Nitazoxanide	• Giardiasis	<ul style="list-style-type: none"> • Orally bioavailable • Can treat resistant infections • Adverse events are rare
Trichomoniasis		
Metronidazole	• Trichomoniasis	<ul style="list-style-type: none"> • Drug of choice • 2 g once • If failure, give second dose in 4–6 weeks
Tinidazole	• Trichomoniasis	<ul style="list-style-type: none"> • 2 g once • Can be used for resistant infection
Toxoplasmosis		
Pyrimethamine	• Acute or congenital toxoplasmosis	<ul style="list-style-type: none"> • Combine with sulfadiazine or clindamycin • Give with leucovorin • Can cause bone marrow suppression
Sulfadiazine	• Acute or congenital toxoplasmosis	<ul style="list-style-type: none"> • Combine with pyrimethamine and folic acid • Can cause bone marrow suppression
Clindamycin	• Acute toxoplasmosis	<ul style="list-style-type: none"> • Combine with pyrimethamine • Use if cannot tolerate sulfonamide
Spiramycin	• Acute toxoplasmosis during early pregnancy	<ul style="list-style-type: none"> • Prevents fetal transmission • Available via individual investigator IND
Cryptosporidiosis		
Nitazoxanide	• Drug of choice for cryptosporidiosis	• Restore immune function in immunocompromised patients
Leishmaniasis		
Pentavalent antimony compounds (sodium stibogluconate)	<ul style="list-style-type: none"> • Cutaneous, mucocutaneous leishmaniasis • Visceral leishmaniasis (not in India) 	<ul style="list-style-type: none"> • 20 days IV/IM for cutaneous disease • 28 days IV/IM for visceral disease • Side effects: pancreatitis, elevated hepatic transaminases, bone marrow suppression • Can cause hemolytic anemia and renal failure • Available only through CDC
Amphotericin B	<ul style="list-style-type: none"> • Visceral leishmaniasis • Second-line agent for cutaneous disease 	<ul style="list-style-type: none"> • Used for antimony-resistant cases • Used during pregnancy • Side effects: renal toxicity, low potassium • Liposomal formulation preferred
Miltefosine	<ul style="list-style-type: none"> • Cutaneous leishmaniasis • Visceral leishmaniasis 	<ul style="list-style-type: none"> • Only oral agent • GI side effects (vomiting/diarrhea) • Teratogenic: do not use in pregnancy

Trypanosomiasis: African sleeping sickness		
Pentamidine	<ul style="list-style-type: none"> Early-stage <i>T. brucei gambiense</i> before CNS involvement 	<ul style="list-style-type: none"> IV administration associated with hypotension, tachycardia, and headache Hypoglycemia occurs; monitor blood glucose Nephrotoxic, can cause renal failure
Suramin	<ul style="list-style-type: none"> Early-stage <i>T. brucei rhodesiense</i> Second-line agent for early-stage <i>T. brucei gambiense</i> (only if pentamidine is contraindicated) 	<ul style="list-style-type: none"> Immediate reactions: malaise, nausea, and fatigue Side effects of multiple doses: renal toxicity, delayed neurological complications (headache, metallic taste, paresthesias, peripheral neuropathy) Only available through CDC
Nifurtimox + eflornithine combination therapy (NECT)	<ul style="list-style-type: none"> Late-stage <i>T. brucei gambiense</i> 	<ul style="list-style-type: none"> Safer and more effective than melarsoprol or eflornithine alone First-line regimen for this indication Side effects: abdominal pain, headache, tissue infections, pneumonia Only available through CDC
Melarsoprol	<ul style="list-style-type: none"> Late-stage <i>T. brucei rhodesiense</i> Second-line agent for late-stage <i>T. brucei gambiense</i> (only if NECT contraindicated) 	<ul style="list-style-type: none"> Fatal encephalopathy: 2%–10% of patients Coadminister with prednisolone to reduce the prevalence of encephalopathy Only available through CDC
Trypanosomiasis: Chagas disease		
Benznidazole	<ul style="list-style-type: none"> Drug of choice for Chagas 	<ul style="list-style-type: none"> Requires 60 days of treatment Urticarial dermatitis in 30% of patients; coadministration of antihistamines or corticosteroids can help Better tolerated in children, less well tolerated in adults > 50 years Most effective if administered early in the course of infection (acute stage) Efficacy in chronic Chagas is lower Give with food to minimize GI effects Monitor blood cell counts Available only through CDC
Nifurtimox	<ul style="list-style-type: none"> Alternative treatment for Chagas 	<ul style="list-style-type: none"> Requires 60 days of treatment Less well tolerated than benznidazole
Other Protozoal Infections		
Clindamycin and quinine	<ul style="list-style-type: none"> Severe babesiosis 	<ul style="list-style-type: none"> Quinine: monitor for cardiac effects (prolonged QT interval)
Azithromycin and atovaquone	<ul style="list-style-type: none"> Mild-moderate babesiosis 	
Tetracycline	<ul style="list-style-type: none"> Balantidiasis 	<ul style="list-style-type: none"> Drug of choice
Trimethoprim-sulfamethoxazole	<ul style="list-style-type: none"> Cyclosporiasis, isosporiasis 	<ul style="list-style-type: none"> Drug of choice

Chapter 55

Chemotherapy of Helminth Infections

Jennifer Keiser, James McCarthy, and Peter Hotez

ANTHELMINTIC DRUGS

- Benzimidazoles
- Diethylcarbamazine
- Doxycycline
- Ivermectin
- Praziquantel
- Mefenquine

- Oxamniquine
- Niclosamide
- Oxantel and Pyrantel Pamoate
- Tribendimidine
- Moxidectin
- Levamisole
- Nitazoxanide

Anthelmintic Drugs

Although a large number of anthelmintic drugs have been approved for human use, only a small number are widely used for treatment of helminth infections that occur worldwide (Figure 55-1). These include two drugs in the benzimidazole (BZ) class, albendazole and mebendazole, which are widely used for treatment of intestinal nematode and cestode infections; the macrocyclic lactone ivermectin, used to treat a variety of nematode and ectoparasite infections; and praziquantel, which is used to treat trematode and some cestode parasites. Because of their role in programs of mass drug administration (MDA), these drugs are amongst the most commonly used agents worldwide. WHO estimated that through MDA approximately 853 million people received one or more anthelmintic drugs in 2014 (WHO, 2016). In many resource-poor developing countries, several different anthelmintic drugs can be provided together through integrated programs of MDA to simultaneously target intestinal and filarial nematodes and trematodes (Webster et al., 2014). Key drugs, their indications, and important pharmacologic properties are listed in the Drug Facts table.

Benzimidazoles

Although a large number of drugs in this class have been synthesized and several have undergone clinical development for treatment of parasitic infections of humans, only two are currently in wide use, namely, *albendazole* and *mebendazole*, with *triclabendazole* reserved for treatment of liver fluke infection caused by *Fasciola hepatica*. *Thiabendazole* was formerly recommended for treatment of strongyloidiasis, but ivermectin is more effective and better tolerated.

Chemistry

Albendazole, mebendazole, and triclabendazole are all poorly water soluble and only slightly soluble in methanol. The chemical structures of these drugs are shown in Figure 55-2.

Mechanism of Action

The primary mechanism of action of BZs is thought to be inhibition of microtubule polymerization by binding to β -tubulin (Prichard, 1994). The selective toxicity of these agents against helminths results from their higher affinity for parasite β -tubulin than for the same target in higher eukaryotes. A range of other biochemical changes occurs in nematodes following BZ exposure, including inhibition of mitochondrial fumarate reductase, reduced glucose transport, and uncoupling of oxidative phosphorylation.

ADME

Mebendazole. The low systemic bioavailability (22%) of mebendazole results from a combination of poor absorption and rapid first-pass

metabolism at the intestinal wall and in the liver. Coadministration of cimetidine increases plasma levels of mebendazole, possibly due to inhibition of first-pass, CYP-mediated metabolism (Dayan, 2003). The small proportion of mebendazole that is absorbed is about 95% bound to plasma proteins and is extensively metabolized. Mebendazole, rather than its metabolites, appears to be the active drug form (Gottschall et al., 1990). Conjugates of mebendazole and its metabolites have been found in bile, but little unchanged mebendazole appears in the urine.

Albendazole. Albendazole is variably and erratically absorbed after oral administration; absorption is enhanced by the presence of fatty foods and possibly by bile salts. Administration following food, especially a fatty meal, enhances absorption by up to 5-fold in humans (Dayan, 2003). Cimetidine decreases albendazole bioavailability. The activity of albendazole against tissue-dwelling helminths is attributable to its active metabolite, albendazole sulfoxide. The better bioavailability of the parent drug and the activity of albendazole sulfoxide explain why albendazole is more active than mebendazole against tissue-dwelling helminths. The level of albendazole sulfoxide is enhanced 3.2-fold by grapefruit juice. However, grapefruit juice shortens its $t_{1/2}$ by 46%. It has been suggested that albendazole is metabolized by CYP3A4 enzymes in the intestinal mucosa, a process that can be inhibited by grapefruit juice (Nagy et al., 2002). After a 400-mg oral dose, albendazole cannot be detected in plasma because the drug is rapidly metabolized in the liver and possibly in the intestine, to albendazole sulfoxide, which has potent anthelmintic activity (Redondo et al., 1999).

Both the (+) and (–) enantiomers of albendazole sulfoxide are formed; the (+) enantiomer reaches much higher peak plasma concentrations in humans and is cleared much more slowly than the (–) form (Marques et al., 1999). Albendazole sulfoxide is about 70% bound to plasma proteins and has a highly variable plasma $t_{1/2}$ of 4–15 h (Marques et al., 1999). It is well distributed into various tissues, including hydatid cysts, where it reaches a concentration of about 20% that in plasma (Morris et al., 1987). Oxidation of the sulfoxide derivatives to the nonchiral sulfone metabolite of albendazole, which is pharmacologically inactive, is probably rate limiting in determining the clearance and therefore the plasma $t_{1/2}$ of the bioactive (+) sulfoxide metabolite. In animal models, BZs can induce their own metabolism (Gleizes et al., 1991). Albendazole metabolites are excreted mainly in the urine.

Triclabendazole. Administration of triclabendazole after food enhances its absorption, which might be due to the stimulation of gastric acid secretion, food-induced increase in drug solubility, or altered GI motility and transit time. After oral administration, triclabendazole is rapidly oxidized into two major metabolites, triclabendazole sulfoxide and triclabendazole sulfone, and only low concentrations of the parent drug can be detected

Abbreviations

AUC: area under the curve

MDA: mass drug administration
OTC: over the counter
STH: soil-transmitted helminth
TPAC: terephalic acid
TPAL: terephthalaldehyde
WHO: World Health Organization

in plasma. Triclabendazole sulfoxide is the metabolite active against *F. hepatica* (Keiser et al., 2005).

Therapeutic Uses

Mebendazole. Mebendazole is an effective drug for treatment of some GI nematode infections. It is only administered orally, with the same dosage schedule applying to adults and to children more than 2 years of age. For treatment of enterobiasis, a single 100-mg tablet is taken; if the patient is not cured, a second dose should be given after 3 weeks. For control of ascariasis, trichuriasis, or hookworm infections, the recommended regimen is 100 mg of mebendazole taken in the morning and evening for three consecutive days (or a single 500-mg tablet administered once). If the patient is not cured 3 weeks after treatment, a second course should be given. A 3-day mebendazole regimen is more effective than single doses of either mebendazole (500 mg) or albendazole (400 mg).

Albendazole. Albendazole is a safe and highly effective therapy for infections with GI nematodes, including *Ascaris lumbricoides*, *Trichuris trichiura*, and hookworms. For programmatic control of soil-transmitted helminths (STH) infections (enterobiasis, ascariasis, trichuriasis, and hookworm), albendazole is administered as a single oral 400-mg dose to adults and children more than 2 years of age. Cure rates for light-to-moderate *Ascaris* infections typically are more than 97%, although heavy infections

Figure 55-1 Relative incidence of helminth infections worldwide.

Figure 55-2 Structure of Benzimidazoles.

may require therapy for 2–3 days. A 400-mg dose of albendazole appears to be superior to a 500-mg dose of mebendazole for curing hookworm infections and reducing egg counts (Keiser and Utzinger, 2008). A 3-day regime of albendazole outperforms single-dose treatments against hookworm and *T. trichiura* infections (Steinmann et al., 2011). When administered at a dose of 400 mg daily for 3 days, albendazole shows some efficacy in treatment of strongyloidiasis but is less effective than ivermectin for treatment of this infection (Marti et al., 1996).

Albendazole is the drug of choice for chemotherapy of cystic hydatid disease due to *Echinococcus granulosus*. Although prolonged treatment with the drug leads to only a modest cure rate, it is useful as adjunctive treatment in the perioperative period to reduce the risk of disseminated infection resulting from spillage of cyst contents at the time of surgery or with nonoperative puncture, aspiration, injection, reaspiration (PAIR) procedures (Horton, 1997; Schantz, 1999). A typical dosage regimen for adults is 400 mg given twice a day (for children, 15 mg/kg per day with a maximum of 800 mg) for 1–6 months. Although it is the only drug available with useful activity against alveolar echinococcosis caused by *Echinococcus multilocularis* (Venkatesan, 1998), it is parasitostatic rather than parasitocidal, and lifelong therapy with or without surgical intervention is usually required to control this infection.

Albendazole also is the preferred treatment of neurocysticercosis caused by larval forms of *Taenia solium* (Evans et al., 1997; Garcia and Del Brutto, 2000). The recommended dosage is 400 mg given twice a day for adults for 8–30 days, depending on the number, type, and location of the cysts. For children, the dose is 15 mg/kg per day (maximum 800 mg) in two doses for 8–30 days. For both adults and children, the course can be repeated as necessary, as long as liver and bone marrow toxicities are monitored. Glucocorticoid therapy is usually begun before initiating albendazole therapy and is continued for several days after commencement of therapy to reduce the incidence of side effects resulting from inflammatory reactions to dead and dying cysticerci. Glucocorticoids increase plasma levels of albendazole sulfoxide. Prior to initiating chemotherapy of neurocysticercosis, consideration should be given to close observation or the administration of presumptive anticonvulsant therapy. Possible complications include arachnoiditis, vasculitis, cerebral edema, damage to the orbit or spinal cord, and the need for surgical intervention should obstructive hydrocephalus occur. A recent randomized trial indicated that albendazole in combination with praziquantel showed superior efficacy against neurocysticercosis compared to albendazole alone, either in standard or high dose (Garcia et al., 2014).

Albendazole, 400 mg per day, also has shown efficacy for therapy of certain microsporidial intestinal infections in patients with AIDS. Infection with *Capillaria philippinensis* can be treated with a 10-day treatment regimen with albendazole (400 mg/d).

Albendazole has been combined with DEC, ivermectin, or DEC plus ivermectin in programs directed toward controlling LF in most parts of the world (Molyneux and Zagaria, 2002; Ottesen et al., 1999; Thomsen et al., 2016). The strategy is annual dosing with combination therapy for

4–6 years to maintain the microfilaremia at such low levels that transmission cannot occur. The period of therapy is estimated to correspond to the duration of fecundity of adult worms. To avoid serious reactions to dying microfilariae, the albendazole/ivermectin combination is recommended in locations where filariasis coexists with either onchocerciasis or loiasis.

Triclabendazole. Triclabendazole is used for the treatment of fascioliasis and represents an alternative to praziquantel for treatment of paragonimiasis. Triclabendazole is administered at 10 mg/kg with a repeated dose administered when patients have high infection intensities (Keiser et al., 2005).

Adverse Effects; Drug Interactions

Apart from thiabendazole, the BZs have excellent safety profiles. Overall, the incidence of side effects, primarily mild GI symptoms, occur in only 1% of treated children. Side effects frequently encountered with therapeutic doses include anorexia, nausea, vomiting, and dizziness. Mebendazole does not cause significant systemic toxicity in routine clinical use, which may be due to its low systemic bioavailability. Transient symptoms of abdominal pain, distention, and diarrhea have occurred in cases of massive infection and expulsion of GI worms.

Albendazole produces few side effects when used for short-term therapy of GI helminth infections, even in patients with heavy worm burdens. In long-term therapy of cystic hydatid disease and neurocysticercosis, albendazole is well tolerated by most patients. The most common side effect is liver dysfunction, generally manifested by an increase in serum transaminase levels; rarely, jaundice may be noted, but liver enzymes return to normal after therapy is completed. Liver function tests should be monitored during protracted albendazole therapy; the drug is not recommended for patients with cirrhosis. The safety of albendazole in children less than 2 years of age has not been established. Long-term albendazole therapy can occasionally cause bone marrow toxicity, so blood counts should be monitored in this setting as well.

The BZs as a group display few clinically significant interactions with other drugs. Albendazole may induce its own metabolism; plasma levels of its sulfoxide metabolites can be increased by coadministration of glucocorticoids and possibly praziquantel. Due to theoretical considerations, caution is advised when using high doses of albendazole together with drugs that inhibit hepatic CYPs, such as ritonavir. Coadministration of cimetidine can increase the bioavailability of mebendazole.

Pediatric and Geriatric Indications and Problems

Although neither albendazole nor mebendazole is recommended for use in pregnancy, a review of the risk of congenital abnormalities from BZs concluded that their use during pregnancy was not associated with an increased risk of major congenital defects. Hookworm infections occur in many pregnant women in developing countries, including up to one-third of pregnant women in sub-Saharan Africa. Because of the increased morbidity conferred by iron deficiency anemia in pregnancy, monthly BZ treatment has been recommended by the WHO during the second and third trimesters of pregnancy on the basis that improved iron status due to eradication of hookworm infection has a demonstrable benefit for both mother and child. Nonetheless, it is recommended that treatment should be avoided during the first trimester of pregnancy. There is no evidence that maternal BZ therapy presents a risk to breastfed infants.

The BZs have not been extensively studied in children less than 2 years of age. The WHO concluded that BZs may be used in children more than 1 year old if the risks from adverse consequences caused by STHs are justified. The recommended dose is 200 mg of albendazole in children between the ages of 12 and 24 months.

Diethylcarbamazine

Chemistry

Diethylcarbamazine (*N,N*-diethyl-4-methylpiperazine-1-carboxamide) is formulated as the water-soluble citrate salt containing 51% by weight of the active base. The drug is soluble in water. Because the compound is tasteless, odorless, and stable to heat, it also can be taken in the form of

fortified table salt containing 0.2%–0.4% by weight of the base. The drug is available outside the U.S.; in the U.S., it is supplied by the CDC.

DIETHYLCARBAMAZINE

Mechanism of Action

The mechanisms of action of DEC against filarial species are unknown. Microfilarial forms of susceptible filarial species are most affected by DEC. These developmental forms of *Wuchereria bancrofti*, *Brugia malayi*, and *Loa loa* rapidly disappear from human blood after consumption of the drug. Microfilariae of *Onchocerca volvulus* rapidly disappear from skin after DEC administration, but the drug does not kill microfilariae in nodules that contain the adult (female) worms. The drug has some activity against the adult life-cycle stages of *W. bancrofti*, *B. malayi*, and *L. loa* but negligible activity against adult *O. volvulus*.

ADME

Diethylcarbamazine is absorbed rapidly from the GI tract. Peak plasma levels occur within 1–2 h; the plasma $t_{1/2}$ varies from 2 to 10 h, depending on the urinary pH. Alkalinizing the urine can elevate plasma levels, prolong the plasma $t_{1/2}$, and increase both the therapeutic effect and the toxicity of DEC (Awadzi et al., 1986). Dosage reduction may be required for people with renal dysfunction. Metabolism is rapid and extensive; a major metabolite, DEC-*N*-oxide, is active.

Therapeutic Uses

Recommended regimens differ according to whether the drug is used for population-based chemotherapy, treatment of confirmed filarial infection, or prophylaxis against infection.

- ***Wuchereria bancrofti*, *B. malayi*, and *B. timori*.** The standard regimen for the treatment of LF traditionally has been a 12-day, 6 mg/kg/d course of DEC. In the U.S., it is common practice to administer small test doses of 50–100 mg (1–2 mg/kg for children) over a 3-day period prior to beginning the 12-day regimen. However, a single dose of 6 mg/kg reportedly has comparable macrofilaricidal and microfilaricidal efficacy to the standard regimen (Addiss and Dreyer, 2000). Single-dose therapy may be repeated every 6–12 months, as necessary. Although DEC does not reverse existing lymphatic damage, early treatment of asymptomatic individuals may prevent progression of lymphatic damage. For mass treatment to interrupt transmission, effective strategies have included the introduction of DEC into table salt (0.2%–0.4% by weight of the base) (Gelband, 1994). DEC, given annually as a single oral dose of 6 mg/kg, is most effective in reducing microfilaremia when coadministered with either albendazole (400 mg) or ivermectin (0.2–0.4 mg/kg). Therapy is usually well tolerated.
- ***Onchocerca volvulus* and *L. loa*.** DEC is contraindicated for the treatment of onchocerciasis because it causes severe reactions related to microfilarial destruction, including worsening ocular lesions (Molyneux et al., 2003), and ivermectin is the preferred drug for this infection. DEC is the drug of choice for therapy of loiasis with some caveats (as discussed in the following material). Treatment is initiated with test doses of 50 mg (1 mg/kg in children) daily for 2–3 days, escalating to maximally tolerated daily doses of 9 mg/kg in three doses for 2–3 weeks. In patients with high-grade microfilaremia, low test doses are used, often accompanied by pretreatment with glucocorticoids or antihistamines, to minimize reactions to dying microfilariae. Albendazole may be useful in patients who either fail therapy with DEC or who cannot tolerate the drug. DEC is clinically effective against microfilariae and adult worms of *D. streptocerca*. DEC is no longer recommended as a first-line drug for the treatment of toxocariasis.

Adverse Effects

Below a daily dose of 8–10 mg/kg, direct toxic reactions to DEC are rarely severe and usually disappear within a few days despite continuation of

1004 therapy. These reactions include anorexia, nausea, headache, and, at high doses, vomiting. Major adverse effects result directly or indirectly from the host response to destruction of parasites, primarily microfilariae. Delayed reactions to dying adult worms may result in lymphangitis, swelling, and lymphoid abscesses in bancroftian and brugian filariasis and small skin wheals in loiasis. The drug occasionally causes severe side effects in heavy *L. loa* infections, including retinal hemorrhage and life-threatening encephalopathy. In patients with onchocerciasis, the Mazzotti reaction typically occurs within a few hours after the first dose. No significant drug interactions have been reported with DEC.

Precautions and Contraindications

Population-based therapy with DEC should be avoided where onchocerciasis or loiasis may be endemic in sub-Saharan Africa, although the drug can be used to protect foreign travelers from these infections. Pretreatment with glucocorticoids and antihistamines often is undertaken to minimize indirect reactions to DEC that result from release of antigen by dying microfilariae. Dosage reduction may be appropriate for patients with impaired renal function or persistent alkaline urine. DEC appears to be safe for use during pregnancy.

Doxycycline

Filarial parasites, including *W. bancrofti* and *O. volvulus*, harbor bacterial symbionts of the genus *Wolbachia*, against which long courses of doxycycline (see Chapter 59) (≥ 6 weeks) in bancroftian filariasis and onchocerciasis are effective. A 6-week regimen of doxycycline (100 mg daily), by killing the *Wolbachia*, leads to sterility of adult female *Onchocerca* worms.

HISTORY

In the mid-1970s, surveys of natural products revealed that a fermentation broth of the soil actinomycete *Streptomyces avermitilis* ameliorated infection with *Nematospiroides dubius* in mice. Isolation of the anthelmintic components from cultures of this organism led to discovery of the avermectins, a novel class of 16-membered macrocyclic lactones (Campbell, 1989). Ivermectin (mectizan; stromectol; 22,23-dihydroavermectin B1a) is a semisynthetic analog of avermectin B1a (abamectin), an insecticide developed for crop management. Ivermectin now is used extensively to control and treat a broad spectrum of infections caused by parasitic nematodes (roundworms) and arthropods (insects, ticks, and mites) that plague livestock and domestic animals (Campbell, 1993).

Ivermectin

Chemistry

Ivermectin exists as an odorless, off-white powder with high lipid solubility but poor solubility in water. It is a mixture of at least 80% 22,23-dihydroavermectin B1a and no more than 20% 22,23-dihydroavermectin B1b. B1a and B1b have nearly identical antiparasitic activities.

Mechanism of Action

Ivermectin immobilizes affected organisms by inducing tonic paralysis of the musculature. Avermectins induce paralysis by activating a family of ligand-gated Cl^- channels, particularly glutamate-gated Cl^- channels found only in invertebrates. Ivermectin probably binds to glutamate-activated Cl^- channels found in nematode nerve or muscle cells and causes hyperpolarization by increasing intracellular chloride concentration, resulting in paralysis. Glutamate-gated Cl^- channels probably are one of several sites of ivermectin action amongst invertebrates (Zufall et al., 1989). Avermectins also bind with high affinity to GABA-gated and other ligand-gated Cl^- channels in nematodes such as *Ascaris* and in insects, but the physiological consequences are less well defined. Lack of high-affinity avermectin receptors in cestodes and trematodes may explain why these helminths are not sensitive to ivermectin (Shoop et al., 1995). Avermectins also interact with GABA receptors in mammalian brain, but their affinity for invertebrate receptors is about 100-fold higher (Schaeffer and Haines, 1989).

ADME

Peak levels of ivermectin in plasma are achieved within 4–5 h after oral administration. The long $t_{1/2}$ (~57 h in adults) primarily reflects low systemic clearance (~1–2 L/h) and a large apparent volume of distribution. Ivermectin is about 93% bound to plasma proteins. The drug is extensively metabolized by hepatic CYP3A4 (Zeng et al., 1998). Virtually no ivermectin appears in human urine in either unchanged or conjugated form (Krishna and Klotz, 1993).

Therapeutic Uses

Onchocerciasis. Ivermectin, administered as a single oral dose (150–200 $\mu\text{g}/\text{kg}$) given every 6–12 months, is the drug of choice for onchocerciasis in adults and children 5 years or older (Goa et al., 1991). Marked reduction of microfilariae in the skin results in major relief of the intense pruritus that is a feature of onchocerciasis. Clearance of microfilariae from skin and ocular tissues occurs within a few days and lasts for 6–12 months; the dose then should be repeated. However, the drug is not curative because ivermectin has little effect on adult *O. volvulus*. Annual doses of the drug are quite safe and substantially reduce transmission of this infection.

Lymphatic Filariasis. Ivermectin is as effective as DEC for controlling LF, and unlike DEC, it can be used in regions where onchocerciasis, loiasis, or both are endemic (Ottesen and Ramachandran, 1995). A single annual dose of ivermectin (200 $\mu\text{g}/\text{kg}$) and a single annual dose of albendazole (400 mg) are even more effective in controlling LF than either drug alone (Ottesen et al., 1999). The duration of treatment is at least 5 years, based on the estimated fecundity of the adult worms.

Strongyloidiasis. Ivermectin, administered as a single dose of 150 to 200 $\mu\text{g}/\text{kg}$, is the drug of choice for human strongyloidiasis (Marti et al., 1996). It is generally recommended that a second dose be administered a week following the first dose. This regimen is more efficacious than a 3-day course of albendazole.

Infections With Other Intestinal Nematodes. Ivermectin is more effective in ascariasis and enterobiasis than in trichuriasis or hookworm infection. In the last two infections, although it is not curative, it significantly reduces the intensity of infection.

Other Indications. Taken as a single 200- $\mu\text{g}/\text{kg}$ oral dose, ivermectin is a first-line drug for treatment of cutaneous *larva migrans* caused by dog or cat hookworms and is an option for treatment of scabies and head lice. In uncomplicated scabies, two doses should be administered, 1–2 weeks apart. In severe (crusted) scabies, ivermectin should be used in repeated doses, with one recommended regimen entailing seven doses of 200 $\mu\text{g}/\text{kg}$ given with food on days 1, 2, 8, 9, 15, 22, and 29. It also is effective in community-driven control programs (Romani et al., 2015). The drug formulated as a topical 0.2% lotion is active against human head lice (Pariser et al., 2012).

Adverse Effects; Drug Interactions

Ivermectin is well tolerated by uninfected humans. In filarial infection, ivermectin therapy frequently causes a Mazzotti-like reaction to dying microfilariae. The intensity and nature of these reactions relate to the

microfilarial burden. After treatment of *O. volvulus* infections, these side effects usually are limited to mild itching and swollen, tender lymph nodes, which occur in 5%–35% of people, last just a few days, and are relieved by aspirin and antihistamines. Rarely, more severe reactions occur that include high fever, tachycardia, hypotension, dizziness, headache, myalgia, arthralgia, diarrhea, and facial and peripheral edema; these may respond to glucocorticoid therapy. Ivermectin induces milder side effects than does DEC, and unlike DEC, ivermectin seldom exacerbates ocular lesions in onchocerciasis. The drug can cause rare but serious side effects, occasionally resulting in permanent disability and encephalopathies in patients with heavy *L. loa* microfilaria. *Loa* encephalopathy is associated with ivermectin treatment of individuals with *Loa* microfilaremia levels 30,000 or more microfilariae per milliliter of blood. Ivermectin interactions with concurrently administered drugs can occur. For example, increased plasma levels of ivermectin have been observed in patients concurrently treated with ivermectin and levamisole (González Canga, 2008).

Precautions and Contraindications

Because of its effects on GABA receptors in the CNS, ivermectin is contraindicated in conditions associated with an impaired blood-brain barrier (e.g., African trypanosomiasis and meningitis). In programs of MDA where loiasis is endemic with either onchocerciasis or LF, ivermectin should be used with caution and in consultation with local or international experts.

Pediatric and Geriatric Indications and Problems. Ivermectin is not approved for use in children with less than 15 kg body weight or in pregnant or lactating women (low levels of the drug appear in the mother's milk). This is principally due to concerns about the passage of the drug across the immature blood-brain barrier.

Praziquantel

Chemistry

Praziquantel, a pyrazinoisoquinoline derivative, is a racemate, consisting of the biologically active enantiomer, R-praziquantel and the inactive diastomer S-praziquantel. The white crystalline powder is slightly soluble in water and freely soluble in alcohol and in methylene chloride.

Mechanism of Action

Praziquantel has two major effects on adult schistosomes. At the lowest effective concentrations, it causes increased muscular activity, followed by contraction and spastic paralysis. Affected worms detach from blood vessel walls and migrate from the mesenteric veins to the liver. At slightly higher concentrations, praziquantel causes tegumental damage and exposes a number of tegumental antigens (Redman et al., 1996). The clinical efficacy of this drug correlates better with tegumental action (Xiao et al., 1985). The drug is ineffective against juvenile schistosomes and therefore is relatively ineffective in early infection. An intact immune response is believed to be required for the clinical efficacy of the drug.

The primary site of action of praziquantel is uncertain (Aragon et al., 2009). The drug may act through generation of reactive oxygen species. It also promotes an influx of Ca^{2+} and possibly interacts with the variant Ca^{2+} channel Ca-var β (Jeziorski and Greenberg, 2006), which is found in schistosomes and other praziquantel-sensitive parasites. However, Ca^{2+} influx does not correlate with sensitivity to the drug (Pica-Mattoccia et al., 2008). Praziquantel inhibits adenosine flux (Angelucci et al., 2007), but definitive evidence that this action contributes to the anthelmintic effect is lacking.

ADME

Praziquantel is readily absorbed after oral administration (<80%), reaching maximal levels in human plasma in approximately 2 h. Praziquantel is highly protein bound (~80%, nearly exclusive to albumin). Praziquantel distributes throughout the body, with highest concentrations measured in the liver and kidneys. It crosses the blood-brain barrier. Breast milk concentrations are approximately 25% of plasma concentrations (Olliaro et al., 2014).

Extensive stereoselective first-pass metabolism takes place. The main metabolite is trans-4-hydroxypraziquantel. The plasma $t_{1/2}$ is 2.2–8.9 h following 40 mg/kg in healthy fasted adults. In patients with severe liver disease, including those with hepatosplenic schistosomiasis, pharmacokinetic parameters might be altered (Olliaro et al., 2014). About 70% of an oral dose is recovered as metabolites in the urine within 24 h; most of the remainder is eliminated in the bile.

Therapeutic Uses

Praziquantel is the drug of choice for treating schistosomiasis caused by all *Schistosoma* species that infect humans. A single oral dose of 40 mg/kg or three doses of 20 mg/kg each, given 4–6 h apart, generally produce cure rates of 70%–95% and consistently high reductions (>85%) in egg counts (Uttinger and Keiser, 2004). Three doses of 25 mg/kg taken 4–8 h apart result in high rates of cure for infections with the liver flukes *Clonorchis sinensis* and *Opisthorchis viverrini* or the intestinal flukes *Fasciolopsis buski*, *Heterophyes heterophyes*, and *Metagonimus yokogawai*. The same three-dose regimen, used over 2 days, is highly effective against infections with the lung fluke *Paragonimiasis westermani*. The liver fluke *F. hepatica* is resistant to praziquantel and should be treated with triclabendazole (Keiser et al., 2005). Low doses of praziquantel can be used to treat intestinal infections with adult cestodes (a single oral dose of 25 mg/kg for *Hymenolepis nana* and 10 to 20 mg/kg for *Diphyllobothrium latum*, *Taenia saginata*, or *T. solium*). Re-treatment after 7–10 days is advisable for individuals heavily infected with *H. nana*. Although albendazole is preferred for therapy of human cysticercosis, praziquantel represents an alternative agent; its use for this indication is hampered by the important pharmacokinetic interaction with dexamethasone and other corticosteroids that should be coadministered in this condition (Evans et al., 1997).

Adverse Effects; Drug Interactions

Abdominal discomfort and drowsiness may occur shortly after taking praziquantel; these direct effects are transient and dose related. Indirect effects such as fever, pruritus, urticaria, rashes, arthralgia, and myalgia are noted occasionally. Such side effects and increases in eosinophilia often relate to parasite burden and may be a consequence of parasite killing and antigen release. In neurocysticercosis, inflammatory reactions to praziquantel may produce meningismus, seizures, and cerebrospinal fluid pleocytosis. These effects usually are delayed in onset, last 2–3 days, and respond to analgesics and anticonvulsants. Praziquantel is contraindicated in ocular cysticercosis because the host response can irreversibly damage the eye. Driving and other tasks requiring mental alertness should be avoided. Severe hepatic disease can prolong the $t_{1/2}$, requiring dosage adjustment. The bioavailability of praziquantel is reduced by inducers of hepatic CYPs, such as carbamazepine and phenobarbital; predictably, coadministration of the CYP inhibitor cimetidine has the opposite effect (Dachman et al., 1994). Dexamethasone reduces the bioavailability of praziquantel. Under certain conditions, praziquantel may increase the bioavailability of albendazole (Homeida et al., 1994).

Pediatric and Geriatric Indications and Problems. Praziquantel is considered safe in children more than 4 years of age. A pediatric formulation, an oral dispersible tablet, based on either racemic praziquantel or enantiopure L-PZQ is under development.

Metrifonate

Metrifonate (trichlorfon) is an organophosphorus compound used first as an insecticide and later as an anthelmintic, especially for treatment of *Schistosoma haematobium*. It remains a second-line drug for this indication. Metrifonate is a prodrug; at physiological pH, it is converted nonenzymatically to dichlorvos (DDVP), a potent cholinesterase inhibitor

1006 (see Chapter 10). However, inhibition of cholinesterase alone is unlikely to explain the antischistosomal properties of metrifonate.

Oxamniquine

Oxamniquine is a second-line drug after praziquantel for the treatment of *Schistosoma mansoni* infection. *Schistosoma haematobium* and *Schistosoma japonicum* are refractory to this drug.

Niclosamide

Niclosamide, a halogenated salicylanilide derivative, was introduced for human use as a taeniocide. Niclosamide is no longer approved for use in the U.S. It has some use in intestinal *T. solium* infection where neurocysticercosis is present or cannot be excluded.

Oxantel and Pyrantel Pamoate

Chemistry

The tetrahydropyrimidine analogues include pyrantel pamoate and the *m*-oxyphenol analogue of pyrantel, oxantel pamoate. Both drugs are practically insoluble in water and alcohol.

Mechanism of Action

Pyrantel and its analogues are depolarizing neuromuscular blocking agents. They open nonselective cation channels and induce persistent activation of nicotinic acetylcholine receptors and spastic paralysis of the worm (Robertson et al., 1994). Pyrantel pamoate is active at the L type, while oxantel pamoate is active on the N subtype of nicotinic acetylcholine receptors (Williamson et al., 2009).

Pyrantel also inhibits cholinesterases. It causes a slowly developing contracture of isolated preparations of *Ascaris* at 1% of the concentration of acetylcholine required to produce the same effect. Pyrantel exposure leads to depolarization and increased spike-discharge frequency, accompanied by increases in tension, in isolated helminth muscle preparations.

ADME

Pyrantel pamoate and oxantel pamoate are poorly absorbed from the GI tract, a property that confines their action to intraluminal GI nematodes. Less than 15% of pyrantel pamoate is excreted in the urine as parent drug and metabolites. The major proportion of an administered dose is recovered in the feces.

Therapeutic Uses

Pyrantel pamoate is an alternative to mebendazole or albendazole for treatment of ascariasis and enterobiasis. High cure rates are achieved after a single oral dose of 11 mg/kg, to a maximum of 1 g. Pyrantel also is effective against hookworm infections caused by *Ancylostoma duodenale* and *Necator americanus*, although repeated doses are needed to cure heavy infections by *N. americanus*. The drug should be used in combination with oxantel pamoate for mixed infections with *T. trichiura*. Indeed, oxantel pamoate was shown to have a higher efficacy than the BZs mebendazole and albendazole against infections with *T. trichiura* (Speich et al., 2016). Oxantel pamoate combined with albendazole is a highly effective

combination in the treatment of ascariasis, trichuriasis, and hookworm infections. For pinworm infections, repeat the treatment after an interval of 2 weeks.

Adverse Effects; Drug Interactions

Transient and mild GI symptoms occasionally occur, as do headache, dizziness, rash, and fever. Pyrantel pamoate has not been studied in pregnant women.

Tribendimidine

Tribendimidine is a drug that has been marketed in China for over a decade. Given the efforts to introduce the drug to Western markets, it is included in this chapter.

Chemistry

Tribendimidine (a symmetrical diamidine derivative) is a yellow crystalline powder that does not dissolve in water and only marginally in anhydrous ethanol, methanol, and acetone. It dissolves in chloroform (Xiao et al., 2005).

Mechanism of Action

Tribendimidine is an agonist of muscle nicotinic acetylcholine receptors of parasitic nematodes. Tribendimidine is more selective for the B subtype than the L subtype of nicotinic acetylcholine receptors; hence, it can activate a different population of nematode parasite nicotinic acetylcholine receptors. This might explain why tribendimidine exhibits activity on a levamisole-resistant isolate of *Oesophagostomum dentatum* and why the spectrum of action of tribendimidine is broader (covering also the trematodes *C. sinensis* and *O. viverrini* and cestodes) to that of other cholinergic anthelmintics like levamisole (Robertson et al., 2015).

ADME

Tribendimidine pharmacokinetics has been studied in Chinese healthy volunteers (Yuan et al., 2010) and in patients infected with *O. viverrini* (Duthaler et al., 2015). Tribendimidine cannot be detected in plasma. It is rapidly and completely broken down to dADT, which is the active metabolite and TPAL. Furthermore, dADT undergoes metabolism to acetylated dADT, and TPAL is transformed into TPAC. The *t*_{1/2} of dADT was 4.7 h in healthy volunteers following 400 mg of tribendimidine. Tribendimidine is mainly excreted through the urine (Yuan et al., 2010).

Therapeutic Uses

Tribendimidine is given to children below 15 years of age and adults at doses of 200 mg and 400 mg, respectively. With regard to STH infections, tribendimidine has a similar activity profile as albendazole: Tribendimidine shows high cure and egg reduction rates against *A. lumbricoides*, moderate-to-good efficacy against hookworm, and a low cure rate but moderate egg reduction rates against *T. trichiura*. Against pinworm infections, cure rates with tribendimidine were 74.1% (single dose) and 97.1% (two doses) (Xiao et al., 2013). Tribendimidine has high activity against *C. sinensis* and *O. viverrini*: Single dosages of tribendimidine (200 and 400 mg) showed similar efficacy than multiple treatments with praziquantel (Qian et al., 2013; Soukhathammavong et al., 2011). The efficacy of tribendimidine against strongyloides and cestode infections remains to be studied.

Adverse Effects; Drug Interactions

Tribendimidine shows a good safety profile. Adverse effects (e.g., dizziness, vertigo, headache, nausea, vomiting, and fatigue) are mainly mild and self-limiting. Drug interactions have not yet been studied thoroughly.

Moxidectin

Moxidectin, a macrocyclic lactone related to ivermectin, is currently under development for the treatment of onchocerciasis and perhaps other helminth infections.

Chemistry

Moxidectin, a white or pale yellow powder, is slightly soluble in water but readily soluble in organic solvents.

Mechanism of Action

The mechanism of action of the avermectins has been described previously. A difference has been demonstrated between ivermectin and moxidectin for interacting with GABA-gated Cl^- channels. In contrast to ivermectin, moxidectin is a poor substrate for P-glycoproteins, hence suggesting a different mechanism or susceptibility to resistance (Cobb and Boeckh, 2009).

ADME

Pharmacokinetics parameters were dose proportional at dosages from 3 to 36 mg. Peak plasma concentrations occurred 2 to 6 h after dosing. Administration with food resulted in an increase of over 30% in C_{max} and in AUC. Moxidectin has a very long elimination $t_{1/2}$ (mean 20–35 days) and very large volume of distribution (Cotreau et al., 2003). Following a single dose, moxidectin was observed in the breast milk of lactating women (Korth-Bradley et al., 2011). Several hydroxy and oxidative metabolites have been identified in vitro (Dupuy et al., 2001); however, in animals the rate of metabolites is low.

Therapeutic Uses

Moxidectin is currently under development for the treatment of *O. volvulus* infections. A dose-finding phase 2 study revealed a significantly higher efficacy of 8 mg moxidectin compared to ivermectin (Awadzi et al., 2014).

Adverse Effects

Mazzotti reactions including pruritus, rash, increased pulse rate, and decreased mean arterial pressure were commonly observed after moxidectin treatment (Awadzi et al., 2014).

Pediatric and Geriatric Indications and Problems. Moxidectin has not been used in children less than 12 years of age; however, pediatric trials are ongoing.

Levamisole

Chemistry

Levamisole, the levorotatory isomer of the racemic molecule tetramisole, belongs to the imidazole derivatives. The hydrochloride salt is a white powder soluble in water and methanol. Levamisole has been discontinued in the U.S.

Mechanism of Action

Levamisole is a cholinergic anthelmintic. The drug is a potent muscle and nerve L-subtype selective nicotinic acetylcholine receptor channel agonist. Opening of these channels produces depolarization, calcium entry, and an increase in sarcoplasmic calcium, producing spastic muscle contraction, resulting in passive elimination of the worms (Martin et al., 2012). Levamisole was also shown to inhibit fumarate reductase and hence succinate production, the main source of ATP, which is key for the survival of worms (Janssen, 1976). With regard to mammalian cells, levamisole inhibits alkaline phosphatases in most tissues (Janssen, 1976). The immunomodulatory activity of levamisole has been explained as a stimulation of antibody formation and enhancement of T cell response by stimulating T-cell activation and proliferation.

ADME

Levamisole is quickly absorbed from the GI tract, and C_{max} levels are reached within 2 h. The drug is extensively metabolized in the liver, and its half-life is about 4 h (Janssen, 1976).

Therapeutic Uses

Levamisole has excellent activity against *A. lumbricoides* but low-to-moderate efficacy against *T. trichiura* and hookworm infections (Keiser and Utzinger, 2008). Levamisole has also been used for its immunomodulatory effects in cancer.

Adverse Effects; Drug Interactions

Adverse effects mostly occur at high dosages used for immunotherapy. At the single low dosages for anthelmintic therapy, adverse effects are minor and include nausea, vomiting, headache, dizziness, or abdominal pain. Severe adverse effects such as agranulocytosis have been described following the use of high dosages. In healthy volunteers, increased plasma levels of ivermectin and decreased plasma concentrations of albendazole sulfoxide were observed when these drugs were coadministered with levamisole (Awadzi et al., 2004).

Nitazoxanide

Nitazoxanide (*N*-[nitrothiazolyl] salicylamide) is an oral synthetic broad-spectrum antiparasitic agent. Nitazoxanide has been used as a single agent to treat mixed infections with intestinal parasites (protozoa and helminths). Nitazoxanide is approved in the U.S. for treatment of cryptosporidiosis and giardiasis and has activity against *E. histolytica* (see Chapter 54 for details). Nitazoxanide also has activity against intestinal helminthes such as *H. nana*, *A. lumbricoides*, *T. trichiura*, and *Enterobius vermicularis* (van den Enden, 2009). It also is an effective broad-spectrum antiviral agent (Rossignol, 2014). Adverse effects are rare with nitazoxanide.

Acknowledgment: Alex Loukas, James W. Tracy, and Leslie T. Webster, Jr contributed to this chapter in recent editions of this book. We have retained some of their text in the current edition.

Sulfonamides

HISTORY

The sulfonamide drugs were the first effective chemotherapeutic agents used systemically for the prevention and cure of bacterial infections in humans. Investigations in 1932 at the I. G. Farbenindustrie in Germany resulted in the patenting of prontosil and several other azo dyes containing a sulfonamide group. Because synthetic azo dyes had been studied for their action against streptococci, Domagk tested the new compounds and observed that mice with streptococcal and other infections could be protected by prontosil. In 1933, Foerster reported giving prontosil to a 10-month-old infant with staphylococcal septicemia and achieving a dramatic cure. Favorable clinical results with prontosil and its active metabolite, sulfanilamide, in puerperal sepsis and meningococcal infections awakened the medical profession to the new field of antibacterial chemotherapy, and experimental and clinical articles soon appeared in profusion. The development of the carbonic anhydrase inhibitor-type diuretics and the sulfonylurea hypoglycemic agents followed from observations made with the sulfonamide antibiotics. For discovering the chemotherapeutic value of prontosil, Domagk was awarded the Nobel Prize in Medicine for 1938 (Lesch, 2007). The advent of penicillin and other antibiotics diminished the usefulness of the sulfonamides, but the introduction of the combination of trimethoprim and sulfamethoxazole in the 1970s increased the use of sulfonamides for the prophylaxis and treatment of specific microbial infections.

Sulfonamides are derivatives of *para*-aminobenzenesulfonamide (sulfanilamide; Figure 56–1) and are congeners of PABA. Most of them are relatively insoluble in water, but their sodium salts are readily soluble. The minimal structural prerequisites for antibacterial action are all embodied in sulfanilamide itself. The sulfur must be linked directly to the benzene ring.

The *para*-NH₂ group (the N of which has been designated as N4) is essential and can be replaced only by moieties that can be converted *in vivo* to a free amino group. Substitutions made in the amide NH₂ group (position N1) have variable effects on antibacterial activity of the molecule; substitution of heterocyclic aromatic nuclei at N1 yields highly potent compounds.

Mechanism of Action

Sulfonamides are competitive inhibitors of *dihydropteroate synthase*, the bacterial enzyme responsible for the incorporation of PABA into *dihydropteroic acid*, the immediate precursor of *folic acid* (Figure 56–2). Sensitive microorganisms are those that must synthesize their own folic acid; bacteria that can use preformed folate are not affected. Sulfonamides administered as single agents are *bacteriostatic*; cellular and humoral defense mechanisms of the host are essential for final eradication of the infection. Toxicity is selective for bacteria because mammalian cells require preformed folic acid, cannot synthesize it, and are thus insensitive to drugs acting by this mechanism (Grayson, 2010).

Synergists of Sulfonamides

Trimethoprim exerts a synergistic effect with sulfonamides. It is a potent and selective competitive inhibitor of microbial *dihydrofolate reductase*, the enzyme that reduces *dihydrofolate* to *tetrahydrofolate*, which is required for one-carbon transfer reactions. Coadministration of a sulfonamide and trimethoprim (as in *trimethoprim-sulfamethoxazole*) introduces sequential blocks in the biosynthetic pathway for tetrahydrofolate (see Figure 56–2); the combination is much more effective than either agent alone (Bushby and Hitchings, 1968). Similar complementary activity is seen with pyrimethamine, which is generally used in combination with agents such as sulfadoxine, sulfadiazine, or dapsone. The predominant systemic use of sulfonamides is now in such combinations.

Antibacterial Spectrum

On their original introduction to therapeutic use, sulfonamides had a wide range of antimicrobial activity against both gram-positive and

gram-negative bacteria; a high percentage of isolates of *Streptococcus pyogenes*, *Streptococcus pneumoniae*, *Staphylococcus aureus*, and *Haemophilus influenzae* were susceptible to systemically achievable concentrations of sulfonamides. However, the increase in sulfonamide resistance in these agents is such that sulfonamide activity against these pathogens in serious infections cannot be assumed, and they play little part in empiric therapy (Grayson, 2010). Potent activity remains against most isolates of *Haemophilus ducreyi*, *Nocardia*, and *Klebsiella granulomatis*. Isolates of *Neisseria meningitidis* and *Shigella* are generally resistant, as are many strains of *Escherichia coli* isolated from patients with UTIs (Olson et al., 2009). Sulfonamides also possess important activity against a number of parasites (see Chapters 53 and 54).

Bacterial Resistance

Bacterial resistance to sulfonamides can originate by random mutation and selection or by transfer of resistance by plasmids (see Chapter 52); it usually does not involve cross-resistance to other classes of antibiotics. Resistance to sulfonamide can result from (1) a lower affinity of dihydropteroate synthase for sulfonamides, (2) decreased bacterial permeability or active efflux of the drug, (3) an alternative metabolic pathway for synthesis of an essential metabolite, or (4) increased production of an essential metabolite or drug antagonist (e.g., PABA) (Gold and Moellering, 1996). Plasmid-mediated resistance is due to plasmid-encoded, drug-resistant dihydropteroate synthetase.

ADME

Except for sulfonamides especially designed for their local effects in the bowel (see Chapter 51), this class of drugs is absorbed rapidly from the GI tract. Approximately 70%–100% of an oral dose is absorbed, and sulfonamide can be found in the urine within 30 min of ingestion. Peak plasma levels are achieved in 2–6 h, depending on the drug. Peak plasma drug concentrations achievable in vivo are about 100–200 $\mu\text{g/mL}$. The small

intestine is the major site of absorption, but some of the drug is absorbed from the stomach. Absorption from other sites, such as the vagina, respiratory tract, or abraded skin, is variable and unreliable, but a sufficient amount may enter the body to cause toxic reactions in susceptible persons or to produce sensitization.

All sulfonamides are bound in varying degree to plasma proteins, particularly to albumin. Sulfonamides are distributed throughout all tissues of the body. The sulfonamides readily enter pleural, peritoneal, synovial, ocular, and similar body fluids and may reach concentrations therein that are 50%–80% of the simultaneously determined concentration in blood. Because the protein content of body fluids usually is low, the drug is present in the unbound active form. After systemic administration of adequate doses, sulfadiazine and sulfisoxazole attain concentrations in CSF that may be effective in meningitis. However, because of the emergence of sulfonamide-resistant microorganisms, these drugs are used rarely for the treatment of meningitis. Sulfonamides pass readily through the placenta and reach the fetal circulation. The concentrations attained in the fetal tissues may cause both antibacterial and toxic effects.

Sulfonamides are metabolized in the liver. The major metabolite is the N4-acetylated sulfonamide. Acetylation results in products that have no antibacterial activity but retain the toxic potential of the parent substance. Sulfonamides are eliminated from the body partly as the unchanged drug and partly as metabolic products. The largest fraction is excreted in the urine, and the $t_{1/2}$ depends on renal function. In acid urine, the older sulfonamides are insoluble, and crystalline deposits may form. Small amounts are eliminated in the feces, bile, milk, and other secretions.

Pharmacological Properties of Individual Sulfonamides

Sulfonamides for Systemic Use

Sulfisoxazole. Sulfisoxazole is a rapidly absorbed and excreted sulfonamide. Its high solubility eliminates much of the renal toxicity inherent in the use of older sulfonamides. Sulfisoxazole is bound extensively to plasma proteins. Following an oral dose of 2–4 g, peak concentrations in plasma of 110–250 $\mu\text{g/mL}$ are found in 2–4 h. Approximately 30% of sulfisoxazole in the blood and about 30% in the urine is in the acetylated form. The kidney excretes about 95% of a single dose in 24 h. Concentrations of the drug in urine thus greatly exceed those in blood and may be bactericidal. The concentration in CSF is about a third of that in the blood. Sulfisoxazole acetyl is tasteless and hence preferred for oral use in children. Sulfisoxazole acetyl in combination with erythromycin ethylsuccinate is used in children with otitis media.

The untoward effects produced by this agent are similar to those that follow the administration of other sulfonamides, as discussed further in the chapter. Because of its relatively high solubility in the urine as compared with sulfadiazine, sulfisoxazole only infrequently produces hematuria or crystalluria (0.2%–0.3%). Despite this, patients taking this drug should ingest an adequate quantity of water. Sulfisoxazole currently is preferred over other sulfonamides by most clinicians when a rapidly absorbed and rapidly excreted sulfonamide is indicated.

Sulfamethoxazole. Sulfamethoxazole is a close congener of sulfisoxazole, but its rates of enteric absorption and urinary excretion are slower ($t_{1/2}$ of 11 h). It is administered orally and employed for both systemic and UTIs. Precautions must be observed to avoid sulfamethoxazole crystalluria because of the high percentage of the acetylated, relatively insoluble,

Figure 56-1 Sulfanilamide and PABA. Sulfonamides are derivatives of sulfanilamide and act by virtue of being congeners of para-aminobenzoate (PABA). The antimicrobial and dermatological anti-inflammatory agent dapsone (4,4'-diaminodiphenyl sulfone; see Chapters 60 and 70) also bears a resemblance to PABA and sulfanilamide.

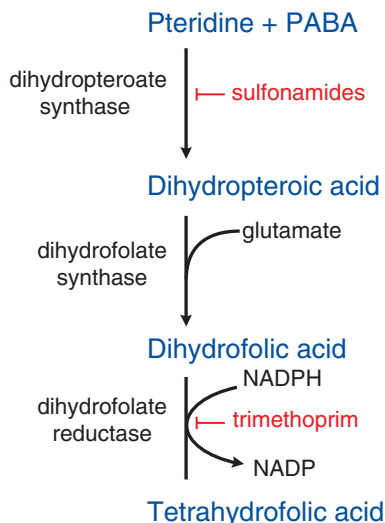

Figure 56–2 Steps in folate metabolism blocked by sulfonamides and trimethoprim. Coadministration of a sulfonamide and trimethoprim introduces sequential blocks in the biosynthetic pathway for tetrahydrofolic acid; the combination is much more effective than either agent alone.

form of the drug in the urine. The clinical uses of sulfamethoxazole are the same as those for sulfisoxazole. In the U.S., it is marketed only in fixed-dose combinations with trimethoprim.

Sulfadiazine. Sulfadiazine given orally is absorbed rapidly from the GI tract. Peak blood concentrations are reached within 3–6 h, with a $t_{1/2}$ of 10 h. About 55% of the drug is bound to plasma protein. Therapeutic concentrations are attained in CSF within 4 h of a single oral dose of 60 mg/kg. Both free and acetylated forms of sulfadiazine are readily excreted by the kidney; 15%–40% of the excreted drug is in acetylated form. Alkalinization of the urine accelerates the renal clearance of both forms by diminishing their tubular reabsorption. Precaution must be taken to ensure fluid intake adequate to produce a daily urine output of at least 1200 mL in adults and a corresponding quantity in children. If this cannot be accomplished, sodium bicarbonate may be given to reduce the risk of crystalluria.

Sulfadoxine. This agent has a particularly long plasma $t_{1/2}$ of 7–9 days. Although no longer marketed in the U.S., its combination with pyrimethamine (500 mg sulfadoxine plus 25 mg pyrimethamine) is listed as WHO essential medicine and is used for the prophylaxis and treatment of malaria caused by mefloquine-resistant strains of *Plasmodium falciparum* (see Chapter 53). However, because of severe and sometimes fatal reactions, including the Stevens-Johnson syndrome, and the emergence of resistant strains, the drug has limited usefulness for the treatment of malaria.

Sulfonamides for Topical Use

Sulfacetamide. Sulfacetamide is the N1-acetyl-substituted derivative of sulfanilamide. Its aqueous solubility is about 90 times that of sulfadiazine. Solutions of the sodium salt of the drug are employed extensively in the management of ophthalmic infections. Very high aqueous concentrations are not irritating to the eye and are effective against susceptible microorganisms. The drug penetrates into ocular fluids and tissues in high concentration. Sensitivity reactions to sulfacetamide are rare, but the drug should not be used in patients with known hypersensitivity to sulfonamides. A 30% solution of the sodium salt has a pH of 7.4, whereas the solutions of sodium salts of other sulfonamides are highly alkaline. See Chapters 69 and 70 for ocular and dermatological uses.

Silver Sulfadiazine. Silver sulfadiazine is used topically to reduce microbial colonization and the incidence of infections from burns. Silver sulfadiazine should not be used to treat an established deep infection. Silver is released slowly from the preparation in concentrations that are selectively

toxic to the microorganisms. However, bacteria may develop resistance to silver sulfadiazine. Although little silver is absorbed, the plasma concentration of sulfadiazine may approach therapeutic levels if a large surface area is involved. Adverse reactions—burning, rash, and itching—are infrequent. Silver sulfadiazine is considered an agent of choice for the prevention of burn infections.

Mafenide. The sulfonamide mafenide is applied topically to prevent colonization of burns by a large variety of gram-negative and gram-positive bacteria. It should not be used in treatment of an established deep infection. Adverse effects include intense pain at sites of application and allergic reactions. Application of the drug over a large burn surface can lead to appreciable systemic absorption. The drug and its primary metabolite inhibit *carbonic anhydrase*, and the urine becomes alkaline. Metabolic acidosis with compensatory tachypnea and hyperventilation may ensue; these effects limit the usefulness of mafenide.

Therapeutic Uses

Urinary Tract Infections

Because a significant percentage of UTIs are caused by sulfonamide-resistant microorganisms, sulfonamides are no longer a therapy of first choice; trimethoprim-sulfamethoxazole is preferred (although resistance to this agent is increasing as well). *Sulfisoxazole* may be used effectively for cystitis in areas where the prevalence of resistance is not high. The usual dosage is 2–4 g initially, followed by 1–2 g orally four times a day for 5–10 days.

Nocardiosis

Trimethoprim-sulfamethoxazole is most commonly used for infections due to *Nocardia* spp., but sulfisoxazole or sulfadiazine are alternative agents, given in dosages of 6–8 g daily. For serious infections, addition of a second agent, such as imipenem, amikacin, or linezolid, is recommended.

Toxoplasmosis

The combination of pyrimethamine and sulfadiazine is the treatment of choice for toxoplasmosis (see Chapter 54). Pyrimethamine is given as a loading dose of 2000 mg followed by 50–75 mg orally per day, with sulfadiazine 1–1.5 g orally every 6 h, plus folinic acid (leucovorin) 10–25 mg orally each day for at least 6 weeks (Panel on Opportunistic Infections, 2016). Patients should receive at least 2 L of fluid intake daily to prevent crystalluria.

Adverse Reactions

Hypersensitivity Reactions

Among the skin and mucous membrane manifestations attributed to sensitization to sulfonamide are morbilliform, scarlatiniform, urticarial, erysipeloid, pemphigoid, purpuric, and petechial rashes, as well as erythema nodosum, erythema multiforme of the Stevens-Johnson type, Behçet syndrome, exfoliative dermatitis, and photosensitivity. These hypersensitivity reactions occur most often after the first week of therapy but may appear earlier in previously sensitized individuals. Fever, malaise, and pruritus frequently are present simultaneously. The incidence of untoward dermal effects is about 2% with sulfisoxazole; patients with AIDS manifest a higher frequency of rashes with sulfonamide treatment than do other individuals. A syndrome similar to serum sickness may appear after several days of sulfonamide therapy. Drug fever is a common untoward manifestation of sulfonamide treatment; the incidence approximates 3% with sulfisoxazole.

Disturbances of the Urinary Tract

The risk of crystalluria is very low with the more soluble agents, such as sulfisoxazole. Crystalluria has occurred in dehydrated patients with HIV who were receiving sulfadiazine for *Toxoplasma* encephalitis. Crystalluria can be prevented by maintaining daily urine volume of at least 1200 mL (in adults) or alternatively urine alkalinization because the solubility of sulfisoxazole increases greatly with slight elevations of pH.

