International Federation) Academic section, and WHO international expert consultant in Pharmaceutical care field. She used to serve as Co-Chair of the FIP World Congress Programme Committee, Expert Member of the Board of Pharmacy Practice at FIP. In Croatia, she is a leader in Croatian Pharmaceutical Society and Croatian Chamber of Pharmacist as a Lecturer and Co-author of New services model in community pharmacy practice. Arijana is dedicated to promoting competency-based education in CPD cycle, so her teaching usually addresses all components of competencies—knowledge, experience, and motivation. In collaboration with ACPE International Services, she has founded and implemented SMART Pharmacy CPD model for pharmacists in more than 12 countries all over the world. She was invited speaker and consultant in more than 40 countries.

Kath Ryan

Kath is Professor of Social Pharmacy at the University of Reading, and Visiting Professor at Bournemouth University, United Kingdom. She has 45 years of experience as a pharmacist in the pharmaceutical industry, community practice, and academia. She has held posts at the University of Otago, New Zealand; Bournemouth University, United Kingdom; La Trobe University, Melbourne, Australia; and the University of Reading, United Kingdom. She also has experience in academic nursing and midwifery. Her research interests include extended roles for pharmacists, especially in general practice; application of the behavioral sciences to pharmacy practice; personal experiences of health and illness; and public and patient involvement, engagement and participation in research, and the education of health professionals. She has expertise in quantitative, qualitative, and mixed methods research. She also has an interest in infant feeding,

particularly breastfeeding research, promotion and support, from lay, professional, and academic perspectives. She has been a health advisor to La Leche League International and La Leche League New Zealand. Kath has been on Scientific Committees for the International Social Pharmacy Workshops and the Australasian Pharmaceutical Sciences Association. She has consulted for the National Institutes of Health, USA; Canadian Forces; Health Technology Assessment, NHS UK; and the NZ Ministry of Health.

Kath has over 100 publications in peer-reviewed journals and several book chapters and reports. She produced two multimedia, online resources for Health Talk: women's experiences of breastfeeding in the United Kingdom, and people's experiences of ageing in Australia. She was a Founding Co-Director of Health Talk Australia.

FOREWORD

This first edition of the Encyclopedia of Pharmacy Practice and Clinical Pharmacy is one-of-a-kind and the most comprehensive amalgamation of an inclusive range of topics relevant to the pharmacy profession brought together to ensure safe and effective provision of pharmaceutical care across the world. Professor Zaheer Babar is a Professor in Medicines and Healthcare at the University of Huddersfield and also a global expert in pharmacy practice and pharmaceutical policy. He has united over hundreds of researchers and practitioners from across the world in a collaborative endeavor to provide a unique insight into current best practice and strategies for the future for the profession of pharmacy and its practice.

As patient care becomes more complex with advances in medicines and new developments in practice, including pharmacogenomics and pharmacoeconomics, there is an ever-evolving demand for practice and policy to keep pace. This encyclopedia contains 180 chapters, from all fields of pharmacy practice and clinical pharmacy, providing an in-depth coverage of modern approaches to the practice of pharmacy and highlighting the directions that will enable advancement to continue.

This encyclopedia includes definitions, concepts, theories, and applications of clinical pharmacy and pharmacy practice, providing background knowledge of the area that will provide valuable information for students of pharmacy practice. By providing relevant and topical summaries on a broad range of subjects, this book is also an excellent resource for those seeking information beyond their specific areas of expertise. In addition, the information contained in this book and its communication is of importance to a range of stakeholders, such as physicians and other healthcare professionals, health regulatory authorities, and the pharmaceutical and health industry, in addition to patients and their caregivers.

This encyclopedia also provides an excellent insight into pharmacy practice research and methods, as well as pharmacovigilance, pharmacoeconomics, social and administrative pharmacy, public health pharmacy, pharmaceutical systems research, the future of pharmacy, and new interventional models of pharmaceutical care. In addition, new treatments, algorithms, standard treatment guidelines, and pharmacotherapies regarding diseases and disorders are also covered.

The six key strands around which this encyclopedia is arranged pay testament to the complex and broad nature of the topic and are key topics of interest in pharmacy today and drivers of change for the future, for the benefit of public health across the world.

1. Pharmacy practice
2. Pharmacy practice research methods
3. Clinical pharmacy education, professional standards, and workforce
4. Clinical pharmacy and pharmacotherapy
5. Pharmacoepidemiology and pharmacovigilance
6. Socio-behavioral and administrative pharmacy

Topics range from the education and training of pharmacists, technicians and assistants to counterfeit medicines, pharmaceutical pricing policies, and implementation of change. As pharmacy practice evolves to meet the ever-more-complex health and medicines needs of patients, practitioners need an understanding of the social, political, and economic contexts across the world, noting particular highlights and challenges in developing countries to reach high standards. While it is acknowledged that there are differences between countries in terms of legislation, regulations, and guidelines (as detailed in individual chapters), the vision for the profession must be for a world in which everyone can access safe, effective, and affordable medicines and pharmaceutical care. The chapters include many examples of innovation and best practice in delivering health

services for the future, embracing additional roles beyond the supply of medicines in a robust manner underpinned by scientific and evidenced practice. Quantitative, qualitative, and mixed methods of pharmacy practice research are presented alongside expanded and evolving roles for pharmacists and where technology may take us. More quality research and coordinating efforts will bring a range of theoretical concepts and an evidence-based practice to the forefront of our activities, to focus a global workforce to meet the challenges of this exciting new era for pharmacy practice. This timely volume exemplifies the willingness and ability of the profession to work collaboratively on global issues, representing an unprecedented opportunity to shape the future of pharmacy practice.

With ever-increasing demands on healthcare systems, alongside growing financial pressures, it is essential that we work collaboratively with other pharmacists and the wider public health workforce who have the expertise, opportunity, and capacity to support and inform development.

In this context, this encyclopedia is an important resource with far-reaching impact on global healthcare community, and I hope this will be well liked by students, researchers, and academics.

Professor Barbara Conway
Department of Pharmacy, University of Huddersfield, Queensgate, Huddersfield, United Kingdom

March 2019

PREFACE

Encyclopedia of Pharmacy Practice and Clinical Pharmacy

This encyclopedia has 180 chapters in total and it covers all domains of pharmacy practice and clinical pharmacy, including pharmacy practice research, socio-administrative and behavioral pharmacy, pharmacy education, pharmacoepidemiology, and the pharmacotherapy. One main question being asked is the need for this work. *What encyclopedia of pharmacy practice and clinical pharmacy adds to the current body of literature and what it means for global pharmacy community?* The answer to that is, though there were a number of books available on pharmacotherapy, however, current landscape lacks material comprehensively covering aspects, such as pharmacy practice, pharmacy practice research, social pharmacy, pharmacoepidemiology, pharmacy education, and the linking of clinical pharmacy with the health system. This encyclopedia aims to provide a collection of chapters on the above-mentioned areas. It also developed, synthesized knowledge, and provided policy guidance in the areas where there were gaps in the literature. For example, filling the gaps and including chapters on health systems, pharmaceutical policy, evidence and impact in pharmacy practice research, and on pharmacy education.

Here is a brief summary of what is being covered in its three volumes: Volume 1, 2, and 3.

Volume 1 includes chapters on pharmacy practice and pharmacy practice research. The pharmacy practice section starts with the historical evolution of pharmacy practice, medicines management, expanded roles of pharmacists, cognitive pharmacy services, community, and ambulatory pharmacy practice, ethics and regulation, and the new models of pharmaceutical care. There are also chapters on prescribing standards, practices, and competencies, interpersonal communication, evidence-based medicine, models on patient counseling, innovative pharmacy services, technology in pharmacy practice, and the pharmacist's role in substance misuse. The case studies chapters include pharmacy practice in high, low, and middle-income countries; United Kingdom, Western Europe, Australia, New Zealand, China, India, Gulf States, Philippines, and Portugal.

It is vital to understand and discuss the quality of evidence in pharmacy practice research, for example, how the evidence is produced and how it could impact on health outcomes. This is a niche section in the encyclopedia covering chapters on quantitative and qualitative methods in pharmacy practice research, quality of qualitative research, philosophical perspective and theories applied in pharmacy practice research, meta-synthesis, mixed methods research, discrete choice experiments, and the use of network meta-analysis in pharmacy practice. There are also chapters on evolution and definition of practice research, evidence, impact, and gaps in pharmacy practice research in low- and middle- and high-income countries.

Volume 2 covers pharmacovigilance, pharmacoepidemiology, and the socio-behavioral and administrative aspects of pharmacy and medicines use. The knowledge regarding pharmacoepidemiology and pharmacovigilance significantly impacts on medicines safety. The chapters included are on definitions, principles, and application of pharmacoepidemiology, descriptive and drug utilization studies, case-control and cohort studies, methodological challenges in epidemiological studies, data sources, and the issues related to medicines safety and comparative effectiveness research.

The socio-administrative and behavioral pharmacy section covers two broad aspects, namely, social pharmacy and pharmacy administration. Social pharmacy section covers concepts, development, and theories related to social pharmacy, public and patient engagement, sociology for pharmacists, implementation of change in pharmacy practice, and the social perspectives in addiction. There are also chapters on medicines adherence, compliance, and concordance, medication narratives, investigating medicines use among elderly

from a sociological perspective, changing nature of pharmacy as a profession, the impact of culture and religion on medicine use, and the issues related to disease mongering.

The understanding of health system is vital when promoting access and the use of medicines, hence in this context understanding administrative aspects of pharmacy are crucial. This section explores the dynamics between public policy, pharmaceutical policy, pharmacy practice, health systems, and patient-health outcomes. It covers a range of pharmaceutical policy and health system issues including access to biosimilars, access to high-cost medicines, counterfeit medicines, factors influencing pharmaceutical policy implementation, funding mechanisms for community pharmacy services, generic drug policies, national medicine policies, essential medicines list, pharmaceutical company sponsored medication assistance programs, and the pharmaceutical pricing policies.

Volume 3 covers clinical pharmacy education and pharmacotherapy. Pharmacy education training and the workforce have a great impact on global health. There are 25 chapters or more on pharmacists' training, and certification exploring the relationship between education, regulation, and practice. This is one of the largest collection of chapters covering pharmacy education and regulation at the global level. This includes chapters on pharmacist workforce, competency standards for clinical pharmacists, quality assurance in the pharmacy education, developing and evaluating clinical skills, continuing professional development, experiential education, inter-professional learning, leadership in pharmacy education, and the needs-based education. There are also case studies chapters on clinical pharmacy professional standards in the United States of America, Canada, the European Union, and in the low- and middle-income countries.

The pharmacotherapy section covers over 70 chapters discussing standard treatment guidelines, pharmacist's role in the central nervous system, infectious diseases, cardiovascular disorders, skin and endocrine disorders, musculoskeletal disorders, neurology, gastrointestinal disorders, and the respiratory disorders. The other key chapters include clinical pharmacy concepts, history, and development, clinical governance principles, pharmacokinetics, therapeutic guidelines, end of life care, palliative care, long-term care, fundamentals of pharmaceutical care planning, health outcomes and quality of life, the role of the pharmacist in the military and prisons, and the pharmacotherapy and deprescribing.

It has been a challenging task to complete this encyclopedia within a short span of 2 years. However, I am very thankful to the support of my section editors, reviewers, and hundreds of authors from all over of the world to come together and to contribute to this exciting project.

I hope you will like this effort and it will serve its purpose.

Professional Ethics in Pharmacy Clinical Governance

Betty B. Chaar*, Sanya Ram†, *The University of Sydney, Sydney, Australia; †Auckland University, Auckland, New Zealand

Introduction

Clinical governance provides a scaffolding structure for a shared professional dedication to developing and attaining highest standards of patient care. It is a commitment to providing quality services through good clinical practice entwined with high ethical standards of patient care. Clinical governance relies on good processes and an environment where continuous improvement is advocated to allow excellence in the provision of care and services to flourish for patients. Integral to the delivery of high-quality patient-centered care is ensuring professional governance and high ethical standards. The main requirement for any health-care service is patient safety and quality improvement (Flynn Maureen et al., 2015). The provision of pharmacy services is no exception. The patient is afforded the right to have pharmacy services delivered to an appropriate quality and standard. Pharmacy is governed and guided by codes, ethical obligations, regulatory authorities, legislation, professional organizations, corporations, and central agencies, ministries, and consumer advocates. A fundamental tenet of ensuring a high standard of service is through embracing ethical leadership and ethical obligations that bind the profession. This chapter explores the topic of professional ethics in pharmacy as a pillar of patient-centered care and consequently the premise of good clinical governance. This chapter explores a history of ethics in pharmacy, emergence of bioethics, professional governance, reasoning, and decision-making.

Ethics in Pharmacy—A Brief History

In ancient times, medicine and pharmacy were merged in one body of practice, interwoven and tightly bound in religious practices. Pharmacy always played a prominent role in the history of civilization. Even in the age of Hippocrates (c.400 BC), physicians knew that disease was not an act of divine providence as much as it was a condition that an experienced doctor could diagnose, and with the help of natural medicines, relieve or cure (Pötzsch, 1996).

The foundations of pharmacy were laid centuries ago by a series of many civilizations; but it was not until the 9th century AD in Baghdad that the first pharmacy was ever established and where pharmaceutical literature in Arabic began to proliferate. This historical event marked the first separation of roles of physicians and pharmacists, and recognition of governmental responsibility for peoples' health, which later spread to Europe (Pötzsch, 1996). Pharmacy as a separate profession from medicine began to emerge in Great Britain in the 17th century.

Ethics in health care as we know it today in the Western world has its roots in history from the time of Hippocrates (Edelstein, 1967). The paradigm of this ethical foundation of health care is the Hippocratic Oath, which, according to some scholars, emerged not from the general milieu of the Greek philosophers in medicine but even further back in history, to the philosophical–religious cult of the Pythagoreans (Carrick, 1985; Edelstein, 1967; Jonsen, 1998).

Although ethics in health care is not necessarily all about codes of ethics (Kerridge et al., 2009), the Hippocratic Oath is generally acknowledged as the first code of ethics in health care and the foundation for medical ethics in the Western world. The

Oath itself is divided into two parts: The first, the opening covenant, relating to the relationship between teacher and scholar. The second part, often referred to as ***the*** "code of ethics," is subdivided into three areas of medicine: dietetics, pharmacology, and surgery, offering detailed statements and instruction on principles of patient care.

The Oath served a number of purposes, including the binding together of professionals into a cohesive and effective social force. However, in relation to medical ethics, the Oath has had the "***most significant influence***" and with only minor amendments, has remained over the millennia central to the ethics of physicians to the present day (Kerridge et al., 2009).

The main reason for the longevity of this code is the patient-centered values it represents. For example, on dietetics, the pledge was to apply measures "*for the benefit of the sick according to my ability and judgment.*" Often referred to as the principle of "*beneficence*" (to do good), this core principle in health care still stands strong today. This one line is considered to be the most important line in the *Oath.* Another long standing principle handed down from the Oath is the principle of *non-maleficence* (to do no harm). These two mainstays of medical ethics have been extended to include all health-care ethics relating to the patient throughout the centuries after it was written, including pharmacy (Veatch, 1989).

Profound issues and perspectives about health-care ethics have come to the forefront over the last decades. In particular, post-World War II, the emergence of human rights as a driving social and political agenda in the Western world—generating movements such as consumerism, feminism, and the rights movements, have immensely influenced ethics in health care (Darvall, 1993). The tradition of representing health-care ethics by reference to the Oath is slowly waning in the face of substantial change in practice as a result of both technological/scientific advances and major changes in societal expectations after the war. Over time, the four major principles of *bioethics* have emerged: (1) Respect for patient autonomy; (2) to do good; (3) to avoid harm; and (4) justice. Along with profession-specific values complementing these principles, most health-care professions today, including pharmacists, recognize the principles of bioethics as fundamental in the practice of health care.

Deliberation and acceptance of ethical principles are often the precursors for the development of regulations and codes. Bioethical principles have been recognized and heavily underpin laws and codes pertaining to patient protections. These patient-centered values that have emerged from principles of bioethics have been enveloped in codes that prescribe the fact that every consumer can expect a high standard of care with respect to their privacy, dignity, and independence.

Patient Rights and Legislation

Codes and legislation governing the rights of particularly vulnerable patients, such as those receiving health and disability services, are prominent in health care and enforced by most health organizations. These regulations prescribe the rights that every health and disability service consumer can expect and impose corresponding duties on the health-care provider to fulfil these obligations (Manning, 2004).

Similarly, the privacy of the patient is today, and around the world, strongly protected through privacy legislation and health information privacy codes, as it is accepted that due to the sensitive nature of health information, it should be treated differently and assumes a need for greater level of privacy. These ethical principles embodied in regulations around the world, help further the creation of a culture, which embraces the aims of clinical governance. The aims of clinical governance are enabled by a focus on quality and safety through quality improvement methodologies as well as good ethical leadership (Goona et al., 2014).

The Emergence of Bioethics

Bioethics has been an area of major growth in moral philosophy since the 1960s (Frey, 1998). Bioethics is principle-based ethics, that is, specifies general principles to guide moral actions and more specific rules to provide clear applicable guides (Kerridge et al., 2009). The concepts of bioethics began to take shape in the decades immediately post-World War II during which the conceptual foundation for evaluating outcomes within tenets of consequentialism was expanded to include other ethical principles beyond *beneficence* and *non-maleficence* (Savulescu, 2003). These newer principles press the practitioner–patient relationship beyond traditional ethical guidelines to include additional principles such as *justice* (strategies or acts that ensure fair allocation of goods and services) and *respect for autonomy* (strategies or acts that respect the self-determination of others) (Buerki and Vottero, 1994).

These four principles, the so-called pillars of bioethics, are at the core of most medical ethics curricula in English speaking world, presented to readers with detailed descriptions of the physician–patient or nurse–patient relationship (Beauchamp and Childress, 2009; Kerridge et al., 2009). Scholars have, however, rarely extended this analysis to the profession of pharmacy or explored the underlying nature of the pharmacist–patient relationship (Buerki, 1994). We explore this extension further in the next section.

There is in fact far more literature available in the philosophy of health professions, such as medicine and nursing, than in pharmacy (APPLET: Pharmacy Law and Ethics, 2006; Morley, 1993; Wingfield et al., 2004). While differences exist between the health care professions in practice, they do have much in common, however, particularly in sharing common values and principles concerning their duties toward patients (Merrills et al., 2002).

Nevertheless, each profession is distinguished by its specific role and duties, necessitating some degree of specificity in ethical principles applicable to practitioners of each health-care profession. For instance, in a case where decision-making relates to the institutionalizing of an aged patient to a nursing home, primary ethical responsibility lies with the physician, not the nurse or pharmacist. Not all principles of professional ethics applicable to medical practitioners are relevant to other health-care providers.

Hence, there is bound to be a specific scope of ethics particular to pharmacy. It may be beneficial at this point therefore to examine ethics relating specifically to the profession of pharmacy.

Professional Governance

While the primary role of a professional code of ethics is to espouse the standards of conduct, the requirements for ensuring competence in the discipline of pharmacy are often emulated by the requirement for registration. Accountability and continuous quality improvement of processes, as well as within professional development, are fundamental tenets of clinical governance (Flynn Maureen et al., 2015). Having a consistent, accountable regime to ensure all health practitioners are working to a set of standards is often embodied in legislation. Regulating health-care professions ensures that practitioners are competent and fit to practice their professions, hence protecting the patient's right to receive care commensurate with an appropriate standard (Manning, 2015). These regulations also serve an essential regulatory function as it provides a framework against which breaches of appropriate standards can be assessed.

Theoretical Foundations in Pharmacy Ethics

Ethics as it applies to the practice of pharmacy has, with only a few exceptions, mainly been articulated in codes or pronouncements from professional bodies, opinions in textbooks or debates, rather than derived on the basis of philosophical analysis of the core values in the profession (Dessing, 2000, 2002; Dorey, 1997; Wingfield et al., 2004).

An endeavor to examine the philosophical foundations of pharmacy ethics has been made in the United States over the past few decades, particularly in the works of Robert Veatch, a renowned ethicist in health care, Robert Buerki, Louis Vottero, and Amy Haddad, who specialized in pharmacy ethics, Charles Hepler, co-founder of the conceptualization of pharmaceutical care, and Joseph Fink among many others. Some research has also been conducted on moral reasoning capabilities of pharmacists in the United States (Buerki and Vottero, 1994; Buerki, 1985; Edgar, 2002; Fink, 1985; Haddad and Buerki, 1996; Haddad, 1991; Knapp, 1985; Latif, 2000a, 2000b, 2001, 2004; Salek and Edgar, 2002; Smith et al., 1991; Veatch, 1985; Vottero, 1995).

Over 20 years ago, in a conference in the United States entitled *"The Challenge of Ethics in Pharmacy Practice,"* the importance of codes and the role of society in pharmacy ethics were examined. Principles such as *beneficence*, *respect for patient autonomy*, *veracity*, *promise keeping*, *non-maleficence*, and *justice* were identified as pertinent to the practice of pharmacy. Moreover, it was observed that with the advent of contemporary patient-focused health care, a shift in ethical orientation in pharmacy practice had taken place rendering traditional paternalism (an approach in which the desire to help, advise, and protect may neglect individual choice) no longer acceptable.

That conference was a pivotal forum for the inaugural discussion of ethics in contemporary pharmacy practice, in which many ethicists presented their interpretations and perspectives. Robert Veatch analyzed the origins of some relatively newer concepts and principles in terms of fundamental theories of utilitarianism and deontology, and the relevance of these principles to pharmacy (Veatch, 1985). The challenge to the Hippocratic principle, according to Veatch, started with changes in the source of moral authority shifting from the professional as articulated in a code of professional ethics, to a broader source, which included the most important stakeholder in the health-care forum: the patient. Other challenges were the lack of training of those who wrote the codes; freedom of speech and the benefits versus risks of advertising, in their role in educating the public.

Flowing on from that, it was also highlighted that ***individualism*** (in health-care manifesting as *patient autonomy*), an essential aspect of Kant's deontology, was the second major challenge to the Hippocratic tradition, calling for changes in practice and the ethical framework within pharmacists to serve the public. The Kantian approach to applied ethics, however, does not address problems associated with fair allocation of resources among patients (*justice of distribution*), an often ignored dimension of pharmacy ethics, or of conflict between the patient's interests and society's interests—a utilitarian approach *(the greater good for the greater number)* might serve better for these issues. The deontology of Kant does, however, raise serious questions with respect to pharmacists' roles in clinical trials, about the well-being of the individual patient participating in a double-blinded placebo controlled trial (a clinical trial in which neither the subjects nor the researchers know which subjects receive active treatment, or placebo-pseudo-treatment, innocuous or inert substance).

Pharmacists' role in medical research, which is designed to increase scientific knowledge and ultimately benefit the general public, would, however, be considered unethical if the moral mandate is stated to be the benefit of the individual patient. Veatch stated that a utilitarian approach would then be the only "corrective" ethical stance. The problem with that approach would be the risk of swamping the patient in a "sea of social considerations" radically sacrificing the welfare of the patient for the benefit to society.

Veatch highlighted in addition to *autonomy*, and *justice*, the relevance in pharmacy of *veracity* and *promise keeping*, derived from the principle of respect for the individual. Interestingly, he also regarded *avoidance of killing*, albeit under the banner of *non-maleficence*, as a stand-alone principle that must be given separate attention. It would prohibit, for example, hospital pharmacists from dispensing medication in quantity and quality that could cause death of a patient; or a pharmacist from dispensing lethal doses of medication used for capital punishment or euthanasia, if the legislation so allowed (Veatch). This may now be considered slightly outdated, as countries around the world endeavor to legislate the right of patients to euthanasia and the profession of pharmacy in its capacity as

"gatekeepers of medicines" is beginning to grapple with implications of this kind of legislation, which has been in place in countries like the Netherlands, Belgium, Switzerland, some states of the United States, and recently Canada.

These analytical perceptions have enriched the tapestry of ethical reflection in pharmacy, and adequately set the scene for further discussion of some of the ethical challenges yet to be resolved, which pharmacists face on a day-to-day basis.

Ethical Concerns in the Practice of Pharmacy Today

As in any profession, pharmacists face an array of ethical dilemmas in the course of their work. Some are related to the details of a task at hand and others are broader in scope. For example, it is not uncommon for a pharmacist to be called upon to provide a medicine late at night, desperately needed to relieve the pain of an elderly patient, but without a legal prescription. The dilemma is every pharmacist's nightmare. There is every chance that compassion for the sick could lead to serious consequence for the pharmacist. As custodians of all restricted medicines, the penalty for misappropriating addictive substances in pharmacy is nothing less than suspension of license or deregistration. This ethical dilemma is clearly a practice-based example of an issue where a critical decision must be made, with little time to deliberate carefully.

Direct to Consumer Advertising

There are also ethical issues related to pharmacy, of a larger scope and/or of greater concern, than an individual pharmacist's perspective. A case in point is the role of advertising medicines generally, particularly Direct-to-Consumer-Advertising (DTCA) of prescription medicines. Although the issue is a marketing one, and of concern to the pharmaceutical industry more than the community pharmacist, its impact is, broadly speaking, one that touches most human beings' lives in one way or another. Commercial promotion of medicines manifests not only in advertising per se but also in gifts to physicians, bonuses for pharmacists, promotions, and grants. Such promotions may be evident in advertisements in the various media outlets, and even on the street. The ethics of marketing pharmaceuticals, in terms of patients' best interests, has been questioned extensively in the literature and many research studies investigating the issue of DTCA have been conducted around the world.

For instance, many studies have explored the impact of DTCA on consumers (Chaar and Lee, 2012; Joseph et al., 2008; Mintzes, 2006; Rosenthal et al., 2002), and on health-care providers, including pharmacy (Chaar, 2010; Chaar and Kwong, 2010). Pharmacists generally perceive DTCA to be disempowering to them in their role as "gatekeepers" of medicines, and are particularly challenged when a patient demands a product as a result of DTCA, that would not be in their best interests to provide them with (the dilemma of best interests of the patient versus respect for patient autonomy). It is again symbolic of the contemporary shift of ethical and moral responsibility from the practitioner to the patient. This shift can be challenging if not frustrating when the practitioner has the knowledge to discern appropriateness, safety, and efficacy of the product based on expertise and the latest evidence.

Duality of Interest

Another unique aspect of pharmacy to consider is the duality of interest vested in the business of pharmacy, resulting from the actual sale of products. Although the pharmacist is the most accessible health-care provider, and can be consulted free of charge by any passer-by, there remains the thorny issue of viability of the business in balance with patient-centered care. Hence, while the pharmacist as a professional enjoys very high levels of social/community trust around the world, almost on an annual basis scoring in the top 10 most trusted professions, there is always a shadow hanging over the integrity of the pharmacist, as an owner of a business. To maintain viability of the business, the community pharmacist must employ marketing strategies, sustaining continuity of their career and livelihood. Some pharmacists unfortunately exacerbate the perception by adopting aggressively competitive marketing ploys, thereby heightening sensitivity to the integrity and trustworthiness of his or her advice. Whether the competitive model of community pharmacy, favored by many Western country governments, is a suitably ethical framework for the profession is quite a contentious issue. Some, more regulated Northern European models of pharmacy practice could exemplify good balance between business concerns and caring for the health and well-being of patients/clients. Another approach would be to train pharmacists not just in marketing and business management, but also in business ethics, which is generally absent from pharmacy curricula.

Other ethical concerns involving pharmacists are issues such as "*conscientious objection*", "*whistle blowing,*" and the most contemporary: what is known as "*social media*" and *privacy*.

Conscientious Objection

Conscientious objection is the right a pharmacist has to refuse supply of a medication or product, as a result of a moral, religious, or other belief. This right to refuse supply is sometimes invoked when a pharmacist is approached for supply of a medicine that might be abortive or contraceptive or a substance used in euthanasia, etc.; that is, those items that may be against one's religious or personal beliefs. In such cases, the best interests of a patient do not theoretically override pharmacists' right to refuse provision of a medicine. The situation is easier to overcome when the pharmacist works in urban areas and the patient may be directed to

another pharmacy close by. It is by far more difficult for those residing in rural areas to find an alternative, with pharmacies separated by many miles of travel.

Although this contentious issue has generated large forums of global debate, no clear resolution has been found. Some states in the United States have legislated supply regardless of the professional's objection, others continue to allow for pharmacists' right to conscientious objection. The world appears to remain divided. In most countries, it is the requirement of the pharmacist to clearly display his or her reasoning in signage easily seen and understood by clients, to avoid the perception of discrimination when the unknowing patient is declined service. In one study, it was found that up to 5% of practitioners in NSW, Australia fall into the category of those who claim conscientious objection to supply the emergency contraception pill (Queddeng et al., 2011). A similar situation exists in the United Kingdom (Aultman, 2008; Wingfield et al., 2004). Despite wide debate, and some legislative resolutions in some areas, little consensus has been achieved so far, as to how best to attend to patients' needs other than to refer the patient to another practitioner (whether within the premises or outside).

Whistle-Blowing

"Whistle-blowing" or mandatory reporting of colleagues is a relatively new dimension of ethical deliberation in the practice of pharmacy. Legislation has recently been passed in some countries, requiring pharmacists to report impaired (i.e., those affected by alcohol, illicit substances, or mental illness) colleagues (Chaar, 2010). Research, currently underway, has revealed that it is a challenge to most pharmacists to have to report a colleague, and to have to cope with a number of ethical and practical concerns. These include risk of loss of employment, or loss of friends/colleagues, being known as an informer, not knowing enough about impairment, and preferring not to have to report or harm anyone. The legislation is meant to protect the public, hence based in utilitarian intent, but difficult for the practitioner to follow. Research is continuing in this area.

Social Media

Social media and privacy is another intriguing contemporary ethical concern. Increasing evidence is becoming available about the incredible expansion of Internet technologies in the last few years in the newly coined domain of "*Social Media.*" Society, in general, has enthusiastically embraced user-generated content such as blogging, personal websites, and online social networking, including health-care practitioners. Research shows that use of social media by the medical profession is common and growing. In one 2010 study, 220 out of 338 (65%) medical students at the University of Otago, New Zealand, had a Facebook account (MacDonald et al., 2010).

As health-care providers and students are increasingly participating in online social media, evidence is now emerging from studies, legal cases, and media reports that the use of these media can pose serious risks and liability for health-care professionals. Inappropriate online behavior can potentially damage personal integrity, health-care provider–patient and interprofessional relationships, and future employment opportunities. Perceptions and regulations regarding professional behavior are evolving to encompass these new forms of media. Guidelines have been developed in some countries to help guide medical students, warning them to maintain patient confidentiality at all costs, to be aware of who is accessing personal sites, to be careful to choose wisely who to allow access, and to consistently consider the destiny of any information posted on the Internet (AMA et al., 2010). These guidelines are applicable to pharmacy.

Pharmacogenetics

Another topic warranting discussion on discerning between help or hype is the emerging interest in pharmacogenetics and direct to consumer genetic testing (DTCGT)? Genetic tests are provided directly to consumers, usually via the Internet (Saukko, 2013). Consumers are provided insight into their genetic makeup and predicted risk of disease, often by sending samples from either saliva or cheek swabs (Kimberly et al., 2012; Ram et al., 2012). A health-care professional is not always involved in accessing these tests, and as a result, misunderstanding of results and inadequate provision of information is perceived by medical practitioners and pharmacists to be one of the risks associated with DTCGT (Ram et al., 2012). While the results provided by some genetic tests have established utility, others have been described as lacking clinical usefulness (Hennen et al., 2010; Saukko, 2013). Furthermore, the onset of a disease results from a complex interplay between an individual's genes, environmental factors, and lifestyle choices and not solely by a person's genetic makeup (Kimberly et al., 2012; Scott, 2011).

Data Protection

It has also recently come to light that dispensing information containing very sensitive patient material may also be subject to storage on the "Cloud" for back up and remote data access (Bratuskins, 2011). This may become all the more pertinent an issue when and if an electronic health care card for every Australian citizen is introduced and accessible to health-care providers (with permission from the patient). The complexities are difficult to fathom. The profession of pharmacy must keep abreast of all new technologies and document all incidents, including social media. It is also essential that guidelines are developed and revised constantly.

Moral Reasoning and Decision-Making in Pharmacy

Good judgment, both clinical and moral, relies on moral reasoning capabilities (Cohen, 2004). These capabilities are acquired by family influences, social assimilation, and professional integration (Thomas, 1997b). The child, born amoral, learns to think in certain ways, according to the way he or she is raised, experiential exposure to external aspects of life, education, environment, and social network (Thomas, 1997b). Cognitive moral development occurs naturally as a result of the accumulation of these processes (Kohlberg, 1976). For those who pursue professional careers, this cognitive moral development is theoretically further expanded with professional skills and acquisition of expert knowledge.

Kohlberg and Rest developed and validated a survey to measure levels of cognitive moral development, called the Defining Issues Test (the DIT), and it has been used extensively as a surrogate measure of moral development in many cohorts of people, including professionals (Rest, 1979; Rest and Narvaez, 1994; Rest et al., 1997, 1999).

Pharmacists and pharmacy students were examined in numerous studies in the United States and in Australia. It was consistently found that they did not score as highly as expected on this measure of cognitive moral development, particularly when compared to medical school students and practitioners (Latif, 1998, 1999, 2000c, 2000d, 2002, 2003; Rest and Narvaez, 1994). This curious finding, repeated in many studies, is difficult to explain; so a number of further studies have been conducted to explore trends and reasons.

In one study, findings indicated that moral reasoning of older male pharmacists in particular was consistently lower than any other group of pharmacists (Chaar et al., 2009). It is hypothesized that older male pharmacists may be less amenable to professional development, and trained in days when it was the norm for a health-care professional to behave paternalistically, and therefore might be less flexible than other age groups for change. Training in pharmacy only a few decades ago required deciphering and dispensing prescriptions written in Latin, working behind an elevated dispensary bench, maintaining a professional elitism, and evading questions asked by the patient. If the questions became too complex, the pharmacist would direct patient to return to the physician for an explanation. It was almost unheard of that a pharmacist intervened or made a suggestion to the patient or the doctor for any reason whatsoever. Some practitioners still practice somewhat, if not completely, in that mind frame.

This finding emphasized the critical importance of continuous life-long learning and professional development. For today, a prescription written in Latin would be a puzzle, and the pharmacist would not be expected to wait for a question but offer proper counseling using clear, unpaternalistic communication techniques, careful not to discriminate or disrespect any client. A pharmacist in this day and age could be sued for *not* properly counseling a patient or warning of some adverse effect that could happen.

These issues in practice are based on ethical and moral norms of the current times. Norms change with time; it is always up to the professional to keep abreast of change and not succumb to an unthinking conformity to the law or to perfunctory performance of a technical skill without exercising moral reasoning.

It also falls on professional organizations to actively promote ethical discourse, consistently revise the Code of Ethics, and provide a platform for continuing education that relates to ethical practices in community pharmacy. Codes are ordinarily regarded as legally nonbinding; however, in the course of investigating a pharmacist for professional misconduct by the local Pharmacy Board in many countries around the world, it is the code of ethics that is referred to for guidance in judging whether the practitioner's behavior can be regarded as right or wrong. On a practical basis therefore, it is crucial that the code remains up to date with contemporary issues, and clearly understood by all practitioners; and not a token document to showcase in the pharmacy dispensary.