Disorders of the Hematopoietic System

Although rare, acute hemolytic anemia may occur. In some cases, it may be due to a sensitization phenomenon; in other instances, the hemolysis

is related to an erythrocytic deficiency of G6PD activity. Agranulocytosis occurs in about 0.1% of patients who receive sulfadiazine; it also can follow the use of other sulfonamides. Although return of granulocytes to normal levels may be delayed for weeks or months after sulfonamide is withdrawn, most patients recover spontaneously with supportive care. Aplastic anemia involving complete suppression of bone marrow activity with profound anemia, granulocytopenia, and thrombocytopenia is an extremely rare occurrence with sulfonamide therapy. It probably results from a direct myelotoxic effect and may be fatal. Reversible suppression of the bone marrow is quite common in patients with limited bone marrow reserve (e.g., patients with AIDS or those receiving myelosuppressive chemotherapy).

Miscellaneous Reactions

Anorexia, nausea, and vomiting occur in 1%–2% of persons receiving sulfonamides. Focal or diffuse necrosis of the liver owing to direct drug toxicity or sensitization occurs in less than 0.1% of patients. Headache, nausea, vomiting, fever, hepatomegaly, jaundice, and laboratory evidence of hepatocellular dysfunction usually appear 3–5 days after sulfonamide administration is started, and the syndrome may progress to acute yellow atrophy and death. The administration of sulfonamides to newborn infants, especially if premature, may lead to the displacement of bilirubin from plasma albumin, potentially causing an encephalopathy called *kernicterus*. Sulfonamides should not be given to pregnant women near term because these drugs cross the placenta and are secreted in milk.

Drug Interactions

Drug interactions of the sulfonamides are seen mainly with the oral anti-coagulants, the sulfonylurea hypoglycemic agents, and the hydantoin anticonvulsants. In each case, sulfonamides can potentiate the effects of the other drug by inhibiting its metabolism or by displacing it from albumin. Dosage adjustment may be necessary when a sulfonamide is given concurrently.

Trimethoprim-Sulfamethoxazole

Trimethoprim inhibits bacterial dihydrofolate reductase, an enzyme downstream from the one that sulfonamides inhibit in the same biosynthetic sequence (see Figure 56–2). The combination of trimethoprim with sulfamethoxazole was an important advance in the development of clinically effective and synergistic antimicrobial agents. In much of the world, the combination of trimethoprim with sulfamethoxazole is known as *cotrimoxazole*. In addition to its combination with sulfamethoxazole, trimethoprim is available as a single-entity preparation.

Mechanism of Action

The antimicrobial activity of the combination of trimethoprim and sulfamethoxazole results from actions on sequential steps of the enzymatic pathway for the synthesis of tetrahydrofolic acid (see Figure 56–2). Tetrahydrofolate is essential for one-carbon transfer reactions (e.g., the synthesis of thymidylate from deoxyuridylate). Selective toxicity for microorganisms is achieved in two ways. Mammalian cells use preformed folates from the diet and do not synthesize the compound. Furthermore, trimethoprim is a highly selective inhibitor of dihydrofolate reductase of lower organisms: About 100,000 times more drug is required to inhibit human reductase than the bacterial enzyme. The optimal ratio of the concentrations of the two agents equals the ratio of the MICs of the drugs acting independently. Although this ratio varies for different bacteria, the most effective ratio for the greatest number of microorganisms is 20:1, sulfamethoxazole:trimethoprim. The combination is thus formulated to achieve a sulfamethoxazole concentration in vivo that is 20 times greater than that of trimethoprim; sulfamethoxazole has pharmacokinetic properties such that the concentrations of the two drugs will thus be relatively constant in the body over a long period. Although each agent alone usually exerts bacteriostatic activity, when the organism is sensitive to both agents, bactericidal activity may be achieved.

Antibacterial Spectrum

The antibacterial spectrum of trimethoprim is similar to that of sulfamethoxazole, although trimethoprim is 20–100 times more potent. *Pseudomonas aeruginosa*, *Bacteroides fragilis*, and enterococci are clinically resistant. There is significant variation in the susceptibility of Enterobacteriaceae to trimethoprim in different geographic locations because of the spread of resistance mediated by plasmids and transposons (see Chapter 52).

Spectrum of Trimethoprim-Sulfamethoxazole in Combination

Although most *S. pneumoniae* are susceptible, there has been a disturbing increase in resistance (paralleling the rise in penicillin resistance), and its value for empiric therapy/use in respiratory tract infections is questionable. Most strains of *S. aureus* and *Staphylococcus epidermidis* remain susceptible, even among methicillin-resistant isolates, although geographic variation exists. *Streptococcus pyogenes* is usually sensitive when proper testing procedures (media with low thymidine content) are followed (Bowen et al., 2012). The *viridans* group of streptococci is typically susceptible, although susceptibility among penicillin-resistant strains is low (Diekema et al., 2001). Susceptibility in *E. coli* varies by geographic region, although it has been declining in general. *Proteus mirabilis*, *Klebsiella* spp., *Enterobacter* spp., *Salmonella*, *Shigella*, *Pseudomonas pseudomallei*, *Serratia*, and *Alcaligenes* spp. are typically susceptible. Also sensitive are *Brucella abortus*, *Pasteurella haemolytica*, *Yersinia pseudotuberculosis*, *Yersinia enterocolitica*, and *Nocardia asteroides*.

Bacterial Resistance

Bacterial resistance to trimethoprim-sulfamethoxazole is a rapidly increasing problem, although resistance is lower than it is to either of the agents alone. Resistance often is due to the acquisition of a plasmid that codes for an altered dihydrofolate reductase.

ADME

The pharmacokinetic profiles of sulfamethoxazole and trimethoprim are closely, but not perfectly, matched to achieve a constant ratio of 20:1 in their concentrations in blood and tissues. After a single oral dose of the combined preparation, trimethoprim is absorbed more rapidly than sulfamethoxazole. Peak blood concentrations of trimethoprim usually occur by 2 h in most patients, whereas peak concentrations of sulfamethoxazole occur by 4 h after a single oral dose. The half-lives of trimethoprim and sulfamethoxazole are 11 and 10 h, respectively.

When 800 mg sulfamethoxazole is given with 160 mg trimethoprim (one “double-strength” tablet; “single strength” ratio is 400 mg to 80 mg, maintaining the same ratio) twice daily, the peak concentrations of the drugs in plasma are about 40 and 2 µg/mL, the optimal ratio. Peak concentrations are similar (46 and 3.4 µg/mL) after intravenous infusion of 800 mg sulfamethoxazole and 160 mg trimethoprim over a period of 1 h.

Trimethoprim is distributed and concentrated rapidly in tissues; about 40% is bound to plasma protein in the presence of sulfamethoxazole. The volume of distribution of trimethoprim is almost nine times that of sulfamethoxazole. The drug readily enters CSF and sputum. High concentrations of each component of the mixture also are found in bile. About 65% of sulfamethoxazole is bound to plasma protein. About 60% of administered trimethoprim and from 25% to 50% of administered sulfamethoxazole are excreted in the urine in 24 h. Two-thirds of the sulfonamide is unconjugated. Metabolites of trimethoprim also are excreted. The rates of excretion and the concentrations of both compounds in the urine are reduced significantly in patients with uremia.

Therapeutic Uses

Urinary Tract Infections

Treatment of an uncomplicated lower UTI with trimethoprim-sulfamethoxazole is highly effective for sensitive bacteria, although some

authorities avoid empiric use for UTIs when local resistance among *E. coli* exceeds 20% (Gupta et al., 2010). Single-dose therapy (320 mg trimethoprim plus 1600 mg sulfamethoxazole in adults) has been effective in some cases for the treatment of acute uncomplicated UTI, but longer courses of therapy are less likely to be associated with recurrence. Most treatment guidelines recommend 160/800 mg administered twice daily for 3 days for uncomplicated cystitis and for 10–14 days for complicated disease or pyelonephritis. Trimethoprim also is found in therapeutic concentrations in prostatic secretions, and trimethoprim-sulfamethoxazole is often effective for the treatment of bacterial prostatitis.

Bacterial Respiratory Tract Infections

Trimethoprim-sulfamethoxazole is effective for mild acute exacerbations of chronic bronchitis. Administration of 800–1200 mg sulfamethoxazole plus 160–240 mg trimethoprim twice a day appears to be effective in decreasing fever, purulence and volume of sputum, and sputum bacterial count. Trimethoprim-sulfamethoxazole should not be used to treat streptococcal pharyngitis because it does not eradicate the microorganism. It is effective for acute otitis media in children and acute maxillary sinusitis in adults that are caused by susceptible strains of *H. influenzae* and *S. pneumoniae*.

GI Infections

The combination is an alternative to a fluoroquinolone for treatment of shigellosis caused by susceptible strains, which are becoming less common worldwide. Trimethoprim and trimethoprim/sulfamethoxazole are no longer recommended for prevention or treatment of traveler's diarrhea because of increasing resistance worldwide among likely pathogens (Hill et al., 2006).

Infection by *Pneumocystis jiroveci*

High-dose therapy (trimethoprim 15–20 mg/kg/d plus sulfamethoxazole 75–100 mg/kg/d in three or four divided doses; typical maximum dose is 20 mg/kg/d of trimethoprim) is effective for *Pneumocystis jiroveci* pneumonia (Panel on Opportunistic Infections, 2016). Adjunctive corticosteroids should be given at the onset of anti-*Pneumocystis* therapy in patients with a P_{O_2} less than 70 mm Hg or an alveolar-arterial gradient less than 35 mm Hg. Prophylaxis with 800 mg sulfamethoxazole and 160 mg trimethoprim once daily or three times a week is effective in preventing pneumonia caused by this organism in patients with HIV as well as other immunocompromising conditions (such as neutropenia and solid-organ transplantation). Adverse reactions are less frequent with the lower prophylactic doses of trimethoprim-sulfamethoxazole.

Methicillin-Resistant *Staphylococcus aureus* Infections

The increasing incidence of community-acquired infections due to MRSA has provided a role for trimethoprim-sulfamethoxazole as an adjunctive therapy to incision and drainage of complicated abscesses. However, it is less effective than standard therapy in the treatment of invasive MRSA infections, including bacteremia (Paul et al., 2015).

Miscellaneous Infections

Nocardia infections have been treated successfully with the combination, but failures also have been reported. Although a combination of doxycycline and streptomycin or gentamicin now is considered the treatment of choice for brucellosis, trimethoprim-sulfamethoxazole may be an effective substitute for the doxycycline combination. Trimethoprim-sulfamethoxazole also has been used successfully for infection by *Stenotrophomonas maltophilia* and infection by the intestinal parasites *Cyclospora* and *Isospora*. Wegener granulomatosis may respond, depending on the stage of the disease.

Adverse Effects

Trimethoprim-sulfamethoxazole may extend the toxicity of the sulfonamides. The margin between toxicity for bacteria and that for humans may be relatively narrow when the patient is folate deficient. In such cases, trimethoprim-sulfamethoxazole may cause or precipitate megaloblastosis, leukopenia, or thrombocytopenia. Hematological reactions include various anemias, coagulation disorders, granulocytopenia, agranulocytosis,

purpura, Henoch-Schönlein purpura, and sulfhemoglobinemia. Trimethoprim-sulfamethoxazole reportedly causes up to three times as many dermatological reactions as does sulfisoxazole alone (5.9% vs. 1.7%). Mild and transient jaundice has been noted and appears to have the histological features of allergic cholestatic hepatitis. Permanent impairment of renal function may follow the use of trimethoprim-sulfamethoxazole in patients with renal disease due to sulfamethoxazole crystalluria; liberal fluid intake should be encouraged to dilute the urine during therapy. An increase in serum creatinine without decrement in glomerular filtration rate may be observed with high-dose therapy due to trimethoprim's inhibition of creatinine secretion. Hyperkalemia can also be observed, as trimethoprim has a similar structure to potassium-sparing diuretics such as triamterene. Patients with HIV frequently have hypersensitivity reactions to trimethoprim-sulfamethoxazole (rash, neutropenia, Stevens-Johnson syndrome, Sweet syndrome, and pulmonary infiltrates). Rapid and slow desensitization protocols have been established for patients intolerant to medically necessary therapy (Gluckstein and Ruskin, 1995).

The Quinolones

The first quinolone, nalidixic acid, was isolated as a by-product of the synthesis of chloroquine and made available for the treatment of UTIs. The introduction of fluorinated 4-quinolones (fluoroquinolones), such as norfloxacin, ciprofloxacin, and levofloxacin (Table 56–1), represents a particularly important therapeutic advance: These agents have broad antimicrobial activity and are effective after oral administration for the treatment of a wide variety of infectious diseases (Mitscher and Ma, 2003). However, due to potentially fatal side effects, many quinolones had to be withdrawn from the U.S. market: lomefloxacin and sparfloxacin (phototoxicity, QTc prolongation); gatifloxacin (systemic forms only; hypoglycemia); temafloxacin (immune hemolytic anemia); trovafloxacin (hepatotoxicity); grepafloxacin (cardiotoxicity); and cinafloxacin (phototoxicity). In all cases, the side effects were discovered during postmarketing surveillance (Sheehan and Chew, 2003).

Mechanism of Action

The quinolone antibiotics target bacterial DNA gyrase and topoisomerase IV. For many gram-positive bacteria, topoisomerase IV is the primary target (Alovero et al., 2000). In contrast, DNA gyrase is the primary quinolone target in many gram-negative microbes. The gyrase introduces negative supercoils into the DNA to combat excessive positive supercoiling that can occur during DNA replication (Figure 56–3) (Cozzarelli, 1980). The quinolones inhibit gyrase-mediated DNA supercoiling at concentrations that correlate well with those required to inhibit bacterial growth (0.1–10 µg/mL). Mutations of the gene that encodes the A subunit of the gyrase can confer resistance to these drugs. Topoisomerase IV, which separates interlinked (catenated) daughter DNA molecules that are the product of DNA replication, also is a target for quinolones.

Eukaryotic cells do not contain DNA gyrase. They do contain a conceptually and mechanistically similar type II DNA topoisomerase, but quinolones inhibit it only at concentrations (100–1000 µg/mL) much higher than those needed to inhibit the bacterial enzymes.

Antibacterial Spectrum

The fluoroquinolones are potent bactericidal agents against *Proteus*, *E. coli*, *Klebsiella*, and various species of *Salmonella*, *Shigella*, *Enterobacter*, and *Campylobacter*. While once a standard therapy for *N. gonorrhoeae* infections, resistance has increased to the point these agents are no longer recommended in many countries for empiric therapy of gonorrhea (Centers for Disease Control and Prevention, 2015). Some fluoroquinolones are active against *Pseudomonas* spp., with ciprofloxacin and levofloxacin having substantial enough activity for use in systemic infections. Fluoroquinolones have good in vitro activity against staphylococci, but they are less active against methicillin-resistant strains, and there is concern over development of resistance during therapy. Activity against streptococci is significantly greater with the newer agents, including levofloxacin,

TABLE 56-1 ■ STRUCTURAL FORMULAS OF SELECTED QUINOLONES AND FLUOROQUINOLONES

CONGENER	R ₁	R ₆	R ₇	X
Nalidixic acid	-C ₂ H ₅	-H	-CH ₃	-N-
Norfloxacin	-C ₂ H ₅	-F		-CH-
Ciprofloxacin		-F		-CH-
Levofloxacin		-F		

gemifloxacin, and moxifloxacin. Several intracellular bacteria are inhibited by fluoroquinolones at concentrations that can be achieved in plasma; these include species of *Chlamydia*, *Mycoplasma*, *Legionella*, *Brucella*, and *Mycobacterium* (including *Mycobacterium tuberculosis*). Ciprofloxacin, ofloxacin, and moxifloxacin have MIC₉₀ values from 0.5 to 3 µg/mL for *Mycobacterium fortuitum*, *Mycobacterium kansasii*, and *M. tuberculosis*. Moxifloxacin also has useful activity against anaerobes.

Bacterial Resistance

Resistance to quinolones may develop during therapy via mutations in the bacterial chromosomal genes encoding DNA gyrase or topoisomerase IV or by active transport of the drug out of the bacteria (Oethinger et al., 2000). Less commonly, plasmid-mediated resistance develops through proteins that bind to and protect the topoisomerases from quinolone effects. Resistance has increased after the introduction of fluoroquinolones, especially in *Pseudomonas* and staphylococci. *Escherichia coli*, *Campylobacter jejuni*, *Salmonella*, *N. gonorrhoeae*, and *S. pneumoniae* are also increasingly fluoroquinolone resistant (Olson et al., 2009).

ADME

Most quinolones are well absorbed after oral administration. Peak serum levels of the fluoroquinolones are obtained within 1–3 h of an oral dose. The volume of distribution of quinolones is high, with concentrations in urine, kidney, lung, and prostate tissue and stool, bile, and macrophages and neutrophils higher than serum levels. Food may delay the time to peak serum concentrations. Ciprofloxacin, ofloxacin, and levofloxacin have been detected in human breast milk; because of their excellent bioavailability, the potential exists for substantial exposure of nursing infants. Except for moxifloxacin, quinolones are cleared predominantly

by the kidney, and dosages must be adjusted for renal failure. Moxifloxacin should not be used in patients with hepatic failure.

Pharmacological Properties of Individual Quinolones

Norfloxacin

Norfloxacin's gram-negative activity is similar to, but somewhat less potent than, that of ciprofloxacin. However, relatively low serum levels are reached with norfloxacin and limit its usefulness in the treatment of UTIs and gastrointestinal infections. The serum *t*_{1/2} is 3–5 h for norfloxacin; approximately 25% of the drug is eliminated unchanged in the urine, with hepatic metabolism also occurring.

Ciprofloxacin

Ciprofloxacin's bioavailability is approximately 70%. Typical oral doses are 250–750 mg and intravenous doses are 200–400 mg twice daily (maximum dose 1.5 g/d). The elimination *t*_{1/2} is about 5 h, and the drug is typically dosed twice daily, with the exception of an extended-release formulation, which can be dosed once daily.

Ofloxacin/Levofloxacin

Ofloxacin has somewhat more potent gram-positive activity; separation of the more active S- or levorotatory isomer yields levofloxacin, which has even better antistreptococcal activity. Bioavailability of both of these agents is excellent, such that intravenous and oral doses are the same; levofloxacin is dosed once daily (250–750 mg) as opposed to twice-daily dosing for ofloxacin (200–400 mg daily divided every 12 h).

Moxifloxacin

Moxifloxacin improves further on the gram-positive potency of levofloxacin, typically having MICs one to two dilutions lower against

Figure 56-3 Model of the formation of negative DNA supercoils by DNA gyrase. DNA gyrase binds to two segments of DNA (1), creating a node of positive (+) superhelix. The enzyme then introduces a double-strand break in the DNA and passes the front segment through the break (2). The break is then resealed (3), creating a negative (–) supercoil. Quinolones inhibit the nicking and closing activity of the gyrase and, at higher concentrations, block the decatenating activity of topoisomerase IV. (Reprinted with permission from AAAS. Cozzarelli NR. DNA gyrase and the supercoiling of DNA. *Science*, 1980, 207:953–960.)

S. pneumoniae. It also has expanded activity against anaerobic pathogens but is substantially less active than ciprofloxacin or levofloxacin against *P. aeruginosa*. Moxifloxacin is well absorbed, with equivalent intravenous and oral doses; the $t_{1/2}$ is about 12 h, allowing for daily dosing (usual dose 400 mg daily). Moxifloxacin undergoes hepatic sulfation and glucuronidation. Less than a quarter of systemic moxifloxacin is excreted unchanged via the kidneys, and because high concentrations are not achieved in the urine, it is not recommended for UTIs.

Gatifloxacin and Gemifloxacin

The agents gatifloxacin and gemifloxacin have a similar spectrum of activity to moxifloxacin, with enhanced potency against gram-positive organisms and poor activity versus *Pseudomonas*. They are less active than moxifloxacin against *B. fragilis*. Both have high bioavailability and renal elimination. Gatifloxacin is no longer available for systemic use in the U.S. due to toxicity concerns, but an ophthalmic preparation is licensed for the treatment of bacterial conjunctivitis.

Therapeutic Uses

Urinary Tract Infections

Nalidixic acid is useful only for UTIs caused by susceptible microorganisms. The fluoroquinolones are significantly more potent and are a mainstay of treatment of upper and lower UTIs (Fihn, 2003). They are more efficacious than trimethoprim-sulfamethoxazole or oral β -lactams for the treatment of UTIs. Because of their broad spectrum of activity, however, recent guidelines suggest reserving their use for complicated cystitis or pyelonephritis when possible. Moxifloxacin does not accumulate in the urine and is not approved for treatment of UTIs. Typical treatment durations for the other quinolones are 3 days for uncomplicated cystitis and 5–7 days for uncomplicated pyelonephritis.

Prostatitis

Norfloxacin, ciprofloxacin, ofloxacin, and levofloxacin are effective in the treatment of prostatitis caused by sensitive bacteria. Fluoroquinolones administered for 4–6 weeks appear to be effective in patients not responding to trimethoprim-sulfamethoxazole.

Sexually Transmitted Diseases

Fluoroquinolones lack activity for *Treponema pallidum* but have activity in vitro against *Chlamydia trachomatis* and *Haemophilus ducreyi*. For chlamydial urethritis/cervicitis, a 7-day course of ofloxacin or levofloxacin is an alternative to a 7-day treatment with doxycycline or a single dose of azithromycin; other available quinolones have not been reliably effective. Previously, a single oral dose of a fluoroquinolone such as ciprofloxacin had been effective treatment of sensitive strains of *N. gonorrhoeae*, but increasing resistance to fluoroquinolones has led to ceftriaxone being the first-line agent for this infection. Chancroid (infection by *H. ducreyi*) can be treated with 3 days of ciprofloxacin.

GI and Abdominal Infections

Norfloxacin, ciprofloxacin, ofloxacin, and levofloxacin given for 1–3 days all have been effective in the treatment of patients with traveler's diarrhea, reducing the duration of loose stools by 1–3 days. Ciprofloxacin in a single daily dose is also effective for prophylaxis of traveler's diarrhea. Ciprofloxacin and ofloxacin can cure most patients with enteric fever caused by *Salmonella typhi*, as well as bacteremic nontyphoidal infections in patients with HIV, and clears chronic fecal carriage. Ciprofloxacin, ofloxacin, and levofloxacin, when combined with metronidazole, may be useful in the management of intra-abdominal infections when *Enterococcus* is not a likely pathogen. Moxifloxacin as a single agent was shown to have similar efficacy to piperacillin/tazobactam for complicated intra-abdominal infection, although there are concerns over increasing resistance in *B. fragilis*.

Respiratory Tract Infections

Many newer fluoroquinolones, including levofloxacin, moxifloxacin, and gemifloxacin, have excellent activity against *S. pneumoniae*, *H. influenzae*, and the atypical respiratory pathogens. Thus, these agents are frequently used in the management of community-acquired pneumonia and for

upper respiratory tract infections such as sinusitis that are not responsive to more narrow-spectrum agents. Mild-to-moderate respiratory exacerbations owing to *P. aeruginosa* in patients with cystic fibrosis have responded to oral fluoroquinolone therapy with ciprofloxacin or levofloxacin.

Bone, Joint, and Soft Tissue Infections

The treatment of chronic osteomyelitis may require prolonged (weeks to months) antimicrobial therapy with agents active against *S. aureus* or gram-negative rods. Failures are associated with the development of resistance, particularly in *S. aureus*. Combination therapy with a fluoroquinolone and rifampin has been effective at reducing the development of resistance and providing good cure rates, especially in the management of early prosthetic joint infections. In diabetic foot infections, the fluoroquinolones in combination with an agent with antianaerobic activity are a reasonable choice.

Other Infections

Ciprofloxacin and levofloxacin are used for the prophylaxis of anthrax and are effective for the treatment of tularemia (Hendricks et al., 2014). The quinolones, especially moxifloxacin, may be used as part of multiple-drug regimens for the treatment of multidrug-resistant tuberculosis and atypical mycobacterial infections as well as *Mycobacterium avium* complex infections in AIDS (see Chapter 60) (American Thoracic Society, 2003). Quinolones, when used as prophylaxis in neutropenic patients, have decreased the incidence of gram-negative rod bacteremias (Hughes et al., 2002). Levofloxacin and ciprofloxacin are approved to treat and prevent anthrax as well as plague due to *Yersinia pestis*.

Adverse Effects

Gastrointestinal Adverse Effects

Common adverse reactions involve the GI tract, with 3%–17% of patients reporting mild nausea, vomiting, and abdominal discomfort. Fluoroquinolones have emerged as a common cause of *Clostridium difficile* colitis due to the spread of quinolone-resistant strains.

Neurologic Adverse Effects

Side effects (1%–11%) of the CNS include mild headache and dizziness. Rarely, hallucinations, delirium, and seizures have occurred, predominantly in patients who were also receiving theophylline or NSAIDs. Patients with a history of epilepsy are at higher risk for fluoroquinolone-induced convulsions. Recently, the fluoroquinolones have been recognized as a rare cause of peripheral neuropathy, which in some cases has been irreversible.

Musculoskeletal Adverse Effects

Arthralgias and joint pain are occasionally reported with fluoroquinolones. Tendon rupture or tendinitis (usually of the Achilles tendon) is a recognized adverse effect, especially in those more than 60 years old, in patients taking corticosteroids, and in solid-organ transplant recipients. Early animal studies suggested an increased risk of cartilage damage and malformation among young animals (Burkhardt et al., 1997). Subsequent human studies have not noted a substantially increased risk of these effects in children or among the offspring of pregnant women who received fluoroquinolones. Nevertheless, the agents are typically avoided in pregnancy and among young children (Sabharwal and Marchant, 2006).

Other Adverse Effects

Among the quinolones available in the U.S., moxifloxacin carries the highest risk for QT interval prolongation and torsades de pointes arrhythmias; gemifloxacin, levofloxacin, and ofloxacin appear to have lower risk; and ciprofloxacin has the lowest risk. However, the overall risk of torsades de pointes is small with the use of fluoroquinolones. Gatifloxacin's propensity to cause both hypo- and hyperglycemia, especially in older adults, led to its removal for systemic use in the U.S. (Park-Wyllie et al., 2006). Other agents such as levofloxacin may rarely be associated with dysglycemias among at-risk patients. Rashes, including photosensitivity reactions, also can occur; patients with frequent sun exposure should be advised to protect themselves with clothing or sunscreen.

All quinolones form complexes with divalent and trivalent cations (e.g., calcium, iron, aluminum). When coadministered orally with quinolones, these cations can chelate the quinolone and reduce systemic bioavailability. Thus, a separation of at least 2 h between oral administration of quinolones and these cations is recommended. Ciprofloxacin inhibits the metabolism of theophylline, and toxicity from elevated concentrations of the methylxanthine may occur (Schwartz et al., 1988). NSAIDs may augment displacement of GABA from its receptors by the quinolones, enhancing neurologic adverse effects (Halliwell et al., 1993). Due to risk for QT prolongation, quinolones should be used with caution in patients on class III (amiodarone) and class IA (quinidine, procainamide) antiarrhythmics (see Chapter 30).

Antiseptic Agents for Urinary Tract Infections

Urinary tract antiseptics are concentrated in the renal tubules, where they inhibit the growth of many species of bacteria. These agents cannot be used to treat systemic infections because effective concentrations are not achieved in plasma with safe doses; however, they can be administered orally to treat UTIs.

Methenamine

Methenamine (hexamethylenamine) is a urinary tract antiseptic and prodrug that acts by generating formaldehyde via the following reaction:

At pH 7.4, almost no decomposition occurs; the yield of formaldehyde is 6% of the theoretical amount at pH 6 and 20% at pH 5. Thus, acidification of the urine promotes formaldehyde formation and formaldehyde-dependent antibacterial action. The decomposition reaction is fairly slow, and 3 h are required to reach 90% completion.

Antimicrobial Activity

Nearly all bacteria are sensitive to free formaldehyde at concentrations of about 20 µg/mL. Microorganisms do not develop resistance to formaldehyde. Urea-splitting microorganisms (e.g., *Proteus* spp.) tend to raise the pH of the urine and thus inhibit the release of formaldehyde.

Pharmacology, Toxicology, and Therapeutic Uses

Methenamine is absorbed orally, but 10%–30% decomposes in the gastric juice unless the drug is protected by an enteric coating. Because of the ammonia produced, methenamine is contraindicated in hepatic insufficiency. Excretion in the urine is nearly quantitative. When the urine pH is 6 and the daily urine volume is 1000–1500 mL, a daily dose of 2 g will yield a urine concentration of 18–60 µg/mL of formaldehyde; this is more than the MIC for most urinary tract pathogens. Low pH alone is bacteriostatic, so acidification serves a double function. The acids commonly used are mandelic acid and hippuric acid. GI distress frequently is caused by doses more than 500 mg four times a day, even with enteric-coated tablets. Painful and frequent micturition, albuminuria, hematuria, and rashes may result from doses of 4 to 8 g/d given for longer than 3–4 weeks. Renal insufficiency is not a contraindication to the use of methenamine alone, but the acids given concurrently may be detrimental; methenamine mandelate is contraindicated in renal insufficiency. Methenamine combines with sulfamethizole and perhaps other sulfonamides in the urine, which results in mutual antagonism; therefore, these drugs should not be used in combination.

Methenamine is not a primary drug for the treatment of acute UTIs but is of value for chronic suppressive treatment of UTIs. The agent is most useful when the causative organism is *E. coli*, but it usually can suppress the common gram-negative offenders and often *S. aureus* and *S. epidermidis* as well. *Enterobacter aerogenes* and *Proteus vulgaris* are usually resistant. A urinary pH less than 5 is typically necessary for methenamine to be active; some clinicians recommend monitoring of the urinary pH and even urinary acidification with ammonium chloride or ascorbic acid.

Nitrofurantoin

Nitrofurantoin is a synthetic nitrofuran that is used for the prevention and treatment of UTIs.

Antimicrobial Activity

Nitrofurantoin is activated by enzymatic reduction, with the formation of highly reactive intermediates that seem to be responsible for the observed capacity of the drug to damage DNA. Bacteria reduce nitrofurantoin more rapidly than do mammalian cells, and this is thought to account for the selective antimicrobial activity of the compound. Nitrofurantoin is active against many strains of *E. coli* and enterococci. However, most species of *Proteus* and *Pseudomonas* and many species of *Enterobacter* and *Klebsiella* are resistant. Nitrofurantoin is bacteriostatic for most susceptible microorganisms at concentrations of 32 µg/mL or less and is bactericidal at concentrations of 100 µg/mL or more. The antibacterial activity is higher in acidic urine.

Pharmacology, Toxicity, and Therapeutic Uses

Nitrofurantoin is absorbed rapidly and completely from the GI tract. Antibacterial concentrations are not achieved in plasma following ingestion of recommended doses because the drug is eliminated rapidly. The plasma $t_{1/2}$ is 0.3–1 h; about 40% is excreted unchanged into the urine. The average dose of nitrofurantoin yields a concentration in urine of about 200 µg/mL. This concentration is soluble at pH greater than 5, but the urine should not be alkalinized because this reduces antimicrobial activity. The rate of excretion is linearly related to the creatinine clearance, so in patients with impaired glomerular function, the efficacy of the drug may be decreased and the systemic toxicity increased. Nitrofurantoin colors the urine brown.

The oral dosage of nitrofurantoin for adults is 50–100 mg four times a day with meals and at bedtime, less for the macrocrystalline formulation (100 mg every 12 h for 7 days). A single 50- to 100-mg dose at bedtime may be sufficient to prevent recurrences. The daily dose for children is 5–7 mg/kg but may be as low as 1 mg/kg for long-term therapy. A course of therapy should not exceed 14 days; repeated courses should be separated by rest periods. Pregnant women, individuals with impaired renal function (creatinine clearance less than 60 mL/min), and children younger than 1 month should not receive nitrofurantoin.

Nitrofurantoin is approved for the treatment of lower UTIs. It is not recommended for treatment of pyelonephritis or prostatitis.

The most common untoward effects are nausea, vomiting, and diarrhea; the macrocrystalline preparation is better tolerated than traditional formulations. Various hypersensitivity reactions occur occasionally, including chills, fever, leukopenia, granulocytopenia, hemolytic anemia (associated with G6PD deficiency and in newborns exhibiting low levels of reduced glutathione in their red blood cells), cholestatic jaundice, and hepatocellular damage. Acute pneumonitis with fever, chills, cough, dyspnea, chest pain, pulmonary infiltration, and eosinophilia may occur within hours to days of the initiation of therapy; these symptoms usually resolve quickly after discontinuation of the drug. Interstitial pulmonary fibrosis can occur in patients (especially the elderly) taking the drug chronically. Headache, vertigo, drowsiness, muscular aches, and nystagmus occur occasionally but are readily reversible. Severe polyneuropathies with demyelination and degeneration of both sensory and motor nerves have been reported; neuropathies are most likely to occur in patients with impaired renal function and in persons on long-continued treatment.

Fosfomycin

Fosfomycin is a phosphonic acid derivative that is used primarily for the prevention and treatment of UTIs.

Antimicrobial Activity

Fosfomycin inhibits MurA, an enolpyruvyl transferase that catalyzes the initial step in bacterial cell wall synthesis. This mechanism is unique among antibacterials; thus, cross-resistance to other agents is rarely seen. Optimal testing of fosfomycin activity requires supplementation of the media with glucose-6-phosphate. Fosfomycin's usual spectrum of activity

includes the uropathogens *E. coli*, *Proteus*, *Enterococcus*, and *Staphylococcus saprophylticus*. Activity against *Klebsiella*, *Enterobacter*, and *Serratia* spp. is variable, and *Pseudomonas* and *Acinetobacter* are typically resistant. *Staphylococcus aureus* is frequently susceptible, although emergence of resistance during therapy has been reported.

Pharmacology, Toxicity, and Therapeutic Uses

Outside the U.S., fosfomycin is available as an intravenous formulation that can achieve adequate levels to treat some systemic infections. However, in the U.S. it is only available as a powder (fosfomycin tromethamine) that is dissolved in water and taken orally. Bioavailability of the oral formulation

is approximately 40%, with a $t_{1/2}$ of 5–8 h. With oral administration of 3 g, systemic concentrations are low, but urinary concentrations are as high as 1000–4000 µg/mL. The FDA-approved dosing regimen is a single 3-g dose for uncomplicated UTI; some investigators have administered 3 g every other day for three doses for complicated UTI or 3 g every 10 days for UTI prophylaxis.

Overall, fosfomycin is well tolerated. Adverse effects are uncommon and usually consist of GI distress, vaginitis, headache, or dizziness.

OTHER β -LACTAM ANTIBIOTICS

- Carbapenems
- Monobactams

β -LACTAMASE INHIBITORS

The β -lactam antibiotics—*penicillins*, *cephalosporins*, *carbapenems*, and *monobactams*—share a common structure (β -lactam ring) and mechanism of action (i.e., inhibition of the synthesis of the bacterial peptidoglycan cell wall). Bacterial resistance against the β -lactam antibiotics continues to increase at a dramatic rate. β -Lactamase inhibitors such as clavulanate and avibactam can extend the utility of these antibiotics against β -lactamase-producing organisms. Unfortunately, resistance includes not only production of β -lactamases but also alterations in the bacterial enzymes targeted by β -lactam antibiotics, as well as decreased entry or active efflux of the antibiotic.

Mechanism of Action: Inhibition of Peptidoglycan Synthesis

Peptidoglycan is a heteropolymeric component of the bacterial cell wall that provides rigid mechanical stability. The β -lactam antibiotics inhibit the last step in peptidoglycan synthesis (Figure 57-1).

In gram-positive microorganisms, the cell wall is 50–100 molecules thick; in gram-negative bacteria, it is only 1 or 2 molecules thick (Figure 57-2A). The peptidoglycan is composed of glycan chains, which are linear strands of two alternating amino sugars (*N*-acetylglucosamine and *N*-acetylmuramic acid) that are cross-linked by peptide chains. Peptidoglycan precursor formation takes place in the cytoplasm. The synthesis of UDP-acetylmuramyl-pentapeptide is completed with the addition of a dipeptide, D-alanyl-D-alanine (formed by racemization and condensation of L-alanine). UDP-acetylmuramyl-pentapeptide and UDP-acetylglucosamine are linked (with the release of the uridine nucleotides) to form a long polymer. The cross-link is completed by a transpeptidation reaction that occurs outside the cell membrane (Figure 57-2B).

The β -lactam antibiotics inhibit this last step in peptidoglycan synthesis (see Figure 57-1), presumably by acylating the transpeptidase via cleavage of the --CO--N-- bond of the β -lactam ring. The targets for the actions of β -lactam antibiotics are collectively termed *PBPs*. The transpeptidase responsible for synthesis of the peptidoglycan is one of these *PBPs*.

The lethality of penicillins for bacteria appears to involve both lytic and nonlytic mechanisms (Bayles, 2000).

Mechanisms of Bacterial Resistance to Penicillins and Cephalosporins

Bacteria can be resistant to β -lactam antibiotics by myriad mechanisms. A sensitive strain may acquire resistance by mutations that decrease the affinity of *PBPs* for the antibiotic. Because the β -lactam antibiotics inhibit many different *PBPs* in a single bacterium, the affinity for β -lactam antibiotics of several *PBPs* must decrease for the organism to be resistant (Spratt, 1994). Altered *PBPs* with decreased affinity for β -lactam antibiotics are acquired by homologous recombination between *PBP* genes of different bacterial species (Zapun et al., 2008). Four of the five high-molecular-weight *PBPs* of the most highly penicillin-resistant *Streptococcus pneumoniae* isolates have decreased affinity for β -lactam antibiotics as a result of interspecies homologous recombination events. In contrast, isolates with high-level resistance to third-generation cephalosporins contain alterations of only two of the five high-molecular-weight *PBPs* because the other *PBPs* have inherently low affinity for the third-generation cephalosporins. *MRSA* is resistant via acquisition of an additional high-molecular-weight *PBP* (via a transposon) with a very low affinity for all β -lactam antibiotics; this mechanism is also responsible for methicillin resistance in the coagulase-negative staphylococci.

Bacterial resistance to the β -lactam antibiotics also results from the inability of the agent to penetrate to its site of action (Figure 57-3) (Fernández and Hancock, 2012). In gram-positive bacteria, the peptidoglycan polymer is very near the cell surface (see Figure 57-2A) and small β -lactam antibiotic molecules can penetrate easily to the outer layer of the cytoplasmic membrane and the *PBPs*. In gram-negative bacteria, the inner membrane is covered by the outer membrane, lipopolysaccharide, and capsule (see Figure 57-2A). The outer membrane functions as an impenetrable barrier for some antibiotics. Some small hydrophilic antibiotics, however, diffuse through aqueous channels in the outer membrane that

are formed by proteins called *porins*. The number and size of pores in the outer membrane vary amongst different gram-negative bacteria, thereby providing greater or lesser access for antibiotics to the site of action. Active efflux pumps serve as another mechanism of resistance, removing the antibiotic from its site of action before it can act (see Figure 57-3) (Nikaido, 1998).

Bacteria also can inactivate β -lactam antibiotics enzymatically via the action of β -lactamases (Figures 57-2 and 57-4). β -Lactamases are grouped into four classes, A through D (Jacoby and Munoz-Price, 2005). Their substrate specificities can be relatively narrow or can extend to almost all β -lactams. In general, gram-positive bacteria produce and secrete a large amount of β -lactamase (see Figure 57-2A). Most of these enzymes are penicillinases. The information for staphylococcal penicillinase is encoded in a plasmid; this may be transferred by bacteriophage to other bacteria and is inducible by substrates. In gram-negative bacteria, β -lactamases are found in relatively small amounts but are located in the periplasmic space between the inner and outer cell membranes (see Figure 57-2A) for maximal protection of the microbe. β -Lactamases of gram-negative bacteria are encoded either in chromosomes or in plasmids and may be constitutive or inducible. The plasmids can be transferred between bacteria by conjugation. Of particular concern are β -lactamases that are capable of hydrolyzing carbapenems as well as penicillins and cephalosporins; organisms possessing such β -lactamases (along with other resistance mechanisms) may be resistant to all or almost all antibacterials in clinical use (Queenan and Bush, 2007).

The local environment can also contribute to resistance to beta-lactam antibiotics. Microorganisms adhering to implanted prosthetic devices (e.g., catheters, artificial joints, prosthetic heart valves) produce biofilms. Bacteria in biofilms produce extracellular polysaccharides and, in part owing to decreased growth rates, are much less sensitive to antibiotic therapy (Donlan, 2001). The β -lactam antibiotics are most active against bacteria in the logarithmic phase of growth and have little effect on microorganisms in the stationary phase. Similarly, bacteria that survive inside viable cells of the host generally are protected from the action of the β -lactam antibiotics.

The Penicillins

Despite the emergence of microbial resistance, the penicillins are currently the drugs of choice for a large number of infectious diseases. Penicillins (Figure 57-4) consist of a thiazolidine ring (A) connected to a β -lactam ring (B) to which is attached a side chain (R). The penicillin nucleus itself

Figure 57-1 Action of β -lactam antibiotics in *Staphylococcus aureus*. The bacterial cell wall consists of glycopeptide polymers (an NAM-NAG amino-hexose backbone) linked via bridges between amino acid side chains. In *S. aureus*, the bridge is (Gly)₅-D-Ala between lysines. The cross-linking is catalyzed by a transpeptidase, the enzyme that penicillins and cephalosporins inhibit.

is the chief structural requirement for biological activity. Side chains can be added that alter the susceptibility of the resulting compounds to inactivating enzymes (β -lactamases) and that change the antibacterial activity and the pharmacological properties of the drug (Table 57-1).

Classification of the Penicillins and Summary of Their Pharmacological Properties

Penicillins are classified according to their spectra of antimicrobial activity.

- **Penicillin G** and its close congener **penicillin V** are highly active against sensitive strains of gram-positive cocci, but they are readily hydrolyzed by penicillinase. Thus, they are *ineffective against most strains of S. aureus*.
- **The penicillinase-resistant penicillins** (*methicillin*, discontinued in the U.S.), *cloxacillin* and *flucloxacillin* (not currently marketed in the U.S.), *nafcillin*, *oxacillin*, and *dicloxacillin* have less-potent antimicrobial activity against microorganisms that are sensitive to penicillin G, but they are *preferred agents for treatment of penicillinase-producing S. aureus and Staphylococcus epidermidis that are not methicillin resistant*.
- *Ampicillin*, *amoxicillin*, and others such as *bacampicillin* and *pivampicillin* (not currently marketed in the U.S.) are the **aminopenicillins**, whose antimicrobial activity is extended to include some gram-negative microorganisms (e.g., *Haemophilus influenzae*, *Escherichia coli*, and *Proteus mirabilis*). These drugs are also available as coformulations with a **β -lactamase inhibitor** such as *clavulanate* or *sulbactam* to prevent hydrolysis by class A β -lactamases.
- **Agents with extended antimicrobial activity against Pseudomonas, Enterobacter, and Proteus spp.** include older agents largely out of use: *azlocillin*, *carbenicillin*, *mezlocillin*, *ticarcillin*, *ticarcillin/sodium*. These agents are inferior to ampicillin against gram-positive cocci and *Listeria monocytogenes* and are less active than piperacillin

Figure 57-2 A. Structure and composition of gram-positive and gram-negative cell walls. B. PBP activity and inhibition. PBPs have two enzymatic activities that are crucial to synthesis of the peptidoglycan layers of bacterial cell walls: a TP that cross-links amino acid side chains and a GT that links subunits of the glycopeptide polymer (see Figure 57-1). The TP and GT domains are separated by a linker region. The glucosyltransferase is thought to be partially embedded in the membrane. (Part A reprinted with permission from Tortora G, et al. *Microbiology: An Introduction*, 3rd ed. Pearson, London, 1989, Figure 4-11, p. 83. © Pearson Education, Inc., New York, New York.)

against *Pseudomonas*. Piperacillin and piperacillin/tazobactam have excellent antimicrobial activity against many isolates of *Pseudomonas*, *E. coli*, *Klebsiella*, and other gram-negative microorganisms. Piperacillin retains the activity of ampicillin against gram-positive cocci and *L. monocytogenes*.

General Common Properties

Following absorption of an oral dose, penicillins are distributed widely throughout the body. Therapeutic concentrations of penicillins are achieved readily in tissues and in secretions such as joint fluid, pleural fluid, pericardial fluid, and bile. Penicillins do not penetrate living phagocytic cells to a significant extent, and only low concentrations of these drugs are found in prostatic secretions, brain tissue, and intraocular fluid. Concentrations of penicillins in CSF are variable but are less than 1% of those in plasma when the meninges are normal. When there is inflammation, concentrations in CSF may increase to as much as 5% of the plasma value. Penicillins are eliminated rapidly by glomerular filtration and renal tubular secretion, such that their half-lives in the body are short, typically 30–90 min. As a consequence, concentrations of these drugs in urine are high.

Penicillin G and Penicillin V

Antimicrobial Activity

The antimicrobial spectra of penicillin G (benzylpenicillin) and penicillin V (the phenoxymethyl derivative) are similar for aerobic gram-positive microorganisms. However, penicillin G is 5–10 times more active than penicillin V against *Neisseria* spp. and certain anaerobes. Most streptococci are very susceptible. However, penicillin-resistant viridans streptococci

Figure 57-3 Antibiotic efflux pumps of gram-negative bacteria. Multidrug efflux pumps traverse both the inner and outer membranes of gram-negative bacteria. The pumps are composed of a minimum of three proteins and are energized by the proton motive force. Increased expression of these pumps is an important cause of antibiotic resistance. (Reprinted with permission from Oxford University Press. Nikaido H. Antibiotic resistance caused by gram-negative multidrug efflux pumps. *Clin Infect Dis*, 1998, 27(suppl 1): S32–S41. © 1998 by the Infectious Diseases Society of America. All rights reserved.)

Most anaerobic microorganisms, including *Clostridium* spp., are highly sensitive. *Bacteroides fragilis* is an exception, displaying resistance to penicillins and cephalosporins by virtue of expressing a broad-spectrum cephalosporinase. Some strains of *Prevotella melaninogenica* also have acquired this trait. *Actinomyces israelii*, *Streptobacillus moniliformis*, *Pasteurella multocida*, and *L. monocytogenes* are inhibited by penicillin G. Most species of *Leptospira* are moderately susceptible to the drug. One of the most sensitive microorganisms is *Treponema pallidum*. *Borrelia burgdorferi*,

Oral Administration of Penicillin G and V. The virtue of penicillin V in comparison with penicillin G is that it is more stable in an acidic medium and therefore is better absorbed from the GI tract, yielding plasma concentrations two to five times those provided by penicillin G. Thus, penicillin V is generally preferred for oral administration. Absorption is rapid, and maximal concentrations in blood are attained in 30–60 min. Ingestion of food may interfere with enteric absorption of all penicillins. Thus, oral penicillins should generally be administered at least 30 min before a meal or 2 h after.

Distribution. Penicillin G is distributed extensively throughout the body, but the concentrations in various fluids and tissues differ widely. Its apparent volume of distribution is about 0.35 L/kg. Approximately 60% of the penicillin G in plasma is reversibly bound to albumin. Significant amounts appear in liver, bile, kidney, semen, joint fluid, lymph, and intestine. Probenecid markedly decreases the tubular secretion of the penicillins and also produces a significant decrease in the apparent volume of distribution of the penicillins.

Penetration Into Cerebrospinal Fluid. Penicillin does not readily enter the CSF but penetrates more easily when the meninges are inflamed. The concentrations are usually in the range of 5% of the value in plasma and are therapeutically effective against susceptible microorganisms. Penicillin and other organic acids are secreted rapidly from the CSF into the bloodstream by an active transport process. Probenecid competitively inhibits this transport and thus elevates the concentration of penicillin in CSF. In uremia, other organic acids accumulate in the CSF and compete with penicillin for secretion; the drug occasionally reaches toxic concentrations in the brain and can produce convulsions.

Addition of substituents (R groups) to the parent structure produces penicillins with altered susceptibility to inactivating enzymes (β -lactamases), antibacterial activity, and pharmacological properties.

HISTORY

The history of the brilliant research that led to the discovery and development of penicillin is well chronicled (Lax, 2004). In 1928, while studying *Staphylococcus* variants in the laboratory at St. Mary's Hospital in London, Alexander Fleming observed that a mold contaminating one of his cultures caused the bacteria in its vicinity to undergo lysis. Broth in which the fungus was grown was markedly inhibitory for many microorganisms. Because the mold belonged to the genus *Penicillium*, Fleming named the antibacterial substance *penicillin*.

A decade later, penicillin was developed as a systemic therapeutic agent by the concerted research of a group of investigators at Oxford University headed by Florey, Chain, and Abraham. By May 1940, a crude preparation was found to produce dramatic therapeutic effects when administered parenterally to mice with streptococcal infections. Sufficient penicillin was accumulated by 1941 to conduct therapeutic trials in several patients desperately ill with staphylococcal and streptococcal infections refractory to all other therapy. At this stage, the crude, amorphous penicillin was only about 10% pure, and it required nearly 100 L of the broth in which the mold had been grown to obtain enough of the antibiotic to treat one patient for 24 h. Bedpans actually were used by the Oxford group for growing cultures of *Penicillium notatum*. Case 1 in the 1941 report from Oxford was that of a policeman who was suffering from a severe mixed staphylococcal and streptococcal infection. He was treated with penicillin, some of which had been recovered from the urine of other patients who had been given the drug. It is said that an Oxford professor referred to penicillin as a remarkable substance grown in bedpans and purified by passage through the Oxford Police Force.

A vast research program soon was initiated in the U.S. There were 122 million units of penicillin made available during 1942, and the first clinical trials were conducted at Yale University and the Mayo Clinic, with dramatic results. By the spring of 1943, there were 200 patients who had been treated with the drug. The results were so impressive that the surgeon general of the U.S. Army authorized a trial of the antibiotic in a military hospital. Soon thereafter, penicillin was adopted throughout the medical services of the U.S. Armed Forces.

The deep-fermentation procedure for the biosynthesis of penicillin marked a crucial advance in the large-scale production of the antibiotic. From a total production of a few hundred million units a month in the early days, the quantity manufactured rose to over 200 trillion units (nearly 150 tons) by 1950. The first marketable penicillin cost several dollars per 100,000 units; today, the same dose costs only a few cents.

Excretion. Approximately 60%–90% of an intramuscular dose of penicillin G in aqueous solution is eliminated in the urine, largely within the first hour after injection. The remainder is metabolized to penicilloic acid (see Figure 57–4). The $t_{1/2}$ for elimination of penicillin G is about 30 min in normal adults. Approximately 10% of the drug is eliminated by glomerular filtration and 90% by tubular secretion. Renal clearance approximates the total renal plasma flow. Clearance values are considerably lower in neonates and infants; as a result, penicillin persists in the blood several times longer in premature infants than in children and adults. The $t_{1/2}$ of the antibiotic in children less than 1 week of age is 3 h; by 14 days of age, it is 1.4 h. After renal function is fully established in young children, the rate of renal excretion of penicillin G is considerably more rapid than in adults. Anuria increases the $t_{1/2}$ of penicillin G from 0.5 to about 10 h. When renal function is impaired, 7%–10% of the antibiotic may be inactivated each hour by the liver. The dose of the drug must be readjusted during dialysis and the period of progressive recovery of renal function. If hepatic insufficiency also is present, the $t_{1/2}$ will be prolonged even further.

Therapeutic Uses

Pneumococcal Infections. Penicillin G remains the agent of choice for the management of infections caused by sensitive strains of *S. pneumoniae*, but resistance is an increasing problem.

Pneumococcal Pneumonia. For parenteral therapy of sensitive isolates of pneumococci, penicillin G is favored. Therapy should be continued for at least 5 days, including at least 2–3 days after the patient's temperature has returned to normal.

Pneumococcal Meningitis. Pneumococcal meningitis should be treated with a combination of vancomycin and a third-generation cephalosporin until it is established that the infecting pneumococcus is penicillin sensitive. Dexamethasone given prior to or at the same time as antibiotics is associated with an improved outcome (de Gans et al., 2002). The recommended therapy is 24 million units of penicillin G daily by constant intravenous infusion or divided into boluses for 10–14 days.

β -Hemolytic Streptococcal Infections. *Streptococcal pharyngitis* (including scarlet fever) is the most common disease produced by *Streptococcus pyogenes* (group A β -hemolytic streptococcus). Penicillin-resistant isolates have yet to be observed. The preferred oral therapy is with penicillin V, 500 mg twice daily for 10 days. Penicillin therapy of streptococcal pharyngitis reduces the risk of subsequent acute rheumatic fever; however, current evidence suggests that the incidence of glomerulonephritis that follows streptococcal infections is not reduced to a significant degree by treatment with penicillin (Shulman et al., 2012).

β -Hemolytic Streptococcal Toxic Shock and Necrotizing Fasciitis. β -Hemolytic streptococcal toxic shock and necrotizing fasciitis are life-threatening infections associated with toxin production. Recommended treatment is with penicillin plus clindamycin (to decrease toxin production) (Brown, 2004).

β -Hemolytic Streptococcal Pneumonia, Arthritis, Meningitis, and Endocarditis. The uncommon conditions of pneumonia, arthritis, meningitis, and endocarditis caused by β -hemolytic streptococci should be treated with penicillin G when they are caused by *S. pyogenes*; daily doses of 12–24 million units are administered intravenously for 2–4 weeks (4 weeks for endocarditis).

Infections Caused by Other Streptococci and Enterococci. The viridans group of streptococci is the most common cause of native valve infectious endocarditis. These are nongroupable α -hemolytic microorganisms that are increasingly resistant to penicillin G. It is important to determine quantitative microbial sensitivities to penicillin G in patients with endocarditis. Patients with penicillin-sensitive viridans group streptococcal native valve endocarditis can be treated successfully with daily doses of 12–20 million units of intravenous penicillin G for 4 weeks or for 2 weeks if given in combination with gentamicin. The recommended therapy for penicillin- and aminoglycoside-sensitive enterococcal endocarditis is 24 million units of penicillin G or 12 g ampicillin daily administered intravenously in combination with a low dose of gentamicin. Therapy usually should be continued for 6 weeks.

Infections with Anaerobes. Pulmonary and periodontal infections usually respond well to penicillin G; clindamycin may be more effective than penicillin for therapy of lung abscess (Levison et al., 1983). Mild-to-moderate infections at these sites may be treated with oral medication (either penicillin G or penicillin V 250 mg four times daily). More severe infections should be treated with 12–24 million units of penicillin G intravenously.

Staphylococcal Infections. Most staphylococcal infections are caused by microorganisms that produce penicillinase; further, half or more isolates of *S. aureus* and *S. epidermidis* are resistant to β -lactams through production of altered PBPs. Thus, penicillin G now has limited utility in the treatment of staphylococcal infections.

Meningococcal Infections. Penicillin G remains the drug of choice for meningococcal disease. Patients should be treated with high doses of penicillin given intravenously. The occurrence of penicillin-resistant strains

should be considered in patients who are slow to respond to treatment. Penicillin G does not eliminate the meningococcal carrier state, and its administration thus is ineffective as a prophylactic measure.

Gonococcal Infections. Gonococci gradually have become more resistant to penicillin G, and penicillins are no longer the therapy of choice.

Syphilis. Therapy of syphilis with penicillin G is highly effective. Primary, secondary, and latent syphilis of less than 1-year duration may be treated with 1–3 weekly intramuscular doses of 2.4 million units of penicillin G benzathine. Patients with neurosyphilis or cardiovascular syphilis typically receive intensive therapy with 18–24 million units of penicillin G daily for 10–14 days. There are no proven alternatives for treating syphilis in pregnant women, so penicillin-allergic individuals must be acutely desensitized to prevent anaphylaxis.

Most patients with secondary syphilis develop the Jarisch–Herxheimer reaction, including chills, fever, headache, myalgias, and arthralgias occurring several hours after the first dose of penicillin. This reaction is thought to be due to release of spirochetal antigens with subsequent host reactions to the products. Antipyretics give symptomatic relief, and therapy with penicillin should not be discontinued.

Actinomycosis. Penicillin G is the agent of choice for the treatment of all forms of actinomycosis (18–24 million units of penicillin G IV per day for 6 weeks). Surgical drainage or excision of the lesion may be necessary before cure is accomplished.

Diphtheria. Penicillin and other antibiotics do not alter the incidence of complications or the outcome of diphtheria; specific antitoxin is the only effective treatment. However, penicillin G eliminates the carrier state. The parenteral administration of 2–3 million units per day in divided doses for 10–12 days eliminates the diphtheria bacilli from the pharynx and other sites in practically 100% of patients. A single daily injection of penicillin G procaine for the same period produces comparable results.

Anthrax. Strains of *Bacillus anthracis* resistant to penicillin have been recovered from human infections. When penicillin G is used for serious infections due to susceptible strains, the dose should be 24 million units per day.

Clostridial Infections. Penicillin G (12–24 million units per day given parenterally) plus clindamycin is recommended for clostridial gas gangrene. Adequate debridement of the infected areas is essential. Antibiotics probably have no effect on the outcome of tetanus. Debridement and administration of human tetanus immune globulin may be indicated.

Fusospirochetal Infections. Gingivostomatitis, produced by the synergistic action of *Leptotrichia buccalis* and spirochetes that are present in the mouth, is readily treatable with penicillin. For simple “trench mouth,” 500 mg penicillin V given every 6 h for several days usually suffices.

Rat-Bite Fever. The two microorganisms responsible for the rat-bite fever infection, *Spirillum minus* in the Far East and *Streptobacillus moniliformis* in the U.S. and Europe, are sensitive to penicillin G, the drug of choice. Because most cases due to *Streptobacillus* are complicated by bacteremia and, in many instances, by metastatic infections, especially of the synovia and endocardium, high doses given parenterally for 3–4 weeks are frequently recommended.

Listeria Infections. Ampicillin or penicillin G (with consideration for addition of gentamicin to both for immunosuppressed patients with meningitis) are the drugs of choice in the management of infections owing to *L. monocytogenes*. The recommended dose of penicillin G is 18–24 million units parenterally per day for at least 2 weeks. For endocarditis, the dose is the same, but the duration of treatment should be no less than 4 weeks.

Lyme Disease. Intravenous penicillin G in doses of 18–24 million units per day for 14 days is an alternative to third-generation cephalosporins in treatment of severe Lyme disease.

Erysiploid. The causative agent of erysiploid, *Erysipelothrix rhusiopathiae*, is sensitive to penicillin. The infection responds well to a single injection of

1.2 million units of penicillin G benzathine. When endocarditis is present, penicillin G, 12–20 million units per day, for 4–6 weeks is required.

Pasteurella multocida. *Pasteurella multocida* is a cause of wound infections after a cat or dog bite. It is susceptible to penicillin G and ampicillin and resistant to penicillinase-resistant penicillins and first-generation cephalosporins. When the infection causes meningitis, a third-generation cephalosporin is preferred.

Prophylactic Uses of the Penicillins

Streptococcal Infections. The administration of penicillin to household contacts exposed to *S. pyogenes* pharyngitis has not been shown to be highly effective in reducing subsequent illness. Indications for this type of prophylaxis might include outbreaks of streptococcal disease in closed populations (e.g., boarding schools or military bases).

Recurrences of Rheumatic Fever. The oral administration of 200,000 units of penicillin G or penicillin V every 12 h decreases the incidence of recurrences of rheumatic fever in susceptible individuals. The intramuscular injection of 1.2 million units of penicillin G benzathine once a month also yields excellent results. Prophylaxis must be continued throughout the year. Some suggest that prophylaxis should be continued for life because instances of acute rheumatic fever have been observed in the fifth and sixth decades, but the necessity of lifetime prophylaxis has not been established.

Syphilis. Prophylaxis for recent sexual contacts of a patient with primary, secondary, or early latent syphilis consists of a course of penicillin as described for primary syphilis.

The Penicillinase-Resistant Penicillins

The penicillinase-resistant penicillins are resistant to hydrolysis by staphylococcal penicillinase. Their appropriate use should be restricted to the treatment of infections that are known or suspected to be caused by staphylococci that elaborate the enzyme since these drugs are much less active than penicillin G against other penicillin-sensitive microorganisms. However, an increasing number of isolates of *S. aureus* (around half in most U.S. hospitals) and *S. epidermidis* (more than three-quarters) express a low-affinity PBP, giving them the MRSA or MRSE phenotype. This term denotes resistance of these bacteria to all the penicillinase-resistant penicillins and cephalosporins (with the exception of ceftaroline and ceftobiprole [not available in the U.S.]). Alternative agents such as vancomycin, daptomycin, clindamycin, or linezolid (see Chapter 59) are typically used for infections due to organisms with this resistance mechanism.

The Isoxazolyl Penicillins: Oxacillin, Cloxacillin, and Dicloxacillin

Oxacillin, cloxacillin (not available in the U.S.), and dicloxacillin are semisynthetic penicillin congeners that are markedly resistant to cleavage by penicillinase. These drugs are not substitutes for penicillin G in the treatment of diseases amenable to it and are not active against enterococci or *Listeria*. Oral administration is not a substitute for the parenteral route in the treatment of serious staphylococcal infections.

Pharmacological Properties. The isoxazolyl penicillins are potent inhibitors of the growth of most penicillinase-producing staphylococci. Dicloxacillin is the most active, and many strains of *S. aureus* are inhibited by concentrations of 0.05–0.8 $\mu\text{g/mL}$. These agents are, in general, less effective against microorganisms susceptible to penicillin G, and they are not useful against gram-negative bacteria. These agents are absorbed rapidly but incompletely (30%–80%) from the GI tract. Absorption increases when administered 1 h before or 2 h after meals. Peak concentrations in plasma are attained by 1 h. All these congeners are bound to plasma albumin to a great extent (~90%–95%); none is removed from the circulation to a significant degree by hemodialysis. The isoxazolyl penicillins are excreted by the kidney; there is also significant hepatic degradation and elimination in the bile. The half-lives for all are between 30 and 60 min. No dosing adjustments are needed for patients with renal failure.

Nafcillin

This semisynthetic penicillin is highly resistant to penicillinase and has proven effective against infections caused by penicillinase-producing strains of *S. aureus*.

Pharmacological Properties. Nafcillin is slightly more active than oxacillin against penicillin G-resistant *S. aureus* (most strains are inhibited by 0.06–2 µg/mL). Although it is the most active of the penicillinase-resistant penicillins against other microorganisms, it is not as potent as penicillin G. The peak plasma concentration is about 8 µg/mL 60 min after a 1-g intramuscular dose. Nafcillin is about 90% bound to plasma protein. Peak concentrations of nafcillin in bile are well above those found in plasma. Dosage adjustment in patients with renal dysfunction is not required. Concentrations of the drug in CSF appear to be adequate for therapy of staphylococcal meningitis.

The Aminopenicillins: Ampicillin and Amoxicillin

Aminopenicillins expand the spectrum of activity of penicillin G in a different direction from the penicillinase-resistant penicillins—they allow for useful activity against some gram-negative organisms. They all are destroyed by β-lactamases (from both gram-positive and gram-negative bacteria); thus, further expansion of their activity is enabled through coformulation with β-lactamase inhibitors (see the end of the chapter for further discussion of the chemistry and activity of β-lactamase inhibitors).

Antimicrobial Activity

Ampicillin and amoxicillin are generally bactericidal for sensitive gram-positive and gram-negative bacteria. The meningococci and *L. monocytogenes* are sensitive to this class of drugs. Many pneumococcal isolates have varying levels of resistance to ampicillin, and penicillin-resistant strains should be considered ampicillin/amoxicillin-resistant. *Haemophilus influenzae* and the viridans group of streptococci exhibit varying degrees of resistance. Enterococci are about twice as sensitive to ampicillin as they are to penicillin G. From 30% to 50% of *E. coli*, a significant number of *P. mirabilis*, and practically all species of *Klebsiella* are resistant. Most strains of *Shigella*, *Pseudomonas*, *Serratia*, *Acinetobacter*, *B. fragilis*, and indole-positive *Proteus* also are resistant to this group of penicillins. Resistant strains of *Salmonella* are recovered with increasing frequency. Concurrent administration of a β-lactamase inhibitor such as *clavulanate* or *sulbactam* markedly expands their spectrum of activity, particularly against *H. influenzae*, *E. coli*, *Klebsiella*, *Proteus*, and *B. fragilis*.

ADME

Ampicillin. Ampicillin is stable in acid and is well absorbed after oral administration. An oral dose of 0.5 g produces peak concentrations in plasma of about 3 µg/mL at 2 h. Intake of food prior to ingestion of ampicillin diminishes absorption. Intramuscular injection of 0.5–1 g sodium ampicillin yields peak plasma concentrations of about 7–10 µg/mL, respectively, at 1 h. Plasma levels decline with a $t_{1/2}$ of about 80 min. Severe renal impairment markedly prolongs the $t_{1/2}$. Peritoneal dialysis is ineffective in removing the drug from the blood, but hemodialysis removes approximately 40% of the body store in about 7 h. Adjustment of the dose of ampicillin is required in the presence of renal dysfunction. Ampicillin appears in the bile, undergoes enterohepatic circulation, and is excreted in the feces.

Amoxicillin. Amoxicillin, a penicillinase-susceptible, semisynthetic penicillin (see Table 57–1), is a close chemical and pharmacological relative of ampicillin. Amoxicillin is stable in acid, designed for oral use, and absorbed more rapidly and completely from the GI tract than ampicillin. The antimicrobial spectrum of amoxicillin is essentially identical to that of ampicillin, except that amoxicillin is less active and less effective than ampicillin for shigellosis. Peak plasma concentrations of amoxicillin are 2–2.5 times greater than for ampicillin after oral administration of the same dose. Food does not interfere with absorption. Perhaps because of more complete absorption of this congener, the incidence of diarrhea with amoxicillin is less than that following administration of ampicillin.

The incidence of other adverse effects appears to be similar. Although the $t_{1/2}$ of amoxicillin is similar to that for ampicillin, effective concentrations of orally administered amoxicillin are detectable in the plasma for twice as long as with ampicillin because of the more complete absorption. For all these reasons, amoxicillin is generally preferred over ampicillin for oral administration. About 20% of amoxicillin is protein bound in plasma, a value similar to that for ampicillin. Most of a dose of the antibiotic is excreted in an active form in the urine, and dose adjustment is required in renal dysfunction. Probenecid delays excretion of the drug.

Therapeutic Indications

Upper Respiratory Infections. Ampicillin and amoxicillin are active against *S. pyogenes* and many strains of *S. pneumoniae* and *H. influenzae*. The drugs constitute effective therapy for sinusitis, otitis media, acute exacerbations of chronic bronchitis, and epiglottitis caused by sensitive strains of these organisms. Amoxicillin is the most active of all the oral β-lactam antibiotics against both penicillin-susceptible and penicillin-nonsusceptible *S. pneumoniae*. Based on the increasing prevalence of pneumococcal resistance to penicillin, an increase in dose of oral amoxicillin (from 40–45 up to 80–90 mg/kg/d) for empirical treatment of acute otitis media in children is recommended (Lieberthal et al., 2013). Ampicillin-resistant *H. influenzae* is a problem in many areas. The addition of a β-lactamase inhibitor to *amoxicillin (clavulanate)* or *ampicillin (sulbactam)* extends the spectrum to β-lactamase-producing *H. influenzae* and *Moraxella*. Amoxicillin is an alternative treatment to penicillin for bacterial pharyngitis.

Urinary Tract Infections. Most uncomplicated urinary tract infections are caused by Enterobacteriaceae, and *E. coli* is the most common species. Aminopenicillins can be effective agents for urinary tract infections, but the high prevalence of resistance amongst *E. coli* and *Klebsiella* makes empiric use of these drugs for urinary tract infections challenging. Enterococcal urinary tract infections are treated effectively with an aminopenicillin alone.

Meningitis. Acute bacterial meningitis in children is frequently due to *S. pneumoniae* or *Neisseria meningitidis*. Because 20%–30% of strains of *S. pneumoniae* now may be resistant to ampicillin, it is not indicated for empiric single-agent treatment of meningitis. Ampicillin has excellent activity against *L. monocytogenes*, a cause of meningitis in immunocompromised persons. The combination of ampicillin and vancomycin plus a third-generation cephalosporin is a recommended regimen for empirical treatment of suspected bacterial meningitis in patients at risk for *L. monocytogenes*.

Antipseudomonal Penicillins: The Carboxypenicillins and the Ureidopenicillins

Antimicrobial Activity

The carboxypenicillins, carbenicillin and ticarcillin (both discontinued in the U.S.), and ureidopenicillins, mezlocillin (discontinued in the U.S.) and piperacillin, are active against some isolates of *Pseudomonas aeruginosa* and certain indole-positive *Proteus* spp. that are resistant to ampicillin and its congeners. The carboxypenicillins are ineffective against most strains of *S. aureus*, *Enterococcus faecalis*, *Klebsiella*, and *L. monocytogenes*, but piperacillin (especially when combined with the β-lactamase inhibitor tazobactam) has useful activity against these pathogens and has superior activity against *P. aeruginosa*.

Pharmacological Properties

Carbenicillin Indanyl Sodium. This indanyl ester of carbenicillin is acid stable and is suitable for oral administration. After absorption, the ester is converted rapidly to carbenicillin by hydrolysis of the ester linkage. The antimicrobial spectrum of the drug is therefore that of carbenicillin. The active moiety is excreted rapidly in the urine, where it achieves effective concentrations. Thus, where available, the only use of this drug is for the management of urinary tract infections caused by *Proteus* spp. other than *P. mirabilis* and by *P. aeruginosa*.

1030 Ticarcillin. The semisynthetic penicillin ticarcillin is more active than carbenicillin versus *P. aeruginosa*, but less active than piperacillin. The combination of ticarcillin and clavulanate has activity against other gram-negative aerobic and anaerobic organisms and has been used for intra-abdominal and urinary tract infections. In the U.S., the manufacture of ticarcillin alone and in combination with clavulanate has been discontinued.

Piperacillin. Piperacillin extends the spectrum of ampicillin to include most strains of *P. aeruginosa*, Enterobacteriaceae (non- β -lactamase producing), many *Bacteroides* spp., and *E. faecalis*. Combined with a β -lactamase inhibitor (piperacillin-tazobactam), it has the broadest antibacterial spectrum of the penicillins, including activity against methicillin-susceptible *S. aureus*, *H. influenzae*, *B. fragilis*, and most *E. coli* and *Klebsiella*. The drug is only available for parenteral administration. High biliary concentrations are achieved. Distribution into the CNS by piperacillin is similar to that of other penicillins, but CSF concentrations of tazobactam may be inadequate to protect piperacillin against β -lactamase-producing organisms. The drug is eliminated renally and requires adjustment in renal dysfunction.

Therapeutic Indications

Piperacillin and related agents are important agents for the treatment of patients with serious infections caused by gram-negative bacteria, including infections often acquired in the hospital. Therefore, these penicillins find their greatest use in treating bacteremias, pneumonias, infections following burns, and urinary tract infections owing to microorganisms resistant to ampicillin; the bacteria especially responsible include *P. aeruginosa*, indole-positive strains of *Proteus*, and *Enterobacter* spp. Because *Pseudomonas* infections are common in neutropenic patients, therapy for severe bacterial infections in such individuals should include a β -lactam antibiotic such as piperacillin with good activity against these microorganisms (Freifeld et al., 2012). Because of piperacillin/tazobactam's good activity against *E. faecalis* and *B. fragilis*, this drug also has utility in mixed intra-abdominal infections.

Adverse Reactions

Hypersensitivity Reactions. Hypersensitivity reactions are by far the most common adverse effects noted with the penicillins, and these agents are amongst the most common causes of drug allergy.

Manifestations of hypersensitivity to penicillins include maculopapular rash, urticarial rash, fever, bronchospasm, vasculitis, serum sickness, exfoliative dermatitis, Stevens-Johnson syndrome, and anaphylaxis (Romano et al., 2003). Hypersensitivity reactions may occur with any dosage form of penicillin. Hypersensitivity reactions may appear in the absence of a previous known exposure to the drug. This may be caused by unrecognized prior exposure to penicillin in the environment (e.g., in foods of animal origin or from the fungus-producing penicillin). Although elimination of the antibiotic usually results in rapid clearing of the allergic manifestations, they may persist for 1–2 weeks or longer after therapy has been stopped. In some cases, the reaction is mild and disappears even when the penicillin is continued; in others, immediate cessation of penicillin treatment is required. In many instances, it is necessary to avoid the future use of penicillin because of the risk of severe reactions, and the patient should be so warned. Patients manifesting hypersensitivity to penicillins may be at increased risk for cross-hypersensitivity reactions on receipt of other β -lactams (cephalosporins, carbapenems). The risk is dependent on the reaction and particular β -lactam administered and is discussed further in the relevant sections for those agents.

Penicillins and their breakdown products act as haptens after covalent reaction with proteins. The most abundant breakdown product is the penicilloyl moiety (MDM), which is formed when the β -lactam ring is opened (see Figure 57–4). A large percentage of IgE-mediated reactions are to the MDM, but at least 25% of reactions are to other breakdown products. The terms *major* and *minor determinants* refer to the frequency with which antibodies to these haptens appear to be formed. They do not describe the severity of the reaction that may result. In fact, anaphylactic

reactions to penicillin usually are mediated by IgE antibodies against the minor determinants. Antipenicillin antibodies are detectable in virtually all patients who have received the drug and in many who have never knowingly been exposed to it. Immediate allergic reactions are mediated by skin-sensitizing or IgE antibodies, usually of minor-determinant specificities. Accelerated and late urticarial reactions usually are mediated by major-determinant-specific skin-sensitizing antibodies. Some reactions may be due to toxic antigen-antibody complexes of major-determinant-specific IgM antibodies.

The most serious hypersensitivity reactions produced by the penicillins are angioedema and anaphylaxis. Acute anaphylactic or anaphylactoid reactions induced by various preparations of penicillin constitute the most important immediate danger connected with their use. Anaphylactoid reactions may occur at any age. Their incidence is thought to be 0.004%–0.04%. About 0.001% of patients treated with these agents die from anaphylaxis. Anaphylaxis most often has followed the injection of penicillin, although it also has been observed after oral or intradermal administration. The most dramatic reaction is sudden, severe hypotension and rapid death. In other instances, bronchoconstriction with severe asthma; abdominal pain, nausea, and vomiting; extreme weakness; or diarrhea and purpuric skin eruptions have characterized the anaphylactic episodes.

Skin rashes of all types may be caused by allergy to penicillin. The incidence of skin rashes appears to be highest following the use of ampicillin, at about 9%. Rashes follow the administration of ampicillin frequently in patients with infectious mononucleosis, but in such cases, patients can tolerate subsequent courses of ampicillin without experiencing a rash (Kerns et al., 1973). Serum sickness of variable intensity and severity, mediated by IgG antibodies, is rare; when it occurs, it appears after penicillin treatment has been continued for 1 week or more; it may be delayed until 1 or 2 weeks after the drug has been stopped and may persist for a week or longer. Vasculitis may be related to penicillin hypersensitivity. The Coombs reaction frequently becomes positive during prolonged therapy, but hemolytic anemia is rare. Reversible neutropenia has been noted, occurring in up to 30% of patients treated with 8–12 g of nafcillin for more than 21 days. The bone marrow shows an arrest of maturation. Eosinophilia is an occasional accompaniment of other allergic reactions to penicillin. Penicillins rarely cause interstitial nephritis; methicillin (no longer marketed in the U.S.) has been implicated most frequently. Fever may be the only evidence of a hypersensitivity reaction to the penicillins. The febrile reaction usually disappears within 24–36 h after administration of the drug is stopped but may persist for days.

Management of the Patient Potentially Allergic to Penicillin. Evaluation of the patient's history is the most practical way to avoid the use of penicillin in patients who are at the greatest risk of adverse reaction. Although many patients are labeled as penicillin allergic, studies suggested that 90% or more of patients with a history of penicillin allergy will not manifest immediate hypersensitivity reactions on immunologic testing. Such testing can be performed in the clinical setting through commercially available penicillin skin-testing kits that contain the major antigenic determinant (benzylpenicilloyl polylysine); such testing may, however, fail to detect allergies to minor determinants (Sogn et al., 1992). Occasionally, *desensitization* is recommended for penicillin-allergic patients who must receive the drug. This procedure consists of administering gradually increasing doses of penicillin in the hope of avoiding a severe reaction and should be performed only in an intensive care setting. When full doses are reached, penicillin should not be discontinued and then restarted because immediate reactions may recur. Patients with life-threatening infections (e.g., endocarditis or meningitis) may be continued on penicillin despite the development of a maculopapular rash, although alternative antimicrobial agents should be used whenever possible. The rash often resolves as therapy is continued, perhaps owing to the development of blocking antibodies of the IgG class. Rarely, exfoliative dermatitis with or without vasculitis develops in these patients if therapy with penicillin is continued.

Other Adverse Reactions. The penicillins have minimal direct toxicity. Apparent toxic effects include bone marrow depression, granulocytopenia, and hepatitis; the last effect is rare but is seen most commonly following the

administration of oxacillin and nafcillin. The administration of penicillin G and piperacillin (also carbenicillin and ticarcillin) has been associated with impaired hemostasis due to defective platelet aggregation (Fass et al., 1987). Most common amongst the irritative responses to penicillins are pain and sterile inflammatory reactions at the sites of intramuscular injections. In some individuals who receive penicillins intravenously, phlebitis or thrombophlebitis develops. Adverse responses to oral penicillin preparations may include nausea, vomiting, and mild-to-severe diarrhea.

When penicillins are injected accidentally into the sciatic nerve, severe pain occurs and dysfunction in the area of distribution of this nerve develops and persists for weeks. Intrathecal injection of penicillin G may produce arachnoiditis or severe and fatal encephalopathy. Because of this, intrathecal or intraventricular administration of penicillins should be avoided. Similarly, high CSF concentrations of penicillins achieved through intravenous administration of excessive doses (including failure to adjust for reduced renal clearance) can lead to CNS dysfunction. The rapid intravenous administration of 20 million units of penicillin G potassium, which contains 34 mEq of K^+ , may lead to severe or even fatal hyperkalemia in persons with renal dysfunction. Accidental intravenous instead of intramuscular injection of penicillin G procaine may result in an immediate reaction, characterized by dizziness, tinnitus, headache, hallucinations, and sometimes seizures. This is due to the rapid liberation of toxic concentrations of procaine. Intravenous injection of benzathine penicillin G has been associated with cardiorespiratory arrest and death.

Reactions Unrelated to Hypersensitivity or Toxicity. Penicillin changes the composition of the microflora in the GI tract by eliminating sensitive microorganisms. Normal microflora are typically reestablished shortly after therapy is stopped; however, in some patients, superinfection results. Pseudomembranous colitis, related to overgrowth and production of a toxin by *Clostridium difficile*, has followed oral and, less commonly, parenteral administration of penicillins.

The Cephalosporins

Compounds containing 7-aminocephalosporanic acid are relatively stable in dilute acid and relatively resistant to penicillinase regardless of the nature of their side chains and their affinity for the enzyme. Modifications at position 7 of the β -lactam ring are associated with alteration in antibacterial activity; substitutions at position 3 of the dihydrothiazine ring alter the metabolism and pharmacokinetic properties of the drugs. The cephamycins are similar to the cephalosporins but have a methoxy group at position 7 of the β -lactam ring of the 7-aminocephalosporanic acid nucleus (Table 57-2).

HISTORY

Cephalosporium acremonium, the first source of the cephalosporins, was isolated in 1948 by Brotzu from the sea near a sewer outlet off the Sardinian coast (Grayson, 2010). Crude filtrates from cultures of this fungus were found to inhibit the in vitro growth of *S. aureus* and to cure staphylococcal infections and typhoid fever in humans. Culture fluids in which the Sardinian fungus was cultivated were found to contain three distinct antibiotics, which were named cephalosporin P, N, and C. With isolation of the active nucleus of cephalosporin C, 7-aminocephalosporanic acid, and with the addition of side chains, it became possible to produce semisynthetic compounds with antibacterial activity very much greater than that of the parent substance.

TABLE 57-2 ■ STRUCTURAL FORMULAS AND DOSAGE DATA FOR SELECTED CEPHALOSPORINS

<div style="text-align: center;">  <p>Cephem Nucleus</p> </div>			
COMPOUND	R ₁	R ₂	DOSAGE FORMS, ^a ADULT DOSAGE FOR SEVERE INFECTION, AND t _{1/2}
First generation Cephalexin		—CH ₃	O: 1 g every 6 h t _{1/2} = 0.9 h
Second generation Cefaclor		—Cl	O: 500 mg every 8 h t _{1/2} = 0.7 h
Third generation Cefdinir		—CH = CH ₂	O: 300 mg every 12 h or 600 mg every 24 h t _{1/2} = 1.7 h
Antipseudomonal Ceftazidime		—CH ₂ 	I: 2 g every 8 h t _{1/2} = 1.8 h
Anti-MRSA Ceftaroline			I: 600 mg every 12 h t _{1/2} = 2.6 h

^aC, capsule; I, injection; O, oral suspension T, tablet.

Cephalosporins and cephamycins inhibit bacterial cell wall synthesis in a manner similar to that of penicillin.

Classification

Classification has been by unofficial *generations*, based on general features of antimicrobial activity (Table 57–3). Recent development of novel cephalosporins makes further use of this classification scheme problematic, as newer agents expand activity in different ways. In the absence of consensus on a new generations scheme to date, we will continue to

employ this scheme for the first three generations and then differentiate agents after the third generation by their notable activity.

The **first-generation** cephalosporins (e.g., cefazolin, cephalexin, and cefadroxil) have good activity against gram-positive bacteria and modest activity against gram-negative microorganisms. Most gram-positive cocci (with the exception of enterococci, MRSA, and *S. epidermidis*) are susceptible. Most oral cavity anaerobes are sensitive, but the *B. fragilis* group is resistant. These agents have modest activity against *Moraxella catarrhalis*, *E. coli*, *Klebsiella pneumoniae*, and *P. mirabilis*.

The **second-generation** cephalosporins have somewhat increased activity against gram-negative microorganisms (including activity against *H. influenzae*) but are much less active than the third-generation agents.

TABLE 57–3 ■ CEPHALOSPORIN GENERATIONS

DRUG CLASS	USEFUL ANTIBACTERIAL SPECTRUM ^a
First generation	
Cefazolin	Streptococci ^b ; <i>Staphylococcus aureus</i> ^c ; some <i>Proteus</i> , <i>E. coli</i> , <i>Klebsiella</i> .
Cephalexin monohydrate	
Cefadroxil	
Cephadrine ^d	
Second generation	
Cefuroxime	<i>Escherichia coli</i> , <i>Klebsiella</i> , <i>Proteus</i> , <i>Haemophilus influenzae</i> , <i>Moraxella catarrhalis</i> . Not as active against gram-positive organisms as first-generation agents.
Cefuroxime axetil	
Cefprozil	
Cefoxitin	
Cefotetan	Inferior activity against <i>S. aureus</i> compared to cefuroxime but with added activity against <i>Bacteroides fragilis</i> and other <i>Bacteroides</i> spp.
Cefmetazole ^d	
Third generation	
Cefotaxime	<i>Escherichia coli</i> , <i>Klebsiella</i> , <i>Proteus</i> , <i>Haemophilus influenzae</i> , <i>Moraxella catarrhalis</i> , <i>Citrobacter</i> ^e , <i>Enterobacter</i> ^e ; <i>Serratia</i> ; <i>Neisseria gonorrhoeae</i> ; activity for <i>S. aureus</i> , <i>Streptococcus pneumoniae</i> , and <i>Streptococcus pyogenes</i> comparable to first-generation agents. Activity against <i>Bacteroides</i> spp. inferior to that of cefoxitin and cefotetan.
Ceftriaxone	
Cefdinir	
Cefditoren pivoxil	
Ceftibuten	
Cefpodoxime proxetil	
Ceftizoxime	
Antipseudomonal cephalosporins	
Ceftazidime	Gram-negative activity similar to third generation with addition of activity against <i>Pseudomonas</i> ^e ; poor activity vs. gram-positive organisms.
Ceftazidime/avibactam	Expands ceftazidime's activity against <i>Pseudomonas</i> ^e and multidrug-resistant Enterobacteriaceae, but not against gram-positives.
Ceftolozane/tazobactam	Similar to ceftazidime, with enhanced activity against <i>Pseudomonas</i> ^e and extended-spectrum β -lactamase-producing Enterobacteriaceae.
Cefepime	Comparable to third generation but more resistant to some β -lactamases (especially those of <i>Pseudomonas</i> ^e and <i>Enterobacter</i> ^e); gram-positive activity similar to cefotaxime.
Anti-MRSA cephalosporins	
Ceftaroline	Similar activity to 3 rd generation but with activity against methicillin resistant <i>Staphylococcus aureus</i> .
Ceftobiprole ^d	

^aAll cephalosporins lack clinically useful activity against enterococci, *Listeria monocytogenes*, and atypical respiratory pathogens (*Legionella*, *Mycoplasma*, *Chlamydia* spp.).

^bExcept for penicillin-resistant strains.

^cExcept for methicillin-resistant strains.

^dNot marketed in the U.S.

^eResistance to cephalosporins may develop during therapy through selection of isolates with de-repression of bacterial chromosomal β -lactamases, which destroy the cephalosporins.

A subset of second-generation agents (cefoxitin and cefotetan) also has modest activity against *B. fragilis*.

Third-generation cephalosporins generally are less active than first-generation agents against gram-positive cocci, although ceftriaxone and cefotaxime in particular have excellent antistreptococcal activity. These agents are much more active than prior generations against the Enterobacteriaceae, although resistance is dramatically increasing due to β -lactamase-producing strains.

Antipseudomonal cephalosporins include ceftazidime (sometimes classified as a third-generation cephalosporin) and ceftepime. These agents expand on the gram-negative activity of the third generation to provide useful activity against *P. aeruginosa*. Ceftazidime and ceftolozane have weaker gram-positive activity than third-generation agents, while ceftepime's activity is similar to that of ceftriaxone.

Anti-MRSA cephalosporins have structural modifications allowing for binding to and inactivation of the altered PBPs expressed by MRSA, MRSE, and penicillin-resistant *S. pneumoniae*. Ceftaroline and ceftobiprole (not available in the U.S.) are the currently used agents in this class. Ceftaroline's gram-negative activity is similar to that of ceftriaxone, while ceftobiprole's is similar to ceftazidime.

None of the cephalosporins has reliable activity against the following bacteria: *Enterococcus*; *L. monocytogenes*; the atypical respiratory pathogens (*Legionella pneumophila*, *Mycoplasma pneumoniae*, *Chlamydia pneumoniae*); *Legionella micdadei*; *C. difficile*; *Campylobacter jejuni*; and *Acinetobacter* spp.

Mechanisms of Bacterial Resistance

As with the penicillins, resistance to the cephalosporins may be related to the inability of the antibiotic to reach its sites of action or to alterations in the PBPs that are targets of the cephalosporins. Alterations in two PBPs (1A and 2X) that decrease their affinity for cephalosporins render pneumococci resistant to third-generation cephalosporins because the other three PBPs have inherently low affinity. With the exception of ceftaroline and ceftobiprole, cephalosporins lack activity against methicillin-resistant staphylococci due to their inability to bind to the low-affinity PBP expressed by these organisms.

The most prevalent mechanism of resistance to cephalosporins is destruction of the cephalosporins by hydrolysis of the β -lactam ring. The cephalosporins have variable susceptibility to β -lactamases. Cefoxitin, cefuroxime, and the third-generation cephalosporins are more resistant to hydrolysis by the β -lactamases produced by gram-negative bacteria than first-generation cephalosporins. Third-generation cephalosporins (such as ceftazidime and ceftriaxone) are susceptible to hydrolysis by inducible, chromosomally encoded (AmpC) β -lactamases present in gram-negative organisms such as *Citrobacter*, *Enterobacter*, and *Pseudomonas*. The inducible nature of these β -lactamases leads to a lower degree of susceptibility amongst wild-type isolates, whereas selection for mutants with high-level expression (stable derepression) can lead to clinical resistance. These class C enzymes are not substantially inactivated by classical β -lactamase inhibitors such as clavulanate and tazobactam. Ceftepime and ceftolozane, by virtue of their structures, may be less susceptible to hydrolysis by class C β -lactamases than are the third-generation agents. They are, however, susceptible to degradation by KPCs and metallo- β -lactamases. The β -lactamase inhibitor avibactam significantly inhibits the activity of AmpC- and KPC-type β -lactamases and is currently available in a coformulation with ceftazidime.

General Pharmacology

Many cephalosporins (cephalexin, cephadrine, cefaclor, cefadroxil, loracarbef, cefprozil, cefpodoxime proxetil, ceftibuten, cefuroxime axetil, cefdinir, and cefditoren) are absorbed readily after oral administration; others can be administered intramuscularly or intravenously. Cephalosporins are excreted primarily by the kidney; thus, in general, the dosage should be reduced in patients with renal insufficiency. Exceptions are ceftiramide (no longer marketed in the U.S.) and cefoperazone, which are excreted predominantly in the bile, and ceftriaxone, which has mixed renal/nonrenal elimination. Just as for penicillins, probenecid slows renal

tubular secretion of most cephalosporins. Cefotaxime is deacetylated to a metabolite with less antimicrobial activity than the parent compound that is excreted by the kidneys. The other cephalosporins do not undergo appreciable metabolism. Several cephalosporins, most notably ceftriaxone, cefotaxime, ceftazidime, and ceftepime, penetrate into the CSF in sufficient concentration to be useful for the treatment of meningitis. Cephalosporins also cross the placenta, and they are found in high concentrations in synovial and pericardial fluids. Penetration into the aqueous humor of the eye is relatively good after systemic administration of third-generation agents, but penetration into the vitreous humor is poor. Concentrations in bile usually are high, especially with cefoperazone and ceftiramide.

Specific Agents

First-Generation Cephalosporins

Cefazolin is relatively well tolerated after either intramuscular or intravenous administration; it is excreted by glomerular filtration and is about 85% bound to plasma proteins. Cefazolin is the only parenteral first-generation cephalosporin marketed in the U.S.

Cephalexin has the same antibacterial spectrum as the other first-generation cephalosporins. It is somewhat less active against penicillinase-producing staphylococci. Oral therapy with cephalexin (usually 0.5 g twice to four times daily) results in peak concentrations in plasma adequate for the inhibition of many gram-positive and gram-negative pathogens. The drug is not metabolized, and 70%–100% is excreted in the urine.

Cephadrine and **cefadroxil** are oral agents similar in activity and pharmacokinetics to cephalexin.

Second-Generation Cephalosporins

Cefoxitin and **cefotetan** are technically **cephamycins** and are resistant to some β -lactamases produced by gram-negative rods. Typical of second-generation cephalosporins, they have broader gram-negative activity, including most strains of *Haemophilus* spp., indole-positive *Proteus* spp., and *Klebsiella* spp. These antibiotics are less active than the first-generation cephalosporins against gram-positive bacteria but are more active against anaerobes, especially *B. fragilis*. **Cefmetazole** is a similar agent only marketed outside the U.S.

Cefuroxime has good activity against *H. influenzae* (including strains resistant to ampicillin), *N. meningitidis*, and *S. pneumoniae*. Activity against *E. coli* and *Klebsiella* is modest. Antistaphylococcal activity is inferior to first-generation cephalosporins. Unlike cefoxitin, cefotetan, and cefmetazole, cefuroxime lacks activity against *B. fragilis*. The drug can be given orally, intravenously, or intramuscularly every 8–12 h. Concentrations in CSF are about 10% of those in plasma, and the drug is effective but inferior to ceftriaxone for treatment of meningitis due to susceptible organisms.

Cefuroxime axetil is the 1-acetyloxyethyl ester of cefuroxime. Between 30% and 50% of an oral dose is absorbed, and the drug then is hydrolyzed to cefuroxime; resulting concentrations in plasma are variable.

Cefprozil, **cefaclor**, and **loracarbef** are orally administered agents generally similar to cefuroxime axetil.

Third-Generation Cephalosporins

Cefotaxime is resistant to many narrow-spectrum β -lactamases and has good activity against most gram-positive and gram-negative aerobic bacteria. However, activity against *B. fragilis* is poor, and the increasingly prevalent ESBLs and KPCs confer resistance to cefotaxime. Cefotaxime has a $t_{1/2}$ in plasma of about 1 h and should be administered every 4–8 h for serious infections. The drug is metabolized in vivo to desacetylcefotaxime, which is less active than is the parent compound. Concentrations achieved in the CSF are adequate for treatment of meningitis caused by *H. influenzae*, penicillin-sensitive *S. pneumoniae*, and *N. meningitidis*.

Ceftriaxone has activity very similar to that of cefotaxime but a longer $t_{1/2}$ (~8 h), allowing for once-daily dosing for most indications. Administration of the drug twice daily has been effective for patients with meningitis. About half the drug can be recovered from the urine; the remainder is eliminated by biliary secretion. Single doses of intramuscular ceftriaxone have long been used in the management of urethral, cervical, rectal, or pharyngeal gonorrhea; increasing resistance has necessitated the use of

1034 higher doses (250 instead of 125 mg) and routine coadministration of azithromycin (Centers for Disease Control and Prevention, 2015).

Ceftizoxime (not marketed in the U.S.) has a spectrum of activity in vitro that is similar to that of cefotaxime, except that it is less active against *S. pneumoniae* and more active against *B. fragilis*. The $t_{1/2}$ is 1.8 h, and the drug thus can be administered every 8–12 h for serious infections. Ceftizoxime is not metabolized; 90% is recovered in urine.

Cefpodoxime proxetil and **cefditoren pivoxil** are orally administered prodrugs that are hydrolyzed by esterases during absorption to the active forms (cefpodoxime and cefditoren, respectively). These drugs provide similar, but less potent, activity as cefotaxime against methicillin-susceptible strains of *S. aureus* and penicillin-susceptible strains of *S. pneumoniae*, *S. pyogenes*, *H. influenzae*, *H. parainfluenzae*, and *M. catarrhalis*. They are eliminated unchanged in the urine.

Cefixime is orally effective against urinary tract infections caused by *E. coli* and *P. mirabilis*; otitis media caused by *H. influenzae* and *S. pyogenes*; pharyngitis due to *S. pyogenes*; and uncomplicated gonorrhea (although intramuscular ceftriaxone is preferred for gonorrhea). It is available as an oral suspension. Cefixime has a plasma $t_{1/2}$ of 3–4 h and is both excreted in the urine and eliminated in the bile. The standard dose for adults is 400 mg/d for 5–7 days and for a longer interval in patients with *S. pyogenes*. Doses must be reduced in patients with renal impairment. Pediatric dosing for children 6 months and older and less than 45 kg is based on weight (8 mg/kg/d).

Ceftibuten and **cefdinir** are orally administered cephalosporins similar in spectrum and pharmacokinetics to cefixime.

Antipseudomonal Cephalosporins

Ceftazidime is one-quarter to one-half as active against gram-positive microorganisms as is cefotaxime; activity against staphylococci is particularly poor. Its activity against the Enterobacteriaceae is similar to ceftriaxone, but its major distinguishing feature is excellent activity against *Pseudomonas*. Ceftazidime has poor activity against *B. fragilis*. It only achieves therapeutic levels through parenteral administration, with a $t_{1/2}$ in plasma of about 1.5 h; the drug is renally eliminated and requires adjustment in renal dysfunction. The activity of ceftazidime against ESBL- and KPC-producing Enterobacteriaceae and AmpC β -lactamase-overexpressing *Pseudomonas* is enhanced when it is combined with the β -lactamase inhibitor avibactam in **ceftazidime/avibactam**.

Ceftolozane is a structural analogue of ceftazidime that has enhanced activity against *Pseudomonas*, including activity against strains resistant to ceftazidime through β -lactamase overexpression. It has similarly weak activity to ceftazidime against gram-positive organisms. It is commercially available as the coformulation **ceftolozane/tazobactam**, which improves its activity against ESBL-producing Enterobacteriaceae. Its pharmacokinetics are similar to ceftazidime, with a half-life after intravenous administration of approximately 2.5 h and renal elimination.

Cefepime and **cefpirime** (not available in the U.S.) are parenteral antipseudomonal cephalosporins sometimes also classified as “fourth-generation” agents. They provide similarly excellent activity to cefotaxime against Enterobacteriaceae and are relatively resistant to AmpC chromosomally encoded β -lactamases. Thus, they are active against many organisms such as *Enterobacter* and *Pseudomonas* that are resistant to other cephalosporins via overexpression of chromosomally encoded AmpC β -lactamases. However, other mechanisms (such as active efflux) in *Pseudomonas* may still confer cefepime resistance. Cefepime is susceptible to varying degrees to hydrolysis by ESBLs and to a great extent to KPCs. Cefepime has higher activity than ceftazidime and comparable activity to cefotaxime for streptococci and methicillin-sensitive *S. aureus*. Cefepime is excreted renally; doses should be adjusted for renal failure. The serum $t_{1/2}$ is 2 h. Cefepime has excellent penetration into the CSF in animal models of meningitis.

Anti-MRSA Cephalosporins

Ceftaroline fosamil is a new cephalosporin with gram-negative activity comparable to cefotaxime. Its distinguishing feature is its enhanced gram-positive activity, especially its ability to bind to the low-affinity PBPs of MRSA and penicillin-resistant *S. pneumoniae*. Over 95% of MRSA and penicillin-resistant *S. pneumoniae* isolates are inhibited by ceftaroline.

The parenteral preparation is a prodrug that is rapidly converted to active ceftaroline on intravenous administration. It is primarily eliminated by the kidneys with a half-life of approximately 2 h. Ceftaroline has minimal protein binding (~20%) and appears to distribute well into most tissues, though penetration into the CSF has not yet been well characterized.

Ceftobiprole medocartil (not available in the U.S.) has similar activity to ceftaroline against gram-positive organisms. In contrast to all other cephalosporins, it has appreciable in vitro activity against *E. faecalis*; however, its clinical utility against this organism is not established. Its gram-negative spectrum includes activity similar to cefepime against *Pseudomonas* spp. and other gram-negative bacilli. As with ceftaroline, its intravenous formulation is a prodrug that is rapidly cleaved to the active moiety. Its pharmacokinetics are similar to those of ceftaroline.

Adverse Reactions

Hypersensitivity reactions to the cephalosporins are the most common side effects; they are similar to those caused by the penicillins. Immediate reactions such as anaphylaxis, bronchospasm, and urticaria are observed. More commonly, maculopapular rash develops, usually after several days of therapy; this may or may not be accompanied by fever and eosinophilia. Because of the common β -lactam ring structure, there is potential for patients who are allergic to one class of β -lactam antibiotics to manifest cross-reactivity to a member of the other class. Some allergic reactions may be directed to the β -lactam side chains, which may be similar between agents in different classes. Thus, estimating the likelihood of cross-reactivity between a penicillin and cephalosporin depends on the agents involved; risk seems to be higher with first-generation cephalosporins as opposed to later generations.

Patients with a history of a mild or a temporally distant reaction to penicillin appear to be at low risk of allergic reaction following the administration of a cephalosporin. However, patients who have a history of a severe, immediate reaction to a penicillin should be skin tested to confirm penicillin allergy before cephalosporin administration, if feasible. If skin testing is not feasible, administration of a cephalosporin should be avoided if possible. A positive Coombs reaction appears frequently in patients who receive large doses of a cephalosporin, but hemolysis is rare. Cephalosporins have produced rare instances of bone marrow depression, characterized by granulocytopenia.

Some cephalosporins are potentially nephrotoxic. Renal tubular necrosis has followed the administration of cephaloridine in doses greater than 4 g/d; this agent is not licensed for use in the U.S. Other cephalosporins, when used by themselves in recommended doses, rarely produce significant renal toxicity. Diarrhea can result from the administration of cephalosporins and may be more frequent with cefoperazone, perhaps because of its greater biliary excretion. The high binding affinity of ceftriaxone for serum albumin may displace bilirubin, potentially causing jaundice in neonates; for this reason, cefotaxime is the preferred agent in this patient population. Ceftriaxone's high biliary concentrations combined with its affinity for calcium can lead to biliary pseudolithiasis. Cephalosporins containing a methylthiotetrazole group (cefamandole [not available in the U.S.], cefotetan, and cefoperazone) can prolong the prothrombin time, an effect that may be associated with clinically significant bleeding amongst patients receiving anticoagulation or with vitamin K deficiency. Encephalopathy and nonconvulsive status epilepticus have been reported with cefepime, especially when administered at high doses or amongst patients with renal dysfunction.

Therapeutic Uses

The **first-generation cephalosporins** are excellent agents for skin and soft tissue infections owing to their activity against *S. pyogenes* and methicillin-susceptible *S. aureus* (Stevens et al., 2014). A single dose of cefazolin just before surgery is the preferred prophylaxis for procedures in which skin flora are the likely pathogens (Bratzler et al., 2013).

Second-generation cephalosporins generally have been displaced by third-generation agents. The oral second-generation cephalosporins can be used to treat respiratory tract infections, although they are

suboptimal (compared with oral amoxicillin) for treatment of penicillin-nonsusceptible *S. pneumoniae* pneumonia and otitis media. Cefoxitin and cefotetan play a useful role in perioperative prophylaxis for patients undergoing intra-abdominal and gynecologic surgical procedures. They may also be used for treatment of certain anaerobic and mixed aerobic-anaerobic infections, such as peritonitis and pelvic inflammatory disease, although because of increasing resistance amongst *B. fragilis*, these agents are best used for mild-to-moderate infections.

The **third-generation cephalosporins** are the drugs of choice for serious infections caused by *E. coli*, *Klebsiella*, *Proteus*, *Providencia*, *Serratia*, and *Haemophilus* spp. Ceftriaxone is the therapy of choice for all forms of gonorrhea and for severe forms of Lyme disease. Cefotaxime or ceftriaxone are used for the empiric treatment of meningitis in nonimmunocompromised adults and children (in combination with vancomycin and ampicillin pending identification of the causative agent), owing to their excellent activity against *H. influenzae*, sensitive *S. pneumoniae*, *N. meningitidis*, and gram-negative enteric bacteria (Tunkel et al., 2004). Third-generation cephalosporins lack activity against *L. monocytogenes* and penicillin-resistant pneumococci, which may cause meningitis. The antimicrobial spectra of cefotaxime and ceftriaxone are excellent for the treatment of community-acquired pneumonia.

The **antipseudomonal cephalosporins** are indicated for the empirical treatment of nosocomial infections where *Pseudomonas* and other resistant gram-negative bacilli are likely to be pathogens. Ceftolozane/tazobactam may have superior activity against some ceftazidime-resistant *Pseudomonas*, whereas cefepime has superior activity against nosocomial isolates of *Enterobacter*, *Citrobacter*, and *Serratia* spp. Activity of ceftazidime, ceftolozane/tazobactam, and cefepime is variable against ESBL-producing isolates and absent against KPC-expressing strains; ceftazidime/avibactam is more likely to be active against these highly resistant organisms.

Other β -Lactam Antibiotics

Carbapenems

Carbapenems are β -lactams that contain a fused β -lactam ring and a five-member ring system that differs from the penicillins because it is unsaturated and contains a carbon atom instead of the sulfur atom. This class of antibiotics has a broader spectrum of activity than most other β -lactam antibiotics.

Imipenem

Imipenem is marketed in combination with cilastatin, a drug that inhibits the degradation of imipenem by a renal tubular dipeptidase.

Antimicrobial Activity. Imipenem, like other β -lactam antibiotics, binds to PBPs, disrupts bacterial cell wall synthesis, and causes death of susceptible microorganisms. It is very resistant to hydrolysis by most β -lactamases. The activity of imipenem is excellent in vitro for a wide variety of aerobic and anaerobic microorganisms. Streptococci (including penicillin-resistant *S. pneumoniae*); enterococci (excluding *Enterococcus faecium* and non- β -lactamase-producing penicillin-resistant strains); staphylococci (including penicillinase-producing strains but not MRSA); and *Listeria* (although ampicillin is more active) all are typically susceptible. Activity is excellent against the Enterobacteriaceae with the exception of emerging KPC-producing strains. Most strains of *Pseudomonas* and *Acinetobacter* are inhibited, but resistance to carbapenems amongst these organisms is increasing. Anaerobes, including *B. fragilis*, are highly susceptible. Imipenem also displays activity against *Nocardia* spp. and some species of rapidly growing mycobacteria.

Pharmacokinetics and Adverse Reactions. Imipenem is not absorbed orally. The drug is hydrolyzed rapidly by a dipeptidase found in the brush border of the proximal tubule. To prolong drug activity, imipenem is combined with cilastatin, an inhibitor of the dehydropeptidase. Both imipenem and cilastatin have a $t_{1/2}$ of about 1 h. When administered concurrently with cilastatin, about 70% of administered imipenem is recovered in the urine as the active drug. Dosage should be modified for patients with renal insufficiency. Nausea and vomiting are the most common adverse reactions (1%–20%). Seizures have been noted in up to 1.5% of patients, especially when high doses are given to patients with CNS lesions and to those with

renal insufficiency. Patients who are allergic to other β -lactam antibiotics may have hypersensitivity reactions when given imipenem, although the incidence of immediate-type hypersensitivity appears to be low (<1%).

Therapeutic Uses. Imipenem-cilastatin is effective for a wide variety of infections, including urinary tract and lower respiratory infections; intra-abdominal and gynecological infections; and skin, soft tissue, bone, and joint infections. The drug combination appears to be especially useful for the treatment of infections caused by cephalosporin-resistant nosocomial bacteria. It is prudent to use imipenem for empirical treatment of serious infections in hospitalized patients who have recently received other β -lactam antibiotics. When imipenem is used for treatment of severe *P. aeruginosa* infections, resistance may develop during therapy.

Meropenem

Meropenem is a derivative of thienamycin. It does not require coadministration with cilastatin because it is not sensitive to renal dipeptidase. Compared to imipenem, it is somewhat less active against gram-positive organisms (particularly *Enterococcus*) and more active against gram-negative organisms. Its toxicity is similar to that of imipenem except that it may be less likely to cause seizures; thus, it is preferred for treatment of meningitis when carbapenem therapy is required.

Doripenem

Doripenem has a spectrum of activity that is similar to that of meropenem, with greater activity against some resistant isolates of *Pseudomonas*.

Ertapenem

Ertapenem differs from imipenem and meropenem by having a longer $t_{1/2}$ that allows once-daily dosing and by having inferior activity against *Enterococcus*, *P. aeruginosa*, and *Acinetobacter* spp. Its activity against Enterobacteriaceae and anaerobes makes it useful in intra-abdominal and pelvic infections.

Monobactams

Monobactams are β -lactams that contain only a fused β -lactam ring, not a thiazolidine or dihydrothiazidine ring. Currently, aztreonam is the only member of this class in therapeutic use.

Aztreonam

Aztreonam is resistant to narrow-spectrum β -lactamases elaborated by most gram-negative bacteria as well as metallo- β -lactamases, but not most extended-spectrum or KPC-type β -lactamases. Aztreonam has activity only against gram-negative bacteria; it has no activity against gram-positive bacteria and anaerobic organisms. Activity against Enterobacteriaceae and *P. aeruginosa* is similar to that of ceftazidime. It is also highly active in vitro against *H. influenzae*. Aztreonam is administered either intramuscularly or intravenously. The $t_{1/2}$ for elimination is 1.7 h; most of the drug is recovered unaltered in the urine. The $t_{1/2}$ is prolonged to about 6 h in anephric patients. The usual dose of aztreonam for severe infections is 2 g every 6–8 h (reduced in patients with renal insufficiency). A notable feature is a lack of allergic cross-reactivity with other β -lactam antibiotics, with the possible exception of ceftazidime, with which it shares an identical side chain (Perez Pimiento et al., 1998). Aztreonam is therefore useful for treating gram-negative infections that normally would be treated with a β -lactam antibiotic were it not for a prior allergic reaction. Aztreonam generally is well tolerated, although hepatotoxicity, especially in infants and young children, can occur.

β -Lactamase Inhibitors

Certain molecules can inactivate β -lactamases and prevent the destruction of β -lactam antibiotic substrates. Older-generation β -lactamase inhibitors (*clavulanate*, *sulbactam*, *tazobactam*) are most active against plasmid-encoded β -lactamases (including those that hydrolyze ceftazidime and cefotaxime), but they are inactive at clinically achievable concentrations against the AmpC chromosomal β -lactamases present in gram-negative bacilli (e.g., *Enterobacter*, *Citrobacter*, and *Pseudomonas*) as well as carbapenemases of the KPC- and metallo- β -lactamase type. *Avibactam* is a new β -lactamase inhibitor that is structurally dissimilar from the older generation, with a broader spectrum of inhibition.

Clavulanic acid has poor intrinsic antimicrobial activity but is a “suicide” inhibitor that binds β -lactamases produced by a wide range of gram-positive and gram-negative microorganisms. Clavulanic acid is well absorbed by mouth and also can be given parenterally. It is combined with amoxicillin as an oral preparation and with ticarcillin as a parenteral preparation.

CLAVULANIC ACID

Sulbactam is a β -lactamase inhibitor similar in structure to clavulanic acid. It is available for intravenous or intramuscular use combined with

ampicillin and with cefoperazone (not available in the U.S.). Sulbactam also possesses intrinsic activity against *Acinetobacter* spp. and has been used in high dosages to treat multidrug-resistant *Acinetobacter* infections.

Tazobactam is a β -lactamase inhibitor with good activity against many of the plasmid β -lactamases, including some of the extended-spectrum class. It is available as parenteral combination products with piperacillin and ceftolozane.

Avibactam is a non- β -lactam β -lactamase inhibitor that provides clinically useful inhibition against narrow-spectrum, ESBL-type, chromosomal AmpC, and KPC-type β -lactamases (although not metallo- β -lactamases). It is available as a parenteral combination product with ceftazidime.

Drug Facts for Your Personal Formulary: β -Lactam Antibiotics

Drugs	Therapeutic Uses	Clinical Pharmacology and Tips
Penicillins—Inhibitors of Bacterial Cell Wall Peptidoglycan Synthesis		
General: Bactericidal, renal elimination, hypersensitivity reactions (rash, anaphylaxis)		
Penicillin G (IV), penicillin V (PO); IM depot formulations (benzathine, procaine)	<ul style="list-style-type: none"> • Penicillin-susceptible <i>Streptococcus pneumoniae</i> infections: pneumonia, meningitis • Streptococcal pharyngitis, endocarditis, skin and soft tissue infection • <i>Neisseria meningitidis</i> infections • Syphilis 	<ul style="list-style-type: none"> • Excellent activity vs. <i>Treponema pallidum</i>, β-hemolytic streptococci, <i>N. meningitidis</i>, gram-positive anaerobes • Good activity vs. <i>S. pneumoniae</i>, viridans streptococci • CSF penetration with inflammation
Penicillinase-resistant penicillins Oxacillin (IV), nafcillin (IV), dicloxacillin (PO)	<ul style="list-style-type: none"> • Skin and soft tissue infections • Serious infections due to MSSA 	<ul style="list-style-type: none"> • Excellent activity vs. MSSA • Good activity vs. streptococci • Nafcillin nonrenal elimination • CSF penetration with inflammation
Aminopenicillins Amoxicillin (PO), ampicillin (PO/IV)	<ul style="list-style-type: none"> • Upper respiratory tract infections (sinusitis, pharyngitis, otitis media) • <i>Enterococcus faecalis</i> infections • <i>Listeria</i> infections 	<ul style="list-style-type: none"> • Excellent activity vs. β-hemolytic streptococci, <i>E. faecalis</i> • Good activity vs. <i>S. pneumoniae</i>, viridans streptococci, <i>Haemophilus influenzae</i> • Some activity vs. <i>Proteus</i>, <i>Escherichia coli</i> • CSF penetration with inflammation • Rash more common than other penicillins
Aminopenicillin/β-lactamase inhibitors Amoxicillin/clavulanate (PO), ampicillin/sulbactam (IV)	<ul style="list-style-type: none"> • Upper respiratory tract infections (sinusitis, otitis media) • Intra-abdominal infections 	<ul style="list-style-type: none"> • Activity: amoxicillin and ampicillin plus • Excellent activity vs. <i>H. influenzae</i>, <i>Bacteroides fragilis</i>, <i>Proteus</i> • Good activity vs. <i>E. coli</i>, <i>Klebsiella</i>, MSSA
Antipseudomonal penicillins Piperacillin/tazobactam (IV)	<ul style="list-style-type: none"> • Nosocomial infections: pneumonia, intra-abdominal infections, urinary tract infections 	<ul style="list-style-type: none"> • Activity: ampicillin/sulbactam plus • Excellent activity vs. <i>E. coli</i>, <i>Klebsiella</i> • Good activity vs. <i>Pseudomonas</i>, <i>Citrobacter</i>, <i>Enterobacter</i> • Poor CSF penetration
Cephalosporins—Inhibitors of Bacterial Cell Wall Peptidoglycan Synthesis		
General: Bactericidal, renal elimination, hypersensitivity reactions (rash, anaphylaxis)		
First-generation cephalosporins Cefazolin (IV), cephalexin (PO), cefadroxil (PO)	<ul style="list-style-type: none"> • Skin and soft tissue infections • Serious infections due to MSSA • Perioperative surgical prophylaxis 	<ul style="list-style-type: none"> • Excellent activity vs. MSSA, streptococci • Some activity vs. <i>Proteus</i>, <i>E. coli</i>, <i>Klebsiella</i> • Poor CSF penetration
Second-generation cephalosporins Cefuroxime (IV/PO), cefoxitin (IV), cefotetan (IV), cefaclor (PO), cefprozil (PO)	<ul style="list-style-type: none"> • Upper respiratory tract infections (sinusitis, otitis media) • Cefoxitin/cefotetan: gynecologic infections, perioperative surgical prophylaxis 	<ul style="list-style-type: none"> • Good activity vs. MSSA, streptococci, <i>H. influenzae</i>, <i>Proteus</i>, <i>E. coli</i>, <i>Klebsiella</i> • Cefoxitin/cefotetan: some activity vs. <i>B. fragilis</i>
Third-generation cephalosporins Cefotaxime (IV), ceftriaxone (IV), cefpodoxime (PO), cefixime (PO), cefdinir (PO), cefditoren (PO), ceftibuten (PO)	<ul style="list-style-type: none"> • Community-acquired pneumonia, meningitis, urinary tract infections • Streptococcal endocarditis • Gonorrhea • Severe Lyme disease 	<ul style="list-style-type: none"> • Excellent activity against streptococci, <i>H. influenzae</i>, <i>Proteus</i>, <i>E. coli</i>, <i>Klebsiella</i>, <i>Serratia</i>, <i>Neisseria</i> • Good activity vs. MSSA • Some activity vs. <i>Citrobacter</i>, <i>Enterobacter</i> • Ceftriaxone renal and nonrenal elimination • Good CSF penetration • Ceftriaxone: neonatal kernicterus (use cefotaxime), biliary pseudolithiasis

Cephalosporins—Inhibitors of Bacterial Cell Wall Peptidoglycan Synthesis		
General: Bactericidal, renal elimination, hypersensitivity reactions (rash, anaphylaxis) (continued)		
Antipseudomonal cephalosporins Ceftazidime (IV), ceftolozane/tazobactam (IV), ceftazidime/avibactam (IV), cefepime (IV)	<ul style="list-style-type: none"> Nosocomial infections: pneumonia, meningitis, urinary tract infections, intra-abdominal infections (with metronidazole) 	<ul style="list-style-type: none"> Excellent activity against <i>H. influenzae</i>, <i>Proteus</i>, <i>E. coli</i>, <i>Klebsiella</i>, <i>Serratia</i>, <i>Neisseria</i>, streptococci,^a MSSA^a Good activity vs. <i>Pseudomonas</i>, <i>Enterobacter</i>^b Some activity vs. <i>Enterobacter</i> (ceftazidime, ceftolozane/tazobactam) Ceftazidime/avibactam active vs. ESBL and KPC-producing Enterobacteriaceae Good CSF penetration Cefepime: encephalopathy at high doses
Anti-MRSA cephalosporins Cefaroline (IV)	<ul style="list-style-type: none"> Community-acquired pneumonia Skin and soft tissue infections 	<ul style="list-style-type: none"> Excellent activity against streptococci, MSSA, MRSA,^c <i>H. influenzae</i>, <i>Proteus</i>, <i>E. coli</i>, <i>Klebsiella</i>, <i>Serratia</i> Some activity vs. <i>Citrobacter</i>, <i>Enterobacter</i>
Carbapenems—Inhibitors of Bacterial Cell Wall Synthesis		
General: Bactericidal, renal elimination, hypersensitivity reactions (rash, anaphylaxis), seizure risk		
Imipenem/cilastatin (IV), meropenem (IV), doripenem (IV)	<ul style="list-style-type: none"> Nosocomial infections: pneumonia, intra-abdominal infections, urinary tract infections Meningitis (meropenem) 	<ul style="list-style-type: none"> Excellent activity against streptococci, MSSA, <i>H. influenzae</i>, <i>Proteus</i>, <i>E. coli</i>, <i>Klebsiella</i>, <i>Serratia</i>, <i>Enterobacter</i>, <i>B. fragilis</i> Good activity vs. <i>Pseudomonas</i>, <i>Acinetobacter</i>, <i>Enterococcus faecalis</i>^d Good CSF penetration Imipenem coformulated with renal dihydropeptidase inhibitor cilastatin Seizures at high doses in patients with prior seizure history (imipenem > meropenem, doripenem)
Ertapenem (IV)	<ul style="list-style-type: none"> Community-acquired infections and nosocomial infections without <i>Pseudomonas</i> risk 	<ul style="list-style-type: none"> Excellent activity against streptococci, MSSA, <i>H. influenzae</i>, <i>Proteus</i>, <i>E. coli</i>, <i>Klebsiella</i>, <i>Serratia</i>, <i>Enterobacter</i>, <i>B. fragilis</i> Lacks activity against <i>Pseudomonas</i>, <i>Enterococcus</i> Lower seizure risk than imipenem
Monobactam—Bactericidal Inhibitor of Bacterial Cell Wall Synthesis		
Aztreonam (IV)	<ul style="list-style-type: none"> Nosocomial infections: pneumonia, urinary tract infections 	<ul style="list-style-type: none"> Excellent activity against <i>H. influenzae</i>, <i>Proteus</i>, <i>E. coli</i>, <i>Klebsiella</i>, <i>Serratia</i> Good activity vs. <i>Pseudomonas</i> Lacks any gram-positive activity Lacks cross-allergenicity with other β-lactams (except ceftazidime) Good CSF penetration, renal elimination

^aCefepime only.^bCefepime, ceftazidime/avibactam.^cOnly β -lactam with significant activity versus MRSA.^dImipenem only.

Chapter 58

Aminoglycosides

Conan MacDougall

MECHANISM OF ACTION

ANTIMICROBIAL ACTIVITY

RESISTANCE TO THE AMINOGLYCOSIDES

ADME

DOSING AND MONITORING

THERAPEUTIC USES OF AMINOGLYCOSIDES

- Urinary Tract Infections
- Pneumonia
- Meningitis
- Peritonitis
- Bacterial Endocarditis
- Sepsis
- Tularemia
- Plague
- Mycobacterial Infections

- Cystic Fibrosis
- Topical Applications

ADVERSE EFFECTS OF AMINOGLYCOSIDES

- Ototoxicity
- Nephrotoxicity
- Neuromuscular Blockade
- Other Adverse Effects

PHARMACOLOGICAL PROPERTIES OF INDIVIDUAL AMINOGLYCOSIDES

- Gentamicin
- Tobramycin
- Amikacin
- Netilmicin
- Streptomycin
- Neomycin
- Paromomycin
- Kanamycin

ORIGINS

Aminoglycosides are natural products or semisynthetic derivatives of compounds produced by a variety of soil actinomycetes. Streptomycin was first isolated from a strain of *Streptomyces griseus*. Gentamicin and netilmicin are derived from species of the actinomycete *Micromonospora*. The difference in spelling (-*micin*) compared with the other aminoglycoside antibiotics (-*mycin*) reflects this difference in origin. Tobramycin is one of several components of an aminoglycoside complex known as “nebramycin” that is produced by *Streptomyces tenebrarius*. It is most similar in antimicrobial activity and toxicity to gentamicin. In contrast to the other aminoglycosides, amikacin, a derivative of kanamycin, and netilmicin, a derivative of sisomicin, are semisynthetic products.

Aminoglycosides are natural products or semisynthetic derivatives of compounds produced by a variety of soil actinomycetes. Amikacin, a derivative of kanamycin, and netilmicin, a derivative of sisomicin, are semisynthetic products.