Clinical Pharmacokinetic Principles and Therapeutic Drug Monitoring

Muhammad Usman, Huma Rasheed, Institute of Pharmaceutical Sciences, University of Veterinary and Animal Sciences, Lahore, Pakistan

Introduction

The success of pharmacotherapy can be achieved by ensuring the five rights of the medication use that is the administration of right drug to the right patient in the right dose at the right time through right route of administration. These five rights are classically included in the clinical decision-making goals of the pharmacist (Reynolds and Rupp, 2017). The selection of the right drug for the right patient depends on the right diagnosis of the underlying disease. However, the selection of right dose for the right patient requires understanding of pharmacokinetics of the drug under the clinical situations of the patients. A properly designed dosage regimen is important to achieve the therapeutic success with minimal adverse drug reactions (Leon Shargel, 2015). Variation in the individuals demands the review of dose selection and initiates the need for clinical pharmacokinetic, a discipline involving application of pharmacokinetic methods for safe and effective use of drugs in man and it is a multidisciplinary approach to individualize dosing strategies based on the disease conditions of the patients (Leon Shargel, 2015). The relationship between drug concentration in biological fluids and pharmacological effects forms the basic principle of clinical pharmacokinetics (Goodman and Gilman, 2017). During the process of drug development, dosage regimens are determined on a large number of patients, and recommendations are made to achieve the desired pharmacological response in the majority of target population. However, inter and intraindividual variability in patients may result in either subtherapeutic drug concentration or toxic drug concentration leading to the need of dose adjustment (Leon Shargel, 2015). This phenomenon is well described by the term "precision medicine," as an innovative approach for the prevention and treatment of diseases by taking into account the variability among individuals based on genetic makeup, lifestyle, and environment (US Food and Drug Administration). The individualized dosage regimen is not necessary for all the drugs as many drugs exhibit a wide therapeutic window (e.g., ibuprofen, naproxen, omeprazole, loratadine, etc.), and dose variation does not influence the safety and effectiveness of these drugs against the labeled indication (Leon Shargel, 2015). However, dose optimization for individual patients is necessary for the drugs having small

difference between minimum effective and toxic concentrations. These drugs are called narrow therapeutic window and aminoglycosides, carbamazepine, digoxin, phenytoin, ciclosporin, phenobarbital, rifampicin, theophylline, and warfarin, etc., are some common examples (Blix et al., 2010). The purpose of individualized dosage regimen for narrow therapeutic index drugs is to keep the plasma drug concentration within the therapeutic window by avoiding the fluctuation of concentration due to variability among the individuals in absorption, distribution, or elimination of drugs. The monitoring of plasma drug concentrations is important only if there is a relationship between the plasma concentration and the clinical outcome or adverse effect of a drug. The pharmacodynamic parameters may also be monitored for drugs in which clinical effect is not related to plasma drug concentration. For example, measurement of clotting time may be used for observation of anticoagulant effect of warfarin. The dose optimization for individual patients may also depend on the ability of patient to tolerate the side effects as in the case of cancer chemotherapy (Leon Shargel, 2015).

The physiological and pathophysiological changes often result in the modification of pharmacokinetic parameters, which ultimately results in the need for dose adjustment. The most important pharmacokinetic parameters that govern the dosage adjustment are clearance (CL), volume of distribution (V_D), and elimination half-life ($t_{1/2}$).

Clearance

Clearance is the volume of plasma or blood that is cleared of drug per unit time. It is the measure of the extent of drug elimination from the body without identifying its mechanism, and it can be calculated by adding the clearance from all the drug eliminating organs (Leon Shargel, 2015) as shown in Eq. (1).

$$\mathrm{CL_{Total}} = \mathrm{CL_R} + \mathrm{CL_{NR}} \tag{1}$$

where $\mathrm{CL_R}$ is the renal clearance, and $\mathrm{CL_{NR}}$ is the clearance from the organs other than kidney, which may include liver, GI tract, etc.

Alternatively, clearance can be calculated by multiplying the rate of elimination k_e by volume of distribution V of the drug as shown in Eq. (2).

$$\mathrm{CL} = k_e * V \tag{2}$$

In case where the rate of elimination process is complex, clearance can be calculated directly from area under the plasma concentration–time curve as

$$\mathrm{CL} = \frac{\mathrm{Dose}}{\mathrm{AUC}} \tag{3}$$

Volume of distribution

The volume of distribution is the second fundamental parameter that is considered for understanding the processes of drug disposition, and it makes a relationship between the amount of total drug in the body and the drug concentration in plasma or blood. This volume does not refer to actual physiological volume, but it is the hypothetical volume of fluid, which will be required to contain the whole administered drug at the same concentration as observed in plasma (Goodman and Gilman, 2017). It can be calculated as

$$V_d = \frac{\mathrm{Dose}}{\mathrm{Cp}} \tag{4}$$

where Cp is the concentration of drug in plasma. A high volume of distribution indicates that the drug is present in extravascular tissues and not in plasma. For drugs that follow a multiple exponential decay, the volume of distribution can be described as

$$V_{\mathrm{area}} = \frac{\mathrm{CL}}{k} = \frac{\mathrm{Dose}}{k.\mathrm{AUC}} \tag{5}$$

where V_{area} is the volume of distribution based on AUC, and k is the elimination rate constant, which reflects the rate of fractional elimination of the drug.

Elimination half life

Half-life is the term used to describe the time required for the plasma concentration of drug to be reduced to its half (i.e., 50%). It can be calculated by simple equation 6.

$$t_{1/2} = \frac{0.693}{k} \tag{6}$$

The half-life changes as the clearance and volume of distribution changes. Therefore, an approximate relation between all these parameters can be described by combining Eqs. (5) and (6) as

$$t_{1/2} = \frac{0.693 \times V}{\mathrm{CL}} \tag{7}$$

Therapeutic Drug Monitoring

Therapeutic drug monitoring (TDM) can be described as dose adjustment based on the measurement of drug concentration in serum, plasma, or other biological fluids in order to maintain the drug level within the therapeutic range of minimum effective concentration (MEC) and minimum toxic concentration (MTC) (Kang and Lee, 2009). This is not the absolute range because some patients may respond to the concentration above and below this range, and some patients may have toxicity within this so-called therapeutic range. Clinical pharmacokinetics quantifies the relationship between dose and response of drug and also describes a framework for therapeutic drug monitoring (TDM) of the patient (Goodman and Gilman, 2017). The plasma concentration of narrow therapeutic index drugs is more closely associated with the therapeutic and toxic effects than the administered dose. As the plasma concentration varies in individuals based on the metabolism and excretion of drugs, this forms the basis for TDM (Hutchinson et al., 2018). In addition to therapeutic success and patient safety, the TDM may also decrease the financial toxicity to the patients by reducing the cost of therapy.

Biological Matrices used for TDM

Only a few biological fluids can be collected safely from the patients for quantification of drug concentration and subsequent TDM. The invasive methods are painful due to surgical intervention and require the services of expert personnel. These include collection of blood samples, synovial fluid, spinal fluid, and tissue biopsy. The noninvasive methods, on the other hand, do not require surgical intervention and can be self-collected by the patients, for example, urine, feces, saliva, etc.

Blood (Plasma/Serum)

Blood sample is obtained by vein puncture and collecting the blood in a vial containing an anticoagulant such as heparin or EDTA. However, the whole blood contains cellular components such as RBCs, WBCs, and platelets, as well as various proteins such as albumin, globulin, etc. The presence of cellular components makes the whole blood unsuitable for storage as freezing will lead to hemolysis of RBCs. Moreover, it is unstable and coagulates in few minutes (Montenarh et al., 2014). Therefore, serum and plasma are most commonly used matrices for therapeutic drug monitoring. There is difference in protein contents of plasma and serum; however, both matrices have been proved comparable in terms of bioanalysis (Montenarh et al., 2014). As the blood cells are removed from plasma or serum sample, the drug concentration in these matrices reflects the concentrations in blood cells as the drug is assumed to be in dynamic equilibrium between blood cells and plasma (Leon Shargel, 2015).

Dried Blood Spot

Plasma or serum samples are the primary choices for TDM; however, the collection of blood samples may be challenging from special populations, particularly neonates and infants; therefore, other less invasive sampling techniques are used for TDM such as dried blood spot (DBS). This involves the collection of blood on a filter paper after pricking the heel or fingertip of the patient and storage of sample as dried spot of blood (Kloosterboer et al., 2018). The DBS sampling was successfully applied for TDM, and pharmacokinetic studies of tacrolimus and mycophenolic acid (Zwart et al., 2018) for antituberculosis drugs including rifampicin and pyrazinamide (Martial et al., 2018). This DBS sampling technique was proved as a reliable alternative to venous blood collection for TDM of fluconazole, voriconazole, and posaconazole. Moreover, the satisfaction level of patients DBS was also documented where most of the patients preferred DBS sampling over venous blood collection (van der Elst et al., 2013). Despite of omission of venous blood collection and success stories, this technique has also some limitations and was not proved successful for the monitoring of antipsychotic drugs (Kloosterboer et al., 2018) and ethambutol among antituberculosis drugs (Martial et al., 2018). Therefore, the application of this technique must be weighed against the errors associated with the sample collection and analysis (Edelbroek et al., 2009).

Saliva

The drug quantification in saliva is becoming more popular due to technical advancements in TDM. This has become a more valuable technique due to noninvasive nature, advantage of self-sampling, and comparability with plasma concentration because most of the drugs present in plasma are also found in saliva. If the pharmacodynamic action of drug is proportional to its plasma/serum concentration and if concentration in saliva is proved comparable to that in serum such as in case of caffeine (Chaabane et al., 2017), then this method is very useful for TDM in order to prevent distress and ensure safety in infants (Hutchinson et al., 2018). Only free drug can diffuse into the saliva; therefore, the salivary drug levels reflect only free drug rather than total plasma drug concentration (Leon Shargel, 2015). The salivary concentrations of drug have been proved suitable for TDM of several drugs, including pregabalin (Idkaidek et al., 2018), nevirapine (Lamorde et al., 2014; van Heeswijk et al., 2001), fluconazole (Koks et al., 2001), and gentamicin (Berkovitch et al., 2000).

Urine

The measurement of drug concentration in urine is the indirect method for estimation of bioavailability of drug, and this has been used for the TDM, enalapril, and its metabolites (Magiera and Kusa, 2015). However, a recent study failed to prove the suitability of urine colorimeter method for therapeutic drug monitoring of pyrazinamide (Zentner et al., 2018).

The advantages and disadvantages of each matrix are described in **Table 1**.

Table 1 Advantages and disadvantages of biological matrices used for therapeutic drug monitoring

Matrix	*Advantages*	*Disadvantages*
Plasma/serum	• Traditional and most commonly used method • Metabolites can also be measured • High drug concentration are measured • Large volume of plasma or serum can be collected • Free and bound drugs can be quantified • Also suitable for estimation of plasma protein binding	• Invasive • Requires services of expert personnel • Plasma proteins can interfere with results • Risk of infection • Painful for patients • Expensive • Storage requires special conditions
Dried blood spot	• Less invasive • Self-sampling • Suitable for neonates and infants • Low risk of infection • Storage and transportation are easy • Small blood volume	• Necessity of expensive and sensitive analytical technique is required, e.g., LC–MS. • Hematocrit can affect the sample volume adsorbed on paper • Not suitable for analysis of metabolites • Not suitable for volatile drugs
Saliva	• Noninvasive • Self-sampling • Repeated sampling is possible • Inexpensive • Low risk of infection • Less interference of lipids and proteins.	• Low volume of sample • Suitable only for free drug quantification • Blood contamination of saliva can affect the results • Highly sensitive analytical method is required • Variation in pH can affect the ionization and then drug levels
Urine	• Noninvasive • Can be tested by dried spots • Useful to quantify drug and its metabolites • Useful for estimation of renal clearance of drugs • May be used for toxicological screening	• Not suitable for all drugs • Catheterization can cause infection • Drug measurement is possible after 2–3 days of administration

Bioanalytical Techniques used for TDM

A bioanalytical method is a series of procedures used for the analysis of chemical compounds or drugs in biological matrix (Bhinge et al., 2014). Different bioanalytical methods are being used for the quantification of drugs in biological fluids and its application to TDM and pharmacokinetic studies.

Immunoassay

Immunoassays are used for quantification of drugs based on antigen–antibody reaction. The drug molecules are labeled and act as antigens to compete with other components of mixture for binding on specific sites of antibodies and form an immune complex, which is separated by physical or chemical methods. The analysis is performed by measuring the activity of labeled drug (enzymes, radiation, fluorescence, or absorbance of light) in either bound or free form (Darwish, 2006).

The most commonly used immunoassays are listed below

- Radio immunoassay (RIA)
- Fluorescence polarization immunoassay (FPIA)
- Enzyme multiplied immunoassay technique (EMIT)
- Particle enhanced turbidimetric inhibition immunoassay (PETINIA)

These immunoassay techniques have advantage of rapid analysis, which is required for decision making in TDM. Moreover, these are inexpensive and suitable for clinical settings. However, the cross-reactivity of analyte with metabolites may cause overestimation of analyte, which can ultimately affect the clinical decision making based on TDM (Gunther et al., 2013).

These immunoassay techniques have been proven comparable with one another, e.g., RIA versus FPIA (Ackerman et al., 1983) and EMIT versus FPIA (Yeo et al., 1989). The overestimation of vancomycin was observed with FPIA when compared with HPLC due to cross-reactivity of degradation products formed from analyte (Morse et al., 1987). However, PETINIA was proved comparable with HPLC (Usman and Hempel, 2016) and EMIT with LC–MS/MS for quantitation of vancomycin (Yuan et al., 2018). **Fig. 1** shows the comparison of PETINIA and HPLC for vancomycin.

HPLC

High-performance liquid chromatography (HPLC) is an analytical technique that is used for separation, identification, and quantification of the components of a mixture. The basic principle of this technique is separation of the components of a mixture based on its interaction with stationary phase and mobile phase when it is passed through a column at high pressure. The separated

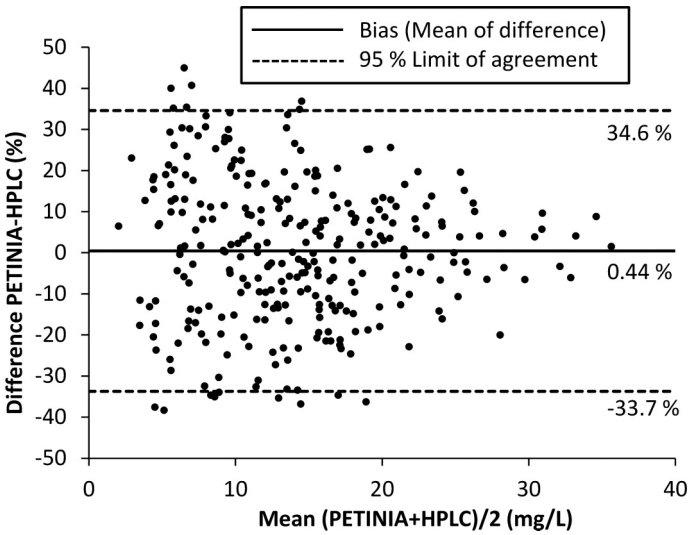

Figure 1 Comparison of HPLC and PETINIA for vancomycin in serum samples. *Adapted after permission from Usman and Hempel, 2016.*

components are then identified and quantified on the basis of signals produced through UV or fluorescent detector. The HPLC method has advantage of high sensitivity and more accuracy as compared to immunoassays. However, this is not as rapid as immunoassay and is not suitable for clinical settings. This techniques has been widely used for the quantification of a number of drugs in biological fluid for TDM and pharmacokinetic analysis such as latamoxef (Dong et al., 2018), vancomycin (Usman and Hempel, 2016), linezolid (Castoldi et al., 2017), and beta lactams (Pinder et al., 2017; Verhoven et al., 2018).

HPLC–MS/MS

This is very sensitive but expensive technique, which utilizes the separating capabilities of liquid chromatography structural identity of separated components by mass spectroscopy (Burkholz, 2014). Despite being expensive, this technique is widely used for the quantification and TDM of narrow therapeutic index drugs such as antituberculosis drugs (Gao et al., 2018), methotrexate (Mulder et al., 2018a), antibiotics (Verhoven et al., 2018), and antidepressant drugs (Weber et al., 2017).

Conditions Requiring TDM

A number of diseased conditions can affect the pharmacokinetics of drugs. Kidney and liver are major routes of drug elimination, and the impairment of these organ functions can affect the drug clearance ultimately needing for dose optimization. In addition to hepatic and renal impairment, age and clinical condition of patient can also affect the clearance of drugs. Some of the conditions requiring TDM are described below:

Renal Impairment

Kidney is the major organ for regulation of body fluids, removal of metabolic waste products, electrolyte balance, and drug elimination (Leon Shargel, 2015). The major reasons for renal impairment are listed in **Table 2**.

The condition of reduced glomerular filtration due to acute kidney disease or damage leads to *uremia* (increased level of urea in blood) and reduced excretion of drugs that are excreted through kidneys ultimately increasing elimination half-life. Uremia can also affect the pharmacokinetics in ways such as change in GIT motility, nausea, vomiting, and diarrhea, leading to reduced absorption of drugs. The change in blood volume due to impaired renal function can affect the protein level in plasma and subsequent alteration in

Table 2 Common reasons of renal failure

Cause	*Description*
Pyelonephritis	Inflammation or destruction of nephrons due to antigens, infection, or other idiopathic reasons.
Diabetes mellitus	The disturbance in metabolism of glucose and acid–base balance can affect renal status.
Hypertension	Excessive fluid and electrolyte load on kidney due to hypertension may cause kidney damage.
Nephrotoxic drugs	Certain drugs are toxic to kidney and can cause irreversible renal damage if taken chronically. Examples are aminoglycosides, vancomycin, heavy metals such as lead and mercury, etc.
Hypovolemia	Reduced blood volume leads to less blood supply to kidney and eventually leads to renal damage due to ischemia.

Table 3 Levels of renal status based on estimated creatinine clearance

Sr. No.	*Description*	*Creatinine Clearance (mL/min)*
1	Normal	>80 mL/min
2	Mild renal failure	50–88 mL/min
3	Moderate renal failure	30–50 mL/min
4	Severe renal failure	<30 mL/min
5	End-stage renal disease	Requiring dialysis

the volume of distribution of drug. The dose adjustment in case of renal impairment is made on the basis of reduced glomerular filtration rate (GFR). The exogenous (Inuline) and endogenous (Serum Creatinine) substances are used as markers for the estimation of GFR. The SeCR is formed as a product of muscle metabolism, and creatinine clearance CL_{CR} is most widely used marker for the estimation of GFR. Different formulae are used for the estimation of CL_{CR} from SeCR among those Cockcroft and Gault equation is most widely used in clinical conditions.

$$CL_{CR} = \frac{[140 - \text{age (years)} \times \text{body wt (kg)}]}{72 \times \text{Serum conc of creatinine}} \times 0.85 \text{ (for female)} \tag{8}$$

Despite the wide application, the Cockcroft and gault formula has some limitations in its applications as this is not suitable for elderly patients due to reduced production of creatinine. Moreover, this can also overestimate GFR in obese patients due to more fat contents than muscle. Therefore, use of ideal body is recommended for estimation of GFR in extremely obese patients.

Another equation is the calculation of GFR from urine collection data which is given below

$$CL_{CR} = \frac{\text{urinari excretion rate of creatinine}}{\text{Serum conc of creatinine}} \times 0.85 \text{ (for female)} \tag{9}$$

FDA describes different levels of renal impairment based on estimated GFR as given in **Table 3** (FDA Guidance for Industry, 2010).

The other less commonly used method for estimation of GFR is modification of diet in renal disease (MDRD), which utilizes serum creatinine (SeCR), age, gender, and ethnicity (Leon Shargel, 2015).

$$\text{eGFR} = 175 \times [\text{SeCR } (\mu\text{mol/L}) \times 0.011312]^{-1.154} \times [\text{age (years)}]^{-0.203} \times [1.212 \text{ if black}] \times [0.742 \text{ if female}]$$

Serum cystatin C is another marker for GFR and was proved as an alternate of creatinine clearance for estimation of meropenem clearance and dose optimization based on renal condition of the surgical ICU patients (Kees et al., 2015).

Methods used to maintain the desired plasma concentration after multiple doses are based on renal clearance of drug. As the total renal drug clearance (Cl_T^u) is changed in uremic patients, the new dose of drug can be calculated by Eq. (10).

$$D^u = \frac{D^N Cl_T^{uN} \tau^u}{Cl_T^N \tau^N} \tag{10}$$

where D^u is the dose for uremic patient, Cl_T^u is the drug clearance in uremic patient, τ^u is the dose interval for uremic patient, Cl_T^N is the clearance of normal individual, and τ^N is the dose interval for normal patients.

If dose interval is kept constant for normal and uremic patient, Eq. (10) becomes,

$$D^u = \frac{D^N Cl_T^{uN}}{Cl_T^N} \tag{11}$$

Hepatic Impairment

Liver is also an important organ for drug elimination. Hepatic disease, therefore, can alter the elimination of drugs and necessitates the dose adjustment in order to maintain plasma level within desired concentration levels (Leon Shargel, 2015). The most common liver diseases include liver cirrhosis, chronic infection with hepatitis B and C virus, while less common diseases include biliary cirrhosis, α_1 antitrypsin deficiency, and primary sclerosing cholangitis (FDA Guidance for Industry, 2003). In addition, the drug intoxication is also a major cause for hepatic impairment (Chang et al., 2007). The dose optimization in hepatic impairment is based on the fraction of drug metabolized and cleared by impaired liver. The drug clearance in hepatic patients is calculated by equation given below

$$Cl_h = Cl(1 - fe) \tag{12}$$

wher, *fe* if the fraction of drug eliminated unchanged.

Critically Ill Patients

The varying pharmacokinetic behavior of drugs is commonly observed in critically ill patients due to unpredictable pathophysiological changes, which poses a substantial threat for the attainment of optimum outcomes, especially with antibiotics. This situation potentially challenges the clinicians to ensure appropriate antibiotic dosing. The TDM is a commonly used dosing strategy to reduce toxicity and maximize the efficacy of drugs, especially with a narrow therapeutic index. Dose optimization of vancomycin is performed through TDM in critically ill patients receiving renal replacement therapy (DelDot et al., 2004; Escobar et al., 2014; Petejova et al., 2014; Udy et al., 2013) as well as critically ill children (Giachetto et al., 2011).

Infants and Children

The dosing requirements are different for infants and children as compared to adults and necessitate a meticulous consideration of the variation in the pharmacokinetics and pharmacodynamics of a particular drug. The major source of variation in pharmacokinetics is the body composition as well as maturity levels of kidney and liver in infants and children. Body weight of children is also reported to be a significant covariate for clearance of drugs (Lo et al., 2010; Stockmann et al., 2013). A number of studies on TDM in infants and children have been reported recently due to advancement in analytical techniques (Wu et al., 2018) and requirement of small blood volume such as in dried blood spot analysis (Martial et al., 2018). The very recent TDM studies performed in children and infants have been reported for voriconazole (Allegra et al., 2018; Hu et al., 2018), antituberculosis drugs (Martial et al., 2018), and anti-TNF therapy (van Hoeve et al., 2018). Dose optimization for infants and children has also been performed by population pharmacokinetic modeling of different drugs including valproic acid (Xu et al., 2018), azithromycin (Zheng et al., 2018), piperacillin (Beranger et al., 2018), and cephalosporins (De Cock et al., 2017; Maksoud et al., 2018; Zhi et al., 2018).

Elderly Patients

The elderly population is defined as the people who are older than 65 years of age although many of these live healthy and active life. In addition, the people who are above 85 years of age are termed as older elderly (Leon Shargel, 2015). The dosing in elderly is more complex as compared to young children and infants because the decrease in homeostatic reserve occurs to a different level in each patient depending on factors including life style, eating habits, occupation, environmental factors, exposure to microorganisms, etc. (Yamni Nigam et al., 2012). These changes lead to altered pharmacokinetics of drugs and may necessitate the dose optimization. However, old age alone is not an indication for dose optimization of certain drugs (Crombag et al., 2018; Pan et al., 2018; Usman et al., 2018). In addition to physiological changes, polypharmacy due to certain pathophysiological conditions attributed to elderly patients requires special consideration for dosing due to possibility of drug interactions. Moreover, elderly patients are more prone to be affected by the adverse effects of certain drugs such as nephrotoxicity caused by vancomycin (Pan et al., 2018).

Obese Patients

Obesity is considered as a major factor for dose optimization due to altered pharmacokinetics (Grace, 2012). According to WHO database, by 2030, approximately 60% of population will be classified as overweight or obese worldwide (Kelly et al., 2008). In addition to body mass, obesity is also associated with high level of plasma proteins that are required for binding of certain drugs and ultimately affects the free drug level in plasma. This condition enhances the need for dose adjustment in obese patients (Grace, 2012). A number of studies have been reported for dose optimization of drugs in obese and morbidly obese patients (Adane et al., 2015; Alobaid et al., 2015, 2016; Grace, 2012).

Candidate Drugs Requiring TDM

The requirement for dose optimization becomes more important when the administered drug has narrow therapeutic window. Below are some examples of most commonly used drugs with the requirement of TDM.

Vancomycin

Vancomycin is used against infections caused by methicillin-resistant *Staphylococcus aureus* (MRSA) and methicillin-susceptible species of *Staphylococcus aureus* (MSSA) (Kullar et al., 2011; Lundstrom and Sobel, 2004; Van Bambeke, 2004). The subtherapeutic levels of vancomycin cause insufficient bacterial killing and overdosing can cause toxicity such as nephrotoxicity. Therefore, TDM of vancomycin is highly recommended for safe and effective administration (Martin et al., 2010). The recommended target trough concentration range for vancomycin is as follows:

- 10–15 mg/L for mild to moderate infection (Helgason et al., 2008),
- 15–20 mg/L for severe infection (Joint Formulary Committee, 2015).

A risk prediction model was constructed and used for the prediction of vancomycin-associated nephrotoxicity at the time of initial TDM. The patients were classified into subgroups as low to high risk of nephrotoxicity based on 5.2%–70% incidents of nephrotoxicity, respectively (Imai et al., 2018). A two point AUC-based TDM approach for vancomycin was implemented on patients with MRSA infections (Mogle et al., 2018).

Antiepileptic Drugs

The requirement of TDM for antiepileptic drugs has provided a pragmatic approach for tailored doses in order to maintain the drug concentrations at optimal levels and to ensure the successful clinical outcome (Patsalos et al., 2018). Much of the data have been accumulated for the first-generation antiepileptic drugs such as phenytoin (Shaikh and Guo, 2017), phenobarbital (Bentue-Ferrer et al., 2012; Messina et al., 2005), carbamazepine (Babaei and Eslamai, 2007; Dalaklioglu, 2013; Shokry et al., 2015; Vucicevic et al., 2007), and valproic acid (Shaikh et al., 2018; Smith et al., 2016). The therapeutic ranges for these drugs are given below (Roger Walker, 2012).

- Phenytoin 10–20 mg/L
- Valproic acid <100 mg/L
- Phenobarbital 15–40 mg/L
- Carbamazepine 4–12 mg/L

Anticancers

Cancer chemotherapy is a big challenge due to the attributed adverse effects of anticancer drugs. Most of the dosing of anticancer drugs are made on the basis of body surface area (BSA) of the patients and this may led to the interindividual variability with high risk of either under or overdosing (Wilhelm et al., 2016). The TDM studies have been conducted to optimize the dosing strategy for the patients receiving 5-fluorouracil (5-FU). The tailored dosing of 5-FU for individual patients based on TDM resulted in significantly improved therapy and minimal incidents of toxicity (Morawska et al., 2018; Wilhelm et al., 2016). Methotrexate is also a target for TDM among the anticancer drugs, and a number of analytical methods have also been reported for its quantification in order to monitor the drug concentration and optimize the dose for individual patients (Fornasaro et al., 2016; Kaneko et al., 2016; Mulder et al., 2018a; Mulder et al., 2018b; Silva et al., 2018).

Ciclosporin

Ciclosporin is a potent immunosuppressant agent and is used to prevent the graft rejection after tissue or organ transplantation. This is a narrow therapeutic index drug with high possibility of interindividual variability, which enhances the need for tailored dosing of ciclosporin (Ni et al., 2013). The whole blood drug concentration within the therapeutic range is used for dose optimization. As this is a lipophilic drug, the pharmacokinetics may be affected due to altered plasma lipid levels. Therefore, the monitoring of ciclosporin concentration in plasma is highly recommended for safe and effective administration (Sugioka et al., 2006). The target therapeutic range for ciclosporin is as (Roger Walker, 2012);

- 100–200 ng/mL for initial 6 months after transplantation
- 80–150 ng/mL from 6 month onward.

Amikacin and Gentamicin

Amikacin and gentamicin belong to aminoglycoside group of antibiotics and are considered among first choices for treatment of infections caused by *Pseudomonas aeruginosa*. These are narrow therapeutic index drugs and produce dose-related nephrotoxicity and ototoxicity (Roger Walker, 2012). Therefore, dose optimization is needed for safe therapy with these aminoglycosides. The therapeutic concentration ranges for gentamicin and amikacin are

- Amikacin 25–48 mg/L (peak) 4–8 mg/L (trough)
- Gentamicin 5–12 mg/L (peak), <2 mg/L (trough)

The TDM of amikacin has been performed in a number of clinical situations in order to keep the serum drug concentration level within the acceptable therapeutic range, which include the population pharmacokinetics of amikacin in critically ill elderly patients (Sadeghi et al., 2018) and patients with cystic fibrosis (Illamola et al., 2018). The dosing recommendation is also made based on TDM of gentamicin in a variety of populations such as neonates and infants (van Donge et al., 2018), obstetrics, and gynecology patients (Singu et al., 2018).

Digoxin

Digoxin is the oldest pharmaceutical agent used for the treatment of heart failure. This is also a narrow therapeutic agent and requires vigilant dosing strategies in order to maintain the plasma concentration within the required limit that is 0.8–2 ng/mL (Roger

Walker, 2012). Dosing strategies have been designed for safe and effective administration through the development of analytical techniques for TDM of digoxin (Dalaklioglu, 2013; Grzesk et al., 2018; Pushkin et al., 2016).

Theophylline

Theophylline has a number of clinical uses including CNS stimulation, diuresis, vasodilation, bronchodilation, and increased cardia output. Bronchodilation is the major therapeutic use of theophylline, and TDM is being performed for safe administration of this drug in chronic respiratory disease (Mennini et al., 2017). The therapeutic range for maintaining the plasma concentration of theophylline is 10–20 mg/L (Roger Walker, 2012).

Recent Advances in Clinical PK and TDM

With the advancement in analytical and sampling techniques, new developments have been introduced for TDM wherein sweat diagnosis is especially taken up by scientists with keen interest due to low volume. A novel noninvasive decentralized monitoring of lithium drug concentration through sweat analysis is proposed using all-solid-state ion-selective electrode (ISE) with a nanostructured solid-contact (SC) to detect lithium ions in sweat even under wide pH variation (pH 4–12) and with fast response (15–30 s) (Criscuolo et al., 2018). Such applications can reduce patients visit to hospitals and provide a measure of close monitoring of narrow therapeutic index medicines under chronic use.

6-Mercaptopurine and azathioprine are common treatment options for inflammatory bowel disease. With the recent discovery of Asian-specific DNA variants in NUDT gene, and their link to thiopurine toxicity, current method of TDM used for purine derivatives has shown limited applicability in this specific population (Lim and Chua, 2018). Hence, the possibility of use of knowledge of ethnicity-specific genetic markers with thiopurine metabolites measurements for predicting therapeutic response is under investigation (Lim and Chua, 2018).

Certain areas also need clarity in the need of TDM. Use of biological TDM, by measuring the serum (anti)-drug level in rheumatoid arthritis is extensively investigated but is found controversial in a recent review as the current evidence do not recommend biological TDM in the treatment of rheumatoid arthritis (den Broeder et al., 2018). However, further study is still needed in selected clinical scenarios (den Broeder et al., 2018).

Interesting findings have come across for Parkinson's disease patients, where theophylline serum levels were found to be lower than the normal human subjects. The information provides applicability of theophylline immunoassay technique used for TDM, as a new diagnostic biomarker for Parkinson's disease. Moreover, this also informs about a varying expected level of theophylline in these patients (Ohmichi et al., 2018).

Metabolomics reveal disease-specific metabolic patterns or metabolic changes produced in response to a therapeutic intervention. Potential of nuclear magnetic resonance (NMR) spectroscopy has been explored in evaluating drug efficacy as well as safety and screening toxicity. Its nondestructive, nonselective, and minimum sample preparation requirement makes it an attractive module for regulators and biopharmaceutical researchers. The technique is high-throughput (i.e., >100 samples a day is attainable) and has high reproducibility of results. Guleria et al. discuss recent developments related to NMR-based metabolomics for use in therapeutic drug monitoring and identification of organ specific toxicity along with other applications (Guleria et al., 2018).

These advances and new approaches in monitoring efficacy and toxicity of medicines will influence the future designs of clinical trials as well as their postmarketing surveillance targeting toward more rational use of drugs.

Conclusion

Therapeutic drug monitoring constitutes essential pharmacy service that is needed to ensure the efficacy and safety of drug use particularly in the pediatric and elderly patients, patients with renal and hepatic impairment, and for the narrow therapeutic index medicines. With advances in the bioanalytical techniques, application of the clinical pharmacokinetics can be made useful by fast and less invasive techniques. Use of techniques like dry blood spot has minimized many reservations previously considered with therapeutic drug monitoring.

Clinical Pharmacy Practice: Concepts, History, and Development

Jo-anne E. Brien*†, *St Vincent's Hospital, University of Sydney, Sydney, NSW, Australia; †Faculty of Medicine, University of New South Wales Australia, Sydney, NSW, Australia

Clinical Pharmacy Concepts and Definitions

"Clinical pharmacy services optimize patient health outcomes and care" (SHPA, 2013). This is the title of the Society of Hospital Pharmacists of Australia Position Statement on Clinical Pharmacy Services, published in 2013.

In the international literature, there are many definitions for clinical pharmacy. While these different statements reflect the development and context for health-care services and medication management in different countries over time, there are common elements in these definitions.

The American College of Clinical Pharmacy (ACCP) has defined clinical pharmacy as an area of pharmacy concerned with the science and practice of rational medication use.

> Clinical pharmacy is a health science discipline in which pharmacists provide patient care that optimizes medication therapy and promotes health, wellness, and disease prevention. The practice of clinical pharmacy embraces the philosophy of pharmaceutical care; it blends a caring orientation with specialized therapeutic knowledge, experience, and judgment for the purpose of ensuring optimal patient outcomes. As a discipline, clinical pharmacy also has an obligation to contribute to the generation of new knowledge that advances health and quality of life.
>
> Clinical pharmacists care for patients in all health-care settings. They possess in-depth knowledge of medications that is integrated with a foundational understanding of the biomedical, pharmaceutical, sociobehavioral, and clinical sciences. To achieve desired therapeutic goals, the clinical pharmacist applies evidence-based therapeutic guidelines, evolving sciences, emerging technologies, and relevant legal, ethical, social, cultural, economic, and professional principles. In accordance, clinical pharmacists assume responsibility and accountability for managing medication therapy in direct patient care settings, whether practicing independently or in consultation or collaboration with other health-care professionals. Clinical pharmacist researchers generate, disseminate, and apply new knowledge that contributes to improved health and quality of life.
>
> Within the system of health care, clinical pharmacists are experts in the therapeutic use of medications. They routinely provide medication therapy evaluations and recommendations to patients and health-care professionals. Clinical pharmacists are a primary source of scientifically valid information and advice regarding the safe, appropriate, and cost-effective use of medications (American College of Clinical Pharmacy, 2008).

It should be noted that this unabridged definition is organized into three sections:

> "the discipline of clinical pharmacy, the clinical pharmacist, and the roles of the clinical pharmacist in the health care system" (American College of Clinical Pharmacy, 2008).

The International Pharmaceutical Federation and the World Health Organization published joint FIP/WHO Guidelines on Good Pharmacy Practice: Standards for Quality of Pharmacy Services (FIP/WHO, 2011).