Aminoglycosides (*gentamicin, tobramycin, amikacin, netilmicin, kanamycin, streptomycin, paromomycin, and neomycin*) are used primarily to treat infections caused by aerobic gram-negative bacteria. Streptomycin and amikacin are important agents for the treatment of mycobacterial infections, and paromomycin is used orally for intestinal amebiasis. Aminoglycosides are *bactericidal inhibitors* of protein synthesis. Mutations affecting proteins in the bacterial ribosome can confer marked resistance to their action. Most commonly, resistance is due to aminoglycoside-metabolizing enzymes or impaired transport of drug into the cell; these mechanisms may confer resistance to all aminoglycosides or only select agents. Resistance genes are frequently acquired via plasmids or transposons.

Aminoglycosides contain amino sugars linked to an aminocyclitol ring by glycosidic bonds (Figure 58–1). They are polycations, and their polarity is responsible in part for pharmacokinetic properties shared by all members of the group. For example, none is absorbed adequately after oral administration, inadequate concentrations are found in CSF, and all are excreted relatively rapidly by the normal kidney. All members of the group share the same spectrum of toxicity, most notably nephrotoxicity and ototoxicity, which can involve the auditory and vestibular functions of the eighth cranial nerve.

Mechanism of Action

The aminoglycoside antibiotics are rapidly bactericidal. Bacterial killing is concentration dependent: the higher the concentration, the greater the rate of bacterial killing. The ratio of the peak concentration to the organism's MIC is thus a key predictor of aminoglycoside efficacy. The inhibitory activity of aminoglycosides persists after the serum concentration has fallen below the MIC, a phenomenon known as the *postantibiotic effect*. These properties probably account for the efficacy of high-dose, extended-interval dosing regimens.

Aminoglycosides diffuse through aqueous channels formed by *porin* proteins in the outer membrane of gram-negative bacteria to enter the periplasmic space. Transport of aminoglycosides across the cytoplasmic (inner) membrane depends on a transmembrane electrical gradient coupled to electron transport to drive permeation of these antibiotics. This energy-dependent phase is rate limiting and can be blocked or inhibited by divalent cations (e.g., Ca^{2+} and Mg^{2+}), hyperosmolarity, a reduction in pH, and anaerobic conditions. Thus, the antimicrobial activity of aminoglycosides is reduced markedly in the anaerobic environment of an abscess and in hyperosmolar acidic urine.

Once inside the cell, aminoglycosides bind to polysomes and interfere with protein synthesis by causing misreading and premature termination

Abbreviations

AC: acetylase
AD: adenylase
ADME: absorption, distribution, metabolism, excretion
CNS: central nervous system
CSF: cerebrospinal fluid
GI: gastrointestinal
IM: intramuscular
IV: intravenous
MIC: minimum inhibitory concentration
mRNA: messenger RNA
PO: by mouth
UTI: urinary tract infection

of mRNA translation (Figure 58–2). The primary intracellular site of action of the aminoglycosides is the 30S ribosomal subunit. At least three of these ribosomal proteins, and perhaps the 16S ribosomal RNA as well, contribute to the streptomycin-binding site. *Aminoglycosides interfere with the initiation of protein synthesis, leading to the accumulation of abnormal initiation complexes; the drugs also can cause misreading of the mRNA template and incorporation of incorrect amino acids into the growing polypeptide chains* (Davis, 1988). The resulting aberrant proteins may be inserted into the cell membrane, leading to altered permeability and further stimulation of aminoglycoside transport (Busse et al., 1992).

Antimicrobial Activity

The antibacterial activity of gentamicin, tobramycin, and amikacin is directed primarily against aerobic gram-negative bacilli (Mingeot-Leclercq et al., 1999). Kanamycin, like streptomycin, has a more limited spectrum. The aerobic gram-negative bacilli vary in their susceptibility to the aminoglycosides (see Table 58–1). Gram-negative aerobic cocci such as *Neisseria*, *Moraxella*, and *Haemophilus* have varying susceptibilities. An increasing number of gram-negative bacilli encountered in healthcare settings (especially *Klebsiella* and *Pseudomonas*) display extensive resistance to multiple classes of antibacterials; in these isolates, aminoglycosides may be the only class of commonly used agents with in vitro activity.

Aminoglycosides have little activity against anaerobic microorganisms or facultative bacteria under anaerobic conditions. Their action against most gram-positive bacteria is limited, and they should not be used as

Figure 58–1 Aminoglycoside structure and sites of activity of plasmid-mediated enzymes capable of inactivating aminoglycosides. Tobramycin is shown as a representative; structural characteristics protect some aminoglycosides from the actions of some of these enzymes, explaining differences in spectrum of activity.

single agents to treat infections caused by gram-positive bacteria. However, in combination with a cell wall-active agent, such as a penicillin or vancomycin, an aminoglycoside can produce a synergistic bactericidal effect in vitro. This effect has been most commonly employed for treatment of infections due to staphylococci, enterococci, viridans group streptococci, and *Listeria*. Clinically, the superiority of aminoglycoside combination regimens over cell-wall agents alone is not proven except in relatively few infections (discussed further in the chapter).

Resistance to the Aminoglycosides

Bacteria may be resistant to aminoglycosides through

- inactivation of the drug by microbial enzymes;
- failure of the antibiotic to penetrate intracellularly; and
- low affinity of the drug for the bacterial ribosome.

Figure 58–2 Effects of aminoglycosides on protein synthesis. **A.** Aminoglycoside (represented by red circles) binds to the 30S ribosomal subunit and interferes with initiation of protein synthesis by fixing the 30S-50S ribosomal complex at the start codon (AUG) of mRNA. As 30S-50S complexes downstream complete translation of mRNA and detach; the abnormal initiation complexes, so-called streptomycin monosomes, accumulate, blocking further translation of the message. Aminoglycoside binding to the 30S subunit also causes misreading of mRNA, leading to **B**, premature termination of translation with detachment of the ribosomal complex and incompletely synthesized protein or **C**, incorporation of incorrect amino acids (indicated by the red X), resulting in the production of abnormal or nonfunctional proteins.

TABLE 58-1 ■ SUSCEPTIBILITY TO AMINOGLYCOSIDES AND TYPICAL MINIMAL CONCENTRATIONS THAT WILL INHIBIT 90% (MIC₉₀) OF CLINICAL ISOLATES FOR SEVERAL SPECIES

SPECIES	% SUSCEPTIBLE (MIC ₉₀ µg/mL)		
	GENTAMICIN	TOBRAMYCIN	AMIKACIN
<i>Enterobacter</i> spp.	97.0% (1)	96.0% (1)	100.0% (2)
<i>Escherichia coli</i>	88.2% (8)	86.3% (8)	99.0% (4)
<i>Klebsiella pneumoniae</i>	89.2% (8)	82.4% (32)	88.2% (32)
<i>Pseudomonas aeruginosa</i>	88.0% (16)	90.0% (4)	98.0% (16)
<i>Serratia</i> spp.	97.0% (1)	94.0% (4)	99.0% (4)
<i>Acinetobacter baumannii</i>	37.0% (>128)	51.0% (>128)	58.0% (>128)
<i>Staphylococcus aureus</i>	95.0% (0.5)	76.0% (>128)	96.0% (8)

Clinically, drug inactivation is the most common mechanism for acquired microbial resistance. The genes encoding aminoglycoside-modifying enzymes are acquired primarily by conjugation and transfer of resistance plasmids (see Chapter 52). These enzymes phosphorylate, adenylate, or acetylate specific hydroxyl or amino groups (see Figure 58-1). The ability of these enzymes to attack these groups in differing aminoglycosides explains some of the variability in antimicrobial activity across the class. Amikacin is a suitable substrate for only a few of these inactivating enzymes; thus, strains that are resistant to multiple other aminoglycosides tend to be susceptible to amikacin, particularly amongst gram-negative bacilli. A significant percentage of clinical isolates of *Enterococcus faecalis* and *Enterococcus faecium* are highly resistant to all aminoglycosides (Eliopoulos et al., 1984). Resistance to gentamicin indicates cross-resistance to tobramycin, amikacin, kanamycin, and netilmicin because the inactivating enzyme is bifunctional and can modify all these aminoglycosides. Owing to differences in the chemical structures between streptomycin and other aminoglycosides, the most common enzyme seen in enterococci does not modify streptomycin, which is inactivated by another enzyme. Consequently, gentamicin-resistant strains of enterococci may be susceptible to streptomycin. Intrinsic resistance to aminoglycosides may be caused by failure of the drug to penetrate the cytoplasmic (inner) membrane. Transport of aminoglycosides across the cytoplasmic membrane is an active process that depends on oxidative metabolism. Strictly anaerobic bacteria thus are resistant to these drugs because they lack the necessary transport system.

Missense mutations in *Escherichia coli* that substitute a single amino acid in a crucial ribosomal protein may prevent binding of streptomycin. Although highly resistant to streptomycin, these strains are not widespread in nature. Similarly, 5% of strains of *Pseudomonas aeruginosa* exhibit such ribosomal resistance to streptomycin. Because ribosomal resistance usually is specific for streptomycin, enterococci with ribosomal mutations typically remain sensitive to a combination of penicillin and gentamicin in vitro.

surfaces also may result in rapid absorption and unexpected toxicity (i.e., neuromuscular blockade). Intoxication may occur when aminoglycosides are applied topically for long periods to large wounds, burns, or cutaneous ulcers, particularly if there is renal insufficiency.

All the aminoglycosides are absorbed rapidly from intramuscular sites of injection. Peak concentrations in plasma occur after 30–90 min. These concentrations range from 4 to 12 µg/mL following a 1.5- to 2-mg/kg dose of gentamicin, tobramycin, or netilmicin and from 20 to 35 µg/mL following a 7.5-mg/kg dose of amikacin or kanamycin. There is increasing use of aminoglycosides administered via inhalation, primarily for the management of patients with cystic fibrosis who have chronic *P. aeruginosa* pulmonary infections (Geller et al., 2002). Amikacin and tobramycin solutions for injection have been used, as well as a commercial formulation of tobramycin designed for inhalation.

Distribution

Because of their polar nature, the aminoglycosides do not penetrate well into most cells, the CNS, or the eye. Except for streptomycin, there is negligible binding of aminoglycosides to plasma albumin. The apparent volume of distribution of these drugs is 25% of lean body weight and approximates the volume of extracellular fluid. The aminoglycosides distribute poorly into adipose tissue, which must be considered when using weight-based dosing regimens in obese patients.

Concentrations of aminoglycosides in secretions and tissues are low (Panidis et al., 2005). High concentrations are found only in the renal cortex and the endolymph and perilymph of the inner ear; the high concentration in these sites likely contributes to the nephrotoxicity and ototoxicity caused by these drugs. As a result of active hepatic secretion, concentrations in bile approach 30% of those found in plasma, but this represents a very minor excretory route for the aminoglycosides. Inflammation increases the penetration of aminoglycosides into peritoneal and pericardial cavities. Concentrations of aminoglycosides achieved in CSF with parenteral administration usually are subtherapeutic (Kearney and Aweeka, 1999). Treatment of meningitis with intravenous administration is generally suboptimal. Intrathecal or intraventricular administration of aminoglycosides has been used to achieve therapeutic levels in the CNS but the availability of extended-spectrum cephalosporins has generally made this unnecessary.

Administration of aminoglycosides to women late in pregnancy may result in accumulation of drug in fetal plasma and amniotic fluid. Streptomycin and tobramycin can cause hearing loss in children born to women who receive the drug during pregnancy. Insufficient data are available regarding the other aminoglycosides; therefore, these agents should be used with caution during pregnancy and only for strong clinical indications in the absence of suitable alternatives.

ADME

Absorption

The aminoglycosides are polar cations and therefore are poorly absorbed from the GI tract. Less than 1% of a dose is absorbed after either oral or rectal administration. Nonetheless, long-term oral or rectal administration of aminoglycosides may result in accumulation to toxic concentrations in patients with renal impairment. Absorption of gentamicin from the GI tract may be increased by GI disease (e.g., ulcers or inflammatory bowel disease). Instillation of these drugs into body cavities with serosal

The aminoglycosides undergo minimal metabolism and are excreted almost entirely by glomerular filtration, achieving urine concentrations of 50–200 µg/mL. The half-lives of the aminoglycosides in plasma are 2–3 h in patients with normal renal function. Because the elimination of aminoglycosides depends almost entirely on the kidney, a linear relationship exists between the concentration of creatinine in plasma and the $t_{1/2}$ of all aminoglycosides in patients with moderately compromised renal function. In anephric patients, the $t_{1/2}$ varies from 20 to 40 times that determined in normal individuals. *Because the incidence of nephrotoxicity and ototoxicity is likely related to the overall exposure to aminoglycosides, it is critical to reduce the maintenance dose and dosing interval of these drugs in patients with impaired renal function.*

Although excretion of aminoglycosides is similar in adults and children older than 6 months, half-lives of aminoglycosides may be prolonged significantly in the newborn: 8–11 h in the first week of life in newborns weighing less than 2 kg and about 5 h in those weighing more than 2 kg. Thus, it is critically important to monitor plasma concentrations of aminoglycosides during treatment of neonates. Aminoglycoside clearances are increased and half-lives are reduced in patients with cystic fibrosis (Mann et al., 1985). Larger doses of aminoglycosides may likewise be required in burn patients because of more rapid drug clearance, possibly because of drug loss through burn tissue. Aminoglycosides can be removed from the body by either hemodialysis or peritoneal dialysis.

Aminoglycosides can be inactivated by various penicillins in vitro and thus should not be admixed in solution (Blair et al., 1982). Some reports indicate that this inactivation may occur in vivo in patients with end-stage renal failure, making monitoring of aminoglycoside plasma concentrations even more necessary in such patients. Amikacin appears to be the aminoglycoside least affected by this interaction; penicillins with more nonrenal elimination (such as piperacillin) may be less prone to cause this interaction.

Dosing and Monitoring

High-dose, extended-interval administration of aminoglycosides is the preferred means of administering aminoglycosides for most indications and patient populations. Administering higher doses at extended intervals (i.e., once daily) is likely to be at least equally efficacious and potentially less toxic than administration of divided doses. This dosing strategy takes advantage of the concentration-dependent activity of aminoglycosides to achieve maximal initial bacterial killing, and because of the postantibiotic effect of aminoglycosides, good therapeutic response can be attained even when concentrations fall below inhibitory concentrations for a substantial fraction of the dosing interval. High-dose, extended-interval dosing schemes for aminoglycosides may also reduce the characteristic oto- and nephrotoxicity of these drugs. This diminished toxicity is probably due to a threshold effect from accumulation of drug in the inner ear or in the kidney. High-dose, extended-interval regimens, despite the higher peak concentration, provide a longer period when concentrations fall below the threshold for toxicity than does a multiple-dose regimen (compare the two dosage regimens shown in Figure 58–3).

Populations in which use of the high-dose/extended-interval dosing strategy is more controversial include pregnancy, neonates, and pediatrics and as combination therapy for endocarditis (Contopoulos-Ioannidis et al., 2004; Knoderer et al., 2003; Nestaas et al., 2005; Ward and Theiler, 2008). In these infections, multiple daily doses (with a lower total daily dose) may be preferred because data documenting equivalent safety and efficacy of extended-interval dosing are limited. Extended-interval dosing is also usually avoided in patients with significant renal dysfunction (i.e., creatinine clearance < 25 mL/min).

Concentrations of aminoglycosides achieved in plasma after a given dose vary widely amongst patients, and therapeutic drug monitoring is standard practice (Bartal et al., 2003). For twice- or thrice-daily dosing regimens, both peak and trough plasma concentrations are determined. The peak concentration documents that the dose produces therapeutic concentrations, while the trough concentration is used to avoid toxicity.

Figure 58–3 Comparison of single-dose and divided-dose regimens for gentamicin. In a hypothetical patient, a dose of gentamicin (5.1 mg/kg) is administered intravenously as a single bolus (red line) or in three portions, a third of the dose every 8 h (purple line), such that the total drug administered is the same in the two cases. The threshold for toxicity (green dashed line) is the plasma concentration of 2 µg/mL, the maximum recommended for prolonged exposure. The single-dose regimen produces a higher plasma concentration than the regimen given every 8 h; this higher peak provides efficacy that otherwise might be compromised due to prolonged subthreshold concentrations later in the dosing interval or that is provided by the lower peak levels achieved with the regimen every 8 h. The once-daily regimen also provides a 13-h period during which plasma concentrations are below the threshold for toxicity. The every-8-h regimen, by contrast, provides only three short (~1 h) periods in 24 h during which plasma concentrations are below the threshold for toxicity. The single high-dose, extended interval is generally preferred for aminoglycosides, with a few exceptions (during pregnancy, in neonates, etc.), as noted in the text.

Steady-state trough concentrations should be less than 1–2 µg/mL for gentamicin, netilmicin, and tobramycin and less than 10 µg/mL for amikacin and streptomycin. Peak level goals vary by indication and infection severity, but range from 4 to 8 µg/mL with gentamicin, netilmicin, and tobramycin and 20–35 µg/mL for amikacin. Monitoring of aminoglycoside plasma concentrations also is important when using an extended-interval dosing regimen. For routine monitoring of extended-interval dosing, a single random concentration obtained 6 to 14 h after the start of the infusion can be obtained and plotted against a standard nomogram to determine if dosage adjustment is required (Barclay et al., 1999). However, the most accurate method for monitoring plasma levels for dose adjustment is to measure the concentration in two plasma samples drawn several hours apart (e.g., at 2 and 12 h after a dose). The clearance then can be calculated and the dose adjusted to achieve the desired target range.

Therapeutic Uses of Aminoglycosides

Gentamicin, tobramycin, amikacin, and netilmicin can be used interchangeably for the treatment of most of the infections mentioned in this section. For most indications, gentamicin is preferred because of long experience with its use and its lower cost. Many different types of infections can be treated successfully with these aminoglycosides; however, owing to their toxicities, prolonged use should be restricted to the therapy of life-threatening infections and those for which a less-toxic agent is contraindicated or less effective.

Aminoglycosides frequently are used in combination with a cell wall-active agent (β -lactam or glycopeptide) for the therapy of serious proven or suspected bacterial infections. The three rationales for this approach are

- to expand the empiric spectrum of activity of the antimicrobial regimen
- to provide synergistic bacterial killing
- to prevent the emergence of resistance to the individual agents

Combination therapy is used in infections such as healthcare-associated pneumonia or sepsis, where multidrug-resistant gram-negative organisms such as *P. aeruginosa*, *Enterobacter*, *Klebsiella*, and *Serratia* may be causative and the consequences of failing to provide initially active therapy are dire. The use of aminoglycosides to achieve synergistic bacterial killing and improve clinical response is most well established for the treatment of endocarditis due to gram-positive organisms, most importantly *Enterococcus* (Le and Bayer, 2003). Clinical data do not support the use of combination therapy for synergistic killing of gram-negative organisms, with the possible exceptions of serious *P. aeruginosa* infections. Aminoglycosides (primarily streptomycin and amikacin) are occasionally used in multidrug regimens for treatment of mycobacterial infections, in part because of the need to suppress the emergence of resistant subpopulations during therapy; data do not strongly support this practice for other bacteria (Bliziotis et al., 2005).

Urinary Tract Infections

Although the spectrum of activity and concentration in the urinary tract of aminoglycosides make them well-suited for treatment of urinary tract infections, less-toxic alternatives are preferred for uncomplicated infections. However, as strains of *E. coli* have acquired resistance to β -lactams, trimethoprim-sulfamethoxazole, and fluoroquinolones, use of aminoglycosides for urinary tract infections may increase. A single intramuscular dose of gentamicin (5 mg/kg) has been effective in uncomplicated infections of the lower urinary tract. A 10- to 14-day course of gentamicin or tobramycin is an alternative for treatment of pyelonephritis if other agents cannot be used.

Pneumonia

The organisms that cause community-acquired pneumonia are susceptible to broad-spectrum β -lactam antibiotics, macrolides, or a fluoroquinolone, and usually it is not necessary to add an aminoglycoside. Aminoglycosides are ineffective for the treatment of pneumonia due to anaerobes or *Streptococcus pneumoniae*, which are common causes of community-acquired pneumonia. In hospital-acquired pneumonia where aerobic multidrug-resistant gram-negative bacilli are frequently causative pathogens, an aminoglycoside in combination with a β -lactam antibiotic is recommended as standard empiric therapy to increase the likelihood that at least one agent is active against the infecting pathogen (American Thoracic Society, 2005). Once it is established that the β -lactam is active against the causative agent, there is generally no benefit from continuing the aminoglycoside.

Meningitis

Availability of third-generation cephalosporins, especially cefotaxime and ceftriaxone, has reduced the need for treatment with aminoglycosides in most cases of meningitis, except for infections caused by gram-negative organisms resistant to β -lactam antibiotics (e.g., species of *Pseudomonas* and *Acinetobacter*). If an aminoglycoside is necessary, direct instillation into the CNS is more likely to achieve therapeutic levels than intravenous administration. In adults, this can be achieved with 5 mg of a preservative-free formulation of gentamicin (or equivalent dose of another aminoglycoside) administered intrathecally or intraventricularly once daily.

Peritonitis

Patients who develop peritonitis as a result of peritoneal dialysis may be treated with aminoglycoside diluted into the dialysis fluid to a concentration of 4–8 mg/L for gentamicin, netilmicin, or tobramycin or 6–12 mg/L for amikacin. Intravenous or intramuscular administration of drug is unnecessary because serum and peritoneal fluid will equilibrate rapidly.

Bacterial Endocarditis

“Synergistic” or low-dose gentamicin (3 mg/kg/d) in combination with a penicillin or vancomycin has been recommended in certain circumstances for treatment of bacterial endocarditis due to certain gram-positive organisms. Penicillin and gentamicin in combination are effective as a short-course (i.e., 2-week) regimen for uncomplicated native-valve streptococcal

endocarditis. For this indication, the administration of gentamicin may be given as a consolidated once-daily dose. In cases of enterococcal endocarditis, concomitant administration of penicillin (or ampicillin) and gentamicin (given as divided doses) for 4–6 weeks is recommended as standard therapy. However, safer alternatives such as ampicillin/ceftriaxone combinations or use of the aminoglycoside for only the first 2–3 weeks, are gaining favor to limit the risk of toxicity due to prolonged aminoglycoside administration (Olaison and Schädewitz, 2002). A 2-week regimen of gentamicin in combination with nafcillin is effective for the treatment of selected cases of staphylococcal tricuspid native-valve endocarditis. For patients with native mitral or aortic valve staphylococcal endocarditis, the risks of aminoglycoside administration likely outweigh the benefits (Cosgrove et al., 2009).

Sepsis

Inclusion of an aminoglycoside in an empirical regimen is commonly recommended for the febrile patient with neutropenia and for sepsis when *P. aeruginosa* is a potential pathogen. However, studies using potent broad-spectrum β -lactams (e.g., carbapenems and antipseudomonal cephalosporins) have demonstrated no benefit from adding an aminoglycoside to the regimen unless there is concern that an infection may be caused by a multiple-drug-resistant organism (Paul et al., 2003). Thus, local susceptibility patterns should be considered when weighing the risks and benefits of adjunctive aminoglycoside administration for empiric therapy in patients with sepsis.

Tularemia

Streptomycin (or gentamicin) is the drug of choice for the treatment of tularemia. Most cases respond to the administration of 1–2 g (15–25 mg/kg) streptomycin per day (in divided doses) for 10–14 days.

Plague

A 10-day treatment course of streptomycin or gentamicin is recommended for severe forms of plague (Boulanger et al., 2004).

Mycobacterial Infections

Streptomycin is a second-line agent for the treatment of active tuberculosis, and streptomycin always should be used in combination with at least one or two other drugs to which the causative strain is susceptible. Amikacin is another alternative agent for infections due to drug-resistant *Mycobacterium tuberculosis* or to other nontuberculous mycobacteria (e.g., *M. avium*, *M. abscessus*, *M. chelonae*).

Cystic Fibrosis

Recurrent infections due to multidrug-resistant gram-negative bacilli, especially *Pseudomonas* species, are a hallmark of cystic fibrosis. Aminoglycosides are frequently used as therapy during acute exacerbations of cystic fibrosis, for which higher-than-standard doses (e.g., 10 mg/kg of tobramycin) are frequently employed due to the unusual pharmacokinetics observed in patients with cystic fibrosis. These agents may also be administered via inhalation between exacerbations to improve lung function and reduce exacerbation frequency.

Topical Applications

Aminoglycosides, especially neomycin and paromomycin, may be employed as topical agents in skin and mucous membrane infections. Oral administration of aminoglycosides may be employed as “bowel prep” prior to surgical procedures or as “selective digestive decontamination” to reduce the risk of ventilator-associated pneumonia.

Adverse Effects of Aminoglycosides

All aminoglycosides have the potential to produce reversible and irreversible vestibular, cochlear, and renal toxicity and neuromuscular blockade.

Vestibular and auditory dysfunction can follow the administration of any of the aminoglycosides (Guthrie, 2008). Aminoglycoside-induced ototoxicity may result in irreversible, bilateral, high-frequency hearing loss or vestibular hypofunction. Degeneration of hair cells and neurons in the cochlea correlates with the loss of hearing. Accumulation within the perilymph and endolymph occurs predominantly when aminoglycoside concentrations in plasma are high. Diffusion back into the bloodstream is slow; the half-lives of the aminoglycosides are five to six times longer in the otic fluids than in plasma. Drugs such as ethacrynic acid and furosemide potentiate the ototoxic effects of the aminoglycosides in animals, but data from humans implicating furosemide are less convincing (Smith and Lietman, 1983).

Streptomycin and gentamicin produce predominantly vestibular effects, whereas amikacin, kanamycin, and neomycin primarily affect auditory function; tobramycin affects both equally. The incidence of ototoxicity is difficult to determine. Audiometric data suggest that the incidence could be as high as 25% (Brummett and Morrison, 1990). The incidence of vestibular toxicity is particularly high in patients receiving streptomycin; nearly 20% of individuals who received 500 mg twice daily for 4 weeks for enterococcal endocarditis developed clinically detectable irreversible vestibular damage. Because the initial symptoms may be reversible, patients receiving high doses or prolonged courses of aminoglycosides should be monitored carefully for ototoxicity; however, deafness may occur several weeks after therapy is discontinued.

A high-pitched tinnitus often is the first symptom of cochlear toxicity. If the drug is not discontinued, auditory impairment may develop after a few days. The tinnitus may persist for several days to 2 weeks after therapy is stopped. Because perception of sound in the high-frequency range (outside the conversational range) is lost first, the affected individual is not always aware of the difficulty, and it will not be detected except by careful audiometric examination. If the hearing loss progresses, the lower sound ranges are affected.

Amongst patients experiencing vestibular toxicity, moderately intense headache lasting 1–2 days may precede the onset of labyrinthine dysfunction. This is followed immediately by an acute stage in which nausea, vomiting, and difficulty with equilibrium develop and persist for 1–2 weeks. Prominent symptoms include vertigo in the upright position, inability to perceive termination of movement (“mental past-pointing”), and difficulty in sitting or standing without visual cues. The acute stage ends suddenly and is followed by chronic labyrinthitis, in which the patient has difficulty when attempting to walk or make sudden movements; ataxia is the most prominent feature. The chronic phase persists for about 2 months. Recovery from this phase may require 12–18 months, and most patients have some permanent residual damage. Early discontinuation of the drug may permit recovery before irreversible damage of the hair cells.

Nephrotoxicity

Approximately 8%–26% of patients who receive an aminoglycoside for several days develop mild renal impairment that is almost always reversible. The toxicity results from accumulation and retention of aminoglycoside in the proximal tubular cells. The initial manifestation of damage at this site is excretion of enzymes of the renal tubular brush border followed by mild proteinuria and the appearance of hyaline and granular casts. The glomerular filtration rate is reduced after several additional days. The nonoliguric phase of renal insufficiency is thought to be due to the effects of aminoglycosides on the distal portion of the nephron with a reduced sensitivity of the collecting duct epithelium to vasopressin. Although severe acute tubular necrosis may occur rarely, the most common significant finding is a mild rise in plasma creatinine. The impairment in renal function is almost always reversible because the proximal tubular cells have the capacity to regenerate (Lietman and Smith, 1983). Toxicity correlates with the total amount of drug administered and with longer courses of therapy (de Jager and van Altena, 2002). High-dose, extended-interval dosing approaches lead to less nephrotoxicity at the same level of total drug exposure (as measured by the area under the curve)

than divided-dose approaches (see Figure 58–3). Neomycin, which concentrates to the greatest degree, is highly nephrotoxic in human beings and should not be administered systemically. Streptomycin does not concentrate in the renal cortex and is the least nephrotoxic. Drugs such as amphotericin B, vancomycin, angiotensin-converting enzyme inhibitors, cisplatin, and cyclosporine may potentiate aminoglycoside-induced nephrotoxicity (Wood et al., 1986).

Neuromuscular Blockade

Acute neuromuscular blockade and apnea have been attributed to the aminoglycosides; patients with myasthenia gravis are particularly susceptible. The order of decreasing potency for blockade is neomycin, kanamycin, amikacin, gentamicin, and tobramycin. In humans, neuromuscular blockade generally has occurred after intrapleural or intraperitoneal instillation of large doses of an aminoglycoside; however, the reaction can follow intravenous, intramuscular, and even oral administration of these agents. Most episodes have occurred in association with anesthesia or the administration of other neuromuscular blocking agents. Neuromuscular blockade may be reversed by intravenous administration of a Ca^{2+} salt.

Aminoglycosides may inhibit presynaptic release of acetylcholine while also reducing postsynaptic sensitivity to the transmitter, but Ca^{2+} can overcome this effect, and the intravenous administration of a calcium salt is the preferred treatment of this toxicity (Sarkar et al., 1992). Inhibitors of acetylcholinesterase (e.g., edrophonium and neostigmine) also have been used with varying degrees of success.

Other Adverse Effects

In general, the aminoglycosides have little allergenic potential. Rare hypersensitivity reactions—including skin rashes, eosinophilia, fever, blood dyscrasias, angioedema, exfoliative dermatitis, stomatitis, and anaphylactic shock—have been reported as cross-hypersensitivity amongst drugs in this class. Aminoglycosides appear to be less commonly associated with superinfection due to *Clostridium difficile* than other classes of antibacterials.

Pharmacological Properties of Individual Aminoglycosides

Gentamicin

Gentamicin is an important agent for the treatment of many serious gram-negative bacillary infections. It is the aminoglycoside of first choice because of its lower cost and reliable activity against all but the most resistant gram-negative aerobes. Gentamicin preparations are available for parenteral, ophthalmic, and topical administration. The typical recommended intramuscular or intravenous dose of gentamicin sulfate when used for the treatment of known or suspected gram-negative organisms as a single agent or in combination therapy for adults with normal renal function is 5–7 mg/kg daily given over 30–60 min. For patients with renal dysfunction, the interval may be extended. For patients who are not candidates for extended-interval dosing, a loading dose of 2 mg/kg and then 3–5 mg/kg per day, given as divided doses every 8–12 h, are recommended. Dosages at the upper end of this range may be required to achieve therapeutic levels for trauma or burn patients, those with septic shock, patients with cystic fibrosis, and others in whom drug clearance is more rapid or volume of distribution is larger than normal.

Several dosage schedules have been suggested for newborns and infants: 3 mg/kg once daily for preterm newborns less than 35 weeks of gestation; 4 mg/kg once daily for newborns more than 35 weeks of gestation; 5 mg/kg daily in two divided doses for neonates with severe infections; and 2–2.5 mg/kg every 8 h for children up to 2 years of age. Peak plasma concentrations range from 4 to 10 mg/mL (dosing: 1.7 mg/kg every 8 h) and 16–24 mg/mL (extended-interval dosing: 5 mg/kg once daily).

It should be emphasized that the recommended doses of gentamicin do not always yield desired concentrations. Periodic determinations of

the plasma concentration of aminoglycosides are recommended strongly. Gentamicin is absorbed slowly when it is applied topically in an ointment and somewhat more rapidly when it is applied as a cream. When the antibiotic is applied to large areas of denuded body surface, as may be the case in burn patients, plasma concentrations can reach 4 µg/mL, and 2%–5% of the drug may appear in the urine.

Tobramycin

The antimicrobial activity, pharmacokinetic properties, and toxicity profile of tobramycin are similar to those of gentamicin. Tobramycin may be given intramuscularly, intravenously, or by inhalation. Tobramycin also is available in ophthalmic ointments and solutions. The superior activity of tobramycin against *P. aeruginosa* makes it the preferred aminoglycoside for treatment of serious infections known or suspected to be caused by this organism, typically in combination with an antipseudomonal β-lactam antibiotic. In contrast to gentamicin, tobramycin shows poor activity in combination with penicillin against many strains of enterococci. Most strains of *E. faecium* are highly resistant. Tobramycin is ineffective against mycobacteria. Dosages and serum concentrations are identical to those for gentamicin.

Amikacin

The spectrum of antimicrobial activity of amikacin is the broadest of the group. Because of its resistance to many of the aminoglycoside-inactivating enzymes, amikacin has a special role for the initial treatment of serious nosocomial gram-negative bacillary infections in hospitals where resistance to gentamicin and tobramycin has become a significant problem. Amikacin is active against most strains of *Serratia*, *Proteus*, and *P. aeruginosa* as well as most strains of *Klebsiella*, *Enterobacter*, and *E. coli* that are resistant to gentamicin and tobramycin. Most resistance to amikacin is found amongst strains of *Acinetobacter*, *Providencia*, and *Flavobacterium* and strains of *Pseudomonas* other than *P. aeruginosa*; these all are unusual pathogens. Amikacin is less active than gentamicin against enterococci and should not be used for this organism. Amikacin is not active against the majority of gram-positive anaerobic bacteria. It is active against *M. tuberculosis*, including streptomycin-resistant strains and atypical mycobacteria.

The recommended dose of amikacin is 15 mg/kg/d as a single daily dose or divided into two or three equal portions, which must be reduced for patients with renal failure. The drug is absorbed rapidly after intramuscular injection, and peak concentrations in plasma approximate 20 µg/mL after injection of 7.5 mg/kg. The concentration 12 h after a 7.5-mg/kg dose is 5–10 µg/mL. A 15-mg/kg once-daily dose produces peak concentrations of 50–60 µg/mL and a trough of less than 1 µg/mL. For treatment of mycobacterial infections, thrice-weekly dosing schedules are used, with doses up to 25 mg/kg (Peloquin et al., 2004). As with the other aminoglycosides, amikacin causes ototoxicity, hearing loss, and nephrotoxicity.

Netilmicin

Netilmicin (not marketed in the U.S.) is similar to gentamicin and tobramycin in its pharmacokinetic properties and dosage (Panwalker et al., 1978). Its antibacterial activity is broad against aerobic gram-negative bacilli. Like amikacin, it is not metabolized by most of the aminoglycoside-inactivating enzymes; thus, it may be active against certain bacteria that are resistant to gentamicin (with the exception of resistant enterococci). Netilmicin is useful for the treatment of serious infections owing to susceptible Enterobacteriaceae and other aerobic gram-negative bacilli. The recommended dose of netilmicin for complicated urinary tract infections in adults is 1.5–2 mg/kg every 12 h. For other serious systemic infections, a total daily dose of 4–7 mg/kg is administered as a single dose or two to three divided doses. Children should receive 3–7 mg/kg/d in two to three divided doses; neonates receive 3.5–5 mg/kg/d as a single daily dose. The $t_{1/2}$ for elimination is usually 2–2.5 h in adults and increases with renal insufficiency. Netilmicin may produce ototoxicity and nephrotoxicity.

Streptomycin

Streptomycin is used for the treatment of certain unusual infections, generally in combination with other antimicrobial agents. It generally is less active than other members of the class against aerobic gram-negative rods. The combination of penicillin G (bacteriostatic against enterococci) and streptomycin is effective as bactericidal therapy for enterococcal endocarditis, although gentamicin is generally preferred for its lesser toxicity. Streptomycin should be used instead of gentamicin when the strain is resistant to the latter and has demonstrable susceptibility to streptomycin, which may occur because the enzymes that inactivate these two aminoglycosides are different.

Streptomycin may be administered by deep intramuscular injection or intravenously. Intramuscular injection may be painful, with a hot tender mass developing at the site of injection. The dose range of streptomycin for most indications is 15–25 mg/kg daily or in divided doses twice daily. During initial therapy for tuberculosis, it is frequently administered as a 1000-mg single daily dose, resulting in peak serum concentrations of about 50–60 and 15–30 µg/mL, and trough concentrations of less than 1 and 5–10 µg/mL, respectively. The dosing frequency may be reduced to two or three times a week after the initial phase of tuberculosis treatment.

Streptomycin has been replaced by gentamicin for most indications because the toxicity of gentamicin is primarily renal and reversible, whereas that of streptomycin is vestibular and irreversible. The administration of streptomycin may produce dysfunction of the optic nerve, including scotomas, presenting as enlargement of the blind spot. Amongst the less-common toxic reactions to streptomycin is peripheral neuritis.

Neomycin

Neomycin is a broad-spectrum antibiotic. Susceptible microorganisms usually are inhibited by concentrations of 10 µg/mL or less. Gram-negative species that are highly sensitive are *E. coli*, *Enterobacter aerogenes*, *Klebsiella pneumoniae*, and *Proteus vulgaris*. Gram-positive microorganisms that are inhibited include *S. aureus* and *E. faecalis*. *Mycobacterium tuberculosis* also is sensitive to neomycin. Strains of *P. aeruginosa* are resistant to neomycin. Neomycin sulfate is available for topical and oral administration. Neomycin currently is available in many brands of creams, ointments, and other products alone and in combination with polymyxin, bacitracin, other antibiotics, and a variety of corticosteroids.

Neomycin is used widely for topical application in a variety of infections of the skin and mucous membranes. The oral administration of neomycin (usually in combination with erythromycin base) has been employed primarily for “preparation” of the bowel for surgery. Orally administered neomycin is poorly absorbed from the GI tract—about 97% of an oral dose of neomycin is not absorbed and is eliminated unchanged in the feces. The portion that is absorbed is excreted by the kidney; a total daily intake of 10 g for 3 days yields a blood concentration below that associated with systemic toxicity if renal function is normal. Neomycin and polymyxin B have been used for irrigation of the bladder to prevent bacteriuria and bacteremia associated with indwelling catheters. For this purpose, 1 mL of a preparation containing 40 mg neomycin and 200,000 units polymyxin B per milliliter is diluted in 1 L of 0.9% sodium chloride solution and is used for continuous irrigation of the urinary bladder through appropriate catheter systems. The bladder is irrigated at the rate of 1 L every 24 h.

Hypersensitivity reactions, primarily skin rashes, occur in 6%–8% of patients when neomycin is applied topically. The most important toxic effects of neomycin are ototoxicity and nephrotoxicity; as a consequence, the drug is no longer available for parenteral administration. Neuromuscular blockade with respiratory paralysis also has occurred after irrigation of wounds or serosal cavities. Individuals treated with 4–6 g/d of the drug by mouth sometimes develop a sprue-like syndrome with diarrhea, steatorrhea, and azotorrhea. Overgrowth of yeasts in the intestine also may occur.

Paromomycin (also known as aminosidine) is an aminoglycoside that is structurally related to neomycin. It has antibacterial activity similar to other aminoglycosides but has particularly notable antiparasitic activity. Parasites that are usually susceptible to paromomycin include *Leishmania* spp., *Entamoeba histolytica*, *Giardia lamblia*, and *Cryptosporidium parvum*. Internationally, the parenteral form is used as a treatment of infections due to *Leishmania* spp. (visceral leishmaniasis), although this formulation is not available in the U.S. (Sundar et al., 2007). Like other aminoglycosides, it has poor systemic absorption when administered orally; this characteristic is exploited to achieve high luminal concentrations in the treatment of intestinal parasitic diseases. It is available as oral capsules and indicated for treatment of intestinal amebiasis at a dose of 25–35 mg/kg/d in three divided doses. It is also used for treatment

of intestinal cryptosporidiosis and giardiasis, which can be particularly challenging to treat in immunocompromised patients. Orally administered paromomycin is associated with dose-related gastrointestinal toxicity, including nausea, abdominal pain, and diarrhea. A topical formulation is also used internationally for treatment of cutaneous leishmaniasis (Ben Salah et al., 2013).

Kanamycin

Kanamycin is amongst the most toxic aminoglycosides, and there are few indications for its use. Its primary remaining indication is for treatment of extensively drug-resistant tuberculosis; even in this condition, less-toxic alternatives are generally preferred.

Chapter 59

Protein Synthesis Inhibitors and Miscellaneous Antibacterial Agents

Conan MacDougall

PROTEIN SYNTHESIS INHIBITORS THAT TARGET THE RIBOSOME

- Tetracyclines and Glycylcyclines
- Chloramphenicol
- Macrolides and Ketolides
- Lincosamides
- Streptogramins
- Oxazolidinones

AGENTS ACTING ON THE BACTERIAL CELL WALL

- Polymyxins
- Glycopeptides
- Lipopeptides

MISCELLANEOUS AGENTS

- Metronidazole
- Bacitracin
- Mupirocin

The agents discussed in this chapter are grouped by their antibacterial mechanism as

1. *bacteriostatic protein synthesis inhibitors that target the ribosome*, such as tetracyclines, macrolides, lincosamides, streptogramins (quinupristin/dalfopristin), and oxazolidinones (e.g., linezolid);
2. *bactericidal agents acting on the cell wall or cell membrane*, such as polymyxins, glycopeptides (e.g., vancomycin), and lipopeptides (daptomycin); and
3. *miscellaneous agents* acting by diverse mechanisms, such as metronidazole, bacitracin, and mupirocin.

Protein Synthesis Inhibitors That Target the Ribosome

Tetracyclines and Glycylcyclines

The tetracyclines are a series of derivatives of a basic four-ring structure shown next for doxycycline. *Demeclocycline*, *tetracycline*, *minocycline*, and *doxycycline* are available in the U.S. for systemic use. Glycylcyclines are tetracycline congeners with substituents that confer broad-spectrum activity and activity against tetracycline-resistant bacteria; the currently available glycylcycline is *tigecycline*.

Mechanism of Action

Tetracyclines and glycylcyclines inhibit bacterial protein synthesis by binding to the 30S bacterial ribosome and preventing access of aminoacyl tRNA to the acceptor (A) site on the mRNA-ribosome complex (Figure 59–1). These drugs enter gram-negative bacteria by passive diffusion through channels formed by porins in the outer cell membrane and by active transport that pumps tetracyclines across the cytoplasmic membrane.

Antimicrobial Activity

Tetracyclines are bacteriostatic antibiotics with activity against a wide range of bacteria. Tetracyclines intrinsically are more active against gram-positive than gram-negative microorganisms. Recent data from the

U.S. on the activity of tetracycline and other agents are displayed in Table 59–1. Activity against *Streptococcus pyogenes* and penicillin-susceptible *Streptococcus pneumoniae* is good, but resistance is common in group B streptococci and penicillin-resistant *S. pneumoniae*. Excellent activity is maintained against both MSSA and MRSA. Activity against enterococci is limited. Doxycycline and minocycline can be active against some tetracycline-resistant isolates. *Bacillus anthracis* and *Listeria monocytogenes* are susceptible.

Activity of tetracyclines against *Haemophilus influenzae* has been largely retained since their introduction, but many Enterobacteriaceae have acquired resistance. Although all strains of *Pseudomonas aeruginosa* are resistant, 90% of strains of *Burkholderia pseudomallei* (the cause of melioidosis) are sensitive. Most strains of *Brucella* also are susceptible. Tetracyclines remain useful for infections caused by *Haemophilus ducreyi* (chancroid), *Vibrio cholerae*, and *Vibrio vulnificus* and inhibit the growth of *Campylobacter jejuni*, *Helicobacter pylori*, *Yersinia pestis*, *Yersinia enterocolitica*, *Francisella tularensis*, and *Pasteurella multocida*. Tetracyclines are alternative agents for treatment of actinomycosis.

Tetracyclines are effective against some microorganisms that are resistant to cell-wall-active antimicrobial agents, such as *Rickettsia*, *Coxiella burnetii*, *Mycoplasma pneumoniae*, *Chlamydia* spp., *Legionella* spp., *Ureaplasma*, some atypical mycobacteria, and *Plasmodium* spp. The tetracyclines are active against many spirochetes, including *Borrelia recurrentis*, *Borrelia burgdorferi* (Lyme disease), *Treponema pallidum* (syphilis), and *Treponema pertenue*.

Glycylcyclines (only tigecycline is currently available) are generally active against organisms that are susceptible to tetracyclines as well as those with acquired resistance to tetracyclines (Gales et al., 2008). In particular, tigecycline displays much greater activity against enterococci, Enterobacteriaceae, *Acinetobacter*, and *Bacteroides fragilis*. In surveillance studies, greater than 95% of isolates of these organisms tested susceptible to tigecycline. However, tigecycline still lacks activity against *Pseudomonas*, *Proteus*, and *Providencia* spp. There are a few exceptions where other tetracyclines may be more active than tigecycline against certain organisms, such as *Stenotrophomonas* and *Ureaplasma*.

Resistance to Tetracyclines and Glycylcyclines

Resistance is primarily plasmid mediated and often inducible. The three primary resistance mechanisms are as follows:

- Decreased accumulation of tetracycline as a result of either decreased antibiotic influx or acquisition of an energy-dependent efflux pathway
- Production of a ribosomal protection protein that displaces tetracycline from its target
- Enzymatic inactivation of tetracyclines

Abbreviations

ADME: absorption, distribution, metabolism, excretion
AUC: area under the curve
CMS: colistin methanesulfonate
CNS: central nervous system
CYP: cytochrome P450
FDA: Food and Drug Administration
HIV: human immunodeficiency virus
IV: intravenous
MAI: *Mycobacterium avium-intracellulare*
MAO: monoamine oxidase
MIC: minimum inhibitory concentration
MRSA: methicillin-resistant *Staphylococcus aureus*
MSSA: methicillin-sensitive *Staphylococcus aureus*
PCN-R: penicillin-resistant
PCN-S: penicillin-susceptible
PO: by mouth
SSRI: selective serotonin reuptake inhibitor
USP: U.S. Pharmacopeia

Figure 59–1 Inhibition of bacterial protein synthesis by tetracyclines. mRNA attaches to the 30S subunit of bacterial ribosomal RNA. The P (peptidyl) site of the 50S ribosomal RNA subunit contains the nascent polypeptide chain; normally, the aminoacyl tRNA charged with the next amino acid (aa) to be added moves into the A (acceptor) site, with complementary base pairing between the anticodon sequence of tRNA and the codon sequence of mRNA. Tetracyclines bind to the 30S subunit, block tRNA binding to the A site, and thereby inhibit protein synthesis.

Cross-resistance, or lack thereof, among tetracyclines depends on which mechanism is operative. Tetracycline resistance due to a ribosomal protection mechanism (*tetM*) produces cross-resistance to doxycycline and minocycline because the target site protected is the same for all tetracyclines. The glycyamido moiety characteristic of tigecycline reduces its affinity for most efflux pumps, restoring activity against many organisms displaying tetracycline resistance due to this mechanism. Binding of glycylcyclines to ribosomes is also enhanced, improving activity against organisms that harbor ribosomal protection proteins that confer resistance to other tetracyclines.

ADME

Oral absorption of most tetracyclines is incomplete. The percentage of unabsorbed drug rises as the dose increases. Tigecycline is available only for parenteral administration. Concurrent ingestion of divalent and trivalent cations (e.g., Ca^{2+} , Mg^{2+} , Al^{3+} , $\text{Fe}^{2+/3+}$, and Zn^{2+}) impairs absorption. Thus, dairy products, antacids, aluminum hydroxide gels; calcium, magnesium, and iron or zinc salts; bismuth subsalicylate and dietary iron and zinc supplements can interfere with absorption of tetracyclines. After a single oral dose, the peak plasma concentration is attained in 2–4 h. These drugs have half-lives in the range of 6–12 h and frequently

TABLE 59–1 ■ ANTIMICROBIAL SUSCEPTIBILITY AND TYPICAL MINIMAL CONCENTRATIONS THAT WILL INHIBIT 90% (MIC_{90}) OF CLINICAL ISOLATES FOR KEY GRAM-POSITIVE PATHOGENS

Entries are percentage of isolates inhibited at established or proposed susceptibility breakpoints. In parentheses are drug concentrations (in $\mu\text{g/mL}$) required to inhibit growth of 90% of isolates of that organism.

NA, not applicable; NR, not reported.

Data from Gales AC, et al. *Diagn Microbiol Infect Dis*, 2008, 60:421–427; Critchley IA, et al. *Antimicrob Agents Chemother*, 2003, 47:1689–1693; Jones RN, et al. *Diagn Microbiol Infect Dis*, 2013, 75:304–307; Mendes RE, et al. *Clin Infect Dis*, 2012, 54(S3):S203–S213; Mendes RE, et al. *Antimicrob Agents Chemother*, 2015, 59:702–706.

are administered two to four times daily. Demeclocycline also is incompletely absorbed but can be administered less frequently because its $t_{1/2}$ of 16 h provides effective plasma concentrations for 24–48 h. Oral doses of doxycycline and minocycline are well absorbed (90%–100%) and have half-lives of 16–18 h; they can be administered at lower doses than tetracycline or demeclocycline. Plasma concentrations are equivalent whether doxycycline is given orally or parenterally. Food, including dairy products, does not interfere with absorption of doxycycline and minocycline.

Tetracyclines distribute widely throughout the body, including urine and prostate. They accumulate in reticuloendothelial cells of the liver, spleen, and bone marrow and in bone, dentine, and enamel of unerupted teeth. Tigecycline distributes rapidly and extensively into tissues, with an estimated apparent volume of 7–10 L/kg. Inflammation of the meninges is not required for the passage of tetracyclines into the CSF. Tetracyclines cross the placenta and enter the fetal circulation and amniotic fluid. Relatively high concentrations are found in breast milk.

Except for doxycycline, most tetracyclines are eliminated primarily by the kidney, although they also are concentrated in the liver, excreted in bile, and partially reabsorbed via enterohepatic recirculation. Comparable amounts of tetracycline (i.e., 20%–60%) are excreted in the urine within 24 h following oral or intravenous administration. Doxycycline is largely excreted unchanged in both the bile and urine, tigecycline is mostly excreted unchanged along with a small amount of glucuronidated metabolites, and minocycline is extensively metabolized by the liver before excretion. Hence, no dose adjustment is needed in patients with renal dysfunction. Specific dosage adjustment recommendations in hepatic disease are available only for tigecycline.

Therapeutic Uses and Dosage

The tetracyclines remain useful as first-line therapy for infections caused by rickettsiae, mycoplasmas, and chlamydiae. Doxycycline, the most important member of the tetracyclines, is a drug of choice for many sexually transmitted diseases, rickettsial infections, plague, brucellosis, tularemia, and spirochetal infections and is also used for treatment of respiratory tract infections and for skin and soft-tissue infections caused by community strains of MRSA, for which minocycline also is effective. The glycylicyclines have restored much of the antibacterial activity lost to the tetracyclines due to resistance and can be used for a number of infections due to gram-positive and gram-negative organisms (De Rosa et al., 2015). However, a pooled analysis of tigecycline clinical trials found a small but statistically significant increased risk of death with tigecycline versus comparators (Food and Drug Administration, 2016). Thus, tigecycline should generally be reserved for situations in which alternative treatment is not appropriate.

The oral dose of tetracycline ranges from 1 to 2 g/d in adults. Children more than 8 years of age should receive 25–50 mg/kg daily in four divided doses (not to exceed 2 g/d). The typical oral or intravenous dose of doxycycline for adults is 100 mg every 12 or 24 h; for children more than 8 years of age, the dose is 4.4 mg/kg/d in two divided doses the first day, then 2.2 mg/kg given once or twice daily. The typical dose of minocycline for adults is 200 mg orally or intravenously initially, followed by 100 mg every 12 h; for children, it is 4 mg/kg initially followed by 2 mg/kg every 12 h. Different dosing recommendations exist for certain diseases (i.e., syphilis); the reader is advised to consult the most current guidelines. Tigecycline is administered intravenously to adults as a 100-mg loading dose, followed by 50 mg every 12 h. For patients with severe hepatic impairment, the loading dose should be followed by a reduced maintenance dose of 25 mg every 12 h. Dosage data are not available for tigecycline in pediatrics.

Respiratory Tract Infections. Doxycycline has good activity against *Streptococcus pneumoniae* and *H. influenzae* and excellent activity against atypical pathogens such as *Mycoplasma* and *Chlamydophila pneumoniae*. Tigecycline is effective for use as a single agent for adults hospitalized with community-acquired bacterial pneumonia.

Skin and Soft-Tissue Infections. Tigecycline is approved for the treatment of complicated skin and soft-tissue infections. Doxycycline and minocycline have good activity against staphylococci and may be useful

in treatment of cutaneous MRSA infections. Low doses of tetracycline have been used to treat acne (25 mg orally twice a day).

Intra-abdominal Infections. Resistance among Enterobacteriaceae and gram-negative anaerobes limits the utility of the tetracyclines for intra-abdominal infections. However, tigecycline possesses excellent activity against these pathogens as well as *Enterococcus*.

Sexually Transmitted Diseases. Doxycycline no longer is recommended for gonococcal infections because of the spread of resistance (Centers for Disease Control and Prevention, 2015). A 7-day treatment course of doxycycline is as effective as, but less convenient than, single-dose azithromycin in the treatment of uncomplicated genital infections due to *Chlamydia trachomatis*. *Chlamydia trachomatis* is often a coexistent pathogen in acute pelvic inflammatory disease, and doxycycline is a component of combination therapy regimens for this condition. Acute epididymitis is caused by infection with *C. trachomatis* or *Neisseria gonorrhoeae* in men less than 35 years of age. Effective regimens include a single injection of ceftriaxone (250 mg) plus doxycycline for 10 days. Sexual partners also should be treated. Doxycycline for 21 days is first-line therapy for treatment of lymphogranuloma venereum. Nonpregnant penicillin-allergic patients who have primary, secondary, or latent syphilis can be treated with a tetracycline regimen, such as doxycycline for 2 weeks. Tetracyclines should not be used for treatment of neurosyphilis.

Rickettsial Infections. Tetracyclines are lifesaving in rickettsial infections, including Rocky Mountain spotted fever, recrudescent epidemic typhus (Brill disease), murine typhus, scrub typhus, rickettsialpox, and Q fever. Clinical improvement often is evident within 24 h after initiation of therapy. Doxycycline is the drug of choice for treatment of Rocky Mountain spotted fever in adults and in children, including those less than 9 years of age, in whom the risk of staining of permanent teeth is outweighed by the seriousness of this potentially fatal infection (Masters et al., 2003).

Anthrax. Doxycycline is indicated for prevention or treatment of anthrax. It should be used in combination with another agent when treating inhalational or GI infection. The recommended duration of therapy is 60 days for bioterrorism exposures.

Local Application. Except for local use in the eye, topical use of the tetracyclines is not recommended, although they are FDA-approved as over-the-counter topical first-aid antibiotics. Sustained-release preparations of minocycline and doxycycline for subgingival administration are used in dentistry.

Other Infections. Tetracyclines in combination with rifampin or streptomycin are effective for acute and chronic infections caused by *Brucella melitensis*, *Brucella suis*, and *Brucella abortus*. Although streptomycin is preferable, tetracyclines also are effective in tularemia. Actinomycosis, although most responsive to penicillin G, may be successfully treated with a tetracycline. Minocycline is an alternative for the treatment of nocardiosis, but a sulfonamide should be used concurrently. Yaws and relapsing fever respond favorably to the tetracyclines. Tetracyclines are useful in the acute treatment and for prophylaxis of leptospirosis (*Leptospira* spp.). *Borrelia* spp., including *B. recurrentis* (relapsing fever) and *B. burgdorferi* (Lyme disease), respond to tetracyclines. The tetracyclines have been used to treat susceptible atypical mycobacterial pathogens, including *Mycobacterium marinum*. Tetracyclines in combination with bismuth and metronidazole can be used for *H. pylori* infections (Peterson et al., 2000).

Adverse Effects

Gastrointestinal. All tetracyclines can produce GI irritation, most commonly after oral administration. Epigastric burning and distress, abdominal discomfort, nausea, vomiting, and diarrhea may occur. Tolerability can be improved by administering these drugs with food, but tetracyclines should not be taken with dairy products or antacids. Tetracyclines have been associated with esophagitis and esophageal ulcers; patients should take oral formulations with a full glass of water while standing. Tigecycline administered intravenously has also been associated with nausea and vomiting.

Many of the tetracyclines are incompletely absorbed from the GI tract, and high concentrations in the bowel can markedly alter enteric flora. Sensitive aerobic and anaerobic coliform microorganisms and gram-positive spore-forming bacteria are suppressed markedly during long-term tetracycline regimens. As the fecal coliform count declines, overgrowth of tetracycline-resistant microorganisms occurs, particularly of yeasts (*Candida* spp.), enterococci, *Proteus*, and *Pseudomonas*. Moniliasis, thrush, or *Candida*-associated esophagitis may arise during therapy with tetracyclines.

Photosensitivity. Demeclocycline, doxycycline, and other tetracyclines and, to a lesser extent, glycylicyclines may produce photosensitivity reactions in treated individuals exposed to sunlight. Onycholysis and pigmentation of the nails may develop with or without accompanying photosensitivity.

Hepatic Toxicity. Hepatic toxicity has developed in patients with renal failure receiving 2 g or more of tetracycline per day parenterally, but this effect also may occur when large quantities are administered orally. Pregnant women are particularly susceptible. Doxycycline is probably not associated with hepatotoxicity.

Renal Toxicity. Tetracyclines may aggravate azotemia in patients with renal disease because of the catabolic effects of the drugs. Doxycycline, minocycline, and tigecycline have fewer renal side effects than other tetracyclines. Nephrogenic diabetes insipidus has been observed in some patients receiving demeclocycline, and this phenomenon has been exploited for the treatment of the syndrome of inappropriate secretion of antidiuretic hormone (see Chapter 25). Fanconi syndrome (characterized by nausea, vomiting, polyuria, polydipsia, proteinuria, acidosis, glycosuria, and aminoaciduria) has been observed in patients ingesting outdated tetracycline, presumably due to toxic effects on the proximal renal tubules.

Effects on Teeth. Children treated with a tetracycline or glycylicycline may develop permanent brown discoloration of the teeth. The duration of therapy appears to be less important than the total quantity of antibiotic administered. The risk is highest when a tetracycline is given to infants before the first dentition but may develop if the drug is given between the ages of 2 months and 5 years when these teeth are being calcified. Treatment of pregnant patients with tetracyclines may produce discoloration of the teeth in their children.

Other Toxic and Irritative Effects. Tetracyclines are deposited in the skeleton during gestation and throughout childhood and may depress bone growth in premature infants. This is readily reversible if the period of exposure to the drug is short. Thrombophlebitis frequently follows intravenous administration. This irritative effect of tetracyclines has been used therapeutically in patients with malignant pleural effusions. Long-term tetracycline therapy may produce leukocytosis, atypical lymphocytes, toxic granulation of granulocytes, and thrombocytopenic purpura. Tetracyclines may cause increased intracranial pressure (pseudotumor cerebri) in young infants, even when given in the usual therapeutic doses. Patients receiving minocycline may experience vestibular toxicity, manifested by dizziness, ataxia, nausea, and vomiting. The symptoms occur soon after the initial dose and generally disappear within 24–48 h after drug cessation. Various skin reactions rarely may follow the use of any of the tetracyclines. Among the more severe allergic responses are angioedema and anaphylaxis; anaphylactoid reactions can occur even after oral use. Other hypersensitivity reactions are burning of the eyes, cheilosis, atrophic or hypertrophic glossitis, pruritus ani or vulvae, and vaginitis; these reactions can persist for weeks or months after cessation of tetracycline therapy. Cross-sensitization among the various tetracyclines is common.

Drug Interactions. As mentioned, oral coadministration of tetracyclines and divalent and trivalent cations can lead to chelation of the tetracycline, with resultant poor absorption. There is some evidence for drug interactions between doxycycline and hepatic enzyme-inducing agents such as phenytoin and rifampin, but not for minocycline or tigecycline.

Chloramphenicol

Chloramphenicol, an antibiotic produced by *Streptomyces venezuelae*, was introduced into clinical practice in 1948. Chloramphenicol can cause serious and fatal blood dyscrasias; consequently, the drug is now reserved for treatment of life-threatening infections (e.g., meningitis, rickettsial infections) in patients who cannot take safer alternatives because of resistance or allergies (Wareham et al., 2002).