In these guidelines Good Pharmacy Practice is stated to be

> " . . . the practice of pharmacy that responds to the needs of the people who use the pharmacists' services to provide optimal, evidence-based care."

This comprehensive and international collaborative document provided guidance to national pharmacy professional organizations and followed the earlier publication of the 2006 Handbook on Developing Pharmacy Practice: A Focus on Patient Care (Wiedenmayer et al., 2006). The handbook provided an international approach to educate pharmacists to provide clinically oriented, patient-centered services.

Historical View of Practice of Pharmacy

Pharmacy practice and models of clinical pharmacy have developed in the context of changing health-care services and roles for many health professions. Just as technology in health care and drug development has evolved, so have the skills and knowledge requirements for practitioners. Social and cultural influences in health and society have also changed perspectives on, and expectations of, the roles of health practitioners and patients. Historically, hierarchical models of health care have reflected the social mores of the time. Increasingly, well-informed patients may view themselves as consumers and this has also influenced the approach to clinical practice for pharmacists. Patients are consumers of medicines and health information provided by pharmacists and other health professionals. In parallel, the pharmacy profession has sought to define and distinguish general and specialist practice and service roles in pharmacy. Defining and developing roles and services require approaches for education, standards of practice, and research-led practice and policy change.

While many historical definitions for pharmacy were based on preparation, procurement, supply, and distribution of pharmaceutical products, there has been an increasing understanding of patient-focused, consumer-centered health care in pharmacy practice. Pharmacists, as "experts in medicines," may contribute to the clinical assessment and management of patients with respect to medicines, often in partnership with consumers, doctors and other health professionals. These roles are broader than "supplier of medicines."

In parallel to these societal changes, global health-care costs continue to increase. There is an evidence-based approach sought for the impact and value of clinical pharmacy services with respect to patient outcomes and health-care costs (Dooley et al., 2004). Health-care spending in the United States and other high-income countries vary (e.g., in the United States 17.8% gross domestic product; Australia 9.6%; Switzerland 12.4% (Papanicolas et al., 2018)), and the increasing costs of newer pharmaceuticals contribute to these figures. Newer, high-cost drugs, along with the associated clinical services (pharmacy and other), are evaluated using health technology assessment approaches to inform policy and access. A systematic review by Schumock et al., published in 2003, reported on the evidence of the economic benefit of clinical pharmacy services and provided some methodological guidance for future studies (Schumock et al., 2003). A subsequent systematic review published in 2017, by Gammie et al., noted that economic evaluations of pharmacy services had become increasingly commonplace (Gammie et al., 2017). This review of 14 studies observed that cost-utility methods were the preferred method of economic evaluation of health-care interventions.

Clinical Pharmacy may be considered to be "part of" or "supported by" other pharmacy services and activities. There has been different terminology used, both within the profession and externally, and this may contribute to some confusion about pharmacy practice and clinical pharmacy. The notion of clinical pharmacy as being a specialist or generalist, patient-centered role has been variously interpreted. These interpretations are important, as they are crucial to pathways in professional education, practice standards, and credentialing of practitioners.

Hospital Pharmacy Services

In the Society of Hospital Pharmacists of Australia Standards for Clinical Pharmacy Services, a figure is used to illustrate the overview of hospital pharmacy services (Taylor et al., 2013). These activities are described as "patient-specific" and "nonpatient-specific," but all are required for delivery of patient care (**Fig. 1**).

Stowasser et al. have described steps in medication management as "understanding the medicines management pathway" (Stowasser et al., 2004). In this model, there are nine steps (cognitive and physical) and three background processes as depicted in **Fig. 2**. The consumer is the central to this approach, and this could be applied to all medicines, in all settings, for all health professionals. Clinical pharmacy practice may be considered as "embedded" in this pathway.

Clinical Pharmacy

Clinical pharmacy services are a range of activities, as documented in the SHPA Standards of Practice for Clinical Pharmacy Services (SHPA, 2013), and include:

- Medication reconciliation
- Assessment of current medication management
- Clinical review, therapeutic drug monitoring, and adverse drug reaction management
- Contribution to the medication management plan
- Providing medicines information

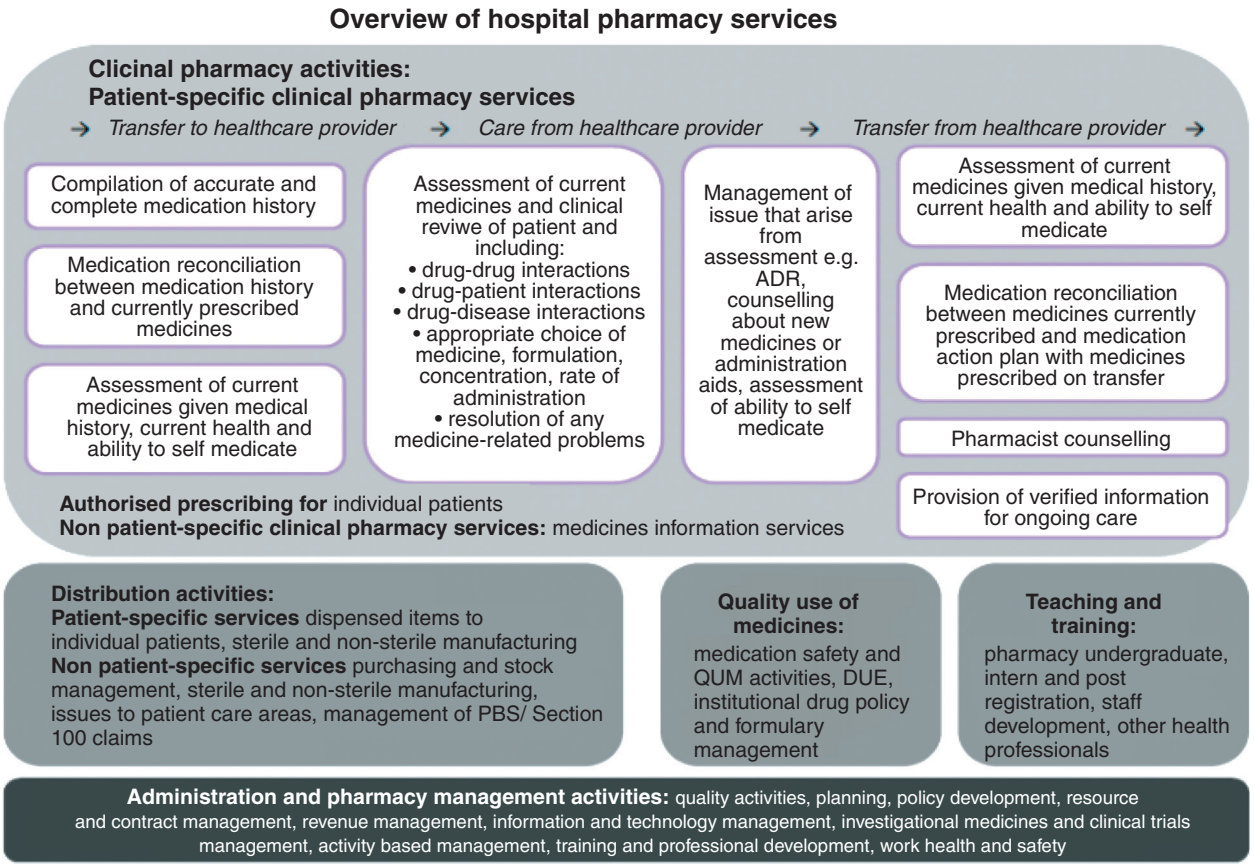

Figure 1 Hospital pharmacy services that support the medicines management pathways. *Source: Taylor, G., Leversha, A., Archer, C., et al., Overview: Standards of Practice for Clinical Pharmacy Services. J. Pharm. Pract. Res. 43 (2 suppl) (2013) S1–S5.*

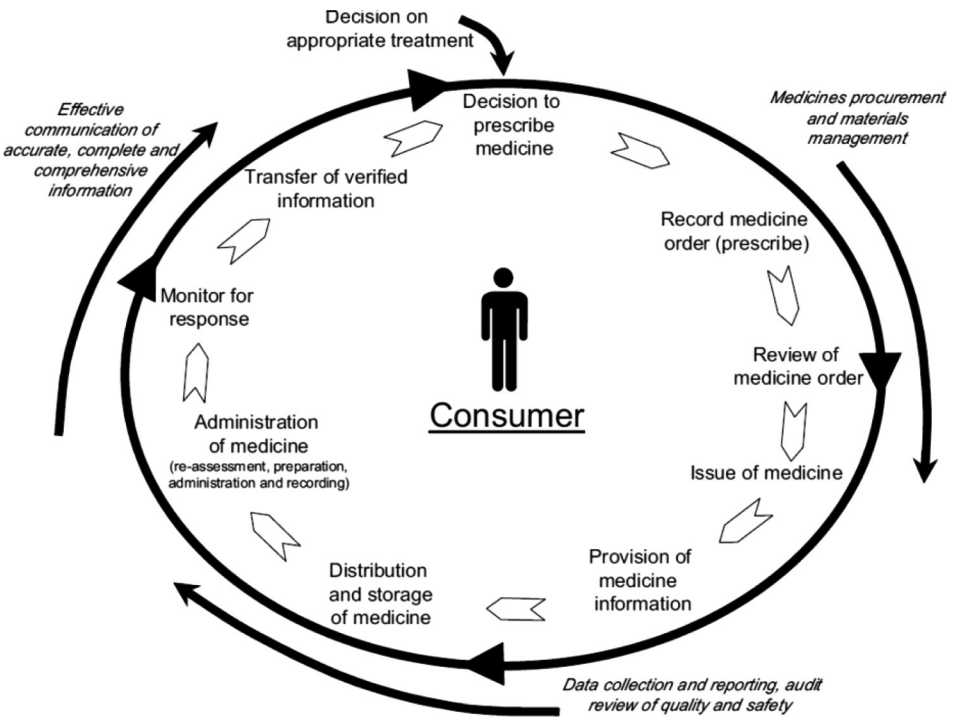

Figure 2 Overview of the medicines management pathway cycle.

- Facilitating the continuity of medication management on discharge or transfer
- Participation in interdisciplinary ward rounds and meetings
- Training and education
- Participating in research
- Quality improvement activities and peer review.

These activities are recognized as key components of medication safety and the quality use of medicines.

The American College of Clinical Pharmacy (ACCP) has sought to distinguish clinical pharmacists from other pharmacists who perform some clinical functions as part of their practice. In 2008, ACCP stated that clinical pharmacists (Burke et al., 2008):

- have a broad scope and depth of pharmacotherapy knowledge and clinical skills;
- spend most of their time providing pharmacotherapy independently or in collaboration with other health-care providers;
- have completed postgraduate residency training; and
- maintain and further develop competence through practice and continued professional development.

In 2016, the ACCP Certification Affairs Committee reviewed and updated these competencies, with the expectation that clinical pharmacists

> "be competent in six essential domains: direct patientcare, pharmacotherapy knowledge, systems-based care and population health, communication, professionalism, and continuing professional development. Although these domains align with the competencies of physician providers, they are specifically designed to better reflect the clinical pharmacy expertise required" (Saseen et al., 2017).

The ACCP has defined clinical pharmacists as

> "practitioners who provide comprehensive medication management and related care for patients in all health care settings" (American College of Clinical Pharmacy, 2014).

ACCP's definitions of clinical pharmacy and required competencies for the clinical pharmacist are composed of statements that encompass the core competencies identified by the Institute of Medicine:

(1) provide patient-centered care to diverse populations,
(2) work effectively as members of interprofessional teams,
(3) employ evidence-based practice to optimize care,
(4) apply quality improvement techniques, and
(5) use informatics in practice (Institute of Medicine, 2003).

These five attributes represent the overarching core competencies for members of all health professions.

Internationally, there have been developments in recognition of, and requirements for, further education and training for advanced (clinical) practice, through residency or certification and credentialing programs. It is generally agreed that clinical pharmacy competence is supported by additional knowledge, skills, and experience during postgraduate clinical training and/or after entering clinical practice (Murphy et al., 2006). It has long been recognized that local national reimbursement models have an impact on clinical pharmacy practice, education, and training (Penna and Knapp, 1986). While education pathways vary across the world, the publication of standards of practice and definitions has assisted the development of clinical pharmacy globally.

An integral component of the definition and development of clinical pharmacy is the incorporation of research-led practice. This is in both the evidence-based approach to therapeutics for individual patients and populations, as well as the research-led models of practice and assessment of impact of clinical pharmacy service provision. A number of research studies have explored the impact of clinical pharmacy services in the hospital setting.

A systematic review of clinical pharmacists and inpatient medical care published in 2006 concluded that:

> "the addition of clinical pharmacy services in the care of inpatients generally resulted in improved care, with no evidence of harm. Interacting with the health care team on patient rounds, interviewing patients, reconciling medications, and providing patient discharge counseling and follow-up all resulted in improved outcomes" (Kaboli et al., 2006).

A seminal series of papers published by Bond, Raehl et al. demonstrated direct relationships and associations between clinical pharmacy services, pharmacist staffing, and drug costs in United States hospitals (Bond et al., 1999a) (as clinical pharmacy staff increased, drug costs decreased) and found associations between health-care professional staffing, hospital characteristics, and mortality rates hospital mortality rates (Bond et al., 1999b) (pharmacists were associated with lower mortality rates). In 2001, Bond, Raehle, and Franke published a comprehensive study evaluating interrelationships among mortality rates, drug costs, total cost of care, and length of stay in United States hospital and provided recommendations for clinical pharmacy services and staffing (Bond et al., 2001). In 2007, a follow-up study on clinical pharmacy services, pharmacy staffing, and hospital mortality rates confirmed previous findings that an increase in clinical pharmacists was associated with reduced mortality rates (Bond and Raehl, 2007). As Angaran had noted in his commentary—"Clinical pharmacy saves money and lives—so what's new?" (Angaran, 1999). Further to these studies, Bond, Raehl, and Patry published recommendations for evidence-based core clinical

services in United States hospitals in 2020 (Bond et al., 2004). The core services identified in their series of studies were "drug information, adverse drug reaction management, drug protocol management, attending medical rounds, and admission drug histories" (Institute of Medicine, 2003).

Clinical Pharmacy in Community Pharmacy Settings

It should be noted, however, that the understanding of clinical pharmacy should not be limited to pharmacists working within a hospital environment. The application of clinical pharmacy skills and knowledge is important in both primary and tertiary health care. In an opinion statement of the of the Ambulatory Care Practice and Research Network of the American College of Clinical Pharmacy (ACCP), it is stated that

> " . . . pharmacists can improve the health of populations by participating in activities that optimize medication management. Multiple published articles support clinical pharmacist involvement in the Patient Centered Medical Home (PCMH) with regard to promotion of team-based care, enhanced access, care coordination, and improved quality and safety of care. A survey of clinical pharmacist members of ACCP who operate in such a model depict a variety of activities, with some members pioneering new and innovative ways to practice clinical pharmacy. Although this is a significant opportunity for pharmacists in the primary care setting, a unified vision of pharmacy services is needed" (Nigro et al., 2014).

There are differences in national and regional health-care regulatory jurisdictions which influence organization of, and reimbursement for, professional pharmacy services. Nonetheless terminology a "unified vision" of pharmacy services may remain difficult when different terminology is applied.

The different definitions and interpretations of pharmacy practice and clinical pharmacy are also important for the promotion of global education for pharmacists. The International Pharmaceutical Federation (FIP) Pharmacy Education Taskforce, whose objective was to develop pharmacy education globally using a local needs-based approach, published a commentary about the difficulties in applying consistent terminology, with regard to pharmaceutical care and pharmacy practice (Whitmarsh et al., 2010).

Pharmaceutical Care

Pharmacists make decisions daily in their practice—managerial, nonclinical, and clinical (Bridie et al., 1980), and in recent decades there has been an established literature basis for recognizing, understanding, and teaching clinical decision making (Einarson et al., 1985). Teaching methods in health disciplines have historically focused on facts and data collection and analysis, rather than decision making. Protocols and algorithms may assist but may not always enlighten clinical judgment. While problem solving and decision making are separate processes, solving a problem that is defined by a number of choices may lead to a decision (Angaran, 1999). Clinical judgment is based on effective decision making.

In 1990, Hepler and Strand provided a taxonomy for pharmacy practice and defined "pharmaceutical care."

> "Pharmaceutical care is the responsible provision of drug therapy for the purpose of achieving definite outcomes that improve a patient's quality of life" (Hepler and Strand, 1990).

Strand et al. developed the framework for pharmaceutical care based on the utility of definitions for drug-related problems (DRPs). In the paper, "Drug-related problems: their structure and function" a means of categorizing DRPs was presented: (Strand et al., 1990)

> "A DRP exists when a patient experiences or is likely to experience either a disease or symptom having an actual or suspected relationship with drug therapy. Eight different categories of DRPs are described and examples of each category are offered. This categorization serves a number of functions, such as: (1) to illustrate how adverse drug reactions form but one category of extant DRPs, (2) to make tangible the pharmacist's role for the future, (3) to serve as a focus for developing a systematic process whereby the pharmacist contributes significantly to the overall positive outcome of patients, (4) to bring to pharmacy practice a vocabulary consistent with that of other healthcare professionals, and (5) to aid in the development of standards of practice for pharmacists."

In adopting the definition for pharmaceutical care in 1998, the International Pharmaceutical Federation (FIP) added one significant amendment:

> "achieving definite outcomes that improve or maintain a patient's quality of life."

The term "pharmaceutical care" has been used broadly as a philosophy of practice, and "comprehensive pharmaceutical care" has been offered to better describe value-added services (Tomechko et al., 1995). However, although the term has spread among different countries, pharmaceutical care is now less used in the United States and is more commonly superseded by medicines management, or medication therapy management services in the UK and elsewhere (Kaboli et al., 2006).

A number of commentators have contributed to these international discussions on terminology and definitions. Simpson wrote "What is medicines management and what is pharmaceutical care?" (Simpson, 2001) McGiveny et al provided comment on the

relationships between medication therapy management, patient counseling, disease management, and pharmaceutical care (McGivney et al., 2007). Barber has asked "Pharmaceutical care and medicines management—is there a difference?" (Barber, 2001)

Twenty-three years after Hepler and Strand published their definition of pharmaceutical care, the Pharmaceutical Care Network Europe (PCNE) has provided an updated definition, intended to be applicable for the present time, representative for various work settings, and valid for countries inside and outside of Europe: (Allemann et al., 2014)

> "Pharmaceutical Care is the pharmacist's contribution to the care of individuals in order to optimize medicines use and improve health outcomes."

Quality Use of Medicines and Medicines Policy

Irrespective of physical location and setting for pharmacy practice, the desired outcomes for clinical pharmacy services are well described in achieving the Quality Use of Medicines.

"Quality Use of Medicines" means:

- Selecting management options wisely by:
  - considering the place of medicines in treating illness and maintaining health, and
  - recognizing that there may be better ways than medicine to manage many disorders.
- Choosing suitable medicines if a medicine is considered necessary so that the best available option is selected by taking into account:
  - the individual
  - the clinical condition
  - risks and benefits
  - dosage and length of treatment
  - any coexisting conditions
  - other therapies
  - monitoring considerations
  - costs for the individual, the community, and the health system as a whole.
- Using medicines safely and effectively to get the best possible results by:
  - monitoring outcomes,
  - minimizing misuse, over-use, and under-use, and
  - improving people's ability to solve problems related to medication, such as negative effects or managing multiple medications.

This definition of QUM applies equally to decisions about medication use by individuals and decisions that affect the health of the population (The National Strategy, 2002).

The Quality Use of Medicines (QUM) is incorporated in the Australian National Medicines Policy and strategy (Bond et al., 2004). Australia began to develop aspects of the National Medicines Policy in the 1950s, and by the 1990s a comprehensive policy was in place. In 1999, a formal policy document entitled *Australia's National Medicines Policy* was launched (National Medicines Policy, 2000). Around the world, many countries have, or are in the process of developing, national policies on medicines (Hoebert et al., 2013).

The World Health Organization (WHO) has defined rational drug use:

> "Medicine use is rational (appropriate, proper, correct) when patients receive the appropriate medicines, in doses that meet their own individual requirements, for an adequate period of time, and at the lowest cost both to them and the community. Irrational (inappropriate, improper, incorrect) use of medicines is when one or more of these conditions is not met" (Holloway and van Dijk, 2011).

Furthermore, the WHO has added the complementary term "responsible use of medicines" that:

> "implies that the activities, capabilities and existing resources of health system stakeholders are aligned to ensure patients receive the right medicines at the right time, use them appropriately, and benefit from them. This incorporates the importance of stakeholder responsibility and recognizes the challenge of finite resources" (World Health Organization, 2012).

Whether at the level of population data or for individual patient management, adherence to "rational and responsible" medications remains elusive. There is evidence that approximately 50% of all patients fail to take their medicine correctly (World Health Organization, 2003) and in many circumstances, the capability of the (health) system is not sufficient to support the optimal use of medicines (The National Strategy, 2002). The fact that prescribed medicines are not taken, as so often is assumed, occurs in highly regulated clinical trials and resource rich environments (Azvolinsky, 2014), as well as in community settings in management of chronic illnesses. Identifying and managing medicines adherence is one core element of pharmaceutical care and clinical pharmacy.

Historical Perspectives

A contemporary view of health care and health professionals is enriched by consideration of some historical perspectives and milestones. While there is focus on current definitions of clinical practice roles and training, it is of note to recognize that this is a continuum.

A description of the hospital of Altopascio (Italy), in 1239, reveals details of clinical staff roles (apothecary, surgeon, physician, and other) and responsibilities with regard to diagnosis, treatments and patient care (Henderson, 2006). Apart from supply of medications, the pharmacy emphasis appears to be on evidence-based formulary management and safety. There were a range of contractual arrangements between hospitals and *speziale* (specialist hospital pharmacists). The staff (and patients) of renaissance hospitals had a wide range of flexibility in roles and different terminology was used, and contracts were used to define responsibilities.

In a contract dated 1507, it is stated that, apart from " . . . making medicines and syrups . . . ," the pharmacist needed to

> " . . . take care not to make mistakes at the times when a patient's fever is increasing . . . ."

A note book was used to record treatments prescribed on daily ward rounds. The pharmacist made up the treatments, and there is guidance on labeling clearly so the right patient received the medication (Azvolinsky, 2014).

In a commentary on the period between the two world wars in the twentieth century, author Isabel Leighton dubbed the era as the "aspirin age," a social commentary on the search for a "cure all" (Leighton, 1949). In 1966, Magnus Pyke captured the sense of excitement about modern science and advances in his book "What scientists are up to," including a chapter on "What medical research is up to" (Pyke, 1966). These are reminders of how clinical practice is embedded in and influenced by in the social, cultural, and scientific milieu of the time. In the twenty-first century, there are expectations that current advances in genomics, big data, robotics will have an impact on all aspects of living, including the practice of pharmacy and delivery of health care. National and international statements of professional roles, knowledge, and skills will continue to be progressed to meet the changing environments.

Future Perspectives

As Carter outlined in his 2016 overview of the evolution of clinical pharmacy and future directions:

> "Clinical pharmacy services and direct patient care have a promising future in many countries. Clinical pharmacists are now more specialized for specific services or complex care. Recent advances in education and clinical pharmacy research enabled development of clinical pharmacy services in many countries all over the world. The large increase in complex older patient populations suggests that the involvement of clinical pharmacists in interdisciplinary care will become more important to improve medication safety, efficacy and effectiveness" (Carter, 2016).

As health care continues to become even more complex and expensive, pharmacists will continue to develop and define clinical roles that are patient-centered, research-led, evidence-based, and cost-effective. Updated knowledge and skills for clinical pharmacy practice will require more integrated, interprofessional, and rigorous education and professional standards. The historical context for the development of clinical pharmacy practice provides a sound basis for future pharmacists. International collaborative approaches to inform and articulate standards for education and practice are key. The published revision of the International Pharmaceutical Federation's "Basel Statements on the future of hospital pharmacy: From Basel to Bangkok" (Vermeulen et al., 2016) provides an example of guidance for the pharmacy profession, health-care funders, and consumers.

Basel Statements on the Future of Hospital Pharmacy: From Basel to Bangkok

Overarching and Governance Statements

1. The overarching goal of hospital pharmacists is to optimize patient outcomes through collaborative, interprofessional, responsible*use of medicines, and medical devices.
2. At a global level, evidence-based hospital pharmacy practice standards should be developed. These should assist national efforts to define standards for the extent and scope of hospital pharmacy services and should include corresponding human resource and training requirements.
3. Hospital pharmacists should engage health authorities and hospital administrators to ensure appropriate resources for, and design of, the hospital medicine-use process.
4. Health authorities should ensure that each hospital is serviced by a pharmacy that is supervised by pharmacists who have completed advanced training in hospital pharmacy.
5. The Chief Pharmacist/Director of Pharmacy should be the accountable professional coordinating the responsible use of medicines* in the hospital.
6. Hospital pharmacists should serve as a resource regarding all aspects of medicines use and be accessible as a point of contact for patients and health-care providers.

7. All prescriptions should be reviewed, interpreted, and validated by a hospital pharmacist prior to the medicine being dispensed and administered.
8. Hospital pharmacists should monitor patients taking medicines to assure patient safety, appropriate medicine use, and optimal outcomes for inpatients and outpatients. When resource limitations do not permit pharmacist monitoring of all patients taking medicines, patient-selection criteria should be established to guide pharmacist monitoring.
9. Hospital pharmacists should be allowed to access and document in the full patient record.
10. Hospital pharmacists should ensure that patients or caregivers are educated and provided written information on the appropriate use of medicines.
11. Hospital pharmacists should provide orientation, drug information and education to nurses, physicians, and other hospital staff regarding best practices for medicines use (a best practice is a method or technique that has consistently shown results superior to those achieved with other means and that is used as a benchmark).
12. Undergraduate pharmacy curricula should include hospital-relevant content, and postgraduate training programs and specializations in hospital pharmacy should be developed.
13. Hospital pharmacists should actively engage in research into new methods and systems to improve the use of medicines and of human resource needs in hospital pharmacy.
14. Hospital pharmacists should take responsibility for the management and disposal of waste related to the medicine-use process and advise on disposal of human waste from patients receiving medicines.
15. Hospital pharmacists should take responsibility for all aspects of selection, implementation, and maintenance of technologies that support the medicine-use process, including distribution devices, administration devices, and other equipment.
16. Hospital pharmacists must ensure proper storage to maintain the integrity of medicines across the supply chain to ensure quality, safety, and security.
17. Hospital pharmacists should ensure appropriate assessment, development, implementation, and maintenance of clinical decision support systems and informatics that guide therapeutic decision making and improve the medicine-use process.
18. Each pharmacy should have contingency plans for medicine shortages and emergencies.
19. The "seven rights" (right patient, medicine, dose, route, information, documentation, and time) should be fulfilled in all medicine-related activities in the hospital.

Theme 1—Procurement

20. Hospital pharmacists should be involved in the complex process of procurement of medicines and health products, promoting equity and access. They should ensure transparent procurement processes are in place in line with best practice and national legislation, are free from conflict of interest, and are based on the principles of safety, quality, and efficacy.
21. Procurement practices must be supported by strong quality assurance principles, regularly reviewed, and adapted to fit different settings and emerging needs in the most appropriate and cost-effective way.
22. Procurement should not occur in isolation but rather be guided by the formulary selection process. This includes the procurement of standard concentrations of high-risk medicines including electrolytes.
23. Procurement must be supported by a reliable information system that provides accurate, timely, and accessible information.

Theme 2—Influences on Prescribing

24. Hospitals should utilize a medicine formulary system (local, regional, and/or national) linked to standard treatment guidelines, protocols, and treatment pathways based on the best available evidence.
25. Hospital pharmacists should be key members of pharmacy and therapeutics committees to oversee all medicines management policies and procedures, including those related to off-label use and investigational medicines.
26. Hospital pharmacists should have a key role in educating prescribers at all levels of training on the access to and evidence for responsible use of medicines, including the required monitoring parameters and subsequent prescribing adjustments.
27. Hospital pharmacists should be an integral part of the multidisciplinary team responsible for therapeutic decision making in all patient care areas.
28. Hospital pharmacists should promote seamless care by contributing to the transfer of information about medicines whenever patients move between and within health-care settings.
29. Appropriately trained and credentialed hospital pharmacists should participate in collaborative prescribing.

Theme 3—Preparation and Delivery

30. Hospital pharmacists should assume responsibility for storage, preparation, dispensing, and distribution of all medicines, including investigational medicines.

31. Hospital pharmacists should assume responsibility for the appropriate labeling and control of medicines stored throughout the facility.
32. Hospital pharmacists should be involved in determining which medicines are included in ward stock and standardizing the storage and handling of ward medicines.
33. Hospital pharmacists should ensure that compounded medicines are consistently prepared to comply with quality standards. This includes taking responsibility for ensuring medicines not commercially available in a suitable formulation are prepared to accepted practice standards and ensuring that injectable admixture services comply with accepted practice standards.
34. The preparation of hazardous medicines including cytotoxics should be under the responsibility of the hospital pharmacist and prepared under environmental conditions that minimize the risk of contaminating the product and environment minimize exposure of hospital personnel to harm using accepted practice standards.
35. Hospital pharmacists should implement evidence-based systems or technologies (e.g., automated prescription filling, unit dose distribution, machine-readable coding systems) to decrease the risk of medication errors.
36. Hospital pharmacists should support the development of policies regarding the use of medicines brought into the hospital by patients, including the evaluation of appropriateness of complementary and alternative medicines.
37. Hospital pharmacists should implement systems for tracing medicines dispensed by the pharmacy (e.g., to facilitate recalls).
38. Concentrated electrolyte products (such as potassium chloride and sodium chloride) and other institutionally identified high-risk medicines should be dispensed in ready-to-administer dilutions and stored in secure, separate areas with distinct labels.
39. Hospital pharmacists should develop simple, rules-based approaches to advancing patient safety; for example, when a large number of dosage units are needed to give a dose (more than two tablets, vials, etc.), the prescription should be verified prior to preparation or dispensing.

Theme 4—Administration

40. Hospital pharmacists should ensure that the information resources needed for safe medicines preparation and administration are accessible at the point of care.
41. Hospital pharmacists should ensure that clinically relevant allergies, drug interactions, contraindications, past adverse events, and other relevant medication history details are accurately recorded in a standard location in patient records and evaluated prior to medicine use.
42. Hospital pharmacists should ensure that medicines are packaged and labeled to ensure identification and to maintain integrity until immediately prior to administration to the individual patient.
43. Medication labels should be clear and have sufficient information to ensure safe administration, including at least two patient identifiers, the name of the medicine, prescribed route, dose in mass and, where appropriate, volume, and rate of administration.
44. Hospital pharmacists should ensure that health-care professionals who administer medicines are appropriately trained in their use, hazards, and necessary precautions.
45. Doses of chemotherapy and other institutionally identified high-risk medicines should be independently checked against the original prescription by at least two health-care professionals, one of whom should be a pharmacist, prior to administration.
46. Hospital pharmacists should develop and implement policies and practices that prevent route errors. Examples include

    a. Labeling of intravenous tubing near insertion site to prevent misconnections,
    b. Use of enteral feeding catheters that cannot be connected with intravenous or other parenteral lines,
    c. Packaging vinca alkaloids to prevent inadvertent intrathecal administration,
    d. Use of oral syringes that are distinctly different from hypodermic syringes to prevent injection of enteral or oral medicines.

47. Hospital pharmacists should ensure the development of quality assurance strategies for medicines administration to detect errors and identify priorities for improvement.
48. The medicines administration process should be designed such that transcription steps between the original prescription and the medicines administration record are eliminated.

Theme 5—Monitoring of Medicines Use

49. An easily accessible reporting system for defective medicines should be established and maintained. Reports of defective or substandard medicines should be reviewed internally and sent in a timely manner to regional or national pharmacovigilance or regulatory reporting programs and the manufacturer.
50. An easily accessible reporting system for adverse drug reactions should be established and maintained. Reports of reactions should be reviewed internally and sent in a timely manner to regional or national pharmacovigilance or regulatory reporting programs. These data should be regularly reviewed to improve the quality and safety of medicine-use practices.
51. An easily accessible, nonpunitive reporting system for medication errors, including near misses, should be established and maintained. Reports of medication errors should be reviewed internally and sent to regional or national medication error

reporting or regulatory programs. These data should be regularly reviewed to improve the quality and safety of medicine-use practices.

52. Medicine-use practices should be self-assessed and compared with benchmarks and best practices to improve safety, clinical effectiveness, and cost-effectiveness.
53. The medicine-use process should be reviewed through an external accreditation or quality-improvement program. Hospitals should act on reports to improve the quality and safety of their practices.
54. Pharmacists' clinically relevant activities should be documented, collected, and analyzed to improve the quality and safety of medicine use and patient outcomes. Activities that significantly impact individual patient care should be documented in the patient record.
55. Systematic approaches (e.g., trigger tools) should be used to provide quantitative data on adverse drug events and optimal medicine use. These data should be regularly reviewed to improve the quality and safety of medicines practices.

Theme 6—Human Resources, Training, and Development

56. At a national level, competency frameworks are defined, established, and regularly assessed.
57. At a national level, hospital pharmacists should engage health authorities to bring together stakeholders to collaboratively develop evidence-based hospital pharmacy human resource plans to support the responsible use of medicines, including those in rural and remote areas.
58. Hospital pharmacists should work with key stakeholders to ensure that work-force education, training, competency, size, and capacity are appropriate to the scope of services, coverage, and responsibilities of all cadres providing pharmacy services.
59. Hospital pharmacy work-force plans should describe strategies for human resource education and training, recruitment and retention, competency development, remuneration and career progression pathways, diversity-sensitive policies, equitable deployment and distribution, management, and roles and responsibilities of stakeholders for implementation.
60. Hospitals should maintain human resource information systems that contain basic data for planning, training, appraising, and supporting the work force. Data should be collated at a national level to improve work-force planning.
61. The training programs of pharmacy support staff should be nationally formalized, harmonized, and credentialed within a defined scope of practice.
62. Hospital human resource policies should be founded in ethical principles, equity, and human rights and be compliant with labor regulations, guidelines, and hospital pharmacy practice standards.
63. Hospitals should use the nationally accepted competency framework to assess individual human resource training needs and performance.
64. To promote interprofessional education and team-based care, the role of hospital pharmacists, including collaborative prescribing, should be included in the curricula of other health-care professionals, and the roles of other health-care professionals should be included in the pharmacy curricula.
65. Postgraduate clinical courses should be developed to prepare hospital pharmacists for collaborative prescribing of medicines, including instruction in legal and professional accountability.

* The responsible use of medicines means

- That a medicine is only used when necessary and that the choice of medicine is appropriate based on what is proven by scientific and/or clinical evidence to be most effective and least likely to cause harm. This choice also considers patient preferences and makes the best use of limited health-care resources.
- There is timely access to and the availability of quality medicine that is properly administered and monitored for effectiveness and safety.
- A multidisciplinary collaborative approach is used that includes patients and those in addition to health professionals assisting in their care.

Development of Therapeutic Guidelines

Samar F. Farid, Cairo University, Cairo, Egypt

Synonyms

Medical guidelines - Clinical guidelines - Clinical pathways- Clinical practice guidelines - Drug therapy guidelines - Therapeutic guidelines – Standard treatment guidelines

Definition of Terms

Clinical guidelines are recommendations on the appropriate treatment and medical care of specific diseases and conditions. They are based on the best available evidence in order to help health-care professionals with their mission, but they do not replace the professional's knowledge, skills, and clinical judgment. Another but similar definition of clinical guideline is "a systematically developed guidance document prepared to assist health-care staff in the safe diagnosis, prescribing, preparation, control, and administration of medicines for specific clinical conditions" (Gagliardi et al., 2011; Gopalakrishnan et al., 2014; Steinberg et al., 2011).

According to the Institute of Medicine (IOM), clinical practice guidelines are defined as "statements that include recommendations, intended to optimize patient care, that are informed by a systematic review of evidence and an assessment of the benefits and harms of alternative care options." In brief, clinical practice guidelines are recommendations for clinicians about the care of patients with specific conditions (Inistitute of Medicine [IOM], 2011).

Some guidelines come in the form of algorithms, which in turn, identify all available and possible decision options and their health outcomes. Clinical guidelines are derived from top quality evidence, most up-to-date data and best practical experience about the prevention, diagnosis, prognosis, and therapy of specific disease(s). They contain some data on the dosage of drugs, risk/benefit, and sometimes cost-effectiveness of therapeutic and/or diagnostic interventions (Woolf et al., 1999).

Terms and Concepts that are Interchangeable with Therapeutic Guidelines

One might think that clinical and therapeutic guidelines are two different terms. Yet, in the literature, the two terms are used interchangeably giving the same meaning. There are many terms that have been used interchangeably with therapeutic guidelines such as clinical practice guidelines, clinical pathways, medical guidelines, drug therapy guidelines, and these will be used throughout this chapter.

The Difference between Evidence-based Guidelines and Consensus/Expert Guidelines

Evidence-based guidelines are the guidelines developed using systematic reviews to report specific clinical situations (Lim et al., 2008). They are developed through a thorough literature review, critical evaluation of the evidence's quality, and interpreting the outcomes according to the patient's preferences and societal values (Guyatt et al., 2004). In order to develop an evidence-based guideline, the clinical question that will be addressed needs to be determined first, followed by setting the eligibility criteria for the included studies in the guidelines' development. Then a systematic literature review is performed, and the evidence is appraised (Guyatt et al., 2008a). The quality of the included studies is graded by a grading system that reflects the guideline's strength and the quality of supporting evidence (Kavanagh, 2009).

Evidence-based guidelines benefit both the patients and health-care providers. From a patient's perspective, guidelines improve the quality of care by backing the useful interventions and discouraging harmful ineffective ones, which eventually decreases the mortality and morbidity and improve the quality of life of patients and benefit the society as a whole (Grimshaw and Russell, 1993). Guidelines can augment consistency of care so that the patients with similar clinical problems receive a consistent and appropriate treatment irrespective of the place or the person offering the treatment (Lim et al., 2008). From a health-care provider's perspective, guidelines improve the quality of clinical decisions; as they act as a reference for clinicians who are uncertain about their interventions (Grimshaw and Russell, 1993).

There are some limitations to evidence-based guidelines. The guideline can be erroneous due to lack of evidence as there are few medical areas that are guided by high number of high-quality studies. Another limitation is that the guideline can be misleading due to limitations in the studies used as evidence leading to biased results. Eventually, guideline's authors can misinterpret the evidence due to conflicts of interest (Grol et al., 1999). These limitations can be overcome by critical valuation and grading of the guidelines (Lim et al., 2008).

The publication by the American College of Chest Physicians (ACCP) Conference on Antithrombotic and Thrombolytic Therapy serves as an example for evidence-based guidelines (Hirsh et al., 2008). This publication provides new important information in the management of thromboembolic disorders.

Consensus guidelines are defined as "systematically developed statements to assist practitioner's and patient's decision about appropriate health care for specific clinical circumstances" (Goodman and Baratz, 1990). The purpose of consensus is to advise health-care providers about the most acceptable way to make a particular decision in diagnosis, management, or treatment. Consensus statements provide new data mainly from recent and ongoing research that may participate in reevaluation of routine medical practices. However, consensus statements do not offer specific algorithms as they are dependent on cost, available expertise, and local circumstances. For production of consensus statement, an independent team of experts are brought to meet together usually by a medical association or governmental authority. The consensus declares the general opinion of the participant experts, but this does not mean that they all agreed on that opinion. Consensus statements must be reevaluated often as they represent the time frame when they are announced (De Boeck et al., 2014). An example for consensus guidelines is the World Heart Federation Expert Consensus Statement on Antiplatelet Therapy in East Asian Patients with Acute Coronary Syndrome or Undergoing Percutaneous Coronary Intervention (Levine et al., 2014).

What Therapeutic Guidelines are not?

As important as it is to understand the purpose of therapeutic guidelines, understanding what therapeutic guidelines are not intended for is important too. Without this understanding, health-care providers may be concerned about the effect of therapeutic guidelines on their professions and organizations may misuse the guidelines in situations where they were never intended. Guidelines are *not* reimbursement policies, performance measures, legal precedents, measures of certification or licensing, not for provider selection or public reporting, or recipes for "cookbook medicine" (Rosenfeld et al., 2013)

Guidelines are never meant to replace professional decision; yet, they may be viewed as a relative restriction on individual clinician judgment in a certain clinical circumstances (Marcuse and Shiffman, 2004). Guidelines simply express the best decision of a team of experienced clinicians and methodologists responding to a particular situation by scientific evidence. Eventually, therapeutic guidelines are not intended for cost control or health-care rationing (Rosenfeld et al., 2013).

History of Development of Therapeutic Guidelines

Historically, textbooks were used as the main sources of information needed for the management of diseases. They were revised every now and then in order to be updated with the latest changes in clinical practice (Dubois and Dean, 2006). However, there was always a time lag between the time content of a book is compiled and the time of publication, where the information often becomes outdated. Many years later, clinical practice guidelines replaced textbooks as primary resources for disease management in clinical practice.

Although available data about the emergence of guidelines are lacking and imprecise, it is apparent that therapeutic guidelines were first produced in the late 1970s in Australia when there was a need to think about outlines that can regulate the use of antibiotics (Hemming et al., 2003). Concerns surrounding bacterial resistance surfaced after inappropriate antibiotic use in Melbourne Teaching Hospitals (Pavillard et al., 1982). This first known guideline consisted of 31 pages focused on antibiotic usage and included guidelines for the use of 31 antibiotics in 59 different indications. These guidelines document was adopted in Victoria's public hospitals where it was printed in the size of the physician's whitecoat pocket. The guidelines were regarded as a good aid for clinicians in decision making for both clinical and cost-effectiveness outcomes. Also it was used as a source of continuous learning. Subsequently, other guidelines were developed. Some examples of the earliest guidelines include:

- The first version of the Joint National Committee (JNC) guidelines, specialized in the management of high blood pressure, appeared in 1977 (Joint National Committee, 1977)
- Analgesic guidelines by World Health Organization (WHO), entitled "WHO Guidelines for the Use of Analgesics in Cancer Pain," was published in 1985 (Ventafridda et al., 1985).
- The first respiratory guidelines were published by the American Thoracic Society in 1987 entitled "American Thoracic Society Standards for the diagnosis and care of patients with chronic obstructive pulmonary disease (COPD) and asthma" (American Thoracic Society, 1987).
- The first guidelines focusing on dyslipidemia were published in 1988 by the National Cholesterol Education Program (National Cholesterol Education Program, 1988).
- Cardiovascular guidelines such as "American Heart Association Task Force on Assessment of Diagnostic and Therapeutic Cardiovascular Procedures" were published in 1991 (American College of Cardiology, 1991).

In the United States of America, guidelines were first defined and published by the institute of medicine in the early 1990s (Lohr and Field, 1990). In England, the Cochrane Collaboration was established in 1993 (Bhaumik, 2017).

Purpose of Developing Therapeutic Guidelines

The guidance of the decision-making process to both clinicians and consumers is considered the main purpose of guidelines development. This results in improvement of the quality of care, risk management, and patient outcomes. It also acts to reduce the diversities in clinical practice toward a more consistent and transparent approach (Martina, 2014).

In the light of the overwhelming medical literature and research nowadays, guidelines serve as systematic and organized sources to represent and implement the best available evidence in clinical practice. Nowadays, and due to limited health-care resources, guidelines are intended to provide evidence about the cost-effectiveness of care as well, which leads the way to judicious allocation of resources in health care (Lohr and Field, 1992; Peetermans and Ramaekers, 2002). This can explain the reason behind the interest of policymakers in the development of therapeutic guidelines.

In addition, guidelines can be employed as a good source for continuing professional development and updating medical information for groups and individuals (Lohr and Field, 1992). In this context, Weisz et al. argued that the main aim for guidelines development, besides the rationalization of medical costs and the maintenance of physicians' professional autonomy, is the "regulation" of the use and quality of medical care (Weisz et al., 2007).

Characteristics of Valid Therapeutic Guidelines

Guidelines should have specific clinically oriented objective(s) and scope that are specified a priori to the guidelines document development. The guidelines presentation should be concise and structured, yet comprehensive enough to fulfil the objectives. A guideline recommendation should be clear and easy to follow. Guidelines development should consider scientific evidence of benefits, harms, and, if feasible, costs. This evidence can be based on randomized controlled clinical trials, cohort or nonrandomized controlled studies. Guidelines should be dynamic and iteratively reviewed and updated in accordance with the emergence of new evidence. Discussion of the benefits shows health gain and discussion of harms such as adverse effects shows the safety of drug therapy. Explicit and practical guidelines should avoid injudicious words (such as "may be, perhaps") and arbitrary numbers (such as months of treatment, intervals between screening tests) (Burgers et al., 2003; Davis and Taylor-Vaisey, 1997; Qaseem et al., 2012).

Benefits of Using Therapeutic Guidelines

Guidelines serve as a great help for clinicians. They serve as a clean and organized presentation of enormous amount of data. Having the level of evidence sorted in guidelines is an important guide for clinicians in taking clinical decisions. In addition, the regular update of guidelines is crucial for providing the most effective management for patients and for continuing education of health-care professionals. Since they contain different options for treatment, guidelines provide flexibility for clinicians in taking therapeutic decisions according to the available resources which vary from one country or setting to another (Shea et al., 2012).

Furthermore, therapeutic guidelines are an important tool for setting priorities that can be considered in conducting future research. Guidelines can also act as a major player in health policy formation (Browman et al., 2003).

Responsible Bodies for Issuing Guidelines

Therapeutic guidelines are issued at local, national or international levels, whereas health professional organizations/associations or governmental bodies issue their own guidelines or adapt other evidence-based ones. Guidelines are either specialized or unspecialized. All guidelines issuing organizations are united in the Guidelines International Network (G-I-N) (www.g-i-n.net), an international network of clinical guidelines developers.

National guidelines issuing bodies, including, for example, the United States Agency for Healthcare Research and Quality (AHRQ), issue national guidelines. Likewise, in England, clinical practice guidelines are primarily developed by the National Institute for Health and Care Excellence (NICE). In the Netherlands, the Institute for Healthcare Improvement (CBO) publishes specialized guidelines, whereas College of General Practitioners (NHG) publishes unspecialized care guidelines. Similarly, the German Agency for Quality in Medicine (ÄZQ) adopts a national program for different disease management guidelines (Shea et al., 2012; Woolf et al., 1999).

The WHO also issues series of guidelines providing recommendations for clinical practice or public health policies. These guidelines are examples of internationally developed and implemented guidelines. Examples of medical associations issuing their own specialized therapeutic guidelines include National Asthma Education and Prevention Program (NAEPP) Guidelines for Diagnosis and Management of Asthma (National Asthma Education Prevention Program, 1998), the Joint National Committee's eighth guidelines (JNC 8) for the management of hypertension (James et al., 2014) and the international clinical practice guidelines for the treatment of acute uncomplicated cystitis and pyelonephritis in women by the Infectious Diseases Society of America and the European Society for Microbiology and Infectious Diseases (Gupta et al., 2011).

To facilitate the implementation of therapeutic guidelines, some specialized computer software packages known as guideline execution engines were developed. Guideline execution engines import guidelines in the form of guideline interchange format (GLIF format) and use an electronic form of medical record system to implement the guidelines. Countries archive their guidelines in medical guideline clearinghouses. The American National Guideline Clearinghouse keeps a catalogue of high-quality guidelines published by numerous health professional associations.

Development of Therapeutic Guidelines

For many decades, the process of development and dissemination of therapeutic guidelines has been well established. However, the process has been much improved from being haphazard and irregular to being well-integrated into the thinking of expert groups and professional clinical organizations (Davis and Taylor-Vaisey, 1997). The improvement of health-care quality, the quality use of medicines (reduction of unnecessary, ineffective, or harmful interventions), and optimum treatment of patients with maximum benefits and minimum risks are the main benefits of developing, writing, and publishing therapeutic guidelines. These guidelines are written mainly for clinicians (including prescribers, particularly general practitioners and trainee physicians, pharmacists, and nurses) to assist them in the management of patient-specific conditions and to ensure receiving the optimum treatment to their patients. This occurs by providing them with clear, practical, and up-to-date therapeutic information that are essential for everyday clinical decision making (Graham and Harrison, 2005).

Key Principles for Developing Therapeutic Guidelines

For developing therapeutic guidelines, nine principles should be applied (Browman et al., 1995; Davis and Taylor-Vaisey, 1997; National Health and Medical Research Council, [NHMRC] 1999; Qaseem et al., 2012):

- The development process has to focus on outcomes, ranging from survival rates to quality of life attributes.
- They have to be based on the best available evidence in addition to including a statement about both the strength and the quality of the recommendations.
- The turning of the evidence into recommendation depends on judgment, experience as well as the good sense of the group who is responsible for developing the guidelines.
- Being multidisciplinary and the inclusion of consumers are necessary in the development process for the guidelines to be relevant.

Figure 1 Therapeutic guidelines development process. *Source*: Adapted from National Health and Medical Research Council (NHMRC), 1999. The Guiding Principles. A guide to the development, evaluation and implementation of clinical practice guidelines. National Health and Medical Research Council, Australia; Shekelle, P.G., Woolf, S.H., Eccles, M., Grimshaw, J., 1999. Developing guidelines. Br. Med. J. 318, 593–596; Davis, D.A., Taylor-Vaisey, A., 1997. Translating guidelines into practice: a systematic review of theoretic concepts, practical experience and research evidence in the adoption of clinical practice guidelines. Can Med Assoc J 157, 408–416; Browman, G.P., Levine, M.N., Mohide, E.A., et al., 1995. The practice guidelines development cycle: a conceptual tool for practice guidelines development and implementation. J. Clin. Oncol. 13, 502–512.

- Guidelines have to be flexible and adaptable to the continuously varying conditions and constraints.
- During the development process, resource constraints are among the main factors that should be considered.
- Therapeutic guidelines should be disseminated and implemented taking into account the practitioners and consumers who are considered the main target audience.
- Evaluation of the validity and usefulness of guidelines should be done.
- Regular revision of guidelines should be done in a scheduled manner.

Therapeutic Guidelines Development Process

For a successful development of therapeutic guidelines, a systematic framework with definitive steps has to be developed (Browman et al., 1995). In addition, the methodology of guideline development should ensure that the desired outcomes will be achieved upon treating the patients according to the guidelines (Shekelle et al., 1999). The steps of the therapeutic guidelines development process are summarized in Fig. 1.

Identification of the Scope and the Need for the Guidelines

The first step in developing therapeutic guidelines is to identify the need for the guidelines. Therefore, a clear and specific scope and clinical objectives should be determined. The responsible body for developing the guidelines should specify the clinical practice problem that may be well resolved by the implementation and dissemination of these guidelines which offer the most appropriate practice (NHMRC, 1999). As an example, a checklist for defining the scope and clinical objectives for the guidelines development process is developed by the American College of Cardiology and American Heart Association (ACC/AHA) (see **Checklist 1**). This checklist defines the important guideline topic-related clinical objectives, the subtopics and related topics that must be included in the guideline, whether they are already covered by another organization, and whether the flow diagrams are appropriate to them, the comorbidities which are being covered or should be covered by the topic area/guideline, the potential benefits and risks for individual patients associated with an intervention or procedure, the amount of clinical flexibility appropriate for the topic area, the available clinical options, and the topics already covered in existing ACC/AHA Guidelines. Consequently, literature searching and sorting, and the compilation of guideline recommendations will be based on these predefined clinical objectives.

To the best of our knowledge, the decision to develop new guidelines is based on many factors such as the expressed need by general or specialist practitioners, feedback from clinicians, evidence from drug usage data, and the presence of a clear problem (e.g., magnitude of health burden, cost, variations in practice and care, lack of evidence) that would be assisted by establishing guidelines for appropriate practice. A precise, structured, and well-defined overall guideline outline should be determined during

Checklist 1 Determining the Guideline Scope and Clinical Objectives

Questions related to the guideline overall

- ☐ What is the guideline's targeted health condition(s), diagnostic test(s), or interventional procedure(s)?
- ☐ What is the purpose of the guideline?
- ☐ What is within the scope of the guideline?
- ☐ What is outside the scope of the guideline?
- ☐ What is the literature inclusion date range?
- ☐ What is the epidemiology of the topic?
- ☐ Who are the guideline's intended users?
- ☐ What is the public health impact?
- ☐ What is the target patient population to be addressed in the guideline?
- ☐ How does the guideline relate to other existing ACCF/AHA documents (e.g., expert consensus, scientific statements, performance measures, data standards, appropriate use criteria, quality improvement)?
- ☐ Can flow diagrams and evidence tables help summarize the guideline, or at least key subsections?
- ☐ How does the guideline impact and improve broad health system based public health improvement goals such as the Healthy People 2010 Initiative?

Questions related to the guideline's clinical objectives

- ☐ What are the important clinical objectives related to the guideline topic?
- ☐ What subtopics and related topics must be included in the guideline? Are the subtopics and related topics already covered by another organization? What comorbidities are being covered or should be covered by the topic area/guideline?
- ☐ Are flow diagrams appropriate to these subtopics and related topics?
- ☐ What are the potential benefits and risks for individual patients associated with an intervention or procedure?
- ☐ What amount of clinical flexibility is appropriate for the topic area?
- ☐ What clinical options are available?

Adapted from (Methodology Manual and Policies From the ACCF/AHA Task Force on Practice Guidelines, 2010)

the early stages of guidelines development to improve consistency across guidelines and facilitate the effectiveness of online searching of these guidelines.

Forming Guideline Development Expert Groups

Expert groups

For each published guidelines, a committee for practice guidelines or expert groups of representative members take the responsibility of text development in therapeutic guidelines. The group or committee has innovative roles in the involvement of these guidelines in the new health-related policies and in clinical practice, prevention, quality assurance, research programs, and health economics for patient-specific conditions. The composition of these groups will vary depending on the nature of the guidelines, but should be designed to be representative of various interests. In general, the following members should be involved in the expert groups, as appropriate: a chairman, an editor, experts in relevant medical specialties, clinicians with general expertise, and other relevant health professionals (pharmacists, experts in physiotherapy and nutrition, and nurses). In addition, consumer groups, public policy analysts, health economists, industry representatives, bioethicists, and representatives of regulatory agencies may be also included in the group (NHMRC, 1999).

Group members are invited to participate in developing recommendations for practice based on the best available published evidence in addition to their knowledge of clinical practice. Besides expert groups, the presence of the editorial office is crucial in the process of therapeutic guidelines development. Both the chairperson and editor have distinguishable roles in the manuscript development process. The main role of the chairperson is to coordinate and ensure that the group functions effectively, that the project proceeds harmoniously, that the aims are achieved, and that true consensus is attained for all recommendations (Shekelle et al., 1999). The editor assists in the communication between the chairperson and expert group members in order to be sure that the manuscript develops effectively, on the scheduled time and within the set budget. Also, he/she is responsible for preparing the documents for each meeting, including the agenda, minutes, feedback on the previously published version (where applicable), correspondence regarding draft manuscripts, content, and other relevant background information. In addition, the editor prepares a detailed transcript of each meeting to document the basis for all recommendations, especially those that are new or controversial.

Planning meeting

Generally, for each expert group, an initial planning meeting or teleconference is done to provide the members with detailed explanation and guidance on several aspects including intellectual property, conflict of interest, objectives and format of the guidelines, clarification of the scope of the content for the target audience, importance of documentation of evidence to support the recommendations, and desirability of consultation with colleague experts in the area.

Before proceeding, a clarification of the purpose and the target audience for the guidelines should be done by the expert group members. Therefore, within each subject area, the group decides on which medical conditions and clinical problems to be covered and the level of detail to be included, in addition to the likelihood that a condition will be encountered. However, advice on rare but serious diseases will also be included. Moreover, feedback from users of earlier version of the guidelines may also influence the decisions about which conditions need to be covered. This means that the starting point for content is what a clinician needs to know in order to appropriately treat a patient with specific condition (Graham and Harrison, 2005; Shekelle et al., 1999). Also, the type of health-care providers and consumers for whom the guidelines are intended and the interventions that have to be evaluated are among the issues that have to be specified by the group members (NHMRC, 1999).

In addition, topics selected by expert group members for guideline development should be feasible where sufficient high-quality evidence derived from randomized controlled trials is available. Also they should adopt the high-priority criteria, which are as follows (Rosenfeld and Shiffman, 2009):

- Significant health burden with high extent of disability, morbidity, or mortality not only on patients but also on families, communities, and society overall.
- The presence of a clear clinical practice problem that will most likely be resolved by the most appropriate practice offered by the guidelines.
- Topics that are controversy or uncertain.
- The presence of significant economic cost of the clinical condition, procedure, treatment.
- The presence of new published evidence that may have the potential to change conclusions.
- High potential impact on health outcomes and quality of life.
- Topics of high public or provider interest.
- The presence of variations in health care.

Reviewing and Assessing Scientific Evidence

After the planning meeting, unbiased and comprehensive literature review should be done by the expert group members to ensure the validity of the evidence-based guidelines, help them in answering the clinical questions, and highlight the gaps in evidence. The process of identifying evidence involves identification of systematic reviews, previously published guidelines, randomized controlled trials, nonrandomized studies, case studies, and opinion documents. All of the literature search should be documented to ensure transparency and reproducibility (Rosenfeld and Shiffman, 2009).

Translating Evidence into Therapeutic Guidelines

Initial drafts, based on the authors' clinical expertise and the current best available evidence from the latest international literature in the relevant area, are prepared. Also, authors in each group are encouraged to prepare a justified summary of their recommendations. At this stage, the editor and the medical librarian help the authors identify and access the relevant supporting information the authors need. This may include primary scientific papers, systematic reviews, and previously developed guidelines.

The drafts are sent to all the group members to give them the opportunity to consider the material before the topics are discussed. Then, successive and more exhaustive discussions are made for each draft until agreement is reached on the content. Consequently, controversial areas are identified and further literature searches are undertaken if necessary. Once the intent of the expert group is clear with respect to specific content, the editor becomes responsible for the text, reorganizing it according to house style and format, and communication as necessary with authors and the chairman. Therefore, the finished manuscript is the result of detailed scrutiny, collaboration, and revision, involving many authors and several editing stages. As a result, all expert group members become responsible for the entire manuscript without any of the topics being attributable to any of them. At the final meeting, all topics are scrutinized to ensure all members approve the whole text (Shekelle et al., 1999). Once sufficient evidence has been collected, the evidence should be synthesized in a systematic way that lends itself to decision making. For each clinical objective within the guideline, the following components have to be included; statement of the clinical objective/question, one or more clinical recommendations answering the clinical question/objective, explanatory text, references, evidence table to identify and extract the key data from the relevant studies, and diagram, table, or graphic summary.

Grading recommendations

Documenting the relevance and strength of the scientific evidence is very important in the development of the content in therapeutic guidelines. It is common to grade each recommendation in the guideline. This information is very important for the users because it gives them an indication of the guideline development group's confidence that the desired health outcomes will be produced using these guidelines. Moreover, the strength of any recommendation depends mainly on two factors: the trade-off between benefits and risks and the quality of the evidence regarding the treatment effect. Regarding the trade-off between benefits and risks, the strength of recommendation falls in one of two categories according to the GRADE system (Atkins et al., 2004): 1 (strong recommendation), in which there is a clear trade-off where the benefits outweigh the risk or vice versa and therefore most patients would make the same choice; and 2 (weak recommendation), in which the trade-off is less clear and the benefits are closely balanced with the risks and therefore patients would have different choices. In some instances, the recommendations may fall in "Not Graded" category. In this category, the guidance is based on common sense or the topic does not allow adequate application of evidence. This includes the recommendations regarding monitoring intervals, counseling, and referral to other clinical specialists.

As for the quality of evidence, it may be high, moderate, low, or very low-quality evidence according to US Preventive Services Task Forces. High-quality evidence (denoted as "A") is obtained from well-designed and performed randomized controlled trials where the expert group members are confident that the estimate of benefit and risk is not possible to be altered by future research. Moderate quality evidence (denoted as "B") is obtained from randomized trials with significant limitations where the confidence of the expert group members in the estimate of benefit and risk is likely to be affected by future research, which may alter that estimate. Low-quality evidence (denoted as "C") the confidence of the expert group members in the estimate of benefit and risk is very likely to be affected by future research, which is likely to alter that estimate. Very-low quality evidence (denoted as "D") is obtained from observational studies, unsystematic clinical experience, or from randomized trials with serious flaws, so any estimate of effect is uncertain. High likelihood of bias, inconsistency of results, imprecision, and indirectness of the evidence are considered the main factors that reduce the strength of an evidence (Guyatt et al., 2008b; Kavanagh, 2009; Shekelle et al., 1999; Woolf et al., 2012). However, other organizations may have different grading systems. Based on the American Academy of Pediatrics, four categories of recommendations are used ("strong recommendation," "recommendation," "option," and "no recommendation") (American Academy of Pediatrics Steering Committee on Quality Improvement and Management, 2004). In addition, lots of guidelines-developing organizations do not use any grading system for defining recommendations' strength (Lomotan et al., 2010). In England and Wales, the NICE does not assign letter grades to its recommendations and uses three levels of certainty. These three levels of certainty include:

1. Recommendations for interventions that must (or must not) be used. These recommendations apply to all patients, and there is a legal duty to apply them.
2. Recommendations for interventions that should (or should not) be used. These mean that there is confidence that the intervention(s) will do more good than harm and will be cost-effective for the majority of patients.
3. Recommendations for interventions that could be used. These mean that there is confidence that the intervention(s) will do more good than harm and will be cost-effective for most of patients. However, other options may have similar cost-effectiveness, or patients prefer a less effective but cheaper intervention. Therefore, the choice of such intervention(s) varies depending on a person's values and preferences.

The written recommendation is considered the core of any guidelines. All recommendations should be written in an unambiguous language with clearly defined terms. Usually, they are written in complete sentences using the correct verbs and with assigned references. The target population, subpopulation, and exceptions should be specified when writing recommendations. The recommendations that are practical in the real-world settings are those which are usually written in the guidelines.

Dissemination of Guidelines

As previously mentioned, therapeutic guidelines should be disseminated and implemented taking into account the practitioners and consumers who are considered the main target audience. During the process of guideline development, the expert groups have to develop a scheduled plan for the dissemination and implementation of therapeutic guidelines targeting all potential users (NHMRC, 1999). The presence of multiple guideline formats will improve the dissemination of the guidelines. Guidelines can be published as booklets, containing comprehensive information, or in summary form providing information about the main findings. Also, they may be published in other forms including professional journals, professional associations' newsletters and magazines, industry newspapers, institutional newsletters, as posters, as brochures, as audio or video tapes, on computer disks, in summary form or as full guidelines published on the Internet and linked to websites appropriate for the target audience. For example, European Society of Cardiology (ESC) Clinical Practice Guidelines are available in different formats including pocket guidelines, mobile application, guidelines presentations, webcasts, summary cards, and reprints. These different formats provide easy access and quick reference guides for the practicing clinician.

Scheduled Reviewing and Updating Guidelines

After the publication of the therapeutic guidelines, it is expected that they will be reviewed and updated with a scheduled review date. As an example, NICE guidelines should be evaluated at least once every three years. More frequent evaluation will be performed in case of subjects areas prone to rapid change. With the increasing rate of published new studies, several concerns will be raised if guidelines are not up-to-date. First, the guideline users will not trust that the care is based on the best available evidence in these outdated guidelines. Second, no reflection of the clinicians' experience and their knowledge of recently published research is presented in that version of the guidelines, making their clinical choices inappropriate, or spending much time searching for more valid published evidence (Clark et al., 2006). Therefore, the review process should be done to ensure that the content of the guidelines is valid, clear, and applicable (Graham and Harrison, 2005; Shekelle et al., 1999). For example, the National Kidney Foundation—Kidney Disease Outcomes Quality Initiative (NKF KDOQI) performs continues update for its clinical practice guidelines. This occurs upon the availability of high quality new evidence that drives them to change the currently available recommendations (e.g., recommended intervention causes unknown harm, presence of new superior intervention to a previously recommended one, new intervention targeting new population).

Briefly, the review process has six components, which includes assessment of guidelines dissemination, assessment of their relevance to clinical practice, assessment of the change of the health outcomes, assessment of the contribution of the guidelines to any changes of clinical practice or health outcomes, assessment of the impact of guidelines on consumers' knowledge and understanding, and finally the economic evaluation of guideline process. The regular review and update of therapeutic guidelines

may result in many changes. Addition, removal, or change to recommendations or suggestions may occur. Moreover, the strength of a recommendation may be upgraded or downgraded based on the new available evidence.

The decision to update the guidelines is based on many factors; changes in evidence, the resources available for health care, feedback from clinicians, changes in practice, changing patterns of drug usage, and other relevant issues (Shekelle et al., 1999; Shekelle et al., 2001). However, clinical areas covered in guidelines may not be considered for updating in certain circumstances. This occurs when the evidence base is poor, and it is unlikely that any of the recommendations will change (Shekelle et al., 2001).

Withdrawal of guidelines

Upon consultation with stakeholders, the decision to withdraw a guideline will be made when inaccurate, misleading, or erroneous recommendations are detected in the published version, when the recommendations in a guideline are no longer applicable and at the same time the guideline is not of sufficiently high priority for updating, or when concerns regarding the effect of conflicts of interests by the authors of the guideline in the critical appraisal of the evidence was detected (Jorge, 2014). In the EUROPAEM EMF Guidelines 2015 for the prevention and treatment of EMF (electromagnetic fields)-related health problems and illnesses, unintentional errors were detected where many citations were lost and deleted during its preparation. Therefore, the authors have retracted the guidelines for a revised version to be published at a later date (Belyaev et al., 2015).

Cons/Harms/Limitations

Clinical guidelines are sometimes resented by some clinicians as an invasion of personal expertise. Specialized guidelines may sound biased to generalists. Often times, to specialists, guidelines developed without their input are lacking adequate expertise.

1. Wrong recommendation (at least for individual subjects).
   Apart from humanistic errors, guideline development groups may miss what is best for patients for:
   a. Lack of scientific evidence.
   b. Misleading scientific evidence: Inappropriate experimental design leads to bias, which compromises generalizability.
   c. Misinterpreted scientific evidence: Lack of time, resources, and skills to gather complete information and criticize every detail of evidence may lead to misinterpreted evidence. Moreover, subjective judgments may miss the best intervention for individual patients.
   d. Guidelines are influenced by the judgment, clinical expertise, and compilation of their development group.
   e. Patients' needs may not represent the only priority during guideline development. From the patient's perspective, suboptimal practices may be recommended to help control costs for example. The implementation of these flawed guidelines can spread serving ineffective, harmful, or wasteful interventions.
   f. Inflexible guidelines impair the feasibility of patient-oriented pharmaceutical care of nonconventional clinical problems, thus the achievement of more consistent practice may impede individualized care.
   g. Clinical guidelines can affect stakeholders to drop access to beneficial interventions and likely costly interventions may displace less costly yet effective intervention thus loses its cost-effectiveness.
2. Potential harms to health-care professionals
   a. Inaccurate scientific information and clinical advice compromise the quality of care.
   b. Conflicting guidelines from different professional bodies
   c. Outdated recommendations may spread outmoded practices
   d. Guidelines can restrict scientific progress if future research is inappropriately discouraged. For example, lack of investment for refining previously ineffective interventions
   e. Simplistic algorithms that reduce patient care to a (yes/no) decisions hierarchy underestimate the iterative thought processes inherent in clinical judgment.

However, the increasing awareness of clinical guidelines limitations (Cabana et al., 1999; Woolf et al., 1999) has done little to the rapid spread of guidelines around the world.

Conclusion

Guidelines are developed by governments or health associations to control acts and sometimes costs of health-care process. These guidelines are written mainly for all clinicians for optimum treatment of their patients. Therapeutic guidelines provide them with clear, practical, and up-to-date therapeutic information that are essential for everyday clinical decision making. Also, guidelines may influence future public health policies. Successful development of therapeutic guidelines requires a systematic framework with definitive steps. The written recommendations, the core of any guidelines, are based on the best available evidence. Guidelines have many benefits that contribute to the provision of better health care, but they are not meant to replace a clinician's expertise and sound clinical judgment. Guidelines should be regarded, as the name implies as "guidelines."

Acknowledgments

The author wishes to acknowledge the efforts made by Aya M. Abdel-Magid, MSc, Iman A. EL-Baraky, MSc, Marwa G. Elhennawy, MSc, and Amani M. Ali, MSc., Assistant Lecturers of Clinical Pharmacy, Faculty of Pharmacy, Cairo University, Egypt.

Glossary

Clinical Guidelines A systematically developed guidance document prepared to assist health-care personnel in the safe diagnosis, prescribing, preparation, control, and administration of medicines for specific clinical conditions.
Clinical Pathways A document outlining a standardized, evidence-based multidisciplinary management plan, which identifies the appropriate sequence of clinical interventions, time frames, milestones, and expected outcomes for a homogenous patient group.
Clinical Practice Guidelines Clinical practice guidelines are statements that include recommendations intended to optimize patient care. They are informed by a systematic review of evidence and an assessment of the benefits and harms of alternative care options (Steinberg et al., 2011). Clinical practice guidelines maybe evidence-based or consensus guidelines.
Consensus Guidelines They are systematically developed statements to assist practitioner's and patient's decision about appropriate health care for specific clinical circumstances (Goodman and Baratz, 1990).
Evidence-based Guidelines They are the guidelines using systematic reviews to report specific clinical situations. They are prepared through a thorough literature review, critical evaluation of the evidence's quality, and interpreting the outcomes according to the patient's preferences and societal values (Guyatt et al., 2004).
Quality Use of Medicines It is the process of selecting patient management options wisely by reducing the use of unnecessary, ineffective, or harmful medicines.

End-of-Life Care Including Pharmaceuticals in Palliative Care

Maree Jensen, Whakatane Hospital, Bay of Plenty District Health Board, New Zealand; Department of Anaesthesiology, Medical Programme, FMHS, University of Auckland, New Zealand

Learning Objectives

1. You should be able to identify what is required in providing good palliative care, and determine those health care providers that will allow you to support the patient and their family during the patient's last months, weeks, and days of life.
2. You should be able to evaluate the services able to be provided by other health care providers and determine any service provision needs for a palliative care service in your location of practice.
3. After reading this chapter, readers should be able to undertake the provision of palliative care in a manner that is appropriate to the needs of the patient and their extended family and carers.

Palliative Care

"Sparse breaths,
then none
and it was done"

The unfinished.

Christopher Reid, describing the last few days, hours, minutes of life of his wife; from his book of poetry about grief, A Scattering (Reid, 2009).

Palliative care is health care provided to any person with a progressive life limiting or life-threatening illness. The care provided is dependent on the needs of the patient, not their prognosis, and takes into account the needs of the patient and carer. Thus, the care offered is delivered in the knowledge that although it is intended to ease or ameliorate the illness, it is not curative.

As such, palliative care incorporates a holistic approach aiming to improve the quality of life of patients with incurable diseases (Palliative Care Expert Group, 2016; Twycross et al., 2009). This approach is to support the whānau or family, friends, and carers of the patient (Palliative Care Expert Group, 2016; Twycross et al., 2009). The ethical principles of respect for the autonomy of the patient and their significant others are the foundation that pharmacists work with other health care professionals to provide a seamless care package for patient entrusted to their care (Gillon, 2003).