Mechanism of Action

Chloramphenicol inhibits protein synthesis in bacteria and, to a lesser extent, in eukaryotic cells. The drug readily penetrates bacterial cells, probably by facilitated diffusion. Chloramphenicol acts primarily by binding reversibly to the 50S ribosomal subunit (near the binding site for the macrolide antibiotics and clindamycin). The drug prevents the binding of the amino acid-containing end of the aminoacyl tRNA to the acceptor site on the 50S ribosomal subunit. The interaction between peptidyltransferase and its amino acid substrate cannot occur, and peptide bond formation is inhibited (Figure 59–2).

Chloramphenicol also can inhibit mitochondrial protein synthesis in mammalian cells, perhaps because mitochondrial ribosomes resemble bacterial ribosomes (both are 70S); erythropoietic cells are particularly sensitive.

Antimicrobial Activity

Chloramphenicol possesses a broad spectrum of antimicrobial activity. Chloramphenicol is bacteriostatic against most species, although it may be bactericidal against *H. influenzae*, *Neisseria meningitidis*, and *S. pneumoniae*. Strains of *S. aureus* tend to be less susceptible, but some isolates of highly resistant MRSA have been susceptible. Chloramphenicol is active against enterococci, including multidrug-resistant *E. faecium*. Chloramphenicol is active against *Mycoplasma*, *Chlamydia*, and *Rickettsia*. Enterobacteriaceae are variably sensitive to chloramphenicol, but *P. aeruginosa* is resistant to even very high concentrations of chloramphenicol. Strains of *V. cholerae* have remained largely susceptible to chloramphenicol. Prevalent strains of *Shigella* and *Salmonella* are resistant to multiple drugs, including chloramphenicol.

Figure 59–2 Inhibition of bacterial protein synthesis by chloramphenicol. Chloramphenicol binds to the 50S ribosomal subunit at the peptidyltransferase site, inhibiting transpeptidation. Chloramphenicol binds near the site of action of clindamycin and the macrolide antibiotics. These agents interfere with the binding of chloramphenicol and thus may interfere with each other's actions if given concurrently. See Figure 59–1 for additional information.

Resistance to Chloramphenicol

Resistance to chloramphenicol usually is caused by a plasmid-encoded acetyltransferase that inactivates the drug. Resistance also can result from decreased permeability and from ribosomal mutation. Acetylated derivatives of chloramphenicol fail to bind to bacterial ribosomes.

ADME

Chloramphenicol has been available in oral, intravenous, and topical (e.g., ophthalmic) preparations. The oral formulation is no longer available in the U.S., although it can be found in other parts of the world. Chloramphenicol administered in oral capsule form is absorbed rapidly from the GI tract. For parenteral use, chloramphenicol succinate is a prodrug that is hydrolyzed by esterases to chloramphenicol *in vivo*. Chloramphenicol succinate is rapidly cleared from plasma by the kidneys; this may reduce overall bioavailability of the drug because as much as 30% of the dose may be excreted before hydrolysis. Poor renal function in the neonate and other states of renal insufficiency result in increased plasma concentrations of chloramphenicol succinate. Decreased esterase activity has been observed in the plasma of neonates and infants, prolonging time to peak concentrations of active chloramphenicol (up to 4 h) and extending the period over which renal clearance of chloramphenicol succinate can occur.

Chloramphenicol is widely distributed in body fluids and readily reaches therapeutic concentrations in CSF. Chloramphenicol is present in bile, milk, and placental fluid. Hepatic metabolism to the inactive glucuronide is the major route of elimination. This metabolite and chloramphenicol are excreted in the urine. Patients with impaired hepatic function have decreased metabolic clearance, and dosage should be adjusted. About 50% of chloramphenicol is bound to plasma proteins; such binding is reduced in cirrhotic patients and in neonates. Half-life is not altered significantly by renal insufficiency or hemodialysis, and dosage adjustment usually is not required. Variability in the metabolism and pharmacokinetics of chloramphenicol in neonates, infants, and children necessitates monitoring of drug concentrations in plasma.

Therapeutic Uses and Dosage

Therapy with chloramphenicol must be limited to infections for which the benefits of the drug outweigh the risks of the potential toxicities. When other antimicrobial drugs that are equally effective and less toxic are available, they should be used instead of chloramphenicol.

Typhoid Fever. Third-generation cephalosporins and quinolones are drugs of choice for the treatment of typhoid fever because they are less toxic and because strains of *Salmonella typhi* often are resistant to chloramphenicol. The adult dose of chloramphenicol for typhoid fever is 1 g every 6 h for 4 weeks.

Bacterial Meningitis. Chloramphenicol remains an alternative drug for the treatment of meningitis caused by *H. influenzae*, *N. meningitidis*, and *S. pneumoniae* in patients who have severe allergy to β -lactams and in developing countries. The total daily dose for children should be 50 mg/kg of body weight, divided into four equal doses given intravenously every 6 h.

Rickettsial Diseases. The tetracyclines usually are the preferred agents for the treatment of rickettsial diseases. However, in patients allergic to these drugs, in pregnant women, and in children less than 8 years of age who require prolonged or repeated courses of therapy, chloramphenicol is an alternative therapy. Rocky Mountain spotted fever, epidemic, murine, scrub, and recrudescent typhus and Q fever respond well to chloramphenicol. For adults and children with these diseases, a dosage of 50 mg/kg/d divided into 6-h intervals is recommended. For severe or resistant infections, doses up to 100 mg/kg/d may be used for short intervals, but the dose must be reduced to 50 mg/kg/d as soon as possible. Therapy should be continued until the general condition has improved and the patient is afebrile for 24–48 h.

Adverse Effects

Chloramphenicol inhibits the synthesis of proteins of the inner mitochondrial membrane, probably by inhibiting the ribosomal peptidyltransferase. These include subunits of cytochrome *c* oxidase, ubiquinone-cytochrome *c* reductase, and the proton-translocating

ATPase critical for aerobic metabolism. Much of the toxicity observed with this drug can be attributed to these effects.

Hypersensitivity Reactions. Skin rashes may result from hypersensitivity to chloramphenicol. Fever may appear simultaneously or be the sole manifestation. Angioedema is a rare complication. Jarisch-Herxheimer reactions may occur after institution of chloramphenicol therapy for syphilis, brucellosis, and typhoid fever.

Hematological Toxicity. Chloramphenicol affects the hematopoietic system in two ways: a dose-related toxicity that presents as anemia, leukopenia, or thrombocytopenia and an idiosyncratic response manifested by aplastic anemia, leading in many cases to fatal pancytopenia. Dose-related, reversible erythroid suppression probably reflects an inhibitory action of chloramphenicol on mitochondrial protein synthesis in erythroid precursors, which in turn impairs iron incorporation into heme. Bone marrow suppression occurs regularly when plasma concentrations are 25 μ g/mL or greater and is observed with the use of large doses of chloramphenicol, prolonged treatment, or both. Dose-related suppression of the bone marrow may progress to fatal aplasia if treatment is continued, but most cases of bone marrow aplasia develop without prior dose-related marrow suppression.

Pancytopenia occurs more commonly in individuals who undergo prolonged therapy and especially in those who are exposed to the drug on more than one occasion. Although the incidence of the reaction is low, about 1 in 30,000 courses of therapy or more, the fatality rate is high when bone marrow aplasia is complete, and there is an increased incidence of acute leukemia in those who recover. Aplastic anemia accounts for about 70% of cases of blood dyscrasias due to chloramphenicol; hypoplastic anemia, agranulocytosis, and thrombocytopenia make up the remainder. The proposed mechanism involves conversion of the nitro group to a toxic intermediate by intestinal bacteria.

Other Toxic and Irritative Effects. Nausea and vomiting, unpleasant taste, diarrhea, and perineal irritation may follow the oral administration of chloramphenicol. Blurring of vision and digital paresthesias may rarely occur. Tissues that have a high rate of oxygen consumption (e.g., heart, brain) may be particularly susceptible to chloramphenicol's effects on mitochondrial enzymes.

Neonates, especially if premature, may develop a serious illness termed *gray baby syndrome*. This syndrome usually begins 2–9 days after treatment is started. Within the first 24 h, vomiting, refusal to suck, irregular and rapid respiration, abdominal distention, periods of cyanosis, and passage of loose green stools occur. Over the next 24 h, neonates turn an ashen-gray color and become flaccid and hypothermic. A similar “gray syndrome” has been reported in adults who were accidentally overdosed with the drug. Death occurs in about 40% of patients within 2 days of initial symptoms. Those who recover usually exhibit no sequelae. Two mechanisms apparently are responsible for chloramphenicol toxicity in neonates: (1) a developmental deficiency of glucuronyl transferase, the hepatic enzyme that metabolizes chloramphenicol; and (2) inadequate renal excretion of unconjugated drug. At the onset of the clinical syndrome, chloramphenicol concentrations in plasma usually exceed 100 μ g/mL and may be as low as 75 μ g/mL.

Drug Interactions. Chloramphenicol inhibits hepatic CYPs and thereby prolongs the half-lives of drugs that are metabolized by this system. Severe toxicity and death have occurred because of failure to recognize such effects. Concurrent administration of phenobarbital or rifampin, which potentially induce CYPs, shortens the $t_{1/2}$ of the antibiotic and may result in subtherapeutic drug concentrations.

Macrolides and Ketolides

Macrolide antibiotics are widely used agents for treatment of respiratory tract infections caused by the common pathogens of community-acquired pneumonia. Four macrolides are available for clinical use: erythromycin, clarithromycin, azithromycin, and fidaxomicin. Erythromycin is the original agent in the class, discovered in 1952 by McGuire and coworkers in the metabolic products of a strain of *Streptomyces erythreus*.

1054 Azithromycin and clarithromycin are semisynthetic derivatives of erythromycin that have largely replaced it in clinical use. Fidaxomicin is a nonsystemically absorbed macrolide used only for the treatment of *Clostridium difficile* colitis. Ketolides are semisynthetic derivatives of erythromycin with activity against some macrolide-resistant strains.

Macrolide antibiotics contain a multimembered lactone ring (14-membered rings for erythromycin and clarithromycin and a 15-membered ring for azithromycin) to which are attached one or more deoxy sugars. Clarithromycin differs from erythromycin only by methylation of the hydroxyl group at the 6 position, and azithromycin differs by the addition of a methyl-substituted nitrogen atom into the lactone ring. These structural modifications improve acid stability and tissue penetration and broaden the spectrum of activity.

ERYTHROMYCIN

Ketolides are structurally similar multimembered ring systems but with different substituents. Telithromycin differs from erythromycin in that a 3-keto group replaces the α -L-cladinose of the 14-member macrolide ring, and there is a substituted carbamate at C11-C12. Telithromycin is the only ketolide currently approved in the U.S. These modifications render ketolides less susceptible to methylase-mediated (*erm*) and efflux-mediated (*mef* or *msr*) mechanisms of resistance. Ketolides therefore are active against many macrolide-resistant gram-positive strains; however, concerns about the safety of telithromycin have limited its use (Brinker et al., 2009).

TELITHROMYCIN

Mechanism of Action

Macrolide and ketolide antibiotics are bacteriostatic agents that inhibit protein synthesis by binding reversibly to 50S ribosomal subunits of sensitive microorganisms (Figure 59–3) at or very near the site that binds chloramphenicol (see Figure 59–2). Erythromycin does not inhibit peptide bond formation per se but rather inhibits the translocation step wherein a newly synthesized peptidyl tRNA molecule moves from the acceptor site on the ribosome to the peptidyl donor site. Gram-positive bacteria accumulate about 100 times more erythromycin than do gram-negative bacteria.

Antimicrobial Activity

Erythromycin usually is bacteriostatic but may be bactericidal in high concentrations against susceptible organisms. Erythromycin has

Figure 59–3 Inhibition of bacterial protein synthesis by erythromycin, clarithromycin, and azithromycin. Macrolide antibiotics are bacteriostatic agents that inhibit protein synthesis by binding reversibly to the 50S ribosomal subunits of sensitive organisms. Erythromycin appears to inhibit the translocation step such that the nascent peptide chain temporarily residing at the A site fails to move to the P, or donor, site. Alternatively, macrolides may bind and cause a conformational change that terminates protein synthesis by indirectly interfering with transpeptidation and translocation. See Figure 59–1 for additional information.

reasonably good activity against streptococci (see Table 59–1), but macrolide resistance among *S. pneumoniae* often coexists with penicillin resistance. Staphylococci are not reliably sensitive to erythromycin, and macrolide-resistant strains of *S. aureus* are potentially cross-resistant to clindamycin and streptogramin B (quinupristin). Gram-positive bacilli also are frequently sensitive to erythromycin, including *Clostridium perfringens*, *Corynebacterium diphtheriae*, and *L. monocytogenes*. Erythromycin is inactive against most aerobic enteric gram-negative bacilli. It has modest activity in vitro against *H. influenzae* and *N. meningitidis* and good activity against most strains of *N. gonorrhoeae*. Useful antibacterial activity also is observed against *P. multocida*, *Borrelia* spp., and *Bordetella pertussis*. Macrolides are usually active against *C. jejuni*. Erythromycin is active against *M. pneumoniae* and *Legionella pneumophila*. Most strains of *C. trachomatis* are inhibited by erythromycin.

Azithromycin has similar activity as erythromycin against sensitive strains of streptococci and staphylococci, while clarithromycin is slightly more potent. Clarithromycin is somewhat less active than erythromycin against *H. influenzae*, whereas azithromycin is the most active macrolide. Clarithromycin and azithromycin have good activity against *Moraxella catarrhalis*, *Chlamydia* spp., *L. pneumophila*, *B. burgdorferi*, *M. pneumoniae*, and *H. pylori*. Azithromycin and clarithromycin have enhanced activity against MAI, as well as against some protozoa (e.g., *Toxoplasma gondii*, *Cryptosporidium*, and *Plasmodium* spp.). Clarithromycin has good activity against *Mycobacterium leprae*. Telithromycin's spectrum of activity is similar to those of clarithromycin and azithromycin, but its capacity to withstand many macrolide resistance mechanisms increases its activity against macrolide-resistant *S. pneumoniae* and *S. aureus*.

Resistance to Macrolides and Ketolides

Resistance to macrolides usually results from one of four mechanisms (Nakajima, 1999):

- Drug efflux by an active pump mechanism
- Ribosomal protection by inducible or constitutive production of methylase enzymes, which modify the ribosomal target and decrease drug binding
- Macrolide hydrolysis by esterases produced by Enterobacteriaceae
- Chromosomal mutations that alter a 50S ribosomal protein (in *Bacillus subtilis*, *Campylobacter* spp., mycobacteria, and gram-positive cocci)

ADME

Erythromycin base is incompletely absorbed from the upper small intestine. Because it is inactivated by gastric acid, it is administered as enteric-coated tablets or as capsules containing enteric-coated pellets that dissolve in the duodenum; food may delay absorption. Esters of erythromycin base (e.g., stearate, estolate, and ethylsuccinate) have improved acid stability, and their absorption is less altered by food. Erythromycin diffuses readily into intracellular fluids, achieving antibacterial activity in essentially all sites except the brain and CSF. Protein binding is about 70%–80% for erythromycin base and even higher for the estolate. Erythromycin traverses the placenta, and drug concentrations in fetal plasma are about 5%–20% of those in the maternal circulation. Concentrations in breast milk are 50% of those in serum. Erythromycin is concentrated in the liver and excreted in the bile. The serum $t_{1/2}$ of erythromycin is about 1.6 h. Although the $t_{1/2}$ may be prolonged in patients with anuria, dosage reduction is not routinely recommended in patients in renal failure. The drug is not removed significantly by either peritoneal dialysis or hemodialysis.

Clarithromycin is absorbed rapidly from the GI tract after oral administration, but hepatic first-pass metabolism reduces its bioavailability to 50%–55%. Peak concentrations occur about 2 h after drug administration. Clarithromycin may be given with or without food, but the extended-release form should be administered with food to improve bioavailability. Clarithromycin and its active metabolite, 14-hydroxylarithromycin, achieve high intracellular concentrations throughout the body, including the middle ear. Clarithromycin is metabolized in the liver to several metabolites; the active 14-hydroxy metabolite is the most significant. The elimination $t_{1/2}$ are 3–7 h for clarithromycin and 5–9 h for 14-hydroxylarithromycin. Metabolism is saturable, resulting in nonlinear pharmacokinetics and longer half-lives with higher dosages. The amount of clarithromycin excreted unchanged in the urine ranges from 20% to 40%, depending on the dose administered and the formulation (tablet vs. oral suspension). An additional 10%–15% of a dose is excreted in the urine as 14-hydroxylarithromycin. Dose adjustment is not recommended unless the creatinine clearance is less than 30 mL/min.

Azithromycin administered orally is absorbed rapidly (although incompletely: bioavailability for the immediate-release formulation is on the order of 30%–40%) and distributes widely throughout the body, except to the brain and CSF. Azithromycin also can be administered intravenously, producing plasma concentrations of 3–4 $\mu\text{g/mL}$ after a 1-h infusion of 500 mg. Azithromycin's unique pharmacokinetic properties include extensive tissue distribution and high drug concentrations within cells (including phagocytes), resulting in much greater concentrations of drugs in tissue or secretions compared to simultaneous serum concentrations. Azithromycin undergoes some hepatic metabolism to inactive metabolites, but biliary excretion is the major route of elimination. Only 12% of drug is excreted unchanged in the urine. The elimination $t_{1/2}$, 40–68 h, is prolonged because of extensive tissue sequestration and binding.

Telithromycin is formulated as a 400-mg tablet for oral administration; there is no parenteral form. It is well absorbed with about 60% bioavailability. Peak serum concentrations are achieved within 30 min to 4 h. Telithromycin penetrates well into most tissues and is concentrated in many tissues, in particular in macrophages and white blood cells, where concentrations of 40 $\mu\text{g/mL}$ (500 times the plasma concentration) are maintained even 24 h after dosing. Telithromycin has a $t_{1/2}$ of 9.8 h and can be given once daily. The drug is cleared primarily by hepatic metabolism, 50% by CYP3A4 and 50% by CYP-independent metabolism. No adjustment of the dose is required for those with hepatic failure or mild-to-moderate renal failure.

Therapeutic Uses and Dosage

The usual oral dose of erythromycin (erythromycin base) for adults ranges from 1 to 2 g/d, in divided doses, usually given every 6 h. Food should not be taken concurrently, if possible, with erythromycin base or the stearate formulations, but this is not necessary with erythromycin estolate. The oral dose of erythromycin for children is 30–50 mg/kg/d, divided into

four portions; this dose may be doubled for severe infections. Intravenous administration is generally reserved for the therapy of severe infections and is now used uncommonly; the usual dose is 0.5–1 g every 6 h.

Clarithromycin usually is given twice daily at a dose of 250 mg for adults with mild-to-moderate infections and 500 mg twice daily for more severe infections. The 500-mg extended-release formulation of clarithromycin is given as 2 tablets once daily. Clarithromycin (500 mg) is also packaged with lansoprazole (30 mg) and amoxicillin (1 g) as a combination regimen that is administered twice daily for 10 or 14 days to eradicate *H. pylori*.

Azithromycin should be given 1 h before or 2 h after meals when administered orally. For outpatient therapy of community-acquired pneumonia, pharyngitis, or sinusitis, a loading dose of 500 mg is given on the first day, and then 250 mg per day is given for days 2 through 5. Treatment or prophylaxis of MAI infection in HIV-infected patients requires higher doses: 500–600 mg daily in combination with one or more other agents for treatment or 1200 mg once weekly for primary prevention. Azithromycin is useful in treatment of sexually transmitted diseases, especially during pregnancy when tetracyclines are contraindicated (Centers for Disease Control and Prevention, 2015). The treatment of uncomplicated nongonococcal urethritis presumed to be caused by *C. trachomatis* consists of a single 1-g dose of azithromycin. This dose also is effective for chancroid. In children, the recommended dose of azithromycin oral suspension for acute otitis media and pneumonia is 10 mg/kg on the first day (maximum 500 mg) and 5 mg/kg (maximum 250 mg/d) on days 2 through 5. A single 30-mg/kg dose is approved as an alternative for otitis media.

Telithromycin's dose in adults is 800 mg orally once daily.

Respiratory Tract Infections. Macrolides are suitable drugs for the treatment of a number of respiratory tract infections. Azithromycin and clarithromycin are suitable choices for treatment of mild-to-moderate community-acquired pneumonia among ambulatory patients. In hospitalized patients, a macrolide is commonly added to an antipneumococcal β -lactam for coverage of atypical respiratory pathogens. Because of excellent in vitro activity, superior tissue concentration, the ease of administration as a single daily dose, and better tolerability compared to erythromycin, azithromycin (or a fluoroquinolone) has supplanted erythromycin as the first-line agent for treatment of legionellosis. Macrolides are also appropriate alternative agents for the treatment of acute exacerbations of chronic bronchitis, acute otitis media, acute streptococcal pharyngitis, and acute bacterial sinusitis. Azithromycin or clarithromycin are generally preferred to erythromycin due to their broader spectrum and superior tolerability.

Telithromycin is effective in the treatment of community-acquired pneumonia, acute exacerbations of chronic bronchitis, and acute bacterial sinusitis and has a potential advantage where macrolide-resistant strains are common. Due to a number of cases of severe hepatotoxicity, the drug's FDA approval is limited to community-acquired pneumonia; *telithromycin should be used only in circumstances where it provides a substantial advantage over less-toxic therapies*.

Skin and Soft-Tissue Infections. Macrolides are alternatives for treatment of erysipelas and cellulitis among patients who have a serious allergy to penicillin (Stevens et al., 2014). Erythromycin has been an alternative agent for the treatment of relatively minor skin and soft-tissue infections caused by either penicillin-sensitive or penicillin-resistant *S. aureus*. However, many strains of *S. aureus* are resistant to macrolides.

Chlamydial Infections. Chlamydial infections can be treated effectively with any of the macrolides. A single 1-g dose of azithromycin is recommended for patients with uncomplicated urethral, endocervical, rectal, or epididymal infections because of the ease of compliance. Erythromycin base is preferred for chlamydial pneumonia of infancy and ophthalmia neonatorum (50 mg/kg/d in four divided doses for 14 days). Azithromycin, 1 g/week for 3 weeks, may be effective for lymphogranuloma venereum.

Diphtheria. Erythromycin for 7 days is very effective for acute infections or for eradicating the diphtheria carrier state. Other macrolides are not FDA-approved for this indication. Antibiotics do not alter the course of an acute infection with diphtheria or decrease the risk of complications. Antitoxin is indicated in the treatment of acute infection.

1056 Pertussis. Erythromycin is the drug of choice for treating persons with *B. pertussis* disease and for postexposure prophylaxis of household members and close contacts. Clarithromycin and azithromycin also are effective. If administered early in the course of whooping cough, erythromycin may shorten the duration of illness; it has little influence on the disease once the paroxysmal stage is reached. Nasopharyngeal cultures should be obtained from people with pertussis who do not improve with erythromycin therapy because resistance has been reported.

Helicobacter pylori Infection. Clarithromycin, 500 mg, in combination with omeprazole, 20 mg, and amoxicillin, 1 g, each administered twice daily for 10–14 days, is effective for treatment of peptic ulcer disease caused by *H. pylori*.

Mycobacterial Infections. Clarithromycin or azithromycin is recommended as first-line therapy for prophylaxis and treatment of disseminated infection caused by MAI in patients with HIV infection and for treatment of pulmonary disease in patients not infected with HIV (Masur et al., 2014). Clarithromycin (500 mg twice daily) plus ethambutol (15 mg/kg once daily) with or without rifabutin is an effective combination regimen. Clarithromycin also has been used with minocycline for the treatment of *M. leprae* in lepromatous leprosy.

Prophylactic Uses. Azithromycin or clarithromycin is recommended for primary prevention of infection due to MAI among patients with HIV infection and less than 50 CD4 cells/mm³. Single-agent therapy should not be used for treatment of active disease or for secondary prevention in patients with HIV. Erythromycin is an effective alternative for the prophylaxis of recurrences of rheumatic fever in individuals who are allergic to penicillin.

Adverse Effects

GI Toxicity. Oral or intravenous administration of erythromycin frequently is accompanied by moderate-to-severe epigastric distress. Erythromycin stimulates GI motility by acting on motilin receptors (see Chapter 51); indeed, erythromycin is used off label as a prokinetic agent in the intensive care setting and in patients with diabetic gastroparesis. Clarithromycin, azithromycin, and telithromycin also may cause GI distress, but to a lesser degree than erythromycin.

Cardiac Toxicity. Erythromycin, clarithromycin, azithromycin, and telithromycin have been reported to cause cardiac arrhythmias, including QT prolongation with ventricular tachycardia. A large cohort study found a small but statistically significant increase in the risk of sudden cardiac death with azithromycin compared to no antibiotic treatment or to amoxicillin. Risk factors for clinically significant cardiac toxicity include receipt of concomitant antiarrhythmic drugs or other agents that prolong QTc.

Hepatotoxicity. Cholestatic hepatitis is associated with long-term treatment with erythromycin. The illness starts after 10–20 days of treatment and is characterized initially by nausea, vomiting, and abdominal cramps. These symptoms are followed shortly thereafter by jaundice, which may be accompanied by fever, leukocytosis, eosinophilia, and elevated transaminases in plasma. Findings usually resolve within a few days after cessation of drug therapy. Hepatotoxicity has also been observed with clarithromycin and azithromycin, although at a lower rate than with erythromycin. Telithromycin may induce severe hepatotoxicity and should only be used if it represents a clear advantage over alternative agents (Brinker et al., 2009).

Other Toxic and Irritative Effects. Allergic reactions observed are fever, eosinophilia, and skin eruptions, which disappear shortly after therapy is stopped. Auditory impairment and tinnitus have been observed with macrolides, especially at higher doses. Visual disturbances due to slowed accommodation have been reported following telithromycin. Telithromycin is contraindicated in patients with myasthenia gravis due to exacerbation of neurological symptoms.

Drug Interactions. Erythromycin, clarithromycin, and telithromycin strongly inhibit CYP3A4 and cause significant drug interactions (Periti et al., 1992). Erythromycin and clarithromycin potentiate the effects of carbamazepine, corticosteroids, cyclosporine, digoxin, ergot alkaloids,

theophylline, triazolam, valproate, and warfarin, probably by interfering with CYP-mediated metabolism of these drugs (see Chapter 6). Telithromycin is both a substrate and a strong inhibitor of CYP3A4. Coadministration of rifampin, a potent inducer of CYP, decreases the serum concentrations of telithromycin by 80%. CYP3A4 inhibitors (e.g., itraconazole) increase peak serum concentrations of telithromycin. Azithromycin is much less likely to be involved in these drug interactions; however, caution is advised when the consequences of interaction are severe.

Lincosamides

The class originator lincomycin and its congener clindamycin are approved in the U.S. Clindamycin has largely replaced lincomycin in clinical practice and is principally used to treat gram-positive aerobic and anaerobic infections, as well as some parasitic infections.

Mechanism of Action

Clindamycin binds exclusively to the 50S subunit of bacterial ribosomes and suppresses protein synthesis. Although clindamycin, erythromycin, and chloramphenicol are not structurally related, they act at sites in close proximity (see Figures 59–2 and 59–3), and binding by one of these antibiotics to the ribosome may inhibit the interaction of the others.

CLINDAMYCIN

Antimicrobial Activity

Bacterial strains are susceptible to clindamycin at MICs of 0.5 µg/mL or less. Clindamycin generally is similar to erythromycin in its in vitro activity against susceptible strains of pneumococci, *S. pyogenes*, and viridans streptococci (see Table 59–1). MSSAs usually are susceptible to clindamycin, but MRSA and coagulase-negative staphylococci are more likely to be resistant. Clindamycin is more active than erythromycin or clarithromycin against anaerobic bacteria, especially *B. fragilis*, but resistance to clindamycin in *Bacteroides* spp. increasingly is encountered. From 10% to 20% of clostridial species other than *C. perfringens* are resistant. Strains of *Actinomyces israelii* and *Nocardia asteroides* are sensitive. Essentially all aerobic gram-negative bacilli are resistant. Clindamycin plus primaquine and clindamycin plus pyrimethamine are second-line regimens for *Pneumocystis jiroveci* pneumonia and *T. gondii* encephalitis, respectively.

Resistance to Lincosamides

Macrolide resistance due to ribosomal methylation also may produce resistance to clindamycin. Because clindamycin does not induce the methylase, there is cross-resistance only if the enzyme is produced constitutively. However, selection for a subpopulation of constitutive methylase producers may occur among staphylococci and streptococci with a macrolide-inducible phenotype (Lewis and Jorgensen, 2005). Clindamycin is not a substrate for macrolide efflux pumps; thus, strains that are resistant to macrolides by this mechanism are susceptible to clindamycin.

ADME

Clindamycin is nearly completely absorbed following oral administration. Peak concentrations of 2–3 µg/mL are attained within 1 h after the ingestion of 150 mg. Food in the stomach does not reduce absorption significantly. The $t_{1/2}$ of the antibiotic is about 3 h. Clindamycin palmitate, an oral preparation for pediatric use, is an inactive prodrug that is hydrolyzed rapidly in vivo. The phosphate ester of clindamycin, which is given parenterally, also is rapidly hydrolyzed in vivo to the active parent compound.

Clindamycin is widely distributed in many fluids and tissues, including good concentrations in bone. CSF concentrations are limited, even when

the meninges are inflamed, but concentrations sufficient to treat cerebral toxoplasmosis are achievable. The drug readily crosses the placental barrier. Ninety percent or more of clindamycin is bound to plasma proteins. Clindamycin accumulates in polymorphonuclear leukocytes and alveolar macrophages and in abscesses.

Clindamycin is inactivated by metabolism to *N*-demethylclindamycin and clindamycin sulfoxide, which are excreted in the urine and bile. Dosage adjustments may be required in patients with severe hepatic failure. Only about 10% of the clindamycin administered is excreted unaltered in the urine, and small quantities are found in the feces.

Therapeutic Uses and Dosage

The oral dose of clindamycin for adults is 150–300 mg every 6 h; for severe infections, it is 300–600 mg every 6 h. Children should receive 8–12 mg/kg/d of clindamycin palmitate hydrochloride in three or four divided doses or, for severe infections, 13–25 mg/kg/d. Clindamycin phosphate is available for intramuscular or intravenous use. For serious infections, intravenous or intramuscular administration is recommended in dosages of 1200–2700 mg/d, divided into three or four equal doses for adults. Children should receive 15–40 mg/kg/d in three or four divided doses; in severe infections, a minimal daily dose of 300 mg is recommended, regardless of body weight.

Skin and Soft-Tissue Infections. Clindamycin is an alternative agent for the treatment of skin and soft-tissue infections, especially in patients with β -lactam allergies (Stevens et al., 2014). It is also useful for oral treatment of skin infections when MRSA and streptococci are potential pathogens. Because clindamycin inhibits toxin production, it is recommended as an adjunctive agent in necrotizing fasciitis or gas gangrene when toxin-producing bacteria (e.g., streptococci, staphylococci, clostridia) are suspected. Topical clindamycin is used for treatment of acne.

Respiratory Tract Infections. Clindamycin is effective for treatment of lung abscess and anaerobic lung and pleural space infections due to susceptible organisms (Levison et al., 1983). It has been used as an alternative agent for treatment of sinusitis, pharyngitis, and otitis media. Clindamycin in combination with primaquine is useful for the treatment of mild-to-moderate cases of *P. jiroveci* pneumonia in patients with HIV.

Other Infections. Owing to its good activity against staphylococci and excellent bone penetration, clindamycin is an alternative agent for treatment of osteomyelitis. Clindamycin in combination with pyrimethamine and leucovorin (folinic acid) is an effective alternative for acute treatment of encephalitis caused by *T. gondii* in patients with AIDS. Clindamycin plus quinine is an alternative regimen for nonsevere malaria. Clindamycin is also administered vaginally for bacterial vaginosis.

Adverse Effects

GI Effects. The reported incidence of diarrhea associated with the administration of clindamycin ranges from 2% to 20%. In most cases, this is mild to moderate in severity and resolves on drug discontinuation. However, clindamycin carries a relatively high risk of superinfection with *C. difficile*. This colitis is characterized by watery diarrhea, fever, and elevated peripheral white blood cell counts. *This syndrome may be lethal.* Discontinuation of the drug, combined with administration of metronidazole or oral vancomycin usually, is curative, but relapses occur. Agents that inhibit peristalsis (e.g., opioids) may prolong and worsen the condition.

Other Toxic and Irritative Effects. Skin rashes occur in about 10% of patients treated with clindamycin and may be more common in patients with HIV infection. Other uncommon reactions include exudative erythema multiforme (Stevens-Johnson syndrome), reversible elevation of aspartate aminotransferase and alanine aminotransferase, granulocytopenia, thrombocytopenia, and anaphylactic reactions. Local thrombophlebitis may follow intravenous administration of the drug. Clindamycin may potentiate the effect of concomitant neuromuscular blocking agents.

Streptogramins

Streptogramins are semisynthetic derivatives of naturally occurring agents produced by *Streptomyces pristinaespiralis*. The only streptogramin in

clinical use is a fixed combination of quinupristin (a streptogramin B) with dalfopristin (a streptogramin A) in a 30:70 ratio. Quinupristin and dalfopristin are more soluble derivatives of the congeners pristinamycin IA and IIA and therefore are suitable for intravenous administration.

Mechanism of Action

Quinupristin and dalfopristin are protein synthesis inhibitors that bind the 50S ribosomal subunit. Quinupristin binds at the same site as macrolides and has a similar effect, with inhibition of polypeptide elongation and early termination of protein synthesis. Dalfopristin binds at a site nearby, resulting in a conformational change in the 50S ribosome, synergistically enhancing the binding of quinupristin at its target site. Dalfopristin directly interferes with polypeptide chain formation. The net result of the cooperative and synergistic binding of these two molecules to the ribosome is *bactericidal* activity.

Antimicrobial Activity

Quinupristin/dalfopristin is active against gram-positive cocci and organisms responsible for atypical pneumonia (e.g., *M. pneumoniae*, *Legionella* spp., and *C. pneumoniae*) but is inactive against gram-negative organisms (Table 59–1). The combination is bactericidal against streptococci and many strains of staphylococci but bacteriostatic against *Enterococcus faecium*.

Resistance to Streptogramins

Resistance to quinupristin is mediated by genes encoding a ribosomal methylase that prevents binding of drug to its target or genes encoding lactonases that inactivate type B streptogramins. Resistance to dalfopristin is mediated by genes that encode acetyltransferases that inactivate type A streptogramins or staphylococcal genes that encode ATP-binding efflux proteins that pump type A streptogramins out of the cell. These resistance determinants are located on plasmids. Resistance to quinupristin/dalfopristin always is associated with a resistance gene for type A streptogramins. Methylase-encoding genes can render the combination bacteriostatic instead of bactericidal, making it ineffective in certain infections in which bactericidal activity is necessary (e.g., endocarditis).

ADME

Quinupristin/dalfopristin is administered by intravenous infusion over at least 1 h. The $t_{1/2}$ is 0.85 h for quinupristin and 0.7 h for dalfopristin. The volume of distribution is 0.87 L/kg for quinupristin and 0.71 L/kg for dalfopristin. Hepatic metabolism by conjugation is the principal means of clearance for both compounds, with 80% of an administered dose eliminated by biliary excretion. Renal elimination of active compound accounts for most of the remainder. No dosage adjustment is necessary for renal insufficiency. Pharmacokinetics are not significantly altered by peritoneal dialysis or hemodialysis. Hepatic insufficiency increases the plasma AUC of active component and metabolites by 180% for quinupristin and 50% for dalfopristin.

Therapeutic Uses and Dosage

Quinupristin/dalfopristin is approved in the U.S. for complicated skin and skin-structure infections caused by methicillin-susceptible strains of *S. aureus* or *S. pyogenes*. It is also used for treatment of infections caused by vancomycin-resistant strains of *E. faecium* (dose of 7.5 mg/kg every 8–12 h), and in Europe it also is approved for treatment of nosocomial pneumonia and infections caused by MRSA. Quinupristin/dalfopristin should be reserved for treatment of serious infections caused by multiple-drug-resistant gram-positive organisms such as vancomycin-resistant *E. faecium*.

Adverse Effects

The most common side effects are infusion-related events, such as pain and phlebitis at the infusion site and arthralgias and myalgias. Phlebitis and pain can be minimized by infusion of drug through a central venous catheter. Arthralgias and myalgias, more likely to be problematic in patients with hepatic insufficiency, are managed by reducing the infusion frequency.

Drug Interactions. Quinupristin/dalfopristin inhibits CYP3A4. The concomitant administration of other CYP3A4 substrates with quinupristin/dalfopristin may result in significant toxicity. Caution and monitoring are recommended for drugs in which the toxic therapeutic window is narrow or for drugs that prolong the QTc interval.

Oxazolidinones are a new class of synthetic protein synthesis inhibitors with activity primarily against gram-positive organisms, including multi-drug-resistant pathogens. Linezolid is the class originator; a second agent, tedizolid, was FDA-approved in 2014.

Antimicrobial Activity

Linezolid is active against the vast majority of gram-positive organisms, including staphylococci, streptococci, enterococci, gram-positive anaerobic cocci, and gram-positive rods such as *Corynebacterium* spp., *Nocardia* spp., and *L. monocytogenes* (see Table 59–1). It has poor activity against most gram-negative aerobic or anaerobic bacteria. It is bacteriostatic against enterococci and staphylococci but may be bactericidal against streptococci. *Mycobacterium tuberculosis* is moderately susceptible, as are most rapidly growing mycobacteria, but MAI is frequently resistant. The available data to date suggest tedizolid has similar activity to linezolid (Rybak et al., 2014).

Mechanism of Action

Oxazolidinones inhibit protein synthesis by binding to the P site of the 50S ribosomal subunit and preventing formation of the larger ribosomal-fMet-tRNA complex that initiates protein synthesis. Because of its unique mechanism of action, these agents are active against strains that are resistant to multiple other agents, including penicillin-resistant strains of *S. pneumoniae*; methicillin-resistant, vancomycin-intermediate, and vancomycin-resistant strains of staphylococci; and vancomycin-resistant strains of enterococci.

Resistance to Oxazolidinones

Resistance in enterococci and staphylococci is most commonly due to point mutations of the 23S rRNA. Because bacteria have multiple copies of 23S rRNA genes, significant resistance generally requires mutations in two or more copies. Recently, a transferable methyltransferase that confers resistance through ribosomal modification has been described. Linezolid resistance remains relatively low among normally susceptible organisms, although some sites report increasing frequency in enterococci, including cases of nosocomial transfer. Although data are limited, tedizolid may be active against some linezolid-resistant isolates.

ADME

Linezolid is well absorbed after oral administration, with a bioavailability of 100%, and may be administered without regard to food. Dosing for oral and intravenous preparations is the same. The $t_{1/2}$ is about 4–6 h. Linezolid is 30% protein bound and distributes widely to well-perfused tissues. Linezolid is nonenzymatically oxidized to aminoethoxyacetic acid and hydroxyethyl glycine derivatives. Approximately 80% of a dose of linezolid appears in the urine, 30% as active compound and 50% as the two primary oxidation products. Ten percent of the administered dose appears as oxidation products in feces. No dose adjustment in renal insufficiency is recommended. Linezolid and its breakdown products are eliminated by dialysis; therefore, the drug should be administered after hemodialysis.

Tedizolid is administered orally and parenterally as a prodrug (tedizolid phosphate) that is rapidly and completely hydrolyzed to tedizolid. Tedizolid is well absorbed after oral administration (bioavailability > 80%). Tedizolid displays greater protein binding (70%–90%) and a longer $t_{1/2}$ of about 12 h. There is minimal elimination of unchanged drug in the urine; the drug undergoes sulfation in the liver and is excreted primarily in the feces.

Therapeutic Uses and Dosage

Linezolid is most commonly administered at a dose of 600 mg twice daily orally or intravenously. A 400-mg twice-daily dosage regimen is recommended only for treatment of uncomplicated skin and skin-structure infections in adults. Tedizolid is given as a 200-mg IV or oral daily dose.

Skin and Soft-Tissue Infections. Linezolid and tedizolid are FDA-approved for treatment of skin and skin-structure infections caused by streptococci and *S. aureus* (MSSA and MRSA). A 6-day regimen of tedizolid provided similar outcomes to 10 days of linezolid.

Respiratory Tract Infections. Linezolid is approved for treatment of community-acquired pneumonia due to *S. pneumoniae* and nosocomial pneumonia due to *S. aureus*. A randomized clinical trial in patients with MRSA pneumonia demonstrated similar or better outcomes to vancomycin (Wunderink et al., 2012). Studies of tedizolid for pneumonia are under way.

Other Infections. Linezolid has clinical and microbiological cure rates in the range of 85%–90% in treatment of a variety of infections caused by vancomycin-resistant *E. faecium*. Linezolid has been used in combination therapy for extensively drug-resistant tuberculosis and in infections due *Nocardia*.

Adverse Effects

Myelosuppression. Myelosuppression, including anemia, leukopenia, pancytopenia, and thrombocytopenia, has been reported in patients receiving linezolid. Thrombocytopenia tends to be the most common effect, with an onset between 7 and 10 days. Effects are reversible on drug discontinuation. Platelet counts should be monitored in patients with risk of bleeding, preexisting thrombocytopenia, or intrinsic or acquired disorders of platelet function and in patients receiving courses of therapy lasting beyond 2 weeks. Treatment durations with tedizolid in clinical trials have been limited; based on early clinical and in vitro data, tedizolid may have a lower propensity for causing myelosuppression.

Mitochondrial Toxicities. Patients receiving treatment with linezolid have developed peripheral neuropathy, optic neuritis, and lactic acidosis (Narita et al., 2007). These effects typically manifest after prolonged treatment durations (at least 6 weeks), although some cases of lactic acidosis have been described after only a few days of therapy. The underlying mechanism of these toxicities is believed to be inhibition of mitochondrial protein synthesis. Linezolid should generally not be used for long-term therapy if there are alternative agents. There are insufficient data to judge the risk of mitochondrial toxicities with tedizolid.

Drug Interactions. Linezolid is a weak nonspecific inhibitor of MAO. Patients receiving concomitant therapy with an adrenergic or serotonergic agent (including SSRIs) or consuming more than 100 mg of tyramine a day may experience serotonin syndrome (e.g., palpitations, headache, hypertensive crisis). Coadministration of these agents is best avoided. However, in patients receiving SSRIs who acutely require linezolid therapy for short-term (10- to 14-day) treatment, coadministration with careful monitoring is reasonable. The relative potential for this interaction with tedizolid is not yet known. Neither linezolid nor tedizolid is a substrate or an inhibitor of CYPs.

Agents Acting on the Bacterial Cell Wall

Polymyxins

The polymyxins are a group of closely related antibiotics elaborated by strains of *Bacillus polymyxa*. Polymyxin B is a mixture of polymyxins B₁ and B₂. Colistin, also known as polymyxin E, is produced by *Bacillus colistinus* and is marketed either as colistimethate for intravenous administration or colistin base for topical use. These agents were initially developed more than 50 years ago but quickly fell out of favor for systemic use due to their toxicities. With the rise of resistant gram-negative organisms in the past decade, their use has increased substantially.

Antimicrobial Activity

The antimicrobial activities of polymyxin B and colistin are similar and restricted to gram-negative bacteria, primarily aerobes. Most *Pseudomonas*, *Acinetobacter*, and Enterobacteriaceae are susceptible, except for *Proteus* and *Serratia* spp. *Stenotrophomonas* and *Burkholderia* are usually resistant.

Mechanism of Action

Polymyxins, simple basic peptides with molecular masses of about 1000 Da, are surface-active amphipathic agents that act as cationic detergents. They interact strongly with phospholipids and disrupt the structure of

cell membranes. Sensitivity to polymyxin B apparently is related to the phospholipid content of the cell wall–membrane complex. Polymyxin B binds to the lipid A portion of endotoxin (the lipopolysaccharide of the outer membrane of gram-negative bacteria) and inactivates this molecule.

Resistance to Polymyxins

Although resistance to polymyxins is rare, emergence of resistance while on treatment has been documented and has become problematic among extensively drug-resistant *Acinetobacter* and *Klebsiella*.

ADME

Polymyxin B and colistin are not absorbed when given orally and are poorly absorbed from mucous membranes and surfaces of large burns. CMS (colistimethate) is the prodrug formulation for parenteral administration; it is hydrolyzed relatively slowly in the bloodstream to the active colistin sulfate moiety. CMS may be administered via inhalation for prevention and adjunctive treatment of lung infections. Limited data are available regarding distribution of these agents in the body. Intraventricular and intrathecal administration has been used for treatment of CNS infections. CMS (but not colistin) is cleared renally; thus modification of the dose is generally required in patients with impaired renal function. Polymyxin B primarily undergoes nonrenal clearance.

Therapeutic Uses and Dosage

Because dosing of these agents varies by drug (polymyxin B or colistin), by the particular commercial preparation marketed in a specific country, and by the patient's degree of renal dysfunction, expert consultation is recommended.

Systemic Uses. Polymyxins are used systemically only for serious infections due to pathogens resistant to other effective therapies. They have been used for treatment of a variety of infections, including bacteremia, pneumonia, bone/joint infections, burns, cellulitis, cystic fibrosis, endocarditis, gynecologic infections, meningitis, and ventriculitis (Nation et al., 2015).

Topical Uses. Polymyxin B sulfate is available for ophthalmic, otic, and topical use in combination with a variety of other compounds. Colistin is available as otic drops. Infections of the skin, mucous membranes, eye, and ear due to polymyxin B–sensitive microorganisms respond to local application of the antibiotic in solution or ointment. External otitis, frequently due to *Pseudomonas*, may be cured by the topical use of the drug. *Pseudomonas aeruginosa* is a common cause of infection of corneal ulcers; local application or subconjunctival injection of polymyxin B often is curative.

Adverse Effects

The primary toxicity of polymyxins is dose-related nephrotoxicity. Neurological reactions include muscle weakness, apnea, paresthesias, vertigo, and slurred speech. Polymyxin B applied to intact or denuded skin or mucous membranes produces no systemic reactions because of its almost complete lack of absorption from these sites. Hypersensitivity reactions are uncommon.

Glycopeptides

The class originator for glycopeptides is vancomycin, a tricyclic glycopeptide antibiotic produced by *Streptococcus orientalis*. Teicoplanin is a mixture of related glycopeptides available as an antibiotic in Europe. It is similar to vancomycin in chemical structure, mechanism of action, spectrum of activity, and route of elimination (i.e., primarily renal). A new generation of glycopeptide congeners, the lipoglycopeptides, has been recently introduced into clinical practice. These agents include telavancin, dalbavancin, and oritavancin (Henson et al., 2015).

Antimicrobial Activity

Vancomycin possesses activity against the vast majority of gram-positive bacteria (see Table 59–1), including MRSA, penicillin-resistant streptococci, and ampicillin-resistant enterococci. Gram-positive organisms intrinsically resistant to vancomycin include *Lactobacillus*, *Leuconostoc*, *Pediococcus*, and *Erysipelothrix*. Essentially all species of gram-negative bacilli and mycobacteria are resistant to glycopeptides. The activity of teicoplanin, telavancin, dalbavancin, and oritavancin is generally similar to that of vancomycin; these agents are also active against some vancomycin-resistant enterococci (Goldstein et al., 2004).

Mechanism of Action

Glycopeptides inhibit the synthesis of the cell wall in sensitive bacteria by binding with high affinity to the D-alanyl-D-alanine terminus of cell wall precursor units (Figure 59–4). Because of their large molecular size, they are unable to penetrate the outer membrane of gram-negative bacteria. The lipoglycopeptides are able to dimerize and anchor their lipid moieties into the bacterial cell membrane, allowing for increased binding to the D-Ala-D-Ala target site and improved potency. Telavancin and oritavancin possess a second mechanism of action: direct disruption of the bacterial cell membrane. This effect leads to more rapid bactericidal activity than that of vancomycin.

Resistance to Glycopeptides

Glycopeptide-resistant strains of enterococci, primarily *E. faecium*, have emerged as major nosocomial pathogens in hospitals in the U.S. Determinants of vancomycin resistance are located on a transposon that is readily transferable among enterococci, and, potentially, other gram-positive bacteria. These strains are typically resistant to multiple antibiotics, including streptomycin, gentamicin, and ampicillin. Resistance to streptomycin and gentamicin is of special concern because the combination of an aminoglycoside with a cell wall synthesis inhibitor is the only reliably bactericidal regimen for treatment of enterococcal endocarditis.

Enterococcal resistance to glycopeptides is the result of alteration of the D-alanyl-D-alanine target to D-alanyl-D-lactate or D-alanyl-D-serine, which bind glycopeptides poorly. Several enzymes within the *van* gene cluster are required for this target alteration to occur. The *vanA* genotype confers inducible resistance to teicoplanin and vancomycin in *E. faecium* and *Enterococcus faecalis*. Consistent with their dual mode of action, while MICs to telavancin and oritavancin may increase in isolates expressing *vanA*,

Figure 59–4 Inhibition of bacterial cell wall synthesis by glycopeptides such as vancomycin. Vancomycin inhibits the polymerization or transglycosylase reaction by binding to the D-alanyl-D-alanine terminus of the cell wall precursor unit attached to its lipid carrier and blocks linkage to the glycopeptide polymer (indicated by the subscript n). These (NAM-NAG)_n peptidoglycan polymers are located within the cell wall. *VanA*-type resistance is due to expression of enzymes that modify cell wall precursor by substituting a terminal D-lactate for D-alanine, reducing affinity for vancomycin by 1000-fold.

they often remain in the susceptible range. In contrast, *vanA*-expressing isolates are frequently dalbavancin resistant. The *vanB* genotype, which tends to be a lower level of resistance, also has been identified in *E. faecium* and *E. faecalis*. The trait is inducible by vancomycin but not teicoplanin; consequently, many strains remain susceptible to teicoplanin. Telavancin, dalbavancin, and oritavancin are usually active as well. The *vanC* genotype, the least important clinically and least well characterized, confers resistance only to vancomycin.

Staphylococcus aureus and coagulase-negative staphylococci may express reduced or “intermediate” susceptibility to vancomycin (MIC 4–8 µg/mL) or, very rarely, high-level resistance (MIC ≥ 16 µg/mL) (Howden et al., 2004). Intermediate resistance is associated with a heterogeneous phenotype in which a small proportion of cells within the population (1 in 10⁵ to 1 in 10⁶) will grow in the presence of vancomycin concentrations greater than 4 µg/mL. Prior treatment courses and low vancomycin levels may predispose patients to infection and treatment failure with vancomycin-intermediate strains. These strains typically are resistant to methicillin and multiple other antibiotics; their emergence is a major concern because until recently vancomycin has been the only antibiotic to which staphylococci were reliably susceptible. High-level vancomycin-resistant *S. aureus* strains (MIC ≥ 32 µg/mL) harbor a conjugative plasmid into which the *vanA* transposon is integrated by an interspecies horizontal gene transfer from *E. faecalis* to an MRSA. These isolates have been variably susceptible to teicoplanin and the lipoglycopeptides (Centers for Disease Control and Prevention, 2004).

ADME

All glycopeptides are poorly absorbed after oral administration; the oral formulation of vancomycin is exclusively used in patients with *C. difficile* colitis. Vancomycin should be only administered intravenously, not intramuscularly, due to pain with intramuscular injection. Approximately 30% of vancomycin is bound to plasma protein. Vancomycin appears in various body fluids, including the CSF when the meninges are inflamed (7%–30%); bile; and pleural, pericardial, synovial, and ascitic fluids. About 90% of an injected dose of vancomycin is excreted by glomerular filtration; elimination $t_{1/2}$ is about 6 h in normal renal function. The drug accumulates if renal function is impaired, and dosage adjustments must be made. The drug can be cleared from plasma with hemodialysis.

Teicoplanin can be administered by intramuscular injection as well as intravenous administration. An intravenous dose of 1 g in adults produces plasma concentrations of 15–30 µg/mL 1 h after a 1- to 2-h infusion. Teicoplanin is highly bound by plasma proteins (90%–95%) and has an extremely long serum elimination $t_{1/2}$ (up to 100 h), allowing for once-daily dosing. Excretion is through glomerular filtration.

Telavancin achieves peak concentrations of approximately 90 µg/mL when administered intravenously at a dose of 10 mg/kg once daily. Telavancin is highly protein bound (>90%), with a $t_{1/2}$ of about 7 h. Studies of penetration into epithelial lining fluid and skin blister fluid demonstrated adequate tissue concentrations to provide effective therapy. Telavancin is eliminated primarily (70%–80%) by renal excretion, with a small component of metabolism. Dosage adjustment is required in renal dysfunction.

Dalbavancin and oritavancin have unique pharmacokinetic properties that allow for intermittent (weekly or less) dosing. Both are characterized by extremely long plasma half-lives (on the order of 10 days for terminal elimination) and are highly (>90%) protein bound. Penetration of dalbavancin into skin blister fluid and bone appears to be adequate, but penetration into CSF is very low. Between 33% and 50% of dalbavancin is eliminated unchanged in the urine, and dosage adjustment is recommended for renal dysfunction. Oritavancin has a large volume of distribution (~1 L/kg). Renal excretion is very slow and dosage adjustment is not required in moderate renal dysfunction.

Therapeutic Uses and Dosage

Vancomycin hydrochloride is available for intravenous use as a sterile powder for solution. It should be diluted and infused over at least a 60-min period to avoid infusion-related adverse reactions; the recommended initial dose for adults is 30–45 mg/kg/d in two or three divided doses. Current recommendations call for monitoring serum trough concentrations

(within 30 min prior to a dose) at steady state, typically before the fourth dose of a given dosage regimen (Rybak et al., 2009). A trough serum concentration of at least 10 µg/mL is recommended. For patients with more serious infections (including endocarditis, osteomyelitis, meningitis, and MRSA pneumonia), trough levels of 15–20 µg/mL are recommended. Pediatric doses are as follows: for newborns during the first week of life, 15 mg/kg initially, followed by 10 mg/kg every 12 h; for infants 8–30 days old, 15 mg/kg followed by 10 mg/kg every 8 h; for older infants and children, 10–15 mg/kg every 6 h. Alteration of dosage is required for patients with impaired renal function. In functionally anephric patients and patients receiving dialysis with non-high-flux membranes, administration of 1 g (~15 mg/kg) every 5–7 days typically achieves adequate serum levels. In patients receiving intermittent high-efficiency or high-flux dialysis, maintenance doses administered after each dialysis session are typically required. For treatment of *C. difficile* colitis, vancomycin is available as capsules for oral administration; alternatively, the intravenous formulation may be compounded into a solution for oral administration. The recommended oral dose of vancomycin is 125 mg four times daily, with escalation up to 500 mg four times daily in patients with life-threatening disease.

Telavancin is administered intravenously at a dose of 10 mg/kg daily, with dosage adjustment required for patients with renal dysfunction. The approved dosage of intravenous dalbavancin for treatment of skin and soft-tissue infection is 1000 mg at the initiation of treatment, followed by a 500-mg dose 7 days later. Oritavancin has been studied for skin and soft-tissue infections as a single 1200-mg intravenous dose.

Skin/Soft-Tissue and Bone/Joint Infections. Vancomycin has long been a mainstay in the treatment of skin/soft-tissue and bone/joint infections, where gram-positive organisms, including MRSA, are the leading pathogens (Stevens et al., 2014). Telavancin, dalbavancin, and oritavancin offer alternatives for treatment of this condition, with dalbavancin and oritavancin offering the option for infrequent dosing.

Respiratory Tract Infections. Vancomycin is employed for the treatment of pneumonia when MRSA is suspected. Because vancomycin penetration into lung tissue is relatively low, aggressive dosing is generally recommended. Telavancin displayed similar efficacy to vancomycin in studies of nosocomial pneumonia due to gram-positive pathogens.

CNS Infections. Vancomycin is a key component in the initial empirical treatment of community-acquired bacterial meningitis in locations where penicillin-resistant *S. pneumoniae* is common (Tunkel et al., 2004). Penetration of vancomycin across meninges is poor, especially with steroid coadministration; thus, aggressive dosing is typically warranted. Vancomycin is also used to treat nosocomial meningitis often caused by staphylococci. Intraventricular vancomycin has been used in ventricular shunt infections.

Endocarditis and Vascular Catheter Infections. Vancomycin is standard therapy for staphylococcal endocarditis when the isolate is methicillin resistant or patients have a severe penicillin allergy (Baddour et al., 2005). However, β -lactams such as nafcillin or cefazolin are more effective than vancomycin for treatment of MSSA bloodstream infections; thus, patients should only receive vancomycin for MSSA infections if they have a documented, life-threatening allergy. Vancomycin is an effective alternative for the treatment of endocarditis caused by viridans streptococci in patients who are allergic to penicillin. In combination with an aminoglycoside, it may be used for enterococcal endocarditis in patients with serious penicillin allergy or for penicillin-resistant isolates. Vancomycin is used for the treatment of vascular catheter infections due to gram-positive organisms.

Other Infections. Vancomycin is the drug of choice for patients with moderate-to-severe pseudomembranous colitis due to *C. difficile*. Vancomycin is frequently employed as a component of empiric therapy for patients with fever and neutropenia. It is also used in surgical prophylaxis in patients with β -lactam allergies or if there is a high risk of MRSA infection.

Adverse Effects

Infusion-Related Reactions. Rapid intravenous infusion of vancomycin may cause erythematous or urticarial reactions, flushing, tachycardia, and

hypotension (“red man” or “red neck” syndrome). The extreme flushing that can occur is not an allergic reaction but a direct effect of vancomycin on mast cells, causing them to release histamine. Typically, this reaction can be ameliorated by administering vancomycin more slowly, sometimes with premedication with histamine blockers. This reaction is generally not observed with teicoplanin but has been reported with lipoglycopeptides (i.e., telavancin).

Nephrotoxicity. Initial formulations of vancomycin contained impurities that were associated with a high incidence of nephrotoxicity. With the availability of formulations free of the impurities, there was a question regarding whether vancomycin was intrinsically nephrotoxic. However, as the recommended dosage range for vancomycin dosages has increased, it seems clear there is indeed a degree of dose-related nephrotoxicity (Lodise et al., 2009). Results of clinical trials suggest telavancin's nephrotoxicity may exceed that of vancomycin.

Other Toxic and Irritative Effects. True hypersensitivity reactions produced by glycopeptides are less common than the pseudoallergic infusion-related reactions and include macular skin rashes and anaphylaxis. Because of the long half-lives of dalbavancin and oritavancin, there is concern over prolonged effects if patients were to experience a severe hypersensitivity reaction. Telavancin can cause QT interval prolongation and is contraindicated in pregnancy due to teratogenic effects observed in animal studies. Auditory impairment, sometimes permanent, has been described in association with vancomycin use; some investigators believe ototoxicity is associated with excessive concentrations of vancomycin in plasma (60–100 µg/mL or greater).

Drug Interactions. Oritavancin has a minor effect on CYP-mediated metabolism; it should be used with warfarin only with careful monitoring. Caution should be used when using other nephrotoxic drugs with vancomycin or telavancin due to risks for additive nephrotoxicity.

Lipopeptides

Daptomycin, the only member of its class, is a cyclic lipopeptide antibiotic derived from *Streptomyces roseosporus* with bactericidal activity against gram-positive bacteria, including vancomycin-resistant isolates (Carpenter et al., 2004).

Antimicrobial Activity

Daptomycin is a bactericidal antibiotic selectively active against aerobic, facultative, and anaerobic gram-positive bacteria (see Table 59–1). Daptomycin may be active against vancomycin-resistant strains, although MICs tend to be higher for these organisms than for their vancomycin-susceptible counterparts (Critchley et al., 2003).

Mechanism of Action

Daptomycin binds to bacterial membranes, resulting in depolarization, loss of membrane potential, and cell death. It has concentration-dependent bactericidal activity.

Resistance to Lipopeptides

Daptomycin resistance has been reported to emerge while on therapy. Resistance occurs most commonly in treatment of high-inoculum infections (such as endocarditis) and among enterococci. The mechanisms of resistance to daptomycin have not been fully characterized but appear to be related to changes in cell surface charge that impede daptomycin binding. Interestingly, coadministration of β-lactams with daptomycin (even when the pathogen is resistant to the β-lactam) can reverse this resistance, suggesting potential combination therapy regimens.