Ideally, palliative care takes the best that each member of the health care team has to offer to prevent and relieve suffering. Often, this may mean that the health care professionals, and particularly the pharmacists working in palliative care, remain abreast of complementary, traditional, as well as integrative medicine approaches to patients (WHO Traditional Medicine Strategy, in press). The palliative pharmacist must strive to compassionately support patients and their families to meet their goals and to live each day as fully as possible (Palliative Care Expert Group, 2016; Twycross et al., 2009).

Take-Home Messages

1. Acknowledging a multifactorial approach to care of the dying.
2. Awareness that the needs of the total family, as well as the patient, may require negotiation at all steps along the trajectory of dying.
3. Remembering that although we cannot cure palliative patients, nor should we actively hasten death, we may ease its progress.

Introduction

Palliative care is not just the care of those dying of or with cancer or neoplastic diseases, as it covers a range of complex and end stage conditions that patients may be diagnosed with. The point of similarity is that any patient should be considered for palliative care if any clinician involved in their care would not be surprised if the patient died in the next 6–12 months (Palliative Care Expert Group, 2016).

As a result, many times medications are used "off license or off label," that is, as an unapproved use, either in the location/country of practice or internationally (Twycross et al., in press). As a matter of principle, when recommending such off-licence use, the clinician (physician or pharmacist) must do so with the knowledge that such use is in the best interest of the patient, in order to ease symptoms, or simplify administration. For example, many medications are administered via the subcutaneous route, as it is less invasive than intravenous route, but often there is little or no data regarding the subcutaneous route.

Worldwide, populations are aging, and an increasing number can be expected to require palliative care, as greater strides are made with treatment approaches and public health initiatives to reduce chronic conditions (United Nations, in press). However, not all governments fully fund hospices or hospice in the home care, or even appropriate analgesics. For example, in Mexico, opiates are largely unavailable outside state capitals, and palliative care services are largely nonexistent. As a result, fundraising, and lobbying governments and local communities are often required to initiate or develop care and treatment of those who would benefit. Those in relatively poor communities frequently struggle to provide services. The paucity of palliative care specialists may be bridged by admission to hospital of palliative patients where they can access specialist health care services such as physiotherapy, occupational therapy, social workers, speech and language therapists, respiratory, cancer, renal, and diabetic specialist nursing care. This is not an appropriate level of service, including medical expertise, and negatively impacts on both the hospital statistics (high rates of inpatient deaths) and impacts on patients receiving holistic palliative care from a multidisciplinary heath care team, trained in palliative care delivery in the nonacute setting. Early referral to palliative care can improve measurable outcomes for the patient as well as reduce futile medical interventions and hospital admissions (Haines, 2011).

Disease/Condition Information

> "There is no cure for birth and death save but to enjoy the interval"
> "How people die remains in the memory of those who live on"
>
> Dame Cicely Saunders (Dame Cicely Saunders, in press).

Initially, palliative care and the modern hospice movement by Christopher was started in 1967 to manage the care of those dying in hospital wards as there was nowhere else for them to go (Dame Cicely Saunders, in press). As such, palliative care then became a specialty for those doctors and nurses who staffed the hospices, as well as a range of other health care professionals who were involved in the care of these patients. As many of the treatments provided during those last days involved medications, pharmacists became integral members of the hospice team.

Hospice patients were largely those suffering from cancer in the early days of hospices, and then other patients under a similar "death sentence" such as Acquired Immunodeficiency Syndrome. These days, all patients who have a life-limiting illness, and whose life expectancy is potentially 6 months or less can benefit from palliative care. Thus, patients often have complex medical conditions about which decisions need to be made with the patients and their family. For example, secondary stroke prevention is not a major issue for palliative patients, and after consultation with the patients and their family, these treatments may be withdrawn to ease the pharmacological burden. In contrast, the patient with a pulmonary embolism may receive low-molecular-weight heparin depending on prognosis. Pharmacists need to be mindful of the spiritual and emotional needs as well as medical needs of patients when determining agreed treatments for their patients.

Epidemiology

Modern medicine has continued to advance management and delay progression of many conditions; however, chronic diseases will eventually cause disability, suffering, and death. Generally, these illnesses occur at the end of a long life, but they may occur in all age groups. The aim of palliative care is the relief of suffering, and as such needs to be addressed at a population-based level as well as for individuals.

Etiology

The WHO's definition of palliative case is "an approach that improves the quality of life for families facing the problems associated with life-threatening illness, through the prevention and relief of suffering by means of early identification and impeccable assessment and treatment of pain and other problems, physical, psychosocial and spiritual." (World Health Organisation, in press).

Diagnosis

The decision to seek assistance from a palliative care team is nowadays made earlier in the trajectory of dying for patients who may ask "how long have I got?" Illness trajectories are used to describe the progress of a chronic condition or disease (Murray et al., 2005), In western society, these are generally conditions that are the result of organ failure (for example, respiratory, diabetes, cardiovascular), cancer neurological conditions (for example, motor neuron disease), as well as dementia. The trajectory model has a clear progression from diagnosis and a decline but the eventual outcome will be death (Murray et al., 2005).

There are three main trajectories for people approaching death—the relatively short period of decline associated with cancer, the gradual episodic nature of organ failure with exacerbations resulting in never achieving base-line status after an episode, or the dwindling trajectory of the frail elderly, associated with dementia (Lunney et al., 2003). Sudden death, for instance, cardiac arrhythmia and stroke, is another trajectory (Palliative Care Expert Group, 2016).

For each of these conditions, advance care planning is essential to involve the patient while they are able, and their family during the course of their illness in decisions relating to the care offered to the patient.

Clinical Presentation—Symptoms

The common symptoms associated with palliative conditions involve any that may be associated with the underlying condition as well as pain, nausea and vomiting, constipation, delirium, agitation, dyspnea, and respiratory secretions. Care is frequently required for the skin, bowel, bladder, and oral areas as well (Potter et al., 2003).

Pain

> "True compassion means not only feeling another's pain but also being moved to help relieve it"
>
> Daniel Goldman (Daniel Goleman, 2005)

> "Pain is a symphony – a complex response that includes not just a distinct sensation but also motor activity, a change in emotion, a focusing of attention, a brand new memory."
>
> Atul Gawande, Complications: A Surgeons Notes on an Imperfect Science (Gawande, 2003)

Pain may be due to a pre-existing disease (such as arthritis), but fear of uncontrolled pain can be overwhelming in the dying patient, as well as for their family and friends. Thus it is important to understand which pain is new and which is due to other treatable conditions (such as constipation, fear of dying). Thorough history taking and assessment is key to ensuring pain needs are met and managed as effectively as possible. In assessing total pain it is vital to consider physical, psychological, social and spiritual aspects (McLeod, 2007).

A useful tool to assess pain is *PQRST* (Twycross et al., 2009):

P Palliative & provocative factors—What makes it better, what makes it worse?
Q Quality—Describe to me what it is like
R Radiation—Does it spread anywhere
S Severity—How severe is it on a scale of 1–10?
T Temporal—Is it always there or does it come and go, is it worse at night?

It is important to remember in cancer related pain that several mechanisms may be causing the pain, so a combination of treatments may be needed for optimal relief.

After assessment of pain consider what is already being used to manage pain. If the patient can still swallow medicines and is not using and analgesics, then use the WHO three-step analgesic ladder for cancer pain (WHO Cancer Pain Ladder for Adults, in press):

Step 1 nonopioid analgesics (e.g., paracetamol or NSAIDS) with adjuvant analgesics such as corticosteroids or antidepressants
Step 2 weak opioid (e.g. codeine, dihydrocodeine) plus nonopioid plus adjuvant analgesics
Step 3 strong opioid plus nonopioid plus adjuvant analgesics

All analgesics used to manage pain should be given regularly in order to prevent pain. As such you would give a patient the maximum dose of step 1 before going on to step 2 and adding in a weak opioid. As maximum doses of weak opioids are reached, then step 3 requires replacing the weak opioid with a strong opioid until management of pain is achieved.

In the Australian context, codeine is not routinely used in palliative care due to its ceiling effect, its reliance on hepatic metabolism for conversion to active metabolite morphine, and possible severe constipation. Tramadol has the disadvantages of adverse effects and potential drugs interactions in this group of patients (Palliative Care Expert Group, 2016).

Morphine is usually the drug of choice for moderate to severe pain (Palliative Care Expert Group, 2016).

Commencing a different opioid may be appropriate due to factors such as moderate to severe renal impairment, severe liver impairment, unacceptable side-effects, and compliance issues.

In severe renal failure, buprenorphine, fentanyl, and methadone can be used as they are not renally excreted (Palliative Care Expert Group, 2016).

Buprenorphine, fentanyl, morphine, and methadone can be used in severe liver impairment (Twycross et al., in press).

Fentanyl is the safest first line opioid when the eGFR is less than 30 mL/min Fentanyl is subject to significant first-pass metabolism, and is unsuitable for oral use, but is frequently used as a transdermal patch or as a nasal spray (Schug and Ting, 2017). Transmucosal forms of fentanyl are also available for short-term pain relief. The available products are not interchangeable (Palliative Care Expert Group, 2016).

Using a combination of dosage forms such as long acting preparations for background pain and short acting preparations for breakthrough and incident pain enables better pain management. Regular reassessment of pain needs is important, ideally each day if possible (WHO Cancer Pain Ladder for Adults, in press).

Adjuvant Analgesics—Which is Better for What (BPAC Palliative Care, in press)?

Nociceptive pain is associated with tissue injury. It may be felt as an ache or a deep pain. Bone pain is a pain that is worsened by movement or weight-bearing activity. Both nociceptor pain and bone pain may be treated with nonsteroidal anti-inflammatory drugs (NSAIDS). The use of neuropathic agents for bone pain may be warranted as research suggests that there is a neuropathic component (Palliative Care Expert Group, 2016).

Neuropathic pain is helped partially by opioids but often better management is to add in an adjuvant analgesic as this may delay the need to increase the opioid dose. Low-dose tricyclic antidepressants (TCAs), such as amitriptyline or nortriptyline, and antiepileptics (AEDs), such as gabapentin and pregabalin, can be trialed, taking into account such factors such as the need for night time sedation and the adverse drug profile.

Tumor compression pain is often managed with corticosteroids, commonly dexamethasone, as they reduce edema and inflammation.

Pain from muscle spasm, especially if related to anxiety, is relieved by skeletal muscle relaxants such as benzodiazepines.

Pain from blockage or visceral distention is relieved by smooth muscle relaxants such as hyoscine butyl bromide.

Nausea and Vomiting

The causes of nausea and vomiting are complex, but in order to minimize them, it is important to consider prevention strategies when commencing treatment with emetogenic medicines such as opiates. Care must also be taken to exclude regurgitation from gastro-esophageal reflux disease, and treat it accordingly. The opportunity to correct the correctable (for example, prescribe a proton pump inhibitor for indigestion) and prevent the preventable (minimize stress, large meals, or spicy foods) must be taken as a first step. Then it is appropriate to use the most appropriate antiemetic. If nausea is the major problem, then oral doses are generally adequate. if vomiting is more problematic or if the oral route is unavailable, then parenteral treatment may be more useful, often via continuous subcutaneous infusion (CSCI) using a syringe driver (Twycross et al., in press).

Prokinetic vomiting is generally caused by gastric stasis and bowel obstruction. It may be treated by using metoclopramide 10 mg three times daily orally, or up to 100 mg in 24 h, if tolerated. Erythromycin, in low doses, is another useful prokinetic agent (Twycross et al., in press).

Chemoreceptor trigger zone vomiting such as from opiates, hypercalcemia, and renal failure may be treated by using haloperidol. It is helpful when initiating opioid analgesia to use a small dose of haloperidol (0.5–3 mg orally) as a once-daily dose at night or up to 20 mg over 24 h (Twycross et al., in press).

Nausea and vomiting caused by colic or from gastric secretions may be treated with hyoscine butyl bromide 20 mg three times a day or up to 300 mg over 24 h (Twycross et al., in press).

Vomiting arising in the vomiting center is frequently caused by intracranial pressure and is best managed by dexamethasone and cyclizine. Other useful treatments include benzodiazepines, cannabinoids, and aprepitant (Twycross et al., in press).

A useful adjuvant antiemetic is levomepromazine at a dose of 6 mg three times a day orally or up to 25 mg over 24 h. It may be used with other antiemetics in order to manage symptoms (Twycross et al., in press).

Constipation

This distressing symptom is common in palliative patients. Causes are varied, and constipation frequently causes considerable pain and distress. Determining what is the patient's usual bowel habit is helpful, but generally passing less than three bowel motions in a week is considered to be constipation. Reduced oral intake, lessened activity, as well as the use of medications such as opioids, those with anticholinergic side effects, as well as diuretics can all play a part in causing constipation. As with nausea and vomiting, prevention is easier to manage than treating severe constipation. When introducing opioids and other motility affecting medications, laxatives should always be prescribed and used regularly. Passing a bowel motion should be pain free, and the aim of treatment is to ensure that it can happen.

As with other conditions, assessment of constipation in palliative patients should be undertaken daily. Check for signs of dehydration, rectal bleeding, as well as fecal impaction. Patients should have access to a private space to defecate; they should be offered fiber-rich foods such as prunes or kiwifruit if able to tolerate them, before offering osmotic or rectal treatments.

For most patients, regular use of a softener plus stimulant agent such as docusate plus senna, taken regularly twice a day, as well as adequate fluid intake works well on patients who can tolerate a normal diet.

Osmotic agents such as macrogol solution are preferred to lactulose as they are less likely to cause abdominal cramps and nausea. High dose macrogol (1 L taken over 6 h) is also useful for fecal impaction as well as usual laxative treatments maximized.

Laxative suppositories or micro-enemas such as bisacodyl suppositories or microlax enemas are useful when feces are present in the rectum. A stimulant suppository should be inserted blunt end first and aimed at the wall of the rectum. Glycerol suppositories should be inserted pointed end first and directly into the fecal mass to soften and allow evacuation (Addison, 2000).

Methylnaltrexone, an opioid antagonist, is useful for patients who have opioid-induced constipation. It is administered as a once-daily dose, by injection, and generally causes a bowel motion within 30–120 min. As it does not cross the blood–brain barrier, it can be used without reversing analgesic effects of opioids (BPAC Palliative Care, in press). Oral laxatives should be continued when methylnaltrexone is used.

Enemas may be helpful for patients for whom oral laxatives have not worked as a last resort, either osmotic (e.g., phosphate enemas) or other softening agents. However, care must be taken to exclude a tumor in the rectum before using any rectal or parenteral treatments for constipation.

Dyspnea

Breathlessness or dyspnea often occurs in the last days of life in palliative patients, but it may also be present in end-stage COPD patients well before then.

Nonpharmacological management strategies found to be helpful for breathlessness include positioning changes and reassurance; however, often these are not sufficient alone to ease symptoms.

Morphine is used as first-line treatment, generally orally, and in low doses (2–10 mg when required) (Barnes et al., 2016). Patients who are already prescribed oral morphine for pain relief may be converted to a CSCI of morphine for pain relief and a small dose of oral morphine prescribed for breathlessness. Those patients on fentanyl or oxycodone for renal impairment may also use low-dose oral oxycodone or nasal fentanyl for their symptoms. In the anxious patient, addition of a short acting benzodiazepine such as oxazepam or lorazepam may be beneficial (Palliative Care Expert Group, 2016).

If symptoms persist or are unrelieved by oral morphine, then midazolam may be used, either added to the CSCI or as a nasal spray. Oxygen if the patient is hypoxic, and if available, is often a comfort, as is a fan blowing air near the patient's head (McLeod et al., 2016).

Respiratory Secretions

Patients who are in the last days of life are frequently unable to cough or swallow in order to clear their airway. As such, respiratory secretions may cause noisy breathing and rattling sounds in the throat.

First-line treatment is to reposition the patient, to allow the patient to expel the secretions more easily and allow drainage. Keep the oral mucosa and airways clear by using oral swabs if the patient is not able to swallow, and direct a fan to keep air blowing near the patient's head.

If this is not sufficient to manage symptoms, then use of anticholinergic agents such as hyoscine butylbromide, glycopyrronium, or hyoscine hydrobromide may be indicated. These agents can reduce the production of new secretions, but will not affect existing secretions (Palliative Care Expert Group, 2016).

The use of anticholinergic agents is less invasive than using suction to clear the build-up of fluid (NICE Guidance, in press).

Delirium can be described as altered consciousness, generally manifesting as a reduced ability to be aroused or orientated to the environment (DSM V, in press).

In palliative care, terminal agitation or restlessness can be defined as agitated delirium with cognitive impairment (Chand, 2014). These symptoms may be caused by multiple conditions, for example raised intracranial pressure, hypercalcemia, medications, organ failure, or psychological distress. These conditions are common when patients are dying and may be acutely distressing to the family

as well as the health care professionals involved in the care of that patient. Generally, delirium and terminal agitation are treated with benzodiazepines. For patients not on a syringe driver, sublingual lorazepam or nasal midazolam is useful; for patients on a syringe driver, midazolam, haloperidol, and levomepromazine are all used.

Assessment is the key to managing symptoms and quality of life in the dying patient. Using tools such as the *PQRST* tool discussed in relation to assessing pain can be applied to all conditions that the dying patient is aware of, as well as asking if there is anything "new" that they have noticed or that their carers are aware of. Determining if a treatment is working is key to symptom management, and will guide you as to total pharmaceutical and nonpharmaceutical management strategies for the variety of symptoms that the patient may be experiencing. Drowsiness may mean to review or reduce the amount of opioid analgesic, antiemetic, or anxiolytic used. Increasing pain, colic, or nausea may mean to increase doses or change therapies. Do not forget that other members of the health care team caring for that patient may have some solutions that can be helpful to consider.

Role of the Pharmacist

The role of the community pharmacist, when the patient is managed in a "hospice in the home" environment rather than an inpatient unit is key, as the pharmacist often knows "their patient" and family, and will have insight as to changes, past and potential treatments; as well as a relationship where the patient and their family may feel safe discussing complementary, "natural" or alternative therapies. These must be taken into account when compiling the current list of medications taken by the patient, as some may be hindering as much as helping symptom management.

In New Zealand, hospices are not fully funded by the state. The management boards of hospices frequently include general practitioners, community pharmacists, and other health care providers in the locale, particularly in rural areas where in-patient beds are with rest homes or aged care facilities that can offer a hospital level of care. All other palliative patients spend their last days and weeks at home, in the care of their family and friends as well as the team of health care professionals involved in filling the anticipated needs of the patient. In these cases, admission to hospital is seen as a failure of hospice care, as hospitals are not always located in convenient proximity to all patients in need of secondary and tertiary level care. Rural hospitals, unlike hospitals (which are generally located in or near city centers), do not have specialized medical and other health care professionals specifically trained in care of patients in their last days of life, as their focus is, in general, curative, not palliative. (Authors opinion, borne out in fact in the region where I currently work.)

Pharmacists working in the community, hospital, or hospice have unique skills in managing symptoms, particularly in the last days of life for patients. Determining the appropriate medications for continuous subcutaneous infusions (CSCI) in the correct diluent is key to good symptom management. The unique skills of pharmacists, particularly when medications used, are frequently for unapproved indications, doses, or routes of administration, that is, "off license." For example, in New Zealand, midazolam is approved as a premedication or a sedative, but it is not approved for use for hiccough or dyspnea, and its use either bucally or subcutaneously is not approved. There is, however, evidence for its use both in New Zealand and overseas exists, so this becomes "common practice" (Medsafe, in press; Canterbury NZ Health Pathways, in press). Consent is assumed to be given because the use of these medications is in the best interest of the patient, if they are unable to specifically consent to its use.

In New Zealand, in some areas, the District Health Boards in some regions have issued contracts for specifically trained community pharmacists to compound by aseptic transfer injections for use in a syringe driver. These services are not available nationwide; so, in the remainder of New Zealand, medications are dispensed from community pharmacies for those patients requiring CSCI and "when required" subcutaneous injections, and the injections are prepared in the patient's home, usually by a hospice or "district nurse" immediately before use.

A training program for community pharmacists was set up in New Zealand in the early 1990s, by a pharmacist at Auckland Hospital, Julia Kennedy. This allowed for skills and training material to be developed and this service was available to pharmacists who wanted to be involved in continuing care for their patients. The service continued to grow, as did the number of pharmacists interested in palliative care. All hospices in the Auckland region have developed great relationships with the community pharmacists delivering this service and are seen as key members of the palliative care team.

When a new School of Pharmacy was opened at the University of Auckland, specific training on aseptic training was included as a core skill for their graduates. As a result, all graduates from the Auckland School of Pharmacy have been trained and validated in aseptic transfer, and CSCI preparation and principles.

Remuneration for the syringe driver and "when required" subcutaneous medication syringes for community pharmacies that provide this service is based on the agreed dispensing fee under the service agreement for community pharmacy. Pharmacies are paid for each syringe prepared, the cost for complete ampoules of each ingredient, and a four-fold dispensing fee to cover the facilities, training, extra time, and consumables involved in syringe preparation. As such, provision of palliative care dispensing is seen by pharmacists as a service to their patients, in providing more seamless care, rather than a profit center for their pharmacy.

All pharmacies providing this service are suggested to subscribe to www.palliativedrugs.com as well as have access to the current Palliative Care Formulary and Notes on Injectable Drugs, produced by the New Zealand Hospital Pharmacists Association.

These resources provide compatibility charts for commonly used medications in syringe drivers, advice on symptom management and indications. The pharmacists actively involved with their local hospice also provide peer support for other pharmacists,

particularly those with less experience in the area. Regional hospital pharmacies can provide guidance and advice relating to management of patients if the nearest hospice does not have specialized pharmacists as part of their staff.

The role of the pharmacist in palliative care in the Australian setting is similar to that in New Zealand.

Medication reviews can be undertaken in the hospital as an outpatient, as well as in the home and aged care facility through government funded programs. An important part of regular medication review as the patient deteriorates is the rationalization of medications including ceasing those no long appropriate. Discussion with the patient and family is a key step in this process (Palliative Care Expert Group, 2016).

The provision of medicines information for patients and health professionals, and medicines reviews for palliative care patients by a pharmacist in the community palliative care team is an emerging role. Two projects have received government funding, with one role continuing (Hussainy et al., 2011; Kuruvilla, 2018).

The palliative care pharmacist needs to be aware of the complexities when changing an opioid, which may be a different route, or a different opioid. Opioid conversion resources are available but should be used as a guide only as patient factors such as age, frailty, renal, and liver function, and the clinical context need to be considered. The availability of modified release opioids, which are administered twice daily or once daily, influences the timing of the change also. As part of the regular assessment of the patient's pain, the pharmacist can monitor the response to the immediate release opioid for breakthrough pain and recommend dose modifications with a change in the background-modified release opioid.

A point of difference in practice is that the preparation of syringe drivers is undertaken by the nurse rather than the pharmacist. Guidelines for syringe driver management and education are available at https://www.health.qld.gov.au/cpcre/subcutaneous/learn_modules.

However, the role of the pharmacist is important as a resource to staff for advice regarding compatibility of medications used in the syringe driver, with access to appropriate references is required.

For the Australian palliative care pharmacist, an additional text or subscription recommended to www.palliativedrugs.org is the Therapeutic Guidelines: Palliative Care (Palliative Care Expert Group, 2016).

Fundamentals of Pharmaceutical Care Planning

S. Adele Print, University of Auckland, Auckland, New Zealand

Pharmaceutical Care—Historical Perspectives

The term pharmaceutical care was first introduced in 1975 by Mikeal et al., who defined pharmaceutical care as "care that a given patient requires and receives which assures safe and rational drug usage" (Mikeal et al., 1975). This was a decade after the new field of clinical pharmacy emerged, in response to the societal need to address poor medicines control systems in hospitals. "Patient-oriented" clinical pharmacists with specialist drug knowledge were contributing to decisions about medicines and gradually becoming therapeutic advisors for hospital clinical teams in large academic centers. The roles of clinical pharmacists slowly evolved, supported by formal residency training programs and Doctor of Pharmacy degree courses. Pharmacists trained through these programs developed both medicines and disease knowledge and the respect of their clinical colleagues, which enabled them to contribute to everything from medicine selection to therapeutic monitoring. Through the 1980s, the number of clinical pharmacists continued to grow and their roles continued to develop, with clinical pharmacists diversifying into a range of highly specialized roles (Kelly, 2018).

The 1985, the American Society of Health-System Pharmacists' Hilton Head Island conference, with Charles Hepler as keynote speaker, attempted to bring this increasingly dispersed field together. This became a defining meeting for the clinical pharmacy profession. For the first time, this meeting defined the roles and responsibilities of clinical pharmacists, including responsibility for the safe and effective use of medicines, leadership of scientifically informed medicine use, and promotion of the best use of medicines. Importantly, while defining the scope of clinical pharmacy, this meeting also identified technical roles that clinical pharmacists would usually supervise, such as drug control, ordering, and distribution (Kelly, 2018).

By 1989 when a second Hilton Head Island conference was held, clinical pharmacy had become a mature branch of the profession. At the conference, Hepler and Strand presented their seminal paper that suggested pharmacists needed to practice patient-centered care rather than drug-centered pharmacy, if they were to achieve their full professional potential (1990). They defined pharmaceutical care as "the responsible provision of drug therapy for the purpose of achieving definite outcomes which improve a patient's quality of life." In addition, Hepler and Strand suggested that to be effective, pharmacists required a philosophy of pharmaceutical care practice and a consistent organizational framework in which to work. This philosophy required pharmacists to accept a higher level of professional responsibility to ensure medicines use is effective and safe for individual patients. Core components to fully benefit patient care were identifying, resolving, and preventing medicines-related problems and cooperate effectively with other health-care professionals (Hepler and Strand, 1990).

As time progressed, with some debate along the way pharmaceutical care practice has progressively but variably penetrated all sectors of the pharmacy profession. The concepts of pharmaceutical care continued to evolve since 1990 and have become cornerstones of pharmacy education.

The definition of pharmaceutical care has also been redefined numerous times since 1990. A recent redefinition by the Pharmaceutical Care Network Europe group to address the lack of clarity on the current meaning of pharmaceutical care and how it differs from other terminology is "pharmaceutical care is the pharmacist's contribution to the care of individuals in order to optimize medicines use and improve health outcomes" (Allemann et al., 2014).

Although the use of the term pharmaceutical care has somewhat fallen out of favor in practicing pharmacists' vernacular, a myriad of concepts, terms and services have evolved which reference Hepler and Strand's vision. Examples of these include medicines optimization (NICE, 2015), medicines management, medication therapy management, quality use of medicines, medication review, medicine use review, and clinical checking (Cipolle et al., 2012; Bluml, 2005; Kanani and Churchill, 2019).

Pharmaceutical Care Practice

Given the rapidly evolving roles of pharmacists, competency in pharmaceutical care practice is needed now more than ever, across the profession. This section will first provide background to pharmaceutical care practice, then will summarize the current barriers and enablers of pharmaceutical care practice, before providing examples of settings in which pharmaceutical care practice can be applied.

Background to Pharmaceutical Care Practice

Medicines are the most common therapeutic intervention in health care. They of course play an essential role both in keeping people well and in treating illness when it occurs. However, when used inappropriately, medicines-related problems and adverse effects cause significant harm. The cost of medicines is continually rising yet the full benefits are not being realized. Up to half of medicines prescribed for long-term conditions are not used by patients as the prescriber intended, or are not taken at all (Nieuwlaat et al., 2014). Appropriate, safe, and cost-effective use of medicines is a priority for policymakers globally (Härkänen et al., in press).

Potential misuse of medicines is being exacerbated by rapid change in health-care systems around the world. Health systems are currently facing a number of significant challenges: an ageing and rapidly growing patient population with significant health inequities, increasing burden from long-term conditions with multimorbidities, rapid implementation of more complex and expensive new therapies, delivered by an ageing health-care workforce not resourced to provide sufficiently patient-centered care (Traulsen and Druedahl, 2018). It is clear that global health needs are not able to be met within current capacities and models of care. The pharmacy profession has been identified by policymakers as providing a relatively untapped resource to address these problems (Kanani and Churchill, 2019; Ministry of Health NZ, 2016a). Assessing the effectiveness of pharmacists applying pharmaceutical care principles to address these problems is challenging, due to the wide range of practice models and services undertaken and inconsistent outcome measures. Nevertheless, across all sectors of health care, pharmaceutical care has been shown to reduce mortality and morbidity and optimize patient outcomes to a range of patient groups, as well as improving quality of life, reducing adverse drug reactions and providing economic benefits (Babar et al., 2018; Jokanovic et al., 2016; Perlroth et al., 2013).

Current Barriers of Pharmaceutical Care Practice

While globally many pharmacists strive to practice using pharmaceutical care ideology and principles, as they take on a growing number of innovative services, pharmaceutical care practice is still not the norm globally. One common reason is that funding models to fully support pharmaceutical care practice are not consistently available. Many pharmacists therefore do not have the opportunity to maintain competence with the required knowledge and skills. In community pharmacy, maintaining financial viability can generate a tension between retail and professional roles (Scahill et al., 2018) with a supply focus remaining prevalent in some community sectors; therefore, technical tasks sometimes need to take precedence over time required for cognitive services (Davies et al., 2014; Traulsen and Druedahl, 2018). In hospital pharmacy practice, patients transition at much higher pace than they did previously, often without a commensurate increase in pharmacy resources, so time to provide adequate pharmaceutical care services has reduced (Dalton and Byrne, 2017).

Current Enablers of Pharmaceutical Care Practice

As described above, more than ever before pharmacists are being recognized as capable of playing a vital role to support peoples' health and well-being. There are a growing number of services being provided across all sectors where pharmaceutical care skills can be utilized (Kanani and Churchill, 2019). The development of extended roles for pharmacy technicians through workforce redesign initiatives has enabled this valuable group to contribute to a greater extent to patient care; for example, with prescription accuracy checking, medication history taking, and providing education to patients. The developing roles of pharmacy technicians and assistants can free up pharmacists to perform more cognitive roles (Keresztes, 2006; Napier et al., 2018).

Examples of Settings in Which Pharmaceutical Care Practice Can Be Applied

In many parts of the developed world, legislative changes and the reclassification of medicines have expanded and extended the scope of pharmacist practice, introducing novel roles. These include the provision of pharmaceutical care within general practice and

aged residential care home settings (Chaplin, 2016; Tan et al., 2013). Pharmacists are increasingly providing pharmaceutical care to vulnerable populations with high health needs such people with intellectual disability (Auckland District Health Board, 2016; Bell et al., 2015), substance misuse, and mental health disorders (McMillan et al., 2017). Pharmacists are now able to utilize their pharmaceutical care skills to a greater extent by prescribing medicines in a number of countries (Shaw et al., 2013).

Pharmaceutical Care—Educational Aspects

To provide quality-assured pharmaceutical care services in any of the settings described above requires pharmacists to be appropriately trained and competent. Pharmaceutical care requires competence in comprehensive patient consultations and medication review, which in turn require skills in person-centered communication and patient assessment, and competent use of frameworks to facilitate consistent pharmaceutical care planning, in addition to the currently recognized pharmacy science, clinical pharmacy practice, and pharmacotherapy subjects. This section will first of all outline the changing expectations of pharmacists, which dictate a change in pharmaceutical care education. The educational benefits of formal pharmaceutical care planning frameworks will then be discussed, followed by the pharmaceutical care learning and assessment needs of both pharmacy students and experienced pharmacists in practice.

Changing Expectations for Pharmaceutical Care Skills

Health-care systems expect consistent quality-assured practice by competent health professionals, which requires both appropriate initial training and assessment and ongoing continuing professional development (Bader and Bates, 2017). Health-care systems also expect that as professionals, pharmacists will continually strive to improve their services, which increasingly includes the pharmaceutical care they provide. In most countries, these qualities are embedded in core competencies defined by the pharmacy profession's regulatory body, linked to the accreditation standards of pharmacy schools and colleges.

As outlined above, roles of pharmacists are changing rapidly. For example, in the United Kingdom, the National Health Service Long Term Plan expects pharmacists to now provide enhanced services that will require person-centered communication skills, additional patient assessment skills, and in some cases prescribing (Kanani and Churchill, 2019). For example, in New Zealand, government policies have refocused on improving access to health services, reducing inequities and increasing sustainability, through new models of practice and a more agile workforce (Ministry of Health NZ, 2016a). The New Zealand Ministry of Health has recognized the value of pharmacists in achieving these goals, and a Pharmacy Action Plan outlines a program of reforms to make better use of pharmacist skills (Ministry of Health NZ, 2016b). As part of this plan, new services are being developed where the pharmacy profession will provide person-centered pharmaceutical care to a much greater extent than it does currently.

However, pharmacists, although highly capable, are recognized as having some learning needs important for person-centered pharmaceutical care roles. Traditionally, pharmacists were not taught person-centered consultation skills, where the focus is on engaging with patients and explore their medicines experiences in order to support them make the best use of their medicines. Learning how to effectively gather information from and provide education to patients has been more usual (Murad et al., 2014). Teaching of patient assessment skills for the purposes of diagnosing and assessing long-term clinical conditions was not commonplace (George et al., 2006). In addition, pharmacists have limited training in precision medicine, where new diagnostic modalities including genomics are used to inform prescribing and prevent medicines-related problems. To meet the new expectations of enhanced skills in pharmaceutical care requires a step change in their learning. For example, the complex skills of clinical reasoning are well researched and systematically taught in medicine and other health professions (Higgs et al., 2018) and are relevant to all aspects of pharmaceutical care planning. However, clinical reasoning remains an emerging and inconsistently taught area for pharmacy (Sinopoulou et al., in press; Wright et al., in press). In addition, team working skills to enable pharmacists to be effective member of health-care teams, while clearly a part of every pharmacists work, may now require reinforced education to support expended pharmaceutical care roles. This education may include formal evidence-based methods to promote safe and effective written and verbal communication, more formal documentation of pharmaceutical care plans, and increasing use of shared patient records with other health professionals.

Above all, to meet these expectations, pharmacy schools and colleges, professional bodies, and governance organizations will in future more than ever need to work together to align the teaching, practice, and assessment/accreditation of pharmaceutical care (Kolar et al., 2017). This will also require a coherent professional identify of pharmacists that incorporates pharmaceutical care as a core skill and activity. At present, the professional identity of pharmacists, and presumably the place of pharmaceutical care practice in their identify, appears to be unclear—this is an area of current research interest.

Pharmaceutical Care Planning Education for Pharmacy Students and Experienced Pharmacists

The pharmacy profession is still transitioning to a position where pharmaceutical care is routine practice in all sectors. This has three consequences for pharmacy education. First, the curricula in some pharmacy schools and colleges are yet to align with the range of roles that may be available to pharmacy students at the time of their graduation. Second, where pharmacy educators are already delivering curricula in which person-centered pharmaceutical care is a key component, they may be preparing students for pharmaceutical care roles that are not yet universally available. Third, pharmacy students may face challenges during their

experiential placements, since not all pharmacists they are placed with will use pharmaceutical care skills. Some students have reported being discouraged from using pharmaceutical care skills by both supervising pharmacists and patients.

In one study, approximately one-quarter of pharmacy student participants reported that their pharmacist supervisors actually discouraged them from even fundamental person-focused practices such as educating patients, which led some of the students having difficulty establishing their pharmacist professional identity (Noble et al., 2014). One approach to these challenges is to openly acknowledge them. Given the transitional nature of pharmacy, it seems sensible to teach pharmaceutical care skills using a range of practice scenarios so that students see how the process can be contextualized to different settings. In pharmacy schools and colleges, ideally pharmaceutical care planning using formal frameworks can be taught intentionally and consistently throughout each program (Kolar et al., 2017). Use of a range of case scenarios can challenge students to apply their nascent pharmaceutical care skills to increasingly more complex medicines-related problems (Farrell et al., in press). This contrasts with curricula that select case scenarios primarily to promote learning about diseases and evidence-based treatment options.

As described above, the current transitional nature of pharmacy means that some experienced pharmacists who have practiced primarily in dispensing roles may need upskilling in pharmaceutical care through continuing professional development. As in pharmacy schools and colleges, the use of a formal pharmaceutical care framework, together with a range of practice scenarios, may be valuable for this continuing education in pharmaceutical care. In addition, case scenarios could be included in regular assessment of pharmaceutical care for practicing pharmacists, as part of the quality assurance programs that are increasingly required by health-care funders. Whether or not ongoing assessment of pharmaceutical care planning skills is formally required, as professionals most pharmacists are likely to seek evaluation of their pharmaceutical care effectiveness, as well as opportunities for ongoing learning. As noted above, formal pharmaceutical care planning frameworks that can be applied to both real patients and case scenarios facilitate both the consistent quality-assured application of pharmaceutical care planning and ongoing evaluation.

Pharmaceutical Care Planning

For the purposes of this chapter, the term pharmaceutical care planning refers to the patient care processes or frameworks through which the pharmacist identifies, resolves, or prevents potential or actual medicines-related problems.

As noted above, there are a large number of pharmacy practice models and services utilized throughout the world that aim to improve patient health outcomes and are informed by the concept of pharmaceutical care. Not surprisingly, there are a corresponding array of approaches to how the activity or service should be conducted, presented as guidance documents, templates, and practice standards. Many contain detailed checklists of points to consider when reviewing patients, rather than overarching frameworks that support clinical reasoning.

A significant initiative in the United States has been the development of the Pharmacists' Patient Care Process (PPCP) by a group of national pharmacy organizations led by the Joint Commission of Pharmacy Practitioners (JCPP) (2014). The JCPP is a national forum of leading pharmacy organizations in the United States. This model is described below as an example of a framework that lends itself to a systematic and consistent approach to pharmaceutical care planning.

The PPCP came about from the recognition of a need for a consistent process for pharmacists and educators that could be applied to any practice setting and service in the delivery of patient care. The Accreditation Council for Pharmacy Education now requires that the PPCP as described by the Joint Commission of Pharmacy Practitioners is included within college of pharmacy curricula.

The model is based on Hepler and Strand's concept of pharmaceutical care and pharmacists using the PPCP are expected to "collaborate, communicate, and document" to optimize patient health outcomes. A person-centered theme is evident throughout, and it is intended that pharmacists support patients to be engaged and involved in their care. While the PPCP is intended to be used in all patient care settings, the time spent on each step and intensity may vary depending on need. The model includes a five-step process, depicted in **Fig. 1**.

The model includes a five-step process:

- Step 1—Collect: Using a person-centered approach, the pharmacist collects necessary subjective and objective information.
- Step 2—Assess: The pharmacist analyzes the information collected in context with the patient's own health goals to identify and prioritize medicine-related problems.
- Step 3—Plan: A person-centered, evidence based, cost-effective care plan is developed in collaboration with the patient or caregiver and other health-care providers.
- Step 4—Implement: The pharmacist implements the care plan in collaboration with the patient or caregiver and other health-care providers.
- Step 5—Follow-up: Monitor and Evaluate: The pharmacist monitors and evaluates the effectiveness of the care plan and makes adjustments as necessary, again in collaboration with the patient or caregiver and other health-care providers.

Further information on the Pharmacists' Patient Care Process can be found in the "Further Reading" section.

The Use of Frameworks and Scaffolds for Effective Pharmaceutical Care Planning

The Pharmacists' Patient Care Process can appear deceptively simple to use; however, pharmaceutical care planning involves a series of complex clinical reasoning steps within the overarching frameworks. Clinical reasoning can be described as "an evidence-based,

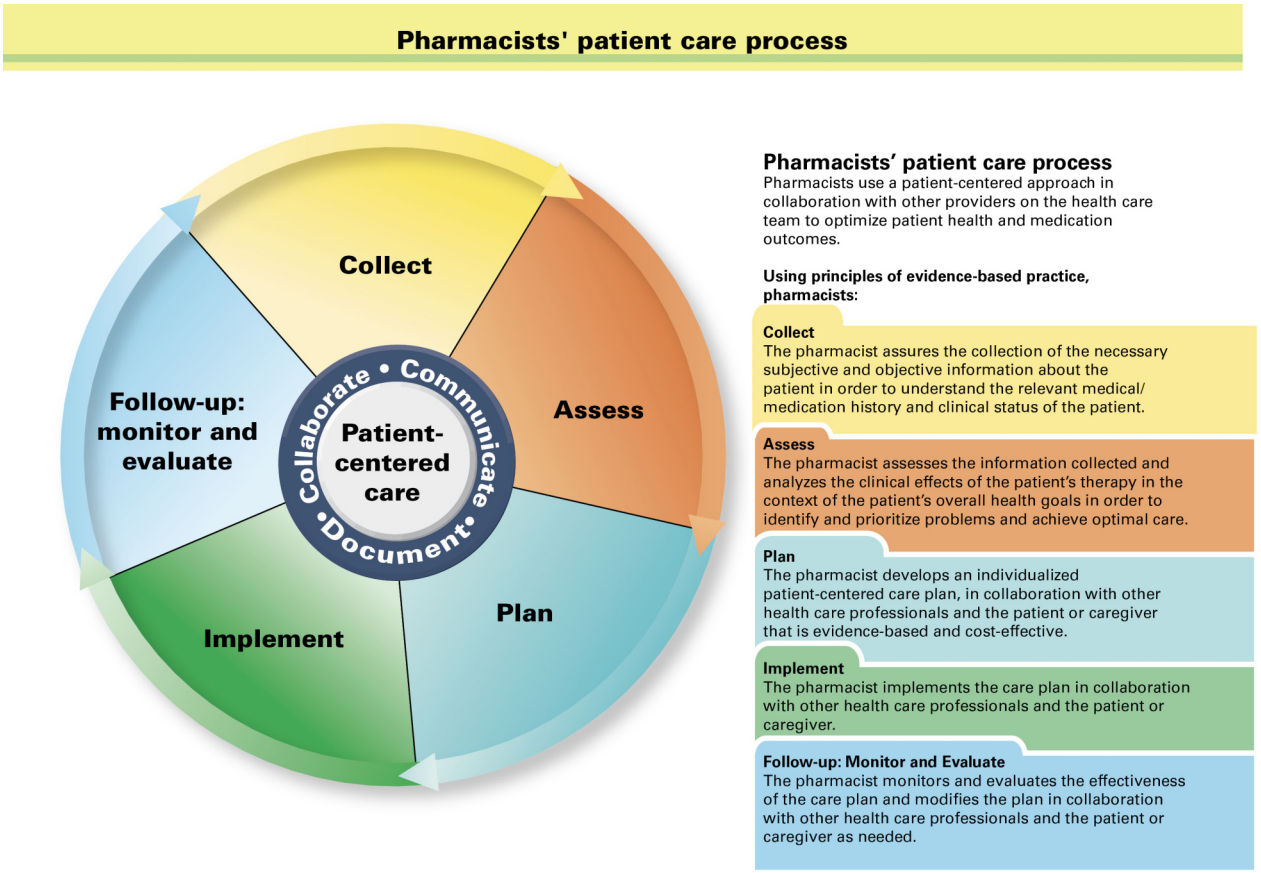

Figure 1 Pharmacists' patient care process (Joint Commission of Pharmacy Practitioners). *Source: Reproduced with permission from: http://www.pharmacist.com/sites/default/files/JCPP_Pharmacists_Patient_Care_Process.pdf.*

dynamic process in which the health professional combines scientific knowledge, clinical experience, and critical thinking, with existing and newly gathered information about the patient" (Sinopoulou et al., in press). Clinical reasoning is required to consider which patients should be targeted for review; the gathering and analyzing of information; generating hypotheses for identifying, prioritizing, and resolving of medicine-related problems; deciding on how the care plan should be enacted; and what follow-up is required, by whom and when.

There is evidence that targeted learning scaffolds are beneficial for novice learners, such as pharmacy students, newly qualified pharmacists, and experienced pharmacists moving into new roles and clinical areas. Scaffolding is "the systematic sequencing of prompted content, materials, tasks, and teacher and peer support to optimize independent learning, it can include instructional elements such as guided questioning; comparing ideas; identifying connections and distinguishing characteristics between concepts; and identifying valid relationships." (Dawn et al., 2011).

The combination of an overarching framework where the big picture can be seen (for example, with the PPCP), combined with targeted learning scaffolds to support clinical reasoning (Higgs et al., 2018), should be considered to promote systematic and consistent learning of pharmaceutical care planning. While formal scaffolds may seem time consuming at first, they promote conceptual learning and reduce the possibility of learning pharmaceutical care planning using flawed clinical reasoning processes once the pharmacist uses a more intuitive approach. As an individual's pharmaceutical care planning skills develop and decision making becomes more intuitive and the scaffolds can be finessed for various clinical contexts.

Students and novice pharmacists can find it challenging to know where to begin when identifying actual or potential medicine-related problems. Examples of frameworks and scaffolds that support a systematic approach to pharmaceutical care planning are provided below.

Medicine-Related Problems Classification Systems

Identifying, resolving, and preventing medicine-related problems (MRPs) is a core component of pharmaceutical care planning. A medicine-related problem has been defined by the Pharmaceutical Care Network Europe as "an event or circumstance involving drug therapy that actually or potentially interferes with desired health outcomes" (van Mil et al., 2017). The use of medicine-related problem or drug therapy problem classification systems is useful to provide a systematic process to identify actual or potential

problems when reviewing a patient's therapy. Some MRPs are more obvious to identify, for example, when a significant medication overdose has unintentionally been prescribed. This may "jump out from the prescription" and prompt the pharmacist to query with the prescriber. Other MRPs can be almost hidden, for example, when venous thromboembolism (VTE) prophylaxis has been inadvertently not considered for a patient at high risk of experiencing a VTE event. It will be missing from the patient's medicine list and may not be thought of.

Unfortunately, many different MRP classification systems have been developed and published, this makes it challenging for pharmacists to learn and use a consistent approach to identifying MRPs and enable comparison of pharmaceutical care services. Nevertheless, MRP classification systems are a useful aid for pharmacists to systematically identify actual or potential MRPs. Basger et al. (2015) have recently developed an aggregated classification system for the causes of MRPs.

The MRP classification system first described by Strand, Morley, and Cipolle et al. is still very relevant (1990). Detailed guidance on the use of this classification system can be found in the Further Reading section below (Cipolle et al., 2012). They identified four unmet medicine-related needs—indication, effectiveness, safety, and adherence. A corresponding list of seven categories of drug therapy problems are associated with these unmet needs:

- Drug therapy problems 1 (unnecessary drug therapy) and 2 (needs additional drug therapy) are associated with the medicine-related need indication;
- Drug therapy problems 3 (ineffective drug) and 4 (dosage too low) are associated with effectiveness;
- Drug therapy problems 5 (adverse drug reaction) and 6 (dosage too high) are associated with safety;
- Drug therapy problem 7 (nonadherence or noncompliance) is associated with adherence.

Categories of Factors to Consider When Identifying Medicine-Related Problems

Table 1 provides a method of systematically identifying problems based on four categories—patient factors, disease factors, medicine factors, and factors related to the environment or system the patient is within.

Table 2 provides some illustrative examples from each of the four categories of factors of actual medicine-related problems that need resolving.

Screening Tools and Guidance Documents to Support Prescribing Appropriateness and Identification of Medicines-Related Problems

A wide range of guidance documents and screening tools have been developed to assess the appropriateness of medicines prescribed for individual patients. Examples include guidance for reducing inappropriate polypharmacy such as the screening tool of older people's prescriptions (STOPP) and screening tool to alert to right treatment (START) criteria; the Beers Criteria; the Medication Appropriateness Index; and deprescribing guidelines. These are useful to complement the clinical reasoning processes utilized

Table 1 Categories of factors to consider when identifying potential or real medicines-related problems

Patient factors	Factors related to the patient themselves, for example, their medicines taking experience, health beliefs, understanding of health and medicines, health literacy, demographics, ability/disability, social circumstances, lifestyle
Disease factors	Factor's related to the patient's health status, for example, current and past medical history, known allergies, or adverse drug reactions, comorbidities
Medicine and prescription factors	Factors related to the patient's medicines—medicine interactions, pharmaceutical and/or formulation issues, funding, prescription legality
Environment and system factors	Factors related to the system or environment the patient is situated in, for example, medication reconciliation errors experienced when transitioning care settings

Reference—Print SA, i.e., author's original work.

Table 2 Illustrative examples of medicine-related problems identified using the factor categories

Patient factors	The patient was unable to afford the prescription fee so was unable to collect his prescription for antibiotics from his community pharmacy
Disease factors	Patient is taking a calcium channel blocker (diltiazem) for hypertension; he has now developed heart failure with reduced ejection fraction. Diltiazem may worsen this comorbidity, and the patient therefore requires an alternative blood pressure medication
Medicine and prescription factors	A one-year-old child has been prescribed a cardiac medicine that is only available in capsule form; therefore, a compounded mixture is required to be prepared
Environment and system factors	An older patient was admitted into hospital from her residential care facility with community-acquired pneumonia. One of her usual medicines was prescribed incorrectly (anticonvulsant medicine for her epilepsy inadvertently left off the hospital prescription chart). This was identified by the pharmacy technician during a medicines reconciliation review. The prescribing pharmacist reviews the patient's medicines history and corrects the error

Reference—Print SA, i.e., author's original work.

during pharmaceutical care planning, and there is some evidence of benefit in terms of preventing adverse drug events, improving medicine appropriateness, and reducing medicine costs (O'Mahony et al., 2014; Rankin et al., 2018).

Tools to Promote Safe and Effective Interprofessional Communication

A number of communication tools such as SBAR (situation, background, assessment, and recommendation) and SOAP (subjective, objective, assessment, and plan) have been developed in order to provide structured frameworks for safe and effective communication between health-care team members (Barnett et al., 2017; Reeves et al., 2017; Shahid and Thomas, 2018).

Future Aspects and Threats

As discussed above, around the world pharmacy as a profession is rapidly changing, with expanded expectations for pharmacists to provide pharmaceutical care. This represents both an opportunity and a threat.

The opportunity is for pharmacists to grow the value they provide to individual patients and health-care systems through person-centered pharmaceutical care. This is especially relevant at a time of major health service challenges. Advances such as automation for dispensing, increased ability to share patient information between health-care providers, "telehealth" consultations for rural patients, pharmacogenomics, artificial intelligence to identify obvious medicine-related problems and guide decisions, as well as expanded technician roles can be harnessed by pharmacists to increase the effectiveness of their pharmaceutical care practice (Spinks et al., 2017). By taking opportunities to expand the scope and quality of their pharmaceutical care in an evidence-based manner, pharmacists have a real but time-limited prospect to jointly lead the new age of precision medicine.

The threat is that if the pharmacy profession does not rise to changing expectations and utilize the new opportunities described above, many pharmacist roles could be lost with the pharmacy profession becoming less relevant (Spinks et al., 2017). Pharmaceutical care practice could cease to be the domain of pharmacists, being overtaken by medicines management roles performed by other health-care professionals. Health systems would be poorer without the skills and academic background of the pharmacy profession.

Conclusion

Since it has been only 30 years since the concept of pharmaceutical care became widely introduced, the pharmacy profession is still transitioned from a focus on medicines to a focus on patient care. Due to inconsistencies in implementing pharmaceutical care, unclear perception of pharmacist roles and inconsistent opportunities for education, pharmaceutical care is still only practiced by a subset of pharmacists globally. In addition, the pharmaceutical care concept originally envisaged by Helper and Strand has evolved into a range of disparate models and services. While these models and services have commonality in their intention to optimize medicines and improve patient outcomes, they use varied methodological approaches and outcome measures. This means that pharmaceutical care, when it is performed, is inconsistent in style and depth, making quality assurance and proof of worth difficult. At the same time, health-care systems face increasing challenges and the viability of the traditional pharmacist roles focused on dispensing and technical functions outside of a person-focused framework are coming under increasing threat. On the up side, the pharmacy profession is very well placed to utilize new opportunities and technologies for repositioning itself as the leader of pharmaceutical care practice within health-care teams. A transformative change in both pharmacy practice and education could prepare the pharmacy workforce for the future. Hopefully, through a refocus on the philosophy of pharmaceutical care, pharmacists will achieve Helper and Strand's vision of meeting an urgent societal need by supporting people to get the best out of their medicines. As a side effect, a focus on pharmaceutical care could ensure the profession's long-term value and sustainability.

Health Outcomes and Quality of Life

Mohammed A. Mohammed*, Rebekah J. Moles†, Jeff Harrison*, Timothy F. Chen†, *The University of Auckland, Auckland, New Zealand; †The University of Sydney, Sydney, NSW, Australia

Introduction

Improvements in socioeconomic status coupled with advances in medical interventions and public health services have contributed to a significant increase in life expectancy, especially in high income countries (Christensen et al., 2009; Salomon et al., 2012, Centers for Disease Control and Prevention, 2003). As a result, people in the older age groups have become the fastest growing age groups, making the 21st century a "century of ageing" (Salomon et al., 2012; World Health organization, 2002). Population estimate data indicate that a quarter of the population in western countries will be aged ≥60 years by 2030 and this figure is projected to be 2 billion by 2050 (Payne et al., 2013; World Health organization, 2002).

Although the increase in life expectancy may be considered one of the great achievements of humankind in the 21st century, it may also contribute to social, economic, and health systems challenges. Longevity of life is often at the expense of an individual's quality of life due to the accompanying ageing and age-related problems. Therefore, as a growing proportion of the population is surviving longer, often with multiple chronic diseases (Islam et al., 2014), the impact on HRQoL is a significant consideration. Chronic disease is associated with increased risks such as mortality, frequency of emergency department visits, unplanned hospital admissions and longer hospital stays, and increased utilization of health care resources (Condelius et al., 2008; Hwang et al., 2001; Lee et al., 2007; Payne et al., 2013, Centers for Disease Control and Prevention, 2003). Having multiple concurrent chronic diseases often leads to poor functional status and decreased quality of life, psychological distress, prescribing of multiple medicines (often polypharmacy and hyper polypharmacy), and adverse drug events (Bayliss et al., 2004; Hwang et al., 2001; Payne et al., 2013; Valderas et al., 2009; Wolff et al., 2002).

Over the past few decades, the rise in the prevalence of chronic disease has become the major public health issue, drawing the attention of health care policy makers and practitioners (Centers for Disease Control and Prevention, 2003). Equally, in concert with the demand and focus of chronic disease management, there has been a move toward slowing disease progression and minimizing functional limitations due to the burden of multimorbidity. However, in meeting this demand, health care systems continue to face structural, organizational, and financial challenges (Fortin et al., 2007; Islam et al., 2014; Schoen et al., 2009). To date, tackling the burden of chronic disease remains a key global health agenda, demanding more research, better delivery of health care services, organizational reform, and re-thinking health care policy (Fortin et al., 2007; Norris et al., 2008; O'Brien

et al., 2011; Sipkoff, 2003; Valderas et al., 2009). In recent years, the emphasis on health care policy has turned to "active aging and healthy living" so that individuals can remain active participants in the society as they become older (Clemson and Laver, 2014; World Health organization, 2002). Therefore, besides longevity, ensuring healthy life expectancy is a key consideration for ageing and its related burden at individual, society, and health care systems. However, in complex and dynamic health care systems, a variety of factors may compromise the quality of health care services. Thus, evaluation of key outcomes associated with health care services and interventions has been a growing area of interest to help ensure informed decisions related to health care practice and policy.

Health Outcomes

Health outcomes refer to the impact that health care services may have on people's life. It encompasses all outcomes or end results associated with health care services. The Donabedian framework for evaluating health services is divided into *structural, process, and outcome indicators* (Donabedian, 1988). The evaluation of health care services has traditionally focused on structure and processes measure. But it is outcome measures which provide insight into the impact of health services or interventions on a patient's life from which informed choice of the service and allocation of resources can be made. Types of evidence may include: what impact does a given health care service have on patient's symptoms and functioning, whether a given disease gets better or worse, and ultimately whether patients live or die as a consequence of the service. The overall focus of health outcome is, to question and investigate end results obtained from what is done for patients and how the end results impact on patient's lives.

Types of Outcomes

Outcomes of health care interventions can be described in different ways. The five D's (death, disease, disability, discomfort, and dissatisfaction) is the classical approach, but is used less in contemporary outcome research (Lohr, 1988) for two main reasons. First, this approach captures only limited outcomes in evaluating the quality of health care. Second, it does not reflect any positive outcomes of health care interventions. The Economic, Clinical and Humanistic Outcome (ECHO) model is a more comprehensive and suitable approach, particularly for the evaluation of pharmaceutical care services (Kozma et al., 1993).

Economic outcomes consider the direct, indirect, and intangible costs associated with health care interventions. Models of health economics which apply economic principles to health are used to evaluate economic outcomes of health care interventions. Health economic models of analysis, for example, cost benefit analysis, cost effectiveness analysis, cost minimization analysis methods, have been widely used to evaluate the economic value of the health care services at patient, societal, and health care system levels. Evaluation of economic outcomes in clinical pharmacy interventions is necessary to establish evidence about "value for money" in relation to the allocation of resources and reimbursement of services. For example, the benefit of the service (e.g., number of days free of pain, cases cured, and prevention of medication related complications) worth the cost or extra cost incurred by provision of the service. To date, there is significant body of evidence generated from research into evaluation of various models of clinical pharmacy services indicating the economic benefits of the service to the patient and health care system (Cheng et al., 2013; Graabaek and Kjeldsen, 2013; Marra et al., 2017; McLean et al., 2003; Viswanathan et al., 2015).

Clinical outcomes are events that occur following a disease or treatment. Clinical outcomes are measured as changes in a patient's health and can be used to generate evidence about the clinical benefits of health care services. For example, disease related morbidity and mortality, adverse drug reactions, and medicine related hospitalizations, in addition to surrogate clinical outcomes such as changes in glucose levels, blood pressure, cholesterol levels (Cheng et al., 2013; Fernandez-Llamazares et al., 2012a,b; Jokanovic et al., 2017; Wal et al., 2013). There is a growing body of research evidence indicating the effectiveness of various models of clinical pharmacy services in improving clinical outcomes in various chronic disease conditions such as diabetes (Al Mazroui et al., 2009; Elnour et al., 2008; Johnson et al., 2010; Machado et al., 2007a; Pinto et al., 2014; Turnacilar et al., 2009; Viswanathan et al., 2015), dyslipidemia (Jokanovic et al., 2017; Paulos et al., 2005; Roughead et al., 2005a,b; Santschi et al., 2011; Tsuyuki et al., 2002; Turnacilar et al., 2009), hypertension (Aguwa et al., 2008; Cheema et al., 2014; de Souza et al., 2007; Machado et al., 2007b; Marra et al., 2017; Santschi et al., 2011; Wal et al., 2013), Heart failure (Korajkic et al., 2011; Koshman et al., 2008; Lopez Cabezas et al., 2006; Sadik et al., 2005; Viswanathan et al., 2015), asthma, and Chronic obstructive pulmonary disease (Jarab et al., 2012; Johnson et al., 2010; Ottenbros et al., 2014; Schulz et al., 2001; Wei et al., 2014; Zhong et al., 2014).

Humanistic outcomes focus on consequences of disease and treatment on patient's functional status and quality of life. Unlike economic and clinical outcomes, humanistic outcomes are subjective measures and often considered as patient reported outcomes (PROs). The term PROs encompass a wide range of important outcomes, including patient's experience of disease or treatment related symptoms, satisfaction with treatment, self-rated health status, the impact of disease and treatment on functioning and well-being. PROs are not only the most commonly used but also the best approach to measure the social, physical, and psychological impact of a disease and its associated therapy. Evidence generated from PROs data complement other indicators of health outcomes (i.e., clinical and economic). In some cases, PROs becomes the only practical end points (e.g., pain management) when there are no other observable biological markers of a disease or treatment. In outcome research, health related quality of life (HRQoL) tools are the most common patient reported measures used to evaluate effects of health care interventions, impact of disease and treatment on functioning and wellbeing.

An increase in life expectancy has resulted in a high demand for the evaluation of the quality of life extended due to medical interventions (Pennacchini et al., 2011). Quality of life (QoL) is an important outcome requiring attention, especially in older people with chronic disease conditions (Ernst et al., 2003; Kozma et al., 1993) and in people taking long-term multiple medicines (Bulpitt and Fletcher, 1994). Without evaluation of QoL, the evaluation of a given health care intervention is incomplete. For example, in older people with multiple chronic conditions, evaluation of outcomes of therapy based on biological criteria alone is inadequate. Similarly, measures of death rates or survival alone do not reflect a complete picture of changes in population health. A holistic evaluation of the effects of chronic diseases and its treatment go beyond biological or physiological outcomes and should also include other domains (e.g., humanistic outcomes) in order to gain a more complete picture of the impact of health care interventions (Ernst et al., 2003; Patrick and Bergner, 1990).

QoL and HRQoL: Historical Development

As medical treatments have increasingly extended length of life (Karimi and Brazier, 2016; Pennacchini et al., 2011) sometimes at the expense of the quality of life (Karimi and Brazier, 2016), measurement of QoL has become a key outcome to consider in clinical care. The term QoL began to appear in the medical literature in the 1960s (Elkinton, 1966; Pennacchini et al., 2011; Spitzer, 1987) and started to be utilized in clinical practice to facilitate decision making in the 1970s (Pennacchini et al., 2011). In 1977, the medical subject heading (MeSH) term for QoL was introduced in Medline as "a generic concept reflecting concern with the modification and enhancement of life attributes, e.g., physical, political, moral and social environment; the overall condition of a human life" (Pennacchini et al., 2011). Since then, there has been a growing interest in the concept of QoL in outcome research as well as clinical settings. The development of new measures with a focus on their psychometric properties (Guyatt et al., 1993) began to proliferate in the 1990s (Pennacchini et al., 2011). During this period (specifically in 1995), the world health organization (WHO) introduced a broader concept of QoL defined as "an individual's perception of their position in life in the context of the culture and value systems in which they live and in relation to their goals, expectations, standards and concerns" (1995). QoL is a broad concept encompassing health and nonhealth issues impacting on an individual's life. In health care interventions we are rarely interested in nonhealth aspects of QoL (Guyatt et al., 1993; Torrance, 1987) as they may not be affected by the disease and its treatment. Thus, nonhealth aspects of QoL are considered of less importance in decision making for health care providers, health care administrators, and health policy makers. This conceptual issue led to the introduction of a new concept of health focused measures of QoL known as HRQoL measures.

Currently, several definitions of HRQoL exist (Karimi and Brazier, 2016) based on various approaches and viewpoints. For example, HRQoL has been defined as "how well a person functions in their life and his or her perceived wellbeing in physical, mental, and social domains of health," "aspects of self-perceived well-being that are related to or affected by presence of disease or treatment," (Ebrahim, 1995) and "values assigned to different health status." Although these definitions have some differences in the interpretation of HRQoL concept, they all encompass the concept that HRQoL is an "aspect of QoL which is related to health, excluding nonhealth factors such as religion, politics and quality of the environment" (Guyatt et al., 1993; Torrance, 1987). Hence, HRQoL is a subset of QoL that is determined primarily by a patient's health status and influenced by health care interventions. Some HRQoL measures focus on a single concept such as emotional functioning while others consider such a concept as one aspect or dimension within a multidomain construct of the measure. There is less agreement about the number or types of dimensions that should be included in HRQoL instruments. However, the general consensus is that HRQoL is a multidimensional construct which includes physical social, psychological, and aspects of patients' health which can be affected by the disease or treatment. In the context of health-related outcomes, it is important to understand and distinguish the conceptual overlap between HRQoL and overall QoL (Karimi and Brazier, 2016). However, the term QoL and HRQoL are often used interchangeably in the literature (Karimi and Brazier, 2016; Spitzer, 1987) without making distinction of their basic differences (Cheema et al., 2014; Leplege and Hunt, 1997; Moons, 2004; Ware, 1995). Readers are advised to infer the implicit definition of a given HRQoL measure from the conceptual characteristics and the level of description of aspects of health the measure is intended to assess, i.e., health states or impairments of health by a disease or treatment.

Relevance of HRQoL Measures: Perspectives of Practice and Research

HRQoL is an outcome through which patients express their feelings and experiences about the impact of a disease and its treatment on their health and wellbeing (Petersson et al., 2013). HRQoL measures are used to obtain information about self-reported health status, that is, improvement or impairment in health status following a health care intervention (Guyatt et al., 1993). HRQoL measures are now commonly called patient-reported outcome measures (PROMs) indicating that patient's self-rated symptoms of the disease and treatment are included in the assessment. In clinical practice, HRQoL measures provide additional information which complement evidence obtained from clinical and biomedical investigations. In evaluating outcomes of therapy, HRQoL measures can be used to assess the impact of acute or curative treatment (e.g., number of days free of symptoms, impact of disease sequelae on productivity) as well as chronic or palliative treatments (e.g., measurement of improvement or deterioration in health status) (Badia and Herdman, 2001). However, in chronic treatment and palliative care where the goal of therapy is ameliorating symptoms rather than a cure, HRQoL becomes a primary outcome to evaluate the long-term impact of an intervention or therapy

(Badia and Herdman, 2001). Information collected from HRQoL measures provides insight into aspects of HRQoL that matters most to patients in relation to their medical condition and or associated therapy. Consequently, this helps to make informed decisions (Carlton and Kaltenthaler, 2011) about therapeutic modalities specific to dimensions of HRQoL requiring attentions of health care providers.

Types of Quality of Life Measures

Since 1990s, numerous HRQoL measures have been developed and used in outcome research including research into evaluation of clinical pharmacy services. These measures have been developed based on various conceptual as well as theoretical approaches and viewpoints. The measures can be broadly classified as generic or disease/condition specific measures (Guyatt et al., 1993).

Generic Measures

A wide range of generic measures are available for evaluation of HRQoL outcomes in medical interventions, e.g., the Medical Outcome Study Short Form Health Survey (SF-36) (Ware, 1995), EQ-5D, WHO-QoL, and Health Utility Index. These measures have been used extensively to evaluate the impact of pharmacotherapy and clinical pharmacy services (Mohammed et al., 2016a; Pickard and Hung, 2006; Pickard et al., 1999) with the SF-36 measure and EQ-5D the most widely used (**Table 1**) (Mohammed et al., 2016a). Conceptually, generic measures are designed to be applicable to all disease conditions (Guyatt et al., 1993), across diverse medical interventions and population groups. Thus, they are preferred measures to assess quality of life outcomes in patients with comorbidities irrespective of the combination of medical conditions (Guyatt et al., 1993). However, generic measures may not be suitable to detect the changes over time in HRQoL of a medical condition, that is, in patients with multimorbidity, the measures lack sensitivity and specificity to differentiate differences between an individual's medical conditions. For instance, despite some similarity between chronic obstructive pulmonary disease and asthma, the two conditions may cause different impairment to an individual's health. Hence, an insight into the burden imposed by an individual condition is obtained by using HRQoL measures specifically designed for that condition. These measures are known as disease/condition specific HRQoL measures (Guyatt et al., 1993).

Table 1 Measures of health-related quality of life (HRQoL) commonly used clinical pharmacy type interventions

Outcome measures	*Domains/dimensions*	*Number of items*
Generic measures		
SF-36	Physical functioning, Role physical, Bodily pain, General health, Vitality, Role emotional, Mental health	36 (12)
EQ-5D	Mobility, Usual activity, Self-care, Pain/discomfort, Anxiety/Depression	15
WHOQOL-BREF	Over all QoL and General health, Physical health, Psychological, Social relationships, Environment	26
PAT-5D	Walk, Hand, Daily, Pain, Feel	100
HUI3	Vision, Hearing, Speech, Ambulation, Dexterity, Cognition, Emotion, Pain & discomfort	45
Q-LES-Q	N/A	16
COOP-WONCA	Physical fitness, Social activities, Feelings, Change in health, Daily activities, Overall health	6
GWBI	General mood/affect, Life satisfaction/vitality, Poor physical health/somatic complaints	22
Health Status		12
Nottingham Health Profile	Emotions, Sleep, Social isolation, Energy, Mobility, Occupation, Social life, Home life, Sex life, Hobbies, Holidays	45
Disease specific		
Heart failure		
MLHF	Physical dimension, Emotional dimension, Overall score	21
CHQ	Dyspnea, Fatigue, Emotional function	16
Hypertension		
HTN/Lipid form 5.1		11
HTN specific Bulpitt Q		46
Diabetes		
DQOL	N/A	15
ADDQOL	Self-care behaviors, Satisfaction with diabetes	13
Gastrointestinal disorders		
GIQLI		36
Asthma		
AQoLQ-J		32
AQLQ-M		20
CAQ		21
PAQLQ		23
LWAQ		68

Table 1 Measures of health-related quality of life (HRQoL) commonly used clinical pharmacy type interventions (*cont.*)

Outcome measures	*Domains/dimensions*	*Number of items*
Chronic obstructive pulmonary disease		
SGRQ	Symptoms, Activity, Impacts	17(58)
CAT		8
Cancer		
QLICP-GM	Physical function, Psychological function, Common symptoms and side effects	32
EORTC QLQ-C30	Physical, Basic physiological function, Sexual function, Independence function, Psychological domain, Emotion, Recognition, Social domain, Social support and safety, Effects on life and economics, Common symptoms and side effect, Side-effect, Common symptom	30
FACT-G	Physical wellbeing, Social/family wellbeing, Emotional wellbeing, Functional wellbeing	27
Arthritis		
LEFS		20
WOMAC	Pain, Stiffness, Physical function	24
QUALEFFO	Pain, Activities of daily living, Jobs around the house, Mobility, Social activities, General health perception, Mental function	41
Renal		
RQLP		43
Epilepsy		
QOLIE-31	Seizure worry, Emotional wellbeing, Energy/Fatigue, Cognitive, Medication effects, Social function, Overall QoL	31
Parkinson's disease		
PDQ-8		8
Psychiatry		
Lehman's QoL	Instrumental, Affiliative	40
Migraine		
HDI	Emotional, Functional	25
Treatment specific		
SCQOL	Social interactions, Self-control, Sleep, Cognitive functioning, Anxiety	21
Ant-coagulant related QoL		32

Disease Specific Measures

Disease specific measures are intended for assessment of longitudinal changes in HRQoL pertaining to a specific disease (Guyatt et al., 1993). However, they are not suitable to make a comparison of HRQoL outcomes across different medical conditions or to assess HRQoL outcomes in patients with multiple medical conditions.

Numerous disease-specific HRQoL measures exist, for a variety of conditions such as asthma, diabetes, heart failure, cancer, and arthritis (Guyatt et al., 1993). Many of these measures have been used to evaluate the outcomes of pharmacotherapy and clinical pharmacy services (**Table 1**) (Mohammed et al., 2016a; Pickard and Hung, 2006; Pickard et al., 1999). A recent systematic review with content analysis by researchers from the university of Sydney (Mohammed et al., 2018a) found that between 1990 and 2015, twenty-seven different disease specific HRQoL measures had been used in research to evaluate various models of clinical pharmacy services.

HRQoL and Clinical Pharmacy Services: Measurement Issues

In any intervention that involves pharmacotherapy, three possible outcomes of HRQoL is expected following the intervention: (i) HRQoL is improved compared to the baseline value, (ii) HRQoL is maintained, or (iii) HRQoL declines compared to the baseline value (see **Fig. 1**) (Mohammed et al., 2018b).