ADME

Daptomycin is poorly absorbed orally and should be administered only intravenously. Direct toxicity to muscle precludes intramuscular injection. The serum $t_{1/2}$ is 8–9 h, permitting once-daily dosing. Approximately 80% of the administered dose is recovered in urine; a small amount is excreted in feces. Although the drug penetrates adequately into the lung, the drug is inactivated by pulmonary surfactant and thus is not useful in the treatment of pneumonia (Silverman et al., 2005). If the creatinine clearance is less than 30 mL/min, the dose is administered

only every 48 h. For patients on hemodialysis, the dose should be given immediately after dialysis.

Therapeutic Uses and Dosage

Daptomycin is indicated for treatment of complicated skin and soft-tissue infections (at 4 mg/kg/d) and complicated bacteremia and right-sided endocarditis (at 6 mg/kg/d), where its efficacy is comparable to that of vancomycin or antistaphylococcal β-lactams (Fowler et al., 2006). Use of higher doses (8–10 mg/kg) appears to be well tolerated and may provide additional benefit in difficult-to-treat infections (Figueroa et al., 2009).

Adverse Effects

Musculoskeletal Toxicity. Elevations of creatine kinase may occur; this does not require discontinuation unless findings suggest an otherwise-unexplained myopathy. Rhabdomyolysis has been reported to occur rarely.

Drug Interactions. Daptomycin does not affect CYPs and has no important drug-drug interactions. Caution is recommended when daptomycin is coadministered with aminoglycosides or statins because of potential risks of nephrotoxicity and myopathy, respectively.

Miscellaneous Agents

Metronidazole

Metronidazole is a nitroimidazole with broad activity against parasites and anaerobic bacteria. Only its antibacterial activity is discussed next; for an in-depth description, see Chapter 54.

Antimicrobial Activity and Resistance

The nitro group of metronidazole is reduced in anaerobic bacteria and some protozoans, producing the active form of the drug that interacts with DNA, disrupting its structure and inhibiting replication. Metronidazole displays excellent activity against most anaerobic bacteria, including *Bacteroides*, *Clostridium*, *Fusobacterium*, *Peptococcus*, *Peptostreptococcus*, and *Eubacterium*. It is less active against *Gardnerella* and *Helicobacter*, and the gram-positive anaerobes *Actinomyces*, *Propionibacterium*, and *Lactobacillus* are typically resistant. It lacks activity against aerobic bacteria. Acquired resistance is uncommon. In the case of *Bacteroides* spp., metronidazole resistance has been linked to a family of nitroimidazole (*nim*) resistance genes that can be encoded chromosomally or episomally. These *nim* genes appear to encode a nitroimidazole reductase capable of converting a 5-nitroimidazole to a 5-aminoimidazole, thus stopping the formation of the reactive nitroso group responsible for microbial killing.

Therapeutic Uses and Dosage

Metronidazole is a relatively inexpensive and versatile drug with efficacy against a broad spectrum of anaerobic bacteria. Typical doses are 250–500 mg three times daily, via the intravenous or oral routes. The drug is frequently given in combination with other antimicrobial agents to treat polymicrobial infections with aerobic and anaerobic bacteria. Metronidazole is used as a component of prophylaxis for colorectal surgery and is employed as a single agent to treat bacterial vaginosis. It is used in combination with other antibiotics and a proton pump inhibitor in regimens to treat infection with *H. pylori* (see Chapter 49). Metronidazole is used as therapy for mild-to-moderate *C. difficile* infection, although vancomycin is more effective for severe disease.

Bacitracin

Bacitracin is an antibiotic produced by the Tracy-I strain of *B. subtilis*. The bacitracins are a group of polypeptide antibiotics. The commercial products have multiple components; the major constituent is bacitracin A.

A unit of the antibiotic is equivalent to 26 µg of the USP standard.

Antimicrobial Activity, Mechanism of Action, and Resistance

Bacitracin inhibits the synthesis of the bacterial cell wall; a variety of gram-positive cocci and bacilli, *Neisseria*, *H. influenzae*, and *T. pallidum*, are sensitive to the drug at 0.1 unit/mL or less. *Actinomyces* and *Fusobacterium* are inhibited by concentrations of 0.5–5 units/mL.

1062 Enterobacteriaceae, *Pseudomonas*, *Candida* spp., and *Nocardia* are resistant to the drug. Few data are available on bacitracin resistance.

Therapeutic Uses and Dosage

Current use is restricted to topical application. Bacitracin is available in ophthalmic and dermatologic ointments; the antibiotic also is available as a powder for the extemporaneous compounding of topical solutions. A number of topical preparations of bacitracin, to which neomycin or polymyxin or both have been added, are available. For open infections, such as infected eczema and infected dermal ulcers, the local application of the antibiotic may be of some help in eradicating sensitive bacteria. Bacitracin rarely produces hypersensitivity. Suppurative conjunctivitis and infected corneal ulcer, when caused by susceptible bacteria, respond well to the topical use of bacitracin. Bacitracin has been used with limited success for eradication of nasal carriage of staphylococci.

Adverse Effects

Nephrotoxicity results from the parenteral use of bacitracin.

Mupirocin

Mupirocin is an antibiotic first isolated from *Pseudomonas fluorescens*. It is a mixture of several pseudomonic acids and is effective against gram-positive bacteria.

Antimicrobial Activity, Mechanism of Action, and Resistance

Mupirocin is for topical use only. The drug is bactericidal against many gram-positive and selected gram-negative bacteria. It has good activity

against *S. pyogenes*, MSSA, and MRSA. Mupirocin inhibits bacterial protein synthesis by reversible binding and inhibition of isoleucyl tRNA synthase. There is no cross-resistance with other classes of antibiotics. High-level resistance is mediated by a plasmid, which encodes a “bypass” Ile tRNA synthase that binds mupirocin poorly.

Therapeutic Uses and Dosage

Mupirocin is available as a 2% cream and a 2% ointment for dermatologic use and as a 2% ointment for intranasal use. The dermatologic preparations are indicated for treatment of traumatic skin lesions and impetigo secondarily infected with *S. aureus* or *S. pyogenes*. The nasal ointment is approved for eradication of *S. aureus* nasal carriage. The consensus is that patients who stand to benefit from mupirocin prophylaxis are those with proven *S. aureus* nasal colonization plus risk factors for distant infection or a history of skin or soft-tissue infections (Perl et al., 2002).

Adverse Effects

Mupirocin may cause irritation and sensitization at the site of application. Contact with the eyes causes irritation that may take several days to resolve. Polyethylene glycol present in the ointment can be absorbed from damaged skin. Application of the ointment to large surface areas should be avoided in patients with moderate-to-severe renal failure to avoid accumulation of polyethylene glycol.

Drug Facts for Your Personal Formulary: Protein Synthesis Inhibitors and Miscellaneous Antibacterial Agents

Drugs	Therapeutic Uses	Clinical Pharmacology and Tips
Tetracyclines and Glycylcyclines—Inhibitors of Bacterial Protein Synthesis		
General: Bacteriostatic; oral formulations interact with orally administered cations (calcium, iron, aluminum); avoid in pregnancy and children < 8 years old due to permanent tooth discoloration, photosensitivity		
Tetracycline (IV, PO)	<ul style="list-style-type: none">• Inflammatory acne• Use for other indications has largely been replaced by doxycycline	<ul style="list-style-type: none">• Good activity vs. rickettsiae, <i>Chlamydia</i>, <i>Mycoplasma</i>, <i>Legionella</i>, <i>Ureaplasma</i>, <i>Borrelia</i>, <i>Francisella tularensis</i>, <i>Pasteurella multocida</i>, <i>Bacillus anthracis</i>, <i>Helicobacter pylori</i>• Some activity vs. <i>Streptococcus pneumoniae</i>, <i>Streptococcus pyogenes</i>, <i>Staphylococcus aureus</i>, <i>Haemophilus influenzae</i>• Good CSF penetration• Renal excretion• Renal toxicity, hepatotoxicity at high doses
Doxycycline (IV, PO)	<ul style="list-style-type: none">• Community-acquired pneumonia• Skin/soft-tissue infection• Urogenital chlamydia• Lymphogranuloma venereum• Syphilis (penicillin alternative)• Rocky Mountain spotted fever• Anthrax, tularemia• Lyme disease, leptospirosis	<ul style="list-style-type: none">• Similar to tetracycline, with improved activity vs. streptococci and staphylococci• Good CSF penetration• Dual renal/biliary elimination• Preferred tetracycline for most indications due to more favorable activity, tolerability, and frequency of administration
Minocycline (IV, PO)	<ul style="list-style-type: none">• Skin/soft-tissue infections• Mycobacterial infections• Nocardiosis	<ul style="list-style-type: none">• Similar to doxycycline, with improved activity vs. staphylococci, <i>Acinetobacter</i>, and <i>Stenotrophomonas maltophilia</i>• Renal elimination• Vestibular toxicity
Tigecycline (IV)	<ul style="list-style-type: none">• Intra-abdominal infection• Skin and soft-tissue infection• Pneumonia• Increased risk of death in pooled analysis; reserve as alternative therapy	<ul style="list-style-type: none">• Similar to minocycline, with improved activity vs. <i>Escherichia coli</i>, <i>Klebsiella</i>, enterococci, <i>Bacteroides fragilis</i>• Wide distribution with low serum levels• Hepatic elimination

Chloramphenicol—Inhibitor of Bacterial Protein Synthesis		
General: Bacteriostatic; dose-dependent bone marrow suppression, idiosyncratic fatal aplastic anemia, fatal “gray baby syndrome” in neonates receiving high doses		
Chloramphenicol (IV, PO – not in the U.S.)	<ul style="list-style-type: none"> Rickettsial infections Bacterial meningitis Because of risk of fatal toxicities, reserve as alternative therapy 	<ul style="list-style-type: none"> Good activity vs. <i>S. pneumoniae</i>, <i>H. influenzae</i>, <i>Neisseria meningitidis</i>, rickettsiae, <i>Vibrio</i>, <i>Enterococcus</i> Variable serum levels due to clearance of prodrug before hydrolysis Excellent CSF penetration Hepatic clearance
Macrolides and Ketolides—Inhibitors of Bacterial Protein Synthesis		
General: Bacteriostatic; widely distributed but with limited CSF penetration, gastrointestinal distress, QT prolongation, major (erythromycin, clarithromycin, telithromycin) to minor (azithromycin) inhibitor of drug-metabolizing CYPs		
Erythromycin (IV, PO, topical)	<ul style="list-style-type: none"> Erysipelas and cellulitis Ophthalmia neonatorum Diphtheria Pertussis 	<ul style="list-style-type: none"> Good activity against <i>Mycoplasma</i>, <i>Chlamydia</i>, <i>Legionella</i>, <i>Campylobacter</i>, <i>Bordetella pertussis</i>, <i>Corynebacterium diphtheriae</i> Some activity against <i>S. pneumoniae</i>, <i>S. pyogenes</i>, <i>H. influenzae</i> Oral formulations have variable absorption Stimulates motilin receptors; gastrointestinal prokinetic properties Cholestatic hepatitis with long-term use
Clarithromycin (PO)	<ul style="list-style-type: none"> Erysipelas and cellulitis Community-acquired pneumonia Acute exacerbations of chronic bronchitis <i>Helicobacter pylori</i> gastritis (in combination with other agents) <i>Mycobacterium avium</i> treatment and prophylaxis 	<ul style="list-style-type: none"> Similar to erythromycin, with improved activity vs. streptococci and staphylococci Good activity vs. <i>Moraxella catarrhalis</i>, <i>H. pylori</i>, and nontuberculous mycobacteria Active metabolite Some drug accumulation in severe renal impairment Tinnitus at high doses
Azithromycin (IV, PO)	<ul style="list-style-type: none"> Community-acquired pneumonia Acute exacerbations of chronic bronchitis Otitis media Bacterial pharyngitis Chlamydia <i>Mycobacterium avium</i> treatment and prophylaxis 	<ul style="list-style-type: none"> Similar to clarithromycin, improved activity vs. <i>H. influenzae</i> Extensive tissue distribution and concentration in tissues Anti-inflammatory properties Long $t_{1/2}$ ~48 h
Telithromycin (PO)	<ul style="list-style-type: none"> Community-acquired infection Due to risk of severe hepatotoxicity, reserve as alternative therapy 	<ul style="list-style-type: none"> Similar to azithromycin with activity against macrolide-resistant streptococci and staphylococci Severe hepatotoxicity
Lincosamides—Bacteriostatic Protein Synthesis Inhibitor		
Clindamycin (IV, PO, topical)	<ul style="list-style-type: none"> Skin and soft-tissue infection Inflammatory acne Lung abscess Streptococcal pharyngitis <i>Pneumocystis pneumonia</i> <i>Toxoplasma encephalitis</i> Nonsevere malaria 	<ul style="list-style-type: none"> Good activity vs. <i>S. pneumoniae</i>, <i>S. pyogenes</i>, viridans streptococci, <i>Actinomyces</i>, <i>Nocardia</i> Some activity versus <i>S. aureus</i>, <i>Bacteroides</i> spp., <i>Toxoplasma</i>, <i>Pneumocystis</i>, <i>Plasmodium</i> Wide tissue distribution, especially into bone; modest CSF penetration Metabolized in liver, excreted in urine and bile Diarrhea, rarely <i>Clostridium difficile</i> colitis
Streptogramins—Bactericidal Protein Synthesis Inhibitor, Components Act Synergistically		
Quinupristin/dalfopristin (IV)	<ul style="list-style-type: none"> Skin and soft-tissue infection Vancomycin-resistant <i>Enterococcus faecium</i> infections 	<ul style="list-style-type: none"> Good activity against streptococci, staphylococci, <i>E. faecium</i>, <i>Mycoplasma</i>, <i>Legionella</i>, <i>Chlamydia</i> Hepatic metabolism with biliary excretion Infusion site phlebitis Arthralgias, myalgias CYP inhibitor
Oxazolidinones—Bacteriostatic Protein Synthesis Inhibitors		
General: Excellent oral absorption; wide distribution, including to CNS; myelosuppression; peripheral neuropathy with long-term use; risk of serotonin syndrome with concomitant antidepressant use		
Linezolid (IV, PO)	<ul style="list-style-type: none"> Skin and soft-tissue infections Pneumonia Vancomycin-resistant enterococcal infections Nocardiosis Drug-resistant tuberculosis 	<ul style="list-style-type: none"> Good activity against streptococci, staphylococci, enterococci, <i>Nocardia</i>, <i>Listeria</i> Some activity against mycobacteria Nonenzymatic degradation with elimination in urine
Tedizolid (IV, PO)	<ul style="list-style-type: none"> Skin and soft-tissue infections 	<ul style="list-style-type: none"> Similar activity to linezolid but lower risk of myelosuppression and drug interactions Hepatic metabolism and fecal excretion Longer $t_{1/2}$ than linezolid

Drug Facts for Your Personal Formulary: Protein Synthesis Inhibitors and Miscellaneous Antibacterial Agents (continued)

Drugs	Therapeutic Uses	Clinical Pharmacology and Tips
Polymyxins—Bactericidal Cell Membrane-Disrupting Agents		
Colistin (polymyxin E) (IV, inhaled)	<ul style="list-style-type: none"> Serious infections due to multidrug-resistant gram-negative organisms Prevention of cystic fibrosis exacerbations (inhaled) 	<ul style="list-style-type: none"> Good activity vs. <i>Acinetobacter</i>, <i>E. coli</i>, <i>Klebsiella</i>, <i>Pseudomonas</i>, including multidrug-resistant strains Prodrug; complex pharmacokinetics with renal and nonrenal elimination Substantial nephrotoxicity and neurotoxicity
Polymyxin B (IV, topical)	<ul style="list-style-type: none"> Serious infections due to multidrug-resistant gram-negative organisms Topical treatment/prevention of skin and soft-tissue infections 	<ul style="list-style-type: none"> Similar activity and toxicity as colistin Nonrenally eliminated; does not achieve high urinary levels
Glycopeptides and Lipoglycopeptides—Bactericidal Inhibitors of Cell Wall Synthesis		
Vancomycin (IV, PO)	<ul style="list-style-type: none"> Skin and soft-tissue infections Bacteremia and endocarditis due to gram-positive bacteria Pneumonia Meningitis <i>Clostridium difficile</i> colitis (oral formulation) Surgical prophylaxis for procedures with high risk of MRSA 	<ul style="list-style-type: none"> Good activity vs. vast majority of gram-positive bacteria, <i>Staphylococcus</i> (including MRSA), streptococci, <i>E. faecalis</i> Oral formulation not well absorbed and only used for treatment of <i>C. difficile</i> colitis Modest CNS penetration in presence of inflammation Renal elimination Infusion-related reactions (red man syndrome) associated with rapid infusion Nephrotoxicity at high doses
Telavancin (IV)	<ul style="list-style-type: none"> Skin and soft-tissue infections Pneumonia 	<ul style="list-style-type: none"> Similar activity to vancomycin with activity against some vancomycin-resistant strains of <i>Enterococcus</i> Renal elimination Higher nephrotoxicity relative to vancomycin QT prolongation Avoid in pregnancy
Dalbavancin (IV)	<ul style="list-style-type: none"> Skin and soft-tissue infections 	<ul style="list-style-type: none"> Similar activity to vancomycin Highly protein bound Extremely long $t_{1/2}$; once-weekly dosing
Oritavancin (IV)	<ul style="list-style-type: none"> Skin and soft-tissue infections 	<ul style="list-style-type: none"> Similar activity to telavancin Highly protein bound Extremely long half-life; single-dose therapy for skin infections
Daptomycin (IV)	<ul style="list-style-type: none"> Skin and soft-tissue infections Staphylococcal and streptococcal bacteremia Vancomycin-resistant enterococcal infections 	<ul style="list-style-type: none"> Lipopeptide, similar activity to vancomycin Retains activity against some vancomycin-resistant strains of <i>Enterococcus</i> Protein bound; limited CNS penetration Inactivated by pulmonary surfactant; not effective for pneumonia Renal elimination Rare myositis and rhabdomyolysis
Nitroimidazoles—Disruptors of DNA Synthesis in Anaerobes		
Metronidazole (IV, PO, topical)	<ul style="list-style-type: none"> <i>Clostridium difficile</i> colitis Empiric coverage of anaerobic organisms, as in intra-abdominal and skin and soft-tissue infections <i>Helicobacter pylori</i> gastritis (in combination with other agents) Bacterial vaginosis 	<ul style="list-style-type: none"> Bacterial spectrum limited to anaerobic organisms, including <i>B. fragilis</i> and <i>Clostridium</i> Excellent absorption Wide distribution, including CNS Hepatic elimination CYP inhibitor; drug interactions with warfarin Peripheral neuropathy with prolonged use
Topical Agents—Inhibitors of Bacterial Cell Wall Synthesis		
Bacitracin (topical)	<ul style="list-style-type: none"> Prevention and treatment of skin and soft-tissue infections Ophthalmic infections 	<ul style="list-style-type: none"> Activity against broad array of gram-positive and gram-negative organisms Nephrotoxicity with parenteral use
Mupirocin (topical)	<ul style="list-style-type: none"> Treatment of minor skin infections Eradication of nasal carriage of <i>S. aureus</i> 	<ul style="list-style-type: none"> Activity against broad array of gram-positive and gram-negative organisms May cause irritation at site of application

Chapter 60

Chemotherapy of Tuberculosis, *Mycobacterium avium* Complex Disease, and Leprosy

Tawanda Gumbo

ANTIMYCOBACTERIAL DRUGS

- Rifamycins: Rifampin, Rifapentine, and Rifabutin
- Pyrazinamide
- Isoniazid
- Ethambutol
- Oxazolidinones: Linezolid, Tedizolid, and Sutezolid
- Aminoglycosides: Streptomycin, Amikacin, and Kanamycin
- Bicyclic Nitroimidazoles: Delamanid and Pretomanid
- Clofazimine
- Fluoroquinolones
- Bedaquiline
- Ethionamide
- *Para*-aminosalicylic Acid
- Cycloserine
- Capreomycin
- β -Lactam Antibiotics for the Treatment of TB
- Macrolides
- Dapsone

- Definitive and Suppressive Therapy

PRINCIPLES OF ANTILEPROSY THERAPY

- Types of Antileprosy Therapy
- Therapy of Other Nontuberculous Mycobacteria

Mycobacteria have caused epic diseases: TB and leprosy have terrorized humankind since antiquity. Although the burden of leprosy has decreased, TB is still the most important infectious killer of humans. *Mycobacterium abscessus* has now been called a new “antibiotic” nightmare because of its tenacity, lack of response to combination antibiotics, and a nearly universal propensity to develop acquired drug resistance. *Mycobacterium avium-intracellulare* (or MAC) infection continues to be difficult to treat, mainly due to three natural barriers:

- **Cell wall.** *Mycobacterium*, from the Greek *mycos*, refers to mycobacteria’s waxy appearance, which is due to the composition of the cell walls. More than 60% of the cell wall is lipid, mainly mycolic acids composed of 2-branched, 3-hydroxy fatty acids with chains made of 76–90 carbon atoms! This extraordinary shield prevents many pharmacological compounds from getting to the bacterial cell membrane or inside the cytosol.
- **Efflux pumps.** A second layer of defense comes from an abundance of efflux pumps in the cell membrane. These transport proteins pump out potentially harmful chemicals from the bacterial cytoplasm back into the extracellular space and are responsible for the native resistance of mycobacteria to many standard antibiotics (Morris et al., 2005). As an example, ABC permeases comprise a full 2.5% of the genome of *Mycobacterium tuberculosis*.
- **Location in host.** A third barrier is the propensity of some of the bacilli to hide inside the patient’s cells, thereby surrounding themselves with an extra physicochemical barrier that antimicrobial agents must cross to be effective.

Mycobacteria are defined by their rate of growth on agar as *rapid* and *slow* growers (see list in Table 60–1). Rapid growers are visible to the naked eye within 7 days; slow growers are visible later. Slow growers tend to be susceptible to antibiotics specifically developed for mycobacteria, whereas rapid growers tend to be also susceptible to antibiotics used against many other bacteria. Recent evidence suggests that in countries such as the U.S.,

M. abscessus now accounts for 80% of rapid growers from the respiratory system (Griffith et al., 2007). The pharmacology of drugs developed against slow growers is discussed in this chapter. However, rapid growers tend to be treated with antibiotics used to treat nonmycobacteria, such as macrolides, aminoglycosides, quinolones, and β -lactams, whose pharmacology is discussed in Chapters 56–59.

The mechanisms of action of the antimycobacterial drugs are summarized in Figure 60–1. The mycobacterial mechanisms of resistance to these drugs are summarized in Figure 60–2. The model termed the *antibiotic resistance arrow of time* has combined these mechanisms in an arrow of time, starting with early induction of efflux pumps that leads to chromosomal mutations in drug target proteins and efflux

HISTORY

The first successful drug for treating TB was PAS, developed by Lehman in 1943. A more dramatic success came when Waksman and Schatz developed streptomycin. Further efforts led to development of thiacetazone by Domagk in 1946; isoniazid by Squibb, Hoffman La Roche, and Bayer in 1952; pyrazinamide by Kushner and colleagues in 1952; and rifamycins by Sensi and Margalith in 1957. Ethambutol was discovered at Lederle Laboratories in 1961. As might be anticipated, the use of all of these drugs presents problems of drug resistance, adverse events, and drug interactions. Therefore, newer classes of agents are being developed. Starting in 2000 with the work of Stover et al. and Matsumoto et al. in 2006, specific antimycobacterial agents such as pretomanid and bedaquiline have been discovered and introduced to clinical care. In addition, pharmacophores in clinical use for other bacteria have been repurposed as antimycobacterial agents, including moxifloxacin and levofloxacin, oxazolidinones, and β -lactams, based on recent clinical trials.

Abbreviations

ABC: ATP binding cassette
ACP: acyl carrier protein
AUC: area under the curve
CNS: central nervous system
CoA: coenzyme A
CSF: cerebrospinal fluid
DDS: diamino-diphenylsulfone
DHFR: dihydrofolate reductase
DOT: directly observed therapy
FAD: flavin adenine dinucleotide
FGD1: NADP-dependent glucose-6-phosphate dehydrogenase
GABA: γ -aminobutyric acid
GFR: glomerular filtration rate
GI: gastrointestinal
G6PD: glucose-6-phosphate dehydrogenase
HIV: human immunodeficiency virus
IC₅₀: concentration causing 50% inhibition
Ig: immunoglobulin
INH: isoniazid
InhA: enoyl acyl carrier protein reductase
KasA: β -ketoacyl-acyl carrier protein synthase
KatG: catalase peroxidase
MAC: <i>Mycobacterium avium</i> complex
MDR-TB: TB resistant to isoniazid and rifampicin
MIC: minimum inhibitory concentration
NO: nitric oxide
NRPB: nonreplicating persistent bacilli
NAT2: N-acetyltransferase type 2
PABA: para-aminobenzoic acid
PAS: para-aminosalicylic acid
PD: pharmacodynamics
PK: pharmacokinetics
POA: pyrazinoic acid
TB: tuberculosis
V_d: volume of distribution
XDR-TB: MDR-TB that is also resistant to fluoroquinolones and at least one of three injectable second-line drugs

pumps (Gumbo et al., 2014; Schmalstieg et al., 2012; Srivastava et al., 2010). This chain of events is initiated by subtherapeutic concentrations due to poor dosing practices in the face of ever-present between-patient PK variability (Pasipanodya et al., 2013; Srivastava et al., 2011a). PK parameter definitions are presented in terms of Figure 52-1 and Equation 52-1.

Antimycobacterial Drugs

Rifamycins: Rifampin, Rifapentine, and Rifabutin

Rifamycins are macrocyclic antibiotics. Rifampin or rifampicin, rifapentine, and rifabutin are macrocyclic antibiotics important in the treatment of mycobacterial diseases.

Mechanism of Action

The mechanism of action for rifamycins is typified by rifampin's action against *M. tuberculosis*. Rifampin enters bacilli in a concentration-dependent manner, achieving steady-state concentrations within 15 min (Gumbo et al., 2007a). Rifampin binds to the β subunit of DNA-dependent RNA polymerase (*rpoB*) to form a stable drug-enzyme complex. Drug binding suppresses chain formation in RNA synthesis.

TABLE 60-1 ■ PATHOGENIC MYCOBACTERIAL SLOW AND RAPID GROWERS (RUNYON CLASSIFICATION)

SLOW GROWERS

Runyon I: Photochromogens

Mycobacterium kansasii

Mycobacterium marinum

Runyon II: Scotochromogens

Mycobacterium scrofulaceum

Mycobacterium szulgai

Mycobacterium goodii

Runyon III: Nonchromogens

Mycobacterium avium complex

Mycobacterium haemophilum

Mycobacterium xenopi

RAPID GROWERS

Runyon IV

Mycobacterium fortuitum complex

Mycobacterium smegmatis group

Mycobacterium abscessus

Slow growers tend to be susceptible to antibiotics specifically developed for Mycobacteria. Rapid growers tend to be susceptible to antibiotics also used against many other bacteria.

Antibacterial Activity

Rifampin inhibits the growth of most gram-positive bacteria as well as many gram-negative microorganisms, such as *Escherichia coli*, *Pseudomonas*, indole-positive and indole-negative *Proteus*, and *Klebsiella*. Rifampin is very active against *Staphylococcus aureus* and coagulase-negative staphylococci. The drug also is highly active against *Neisseria meningitidis* and *Haemophilus influenzae*. Rifampin inhibits the growth of *Legionella* species in cell culture and in animal models.

Rifampin inhibits the growth of many *M. tuberculosis* clinical isolates in vitro at concentrations of 0.06–0.25 mg/L (Heifets, 1991). Rifampin is also bactericidal against *Mycobacterium leprae*. *Mycobacterium kansasii* is inhibited by 0.25–1 mg/L. Most strains of *Mycobacterium scrofulaceum*, *Mycobacterium intracellulare*, and *Mycobacterium avium* are suppressed by concentrations of 4 mg/L. *Mycobacterium abscessus* inactivates rifampin via an ADP-ribosyltransferase and monooxygenase, making the bacteria innately resistant to rifamycins (Nessar et al., 2012). Rifapentine MICs are similar to those of rifampin. Rifabutin inhibits the growth of most MAC isolates at concentrations ranging from 0.25 to 1 mg/L. Rifabutin also inhibits the growth of many strains of *M. tuberculosis* at concentrations of 0.125 mg/L or less and in vitro has better MICs than rifampin.

Bacterial Resistance

The prevalence of rifampin-resistant isolates (1 in every 10⁷ to 10⁸ bacilli) is due to an alteration of the target of this drug, *rpoB*, with resistance in 86% of cases due to mutations at codons 526 and 531 of the *rpoB* gene (Somoskovi et al., 2001). Rifamycin monoresistance occurs at higher rates when patients with AIDS and multicavitary TB are treated with either rifapentine or rifabutin (Burman et al., 2006). Efflux pump induction, and mutations in efflux pumps, have now been demonstrated to be associated with rifamycin resistance (Li et al., 2015).

ADME

After oral administration, the rifamycins are absorbed to variable extents (Table 60-2) (Burman et al., 2001). Food decreases the rifampin C_{pmax} by one-third; a high-fat meal increases the AUC of rifapentine by 50%. Food has no effect on rifabutin absorption. Thus, rifampin should be taken on an empty stomach, whereas rifapentine should be taken with food if possible.

Figure 60-1 Mechanisms of action of established and experimental drugs used for the chemotherapy of mycobacterial infections. Approved drugs for the chemotherapy of mycobacterial diseases may be grouped according to the sites of action indicated by the pictures above that expand regions of the mycobacterium: inhibitors of nucleic acid and protein synthesis; disruptors of cell wall and cell membrane synthesis; inhibitors of membrane transport. Specific antimycobacterial agents and their mechanisms of action are also listed. Rifamycin is used as a generic term for several drugs, of which rifampin is used most frequently. Clofazimine, whose mode of action is not understood, is omitted.

Rifamycins are metabolized by microsomal B-esterases and cholinesterases. A major pathway for rifabutin elimination is CYP3A. Due to autoinduction, all three rifamycins reduce their own AUCs with repeated administration (Table 60-3). They have good penetration into many tissues, but peak concentration and AUCs in the CNS and pericardial fluid reach only about 13%–20% of those in plasma (Nau et al., 1992; Shenje et al., 2015). The drugs and metabolites are excreted by bile and eliminated via feces, with urine elimination accounting for only one-third and less of metabolites.

The population PK of rifampin are best described using a one-compartment model with transit compartment absorption (Wilkins

et al., 2008), using the PK parameters in Table 60-2. Rifapentine PK are likewise best described using a one-compartment open model with first-order absorption and elimination (Langdon et al., 2005). The PK parameters are summarized in Table 60-2. However, for each 1-kg weight increase above 50 kg, systemic clearance increases by 0.05 L/h and V_d by 0.69 L. Thus, C_{pmax} and AUC decrease with increasing patient weight above 50 kg.

In contrast, rifabutin PK are best described by a two-compartment open model with first-order absorption and elimination. Rifabutin disposition is biexponential. Rifabutin concentrations are substantially higher in tissue than in plasma due to its lipophilic properties, leading to the very high

Figure 60-2 Mechanisms of resistance in mycobacteria.

TABLE 60-2 ■ POPULATION PHARMACOKINETIC PARAMETER ESTIMATES FOR ANTIMYCOBACTERIAL DRUGS IN ADULT PATIENTS

	PARAMETER ESTIMATE		
	k_a (h ⁻¹)	Systemic clearance (L/h)	V_d (L)
Rifampin	1.15	19	53
Rifapentine	0.6	2.03	37.8
Rifabutin	0.2	61	231/1050 ^a
Pyrazinamide	3.56	3.4	29.2
Isoniazid	2.3	22.1	35.2
Ethambutol	0.7	1.3 ^b	6.0 ^b
Clofazimine	0.7	0.6/76.7	1470
Dapsone	1.04	1.83	69.6
Bedaquiline	—	2.62	198/8550 ^a
Ethionamide	0.25	1.9 ^b	3.2 ^b
Para-aminosalicylic acid	0.4	0.3 ^b	0.9 ^b
Cycloserine	1.9	0.04 ^b	0.5 ^b

k_a is the absorption constant (see Chapter 52).

^aVolume of central compartment/volume of peripheral compartment.

^bExpressed per kilogram of body weight.

apparent volumes of distribution (Table 60-2). The consequence is that C_{pmax} values for rifabutin are lower than one would predict by comparison with other rifamycins. The volume of peripheral compartment decreases by 27% with concomitant azithromycin administration; tobacco smoking increases the volume by 39%.

Microbial Pharmacokinetics-Pharmacodynamics

Rifampin's bactericidal and sterilizing effect activity are best optimized by high AUCs and a high AUC/MIC ratio (Gumbo et al., 2007a; Pasipanodya et al., 2013). However, resistance suppression and rifampin's enduring postantibiotic effect are best optimized by high C_{pmax}/MIC . Therefore, the duration of time that the rifampin concentration persists above the MIC is of less importance. This means that the $t_{1/2}$ of a rifamycin is less of an issue in optimizing therapy, and that if patients could tolerate it, higher doses would lead to higher bactericidal activities while suppressing resistance. Recent clinical trials have confirmed better sputum bacillary decline with up to 3.5 times higher rifampin doses than currently used, which would increase both AUC/MIC and C_{pmax}/MIC

nonlinearly (Boeree et al., 2015). Currently, these larger rifampin doses are in phase III trials.

Therapeutic Uses

Rifampin for oral administration is available alone and as a fixed-dose combination with isoniazid (150 mg isoniazid, 300 mg rifampin) or with isoniazid and pyrazinamide (50 mg isoniazid, 120 mg rifampin, and 300 mg pyrazinamide). A parenteral form of rifampin is also available. The dose of rifampin for treatment of TB in adults is 600 mg, given once daily, either 1 h before or 2 h after a meal. Children should receive 15 mg/kg (range 10–20 mg/kg), with the maximum dose 600 mg/d, given in the same way. Rifabutin is administered at 5 mg/kg/d and rifapentine at 10 mg/kg once a week.

Rifampin is also useful for the prophylaxis of meningococcal disease and *H. influenzae* meningitis. To prevent meningococcal disease, adults may be treated with 600 mg twice daily for 2 days or 600 mg once daily for 4 days; children older than 1 month should receive 10–15 mg/kg, to a maximum of 600 mg. Combined with a β -lactam antibiotic or vancomycin,

TABLE 60-3 ■ PHARMACOKINETIC PARAMETERS OF RIFAMPIN, RIFABUTIN, AND RIFAPENTINE

	RIFABUTIN	RIFAMPIN	RIFAPENTINE
Protein binding (%)	71	85	97
Oral bioavailability (%)	20	68	—
t_{max} (h)	2.5–4.0	1.5–2.0	5.0–6.0
C_{max} total (μg/mL)	0.2–0.6	8–20	8–30
C_{max} free drug (μg/mL)	0.1	1.5	0.5
$t_{1/2}$ (h)	32–67	2–5	14–18
Intracellular/extracellular penetration	9	5	24–60
Autoinduction (AUC decrease)	40%	38%	20%
CYP3A induction	Weak	Pronounced	Moderate
CYP3A substrate	Yes	No	No

rifampin may be useful for therapy in selected cases of staphylococcal endocarditis or osteomyelitis, especially those caused by staphylococci “tolerant” to penicillin. Rifampin may also be indicated for the eradication of the staphylococcal nasal carrier state in patients with chronic furunculosis. In the treatment of brucellosis, 900 mg a day rifampin can be combined with doxycycline for 6 weeks.

Untoward Effects

Rifampin is generally well tolerated in patients. Usual doses result in less than 4% of patients with TB developing significant adverse reactions; the most common are rash (0.8%), fever (0.5%), and nausea and vomiting (1.5%). Rarely, hepatitis and deaths due to liver failure have been observed in patients who received other hepatotoxic agents in addition to rifampin or who had preexisting liver disease. Chronic liver disease, alcoholism, and old age appear to increase the incidence of severe hepatic problems. GI disturbances have occasionally required discontinuation of the drug. Various nonspecific symptoms related to the nervous system also have been noted.

Hypersensitivity reactions may be encountered. High-dose rifampin should not be administered on a dosing schedule of less than twice weekly because this is associated with a flu-like syndrome of fever, chills, and myalgias in 20% of patients so treated. The syndrome also may include eosinophilia, interstitial nephritis, acute tubular necrosis, thrombocytopenia, hemolytic anemia, and shock. Light chain proteinuria has also been documented with rifampin use. Thrombocytopenia, transient leukopenia, and anemia have occurred during therapy. Because the potential teratogenicity of rifampin is unknown and the drug is known to cross the placenta, it is best to avoid the use of this agent during pregnancy.

Rifabutin is generally well tolerated; primary reasons for discontinuation of therapy include rash (4%), GI intolerance (3%), and neutropenia (2%) (Nightingale et al., 1993). Neutropenia occurred in 25% of patients with severe HIV infection who received rifabutin. Uveitis and arthralgias have occurred in patients receiving rifabutin doses greater than 450 mg daily in combination with clarithromycin or fluconazole. Patients should be cautioned to discontinue the drug if visual symptoms (pain or blurred vision) occur. Rifabutin causes an orange-tan discoloration of skin, urine, feces, saliva, tears, and contact lenses, like rifampin. Rarely, thrombocytopenia, a flu-like syndrome, hemolysis, myositis, chest pain, and hepatitis develop in patients treated with rifabutin. Unique side effects include polymyalgia, pseudojaundice, and anterior uveitis.

Rifamycin Overdose

Rifampin overdose is uncommon. The most prominent symptoms are the orange discoloration of skin, fluids, and mucosal surfaces, leading to the term *red-man syndrome*. Overdose can be life threatening. Treatment consists of supportive measures; there is no antidote.

Drug Interactions

Because rifampin potently induces CYPs 1A2, 2C9, 2C19, and 3A4, its administration results in a decreased $t_{1/2}$ for a number of compounds that are metabolized by these CYPs. Rifabutin is a less-potent inducer of CYPs than rifampin; however, rifabutin does induce hepatic microsomal enzymes and decreases the $t_{1/2}$ of zidovudine, prednisone, digitoxin, quinidine, ketoconazole, propranolol, phenytoin, sulfonyleureas, and warfarin. It has less effect than rifampin on serum levels of indinavir and nelfinavir. Compared to rifabutin and rifampin, the CYP-inducing effects of rifapentine are intermediate.

Pyrazinamide

Pyrazinamide is the synthetic pyrazine analogue of nicotinamide. Pyrazinamide is also known as pyrazinoic acid amide, pyrazine carboxylamide, and pyrazinecarboxamide. Pyrazinamide was first synthesized at Merck in 1936 in Germany but was first examined as an anti-TB agent in 1952.

Mechanism of Action

Pyrazinamide is activated by acidic conditions. Several mechanisms of action have been proposed. In one model, pyrazinamide passively diffuses into mycobacterial cells, in which *M. tuberculosis* pyrazinamidase (encoded by the *pncA* gene) deaminates pyrazinamide to pyrazinoic acid (POA⁻, in its dissociated form), which is then followed by passive diffusion of the POA⁻ to the extracellular milieu (Zhang et al., 1999). In an acidic extracellular milieu, a fraction of POA⁻ is protonated to the uncharged form, POAH, a more lipid-soluble form that reenters the bacillus and accumulates due to a deficient efflux pump. The Henderson-Hasselbalch equilibrium (Chapter 2) progressively favors the formation of POAH and its equilibration across membranes as the pH of the extracellular medium declines toward the pK_a of pyrazinoic acid, 2.9. The acidification of the intracellular milieu is believed to inhibit enzyme function and collapse the transmembrane proton motive force, thereby killing the bacteria. Inhibitors of energy metabolism or reduced energy production states lead to enhanced pyrazinamide effect (Zhang et al., 2014). A specific target of pyrazinamide has been proposed to be ribosomal protein S1 (encoded by *RpsA*) in the trans-translation process, so that toxic proteins due to stress accumulate and kill the bacteria (Shi et al., 2011). In addition, pyrazinamide's target may include an aspartate decarboxylase (encoded by *panD*) involved in making precursors needed for pantothenate and CoA biosynthesis in persistent *M. tuberculosis* (Zhang et al., 2013).

Antibacterial Activity

Pyrazinamide exhibits antimicrobial activity in vitro only at acidic pH. At pH 5.9, 95% of clinical isolates have an MIC of 6.25–200 mg/L (Gumbo et al., 2014).

Mechanisms of Resistance

Pyrazinamide-resistant *M. tuberculosis* expresses pyrazinamidase with reduced affinity for pyrazinamide. This reduced affinity decreases the conversion of pyrazinamide to POA. Single point mutations in the *pncA* gene are encountered in some clinical isolates. In addition, mutations in the genes encoding proposed pyrazinamide targets of *RpsA* and *panD* are encountered in pyrazinamide resistance (Zhang et al., 2014). Finally, it has been demonstrated that the efflux rate of POA predicts pyrazinamide resistance with greater than 93% sensitivity and specificity, suggesting a role for efflux pumps in this drug's resistance (Zimic et al., 2012).

ADME

The oral bioavailability of pyrazinamide exceeds 90%. GI absorption segregates patients into two groups: fast absorbers (56%), with an absorption rate constant of 3.56/h, and slow absorbers (44%), with an absorption rate of 1.25/h (Wilkins et al., 2006). The drug is concentrated 20-fold in lung epithelial lining fluid (Conte et al., 2000). Pyrazinamide is metabolized by microsomal deamidase to POA and subsequently hydroxylated to 5-hydroxy-POA, which is then excreted by the kidneys. CL (clearance) and V_d (volume of distribution) increase with patient mass (0.5 L/h and 4.3 L for every 10 kg above 50 kg), and V_d is larger in males (by 4.5 L) (see Table 60–2). This has several implications: The $t_{1/2}$ of pyrazinamide will vary considerably based on weight and gender, and the AUC_{0-24} will decrease with increase in weight for the same dose (same mg drug/kg body weight). Pyrazinamide clearance is reduced in renal failure; therefore, the dosing frequency is reduced to three times a week at low glomerular filtration rates. Hemodialysis removes pyrazinamide; therefore, the drug needs to be redosed after each session of hemodialysis (Malone et al., 1999b).

Microbial Pharmacokinetics-Pharmacodynamics

Pyrazinamide's sterilizing effect is closely linked to AUC_{0-24}/MIC (Chigutsa et al., 2015; Gumbo et al., 2009). Such clinical parameters as relapse, cure at the end of therapy, and patient death have been confirmed to be predicted by the AUC_{0-24} and by the MIC (Gumbo et al., 2014; Pasipanodya et al., 2013).

Therapeutic Uses

The coadministration of pyrazinamide with isoniazid or rifampin has led to a one-third reduction in the duration of anti-TB therapy and a

1072 two-thirds reduction in TB relapse. This led to reduction in length of therapy to 6 months, producing the current “short-course” chemotherapy. Pyrazinamide is administered at an oral dose of 35 mg/kg (30–40) mg/kg/d.

Untoward Effects

Injury to the liver is the most serious side effect of pyrazinamide. When a dose of 40–50 mg/kg is administered orally, signs and symptoms of hepatic disease appear in about 15% of patients, with jaundice in 2%–3% and death due to hepatic necrosis in rare instances. Current regimens employed (15–30 mg/kg/d) are much safer. Prior to pyrazinamide administration, all patients should undergo studies of hepatic function, and these studies should be repeated at frequent intervals during the entire period of treatment. If evidence of significant hepatic damage becomes apparent, therapy must be stopped. Pyrazinamide should not be given to individuals with hepatic dysfunction unless this is absolutely unavoidable.

In nearly all patients, pyrazinamide inhibits excretion of urate, resulting in hyperuricemia, which may cause acute episodes of gout. Other untoward effects observed with pyrazinamide include arthralgias, anorexia, nausea and vomiting, dysuria, malaise, and fever. In the U.S., the use of pyrazinamide is not approved during pregnancy because of inadequate data on teratogenicity.

Isoniazid

Isoniazid (isonicotinic acid hydrazide), also called INH (Figure 60–3), is an important drug for the chemotherapy of drug-susceptible TB. All patients infected with isoniazid-sensitive strains of the tubercle bacillus receive the drug if they can tolerate it. The use of combination therapy (isoniazid + pyrazinamide + rifampin) provides the basis for short-course therapy and improved cure rates.

Mechanism of Action

Isoniazid enters bacilli by passive diffusion. The drug is not directly toxic to the bacillus but must be activated to its toxic form within the bacillus by KatG, a multifunctional catalase-peroxidase. KatG catalyzes the production from isoniazid of an isonicotinoyl radical that subsequently

interacts with mycobacterial NAD and NADP to produce a dozen adducts (Argyrou et al., 2007). One of these, a nicotinoyl-NAD isomer, inhibits the activities of enoyl acyl carrier protein reductase (InhA) and KasA. Inhibition of these enzymes inhibits synthesis of mycolic acid, an essential component of the mycobacterial cell wall, leading to bacterial cell death. Another adduct, a nicotinoyl-NADP isomer, potentially inhibits ($K_i < 1$ nM) mycobacterial dihydrofolate reductase, thereby interfering with nucleic acid synthesis (Argyrou et al., 2006) (see Figure 60–3).

Other products of KatG activation of INH include superoxide, H_2O_2 , alkyl hydroperoxides, and the NO radical, which may also contribute to the mycobactericidal effects of INH (Timmins and Deretic, 2006). *Mycobacterium tuberculosis* could be especially sensitive to damage from these radicals because the bacilli have a defect in the central regulator of the oxidative stress response, *oxyR*. Backup defense against radicals is provided by alkyl hydroperoxide reductase (encoded by *ahpC*), which detoxifies organic peroxides. Increased expression of *ahpC* reduces isoniazid effectiveness.

Antibacterial Activity

The isoniazid MICs with clinical *M. tuberculosis* strains vary from country to country. In the U.S., for example, the MICs are 0.025–0.05 mg/L. Activity against *Mycobacterium bovis* and *Mycobacterium kansasii* is moderate. Isoniazid has poor activity against MAC. It has no activity against any other microbial genus.

Mechanisms of Resistance

The prevalence of drug-resistant mutants is about 1 in 10^6 bacilli. Because TB cavities may contain as many as 10^7 to 10^9 microorganisms, preexistent resistance can be expected in pulmonary TB cavities of untreated patients. These spontaneous mutants can be selected and amplified by isoniazid monotherapy. Thus, two or more agents are usually used. Because the mutations resulting in drug resistance are independent events, the probability of resistance to two antimycobacterial agents is small, about 1 in 10^{12} ($1 \times 10^6 \times 10^6$), a low probability considering the number of bacilli involved.

Resistance to INH is associated with mutation or deletion of KatG, overexpression of the genes for InhA (confers low-level resistance to INH

Figure 60–3 Metabolism and activation of isoniazid. The prodrug isoniazid is metabolized in humans by NAT2 isoforms to its principal metabolite, N-acetyl isoniazid, which is excreted by the kidney. Isoniazid diffuses into mycoplasma, where it is “activated” by KatG (oxidase/peroxidase) to the nicotinoyl radical. The nicotinoyl radical reacts spontaneously with NAD⁺ to produce adducts that inhibit essential enzymes in synthesis of the cell wall and with NADP⁺ to produce an inhibitor of nucleic acid synthesis.

and some cross-resistance to ethionamide), and *ahpC* and mutations in the *kasA* and *katG* genes. KatG mutants exhibit a high level of resistance to isoniazid. The most common mechanism of isoniazid resistance in clinical isolates is due to single point mutations in the heme-binding catalytic domain of KatG, especially a serine-to-asparagine change at position 315. Although isolates with this mutation completely lose the ability to form nicotinoyl-NAD⁺/NADP⁺ adducts, they retain good catalase activity and maintain good biofitness. Compensatory mutations in the *ahpC* promoter occur and increase survival of *katG* mutant strains under oxidative stress. Efflux pump induction by isoniazid has been demonstrated, and it also confers resistance to ethambutol (Colangeli et al., 2005). In an in vitro pharmacodynamic model, efflux pump-induced resistance developed within 3 days and was followed by development of *katG* mutations (Gumbo et al., 2007b).

ADME

The bioavailability of orally administered isoniazid is about 100% for the 300-mg dose. The PK of isoniazid are best described by a two-compartment model, with the PK parameters in Table 60–2 (Pasipanodya et al., 2013). The ratio of isoniazid in the epithelial lining fluid to that in plasma is 1–2 and for CSF is 0.9 (Conte et al., 2002). Approximately 10% of drug is bound to protein. From 75% to 95% of a dose of isoniazid is excreted in the urine within 24 h, mostly as acetylisoniazid and isonicotinic acid.

Isoniazid is metabolized by hepatic arylamine NAT2, encoded by a variety of NAT2* alleles (Figure 60–3). Isoniazid clearance in patients has been traditionally classified as one of two phenotypic groups: “slow” and “fast” acetylators, as seen in Figure 60–4. Recently, the phenotypic groups have been expanded to fast, intermediate, and slow acetylators, and population PK parameters of isoniazid have been estimated and related to NAT2 genotype, and the number of NAT2*4 alleles accounts for 88% of the variability of isoniazid clearance.

Figure 60–4 Multi-modal distribution of INH clearance due to NAT2 polymorphisms. A group of matched male volunteers received INH (250 mg orally), and the time courses of plasma drug levels (C_p) were assessed. One-third of the subjects had INH elimination $t_{1/2}$ values less than 1.5 h; these were the *fast acetylators*. Two-thirds had $t_{1/2}$ values ranging from 2.1 to 4.0 h, with a suggestion of multiple groups; these were the *slow acetylators*. Plots of the mean data (C_p vs. time after administration) demonstrate the PK effects of acetylation rate. Both groups reached C_{pmax} at 1 h. The slow acetylators (red line) achieved a higher C_p (4 µg/mL) with a mean elimination $t_{1/2}$ of 3.0 h; the fast acetylators (green line) reached a lower maximal C_p (2 µg/mL) with a mean elimination $t_{1/2}$ of 1.0 h. The acetylation rate reflects variable expression of active polymorphic forms of NAT2. Slow acetylators may be a greater risk for adverse effects from INH, sulfonamides, and procainamide; fast acetylators may have diminished responses to standard doses of these agents but greater risk from bioactivation by NAT2 of arylamine/hydrazine carcinogens. Recently, researchers have identified three elimination subgroups for INH metabolism: *fast*, *slow*, and *intermediate* (codominant fast and slow alleles).

The frequency of each acetylation phenotype depends on race but is not influenced by sex or age. Fast acetylation is found in Inuit and Japanese. Slow acetylation is the predominant phenotype in most Scandinavians, Jews, and North African whites. The high acetyltransferase activity (fast acetylation) is inherited as an autosomal dominant trait; fast acetylators of isoniazid are either heterozygous or homozygous.

Microbial Pharmacokinetics-Pharmacodynamics

Isoniazid's microbial kill, as well as resistance emergence, is best explained by the ratios of AUC_{0-24} to MIC and C_{pmax}/MIC (Gumbo et al., 2007c; Pasipanodya et al., 2013). Because AUC is proportional to dose/CL, this means that efficacy is most dependent on drug dose and CL and thus on the activity of NAT2 polymorphic forms. Thus, rapid acetylators are more likely to have reduced microbial cure, increased relapse, and increased acquired resistance (Pasipanodya et al., 2012).

Therapeutic Uses

Isoniazid is available as a pill, as an elixir, and for parenteral administration. The recommended total daily dose of isoniazid is 5 mg/kg with a maximum of 300 mg administered daily or 10 mg/kg (range 10–15 mg/kg with a maximum of 900 mg) two or three times a week; oral and intramuscular doses are identical.

Untoward Effects

After NAT2 converts isoniazid to acetylisoniazid, which is excreted by the kidney, acetylisoniazid can also be converted to acetylhydrazine (Roy et al., 2008) and then to hepatotoxic metabolites by CYP2E1. Alternatively, acetylhydrazine may be further acetylated by NAT2 to diacetylhydrazine, which is nontoxic. In this scenario, rapid acetylators will rapidly remove acetylhydrazine, while slower acetylation or induction of CYP2E1 will lead to more of the toxic metabolites. Rifampin is a potent inducer of CYP2E1, which is why it potentiates isoniazid hepatotoxicity.

Elevated serum aspartate and alanine transaminases are encountered commonly in patients on isoniazid. However, the enzyme levels often normalize even when isoniazid therapy is continued (Blumberg et al., 2003). Severe hepatic injury occurs in about 0.1% of all patients taking the drug. Hepatic damage is rare in patients less than 20 years old, but the incidence increases with age. Overall risk is increased to about 3% by coadministration with rifampin. Most cases of hepatitis occur 4–8 weeks after the start of therapy.

If pyridoxine is not given concurrently, peripheral neuritis (most commonly paresthesias of feet and hands) is encountered in about 2% of patients receiving 5 mg/kg isoniazid daily. Neuropathy is more frequent in slow acetylators and in individuals with diabetes mellitus, poor nutrition, or anemia. Other neurological toxicities include convulsions in patients with seizure disorders, optic neuritis and atrophy, muscle twitching, dizziness, ataxia, paresthesias, stupor, and toxic encephalopathy. Mental abnormalities may appear during the use of this drug, including euphoria, transient impairment of memory, loss of self-control, and florid psychoses.

Patients may develop hypersensitivity to isoniazid. Hematological reactions also may occur. Vasculitis associated with antinuclear antibodies may appear during treatment but disappears when the drug is stopped. Arthritic symptoms have been attributed to this agent. Miscellaneous reactions associated with isoniazid therapy include dryness of the mouth, epigastric distress, methemoglobinemia, tinnitus, and urinary retention. In persons predisposed to pyridoxine deficiency anemia, the administration of isoniazid may result in dramatic anemia. Treatment of the anemia with large doses of vitamin B₆ gradually returns the blood count to normal. A drug-induced syndrome resembling systemic lupus erythematosus has also been reported.

Isoniazid Overdose

As little as 1.5 g of isoniazid can be toxic. Isoniazid overdose has been associated with the clinical triad of

- Seizures refractory to treatment with phenytoin and barbiturates
- Metabolic acidosis with an anion gap that is resistant to treatment with sodium bicarbonate
- Coma

The common early symptoms appear within 0.5–3 h of ingestion and include ataxia, peripheral neuropathy, dizziness, and slurred speech. The most dangerous are grand mal seizures and coma, encountered when patients ingest 30 mg/kg or more of the drug. Mortality in these circumstances is as high as 20%. Intravenous pyridoxine is administered over 5–15 min on a gram-to-gram basis with the ingested isoniazid. If the dose of ingested isoniazid is unknown, then a pyridoxine dose of 70 mg/kg should be used. In patients with seizures, benzodiazepines are utilized.

Isoniazid binds to pyridoxal 5'-phosphate to form isoniazid-pyridoxal hydrazones, thereby depleting neuronal pyridoxal 5'-phosphate and interfering with pyridoxal phosphate-requiring reactions, including the synthesis of the inhibitory neurotransmitter GABA. Decreased levels of GABA lead to cerebral overexcitability and lowered seizure threshold. The antidote is replenishment of pyridoxal 5'-phosphate.

Drug Interactions

Isoniazid is a potent inhibitor of CYP2C19 and CYP3A and a weak inhibitor of CYP2D6 (Desta et al., 2001). However, isoniazid induces CYP2E1. Drugs that are metabolized by these enzymes will potentially be affected (Table 60–4).

Ethambutol

Ethambutol hydrochloride is a water-soluble and heat-stable compound.

Mechanism of Action

Ethambutol inhibits arabinosyl transferase III, thereby disrupting the transfer of arabinose into arabinogalactan biosynthesis, which in turn disrupts the assembly of mycobacterial cell wall. The arabinosyl transferases are encoded by *embAB* genes.

Antibacterial Activity

Ethambutol has activity against a wide range of mycobacteria but has no activity against any other genus. Ethambutol MICs are 0.5–2 mg/L in clinical isolates of *M. tuberculosis*, about 0.8 mg/L for *M. kansasii*, and 2–7.5 mg/L for *M. avium*. The following *Mycobacterium* species are also susceptible: *M. gordonae*, *M. marinum*, *M. scrofulaceum*, and *M. szulgai*. However, the majority of *M. xenopi*, *M. fortuitum*, and *M. chelonae* have been reported as resistant.

TABLE 60–4 ■ SOME ISONIAZID-DRUG INTERACTIONS VIA INHIBITION AND INDUCTION OF CYPs

COADMINISTERED DRUG	CYP ISOFORM	ADVERSE EFFECTS
Acetaminophen	CYP2E1 induction	Hepatotoxicity
Carbamazepine	CYP3A inhibition	Neurological toxicity
Diazepam	CYP3A and CYP2C19 inhibition	Sedation and respiratory depression
Ethosuximide	CYP3A inhibition	Psychotic behaviors
Isoflurane and enflurane	CYP2E1 induction	Decreased effectiveness
Phenytoin and fosphenytoin	CYP2C19 inhibition	Neurological toxicity
Theophylline	CYP3A inhibition	Seizures, palpitation, nausea
Vincristine	CYP3A inhibition	Limb weakness and tingling
Warfarin	CYP2C9 inhibition	Possibility of increased bleeding (higher risk with isoniazid doses > 300 mg/d)

Mechanisms of Resistance

In vitro, mycobacterial resistance to the drug develops via mutations in the *embB* gene. In 30%–70% of clinical isolates that are resistant to ethambutol, mutations are encountered at codon 306 of the *embB* gene. However, mutations in this codon are also encountered in ethambutol-susceptible mycobacteria, as though this mutation is necessary, but not sufficient, to confer ethambutol resistance (Safi et al., 2008). Enhanced efflux pump activity may induce resistance to both isoniazid and ethambutol in vitro.

ADME

The oral bioavailability of ethambutol is about 80%. Approximately 10%–40% of the drug is bound to plasma protein. Ethambutol drug concentrations have been modeled using a two-compartment open model, with first-order absorption and elimination (Zhu et al., 2004). The decline in ethambutol is biexponential, with a $t_{1/2}$ of 3 h in the first 12 h and a $t_{1/2}$ of 9 h between 12 and 24 h due to redistribution of drug. Clearance and V_d are greater in children than in adults on a per kilogram basis. Slow and incomplete absorption is common in children, so that good peak concentrations of drug are often not achieved with standard dosing (Zhu et al., 2004). See Table 60–2 for PK data on this drug.

About 80% of the drug is not metabolized at all and is renally excreted. Therefore, in renal failure ethambutol should be dosed at 15–25 mg/kg three times a week instead of daily, even in patients receiving hemodialysis. The remainder of ethambutol (~20%) is oxidized by aldehyde dehydrogenase and excreted as aldehyde and dicarboxylic acid derivatives.

Microbial Pharmacokinetics-Pharmacodynamics

Ethambutol's microbial kill of *M. tuberculosis* is optimized by AUC/MIC, while that against disseminated MAC is optimized by C_{max}/MIC (Deshpande et al., 2010). Thus, to optimize microbial kill, high intermittent doses such as 25 mg/kg every other day to 50 mg/kg twice a week may be superior to daily doses of 15 mg/kg.

Therapeutic Uses

Ethambutol is available for oral administration in tablets containing the D-isomer. It is used for the treatment of TB, disseminated MAC, and in *M. kansasii* infection. Ethambutol is administered at 20 mg/kg (15–25 mg/kg) per day for both adults and children.

Untoward Effects

Ethambutol produces very few serious untoward reactions: About 1% experience diminished visual acuity, 0.5% a rash, and 0.3% drug fever. Other side effects that have been observed are pruritus, joint pain, GI upset, abdominal pain, malaise, headache, dizziness, mental confusion, disorientation, and possible hallucinations. Therapy with ethambutol results in an increased concentration of urate in the blood in about 50% of patients, owing to decreased renal excretion of uric acid.

The most important side effect is optic neuritis, resulting in decreased visual acuity and loss of red-green discrimination. The incidence of this reaction is proportional to the dose of ethambutol and is observed in 15% of patients receiving 50 mg/kg/d, in 5% of patients receiving 25 mg/kg/d, and in less than 1% of patients receiving daily doses of 15 mg/kg. The intensity of the visual difficulty is related to the duration of therapy after the decreased visual acuity first becomes apparent and may be unilateral or bilateral. Tests of visual acuity and red-green discrimination prior to the start of therapy and periodically thereafter are thus recommended. Recovery usually occurs when ethambutol is withdrawn. Drug interactions involving ethambutol are not significant.

Oxazolidinones: Linezolid, Tedizolid, and Sutezolid

Oxazolidinones have been in clinical use for over a decade for the treatment of gram-positive cocci. *Linezolid* and *tedizolid* have been found to be highly efficacious in the treatment of TB. Several studies have examined the utility of linezolid for the treatment of MDR-TB. The first study enrolled 41 patients with MDR-TB, who were immediately assigned to linezolid therapy without change of background regimen, or to a delay of 2 months (Lee et al., 2012). By month 4, 79% in the immediate-start group had sputum culture conversion compared to 35%

in the delayed-start group. However, 4 of every 5 patients had significant adverse events. In a randomized controlled trial of 65 patients with MDR-TB, linezolid therapy was associated with a 79% sputum conversion at 24 months compared to 38% among controls (Tang et al., 2015). However, 82% developed adverse events.

In a recent meta-analysis of 12 studies, Sotgiu et al. (2012) found that 94% of patients on linezolid achieved sputum conversion over an average period of 61 days; however, 68% developed major adverse events. Thus, linezolid is associated with extremely high sputum conversion rates, but at a price of a high rate of adverse events. As a result, studies are examining other oxazolidinones, such as *tedizolid* and *sutezolid*, the latter drug specifically designed for the treatment of TB. It is hoped these will have the same efficacy, but with fewer side effects. The pharmacology of oxazolidinones is discussed in Chapter 59.

Aminoglycosides: Streptomycin, Amikacin, and Kanamycin

The aminoglycosides streptomycin, amikacin, and kanamycin are used for the treatment of mycobacterial diseases. The MICs for *M. tuberculosis* in Middlebrook broth are 0.25–3.0 mg/L for all three aminoglycosides. For *M. avium*, streptomycin and amikacin MICs are 1–8 mg/L; those of kanamycin are 3–12 mg/L. *Mycobacterium kansasii* is frequently susceptible to these agents, but other nontuberculous mycobacteria are only occasionally susceptible. As an example, for amikacin in treatment of *M. abscessus*, an MIC range of 2–128 mg/L has been noted (Ferro et al., 2016). The pharmacological properties and therapeutic uses of aminoglycosides are discussed in full in Chapter 58.

Bacterial Resistance

Primary resistance to streptomycin is found in 2%–3% of *M. tuberculosis* clinical isolates. Resistance to aminoglycosides involves several genetic loci, as well as efflux pumps.

Aminoglycosides inhibit protein synthesis by binding to the 30S ribosomal subunit and causing misreading of the genetic code during translation. The 30S ribosomal unit is made of the 16S mRNA (encoded by *rpsL*), which binds to the ribosomal protein S12 (encoded by *rrs*) to optimize tRNA binding and mRNA decoding. Mutations in *rpsL* and *rrs* are associated with high-level aminoglycoside resistance in mycobacteria. However, mutations in these genes are only encountered in half of clinical isolates with aminoglycoside resistance. GidB is an rRNA methyltransferase for 16S rRNA, and mutations in the *gidB* gene are associated with low-level streptomycin resistance (Okamoto et al., 2007). The *gidB* mutations lead to high-level streptomycin-resistant mutants at a rate 2000 times that in wild type. Mutations in *gidB* are encountered in 33% of streptomycin-resistant clinical isolates of *M. tuberculosis*. Finally, efflux pump-mediated resistance was recently demonstrated in clinical isolates with low-level streptomycin-resistant *M. tuberculosis* and interacted with chromosomal mutations in *gidB* (Spies et al., 2008).

Therapeutic Uses

Therapeutic uses of aminoglycosides in treatment of mycobacterial infections are discussed further in the chapter.

Bicyclic Nitroimidazoles: Delamanid and Pretomanid

Pretomanid, discovered by Stover et al. in 2000, and *delamanid*, discovered by Matsumoto et al. in 2006, are bicyclic nitroimidazopyrans that are being used in the treatment of extensively drug-resistant and multidrug-resistant TB and are in clinical trials for use in drug-susceptible TB.

Mechanisms of Action

Pretomanid has two mechanisms of action. First, under aerobic conditions it inhibits *M. tuberculosis* mycolic acid and protein synthesis at the step between hydroxymycolate and ketomycolate (Stover et al., 2000). Similar to the structurally related metronidazole, pretomanid is a prodrug that requires activation by the bacteria via a nitroreduction step that requires, among other factors, a specific G6PDX, FGD1, and the reduced deazaflavin cofactor F₄₂₀ encoded by Rv3547 (Bashiri et al., 2008). Second, in NRPB, it

generates reactive nitrogen species such as NO via its des-nitro metabolite, which then augment the kill of intracellular NRPB by the innate immune system (Singh et al., 2008). In addition, direct poisoning of the respiratory complex in the NRPB leads to ATP depletion.

Delamanid is also a prodrug that is activated by the same enzyme encoded by Rv3547 (Xavier and Lakshmanan, 2014). Similarly, it also forms a reactive intermediate metabolite that inhibits mycolic acid production.

Antibacterial Activity

The MICs of pretomanid against *M. tuberculosis* range from 0.015 to 0.25 mg/L, but the drug lacks activity against other mycobacteria. Similarly, for delamanid, MICs range from 0.006 to 0.012 mg/L (Matsumoto et al., 2006).

Mechanism of Resistance

The proportion of mutants resistant to 5 mg/L of pretomanid is 10⁻⁶. Resistance arises due to changes in structure of FGD, which is due to a variety of point mutations in the *fgd* gene. However, resistant isolates have also been identified that lack *fgd* mutations, so that resistance may also be due to other mechanisms (Stover et al., 2000). Mutation frequencies for delamanid are unclear; however, resistance has also been shown to be due to *fgd1* and also *fbtA* mutations (Bloemberg et al., 2015).

ADME

The PK parameters of pretomanid include a clearance of 6.7–8.8 L/h at steady state, with a terminal *t*_{1/2} of 16–20 h, based on a noncompartmental analysis (Ginsberg et al., 2009). Similarly, no compartmental PK analyses have been published yet with delamanid, with noncompartmental PK published as an AUC_{0–24} of 7.9 mg·h/L after a dose of 100 mg twice a day and 11.8 mg·h/L after a 200 mg twice-a-day dose; *t*_{1/2} = about 38 h (Gler et al., 2012). Systemic exposures increase on uptake with food.

Microbial Pharmacokinetics-Pharmacodynamics

No formal microbial PK-pharmacodynamic work has been performed with delamanid. Pretomanid microbial kill is driven by percentage time concentration persists above MIC (Ahmad et al., 2011). The dose of 200 mg a day in humans achieves optimal PK-pharmacodynamic exposure in most patients.

Therapeutic Uses

Delamanid is currently dispensed in 50-mg tablets at 100 mg twice daily, with food. It is used in the treatment of multidrug-resistant TB and is being examined in combination with other drugs. Pretomanid is administered at 200 mg a day and is undergoing phase III trials in combination with other drugs for treatment of both drug-susceptible and drug-resistant TB.

Untoward Effects

Data on untoward effects are currently being gathered. It has been noted that delamanid is associated with QT segment prolongation; however, the clinical significance is unclear.

Clofazimine

Clofazimine is a fat-soluble riminophenazine dye.

Mechanism of Action

The biochemical basis for the antimicrobial actions of clofazimine remains to be established (Anonymous, 2008a). Possible mechanisms of action include membrane disruption, inhibition of mycobacterial phospholipase A₂, inhibition of microbial K⁺ transport, generation of hydrogen peroxide, interference with the bacterial electron transport chain, or efflux pump inhibition.

However, it is known that clofazimine has both antibacterial activity and anti-inflammatory effects via inhibition of macrophages, T cells, neutrophils, and complement.

Antibacterial Activity

The MICs for *M. avium* clinical isolates are 1–5 mg/L. The MICs for *M. tuberculosis* are about 1.0 mg/L. The compound also is useful for treatment of chronic skin ulcers (Buruli ulcer) produced by *Mycobacterium ulcerans*. It has activity against many gram-positive bacteria with an MIC of

1076 1.0 mg/L or less against *S. aureus*, coagulase-negative staphylococci, *Streptococcus pyogenes*, and *Listeria monocytogenes*. Gram-negative bacteria have MICs greater than 32 mg/L.

Bacterial Resistance

Clofazimine-resistant *Mycobacterium tuberculosis* carries a mutation in the gene encoding a transcription repressor for efflux pump MmpL; this is associated with cross resistance to bedaquiline (Hartkoorn et al., 2014; Zhang et al., 2015).

ADME

Clofazimine is administered orally at doses up to 300 mg a day. Clofazimine's oral bioavailability is 45%–60%; it is increased 2-fold by high-fat meals and decreased 30% by antacids (Nix et al., 2004). After a single dose, clofazimine is best modeled using a one-compartment model and has a prolonged absorption phase; after 200 mg of clofazimine, the t_{\max} is 5.3–7.8 h. After prolonged repeated dosing, the $t_{1/2}$ is about 70 days. For PK data, see Table 60–2. As a result of the good penetration into many tissues, a reddish-black discoloration of skin and body secretions may occur and take a long time to resolve. Crystalline deposits of the drug have been encountered in many tissues at autopsy (Anonymous, 2008a). Clofazimine is metabolized in the liver in four steps: hydrolytic dehalogenation, hydrolytic deamination, glucuronidation, and hydroxylation.

Untoward Effects

Gastrointestinal problems are encountered in 40%–50% of patients. In patients who have died following the abdominal pain, crystal deposition in intestinal mucosa, liver, spleen, and abdominal lymph nodes has been demonstrated (Anonymous, 2008a). Body secretion discoloration, eye discoloration, and skin discoloration occur in most patients and can lead to depression in some patients.

Drug Interactions

Anti-inflammatory effects may be inhibited by dapsone.

Fluoroquinolones

Fluoroquinolones are DNA gyrase inhibitors. Their chemistry, spectrum of activity, and pharmacology are discussed in detail in Chapter 56. Drugs such as *ofloxacin* and *ciprofloxacin* have been second-line anti-TB agents for many years, but they are limited by the rapid development of resistance. Adding C8 halogen and C8 methoxy groups markedly reduces the propensity for drug resistance. Of the C8 methoxy quinolones, *moxifloxacin*, *gatifloxacin*, and *levofloxacin* have been examined in the clinic for the treatment of pulmonary TB and meningeal TB.

Microbial Pharmacokinetics-Pharmacodynamics Relevant to TB

Fluoroquinolone microbial kill is best explained by the AUC_{0-24}/MIC ratio. In preclinical models, moxifloxacin AUC_{0-24}/MIC exposures equivalent to those from the standard 400-mg dose were associated with good microbial kill but amplified the drug-resistant subpopulation, so that resistance emerged in 7–13 days with monotherapy (Gumbo et al., 2004). This time to emergence of resistance harmonizes well with speed of resistance emergence in patients (Ginsburg et al., 2003). Moxifloxacin exposure best associated with minimizing emergence of resistance was a non-protein bound AUC_{0-24}/MIC of 53. Clinical trial simulations revealed that doses greater than 400 mg a day might better achieve this AUC/MIC . Given that rifamycins reduce the moxifloxacin AUC , these results point to a potential concern of quinolone resistance.

Therapeutic Uses in Treatment of TB

Fluoroquinolones have been examined for therapeutic use in two TB contexts: for an attempt to shorten therapy duration in pulmonary TB and for the treatment of TB meningitis.

The first study was a randomized, double-blind, placebo-controlled trial that examined the effect of replacing either isoniazid or ethambutol in the standard regimen with moxifloxacin 400 mg/d for 17 weeks versus standard short-course chemotherapy (6 months) consisting of rifampin, isoniazid, ethambutol, and pyrazinamide for therapy failure or relapse

(poor outcome) (Gillespie et al., 2014). While the moxifloxacin-containing regimens produced a more rapid sputum decline, there was a 6%–11% higher poor outcome compared to standard therapy. In a second randomized study, the standard short-course chemotherapy (6 months) was compared to a 4-month regimen in which isoniazid was replaced by 400 mg of gatifloxacin once a day (Merle et al., 2014). The gatifloxacin regimen was associated with greater than 2-fold higher recurrences/relapses. Thus, the quinolones failed to reduce therapy duration at the doses tested.

Fluoroquinolones have very good penetration into the CNS (Thwaites et al., 2011). A study investigating a regimen of standard therapy that included high-dose rifampicin plus two different moxifloxacin regimens found that 6-month mortality was half in patients who received the high-dose rifampicin intravenously and moxifloxacin (Ruslami et al., 2013). However, in a recent study of 817 patients, intensified anti-TB treatment with high-dose rifampin plus levofloxacin was not associated with a higher rate of survival among patients with tuberculous meningitis than standard treatment (Heemskerk et al., 2016).

Currently, fluoroquinolones, especially moxifloxacin, continue to be central for the treatment of pulmonary MDR-TB, and their presence or absence correlates with clinical outcomes.

Bedaquiline

Bedaquiline was discovered by Andries et al. in 2005 and entered clinical use in the treatment of TB difficult to treat with current anti-TB drugs. Bedaquiline is a cationic amphiphilic drug, which may account for its high accumulation in tissues.

Mechanism of Action

Bedaquiline acts by targeting subunit *c* of the ATP synthase of *M. tuberculosis*, leading to inhibition of the proton pump activity of the ATP synthase (Andries et al., 2005; Koul et al., 2007). Thus, the compound targets bacillary energy metabolism.

Antibacterial Activity

The bedaquiline MIC for *M. tuberculosis* is 0.03–0.12 mg/L. It has good activity against MAC, *M. leprae*, *M. bovis*, *M. marinum*, *M. kansasii*, *M. ulcerans*, *M. fortuitum*, *M. szulgai*, and *M. abscessus* (Andries et al., 2005; Huitric et al., 2007).

Bacterial Resistance

The proportion of *M. tuberculosis* mutants resistant to four times the MIC is 5×10^{-7} to 2×10^{-8} . Resistance is associated with two point mutations: D32V and A63P. This region of the gene encodes the membrane-spanning domain of the ATP synthase *c* subunit. Recently, resistance due to efflux pump mutations and their regulators has been described.

ADME

The population PK of bedaquiline are well characterized (Swenson et al., 2016). After oral ingestion, there is a large lag time in absorption, resulting in a t_{\max} of 5 h. The PKs are best described using a three-compartment model, with a central compartment and two peripheral compartments. The total clearance is 2.62 L/h, and the total volume of all compartments is more than 10,000 L (Swenson et al., 2016). Clearance is 52% higher in people of African descent, but 16% lower in women compared to men. The terminal $t_{1/2}$ is about 5.5 months, mainly driven by redistribution from the tissues. Despite the extremely large volume of distribution, bedaquiline has poor CNS penetration. Bedaquiline is metabolized by CYP3A4 to M2, an *N*-monodesmethyl metabolite.

Microbial Pharmacokinetics-Pharmacodynamics

Microbial kill of bedaquiline is believed to be linked to AUC/MIC ratios (Rouan et al., 2012). The PK-pharmacodynamic parameters linked to resistance suppression are unknown.

Efficacy and Therapeutic Use

A regimen of bedaquiline 400 mg daily for 2 weeks followed by 200 mg three times a day thereafter was added to a background second-line regimen of either kanamycin or amikacin, ofloxacin with or without ethambutol in patients with MDR-TB and led to an 8-week sputum conversion of

about 50% with bedaquiline compared to 9% without (Diacon et al., 2009). This led to licensing of the drug, which is currently being used in combination with others for treatment of MDR-TB that is difficult to treat with other antibiotics. In a second larger study of patients with MDR-TB, at week 24, 79% of patients on bedaquiline had sputum conversion compared to 58% of those not on bedaquiline, and at 120 weeks the culture conversion rates were 62% versus 44% (Diacon et al., 2014).

Untoward Effects

The adverse events of bedaquiline include nausea in 26% of patients and diarrhea in 13% of patients. Other adverse effects include arthralgia, pain in extremities, and hyperuricemia and occur in a small proportion of patients (Diacon et al., 2009). The major concern with this drug is cardiovascular toxicity and death. First, there was an increased corrected QT interval of between 450 and 480 ms in 27% versus 9% on this drug compared to placebo (Kakkar and Dahiya, 2014). However, no cases of torsades de pointes have been reported. A 5-fold higher rate of death has been reported in patients on bedaquiline versus those on placebo among 160 patients. The reasons are unclear, but this has led some to question the cost-benefit effect of using this drug (Avorn, 2013). Only a limited number of patients have been exposed to this drug, so that the full side-effect profile is unclear.

Ethionamide

Ethionamide is a congener of thioisonicotinamide.

Mechanism of Action

Mycobacterial EthA, an NADPH-specific, FAD-containing monooxygenase, converts ethionamide to a sulfoxide and then to 2-ethyl-4-aminopyridine (Vannelli et al., 2002). Although these products are not toxic to mycobacteria, it is believed that a closely related and transient intermediate is the active antibiotic. Ethionamide inhibits mycobacterial growth by inhibiting the activity of the *inhA* gene product, the enoyl-ACP reductase of fatty acid synthase II (Larsen et al., 2002). This is the same enzyme that activated isoniazid inhibits. Although the exact mechanisms of inhibition may differ, the results are the same: inhibition of mycolic acid biosynthesis and consequent impairment of cell wall synthesis.

Antibacterial Activity

The multiplication of *M. tuberculosis* is suppressed by concentrations of ethionamide ranging from 0.6 to 2.5 mg/L. A concentration of 10 mg/L or less will inhibit about 75% of photochromogenic mycobacteria; the scotochromogens are more resistant.

Bacterial Resistance

Resistance occurs mainly via changes in the enzyme that activates ethionamide, and mutations are encountered in a transcriptional repressor gene that controls its expression, *etaR*. Mutations in the *inhA* gene lead to resistance to both ethionamide and isoniazid.

ADME

The oral bioavailability of ethionamide approaches 100%. The PK are adequately explained by a one-compartment model with first-order absorption and elimination (Zhu et al., 2002) (see PK values in Table 56–2). After oral administration of 500 mg of ethionamide, a C_{max} of 1.4 mg/L is achieved in 2 h. The $t_{1/2}$ is about 2 h. The concentrations in the blood and various organs are approximately equal. Ethionamide is cleared by hepatic metabolism. Metabolites are eliminated in the urine, with less than 1% of ethionamide excreted in an active form.

Therapeutic Uses

Ethionamide is administered only orally. The initial dosage for adults is 250 mg twice daily; it is increased by 125 mg/d every 5 days until a dose of 15–20 mg/kg/d is achieved. The maximal dose is 1 g daily. The drug is best taken with meals in divided doses to minimize gastric irritation. Children should receive 10–20 mg/kg/d in two divided doses, not to exceed 1 g/d.

Untoward Effects

Approximately 50% of patients are unable to tolerate a single dose larger than 500 mg because of GI upset. The most common reactions are anorexia, nausea and vomiting, gastric irritation, and a variety of neurologic symptoms.

Severe postural hypotension, mental depression, drowsiness, and asthenia are common. Other reactions referable to the nervous system include olfactory disturbances, blurred vision, diplopia, dizziness, paresthesias, headache, restlessness, and tremors. Pyridoxine (vitamin B₆) relieves the neurologic symptoms, and its concomitant administration is recommended. Severe allergic skin rashes, purpura, stomatitis, gynecomastia, impotence, menorrhagia, acne, and alopecia have also been observed. A metallic taste also may be noted. Hepatitis has been associated with the use of the ethionamide in about 5% of cases. Hepatic function should be assessed at regular intervals in patients receiving the drug.

Para-aminosalicylic Acid

Para-aminosalicylic acid, discovered by Lehman in 1943, was the first effective treatment of TB.

Mechanism of Action

Para-aminosalicylic acid is a structural analogue of PABA, the substrate of dihydropteroate synthase (*folP1/P2*). As a result, PAS is thought to be a competitive inhibitor *folP1*, but in vitro the inhibitory activity against *folP1* is very poor. However, mutation of the thymidylate synthase gene (*thyA*) results in resistance to PAS, but only 37% of the PAS-resistant clinical isolates or spontaneous mutants encode a mutation in the *thyA* gene or in any genes encoding enzymes in the folate pathway or biosynthesis of thymine nucleotides (Mathys et al., 2009). Unidentified actions of PAS likely play more important roles in its anti-TB effects.

Antibacterial Activity

Para-aminosalicylic acid is bacteriostatic. In vitro, most strains of *M. tuberculosis* are sensitive to a concentration of 1 mg/L. It has no activity against other bacteria.

Bacterial Resistance

Mutations in *thyA*, *folC*, and *ribD* lead to PAS resistance in up to 61% of resistant isolates (Zhang et al., 2015). Recently, MDR-TB strains due to deletions of entire *dfrA* and *thyA* have been identified, a surprise given the conserved nature of folate synthesis (Moradigaravand et al., 2016).

ADME

Para-aminosalicylic acid oral bioavailability is more than 90%. PAS PK are described by a one-compartment model (Peloquin et al., 2001) (see the PK values in Table 60–2). The C_{max} increases 1.5-fold and AUC 1.7-fold with food compared to fasting (Peloquin et al., 2001). Administration with food also reduces gastric irritation. Protein binding is 50%–60%. PAS is *N*-acetylated in the liver to *N*-acetyl PAS, a potential hepatotoxin. Over 80% of the drug is excreted in the urine; more than 50% is in the form of the acetylated compound. Excretion of PAS acid is reduced by renal dysfunction; thus, the dose must be reduced in renal dysfunction.

Therapeutic Uses

Para-aminosalicylic acid is administered orally in a daily dose of 12 g. The drug is best administered after meals, with the daily dose divided into three equal portions. Children should receive 150–300 mg/kg/d in three or four divided doses.

Untoward Effects

The incidence of untoward effects associated with the use of PAS is about 10%–30%. GI problems predominate and often limit patient adherence. Hypersensitivity reactions to PAS are seen in 5%–10% of patients and manifest as skin eruptions, fever, eosinophilia, and other hematological abnormalities.

Cycloserine is D-4-amino-3-isoxazolidone. It is a broad-spectrum antibiotic produced by *Streptococcus orchidaceus*.

Mechanism of Action

Cycloserine and D-alanine are structural analogues; thus, cycloserine inhibits *alanine racemase*, which converts L-alanine to D-alanine and *D-alanine: D-alanine ligase*, stopping reactions in which D-alanine is incorporated into bacterial cell wall synthesis.

Antibacterial Activity

Cycloserine is a broad-spectrum antibiotic. It inhibits *M. tuberculosis* at concentrations of 5–20 mg/L. It has good activity against MAC, enterococci, *E. coli*, *S. aureus*, *Nocardia* species, and *Chlamydia*.

Mechanisms of Resistance

Cycloserine resistance in clinical isolates of *M. tuberculosis* has been detected in 10%–82% of isolates (Anonymous, 2008b). Nonsynonymous SNPs and loss-of-function mutations in *ald* cause resistance to D-cycloserine. In addition, resistance also involves *alr*, the gene for alanine racemase. Nonsynonymous SNPs in *alr* and SNPs in the *alr* promoter can confer resistance to D-cycloserine (Desjardin et al., 2016).

ADME

Oral cycloserine is almost completely absorbed. The population PK are best described using a one-compartment model with first-order absorption and elimination. The drug's $t_{1/2}$ is 9 h. The C_{max} in plasma is reached in 45 min in fasting subjects but is delayed for up to 3.5 h with a high-fat meal. See Table 56–2 for PK values. Cycloserine is well distributed throughout body. There is no appreciable barrier to CNS entry for cycloserine, and CSF concentrations are approximately the same as those in plasma. About 50% of cycloserine is excreted unchanged in the urine in the first 12 h; a total of 70% is recoverable in the active form over a period of 24 h. The drug may accumulate to toxic concentrations in patients with renal failure. About 60% of it is removed by hemodialysis, and the drug must be redosed after each hemodialysis session (Malone et al., 1999a).

Therapeutic Uses

Cycloserine is available for oral administration. The usual dose for adults is 250–500 mg twice daily.

Untoward Effects

Neuropsychiatric symptoms are common and occur in 50% of patients on 1 g/d, so much so that the drug has earned the nickname “psych-serine.” Symptoms range from headache and somnolence to severe psychosis, seizures, and suicidal ideas. Large doses of cycloserine or the concomitant ingestion of alcohol increases the risk of seizures. Cycloserine is contraindicated in individuals with a history of epilepsy and should be used with caution in individuals with a history of depression.

Capreomycin

Capreomycin is an antimycobacterial cyclic peptide. It consists of four active components: capreomycins IA, IB, IIA, and IIB. The agent used clinically contains primarily IA and IB. Antimycobacterial activity is similar to that of aminoglycosides, as are adverse effects, and capreomycin should not be administered with other drugs that damage cranial nerve VIII.

Bacterial resistance to capreomycin develops when it is given alone; such microorganisms show cross-resistance with kanamycin and neomycin. The adverse reactions associated with the use of capreomycin are hearing loss, tinnitus, transient proteinuria, cylindruria, and nitrogen retention. Severe renal failure is rare. Eosinophilia is common. Leukocytosis, leukopenia, rashes, and fever have also been observed. Injections of the drug

may be painful. Capreomycin is given for MDR-TB. The recommended daily dose is 1 g (no more than 20 mg/kg) per day for 60–120 days, followed by 1 g two or three times a week.

β -Lactam Antibiotics for the Treatment of TB

Until recently, it was assumed that β -lactam antibiotics lacked activity against mycobacteria because the bacteria have Ambler class A β -lactamases such as BlacC. Carbapenems, which are poorer substrates of these enzymes, in conjunction with inhibitors such as clavulanate, have demonstrated efficacy against *M. tuberculosis*. In addition, penems such as faropenem, which possess both carbapenem and cephalosporin structures, are effective against *M. tuberculosis* without a β -lactamase inhibitor. The general pharmacology of this class of compounds is discussed in Chapter 57. Recently, reports of patients with MDR-TB who have responded to β -lactam antibiotics such as ertapenem have been published (Tiberi et al., 2016). A recent meta-analysis identified seven clinical studies in which ertapenem, imipenem, and meropenem were used to treat MDR-TB and identified sputum conversion rates of greater than 60% (Sotgiu et al., 2016). The optimal doses for the treatment of MDR-TB and which antibiotics to combine are currently unknown.

Macrolides

The pharmacology, bacterial activity, and resistance mechanisms of macrolides are discussed in Chapter 59. Azithromycin and clarithromycin are used for the treatment of MAC.

Dapsone

Dapsone (DDS) is a broad-spectrum agent with antibacterial, antiprotozoal, and antifungal effects.

Mechanism of Action

Dapsone is a structural analogue of PABA and a competitive inhibitor of dihydropteroate synthase (*folP1/P2*) in the folate pathway, shown in

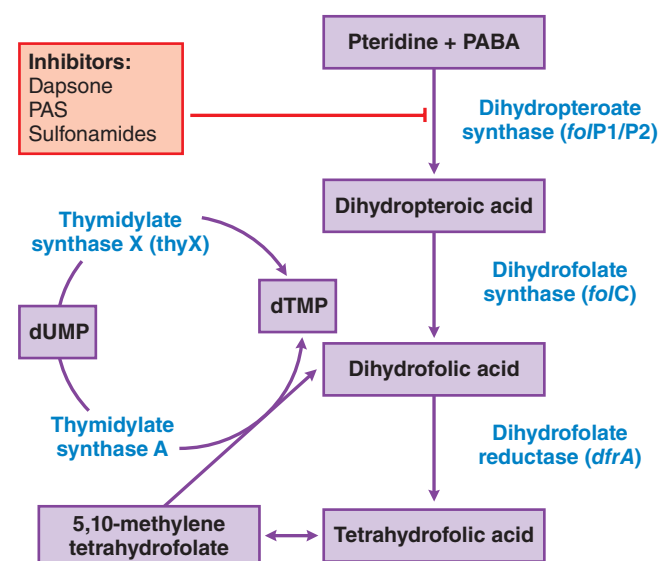

Figure 60–5 Effects of antimicrobials on folate metabolism and deoxynucleotide synthesis. dTMP, deoxythymidine monophosphate; dUMP, deoxyuridine monophosphate.

Figure 60–5. The anti-inflammatory effects of dapsone occur via inhibition of tissue damage by neutrophils (Wolf et al., 2002). Dapsone inhibits neutrophil myeloperoxidase activity and respiratory burst, and it inhibits activity of neutrophil lysosomal enzymes. Dapsone may act as a free-radical scavenger of free radicals generated by neutrophils, and dapsone may inhibit migration of neutrophils to inflammatory lesions (Wolf et al., 2002). Dapsone is extensively used for acne, but this therapy is not recommended.

Antimicrobial Effects

Antibacterial. Dapsone is bacteriostatic against *M. leprae* at concentrations of 1–10 mg/L. More than 90% of clinical isolates of MAC and *M. kansasii* have an MIC of 8 mg/L or less, but the MICs for *M. tuberculosis* isolates are high. It has little activity against other bacteria.

Antiparasitic. Dapsone is also highly effective against *Plasmodium falciparum* with IC_{50} of 0.6–1.3 mg/L even in sulfadoxine-pyrimethamine-resistant strains. Dapsone has an IC_{50} of 0.55 mg/L against *Toxoplasma gondii* tachyzoites.

Antifungal. Dapsone is effective at concentrations of 0.1/mg/L against the fungus *Pneumocystis jiroveci*.

Drug Resistance

Resistance to dapsone in *P. falciparum*, *P. jiroveci*, and *M. leprae* results primarily from mutations in genes encoding dihydropteroate synthase (Figure 60–5).

ADME

After oral administration, absorption is complete; the elimination $t_{1/2}$ is 20–30 h. The population PK of dapsone are shown in Table 60–2 (Simpson et al., 2006). Dapsone undergoes *N*-acetylation by NAT2. *N*-Oxidation to dapsone hydroxylamine is via CYP2E1 and to a lesser extent by CYP2C. Dapsone hydroxylamine enters red blood cells, leading to methemoglobin formation. Sulfones tend to be retained for up to 3 weeks in skin and muscle and especially in liver and kidney. Intestinal reabsorption of sulfones excreted in the bile contributes to long-term retention in the bloodstream; periodic interruption of treatment is advisable for this reason. Epithelial lining fluid-to-plasma ratio is between 0.76 and 2.91; CSF-to-plasma ratio is 0.21–2.01 (Gatti et al., 1997). Approximately 70%–80% of a dose of dapsone is excreted in the urine as an acid-labile mono-*N*-glucuronide and mono-*N*-sulfamate.

Therapeutic Uses

Dapsone is administered as an oral agent. Therapeutic uses of dapsone in the treatment of leprosy are described later in this chapter. Dapsone is combined with chlorproguanil for the treatment of malaria. Dapsone is also used for *P. jiroveci* infection and prophylaxis and for the prophylaxis for *T. gondii* (see Chapter 54). The anti-inflammatory effects are the basis for therapy of pemphigoid, dermatitis herpetiformis, linear IgA bullous disease, relapsing chondritis, and ulcers caused by the brown recluse spider (Wolf et al., 2002).

Dapsone and Glucose-6-Phosphate Dehydrogenase Deficiency

Glucose-6-phosphate dehydrogenase protects red cells against oxidative damage. However, G6PD deficiency is encountered in nearly half a billion people worldwide, the most common of 100 variants being G6PD-A[−]. Dapsone, an oxidant, causes severe hemolysis in patients with G6PD deficiency. Thus, G6PD deficiency testing should be performed prior to use of dapsone whenever possible.

Other Untoward Effects

Hemolysis develops in almost every individual treated with 200–300 mg of dapsone per day. Doses of 100 mg or less in healthy persons and 50 mg or less in healthy individuals with a G6PD deficiency do not cause hemolysis. Methemoglobinemia also is common. A genetic deficiency in NADH-dependent methemoglobin reductase can result in severe methemoglobinemia after administration of dapsone. Isolated instances of headache, nervousness, insomnia, blurred vision, paresthesias, reversible peripheral neuropathy (thought to be due to axonal degeneration), drug fever, hematuria, pruritus, psychosis, and a variety of skin rashes

have been reported. An infectious mononucleosis-like syndrome, which may be fatal, occurs occasionally.

Principles of Antituberculosis Chemotherapy

Evolution and Pharmacology

Mycobacterium tuberculosis is not a single species, but a complex of species with 99.9% similarity at the nucleotide level. The complex includes *M. tuberculosis* (*typus humanus*), *M. canettii*, *M. africanum*, *M. bovis*, and *M. microti*. They all cause TB, with *M. microti* responsible for only a handful of human cases.

Antituberculosis Therapy

Traditionally, isoniazid, pyrazinamide, rifampin, and ethambutol have been considered first-line anti-TB agents. However, the notions are shifting, with new regimens being tested with the aim of treating TB in less than 6 months, many of which are rifampin and isoniazid sparing. Moreover, antagonism between these “first-line” drugs such as isoniazid versus both rifampin and pyrazinamide has been described in murine TB models, in the hollow-fiber TB model, and in the clinic in adults and children (Chigutsa et al., 2015; Srivastava et al., 2011b; Swaminathan et al., 2016). Moxifloxacin is being studied as an agent for drug-susceptible TB, as is pretomanid and oxazolidinones. As a result, the concept of specific drugs as first line is being replaced with focus on regimens to be ranked by faster sterilizing effect. Traditionally, first-line agents were more efficacious and better tolerated relative to second-line agents. Second-line agents were used in case of poor tolerance or resistance to first-line agents. Second-line drugs included ethionamide, PAS, cycloserine, amikacin, kanamycin, and capreomycin.

The mutation rates to anti-TB drugs are between 10^{-6} and 10^{-10} , so that the likelihood of resistance is high to any single anti-TB drug in patients with cavitary TB who have about 10^9 CFU of bacilli in a 3-cm pulmonary lesion. However, the likelihood that bacilli would develop mutations to two or more different drugs is the product of two mutation rates (between 1 in 10^{14} and 1 in 10^{20}), which makes the probability of resistance emergence to more than two drugs acceptably small. Thus, only combination anti-TB therapy is currently recommended. Multidrug therapy has led to a reduction in length of therapy.

Types of Antituberculosis Therapy

Prophylaxis

After infection with *M. tuberculosis*, about 10% of people will develop active disease over a lifetime. The highest risk of reactivation TB is in patients with Mantoux tuberculin skin test reaction 5 mm or greater who also fall into one of the following categories: recently exposed to TB, have HIV coinfection, have fibrotic changes on chest radiograms, or are immunosuppressed due to HIV infection or posttransplantation or are taking immunosuppressive medications for any reason. If the tuberculin skin test is 10 mm or greater, a high risk of TB is encountered in recent (≤ 5 years) immigrants from areas of high TB prevalence, children younger than 4 years, children exposed to adults with TB, intravenous drug users, as well as residents and employees of high-risk congregate settings. Any person with a skin test greater than 15 mm is also at high risk of disease.

In these patients at high risk of active TB, prophylaxis is recommended to prevent active disease. Prophylaxis consists of four regimens. The shortest-duration regimen that is effective consists of isoniazid 15 mg/kg (maximum 900 mg) and weight band–based rifapentine doses administered orally once a week for 12 weeks. The weight bands for rifapentine are 300 mg for 10–14 kg, 450 mg for 14.4–25 kg, 600 mg for 25.1–32 kg, 750 mg for 32.1–49.9 kg, and 900 mg for above 50 kg. The traditional regimens consist of oral isoniazid, 300 mg daily or twice weekly, for 6 months in adults. Those who cannot take isoniazid should be given rifampin, 10 mg/kg daily, for 4 months. In children, isoniazid 10–15 mg/kg daily (maximum 300 mg) is administered, or 20–30 mg/kg two times a week directly observed, for 9 months. In children who cannot tolerate isoniazid, rifampin 10–20 mg/kg daily for 6 months is recommended.

All active TB cases should be confirmed by culture or rapid diagnostic methods such as nucleic acid amplification tests (e.g., Xpert MTB/RIF) and have antimicrobial susceptibilities determined. In adults, the current standard regimen for drug-susceptible TB consists of isoniazid (5 mg/kg, maximum 300 mg/d), rifampin (10 mg/kg, maximum 600 mg/d), and pyrazinamide (15–30 mg/kg, maximum of 2 g/d) for 2 months, followed by intermittent 10-mg/kg rifampin and 15-mg/kg isoniazid two or three times a week for 4 months. Children should receive rifampin 10–20 mg/kg at a maximum dose of 600 mg/d, pyrazinamide 30–40 mg/kg/d, and isoniazid 10–15 mg/kg at a maximum dose of 300 mg/d. Rifabutin 5 mg/kg/d can be used for the entire 6 months of therapy in adult HIV-infected patients because rifampin can adversely interact with some antiretroviral agents to reduce their effectiveness. If there is resistance to isoniazid, initial therapy also may include ethambutol (15–20 mg/kg/d) or streptomycin (1 g/d) until isoniazid susceptibility is documented. Ethambutol doses in children are 20 mg/kg/d (maximum 1 g) or 50 mg/kg twice weekly (2.5 g). Because monitoring of visual acuity is difficult in children younger than 5 years, caution should be exercised in using ethambutol in these children.

The first 2 months of the four-drug regimen is termed the *initial phase of therapy* and the last 4 months the *continuation phase of therapy*. Rifapentine (10 mg/kg once a week) may be substituted for rifampin in the continuation phase in patients with no evidence of HIV infection or cavitary TB. Pyridoxine, vitamin B₆, (10–50 mg/d) should be administered with isoniazid to minimize the risks of neurological toxicity in patients predisposed to neuropathy (e.g., the malnourished, elderly, pregnant women, HIV-infected individuals, diabetic patients, alcoholic patients, and uremic patients). To ensure compliance, therapy is administered as DOT. Although DOT is the standard of care, an analysis of a series of randomized clinical trials found no difference in outcome between DOT and self-administered therapy (Paspianodya and Gumbo, 2013; Volmink and Garner, 2007).

The duration of therapy of drug-susceptible pulmonary TB is 6 months. A 9-month duration should be used for patients with cavitary disease who are still sputum culture positive at 2 months. HIV-infected patients with CD4⁺ lymphocyte cell counts less than 100/mm³ are at increased risk of developing rifampin resistance. Therefore, daily therapy is recommended during the continuation phase. Most cases of extrapulmonary TB are treated for 6 months. TB meningitis is an exception that requires a 9- to 12-month duration. In addition, results of a meta-analysis suggest that corticosteroids should be used in TB meningitis (Prasad et al., 2016).

The treatment of TB pericarditis is a special case in which the use of steroids has been advocated for many decades. In the IMPI trial that randomized 1400 patients, Mayosi and colleagues (2014) examined the effect of prednisolone on the composite outcome of death, cardiac tamponade requiring pericardiocentesis, or constrictive pericarditis. There was no significant difference in the primary outcome between patients who received prednisolone and those who received placebo, even though the corticosteroids were associated with 44% decrease in the development of constrictive pericarditis. The corticosteroids were associated with a 3-fold increase in the incidence of cancer, especially in the context of HIV/TB coinfection. Moreover, even with the four-drug regimen of rifampin, isoniazid, ethambutol, and pyrazinamide, mortality is still very high at 26% at 6 months (and 40% in HIV-infected patients), and over several years is 1.43 per 100 person-months overall. A recent study found that free drug concentrations of rifampin in pericardial fluid were virtually close to zero, ethambutol concentrations were low, and the pH in the infected pericardial fluid was 7.34, which is the pH at which pyrazinamide has no effect (Shenje et al., 2015). The optimal regimen for treatment of TB pericarditis thus remains to be identified.

Definitive Therapy of Drug-Resistant TB

The XDR-TB is MDR-TB that is also resistant to fluoroquinolones and at least one of three injectable second-line drugs (i.e., amikacin, kanamycin, or capreomycin). These diseases, virtually untreatable, led to the clinical trials of bedaquiline and delamanid in combination with optimized background regimens, as well as studies of linezolid. These studies demonstrated improved sputum conversion rates with these drugs. However, the

adverse event rates when linezolid or bedaquiline are used are high, and it is unclear which drugs to combine with these agents to optimize efficacy and minimize adverse events rates. Thus, the exact regimens to use are still unknown. Thus, in documented drug resistance, therapy should be based on evidence of susceptibility and should include:

- at least three drugs to which the pathogen is susceptible, with at least one of the injectable anti-TB agents
- in the case of MDR-TB, a prolonged course of 5 to 7 agents, except a shorter 9-12 month regimen if there is no resistance to fluoroquinolones and second-line injectable agents (WHO, 2016).

The addition of a fluoroquinolone and surgical resection of the main lesions have been associated with improved outcome (Chan et al., 2004).

Principles of Therapy Against *Mycobacterium avium* Complex

The MAC is made up of at least two species: *M. intracellulare* and *M. avium*. *Mycobacterium intracellulare* causes pulmonary disease often in immunocompetent individuals. *Mycobacterium avium* is further divided into a number of subspecies: *M. avium* subsp. *hominissuis* causes disseminated disease in immunocompromised patients, *M. avium* subsp. *paratuberculosis* has been implicated in the etiology of Crohn disease, and *M. avium* subsp. *avium* causes TB of birds. These bacteria are ubiquitous in the environment and can be encountered in water, food, and soil. Therefore, when MAC bacteria are isolated from a nonsterile site in a patient's body, one cannot assume they are causing an infection.

Therapy of MAC Pulmonary Infection

Mycobacterium intracellulare often infects immunocompetent patients. Criteria in favor of therapy includes bacteriological evidence, which consists of positive cultures from at least two sputums or one positive culture from bronchoalveolar lavage or pulmonary biopsy with a positive culture or histopathological features, and clinical evidence of infection, and radiological evidence of infection such as pulmonary cavitation, nodular lesions, or bronchiectasis (Griffith et al., 2007).

In newly diagnosed patients with MAC pneumonia, triple-drug therapy is recommended. These drugs include a rifamycin, ethambutol, and a macrolide (Griffith et al., 2007; Kasperbauer and Daley, 2008). For the macrolides, either oral clarithromycin or azithromycin may be used. Rifampin is often the rifamycin of choice. Clarithromycin, 1000 mg, or azithromycin, 500 mg, are combined with ethambutol, 25 mg/kg, and rifampin, 600 mg, and administered three times a week for nodular and bronchiectatic disease. Therapy is continued for 12 months after the last negative culture. The same drugs are administered for patients with cavitary disease, but the dosing regimens are azithromycin 250 mg, ethambutol 15 mg/kg, and rifampin 600 mg. Parenteral streptomycin or amikacin at 15 mg/kg is recommended as a fourth drug. The effect of the aminoglycosides on clinical outcomes is unclear.

Duration of therapy is as for nodular disease. In advanced pulmonary disease or during re-treatment, rifabutin 300 mg daily may replace rifampin. Because clarithromycin susceptibility correlates with outcome, risk of failure is high when high clarithromycin MICs are documented. Patients at risk for failure also include those with cavitary disease, presumably due to higher bacillary load. Even with these therapies, long-term success is still fairly limited. Only half of patients have successful outcomes as defined by both culture conversion and clinical outcomes.

Therapy of Disseminated *M. avium* Complex

Disseminated MAC disease is caused by *M. avium* in 95% of patients. This is a disease of the immunocompromised patient, especially with reduced cell-mediated immunity. MAC usually occurs in patients whose CD4 cell count is less than 50/mm³. Patients at risk for infection are those who have had other opportunistic infections, are colonized with MAC, or have an HIV RNA burden greater than 5 log copies/mm³.

The symptoms and laboratory findings of disseminated disease are nonspecific and include fever, night sweats, weight loss, elevated serum alkaline phosphates, and anemia at the time of diagnosis. However, when disease occurs in patients already on antiretroviral therapy, it may manifest as a focal disease of the lymph nodes, osteomyelitis, pneumonitis, pericarditis, skin or soft-tissue abscesses, genital ulcers, or CNS infection (DHHS Panel, 2008). In addition to a compatible clinical picture, isolation of MAC from cultures of blood, lymph node, bone marrow, or other normally sterile tissue or body fluids is required for diagnosis.

Prophylactic Therapy

The goals of prophylactic therapy are to prevent the development of disease during the time when a patient's CD4 count is low. Monotherapy with either oral azithromycin 1200 mg once a week or clarithromycin 500 mg twice a day is started when patients present with a CD4 count below 50/mm³ (DHHS Panel, 2008). For patients intolerant to macrolides, rifabutin 300 mg a day is administered. Once the CD4 count is greater than 100 per mm³ for 3 months or longer, MAC prophylaxis should be discontinued.

Definitive and Suppressive Therapy

In patients with disease due to MAC, the goals of therapy include suppression of symptoms and conversion to negative blood cultures. The infection itself is not completely eradicated until immune reconstitution. Therapy is divided into initial therapy and chronic suppressive therapy. Recommended therapy consists of a combination of clarithromycin 500 mg twice a day with ethambutol 15 mg/kg daily, administered orally (DHHS Panel, 2008). Azithromycin 500–600 mg daily is an acceptable alternative to clarithromycin, especially in those patients in whom clarithromycin would adversely interact with other drugs. The addition of rifabutin 300 mg/d may improve outcomes. Mortality in disseminated MAC is high in patients with either a CD4 cell count below 50/mm³ or an MAC burden of greater than 2 log₁₀ CFU/mm³ of blood or in the absence of effective antiretroviral therapy. In these patients, a fourth drug may be added, based on susceptibility testing. Potential fourth agents include amikacin, 10–15 mg/kg intravenously daily; streptomycin, 1 g intravenously or intramuscularly daily; ciprofloxacin, 500–750 mg orally twice daily; levofloxacin, 500 mg orally daily; or moxifloxacin, 400 mg orally daily. Patients should be continued on suppressive therapy until all three of the following criteria are met:

- therapy duration of at least 12 months
- CD4 count greater than 100/mm³ for at least 6 months
- asymptomatic for MAC infection

Principles of Antileprosy Therapy

The global prevalence of leprosy has markedly declined, largely due to the global initiative of the WHO to eliminate leprosy (Hansen disease) as a public health problem by providing multidrug therapy (rifampin, clofazimine, and dapsone) free of charge. Prevalence of the disease has dropped by about 90% since 1985. Nevertheless, there are pockets of disease around the world, especially in Africa, Asia, and South America. In the U.S., fewer than 200 new cases were reported in 2005, mainly among immigrants.

Four major clinical types of leprosy affect therapy. At one end of the spectrum is *tuberculoid leprosy*, also termed paucibacillary leprosy because the bacterial burden is low and *M. leprae* is rarely found in smears. On the other end of the spectrum is the *lepromatous* form of the disease (Levis and Ernst, 2005). This is characterized by a disseminated infection and a high bacillary burden. Two major intermediate forms of the disease are recognized: (1) borderline (dimorphous) tuberculoid disease, which has features of both tuberculoid and lepromatous leprosy; and (2) indeterminate disease, which has early hypopigmented lesions without features of the lepromatous and tuberculoid leprosy.

Mycobacterium leprae was discovered by Armauer Hansen in 1873. The *M. leprae* genome has undergone reductive evolution and has radically downsized its genome (Cole et al., 2001). As a result, *M. leprae* cannot produce ATP from NADH or utilize acetate or galactose as carbon sources;

moreover, it has lost the anaerobic electron transfer system and cannot survive under hypoxic conditions. It has a long doubling time (14 days) and is an obligate intracellular pathogen. As a result, *M. leprae* is difficult to culture on synthetic media, an impediment to basic research on the disease.

Types of Antileprosy Therapy

Therapy of leprosy is based on multidrug regimens using rifampin, clofazimine, and dapsone. The reasons for using combinations of agents include reduction in the development of resistance, the need for adequate therapy when primary resistance already exists, and reduction in the duration of therapy. The most bactericidal drug in current regimens is rifampin. Because of high kill rates and massive release of bacterial antigens, rifampin is not often given during a “reversal” reaction (see discussion that follows) or in patients with erythema nodosum leprosum. Clofazimine is only bacteriostatic against *M. leprae*. However, it also has anti-inflammatory effects and can treat reversal reactions and erythema nodosum leprosum. The third major agent in the regimen is dapsone. The objective of administering these drugs is total cure.

Definitive Therapy; Standard Therapy

Paucibacillary Leprosy. The WHO regimen consists of a single dose of oral rifampin, 600 mg, combined with dapsone, 100 mg, administered under direct supervision once every month for 6 months, and dapsone, 100 mg a day, in between for 6 months. In the U.S., the regimen consists of dapsone, 100 mg, and rifampin, 600 mg, daily for 6 months, followed by dapsone monotherapy for 3–5 years.

Multibacillary Therapy. The WHO recommends the same regimen as for paucibacillary leprosy, with two major changes. First, clofazimine, 300 mg a day, is added for the entirety of therapy. Second, the regimen lasts 1 year instead of 6 months. In the U.S., the regimen is also the same as for paucibacillary, but dual therapy continues for 3 years, followed by dapsone monotherapy for 10 years. Clofazimine is added when there is dapsone resistance or for patients who are chronically reactional.

The duration of therapy of multibacillary leprosy is a drawback. Studies in murine leprosy, and in patients, have demonstrated that viable bacilli are killed within 3 months of therapy (Ji et al., 1996), suggesting that the length of current therapy of multibacillary leprosy may be unnecessarily long. Recently, the WHO proposed that all forms of leprosy be treated with the same dose as for paucibacillary leprosy; a clinical trial was promising (Kroger et al., 2008). This new shorter regimen promises to reduce duration of therapy radically.

Treatment of Reactions in Leprosy

Patients with tuberculoid leprosy may develop “reversal reactions,” manifestations of delayed hypersensitivity to antigens of *M. leprae*. Cutaneous ulcerations and deficits of peripheral nerve function may occur. Early therapy with corticosteroids or clofazimine is effective. Reactions in the lepromatous form of the disease (erythema nodosum leprosum) are characterized by the appearance of raised, tender, intracutaneous nodules, severe constitutional symptoms, and high fever. This reaction is often associated with therapy. It is thought to be an Arthus-type reaction related to release of microbial antigens in patients harboring large numbers of bacilli. Treatment with clofazimine or thalidomide is effective.

Therapy of Other Nontuberculous Mycobacteria

Mycobacteria other than those already discussed can be recovered from a variety of lesions in humans. Because they frequently are resistant to many of the commonly used agents, they must be examined for sensitivity in vitro and drug therapy selected on this basis. Therapy of infections from these organisms is summarized in Table 60–5. In some instances, surgical removal of the infected tissue followed by long-term treatment with effective agents is necessary. *M. kansasii* causes disease similar to that caused by *M. tuberculosis*, but it may be milder. Therapy with isoniazid, rifampin, and ethambutol has been successful.

Acknowledgment: William A. Petri, Jr contributed to this chapter in earlier editions of this book. We have retained some of his text in the current edition.

TABLE 60–5 ■ PHARMACOTHERAPY OF MYCOBACTERIAL INFECTIONS OTHER THAN TUBERCULOSIS, LEPROSY, AND MAC

MYCOBACTERIAL SPECIES	FIRST-LINE THERAPY	ALTERNATIVE AGENTS
<i>M. kansasii</i>	Isoniazid + rifampin ^a + ethambutol	Trimethoprim-sulfamethoxazole; ethionamide; cycloserine; clarithromycin; amikacin; streptomycin; moxifloxacin or gatifloxacin
<i>M. fortuitum</i> complex	Amikacin + doxycycline	Cefoxitin; rifampin; a sulfonamide; moxifloxacin or gatifloxacin; clarithromycin; trimethoprim-sulfamethoxazole; imipenem
<i>M. marinum</i>	Rifampin + ethambutol	Trimethoprim-sulfamethoxazole; clarithromycin; minocycline; doxycycline
<i>M. ulcerans</i>	Rifampin + streptomycin ^c	Clarithromycin ^b ; rifapentine ^b
<i>M. abscessus</i>	Cefoxitin (or imipenem) + amikacin + clarithromycin	Tigecycline, moxifloxacin,
<i>M. malmoense</i>	Rifampin + ethambutol ± clarithromycin	Fluoroquinolone
<i>M. haemophilum</i>	Clarithromycin + rifampin + quinolone	—

^aIn HIV-infected patients, the substitution of rifabutin for rifampin minimizes drug interactions with the HIV protease inhibitors and nonnucleoside reverse transcriptase inhibitors.

^bBased on animal models.

^cFor *M. ulcerans*, surgery is the primary therapy.

Drug Facts for Your Personal Formulary: Antimycobacterial Drugs

Drug	Therapeutic Uses	Major Toxicity and Clinical Pearls
Rifamycins		
Rifampin	<ul style="list-style-type: none"> Tuberculosis <i>M. kansasii</i> disease Leprosy <i>M. marinum</i>, <i>M. ulcerans</i>, <i>M. malmoense</i>, and <i>M. haemophilum</i> diseases Prophylaxis of meningococcal disease and <i>Haemophilus influenzae</i> meningitis Brucellosis Combination therapy in selected cases of staphylococcal endocarditis or osteomyelitis, especially those caused by staphylococci “tolerant” of penicillin 	<ul style="list-style-type: none"> Peak concentration and AUC-driven efficacy Rifampin potently induces CYPs and thus increases metabolism of many classes of drugs. Prior to putting a patient on rifampin, all the patient’s medications and contraception should be examined for potential interactions. Hypersensitivity reactions, especially with high-dose intermittent therapy, including flu-like symptoms, eosinophilia, interstitial nephritis, acute tubular necrosis, thrombocytopenia, hemolytic anemia, and shock Hepatitis, especially in combination with other anti-TB agents, in alcoholics, or preexistent liver disease
Rifapentine	<ul style="list-style-type: none"> Treatment of tuberculosis Prophylaxis of tuberculosis 	<ul style="list-style-type: none"> 97% protein binding Long $t_{1/2}$ of ~ 14–18 h, allowing more intermittent dosing (1–2 times weekly) Moderate CYP3A induction
Rifabutin	<ul style="list-style-type: none"> Used as rifampin replacement to avoid drug interactions of rifampin with other medications, especially in HIV coinfection Treatment of disseminated MAC in patients with AIDS 	<ul style="list-style-type: none"> Weaker CYP3A induction than rifampin Concentrations higher in tissue than plasma $t_{1/2}$ ~ 45 h Neutropenia in 25% of patients with HIV Primary reasons for therapy discontinuation include rash, GI intolerance, and neutropenia. Uveitis and arthralgias in patients receiving rifabutin doses > 450 mg daily
Isoniazid		
Isoniazid	<ul style="list-style-type: none"> <i>M. tuberculosis</i> infection <i>M. kansasii</i> infection Prophylaxis of tuberculosis disease 	<ul style="list-style-type: none"> Patients divided into slow, intermediate, and fast acetylators, which has consequence of efficacy and toxicity. Hepatotoxicity, increased above age of 42 years Peripheral neuritis: should be administered with pyridoxine Reversible vasculitis Overdose is associated with the clinical triad of (1) seizures refractory to treatment with phenytoin and barbiturates, (2) metabolic acidosis, and (3) coma Many drug interactions via inhibition and induction of several CYP450 enzymes

Pyrazinamide		
Pyrazinamide	<ul style="list-style-type: none"> Tuberculosis 	<ul style="list-style-type: none"> No activity against <i>M. bovis</i> Activated under acidic conditions; synergizes with rifampin Pyrazinamide clearance reduced in renal failure; reduce dosing frequency is reduced to 3 x/week at low GFR. Removed by hemodialysis; redose after each session Adverse effects: hepatotoxicity and hyperuricemia
Ethambutol		
Ethambutol	<ul style="list-style-type: none"> Tuberculosis <i>M. avium</i> complex infections <i>M. kansasii</i> infection Activity against <i>M. gordonae</i>, <i>M. marinum</i>, <i>M. scrofulaceum</i>, and <i>M. szulgai</i> 	<ul style="list-style-type: none"> Incidence of optic neuritis leading to decreased visual acuity and loss of red-green discrimination. Test visual acuity and red-green discrimination prior to the start of therapy and periodically thereafter. In renal failure, ethambutol should be dosed at 15–25 mg/kg three times a week instead of daily, even in patients receiving hemodialysis.
Bicyclic Nitroimidazoles		
Pretomanid, delamanid	<ul style="list-style-type: none"> Treatment of MDR-TB; being tested for regimens used to treat drug-susceptible TB 	<ul style="list-style-type: none"> Kills both replicating and nonreplicating <i>M. tuberculosis</i> Delamanid: QT segment prolongation
Riminophenazines		
Clofazimine	<ul style="list-style-type: none"> Treatment of leprosy 	<ul style="list-style-type: none"> GI problems are encountered in 40%–50% of patients. Abdominal pain due to crystal deposition in cavities and tissues Body secretion, eye, and skin reddish-black discoloration occur in most patients
Diarylquinone		
Bedaquiline	<ul style="list-style-type: none"> Treatment of MDR-TB; being tested for regimens used to treat drug-susceptible TB 	<ul style="list-style-type: none"> Apparent volume of distribution > 10,000 L Controversy regarding side effects profile and increased number of deaths compared to placebo QT interval prolongation
Ethionamide		
Ethionamide	<ul style="list-style-type: none"> Treatment of MDR-TB and XDR-TB 	<ul style="list-style-type: none"> Same mutations in ethionamide-resistant bacteria as for isoniazid-resistant bacteria 50% of patients are unable to tolerate a single dose larger than 500 mg because of GI toxicity. Adverse effects: postural hypotension, mental depression, drowsiness, asthenia; neurological toxicity Concomitant administration with pyridoxine is recommended. Hepatitis in ~ 5% of cases
Para-aminobenzoic Acid Analogues		
Dapsone	<ul style="list-style-type: none"> Treatment of leprosy Combined with chlorproguanil for the treatment of malaria Treatment of <i>Pneumocystis jirovecii</i> infection and prophylaxis Prophylaxis of <i>Toxoplasma gondii</i> infection Anti-inflammatory effects for treatment of pemphigoid, dermatitis herpetiformis, linear IgA bullous disease, relapsing chondritis, and brown recluse spider bite ulcers 	<ul style="list-style-type: none"> G6PD deficiency should be tested prior to use. NADH-dependent methemoglobin reductase deficiency–associated methemoglobinemia Hemolysis at doses of 200–300 mg of dapsone per day Used topically for acne
Aminosalicic acid	<ul style="list-style-type: none"> Treatment of MDR-TB 	<ul style="list-style-type: none"> Should be administered with food Dose must be reduced in renal dysfunction. Adverse events incidence is ~ 10%–30%. GI problems predominate Hypersensitivity reactions in 5%–10% of patients
Cycloserine		
Cycloserine	<ul style="list-style-type: none"> Treatment of MDR-TB 	<ul style="list-style-type: none"> Oral second-line drug “Psych-serine”: 50% of patients develop neuropsychiatric symptoms; headache, somnolence, severe psychosis, seizures, and suicidal ideas Must be redosed after dialysis

Kingdom Fungi and Its Impact on Humans

There are 200,000 known species of fungi, and estimates of the total size of the kingdom Fungi range to well over a million. Residents of the kingdom are quite diverse and include yeasts, molds, mushrooms, and smuts. About 400 fungal species cause disease in animals, and even fewer cause human disease. Nonetheless, fungal infections are associated with significant morbidity and mortality. The incidence of life-threatening fungal infections has increased in recent decades owing to an increase in immunocompromised patient populations, such as those receiving hematologic or solid-organ transplantation, cancer chemotherapy, and immunosuppressive medications, as well as those with HIV/AIDS (Richardson, 2005). This has made antifungal agents increasingly important to the practice of modern medicine. With the currently available antifungal pharmacopeia, mortality rates for invasive fungal disease remain unacceptably high (Brown et al., 2012).

Fungi are eukaryotes, making the discovery and development of drugs that target the pathogen without posing significant toxicity to the host a challenging undertaking. Differences in the biosynthesis of membrane sterols, the ability of fungi to deaminate cytosine, and the unique fungal cell wall that contains glucans and chitin have all been exploited to produce relatively safe and effective antifungal agents for the treatment of fungal infections (Roemer and Krysan, 2014). Since the advent of amphotericin B-deoxycholate in the late 1950s, research has sought safer and more effective alternatives for the treatment of systemic fungal infections. While amphotericin B remains the gold standard of systemic antifungal pharmacotherapy for a wide range of infections, alternative therapies have emerged for many clinically important fungal pathogens.

This chapter provides a comprehensive overview of currently available therapeutic options for the management of invasive, mucosal, and superficial fungal infections. With only a few exceptions, the antifungals in common clinical use act mainly at sites involving the cell wall and cell membrane (Figure 61–1). Table 61–1 summarizes common fungal infections and their pharmacotherapy. Recommended adult dosages are briefly discussed for each agent. Dosing recommendations for antifungal agents in children have been recently reviewed elsewhere (Autmizguine et al., 2014).