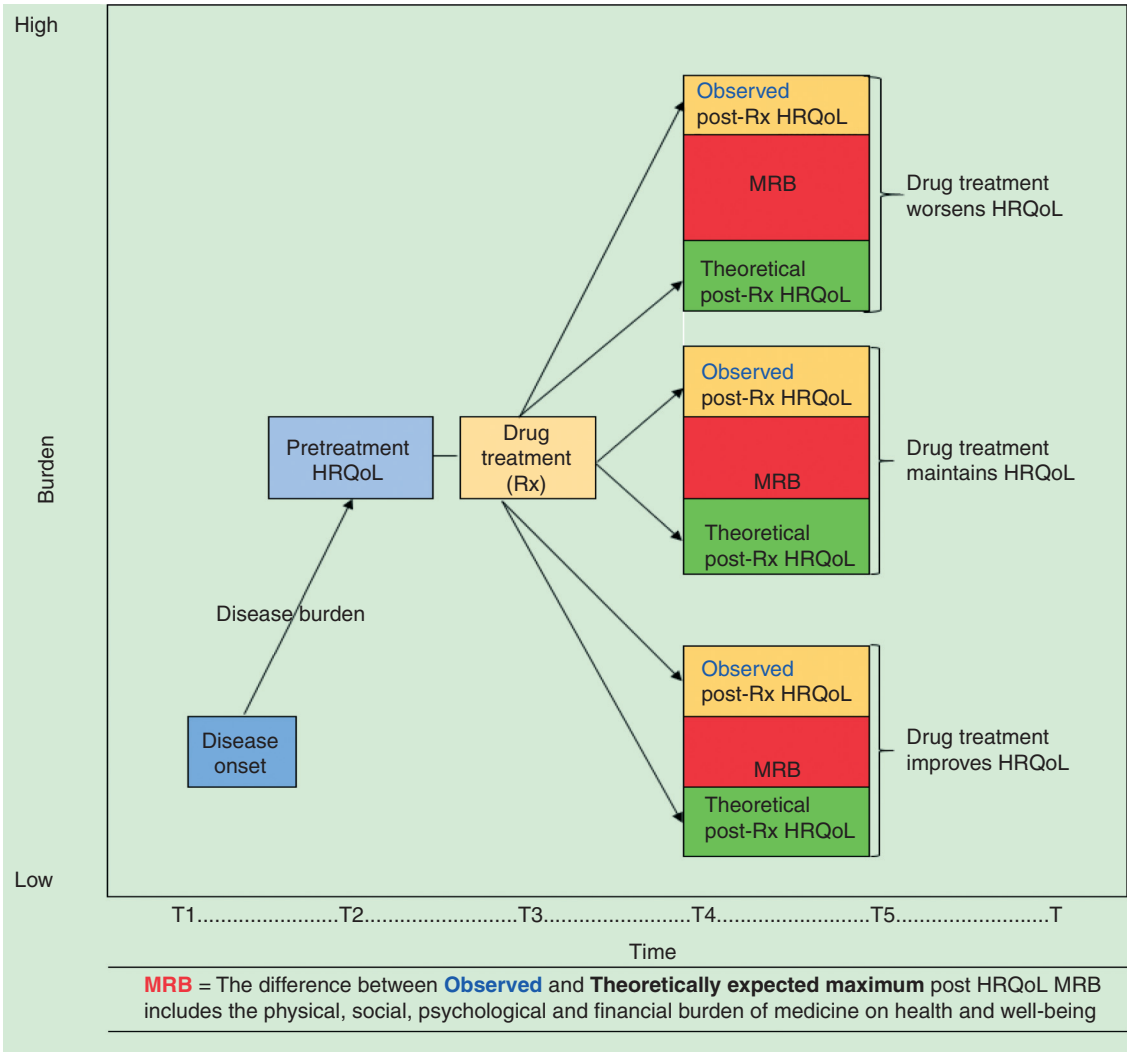

Figure 1 Pre- and posttreatment HRQoL outcomes in relation to disease and medicine burden. *Source: this figure is reproduced from "Figure 3: The gap in literature that this thesis aims to address through the development and validation of a novel measure of medicine burden" a doctoral thesis at the University of Sydney (Mohammed et al., 2018b), with a permission of the owners of copy right.*

The ultimate goal of provision of a patient-centered and outcome oriented clinical pharmacy interventions is to achieve improved therapeutic outcomes and thereby improve the patient's quality of life. This is anticipated to be achieved through identification and resolution of a patient's drug related problems (DRPs) which are an important component of the therapeutic care plan in the provision of pharmaceutical care services. If the causes of DRPs such as suboptimal dose, drug-drug interactions remain unresolved, a patient's pharmacotherapy goals may not be achieved and pharmacotherapy may result in undesirable consequences (Basger et al., 2015). Causes DRPs such as the need for additional therapy or wrong dose can result in poorer quality of life outcomes (Ernst et al., 2003; Wallace et al., 2015). However, there is limited evidence on how resolution of DRPs can pragmatically translate to improvement in HRQoL outcomes (Alldred et al., 2016). This is mainly due to the fact that existing measures of HRQoL used in evaluation of the impact of pharmacotherapy as well as the benefit of pharmaceutical care services do not encompass the concept of DRPs or medicines as a domain. Similarly, measures or classification systems for the causes of DRPs are neither humanistic measures nor patient-centric or self-rated measures.

The lack of a suitable measure that encompasses the concept of medicines and HRQoL has been a challenge to link DRPs and changes in HRQoL outcome. As a result, despite a significant body of research in this area (Mohammed et al., 2016a; Pickard and Hung, 2006; Pickard et al., 1999; Roughead et al., 2005a,b), evidence of clinical pharmacy interventions improving patients' HRQoL remains mixed and inconclusive (Bladh et al., 2011; de Lyra et al., 2007; Gourley et al., 1998; Holland et al., 2008; Isetts et al., 2006; Jarab et al., 2012; Malone et al., 2001; Mohammed et al., 2016a; Petersson et al., 2013; Pickard and Hung, 2006; Pickard et al., 1999; Pinto et al., 2014; Renberg et al., 2006; Schulz et al., 2001; Viswanathan et al., 2015). In general, HRQoL measures used in the evaluation of clinical pharmacy services lack sensitivity and specificity to capture aspects of humanistic outcomes related to the impact of pharmacotherapy (Mohammed et al., 2016a). Conceptually, all generic or disease specific HRQoL measures, are

specifically designed for evaluation of the burden of chronic disease, not specifically the burden associated with long term medicine use and the consequence of unresolved DRPs on patients' health and wellbeing (Malone et al., 2001; Mohammed et al., 2016a, 2018a).

Choosing a Suitable HRQoL Measure for Clinical Pharmacy Services

A comprehensive evaluation of the social, psychological, and physical impact of drug therapy on patients' lives is essential to determine the benefit of medicine-focused interventions (Mohammed et al., 2016a). Currently, with available instruments, there are only three options to evaluate HRQoL in clinical pharmacy type interventions: (1) using generic measures, (2) using disease specific measures, or (3) combination of generic with disease specific measures (Mohammed et al., 2016a; Pickard and Hung, 2006; Pickard et al., 1999). There is a number of theoretical and methodological issues regarding the suitability of existing HRQoL measures for clinical pharmacy interventions. Both generic and disease specific measures of HRQoL may generate some evidence for the value of clinical pharmacy interventions on a patient's HRQoL. However, it should be noted that generic and disease specific HRQoL measures used in clinical pharmacy interventions have been designed to evaluate the burden of disease on patients' health and wellbeing, not specifically the impact of drug therapy (Mohammed et al., 2016a, 2018a). The lack of sensitivity and specificity of HRQoL measures to clinical pharmacy interventions has been reported (Mohammed et al., 2018a). A recent systematic review with content analysis identified 37 different HRQoL measures (n = 1019 items) in 117 research studies into clinical pharmacy published between 1990 and 2015 (Mohammed et al., 2018a). The findings of this review indicated that only 34 of the 1019 items identified (from 37 measures), pertained to medicines (Mohammed et al., 2018a). This review further highlighted that items about medicines were also not focused on the burden of medicines, indicating that the measures may lack specificity to the types of services provided in clinical pharmacy interventions and sensitivity to detect changes in HRQoL attributed to the burden of long term medicines.

Drug Therapy Focused Measures of Quality of Life: Rationale for the Need

The importance of measuring quality of life related to drug therapy is to ensure not only the longevity of life after a particular drug therapy, but also the quality of life extended as a result of drug therapy taking into account the burden attributed to drug therapy on patient's functioning and wellbeing. The general principle is that longevity should be improved following a drug therapy in a biological sense, and that therapeutic options chosen should be those that ensure the patient's health condition is better than a pretreatment stage, if not similar to a predisease health condition.

Along with the expansion of medical services and an increase in longevity of life, there has been a gradual shift in the focus of chronic disease management from disease mortality to limiting disease morbidity and PROs of disease morbidity. Pharmacotherapy is by far the most common health care intervention in chronic disease management. As a result, there has been a surge in interest in collecting information about the impact of drug therapy on patient's lives for evaluation of clinical and nonclinical aspects of medical interventions. Collecting patient experiences about the impact of drug therapy on their functioning and wellbeing is essential to compliment a wide range of clinical outcomes of medical interventions. However, the traditional approach to evaluation of quality of life outcomes in drug therapy interventions has focused on using HRQoL measures, which were designed based on theoretical and conceptual models of HRQoL not related to drug therapy. This provides an explanation for why clinical pharmacy interventions have had a mixed and inconclusive impact of HRQoL. The lack of a drug therapy specific quality of life measure suitable for evaluation of the effectiveness of clinical pharmacy interventions, and the variability in HRQoL measures used in the evaluation of clinical pharmacy services has been reported as a major contributory factor (Mohammed et al., 2016a,b, 2018a,b; Pickard and Hung, 2006; Pickard et al., 1999).

A growing body of literature indicate that long-term drug therapy can lead to poor outcomes particularly in people with complex disease conditions and therapy (Gallacher et al., 2011, 2013; Mohammed et al., 2016b; Sav et al., 2013a,b, 2015b; Tran et al., 2015b). Investigation of medication related burden (MRB) on a health and well-being is relatively a new concept that has been gaining more emphasis in recent literature (Gallacher et al., 2011; Mohammed et al., 2016b; Sav et al., 2013a,b, 2015b; Tran et al., 2015b). The burden of long-term medicine use on patient's beliefs and behaviors and the impact on psychological, social, physical, and financial wellbeing has now been well documented (Gallacher et al., 2011, 2013; Mohammed et al., 2016b; Sav et al., 2013a,b, 2015b; Tran et al., 2015b). MRB can induce nonadherence to care plans, predisposes patients to DRPs, decreases quality of life, and increases utilization of health care resources (Mohammed et al., 2016b, 2018a). Findings from research studies into this area emphasized that sound medication therapy decisions cannot be made without good insights and attentions to the lived experiences of patients with medicines (Mohammed et al., 2016b). Some researchers argue that the impact that medicine attributed burden imposes on a patient's health and wellbeing would be underappreciated if measurements of humanistic outcomes are restricted to existing generic and or disease specific measures of HRQoL (Mohammed et al., 2016a,b, 2018a,b). Moreover, in clinical practice, health care providers face ongoing challenges in differentiating the decline in patient's quality of life due to the burden of drug therapy that a patient is taking, from the burden imposed by underlying disease conditions for which drug therapy has been prescribed. Similarly, it is difficult to distinguish between improvements in a patient's quality of life outcome due to drug therapy focused interventions or other nonpharmacologic treatment modalities prescribed along with drug therapy. Furthermore, unless

Table 2 Drug therapy focused measures of quality of life and their psychometric properties

Measure	Measurement properties							
	Reliability		Validity					
	Internal consistency (Cronbach's α)	Test-retest reliability	Convergence or discriminant validity, reference measure(s)	Known-groups validity	Other validity	Final domains and items	Conceptual Framework	Psychometric analyses, country/ population

Abbreviations: C: Convergent validity; D: Discriminant validity; DBI: Drug Burden Index; EFA: Exploratory Factor Analysis; MRCI: Medication Regimen Complexity Index; MBRS: Medication Behavior Rating Scale; MRB-QoL: Medication Related Burden Quality of Life; MRQoL: Medication Related Quality of Life; NR: Not Reported; PDC: Psychological Distress Checklist; PROMPT-QoL: Patient Reported Outcome Measure of Pharmaceutical Therapy for Quality of Life.

evaluated with a suitable measure, it would be impossible to generate strong evidence that reflects the real benefits of some widely practiced clinical pharmacy services such as pharmacist-led medication management reviews. Consequently, this may have an impact on policy decisions and influence professional remuneration for professional services.

To date, the sensitivity and specificity of existing HRQoL measures for evaluation of clinical pharmacy interventions is questionable. There is also no consensus regarding which HRQoL measure to use in clinical pharmacy interventions. These issues imply that an alternative drug therapy-focused measures of quality of life are needed for evaluation of clinical pharmacy interventions (Kheir et al., 2004; Krska and Rowe, 2010; Krska et al., 2013; Mohammed et al., 2016a,b). The ideal drug therapy-specific measures of quality of life should include dimensions of HRQoL relevant to clinical pharmacy services (Kheir et al., 2004; Mohammed et al., 2016a), incorporate key aspects of the burden of drug therapy on functioning and wellbeing (Krska et al., 2013; Mohammed et al., 2016b; Sav et al., 2015a; Tran et al., 2015a) and have greater sensitivity to pharmacist interventions (Mohammed et al., 2016a, b, 2018a). However, development and validation of such a measure is labor intensive requiring long-term efforts and various stages of evaluation before the measure is applicable in research and practice. In the past few years there have been attempts to design a more sensitive measure of quality of life, suitable for evaluation of humanistic outcomes in clinical pharmacy interventions. Measures such as medication related burden quality of life (MRB-QoL) (Mohammed et al., 2018b), patient-reported outcomes measure of pharmaceutical therapy for quality of life (PROMPT-QoL) (Sakthong et al., 2015), and medication related quality of life (MRQoL) (Tseng et al., 2016) are some of the novel measures that are receiving attention.

Although these measures aim to target drug therapy, they were designed based on different approaches and conceptual models. A conceptual model is a comprehensive description for the underlying concepts of the measurement and the interrelationships between concepts that a given measure is intended to measure. It provides the rationale for the measurement and reflects procedures followed to develop scales and subscales of the measure. An example of a conceptual model in drug therapy related quality of life measure is the medication related burden quality of life (MRB-QoL) model (Mohammed et al., 2018a,b). This model was developed by integrating three concepts: pharmacist-led pharmaceutical care, HRQoL, and the burden attributed to drug therapy, i.e., medication related burden. In this conceptual model Mohammed et al. stated that MRB is the difference between the observed and theoretically expected posttreatment HRQoL (**Fig. 1**). Major dimensions of medication related burden commonly encountered by patients on long term medicines; the interrelationships between dimensions of medicine burden; how MRB predisposes patients to DRPs, nonadherence to therapeutic care plans and poor quality of life outcomes has been reported in qualitative research used in the development of this measure (Mohammed et al., 2016b, 2018a). The development of other measures such as PROMPT-QoL and PTRQoL were based on conceptual models of quality of life and patient-centered pharmaceutical care (Sakthong et al., 2015). In addition to variability in the conceptual model on which these measures were based, there are also variations in the methods employed to developing the measures such as item generation and statistical analysis approach in psychometric testing, and concurrent measures used in their validation process (**Table 2**).

Approaches to Developing a New Patient Reported Measure of Quality of Life

The development of a new measure of QoL should follow a process that involves rigorous stages of development and validation. This includes definitions and conceptual framework specific to the quality of life measure intended, generation of an initial item bank; refining the items and pretesting; and then testing for validity. It is recommend that the research questions should be formulated a priori and be informed by a comprehensive review of literature. Furthermore, it is suggested that there be a clear justification for the

importance of a new measure in the area, specification of the objectives in measuring QoL, development of a comprehensive framework reflecting major issues that a new measure encompasses, proposal of dimensions that are to be assessed, and identification of intended end users and groups of respondents to be involved in the process. The development and validation process can be labor intensive and often requires multimethod approach. Qualitative methods (focus group and interviews with end users of the measure) are a critical component in the development process and a well-recognized traditional approach for generation of items. However, methods other than focus group discussion and interviews have now also been used (Mohammed et al., 2018b; Terwee et al., 2007).

Following a literature review, qualitative methods of concept elicitation, item development and refinement; the next stage is testing the psychometric properties of the measure. Commonly tested measurement properties include: (a) validity such as content validity, construct, criterion, and known-groups validity; (b) reliability such as internal consistency and test-re-test reliability; and (c) sensitivity and responsiveness (ability to detect clinically important change) of the measure.

Validity

Assessment of the validity of a new PROM generally focuses on whether the instrument measures what it intends to measure (De Civita et al., 2005; Gable and Wolf, 1993; Walters, 2009). Although other measurement properties are important, evaluation of the validity is the ultimate question to be addressed when developing a new measure (Gable and Wolf, 1993; Nunnally, 1978). In contrast to evaluation of reliability of a measure, there is no "gold standard" and clear cut measurement for validity (Gable and Wolf, 1993). Hence, validity is not directly measured but it is inferred from empirical evidence. Commonly evaluated types of validity include content validity, construct validity, criterion, and known-groups validity.

Content Validity

Content validity refers to the extent to which a given measure comprehensively covers relevant issues both in terms of its scope and content of the items that it contains. This validation process may involve assessing the conceptual constructs and how it has been defined, the importance and applicability of the measure for the intended purpose (Gable and Wolf, 1993). Expert panel from diverse background in the area of interest including end users of the measure (e.g., patients) are invited to critique the coverage, relevance, and importance of each item within a measure. Relevance and coverage are the two central elements in evaluating the content validity. Evaluation of relevance is focused on whether all items are relevant to the concept being assessed while coverage is mainly related to whether the entire range of relevant issues are considered in the measure. Following expertise feedback, the developers of the measure may need to critically revise the items to enhance the clarity by remove ambiguity on the wording of some items. There are also quantitative approaches (e.g., content validity index) to help decision making about the number of items in the measure, that is, whether to retain or remove a given item from the measure.

Construct Validity

Construct validity refers to the extent to which a given instrument measures the construct that it intends to measure (Bowling, 2014), and it is considered the most important approach to testing validity of a measure (Kline, 2000). Construct validity encompasses a number of known types of validity such as convergent validity and discriminant validity. Some people also consider known-groups validity as construct validity. Evaluation of construct validity involves defining and framing a priori hypothesis, domains of the measure being assessed and whether they are related or unrelated to each other (Kline, 2000). A priori hypothesis and the relationships between domains of the measure are then statistically tested. For example, if the domain/s of a given measure strongly correlates with other domain/s that a priori hypothesis or theory suggests, then that relationship indicates convergent validity. Whereas a weak correlation confirms a discriminant validity of the measure indicating that there are domains which are relatively unrelated. Convergent and discriminant validity are assessed together and may sometimes be assessed across domains of different measures rather than comparing domains within an instrument.

Known-Groups Validity

Known-groups validity refers to testing the sensitivity of a new measure in distinguishing differences between groups hypothesized to differ. For example, a priori hypothesis could be people with multimorbidity and polypharmacy may have poorer scores in a new quality of life measure contrary to those without those issues. Based on this assumption, instrument's ability to detect the difference between the specified groups can be tested. If a measure is not sensitive to distinguish groups with known differences, it is an indication that something may be wrong in development process and thus, usefulness of the measure may be questionable.

Criterion Validity

Criterion validity refers to whether the domains or overall score of a measure correlates with other measure/s often regarded as "gold standard" criteria (Gable and Wolf, 1993). Criterion validity is of two types: predictive validity and concurrent validity. Predictive

validity relates to the ability of the measure to predict future health events, for example, providing prognostic information that complement objective measures. In concurrent validity, a new measure and a standard criterion are concurrently measured/administered and then the magnitude of the relationship is tested. It should be noted that there is no "gold standard" criteria for PROs mainly for two reasons. First, all the instruments measure hypothesized constructs. Second, PROs are subjective in nature and thus, slight variations between measures are inevitable even if they are meant to measure same constructs. Therefore, commonly used approach in testing concurrent validity is by comparing the new measure with other measures which are considered as relatively well established measures. The comparison may be useful to support the rationale for developing a new measure, for example, if it was intended for designing a shorter/simplified version or addressing new concepts/constructs which have not been considered in the other measures.

Reliability

Reliability is about testing if the measure is reproducible and internally consistent (Walters, 2009). Evaluation of reliability of a measure focuses on two areas: (a) whether items within a domain of the measure should all measure same thing, (b) whether the scores of a measure is stabile over time period. The former type of reliability testing is called internal consistency reliability and the latter one is known as test-rest reliability.

Internal Consistency Reliability

Internal consistency of the measure is relates to the coherence between items within a domain, i.e., the degree to which the items are related to each other and the domain they represent. Internal consistency of a measure can be used to check homogeneity of the items in measuring same construct (Nunnally, 1978). Cronbach's alpha, correlation between items, item-domain correlation, and reliability coefficients can be used to check homogeneity of the items (Bowling, 2014; Briggs and Cheek, 1986) however, the most commonly used method to report internal consistency is Cronbach's alpha index (Nunnally, 1978). The ranges for Cronbach's alpha may depend on the nature and purpose of the measure. Commonly reported values are between 0.6 and 0.9. It may also be important to inspect correlations between items within the domain/scale. A very low inter-item correlation (value <0.1) may indicate the items do not hang together (i.e., they do not belong to the same domain) while a very high correlation (value >0.5) may indicate that there is redundancy of the items (Briggs and Cheek, 1986) and thus, removing some items may be needed.

Test-Retest Reliability

Test-retest reliability refers to the stability of the score of the measure. In other words, measure's ability to yield consistent score over time. Scores are compared after administering the measure repeatedly to the same person over a period of time. Intra-class correlation coefficient or Kappa coefficient are commonly used approaches in evaluating test-retest reliability.

Responsiveness

Responsiveness of a measure reflects the extent to which the measure detects clinically important and practically meaningful changes over time (Walters, 2009). Measure's scores are compared after administering to same person before and after an intervention. It is often difficult and challenging to prove measure's responsiveness and the process usually requires longitudinal data. In any measures claiming responsiveness, minimal clinically important difference (MCID) should be reported. MCID reflects the minimum changes in the scores of the measure that is considered clinically important and practically meaningful to inform decision making.

Conclusions

Incorporation of patient-centric measures has become critical component of measuring the value of health care interventions. In outcomes research, including clinical trials of drug therapy, PROs have now become the standard assessment to evaluate the benefits and negative consequences of therapy. PROs have the potential to generate evidence about the benefits gained in treating some chronic diseases in comparison to associated adverse events and functional impairment of the therapy. PROs data are often used to complement biological markers of safety and efficacy of medical interventions. Sometimes they are the only viable approach when other measurable biological markers of a disease and therapy is lacking.

HRQoL instruments are the most commonly used approach to evaluate PROs in relation to the impact of a disease and treatment on functioning and wellbeing. Traditionally, evaluation of HRQoL outcomes in clinical pharmacy interventions has used measures which were conceptualized based on models of disease burden, not specifically for drug therapy. There are different views about suitability of existing HRQoL measures for the evaluation of clinical pharmacy interventions. The use of generic and or disease specific measures of HRQoL in research into evaluation of clinical pharmacy services has been reported as a potential factor for the mixed and inconclusive evidence regarding the benefit of clinical pharmacy services for improving HRQoL. A growing body of

literature indicates that existing HRQoL measures lack sensitivity and specificity for the evaluation of clinical pharmacy interventions. Some researchers argue that until the burden attributed to drug therapy is directly measured with a more suitable measure, it is unlikely that it will be possible to distinguish between the changes in a patients' quality of life attributed to drug therapy, from the burden imposed by a disease condition. Moreover, in the absence of standardized drug therapy specific measures of quality of life, the challenges of distinguishing the improvement in patients' quality of life due to drug therapy focused interventions from that of other treatment modalities will likely remain.

In recent years, there has been increasing efforts to develop alternative medication therapy related quality of life measures specifically designed for evaluation of clinical pharmacy interventions. However, all of the proposed medicine related quality of life measures (**Table 2**) require further evaluation, before they can be applicable to inform decision making. Pending further investigations into measurement properties of medicine related quality of life measures, evaluation of quality of life outcomes in clinical pharmacy services may continue using available of HRQoL measures. Researchers should be aware and careful about the overarching principles in the measurement of HRQoL in clinical pharmacy interventions. The choice of a given HRQoL measure should be based on the type and intensity of the service provided and the sensitivity of a chosen measure to capture aspects of quality of life affected by the burden of medication therapy.

This chapter provides a brief overview of the concepts of HRQoL in relation to medical interventions in general, and clinical pharmacy services in particular. The chapter highlights the importance of HRQoL as a critical component of evaluation of patient outcomes. The chapter also provides new perspectives and insights into how medicine specific quality of life components should be incorporated into the evaluation of overall HRQoL outcomes in medical interventions.

Military Pharmacy Practice Around the World and the Role of the Pharmacy Officer

Artyom Korenevsky*, Sylvain Grenier†, *Department of National Defence, Canadian Armed Forces, ON, Canada; †University of Ottawa, Canadian Armed Forces, ON, Canada

Introduction

For most people, the term "military pharmacist" is not clear. When one thinks of military, images of tanks, ships, and parades come to mind (Duffy, 2015). When we think of soldiers and officers, we either have an image of a parade uniform or camouflage, someone carrying a rifle and executing combat tactics (Duffy, 2015). A pharmacist on the other hand is someone in a white lab coat, perhaps providing patient care at a community pharmacy, working at a research facility or providing advice to physicians and nurses in a hospital. Most people can imagine what a combat medic does or even a surgeon at a field hospital.

While these images form the public perception of both military officers and of pharmacists, they do not reflect the reality of how a modern military functions. For the purpose of this chapter, we will define military pharmacists as a uniformed military officer with formal education in pharmacy who is subject to the rules, regulations, and discipline of the military force they belong to—a Pharmacy Officer. It is important to note the distinction between a civilian pharmacist who works in a military facility and a Pharmacy Officer. For example, the Canadian, United States, Australian, and British forces directly employ civilian pharmacists to provide pharmacy services to its members, but this is in augmentation of their Pharmacy Officers. This chapter then will focus on the practice and roles of Pharmacy Officers around the world.

Historical Accounts of Military Pharmacists

Historical accounts of military pharmacists have been published across the globe. From French and Turkish military campaigns, the American Civil War to the Imperial Army of the Meiji period of 19th century Japan—military pharmacists have been an important part of force sustainment presence (Bonnemain, 2008; Hasegawa, 2000; Horiguchi, 2008; Kleider and Pabst, 2005; Miroshnichenko et al., 2014; Trépardoux, 2014; Yildirim, 1998). Military pharmacists have managed formularies for centuries, as seen in the specific establishment of the Danish Military Pharmacopoeia in 1812 (Kruse, 2000).

Pharmacy Officers are deployed on missions around the world to support the military forces they are part of. There are peer-reviewed publications documenting US Pharmacy Officers deployed to Haiti (Frank, 1996), Operation Desert Storm (Spain et al., 1993; Spain, 1994), and to Honduras (Dasher, 1985). In operations, pharmacists take on many roles.

Pharmacists take part in preparing and planning for operations (Gallup and Masterson, 2007) and provide medication therapy management (Ridderhoff et al., 2015). As the Chief Pharmacists of the Kenyan and Chinese Militaries have put it "pharmacist[s] are part and parcel of the troops in the operational areas both during peace time and war" and when providing "deployed pharmacy services, the military pharmacists usually work as an important part of a medical team, mainly responsible for the medicine [procurement] and supply."

Current Military Pharmacy Practice

While there are many accounts in published journals and mentions of military pharmacists are made in many books, there does not exist a single account describing current military practice at the international level (Anderson, 2002; Worthen, 2001). Military pharmacy practice is a specialty in that it both covers a unique patient population and a unique practice environment. We would like to endeavor to describe what military pharmacy practice is and how it is practiced in different countries throughout the world.

To understand the practice of military pharmacy, we need to begin with defining the domains and populations that this practice covers. Broadly speaking a military force requires health service support both when stationed in garrison and when deployed on operations. When in garrison, military members will require the services of health care providers predominantly for their primary care and mental health. When deployed on operations, a military force can be engaged in several kinds of missions. The two most common ones are the combat operations and the humanitarian missions (NATO, 2018). During combat operations, the health care providers of the military forces will provide care mainly to their own members, as well as members of allied and enemy forces. However, they will not deny care to civilian casualties. In humanitarian missions, mainly following disaster situations, where the military force is providing aid to the civilian population, the role of the health care provider will be to treat patients affected by these disasters. Therefore, military health care providers, including Pharmacy Officers, are required to provide care to both military members (typically healthy adults, between 16 and 60 years of age, predominantly male) as well as civilians (entire spectrum of human population, from all age groups, various geographic locations, different cultural and ethnic groups, and all socioeconomic circumstances).

The domains that military Health Service Support covers are: Education and Training; Patient Care; Health care Logistics; and Policy and Research. All four of these domains take place both in garrison and when deployed on operations.

Health care Logistics is an extensive area of Health Services Support. For the purpose of this chapter, health logistics will be broken down into pharmacy logistics and health materiel logistics and defined as the part of military pharmacy practice dealing with the procurement and supply, of health equipment and blood and blood products. Procurement can be defined as contract negotiation and selection with vendors, payment terms and financial arrangements and purchasing. Health materiel can be defined as any physical good that comprise the health service support framework: pharmaceuticals, blood products, health consumables such as injection devices and dressing materials, and health equipment.

Patient care includes primary care, mental health, urgent care, inpatient care, critical care, and surgical care. The shift in areas of patient care is quite dramatic: from chronic disease management in garrison to surgery in combat operations. Preventive care involves such aspects as prophylaxis of preventable diseases, immunizations, protection of military force from environmental health threats and monitoring of the quality of food, water, and sanitation within military organizations.

Policy management involves defining such things as the scope of health services support, scope of clinicians' practice, spectrum of care, pharmaceutical policy, and formulary management.

Regulatory management includes quality assurance and quality control, patient safety, medical device regulations, manufacturing and licensing of pharmaceuticals.

Education and training involves entry-to-practice training requirements as well as education and training provided at military training facilities to health service support personnel. Education and training also includes providing training to other nations on deployments and international exercises.

Research and development include studying the health of the military population, tracking health data from missions, and conducting health factors research involving military equipment.

Synthesis of Literature on Current Military Pharmacy Practice

This chapter presents a synthesis of literature on current military pharmacy practice. The literature search was conducted by searching PubMed, Google Scholar, Google, and reviewing the references in the obtained articles and books. Senior pharmacy officers from 21 nations were contacted to obtain descriptions of the roles and involvement of pharmacists within their respective organizations. A follow up was done to request original respondents to fill in any missing data using the format seen in the tables in this chapter. Data and graphs were analyzed and prepared in Microsoft Excel.

It is also important to note some limitations to these methods. The authors of this chapter are both Canadian Pharmacy Officers. As with any practice, the details and nuances of the practice are best described by the practitioner. While every effort was made to elicit details from the Pharmacy Officers of countries other than Canada, the details may still be lost to interpretation. Given that this is the first time such a publication is produced, to create order and flow in the chapter, a Canadian bias is introduced into the theoretical framework of this chapter. It is certainly our hope that this is only the first edition and with future editions, more fidelity can be introduced into the data.

Figure 1 Countries which are known to employ Pharmacy Officers are shown in *green*. Countries that do not employ Pharmacy Officers are shown in *red*. Countries not highlighted may or may not employ Pharmacy Officers; however, no information about such employment could be located either through personal communication or through literature searches. It is likely that there are many more countries which employ Pharmacy Officers given that there is such practice on every continent.

Synthesis of Results and Discussion

As we began planning and collecting data for this chapter, we anticipated encountering a wide variety of military pharmacy practice settings and having to analyze very heterogeneous data. As with most things in life however, we are much more alike than we are different. Between the two authors, one of whom is the President of the FIP military pharmacy section, there are more than 30 years of military pharmacy practice—and yet we were surprised to see the homogeneity of the responses we received. We will attempt to highlight some of the unique aspects of the various national pharmacy practices, but it is not the differences but rather the similarities that tell the fascinating story of military pharmacy practice in this chapter.

Responses were received from all the senior pharmacy officers contacted as well as their colleagues. The responses which were received were then grouped into five tables. The follow up solicitations were also received and added to the final tables. A world map was designed to provide a visual demonstration of the geographical distribution of military forces employing Pharmacy Officers (Fig. 1 and Table 1).

Education and Training of Pharmacy Officers

In order to become a Pharmacy Officer, one must not only complete all the requisite education and training to become a pharmacist but must also complete additional military training and specific occupational training. This results in many years of education and training for Pharmacy Officers (Table 2).

Pharmacy Officers begin their careers by obtaining their entry-to-practice degrees at civilian universities. The only exceptions identified were Russia and Greece. Russia trains military pharmacists at military medical academies. In Greece, aspiring military pharmacists must concurrently attend a civilian university and a military academy. In all cases, to become a Pharmacy Officer in the military, pharmacists must undergo military training.

Military training for Pharmacy Officers usually includes basic military training and occupation-specific military training. Basic military training is common to all military officers (such as learning military laws and regulations, how to wear a uniform, use a weapon, and perform parade drill). Occupation-specific training is unique to Pharmacy Officers. Considering, however, the specialized nature of Pharmacy Officers, in some cases the duration of overall military training is shorter than other military officers, as is the case in United Kingdom.

While nonhealth service officers will often receive most of their formative training within the military, Pharmacy Officers will often undertake training outside of the military. For example, Canadian Pharmacy Officers will complete a six-month hospital residency program that is also considered a military qualification. Additionally, Pharmacy Officers do undergo some specialized

Table 1 General overview of the functions of Pharmacy Officers around the world

Country	*Undergo military training*	*Pharmacy policy and regulation*	*Pharmacy administration and logistics*	*Health materiel administration and logistics*	*Provide support on missions (deployments)*	*Work in hospitals (inpatient)*	*Work in field hospitals*	*Work pre-hospital (field care)*	*Work in clinics (outpatient)*

The "●" indicates the country utilizes pharmacist for that area of function. A blank indicates that it was not clear to the authors from the obtained documentation whether pharmacists are utilized in this function or information was simply not available. An "X" indicates that evidence exists that Pharmacy Officers of that force are not employed in the specific area.
[a]Russian military is working on new training for military pharmacists and new definitions for their postgraduate training (Gushchenko et al., 2007). The Russian Military Medical Academy teaches various programs in Pharmacy, Medical Supply Management and even pharmacy economics programs for physicians (Miroshnichenko et al., 2013a,b).

military training beyond a basic course. For example, in Australia, Pharmacy Officers take part in Intermediate and Advance Military Logistics courses. In many cases, Pharmacy Officers are also encouraged to obtain postgraduate degrees. In Canada, most Pharmacy Officers continue to maintain their clinical pharmacy practice skills throughout their careers, regardless of their military duties.

US Pharmacy Officers work in a unique environment because the US military is one of the largest in the world and the military provides care to families and veterans. This unique combination creates a need for a large military health system and creates opportunities for a variety of clinical postgraduate education for Pharmacy Officers. For example, US Army Pharmacy Officers participate in specialty patient safety residency programs and can complete clinical fellowship programs (Watkins, 2003). Tunisian Pharmacy Officers, on the other hand, have a unique training path spending their first six postgraduate months at a military academy followed by a year spent obtaining experience in multiple practical settings. They compete in a specialization examination which separates Pharmacy Officers into the "Hospital-University (HU)" stream and the "Hospital-Sanitary (HS)" stream. The Tunisian training system effectively creates three classes of pharmacy professionals with the HU Pharmacy Officers considered the most specialized and the HU Pharmacy Officers performing in assisting roles with pharmacy technicians looking after technical pharmacy activities.

Belgian Pharmacy Officers also specialize in "CBRN (Chemical, Biological, Radiological and Nuclear) [operations], hospital [pharmacy practice], industrial [pharmacy] or [. . .] in clinical biology." These specializations do not hold any superiority over one another.

German Pharmacy Officers specialize in food science, which is what (from an education point of view) differentiates them from their civilian counterparts. Moreover, German Pharmacy Officers employed in Reserve (or part-time) positions do not require food science specialization.

British Pharmacy Officers may undertake training to become independent prescribers, although this does not alter their employment or career path within the military and therefore is specialization only in a medico-legal sense.

In addition to having opportunities to undertake postgraduate training such as Masters and Doctoral studies, most Pharmacy Officers undertake advanced certification programs. For example Canadian Pharmacy Officers may obtain advanced training in Travel Medicine, Pharmacoepidemiology, Dive Medicine, and Aviation Medicine (Gendron et al., 2017). Many Pharmacy Officers go on to teach other health professionals, teach new Pharmacy Officers and teach at academic institutions. Pharmacy officers also mentor pharmacists from other nations such as the mentoring missions in Afghanistan (Wright, 2003).

Location and Employment of Pharmacy Officers

Pharmacy Officers are present throughout the entire Health Services spectrum of operations. Pharmacy Officers can find themselves on land, at sea, deployed abroad, and sharing their time between civilian and military practice. In some countries, Pharmacy Officers belong to a unified health services group or command and support any branch of the military. This is the case in Canada, Germany, and Belgium for example, whereas some countries specifically assign Pharmacy Officers to support separate branches of the military.

The US Navy, Army, and Air Force each have their own cadre of military pharmacists. In addition, a fourth group of uniformed pharmacists, the US Public Health Services, support the US Coast Guard, and other health functions under the Federal jurisdiction (e.g., the Food and Drug Administration, Correctional Services, Indian Services, and more) (Flowers et al., 2009).

In the UK and Australia there are no Navy Pharmacy Officers, but Army Pharmacy Officers still support the Navy personnel.

Some countries use different uniforms or unique medical insignia to identify Pharmacy Officers. This is the case in the French, Greek, German, and Belgian forces. Most Pharmacy Officers are full-time military officers. Nonetheless, Reserve (or part time) Pharmacy Officers can be found in Austrian, Canadian, German, Swedish, UK, and US forces. Reservists are part-time Pharmacy Officers who spend most of their time in civilian practice and serve their military force on a part time basis. Each military relies on its Reserve Pharmacy Officers to a different extent, with minimal requirement in Canada, to a major contributing component of the Pharmacy Officer workforce in Sweden and Austria.

Patient Care in Garrison

Pharmacy Officers provide patient care and support when military forces are not deployed. The only exception to this is the Swedish military which utilizes the civilian pharmacy provider network. In the Canadian system, provision of care in garrison is a major responsibility of Pharmacy Officers since military members' health care is the responsibility of the Canadian Armed Forces. This is also the case in the US military. Generally, in garrison care provided by Pharmacy Officers is not significantly different from their civilian counterparts other than possibly utilizing a different scope of practice and focusing on different population group. In large health systems, such as in the USA, Pharmacy Officers work in large military hospital centers. In small systems such as in Canada, the military relies on civilian hospital infrastructure to provide inpatient care, when not deployed on missions. This is often referred to as Role 4 care, where patients of any severity can receive definitive care.

Providing Care on Operations

Pharmacy Officers provide support and patient care when forces are deployed in a field environment such as exercises and domestic operations (this usually means work at a Role 1 medical facility, looking after primary care requirements and urgent care which does not require surgery or long-term hospitalization). Pharmacy Officers also work at Role 1 facilities on humanitarian deployments where they provide population level support and care. Pharmacy Officers work at Role 2 and Role 3 Field Hospitals which provide surgical and in-patient care to deployed military members as well as local nationals. US Navy pharmacists also deploy to provide clinical services on large ships (such as aircraft carriers) and Australian pharmacists who deploy on Landing Helicopter Docks (LHDs) (Brouker et al., 2000).

Role of Pharmacy Technicians in the Military

While it is beyond the scope of this chapter to discuss Pharmacy Technician roles in detail, we would be remiss if their role was missed. For the purpose of this chapter, we will use the term pharmacy technician to include trained personnel to assist pharmacists with the technical aspect of pharmacy practice. In some countries, the United Kingdom, for example, the drug distribution function is largely the domain of pharmacy technicians. Austria, Greece, Switzerland, Tunisia, United Kingdom, and the USA employ military pharmacy technicians (in most cases pharmacy technicians are noncommissioned members or noncommissioned officers). The US has an especially large corps of pharmacy technicians and conduct formal military training courses for pharmacy technicians (Erikson, 2015; Holt, 1992; Meadows, 1999; Whisenant, 1984). Military pharmacists in the US work collaboratively with pharmacy technicians to improve patient care (Evans et al., 2016). Internationally, pharmacy technicians are important contributors to military operations.

Providing Patient Care

Most Pharmacy Officers carry out clinical pharmacy functions at almost all levels of care (in primary care clinics, hospitals, Role 1, 2, 3, and 4 facilities). From the Canadian perspective, across the spectrum of military pharmacy practice, logistics will always play an important role, while patient care and clinical practice, although present across the spectrum, will require more specialized clinical skills as you move from the Role 1 health care facilities to the Role 4 hospitals.

For the purpose of this chapter military pharmacy practice patient care is subdivided into four main areas: basic pharmacy, clinical pharmacy, advanced pharmacy practice, and preventive care. The intent of this categorization is to attempt to place pharmacy practice on a continuum from where it historically started (i.e., basic pharmacy) to where it is evolving (i.e., advanced pharmacy practice). Preventive care is a separate category, but it ultimately means that the pharmacist must evolve from basic functions to addressing population health.

This categorization was done to provide a qualitative visualization of the continuum of practice of military pharmacists. It is beyond the scope of this chapter to provide a nuanced description of every type of practice and specialty area. It is also worth noting that military pharmacy practice is a specialty in its own kind and military pharmacists comprise a small group of professionals (both in their own countries and internationally). This categorization is therefore intended to describe this small group of practitioners and not meant to be applied to general pharmacy practice (**Table 3**).

Basic Pharmacy Function

Within the basic pharmacy function, all Pharmacy Officers dispense medications, counsel patients and most will undertake patient-specific drug compounding. In Canada, Pharmacy Officers are not involved in sterile products preparation (intravenous admixtures, ophthalmic preparations, and total-parenteral nutrition preparation). The scope of practice of pharmacy officers may also differ from that of their civilian counterparts. Therefore, "basic" pharmacy does not mean simple pharmacy as some of these skills can be extremely complex.

Clinical Pharmacy

Clinical pharmacy is the next step on the practice evolution continuum. As of 2016, the clinical role of Canadian Pharmacy Officers expanded (The Maple Leaf, 2016). The expanded role includes five clinical activities related to prescribing medications for patients (The Maple Leaf, 2016). Canadian military pharmacists can adapt prescriptions (which mean changing the dose, route of administration, or dosage form of the drug). They can perform "therapeutic substitution" which means substituting a drug from the same pharmacologic class instead of the drug that was prescribed. This is especially useful in times when there are drug shortages. They can also refill medications which were previously prescribed for the patient or refill medications in an emergency (such as providing a patient with inhaled salbutamol in a case of an asthma exacerbation). Finally, they can prescribe independently for a list of preapproved indications. For example, Canadian Military Pharmacists can initiate antimalaria prophylaxis medications for deploying military members or prescribe smoking cessation medications for those wishing to quit smoking (The Maple Leaf, 2016). This new expanded role allows for more efficient utilization of health-resources and better access to care for patients (The Maple

The "●" indicates the country utilizes pharmacist for that area of function. A blank indicates that it was not clear to the authors from the obtained documentation whether pharmacists are utilized in this function or information was simply not available. An "X" indicates that evidence exists that Pharmacy Officers of that force are not employed in the specific area. Initiating Prophylactic Treatment was categorized under "preventive medicine" as it is usually highly linked to travel and selection of drugs such as antimalarials and vaccines for specific endemic areas. As such, this category is inextricably linked to preventive medicine physicians and scientists and usually linked to Force Health Protection functions in a military organization.

[a]Dagenais and Grenier (2013) and Gendron et al. (2017).

[b]French Military pharmacists are involved in sterilization services depending on the size of operation (Role 2 vs. Role 3 or larger hospital) (Rouault et al., 2017). The French military focuses its reserve pharmacy officer training on the following subjects: drug supply, use of chemical, biological and nuclear weapons in warfare and terrorism, clinical chemistry, toxicology, and hygiene (Labrude, 2004).

[c]Only water monitoring in the Swiss Armed Forces (no food monitoring).

Leaf, 2016). From a US perspective, the US Navy has piloted pharmacy refill authorization services since the 1990s (Riege, 2005). The US Navy has also implemented telepharmacy systems (Traynor, 2010). US Navy pharmacists are involved in running clinics such as pharmacist-led lipid clinics (Cording et al., 2002). Coast guard pharmacists are also involved in clinical services, such as smoking cessation programs (Huntzinger, 2002).

Advanced Pharmacy Practice

One of the newly developing areas is the concept of the pharmacists as advanced practice pharmacists providing independent prescribing, taking on more expanded clinical responsibilities and becoming a more integral part of the patient-care team. The British model has allowed for Pharmacy Officers to become independent prescribers after undertaking a formal qualification. As previously mentioned, in the Canadian model, Pharmacy Officers have gained the authority to independently treat a defined list of conditions (The Maple Leaf, 2016). Of all the countries surveyed, it appears that Canada, UK, and the USA are the only ones which are employing Pharmacy Officers in such a role.

Preventive Care

Preventive health care is another unique role filled by Pharmacy Officers. This area is uniquely important in the military setting due to the exposure of military members to adverse field conditions and environmental stressors on deployments (both domestic and international). For example, Pharmacy Officers in Canada, UK, and the USA can initiate prophylactic treatment of malaria for deploying military members (notice that these activities also fall into either clinical or advanced practice depending on how they are practiced). In Germany and Uruguay, Pharmacy Officers are involved in food and water safety. In Belgium and France, Pharmacy Officers are involved in sterilization of medical and surgical instruments. Finally, Pharmacy Officers from Belgium, China, France, Germany, Switzerland, and Uruguay are involved in hygiene and sanitation.

Health Care Logistics

In almost all cases Pharmacy Officers are not only responsible for patient care, clinical pharmacy, and pharmacy administration, but they are also responsible for Health Materiel Logistics as well. The only exception to that is with the United States military where Health Materiel Logistics is managed by Health Services Materiel Officers (Table 4).

When we think about the logistical support that a Pharmacy Officer provides, it is helpful to think about two groups of products: pharmaceuticals and all other health materiel. Procurement and supply of pharmaceuticals is typically a pharmacists or pharmacy technician responsibility, both in the civilian sector and in the military. On the other hand, procurement and supply of health material is a common function of Pharmacy Officers that is not normally performed by their civilian counterparts.

Procurement and supply are two separate functions given that the two are functionally independent (for example, medicines can be purchased by nonpharmacists, but the storage and distribution of medicines should ultimately fall to those with pharmacy expertise and education). It is not surprising then that every nation surveyed provides some level of pharmaceutical procurement and supply function.

When it comes to health materiel logistics, however, the picture is somewhat more diverse but not drastically so (except, as mentioned, in the case of the US military). Pharmacy Officers within every nation provide some degree of health materiel support and management. The health equipment management function is somewhat more questionable than other areas. This is likely because Pharmacy Officers are rarely involved in technical work on medical equipment (although the Belgian military does train its Pharmacy Officers to conduct technical functions on health equipment). Normally, however, medical equipment is managed by biomedical equipment personnel and (as is the case with the Canadian military). Pharmacy Officers oversee the procurement and management functions.

A special mention must be made of temperature and time sensitive products (TTSP) and their logistics. In a static civilian environment TTSP, also colloquially known as “cold-chain” products, pose a challenge. Storing vaccines, laboratory reagents or drugs requiring refrigeration introduces complexity to the health care system. The complexity is multiplied many fold in the military setting. For example, a field hospital operating in the Middle East would experience winter temperatures dropping below freezing and summer temperatures easily exceeding 50°C. In this environment, maintaining controlled storage conditions for medicines, vaccines, lab reagents, and blood products can be uniquely challenging. The successful transport and storage of such products could indeed be a matter of life and death for the patients waiting to receive treatment.

Another special mention must be made of blood and blood products. Blood and blood clotting factor replacement is critical in saving lives in trauma cases and is especially critical for combat casualties. Blood is also a very clinically complex intervention requiring the expertise of laboratory technologists, specially trained medics and nurses, physicians, and surgeons. Many countries delegate full management of blood products to laboratory scientists as is the case with USA, UK, Australia, and China. In other systems, such as Canada, for example, the military leverages Pharmacy Officers expertise in TTSP management, quality assurance, and health materiel management to oversee and manage the supply of blood and blood products into theatres of operation. In the Netherlands, Pharmacy Officers specialize in blood product management.

Table 4 Pharmacy Officer involvement in health logistics

The "●" indicates the country utilizes pharmacist for that area of function. A blank indicates that it was not clear to the authors from the obtained documentation whether pharmacists are utilized in this function or information was simply not available. An "X" indicates that evidence exists that Pharmacy Officers of that force are not employed in the specific area.

Pharmacy Logistics refers to any logistical (as opposed to patient care or clinical) functions that are required to carry out pharmacy operations related to pharmaceuticals only. Pharmacy Logistics functions can also be thought of as pharmacy management functions that involve stocking the pharmacy and procurement of medications. If any of the criteria listed were met, the country was counted as performing that overall function, not all criteria had to be met. In the "Blood and Blood Products" category, Pharmacy Officer involvement in planning the movement of blood products and managing the TTSP conditions are sufficient criteria to include that as a function of pharmacy practice (normally administration of blood and selection of blood products is managed by physicians and laboratory scientists respectively). In the "Health Equipment" category, Pharmacy Officer oversight and management of biomedical repair or engineering functions was sufficient to count as part of military pharmacy practice as normally the actual technical details and repair of health equipment is carried out by biomedical technicians.

[a]With respect to blood products, Belgian Pharmacy Officer deal with the transport of these products only.

Policy and Research

From a policy and regulatory perspective, it is not surprising that in a specialized and unique environment of military pharmacy practice, a unique set of pharmacy policies and regulations is required. It is also not surprising that to produce effective guidance and policy, Pharmacy Officers involved in this field of practice require extensive and diverse prior experience (Table 5).

For example, The New Zealand Defence Force is very small, but pharmacists are considered a resource of technical expertise and policy advice. Not only have we found that all countries are involved in regulating pharmacy policy, but respondents from Belgium, Canada, Greece, UK have specifically stated that policy and regulation are the domains of the most senior Pharmacy Officers. It is not surprising that Pharmacy Officers of many countries are not involved in manufacturing drugs and medical devices as these functions require processes to meet strict standards, requiring extensive resources, which often, only drug manufacturers can meet. Some countries, such as Belgium, are phasing out this function for Pharmacy Officers.

Nonetheless, Germany, Greece, Russia, Switzerland, and Turkey are still involved in manufacturing. One surprising finding was the low involvement of Pharmacy Officers in research and development activities. For example, Australian and UK Pharmacy Officers are not explicitly involved in research activities. While the many functions that Pharmacy Officers carry out in the military are critical to supporting health services, providing effective patient care and ensuring high standard of care on missions, the majority of research done appears to be in the areas of practice rather than formal research positions. Nonetheless, Belgium, Cameroon, Canada, China, Germany, Russia, Tunisia, and USA have reported Pharmacy Officers employed in research positions, with Canada, China, and USA having formal research positions for Pharmacy Officers. In comparison to pharmacy and health care logistics, however, it appears that there is less information on Pharmacy Officer involvement in research.

The "●" indicates the country utilizes pharmacist for that area of function. A blank indicates that it was not clear to the authors from the obtained documentation whether pharmacists are utilized in this function or information was simply not available. An "X" indicates that evidence exists that Pharmacy Officers of that force are not employed in the specific area. For Pharmaceutical Policy, a country meeting any of the criteria listed was counted as performing this overall function (i.e., not every country met every function listed in that criteria).
[a]As of 2018, the Belgian Military will be discontinuing its drug manufacturing activities and their associated research activities.

Impact of Pharmacy Officers

Despite the wide range of important health services support and clinical functions that Pharmacy Officers undertake, the amount of detailed study of their activities is quite limited. To our knowledge, there is only one published study that reviewed the roles of Pharmacy Officers and assessed their impact on patient care (Gendron et al., 2017). The review conducted by these authors identified only fourteen published accounts which assessed the impact of the role of Pharmacy Officers (Gendron et al., 2017). Thirteen of the fourteen studies described military pharmacy practice in the US, not a surprising finding as military pharmacy services in the US military are likely the most widely described in literature (Bartholomew et al., 1995; Bayles et al., 1997; Cammarata et al., 1987; Lambert, 2014; Snook et al., 1987; Strate and Brier, 1987; Troy, 2006; Williams et al., 1997; Young, 1997). Of the fourteen studies, five described the outcome of clinical interventions: successful dyslipidemia, diabetes, hypertension, anticoagulation, and asthma management by Pharmacy Officers (Gendron et al., 2017; Wallgren et al., 2012). One study described the monitoring of *A. baumannii* infected patients on Imipenem-Cilastatin and managing them to prevent drug shortages (Gendron et al., 2017). One study delved into the impact of Pharmacy Officers on occupational medicine where their interventions prevented soldiers from being deployed (Gendron et al., 2017). Two studies reviewed Pharmacy Officer impact on improved fiscal management and resource oversight (Gendron et al., 2017).

The remainder of the studies was mostly descriptive in nature (Gendron et al., 2017). While it is not surprising that most studies originate in the USA, it is nonetheless unfortunate given that US Pharmacy Officers are the only group not involved in broader range of health materiel management functions. For example, does an all-in-one integrated approach to health materiel management results in faster delivery of care and potentially reduced morbidity and mortality on deployed missions? Perhaps the ability of Pharmacy Officers to manage such critical components as surgical sterilization capabilities and blood delivery to the battlefield could result in increased availability of higher-level care in austere and humanitarian aid environments. Such questions remain unanswered.

The systematic review conducted concluded that further research into the impact of military pharmacy is required. The information collected in this chapter further supports and reinforces this conclusion.

The Future of Military Pharmacy Practice

As the profession of pharmacy evolves outside of the military, so will the practice of pharmacy in the military. The need to provide equivalent standard of care to military members coupled with increasing workload and health care costs undoubtedly means expanded roles for pharmacy officers in patient care, taking greater responsibility for not just pharmacotherapy, but also for more advanced pharmacy practice and greater health care-team involvement. What makes the military environment unique is that pharmacy practice is also affected by the changing nature of international conflict and new demands on leadership abilities of officers.

A survey of US military pharmacists at the rank of Lieutenant-Colonel and above has identified the need for senior pharmacists to have expanded clinical abilities, but also to improve their collaboration and communication skills with other professionals (Meadows et al., 2003a,b). Another US study described the criteria of importance in the domains of managerial and administrative pharmacy (Meadows et al., 2003a,b). These domains included: human resources, pharmacy operations and business practices, drug therapy management, and leadership (Meadows et al., 2003a,b).

The changing nature of conflict and new evidence in managing combat casualties by evacuating them to surgical care faster means surgeons, physicians, and other health care providers increasingly find themselves outside of the robust support frameworks of hospitals and clinics. In a special feature in the *American Journal of Health-Systems Pharmacy* titled "Redefining the practice of military pharmacy," some of the future directions would be to provide "pharmacy technicians to forward surgical teams" and "provide drug therapy advice during high-volume casualty management" (Normark et al., 1999).

Another area suggested in the special feature is for pharmacists to "be prepared to assist in triage, trauma management, and preventive field medicine" and act as advanced practice pharmacists on deployments (Normark et al., 1999). Therefore, the increasing demands on military health systems both domestically and on operations will mean both expanded clinical roles for Pharmacy Officers and expanded executive participation of senior Pharmacy Officers at the levels of medical planning, operational planning, and logistical support planning.

Conclusion

The practice of pharmacy in a Military environment offers unique challenges and opportunities to pharmacists. Some may consider this a specialty of pharmacy, while others may debate that the military pharmacy practice uses skills and knowledge from a wide range of pharmacy specialties (community, hospital, administrative, etc.) in a different and unique environment: the military environment. Pharmacy Officers represent a small proportion of all practicing pharmacists and may explain the paucity of publications describing their work. This chapter now presents a broad description of what is a Pharmacy Officer globally. Looking at the large number of military forces that employ them, it is evident that they play a vital role to the function of a military force. Pharmacy Officers must be able to provide the same pharmaceutical services as their civilian counterparts: work in hospitals and clinics, be adept at pharmacy administration, conduct research and write pharmaceutical policy. Additionally, several organizations require their Pharmacy Officers to undertake military training and to work as health care logisticians, to provide deployed forces with all the required health materiel. They will work in unique settings such as Field Hospitals, Field Health care facilities and even in Prehospital settings (such as in support of Field Ambulances)—both domestically and on international deployments. These environments do not systematically exist outside of the military or disaster-relief settings. Pharmacy Officers are required to gain expertise to work in these setting through life-long military training and additional certifications to enable such skill sets to exist. Considering the impact this relatively small group of professionals has on supporting global military operations, further in-depth research is decidedly required.

Acknowledgments

We would like to acknowledge the contribution of the following military pharmacists without whose willingness to contribute to this project would have made it impossible to write a chapter on international military pharmacy practice: Nicole Such, Captain, Pharmacist, Australian Defense Force; Richard Wosolsobe, Colonel, Senior Pharmacist of Austrian Armed Forces; Eric Wagemans, Colonel, Inspecteur Pharmaceutique Militaire, Belgian Armed Forces; Belinga Mekui Barbare, Lieutenant Colonel, Chief Pharmacist, Cameroonian Armed Forces; Dr. Chen Zheng-yu, Senior Colonel, Associate Chief Pharmacist, PharmD, People's Liberation Army of China; Arne Krappitz, Senior Colonel, Senior Pharmacy Officer of the Bundeswehr; Andrea Steinbeck, Lt. Col Pharm, Bundeswehr; Dr. Nadja Herkert, Maj Pharm, Bundeswehr; Dimitrios Diolatzis, Captain(N) (Retired), Pharmacist, Hellenic Armed Forces; Maureen Martin, Comdt, Pharmacist, Defense Forces Training Center, Irish Defense Forces; Dr. Ismail A. Awle, Col, Chief Pharmacist, Defence Forces Memorial Hospital, Kenya Defence Forces; Mrs. Jane Dawson, FFIP, FPS, Director Defence Health Policy, Defence Health Directorate, New Zealand Defense Force; Ulf Landberg, Major, Chief Pharmacist, Swedish Armed Forces; Nicolas Widmer, Major, Pharmacy Officer, Logistics Training Unit, Training Command, Swiss Armed Forces; Dr. Mehdi Dridi, Lt. Colonel Pharmacien, PharmD, MSc, Tunisian Armed Forces; Prof. Dr. Ahmet Aydin, Turkish Armed Forces (Retired); Lt. Col. E.F. Williams RAMC, FRPharmS (Head of Defence Pharmacy Services); Mayor (Pharmacist) (Retired) Washington Diaz, Uruguayan

Armed Forces; Benjamin R. Beidel, Captain, USAF, BSC, PharmD, Chief of Pharmacy Operations 51st Medical Support Squadron, Osan Air Base, Republic of Korea.

Glossary

Air force Military force comprises of airborne assets such as helicopters, airplanes, and their supporting elements such as the airports and bases on which they are stationed.
Blood and blood products Any products intended to replace lost blood due to trauma and bleeding. Examples range from whole blood, packed red blood cells, blood plasma as well as individual clotting factors such as fibrinogen concentrate preparations.
Dispensing pharmaceuticals A patient care function whereby a health care provider (usually a pharmacist) provides pharmaceutical to a patient and ensures the pharmaceutical is safe and therapeutically appropriate for that specific patient.
Health equipment Any equipment used for monitoring and medical/surgical interventions, which requires the oversight and maintenance by qualified biomedical technicians and/or engineers. Such equipment normally requires complex validation, calibration and typically receives a regulatory authority license. Examples of such equipment would be defibrillators, telemetry monitors, infusion pumps, ultrasounds, radiographic equipment (such as computed tomography scanners), and oxygen delivery devices.
Health supplies Any consumable health care supplies which are not specifically categorized as pharmaceuticals. These would include dressings, injection devices, surgical instruments, laboratory reagents and supplies, medical/surgical sets, and first aid kits.
In Garrison A term used to describe the disposition of a military force when it is not engaged on a mission and is stationed in its home country.
Land Force A military force consisting of elements employed on land such as infantry, vehicles, armored vehicles, artillery, and any supporting elements such as the bases on which they are stationed.
Maritime Force or Navy A water-based military force consisting of ships and submarines as well as their supporting elements such as the ports at which they are normally stationed.
Mission An overall operational goal given to a defined military force, typically by a government or an international body (such as the United Nations).
Role 1 Medical Treatment Facility Terminology used by the North American Treaty Organization (NATO) to describe a health care facility providing primary care and prehospital care in a field setting.
Role 2 Hospital Terminology used by the North American Treaty Organization (NATO) to describe a field hospital with surgical and medical facilities with the ability to provide emergency care and initial wound surgery to stabilize an injured patient for transporting the patient to definitive care.
Role 3 Hospital Terminology used by the North American Treaty Organization (NATO) to describe a field hospital providing specialized care such as neurosurgery, orthopedic surgery, radiology, and full pathology laboratory services and the ability to care for a patient for a longer period in an intensive-care or postsurgical care setting.
Role 4 Hospital Terminology used by the North American Treaty Organization (NATO) describe a military hospital providing definitive care outside of the theatre of operations serving as a definitive evacuation point for casualties from Role 1, 2, and 3 facilities.
Supplying pharmaceuticals A logistic function of appropriately storing and transporting pharmaceuticals and distributing them to health care facilities and health care providers as well as issuing medication to a patient without a clinical assessment of the medication.
Theatre of operations In military terms, an area within which a military force conducts its mission. This includes the specific area of where the humanitarian activities, peacekeeping activities, or war fighting activities take place as well as any adjoining areas where supporting military units (such as a Role 3 hospital) are located.
Time & temperature sensitive health care products (TTSP) Health care materiel which requires defined temperature range and humidity conditions during storage and transport. TTSP includes all pharmaceuticals, fluids for injection, vaccines, blood and blood products, laboratory reagents as well as any medical supplies which may lose their effectiveness, physical properties or whose sterility may be compromised if exposed to conditions outside of the recommended range.

Role of Pharmacist in Provision of Clinical Services in Prisons

Rabia Hussain*, Tehmina Tayyab†, Mohamed Azmi Hassali*, Mahendra Patel‡, Zaheer-Ud-Din Babar‡, *Universiti Sains Malaysia, Penang, Malaysia; †University of Lahore, Lahore, Pakistan; ‡University of Huddersfield, Huddersfield, United Kingdom

Introduction

WHO provides the definition for prison as the institutions that held the law offenders, sentenced by courts of law for a period of time in imprisonment (Møller et al., 2007). Prison or jail can be any place including all lands, buildings, where the prisoners are kept in custody on temporary or permanent basis or by the special orders of the government (Bureau of Justice Statistics, 2018). It does not include the place which is used by the police or a subsidiary jail for the detention of criminals (Bureau of Justice Statistics, 2018). Thus, a prisoner is any person whose liberty is restrained as a result of the interaction with the criminal justice system (Enggist et al., 2014).

Prison population represents the most underserved and most marginalized section of a society, mostly from lower socio-economic background with poor education status. Prisoners usually have poor health conditions and present themselves with chronic and untreated disease conditions, thus carrying more burden of disease than other members of society (Møller et al., 2007).

In general, the prison population is characterized by three key features: the population is mostly young, male and the turn-over of the prisoners is quite high among inmate population (Ministry of Justice, 2010). Every year new prisoners make the number up to four times the prison population. Moreover, local prisons receiving prisoners on short sentence or remand prisoners from courts represent the highest turnover. Contrary to this, high security and training prisons have the lowest turnover (Enggist et al., 2014). A total of 60% of the prison population is male and under 30 years of age (Ginn, 2012). Female prisoners are few in number globally, such as, in every 20 prisoners, there is one female prisoner. In England, there are 13 prisons for females, and females make just only 5% of the total prison population (Ginn, 2012). Contrary to this, in Wales, there are no specific prisons for females. However, Northern Ireland and Scotland have one prison, specified for females, and there are two Scottish male prisons with one female unit inside (Prison Reform Trust, 2011).

The prison environment is restricted and the inmates themselves are a challenging population to treat effectively. The social and health needs of patients inside jails are diverse, and the inmates may experience poor health conditions, including both mental and physical health (Ginn, 2012). Also, high turnover and short sentences make effective healthcare delivery difficult.

Moreover, the exposure to illicit drugs and physical abuse is quite common in prisons. Prisoners are dependent on prison staff for almost every aspect of their existence, including right to choose the food, accommodation as well as the ability to exercise (Ginn, 2012).

Population in Prisons

Globally, it is estimated that more than 10.2 million people are held in legal custody as remanded or sentenced prisoners (Walmsley, 2013). Between different regions of the world, the rate of prison population varies considerably; however, the prison population is on a great rise in all five continents of the globe (Walmsley, 2013). The world population has increased by over 20% and however the world prison population has increased to 30% (Walmsley, 2013).

Country-wise Distribution

There are more than 2.2 million prisoners in the United States of America, more than 1.65 million in China, 640,000 in Russian Federation 607,000 in Brazil, with 418,000 in India, 311,000 in Thailand, 255,000 in Mexico and 225,000 in Iran. However, the countries with the highest prison population rate (the number of prisoners per 100,000 of the national population) of Seychelles ranks first with 799 per 100,000, followed by the United States having 698 per 100,000, St. Kitts & Nevis having 607, followed by Turkmenistan with 583, U.S. Virgin Islands having 542, Cuba with 510, El Salvador comes next with 492, followed by Thailand with 461, Russian Federation with 445, then Rwanda with 434 and British Virgin Islands having 425 per 100,000 (Walmsley, 2015).

Based on the data from the United Nations, the world prison population rate, is 144 per 100,000 adult population. Female prison population has raised from 5.4% in about 2000 to 6.8% in 2015 (Walmsley, 2015). Netherlands has the highest number of female prisoners, while Belgium has the most unsentenced prisoners (BBC News, 2018). In Australia the rate of national imprisonment increased from 208 to 216 per 100,000 adult population showing an increase of 4% (Australian Bureau of Statistics, 2017).

Common Health Problems in Prisons

Prisoners have a higher chance to get any clinical problem, compared to the normal population in community, although the problems are common in both settings, but the likelihood of prevalence of the clinical conditions increase in prisons (Marshall et al., 2000). The conditions include air-borne infections, mental health, depression, anxiety, and other mental health affecting problems (Fraser, 2014). However, the following four are considered as priority areas:

- Primary care including epilepsy, respiratory and cardiac diseases, and reproductive system problems in female inmates.
- Infections diseases such as tuberculosis, HIV, and other skin conditions.
- Mental health.
- Dependence to drugs and alcohol (Fraser, 2014).

There are also problems of drug abuse, alcoholism, trauma, homicide, suicide, violence, neuropsychiatric diseases, epilepsy, stress manifestations, HIV infection and AIDS, sexually transmitted diseases, tuberculosis, and skin infections (Marshall et al., 2000).

Globally, noncommunicable diseases are considered as a matter of serious consideration as these diseases are responsible for 36 million deaths each year and constituting a total 63% of the deaths worldwide (World Health Assembly 66, 2013). These diseases mainly comprise of the most common four diseases such as cardiovascular disease 48%, diabetes 3.5%, cancers 21%, respiratory diseases which constitute 12% of the people in incarceration (Enggist et al., 2014). Although these diseases affect people from all nationalities and all socioeconomic background, but it is seen that socioeconomic status and noncommunicable diseases have a direct link, given that most of the 10 million imprisoned belong to the most marginalized part of society with a poor socioeconomic background and are at a greater risk to develop noncommunicable diseases (World Health Organization, 2013). The prison environment offers various risk factors towards the development of noncommunicable diseases such as unavailability of healthy diet, lack of physical exercise, smoking, and use of alcohol. Hence the problems associated with diseases and associated risk factors present a major challenge in providing appropriate prevention and treatment strategies for the treatment of prisoners (World Health Organization, 2013). The risk of blood-borne infections is also very high, especially the infections responsible for HIV, TB, viral hepatitis B and C and other sexually transmitted disease (Hammett et al., 2002). This is coupled with the factors such as over-crowding, delay in diagnosis, less or no hygienic condition of prisons (Hammett et al., 2002).

It is estimated that, female prisoners constitute about 2%–9% of the prison in each country (Walmsley, 2006). Most women in prisons are usually mothers and are sole caregivers for their children. In Brazil, the percentage of mother prisoners is as much as 87% (Atabay, 2014), followed by Thailand with 82% (Atabay and Owen, 2013), United States and Russian Federation have 80% and United Kingdom has 60% of the inmate population as mothers (Atabay, 2014). They require special health care needs, as women in prison have higher mental illness rate compared to the male prison population (Bastick and Townhead, 2008). A high percentage of female prisoners experience physical or sexual abuse, even before their imprisonment (Quaker Council for European Affairs, 2007). Thus, female inmates are at a greater risk to develop Hepatitis C, HIV, and reproductive system related infections such as syphilis, chlamydia infection, and gonorrhea (Stöver, 2008). The health needs of the female prisoners demand personalized care including

treatment for substance abuse, mental health issues, violence, abuse, reproductive health, infectious diseases, and dental health (Enggist et al., 2014).

Healthcare Facilities for the Prisoners

Prisoners like everyone in the community have the right to enjoy good physical and mental health and retain to be entitled for healthcare facilities that are at least equivalent to those outside the confinement (Enggist et al., 2014; United Nations, 2016). The health care delivery starts right at the arrival of the prisoner, when he or she appears for a medical examination and continues throughout the detention period (Enggist et al., 2014).

In this regard, various international standards define the health care quality that should be provided to the prisoners. These standards are discussed below:

United Nations Guidelines

In providing the basic health care to the inmates, the United Nation has established standards as guideline for the provision of healthcare services in prisons (United Nations Organizations, 1990). Article 12 of the International Covenant on Economic, Social and Cultural Rights (United Nations, 1966) described the basic right as "the right of everyone to the enjoyment of the highest attainable standard of physical and mental health". This applies to the prisoners as it applies to every human being. Similarly, the United Nations (1990) mentioned in the principle 9 of their Basic Principle for the Treatment of prisoners that "Prisoners shall have access to the health services available in the country without discrimination on the grounds of their legal situation". This is to strengthen the concept that people in prison should be treated with high standard of health care facilities as this reflects on the part of the state's responsibility (United Nations Office on Drug and Crime, 2008; 2013).

Prison administration not only have a responsibility to fulfill the basic health needs of the prisoners but also to promote the well-being of the prisoners by establishing health care standards in the territory (Gatherer et al., 2014). Around the world prisoners are facilitated with varying levels of health care (Miller, 2013). They have different level of access to health care ranging from places in developing countries, where there is no facility of medical treatment to where there is very little access to the health care facility. However, in developed countries like United States, Canada, New Zealand, Australia, and Europe, the scenario is different as prisons over there are quite advanced in providing health care to the prisons with high standards of care and services (Miller, 2013).

European Prison Rules by the Council of Europe

In Europe, the council of Europe formulated European Prison Rules with the intention to provide the inmates with necessary healthcare needs in the region (Council of Europe, 2006). These rules were formulated with the assistance from the World Medical Association, European Committee for the Prevention of Torture and Inhuman or Degrading Treatment or Punishment (CPT), the International Council of Nurses, the Swiss Academy of Medical Sciences and the World Health Organization. Those rules are based on seven basic principles: "access to a doctor, equivalence of care, patient's consent and confidentiality, preventive health care, humanitarian assistance, professional independence, and professional competence" (Council of Europe, 2018).