Systemic Antifungal Agents: Drugs for Deeply Invasive Fungal Infections

Amphotericin B

Chemistry

Amphotericin B is an amphipathic or amphoteric polyene macrolide molecule with the broadest spectrum of activity of any of the currently

available antifungal drugs. Polyene macrolide compounds share the characteristics of four to seven conjugated double bonds, an internal cyclic ester, poor aqueous solubility, substantial toxicity when administered systemically, and a common mechanism of antifungal action. Amphotericin B, a heptaene macrolide, contains seven conjugated trans-double bonds and a 3-amino-3,6-dideoxymannose (mycosamine) connected to the macrolide ring through a glycosidic bond (Figure 61–2). The amphoteric properties of the drug, from which it derives its name, are due to the presence of a carboxyl group on the main ring and a primary amino group on mycosamine; these groups confer aqueous solubility at extremes of pH.

Mechanism of Action

The antifungal activity of amphotericin B depends principally on its ability to bind *ergosterol* in the membrane of sensitive fungi. Amphotericin B has long been thought to form pores or channels that increase the permeability of the membrane and allow leakage of cytosolic molecules and ions, leading to loss of membrane integrity. However, recent evidence suggests amphotericin B forms aggregates that sequester ergosterol from lipid bilayers much like a sponge, resulting in fungal cell death (Anderson et al., 2014) (Figure 61–2).

Formulations

Four formulations of amphotericin B are commercially available: C-AMB, ABCD, L-AMB, and ABLC. Table 61–2 summarizes the pharmacokinetic properties of the available amphotericin B preparations, which have recently been extensively reviewed (see Hamill, 2013).

C-AMB. Amphotericin B is insoluble in water but, when formulated with the bile salt deoxycholate, becomes suitable for intravenous infusion. The complex is marketed as a lyophilized powder for injection. C-AMB forms a colloid in water, with particles largely less than 0.4 μm in diameter. As a result, filters in intravenous infusion lines that trap particles larger than 0.22 μm in diameter will remove significant amounts of drug.

Abbreviations

ABC: ATP-binding cassette
ABCD: amphotericin B colloidal dispersion
ABLC: amphotericin B lipid complex
AUC: area under the C_p -time curve.
C-AMB: conventional amphotericin B
CGD: chronic granulomatous disease
CNS: central nervous system
CSF: cerebrospinal fluid
CYP: cytochrome P450
dTMP: deoxythymidine-5'-monophosphate
dUMP: deoxyuridine-5'-monophosphate
FDA: Food and Drug Administration
5FdUMP: 5-fluoro-2'-deoxyuridine-5'-monophosphate
5FU: 5-fluorouracil
5FUDP: 5-fluorouridine-5'-diphosphate
5FUMP: 5-fluorouracil-ribose monophosphate
5FUTP: 5-fluorouridine triphosphate
GVHD: graft-versus-host disease
ART: antiretroviral therapy
HIV-AIDS: human immunodeficiency virus-acquired immunodeficiency syndrome
L-AMB: liposomal amphotericin B
PCP: *Pneumocystis carinii* pneumonia
PJP: *Pneumocystis jiroveci* pneumonia
SBECD: sulfobutyl ether β -cyclodextrin
TLR: toll-like receptor
UPRTase: uracil phosphoribosyl transferase

Furthermore, the addition of electrolytes to infusion solutions will cause the colloid to aggregate and complicate administration.

ABCD. Amphotericin B colloidal dispersion contains roughly equimolar amounts of amphotericin B and cholesteryl sulfate formulated for injection. Like C-AMB, ABCD forms a colloidal solution when reconstituted in aqueous solution. ABCD provides much lower blood levels than C-AMB in humans. In a study of patients with neutropenic fever that compared daily ABCD (4 mg/kg) with C-AMB (0.8 mg/kg), chills and hypoxia were significantly more common in patients who received ABCD as compared with C-AMB (White et al., 1998). Hypoxia was associated with severe febrile reactions. In a study that compared ABCD (6 mg/kg) to C-AMB (1–1.5 mg/kg) in patients with invasive aspergillosis, ABCD was less nephrotoxic than C-AMB (15% vs. 49%) but caused more fever (27% vs. 16%) and chills (53% vs. 30%) (Bowden et al., 2002). ABCD is currently not commercially available in the U.S.

L-AMB. Liposomal amphotericin B is a formulation in which AMB is incorporated within a small, unilamellar liposomal vesicle formulation. The drug is supplied as a lyophilized powder and is reconstituted with sterile water for injection (Boswell et al., 1998). Blood levels following intravenous infusion are almost equivalent to those obtained with C-AMB, and because L-AMB can be given at higher doses, blood levels have been achieved that exceed those obtained with C-AMB (Boswell et al., 1998) (Table 61–2).

ABLC. Amphotericin B lipid complex is a complex of amphotericin B with two phospholipids (dimyristoylphosphatidylcholine and dimyristoylphosphatidylglycerol) (Slain, 1999). ABLC is given in a dose of 5 mg/kg in 5% dextrose in water, infused intravenously once daily over 2 h. Blood levels of amphotericin B are much lower with ABLC than with the same dose of C-AMB. ABLC is effective in a variety of mycoses, with the possible exception of cryptococcal meningitis. The drug is approved for salvage therapy of deep mycoses.

Figure 61–1 Sites of action of antifungal agents. Many antifungal agents act at sites involving cell wall and cell membrane function. Amphotericin B and other polyenes (e.g., nystatin) bind to ergosterol in fungal cell membranes and increase membrane permeability. The imidazoles and triazoles (itraconazole, etc.) inhibit 14- α -sterol demethylase, prevent ergosterol synthesis, and lead to the accumulation of toxic 14- α -methylsterols. The allylamines (e.g., naftifine and terbinafine) inhibit squalene epoxidase and prevent ergosterol synthesis. The echinocandins (e.g., caspofungin) inhibit the formation of glucans in the fungal cell wall. Metabolites of 5-fluorocytosine can disrupt fungal RNA and DNA synthesis. Griseofulvin inhibits microtubule assembly, thereby blocking fungal mitosis. Oxaboroles inhibit fungal aminoacyl tRNA synthase, thereby inhibiting fungal protein synthesis.

Comparisons

Compared to C-AMB, all three of the amphotericin B lipid formulations appear to reduce the risk of acute kidney injury (defined as a doubling of patient serum creatinine) during therapy by 58% (Barrett et al., 2003). In patients at high risk for nephrotoxicity, ABLC has been observed to be more nephrotoxic than L-AMB (Wingard et al., 2000). Infusion-related reactions are not consistently reduced with the use of lipid preparations. ABCD causes more infusion-related reactions than C-AMB. Although L-AMB reportedly causes fewer infusion-related reactions than ABLC during the first dose (Wingard et al., 2000), the difference depends on whether premedication is given and varies considerably amongst patients. Infusion-related reactions typically decrease with subsequent infusions. While less toxic, the lipid formulations are much more costly than C-AMB, making them unavailable in many countries and dictating prudent use in the U.S. and other resource-rich areas. Interestingly, C-AMB is tolerated by premature neonates much better than older children and adults; as a result, it remains an important part of the antifungal formulary in the critical care nursery (Autmizguine et al., 2014).

ADME

Gastrointestinal absorption of all amphotericin B formulations is negligible, and intravenous delivery is indicated for systemic use. In plasma, amphotericin B is more than 90% bound to proteins. Pharmacokinetic properties differ amongst the preparations (Table 61–2). Azotemia, liver failure, and hemodialysis do not have a measurable impact on plasma concentrations. The concentration of amphotericin B (via C-AMB) in fluids from inflamed pleura, peritoneum, synovium, and aqueous humor is approximately two-thirds that of trough concentrations in plasma. Regardless of formulation, very little amphotericin B penetrates into CSF, vitreous humor, or normal amniotic fluid.

Antifungal Activity

Amphotericin B has useful clinical activity against a broad spectrum of pathogenic fungi, including *Candida* spp., *Cryptococcus neoformans*, *Blastomyces dermatitidis*, *Histoplasma capsulatum*, *Sporothrix schenckii*, *Coccidioides* spp., *Paracoccidioides braziliensis*, *Aspergillus* spp., *Penicillium marneffeii*, *Fusarium* spp., and *Mucorales*. Amphotericin B has limited activity against the protozoa *Leishmania* spp. and *Naegleria fowleri*. The drug has no antibacterial activity.

TABLE 61-1 ■ PHARMACOTHERAPY OF MYCOSES

DEEP MYCOSES	DRUGS	SUPERFICIAL MYCOSES	DRUGS (<i>Administration mode</i>)
Invasive aspergillosis		Candidiasis	
Immunosuppressed	Voriconazole, isavuconazole, amphotericin B	Vulvovaginal	<i>Topical</i> Butoconazole, clotrimazole, miconazole, nystatin, terconazole, tioconazole
Nonimmunosuppressed	Voriconazole, isavuconazole, amphotericin B, itraconazole		<i>Oral</i> Fluconazole
Blastomycosis		Oropharyngeal	<i>Topical</i> Clotrimazole, nystatin
Rapidly progressive or CNS	Amphotericin B		<i>Oral (systemic)</i> Fluconazole, itraconazole
Indolent and non-CNS	Itraconazole		Posaconazole
Candidiasis		Cutaneous	<i>Topical</i> Amphotericin B, clotrimazole, ciclopirox, econazole, ketoconazole, miconazole, nystatin
Deeply invasive	Amphotericin B, fluconazole, voriconazole, caspofungin, micafungin, anidulafungin	Ringworm	<i>Topical</i> Butenafine, ciclopirox, clotrimazole, econazole, haloprogin, luliconazole, ketoconazole, miconazole, naftifine, oxiconazole, sertaconazole, sulconazole, terbinafine, tolnaftate, undecylenate
Coccidioidomycosis			<i>Systemic</i> Griseofulvin, itraconazole, terbinafine
Rapidly progressing	Amphotericin B	Onychomycosis	<i>Systemic</i> Griseofulvin, itraconazole, terbinafine
Indolent	Itraconazole, fluconazole		<i>Topical</i> Efinaconazole
Meningeal	Fluconazole, intrathecal amphotericin B		
Cryptococcosis			
Non-AIDS and initial AIDS	Amphotericin B, flucytosine		
Maintenance AIDS	Fluconazole		
Histoplasmosis			
Chronic pulmonary	Itraconazole		
Disseminated			
Rapidly progressing or CNS	Amphotericin B		
Indolent non-CNS	Itraconazole		
Maintenance AIDS	Itraconazole		
Mucormycosis	Amphotericin B, isavuconazole		
Pseudallescheriasis	Voriconazole, itraconazole		
Sporotrichosis			
Cutaneous	Itraconazole		
Extracutaneous	Amphotericin B, itraconazole		
Prophylaxis in the immunocompromised host	Fluconazole Posaconazole Micafungin		
Empirical therapy in the immunocompromised host (category not recognized by FDA)	Amphotericin B Caspofungin Fluconazole		
Microsporidia Infection	Albendazole Fumagillin		
Pneumocystis jiroveci pneumonia	Trimethoprim-sulfamethoxazole Pentamidine		

Fungal Resistance

Isolates of *Candida lusitanae* are frequently resistant to amphotericin B. *Aspergillus terreus* and *Aspergillus nidulans* likewise appear to be less susceptible to amphotericin B than other *Aspergillus* species (Steinbach et al., 2004). Mutants selected in vitro for resistance to nystatin (a related polyene antifungal used topically) or amphotericin B replace ergosterol with certain precursor sterols. Mutations in ergosterol biosynthesis genes *ERG2*, *ERG3*, *ERG5*, *ERG6*, and *ERG11* reduce susceptibility to amphotericin B, likely the result of reduced ergosterol in the cell membrane of these isolates (Geber et al., 1995; Hull et al., 2012; Martel et al., 2010). Resistance amongst clinical isolates of any fungal species is exceedingly rare, presumably because amphotericin B is fungicidal, and mutations that affect this critical membrane sterol are associated with significant fitness costs.

Therapeutic Uses

Typical adult doses for each amphotericin B formulation are summarized in Table 61-2. *Candida* esophagitis responds to much lower doses than deeply invasive mycoses. Intrathecal infusion of C-AMB appears to be useful in patients with meningitis caused by *Coccidioides*. Small doses of C-AMB (from 0.01 to 1.5 mg, one to three times weekly) can be injected into the CSF of the lumbar spine, cisterna magna, or lateral cerebral ventricle. Fever and headache are common reactions that may be decreased by intrathecal administration of 10–15 mg of hydrocortisone. However, the general use of intrathecal C-AMB administration cannot be recommended due to a lack of clinical data. Local injections of amphotericin B into a joint or peritoneal dialysate fluid commonly produce irritation and pain. Intraocular injection following pars plana vitrectomy has been used to treat fungal endophthalmitis.

Figure 61–2 Mechanism of action of amphotericin B. The antifungal activity of amphotericin B depends on its capacity to bind ergosterol in the fungal cell membrane. **A.** Amphotericin is an amphipathic molecule with a mycosamine moiety (shown in blue) at one end of a 14-carbon hydrophobic chain. X-ray crystallography shows the molecule to be rigid and rod shaped, with the hydrophilic hydroxyl groups of the macrolide ring forming an opposing face to the lipophilic polyenic portion. **B.** Ergosterol, here depicted as a green rod, decorates both bilayers of the fungal membrane. **C.** Amphotericin B appears to form aggregates that sequester and effectively extract ergosterol from lipid bilayers, much like a selective sponge, disrupting membrane structure and resulting in fungal cell death.

Intravenous administration of amphotericin B is the treatment of choice for invasive mucormycosis and in combination with 5-flucytosine is the gold standard for induction treatment of cryptococcal meningitis. Amphotericin B is also indicated for the treatment of severe or rapidly progressive histoplasmosis, blastomycosis, coccidioidomycosis, and penicilliosis. Amphotericin B is a salvage therapy for patients not responding to azole therapy for invasive aspergillosis, extracutaneous sporotrichosis, fusariosis, alternariosis, or trichosporonosis. Amphotericin B (C-AMB or L-AMB) can also be given to selected patients with profound neutropenia with fever who do not respond to broad-spectrum antibacterial agents over 5–7 days. However, the more recently developed azoles and echinocandins are generally the drugs of choice for such patients because of their reduced toxicity.

Adverse Effects

The major acute reactions to intravenous amphotericin B formulations are infusion-related fever and chills. These are due to the induction of a proinflammatory response in cells of the innate immune system signaling through TLR2 and CD14 (Rogers et al., 1998; Sau et al., 2003). Infusion-related reactions are most prominent with ABCD, while L-AMB administration appears to be less commonly associated with this adverse event. Tachypnea, respiratory stridor, or modest hypotension can also occur, but frank bronchospasm and anaphylaxis are rare. Patients with preexisting cardiac or pulmonary disease may tolerate the metabolic demands of the reaction poorly and develop hypoxia or hypotension. The reaction ends spontaneously in 30–45 min; treatment with meperidine may shorten it.

Pretreatment with oral acetaminophen or ibuprofen or use of intravenous hydrocortisone sodium succinate (hemisuccinate), 0.7 mg/kg, at the start of the infusion decreases reactions. Febrile reactions tend to abate with subsequent infusions.

Azotemia occurs in 80% of patients who receive C-AMB for deep mycoses (Carlson and Condon, 1994). The lipid formulations are significantly less nephrotoxic than C-AMB. Toxicity is dose dependent, usually transient, and increased by concurrent therapy with other nephrotoxic agents, such as aminoglycosides or cyclosporine. Although permanent histological changes in renal tubules occur even during short courses of C-AMB, permanent functional impairment is uncommon in adults with normal renal function prior to treatment unless the cumulative dose exceeds 3–4 g. Renal tubular acidosis and renal wasting of K^+ and Mg^{2+} also may be seen during and for several weeks after therapy. Supplemental K^+ is required in one-third of patients on prolonged therapy. Saline loading has decreased nephrotoxicity, even in the absence of water or salt deprivation. Administration of 1 L of normal saline intravenously on the day that C-AMB is to be given has been recommended for adults who are able to tolerate the Na^+ load.

Hypochromic, normocytic anemia commonly occurs during treatment with C-AMB. Anemia is less with lipid formulations and usually not seen over the first 2 weeks. The anemia is most likely due to decreased production of erythropoietin and often responds to administration of recombinant erythropoietin. Headache, nausea, vomiting, malaise, weight loss, and phlebitis at peripheral infusion sites are common. Arachnoiditis has been observed as a complication of intrathecal administration of C-AMB.

Flucytosine

Flucytosine (5-fluorocytosine) is a fluorinated pyrimidine related to fluorouracil that has a limited role in the treatment of invasive fungal infections.

Mechanism of Action

All susceptible fungi are capable of deaminating flucytosine to 5FU (Figure 61–3), a potent antimetabolite that is used in cancer chemotherapy. Fluorouracil is metabolized first to 5FUMP by the enzyme *UPRTase*. 5FUMP is then either incorporated into RNA (via synthesis of 5-fluorouridine triphosphate) or metabolized to 5FdUMP, a potent inhibitor of *thymidylate synthase*, ultimately inhibiting DNA synthesis. The selective action of flucytosine is due to the lack of *cytosine deaminase* in mammalian cells, which prevents metabolism to fluorouracil.

ADME

Flucytosine shows excellent bioavailability on oral administration and is absorbed rapidly from the GI tract. It is widely distributed in the body,

TABLE 61–2 ■ PK DATA FOR AMPHOTERICIN B FORMULATIONS AFTER MULTIPLE ADMINISTRATIONS IN HUMANS

PRODUCT	DOSE (mg/kg)	C_{max} (μg/mL)	AUC _(1-24h) (μg·hr/mL)	V (L/kg)	Cl (mL/h/kg)
L-AMB	5	83 ± 35.2	555 ± 311	0.11 ± 0.08	11 ± 6
ABCD	5	3.1	43	4.3	117
ABLC	5	1.7 ± 0.8	14 ± 7	131 ± 7.7	426 ± 188.5
C-AMB	0.6	1.1 ± 0.2	17.1 ± 5	5 ± 2.8	38 ± 15

For details, see the work of Boswell et al. (1998). From Boswell GW, et al. AmBisome (liposomal amphotericin B): a comparative review. *J Clin Pharmacol*, 1998, 38:583–592. © 1998 The American College of Clinical Pharmacology. Reprinted by permission of SAGE Publications.

Figure 61-3 Action of flucytosine in fungi. Flucytosine is transported by cytosine permease into the fungal cell, where it is deaminated to 5FU. The 5FU is then converted to 5FUMP and then is either converted to 5FUTP and incorporated into RNA or converted by ribonucleotide reductase to 5FdUMP, which is a potent inhibitor of thymidylate synthase.

with a volume of distribution that approximates total body water, and is minimally bound to plasma proteins. The peak plasma concentration in patients with normal renal function is about 70–80 $\mu\text{g/mL}$, achieved 1–2 h after a dose of 37.5 mg/kg. The flucytosine concentration in CSF is about 65%–90% of that found simultaneously in the plasma. The drug also appears to penetrate into the aqueous humor.

Approximately 80% of a given dose is excreted unchanged in the urine; concentrations in the urine range from 200 to 500 $\mu\text{g/mL}$. The $t_{1/2}$ of the drug is 3–6 h in normal individuals and may be as long as 200 h in patients with renal failure. The clearance of flucytosine is approximately equivalent to that of creatinine. In patients with decreased renal function, reduction of dosage is necessary; C_r should be measured periodically. Peak concentrations should range between 50 and 100 $\mu\text{g/mL}$. Flucytosine is cleared by hemodialysis, and patients undergoing such treatment should receive a single dose of 37.5 mg/kg after dialysis. The drug also is removed by peritoneal dialysis.

Antifungal Activity and Fungal Resistance

Flucytosine is currently used primarily as an adjunctive agent with amphotericin B in the induction phase of cryptococcal meningoencephalitis therapy. It has in vitro activity against a number of pathogens, but the emergence of resistance limits its usefulness as single-agent therapy.

Drug resistance arising during therapy (secondary resistance) is an important cause of therapeutic failure when flucytosine is used alone for cryptococcosis and candidiasis. The mechanism for this resistance can be loss of the permease necessary for cytosine transport or decreased activity of either UPRTase or cytosine deaminase (Figure 61-3).

In *C. albicans*, substitution of thymidine for cytosine at nucleotide 301 in the gene encoding UPRTase (*FURI*) causes a cysteine to become an arginine, modestly increasing flucytosine resistance (Dodgson et al., 2004). Flucytosine resistance is further increased if both *FURI* alleles in the diploid fungus are mutated.

Therapeutic Uses

Flucytosine is given orally, 50–150 mg/kg/d, in four divided doses at 6-h intervals. Dosage must be adjusted for decreased renal function. Flucytosine is used almost exclusively in combination with amphotericin B for the treatment of cryptococcal meningitis, and this combination, as compared with amphotericin B alone, is associated with improved survival amongst patients with cryptococcal meningitis (Day et al., 2013). Based on this trial, the addition of flucytosine to amphotericin B is the current gold standard for the treatment of HIV-associated cryptococcal meningitis.

In cryptococcal meningitis of non-AIDS patients, the role of flucytosine is less clear. The addition of flucytosine to 6 weeks or more of therapy with C-AMB runs the risk of substantial bone marrow suppression or colitis if the flucytosine dose is not promptly adjusted downward as amphotericin B-induced azotemia occurs.

Adverse Effects

Flucytosine may depress the bone marrow and lead to leukopenia and thrombocytopenia. Patients are more prone to this complication if they have an underlying hematological disorder, are being treated with radiation or drugs that injure the bone marrow, or have a history of treatment with such agents. Other untoward effects, including rash, nausea, vomiting, diarrhea, and severe enterocolitis, have been noted. In about 5% of patients, plasma levels of hepatic enzymes are elevated, but this effect reverses when therapy is stopped. Toxicity is more frequent in patients with AIDS or azotemia (including those who are concurrently receiving amphotericin B) and when plasma drug concentrations exceed 100 $\mu\text{g/mL}$. Toxicity may result from conversion of flucytosine to 5FU by the microbial flora in the intestinal tract of the host.

Imidazoles and Triazoles

The azole antifungals include two broad classes, imidazoles and triazoles. Of the drugs now on the market in the U.S., clotrimazole, miconazole, ketoconazole, econazole, butoconazole, oxiconazole, sertaconazole, sulconazole, tioconazole, and luliconazole are *imidazoles*; efinaconazole, terconazole, itraconazole, fluconazole, voriconazole, posaconazole, and isavuconazole are *triazoles*. The topical use of azole antifungals is described in the second section of this chapter.

Mechanism of Action

The major effect of imidazoles and triazoles on fungi is inhibition of 14- α -sterol demethylase, a CYP and the product of the gene *ERG11* (Figure 61-4). Imidazoles and triazoles thus impair the biosynthesis of ergosterol, resulting in depletion of membrane ergosterol and accumulation of the toxic product 14 α -methyl-3,6-diol, leading to growth arrest (Kanafani and Perfect, 2008), possibly by disrupting the close packing of acyl chains of phospholipids and impairing the functions of membrane-bound enzyme systems. Some azoles directly increase permeability of the fungal cytoplasmic membrane, but the concentrations required are likely only obtained with topical use.

Antifungal Activity

Azoles as a group have clinically useful activity against *C. albicans*, *Candida tropicalis*, *Candida parapsilosis*, *C. neoformans*, *Blastomyces dermatitidis*, *H. capsulatum*, *Coccidioides* spp., *Paracoccidioides brasiliensis*, and ringworm fungi (dermatophytes). *Aspergillus* spp., *Scedosporium apiospermum* (*Pseudallescheria boydii*), *Fusarium*, and *Sporothrix schenckii* are intermediate in susceptibility. *Candida glabrata* exhibits reduced

Figure 61–4 Ergosterol biosynthesis and the mechanism of action of the azole antifungals. **A.** Fungal ergosterol synthesis proceeds via a series of enzymic steps that include Erg11, a 14- α -sterol demethylase. The completed ergosterol is then inserted into both leaflets of the membrane bilayer. **B.** Imidazole and triazole antifungals inhibit the activity of 14- α -sterol demethylase, thereby reducing the biosynthesis of ergosterol and leading to the accumulation of 14- α -methylsterols. These methylsterols are toxic, disrupting the close packing of acyl chains of phospholipids, impairing the functions of certain membrane-bound enzyme systems, and thus inhibiting growth of the fungi.

susceptibility to the azoles, whereas *Candida krusei* and the agents of mucormycosis are more resistant. Posaconazole and isavuconazole have modestly improved spectrum of activity in vitro against the agents of mucormycosis.

Resistance

In *C. albicans*, azole resistance can be due in part to accumulation of mutations in *ERG11*, the gene encoding the azole target, 14- α -sterol demethylase. Increased azole efflux by overexpression of ABC and/or major facilitator superfamily transporters impart azole resistance in *C. albicans* and *C. glabrata*. Overexpression of these genes is due to activating mutations in genes encoding their transcriptional regulators. Mutation of the C5,6 sterol desaturase gene *ERG3* also can increase azole resistance in some species (Cowen et al., 2014); such mutations prevent formation of the toxic product 14 α -methyl-3,6-diol from 14 α -methylfecosterol; the resulting accumulation of 14 α -methylfecosterol produces functional membranes and overcomes the effect of azoles. Increased production of 14- α -sterol demethylase due to overexpression of *ERG11* occurs, owing to activating mutations in the gene encoding its transcriptional regulator Upc2.

Primary azole resistance has been described in some isolates of *A. fumigatus* with increased azole export and decreased ergosterol content, but the clinical significance is unknown. Decreased fluconazole susceptibility has been described in *C. neoformans* isolated from patients with AIDS failing prolonged therapy.

Interaction of Azole Antifungals With Other Drugs

The azoles interact with hepatic CYPs as substrates and inhibitors (Table 61–3), providing myriad possibilities for the interaction of azoles with many other medications. Thus, azoles can elevate plasma levels of some coadministered drugs (Table 61–4). Other coadministered drugs can decrease plasma concentrations of azole antifungal agents (Table 61–5). As a

consequence of these and other interactions, combinations of certain drugs with azole antifungal medications may be contraindicated (Table 61–6).

Available Agents

Ketoconazole. Ketoconazole, administered orally, has been replaced by itraconazole except when the lower cost of ketoconazole outweighs the advantage of itraconazole. Ketoconazole is available for topical use, as described further in this chapter.

Itraconazole. Itraconazole is a triazole that lacks the corticosteroid suppression associated with ketoconazole while retaining most of ketoconazole’s pharmacological properties and extending the antifungal spectrum. Importantly, itraconazole has activity against *Aspergillus* spp. while imidazoles do not. Itraconazole has been supplanted by other triazoles in the treatment of invasive mold infections but remains an important prophylactic agent in the prevention of mold infections in some patients (e.g., patients with CGD).

ADME. Itraconazole is available as a tablet, capsule, and a solution in hydroxypropyl- β -cyclodextrin for oral use. The capsule form of the drug is best absorbed in the fed state, but the oral solution is better absorbed in the fasting state, providing peak plasma concentrations more than 150% of those obtained with the capsule. Itraconazole is metabolized in the liver. It is both a substrate for and a potent inhibitor of CYP3A4. Itraconazole is present in plasma with an approximately equal concentration of a biologically active metabolite, hydroxy-itraconazole. The native drug and metabolite are more than 99% bound to plasma proteins. Neither appears in urine or in CSF. The $t_{1/2}$ of itraconazole at steady state is about 30–40 h. Steady-state levels of itraconazole are not reached for 4 days and those of hydroxy-itraconazole for 7 days; thus, loading doses are recommended when treating deep mycoses. Severe liver disease will increase itraconazole plasma concentrations, but azotemia and hemodialysis have no effect.

TABLE 61–3 ■ INTERACTIONS OF AZOLE ANTIFUNGAL AGENTS WITH HEPATIC CYPs				
FLUCONAZOLE	VORICONAZOLE	ITRACONAZOLE	POSACONAZOLE	ISAVUCONAZOLE
CYP3A4, 5, 7 inhibitor (moderate)	CYP2C9 inhibitor and substrate	CYP3A4, 5, 7 inhibitor and substrate	CYP3A4 inhibitor (potent)	CYP3A4 inhibitor and substrate
CYP2C9 inhibitor (strong)	CYP3A4, 5,7 inhibitor			CYP2B6 inhibitor
CYP2C19 inhibitor	CYP2C19 inhibitor and substrate			

TABLE 61-4 ■ DRUGS EXHIBITING ELEVATED C_p WHEN COADMINISTERED WITH AZOLE ANTIFUNGAL AGENTS

Alfentanil	Eplerenone	Losartan	Saquinavir
Alprazolam	Ergot alkaloids	Lovastatin	Sildenafil
Astemizole	Erlotinib	Methadone	Sirolimus
Buspirone	Eszopiclone	Methylprednisolone	Solifenacin
Busulfan	Felodipine	Midazolam	Sunitinib
Carbamazepine	Fexofenadine	Nevirapine	Tacrolimus
Cisapride	Gefitinib	Omeprazole	Triazolam
Cyclosporine	Glimepiride	Phenytoin	Vardenafil
Digoxin	Glipizide	Pimozide	Vinca alkaloids
Docetaxel	Halofantrine	Quinidine	Warfarin
Dofetilide	Haloperidol	Ramelteon	Zidovudine
Efavirenz	Imatinib	Ranolazine	Zolpidem
Eletriptan	Irinotecan	Risperidone	

Mechanism of interaction presumably occurs largely at the level of hepatic CYPs, especially CYPs 3A4, 2C9, and 2D6, but can also involve P-glycoprotein and other mechanisms. Not all drugs listed interact equally with all azoles.

Therapeutic Uses. Itraconazole is the drug of choice for patients with indolent, nonmeningeal infections due to *B. dermatitidis*, *H. capsulatum*, *P. brasiliensis*, and *Coccidioides immitis*. The drug also is useful in the therapy of indolent invasive aspergillosis outside the CNS, particularly after the infection has been stabilized with amphotericin B. Approximately half of the patients with distal subungual onychomycosis respond to itraconazole (Evans and Sigurgeirsson, 1999). Although not an approved use, itraconazole is a reasonable choice for the treatment of pseudallescheriasis, an infection that does not respond to amphotericin B therapy, as well as cutaneous and extracutaneous sporotrichosis, tinea corporis, and extensive tinea versicolor. HIV-infected patients with disseminated histoplasmosis or penicilliosis have a decreased incidence of relapse if given prolonged itraconazole “maintenance” therapy. Itraconazole is not recommended for maintenance therapy of cryptococcal meningitis in HIV-infected patients because of a high incidence of relapse. Long-term itraconazole therapy has been used in non-HIV-infected patients with allergic bronchopulmonary aspergillosis to decrease the dose of glucocorticoids and reduce attacks of acute bronchospasm (Salez et al., 1999).

Itraconazole solution is effective and approved for use in oropharyngeal and esophageal candidiasis. Because the solution has more GI side effects than fluconazole tablets, itraconazole solution usually is reserved for patients not responding to fluconazole. Finally, itraconazole is also used as *Aspergillus* prophylaxis in patients with CGD.

Dosage. In treating deep mycoses, a loading dose of 200 mg of itraconazole is administered three times daily for the first 3 days. After the loading doses, two 100-mg capsules are given twice daily with food. Divided doses may increase the AUC. For maintenance therapy of HIV-infected patients with disseminated histoplasmosis, 200 mg once daily is used. Onychomycosis can be treated with either 200 mg once daily for 12 weeks or, for infections isolated to fingernails, two monthly cycles consisting of 200 mg twice daily for 1 week followed by a 3-week period of no therapy—so-called pulse therapy (Evans and Sigurgeirsson, 1999). Once-daily terbinafine (250 mg), however, is superior to pulse therapy with itraconazole. For oropharyngeal candidiasis, itraconazole oral solution should be taken during fasting in a dose of 100 mg (10 mL) once daily and swished vigorously in the mouth before swallowing to optimize any topical effect.

TABLE 61-5 ■ SOME DRUGS THAT DECREASE AZOLE CONCENTRATION WHEN COADMINISTERED

Patients with esophageal thrush unresponsive or refractory to treatment with fluconazole tablets are given 100 mg of the solution twice a day for 2–4 weeks. The typical dose for fungal prophylaxis in patients with CGD is 5 mg/kg per day.

Adverse Effects. Serious hepatotoxicity has led, in rare cases, to hepatic failure and death. If symptoms of hepatotoxicity occur, the drug should be discontinued and liver function assessed. In the absence of interacting drugs, itraconazole capsules and suspension are well tolerated at 200 mg daily. Diarrhea, abdominal cramps, anorexia, and nausea are more common than with the capsules. Of patients receiving 50–400 mg of the capsules per day, nausea and vomiting, hypertriglyceridemia, hypokalemia, increased serum aminotransferase, and rash occurred in 2%–10%. Occasionally, rash necessitates drug discontinuation, but most adverse effects can be handled with dose reduction. Profound hypokalemia has been seen in patients receiving 600 mg or more daily and in those who recently have received prolonged amphotericin B therapy. Doses of 300 mg twice daily have led to other side effects, including adrenal insufficiency, lower limb edema, hypertension, and in at least one case, rhabdomyolysis. Doses greater than 400 mg per day are not recommended for long-term use. Anaphylaxis has been observed rarely, as well as severe rash, including Stevens-Johnson syndrome. Itraconazole is contraindicated for the treatment of onychomycosis during pregnancy or for women contemplating pregnancy.

Drug Interactions. Tables 61-4, 61-5, and 61-6 list select interactions of azoles with other drugs. Many of the interactions can result in serious toxicity from the companion drug, such as inducing potentially fatal cardiac arrhythmias when used with quinidine, halofantrine (an orphan drug used for malaria), levomethadyl (an orphan drug used for heroin addiction), pimozide, or cisapride (available only under an investigational limited access program in the U.S.). Other drugs may decrease itraconazole serum levels below therapeutic concentrations (Table 61-5).

Fluconazole. Fluconazole is a fluorinated bis-triazole.

ADME. Fluconazole is almost completely absorbed from the GI tract. Plasma concentrations are essentially the same whether the drug is given orally or intravenously, and its bioavailability is unaltered by food or gastric acidity. Peak plasma concentrations are 4–8 µg/mL after repetitive doses of 100 mg. Renal excretion accounts for more than 90% of elimination, and the elimination $t_{1/2}$ is 25–30 h. Fluconazole diffuses readily into body fluids, including breast milk, sputum, and saliva; concentrations in CSF can reach 50%–90% of the simultaneous values in plasma. The dosage interval should be increased from 24 to 48 h with a creatinine clearance of 21–40 mL/min and to 72 h at 10–20 mL/min. A dose of 100–200 mg should be given after hemodialysis. About 11%–12% of drug in the plasma is protein bound.

Therapeutic Uses.

- **Candidiasis.** Fluconazole, 100–200 mg daily for 7–14 days, is effective in oropharyngeal candidiasis. A single dose of 150 mg is effective in uncomplicated vaginal candidiasis. A loading dose of 800 mg followed by 400 mg daily is useful in treating candidemia of nonimmunosuppressed patients (Pappas et al., 2007; Rex et al., 1994). Although response to *C. glabrata* bloodstream infections in randomized trials using fluconazole has been comparable to that with *C. albicans*, *C. glabrata* exhibits inherent reduced susceptibility and can become highly resistant on prolonged exposure to fluconazole. Empirical use of fluconazole for suspected candidemia may not be advisable in patients who have received long-term fluconazole prophylaxis and, as a result, may be colonized with azole-resistant *C. glabrata*. Based on resistance in vitro, *C. krusei* would not be expected to respond to fluconazole or other azoles.
- **Cryptococcosis.** Fluconazole, 400 mg daily, is used for the initial 8 weeks of the consolidation phase of the treatment of cryptococcal meningitis in patients with AIDS. Induction therapy involves an initial course of at least 2 weeks of intravenous amphotericin B. If, after 8 weeks at 400 mg per day, the patient is no longer symptomatic, then the dose is decreased to 200 mg daily and continued indefinitely. If the patient has completed 12 months of treatment of cryptococcosis, responds to HAART, has a CD4 count maintained above 200/mm³ for at least 6 months, and is asymptomatic from cryptococcal meningitis, it is reasonable to discontinue maintenance fluconazole as long as the CD4 response is maintained. Fluconazole, 400 mg daily, has been recommended as continuation therapy in patients without AIDS with cryptococcal meningitis who have responded to an initial course of C-AMB or L-AMB and for patients with pulmonary cryptococcosis (Perfect et al., 2010).
- **Other Mycoses.** Fluconazole is the drug of choice for treatment of coccidioid meningitis because of good penetration into the CSF and much less morbidity than with intrathecal amphotericin B. In other forms of coccidioidomycosis, fluconazole is comparable to itraconazole. Fluconazole has no useful activity against histoplasmosis, blastomycosis, or sporotrichosis and is not effective in the prevention or treatment of aspergillosis. Fluconazole has no activity in mucormycosis.

Dosage. Fluconazole is marketed in the U.S. as tablets of 50, 100, 150, and 200 mg for oral administration, powder for oral suspension providing 10 and 40 mg/mL, and intravenous solutions containing 2 mg/mL in saline and in dextrose solution. The daily dose of fluconazole should be based on the infecting organism and the patient's response to therapy. Generally, recommended dosages are 50–400 mg once daily for either oral or intravenous administration. A loading dose of twice the daily maintenance dose is generally administered on the first day of therapy. Prolonged maintenance therapy may be required to prevent relapse. Children are treated with 12 mg/kg once daily (maximum 600 mg/d) without a loading dose. In adult patients, doses of up to 1200 mg have been safely administered in clinical trials for the treatment of cryptococcal meningitis.

Adverse Effects. Side effects in patients receiving more than 7 days of drug, regardless of dose, include nausea, headache, skin rash, vomiting, abdominal pain, and diarrhea (all at 2%–4%). Reversible alopecia may occur with prolonged therapy at 400 mg daily. Rare cases of deaths due to hepatic failure or Stevens-Johnson syndrome have been reported. Fluconazole has been associated with skeletal and cardiac deformities in at least three infants born to two women taking high doses during pregnancy. Although a recent clinical study found no association between fluconazole receipt by mothers and most birth defects in their children, this study did find a statistically significant increase in tetralogy of Fallot in babies born to mothers who received fluconazole (Mølgaard-Nielsen et al., 2013). Fluconazole should be avoided during pregnancy.

Drug Interactions. Fluconazole is an inhibitor of CYP3A4 and CYP2C9. Fluconazole's drug-drug interactions are shown in Tables 61–4, 61–5, and 61–6. Patients who receive more than 400 mg daily or azotemic patients who have elevated fluconazole blood levels may experience drug interactions not otherwise seen.

Voriconazole. Voriconazole is a triazole with a structure similar to fluconazole but with increased activity in vitro, an expanded spectrum, and poor aqueous solubility.

ADME. Voriconazole is available as 50- or 200-mg tablets or a suspension of 40 mg/mL when hydrated. The tablets, but not the suspension, contain lactose. Because high-fat meals reduce voriconazole bioavailability, oral drug should be given either 1 h before or 1 h after meals. Oral bioavailability is 96%; volume of distribution is high (4.6 L/kg), with extensive drug distribution in tissues. Metabolism occurs through CYPs 2C19 and 2C9; CYP3A4 plays a limited role. Plasma elimination $t_{1/2}$ is 6 h. Voriconazole exhibits nonlinear metabolism so that higher doses cause greater-than-linear increases in systemic drug exposure. Genetic polymorphisms in CYP2C19 can cause up to 4-fold differences in drug exposure: About 20% of Asians are homozygous poor metabolizers, compared with 2% of whites and African Americans. Less than 2% of parent drug is recovered from urine; 80% of the inactive metabolites are excreted in the urine. The oral dose does not have to be adjusted for azotemia or hemodialysis. Patients with mild-to-moderate cirrhosis should receive the same loading dose of voriconazole but half the maintenance dose. The intravenous formulation of voriconazole contains SBECD, which is excreted by the kidney. Significant accumulation of SBECD occurs with a creatinine clearance less than 50 mL/min; in that setting, oral voriconazole is preferred. Therapeutic drug monitoring is frequently used, with target serum concentrations between 1 and 5 mg/L thought to maximize efficacy and minimize adverse events.

Therapeutic Uses. Voriconazole shows superior efficacy to C-AMB in the therapy of invasive aspergillosis using rate of response as the primary end point (Herbrecht et al., 2002); survival also is superior with voriconazole. Voriconazole was compared to L-AMB for empirical therapy of neutropenic patients whose fever did not respond to more than 96 h of antibacterial therapy. Because the 95% confidence interval in this noninferiority trial permitted the possibility that voriconazole might be more than 10% worse than L-AMB, the FDA did not approve voriconazole for this use (Walsh et al., 2002); however, in a secondary analysis, there were fewer breakthrough infections with voriconazole (1.9%) than with L-AMB (5%).

Voriconazole is approved for use in esophageal candidiasis. In nonneutropenic patients with candidemia, voriconazole is comparable in efficacy and less toxic than initial C-AMB followed by fluconazole (Kullberg et al., 2005). Voriconazole is approved for initial treatment of candidemia and invasive aspergillosis, as well as for salvage therapy in patients with *P. boydii* (*S. apiospermum*) and *Fusarium* infections. Positive responses in patients with cerebral fungal infections suggest that the drug penetrates infected brain.

Dosage. Treatment is usually initiated with an intravenous infusion of 6 mg/kg every 12 h for two doses, followed by 3–4 mg/kg every 12 h, administered no faster than 3 mg/kg/h. As the patient improves, oral administration is continued as 200 mg every 12 h. Patients failing to respond may be given 300 mg every 12 h.

Adverse Effects. Voriconazole is teratogenic in animals and generally contraindicated in pregnancy. Although voriconazole is generally well tolerated, occasional cases of hepatotoxicity have been reported, and liver function should be monitored. Voriconazole can prolong the QTc interval, a significant issue in patients with other risk factors for torsades de pointes. Transient visual or auditory hallucinations are frequent after the first dose, usually at night and particularly with intravenous administration. Symptoms diminish with time. Patients receiving their first intravenous infusion have had anaphylactoid reactions. Rash occurs in 6% of patients. The cyclodextrin component of intravenous formulations may be toxic to the kidney; thus, intravenous voriconazole should be used with caution in patients with renal failure (Neofytos et al., 2012).

Drug Interactions. Voriconazole is metabolized by, and inhibits, CYPs 2C19, 2C9, and 3A4 (in that order of decreasing potency). The major metabolite of voriconazole, the voriconazole N-oxide, also inhibits these CYPs. Inhibitors or inducers of these CYPs may increase or decrease voriconazole plasma concentrations, respectively. Voriconazole and its major metabolite can increase the plasma concentrations of other drugs metabolized by these enzymes (Tables 61–4, 61–5, and 61–6). Because the

1096 AUC of sirolimus increases 11-fold in the presence of voriconazole, coadministration is contraindicated. When starting voriconazole in a patient receiving 40 mg/d or more of omeprazole, the dose of omeprazole should be reduced by half.

Posaconazole. Posaconazole is a synthetic structural analogue of itraconazole with the same broad antifungal spectrum but with up to 4-fold greater activity in vitro against yeasts and filamentous fungi, including some, but not all, of the agents that cause mucormycosis (Frampton and Scott, 2008). Activity against yeasts in vitro is similar to voriconazole. The mechanism of action is the same as other imidazoles, inhibition of sterol 14- α -demethylase.

ADME. Posaconazole is available as a flavored suspension containing 40 mg/mL. Bioavailability of the oral suspension is significantly enhanced by the presence of food (Courtney et al., 2003; Krieter et al., 2004). The drug has a long $t_{1/2}$ (25–31 h), a large volume of distribution (331–1341 L), and extensive protein binding (>98%). Systemic exposure is four times higher in homozygous CYP2C19 slow metabolizers than in homozygous wild-type metabolizers. Steady-state concentrations are reached in 7–10 days when dosed four times daily. Renal impairment does not alter plasma concentrations; hepatic impairment causes a modest increase. Almost 80% of the drug is excreted in the stool, with 66% as unchanged drug. The major metabolic pathway is hepatic UDP glucuronidation (Krieter et al., 2004). Hemodialysis does not remove drug from the circulation. Gastric acid improves absorption (Krishna et al., 2009); drugs that reduce gastric acid (e.g., cimetidine and esomeprazole) decrease posaconazole exposure by 32%–50% (Frampton and Scott, 2008). Diarrhea reduces the average C_p by 37% (Smith et al., 2009). The delayed-release tablet and intravenous formulations provide a more consistent bioavailability in the presence of concomitant disease states, medications, and dietary considerations that alter concentrations achievable with the oral suspension (Guarascio and Slain, 2015).

Therapeutic Uses. Posaconazole is approved for treatment of oropharyngeal candidiasis, although fluconazole is the preferred drug because of safety and cost. Posaconazole is also approved for prophylaxis against candidiasis and aspergillosis in patients more than 13 years of age who have prolonged neutropenia or severe GVHD (Ullmann et al., 2007). It is approved in the E.U. as salvage therapy for aspergillosis and several other infections, as are itraconazole and voriconazole.

Dosage. For prophylaxis of invasive *Aspergillus* and *Candida* infections, the adult intravenous dose is 300 mg twice on day 1 and 300 mg daily thereafter. Duration of therapy is based on recovery from neutropenia or immunosuppression. The same dose is used for the delayed-release tablets. The dose for the oral suspension is 200 mg (5 mL) three times daily.

Adverse Effects. Common adverse effects include nausea, vomiting, diarrhea, abdominal pain, and headache (Smith et al., 2009). Although adverse effects occur in at least a third of patients, the rate of discontinuation due to adverse effects in long-term studies has been only 8%.

Drug Interactions. Posaconazole inhibits CYP3A4. Coadministration with rifabutin or phenytoin increases the plasma concentration of these drugs and decreases posaconazole exposure by 2-fold. Posaconazole increases the AUC of cyclosporine, tacrolimus (121%), sirolimus (790%), midazolam (83%), and other CYP3A4 substrates (Table 61–4) (Frampton and Scott, 2008; Krishna et al., 2009; Moton et al., 2009). Posaconazole can prolong the QTc interval and should not be coadministered with drugs that are CYP3A4 substrates that likewise prolong the QTc interval, such as methadone, haloperidol, pimozide, quinidine, risperidone, sunitinib, tacrolimus, and halofantrine (Table 61–4).

Isavuconazole. Isavuconazole is a triazole that is administered as the isavuconazonium prodrug.

ADME. Isavuconazole is available in both oral and cyclodextrin-free intravenous formulations. It is highly bioavailable (98%) and is more than 99% protein bound in serum. Administration of oral isavuconazonium with food reduces AUC by about 20%. Isavuconazole is eliminated by hepatic metabolism, predominantly by CYP3A4 and CYP3A5. Less than 1% of isavuconazole is excreted unchanged in urine. No renal dose adjustments are needed (Rybak et al., 2015).

Therapeutic Uses. Isavuconazole exhibits a broad spectrum of activity against most yeast species, including *Candida* species, *Cryptococcus gattii* and *C. neoformans*, and molds such as *Aspergillus* species and *Mucorales* species complex. The drug is approved for the treatment of invasive aspergillosis and invasive mucormycosis and is under investigation for treatment of candidemia and invasive candidiasis.

Dosage. Isavuconazole is dosed as 372 mg isavuconazonium sulfate (equivalent to 200 mg of isavuconazole) every 8 h for six doses followed by 372 mg isavuconazonium sulfate by mouth or intravenously once daily starting 12 to 24 h after the last loading dose.

Adverse Effects. Isavuconazole is generally well tolerated. GI disorders, pyrexia, hypokalemia, headache, constipation, and cough are the most frequently reported adverse effects.

Drug Interactions. Isavuconazole is both a substrate and an inhibitor of CYP3A4. Consequently, a 5-fold increase in isavuconazole AUC results when it is administered with strong CYP inhibitors such as ketoconazole. Substantial reductions in isavuconazole AUC also result from coadministration of isavuconazole with rifampin. Midazolam and sirolimus AUCs are increased by coadministration with isavuconazole. Importantly, isavuconazole does not appear to prolong QTc.

Echinocandins

Echinocandins are cyclic lipopeptides with a hexadepsipeptide nucleus. Three echinocandins are approved for clinical use: caspofungin, anidulafungin, and micafungin. All act through the same mechanism but differ in pharmacological properties. Fungi that are susceptible to echinocandins include *Candida* and *Aspergillus* spp. (Bennett, 2006).

General Pharmacological Characteristics

Mechanism of Action. The echinocandins inhibit 1,3- β -D-glucan synthesis, which is an essential component of the fungal cell wall and is required for in cellular integrity (Figure 61–5).

Antifungal Activity. Echinocandins exhibit fungicidal activity against *Candida* species. In contrast, they are fungistatic against *Aspergillus* species and cause morphological changes to the filaments. Echinocandins do not appear to have clinically useful activity against dimorphic fungi such as *H. capsulatum* and have no activity against *C. neoformans*, *Trichosporon* spp., *Fusarium* spp., or agents of mucormycosis.

Resistance. Echinocandin resistance has emerged as a clinical problem and results from mutations leading to amino acid substitutions in the Fks subunits of glucan synthase (Cowen et al., 2014). Multidrug transporters do not appear to play a role in echinocandin resistance. Mutations conferring resistance occur in two conserved “hot spot” regions of *FKS1* in *C. albicans* and in *FKS1* and *FKS2* in *C. glabrata*. *Candida parapsilosis* complex and *Candida guilliermondii* display reduced in vitro echinocandin susceptibility as compared to other *Candida* species owing to inherently occurring polymorphisms in Fks hot spot regions. Species-specific clinical breakpoints for echinocandins have been recently described.

Echinocandins differ somewhat pharmacokinetically (Table 61–7) but all share extensive protein binding (>97%), inability to penetrate into CSF, lack of renal clearance, and only a slight-to-modest effect of hepatic insufficiency on plasma drug concentrations (Kim et al., 2007; Wagner et al., 2006). Currently available echinocandins also lack oral bioavailability and are available only for intravenous administration. Generally speaking, adverse effects are minimal and rarely lead to drug discontinuation (Kim et al., 2007). All three agents are well tolerated, with the exception of phlebitis at the infusion site. Histamine-like effects have been reported with rapid infusions. All three echinocandins are contraindicated in pregnancy.

Available Agents

Caspofungin. Caspofungin acetate is a water-soluble, semisynthetic lipopeptide synthesized from the fermentation product of *Glarea lozoyensis* (Johnson and Perfect, 2003; Keating and Figgitt, 2003).

Figure 61-5 The fungal cell wall and membrane and the action of echinocandins. The strength of the fungal cell wall is maintained by fibrillar polysaccharides, largely β -1,3-glucan and chitin, which bind covalently to each other and to proteins. A glucan synthase complex in the plasma membrane catalyzes the synthesis of β -1,3-glucan; the glucan is extruded into the periplasm and incorporated into the cell wall. Echinocandins inhibit the activity of the glucan synthase complex, resulting in loss of the structural integrity of the cell wall. The Fks1p subunit of glucan synthase appears to be the target of echinocandins, and mutations in Fks1p cause resistance to echinocandins.

CASPOFUNGIN

ADME. Catabolism is largely by hydrolysis and *N*-acetylation, with excretion of the metabolites in the urine and feces. Mild and moderate hepatic insufficiency increase the AUC by 55% and 76%, respectively.

Therapeutic Use. Caspofungin is approved for the treatment of invasive candidiasis and as salvage therapy for patients with invasive aspergillosis who fail or are intolerant of approved drugs, such as amphotericin B formulations or voriconazole. Caspofungin is also approved for both esophageal and invasive candidiasis (Mora-Duarte et al., 2002; Villanueva et al., 2001) and for treatment of persistently febrile neutropenic patients with suspected fungal infections (Walsh et al., 2004).

Dosage. Caspofungin is administered intravenously once daily over 1 h. For candidemia and salvage therapy of aspergillosis, the initial dose is 70 mg, followed by 50 mg daily. The dose should be increased to 70 mg daily in patients receiving rifampin as well as in those failing to respond

to 50 mg. Esophageal candidiasis is treated with 50 mg daily. In moderate hepatic failure, the dose should be reduced to 35 mg daily.

Drug Interactions. Caspofungin increases tacrolimus levels by 16%, which should be managed by standard monitoring. Cyclosporine slightly increases caspofungin levels. Rifampin and other drugs activating CYP3A4 can cause a slight reduction in caspofungin levels.

Micafungin. Micafungin is a water-soluble semisynthetic echinocandin derived from the fungus *Coleophoma empedri*.

ADME; Drug Interactions. Micafungin has linear pharmacokinetics over a large range of doses (1–3 mg/kg) and ages (premature infants to elderly). Small amounts of drug are metabolized in the liver by arylsulfatase and catechol *O*-methyltransferase. Hydroxylation by CYP3A4 is barely detectable. Unlike caspofungin, reduction of the micafungin dose in moderate hepatic failure is not required. Micafungin shows age-dependent clearance in children, with rapid clearance in premature infants and intermediate clearance in children 2–8 years of age, compared to older children and adults.

In normal volunteers, micafungin appears to be a mild inhibitor of CYP3A4, increasing the AUC of nifedipine by 18% and sirolimus by 21%. Micafungin has no effect on tacrolimus clearance.

Therapeutic Uses. Micafungin is approved for the treatment of invasive candidiasis (Fritz et al., 2008) and esophageal candidiasis and for prophylaxis in hematopoietic stem cell transplant recipients.

Dosage. Micafungin is administered intravenously as a 100-mg daily dose over 1 h for adults, with 50 mg recommended for prophylaxis and 150 mg for esophageal candidiasis. No loading dose is required.

Anidulafungin. Anidulafungin is a water-insoluble semisynthetic compound extracted from the fungus *A. nidulans*, from which the drug's name derives.

ADME; Drug Interactions. Anidulafungin is cleared from the body by slow chemical degradation (Vazquez and Sobel, 2006). No hepatic metabolism or renal excretion of active drug occurs; thus, no dose adjustment for hepatic or renal failure is needed. No clinically relevant drug-drug

TABLE 61-7 PK DATA FOR ECHINOCANDINS IN HUMANS

DRUG	DOSE (mg)	C_{max} (μ g/mL)	AUC _{0-24h} (mg · h/L)	$t_{1/2}$ (h)	CL (mL/min/kg)	V_d (L)
Caspofungin	70	12	93.5	10	0.15	9.5
Micafungin	75	7.1	59.9	13	0.16	14
Anidulafungin	200	7.5	104.5	25.6	0.16	33.4

For details, see Wagner C, et al. The echinocandins: comparison of their pharmacokinetics, pharmacodynamics and clinical applications. *Pharmacology*, 2006, 78:161–177.

1098 interactions have been observed with drugs likely to be coadministered with anidulafungin.

Therapeutic Use and Dosing. Anidulafungin is approved for the treatment of candidemia and other forms of *Candida* infections (Reboli et al., 2007), including intra-abdominal abscess, peritonitis, and esophageal candidiasis. For invasive candidiasis, anidulafungin is given daily as a loading dose of 200 mg followed by 100 mg daily. For esophageal candidiasis, a loading dose of 100 mg is followed by 50 mg daily.

Other Systemic Antifungal Agents

Griseofulvin. Griseofulvin is an orally administered, fungistatic antifungal agent originally isolated from the mold *Penicillium griseofulvum*. It is practically insoluble in water.

Mechanism of Action. Griseofulvin inhibits microtubule function and thereby disrupts assembly of the mitotic spindle, which disrupts fungal cell division.

ADME. Blood levels after oral administration of griseofulvin are quite variable. Some studies have shown improved absorption when the drug is taken with a fatty meal. Because the rates of dissolution and disaggregation limit the bioavailability of griseofulvin, microsize and ultramicrosize powders are now used. Griseofulvin has a plasma $t_{1/2}$ of about 1 day; about 50% of the oral dose can be detected in the urine within 5 days, mostly in the form of metabolites. The primary metabolite is methylgriseofulvin. Barbiturates decrease griseofulvin absorption from the GI tract.

Griseofulvin is deposited in keratin precursor cells; when these cells differentiate, the drug is tightly bound to, and persists in, keratin, providing prolonged resistance to fungal invasion. For this reason, the new growth of hair or nails is the first to become free of disease. As the fungus-containing keratin is shed, it is replaced by normal tissue. Griseofulvin is detectable in the stratum corneum of the skin within 4–8 h of oral administration. Sweat and transepidermal fluid loss play an important role in the transfer of the drug in the stratum corneum. Only a very small fraction of a dose of the drug is present in body fluids and tissues.

Antifungal Activity. Griseofulvin is fungistatic in vitro for various species of the dermatophytes *Microsporum*, *Epidermophyton*, and *Trichophyton*. The drug has no effect on other fungi or on bacteria. Although failure of ringworm lesions to improve is not rare, isolates from these patients usually are still susceptible to griseofulvin in vitro.

Therapeutic Uses. Mycotic disease of the skin, hair, and nails due to *Microsporum*, *Trichophyton*, or *Epidermophyton* responds to griseofulvin therapy. For tinea capitis in children, griseofulvin remains the drug of choice for efficacy, safety, and availability as an oral suspension. Efficacy is best for tinea capitis caused by *Microsporum canis*, *Microsporum audouinii*, *Trichophyton schoenleinii*, and *Trichophyton verrucosum*. Griseofulvin is also effective for ringworm of the glabrous skin; tinea cruris and tinea corporis caused by *M. canis*, *Trichophyton rubrum*, *T. verrucosum*, and *Epidermophyton floccosum*; and tinea of the hands (*T. rubrum* and *Trichophyton mentagrophytes*) and beard (*Trichophyton* species). Griseofulvin also is highly effective in the treatment of tinea pedis, the vesicular form of which is most commonly due to *T. mentagrophytes* and the hyperkeratotic type to *T. rubrum*. Topical therapy is sufficient for most cases of tinea pedis. *Trichophyton rubrum* and *T. mentagrophytes* infections may require higher-than-conventional doses of griseofulvin. Treatment must be continued until infected tissue is replaced by normal hair, skin, or nails, which requires 1 month for scalp and hair ringworm, 6–9 months for fingernails, and at least a year for toenails. Itraconazole or terbinafine is much more effective for onychomycosis.

Adverse Effects. The incidence of serious reactions due to griseofulvin is very low: headache (15% of patients), GI and nervous system manifestations, and augmentation of the effects of alcohol. Hepatotoxicity has been observed. Hematological effects include leukopenia, neutropenia, punctate basophilia, and monocytosis; these often disappear despite continued therapy. Blood studies should be carried out at least once a week during the first month of treatment or longer. Common renal effects include albuminuria and cylindruria without evidence of renal insufficiency. Reactions involving the skin are cold and warm urticaria, photosensitivity,

lichen planus, erythema, erythema multiforme–like rashes, and vesicular and morbilliform eruptions. Serum sickness syndromes and severe angioedema develop rarely. Estrogen-like effects have been observed in children. A moderate but inconsistent increase of fecal protoporphyrins has been noted with chronic use.

Drug Interactions. Griseofulvin induces hepatic CYPs and thereby increases the rate of metabolism of warfarin. Consequently, the dose of warfarin should be adjusted in some patients. The drug may also reduce the efficacy of low-estrogen oral contraceptive agents, probably by a similar mechanism.

Terbinafine. Terbinafine is a synthetic allylamine, structurally similar to the topical agent naftifine (see discussion that follows). It inhibits fungal squalene epoxidase and thereby reduces ergosterol biosynthesis.

ADME. Terbinafine is well absorbed, but bioavailability is about 40% due to first-pass metabolism in the liver. The drug accumulates in skin, nails, and fat. The initial $t_{1/2}$ is about 12 h but extends to 200–400 h at steady state. Terbinafine is not recommended in patients with marked azotemia or hepatic failure. Rifampin decreases and cimetidine increases plasma terbinafine concentrations.

Therapeutic Uses. Terbinafine, given as one 250-mg tablet daily for adults, is somewhat more effective than itraconazole for nail onychomycosis. Duration of treatment varies with the site of infection but typically ranges between 6 and 12 weeks. The efficacy for the treatment of onychomycosis can be improved by the simultaneous use of amorolfine 5% nail lacquer (amorolfine is not approved for use in the U.S.). Terbinafine is also effective for the treatment of tinea capitis and has been used for the off-label treatment of ringworm elsewhere on the body.

Adverse Effects. The drug is well tolerated, with a low incidence of GI distress, headache, or rash. Very rarely, fatal hepatotoxicity, severe neutropenia, Stevens-Johnson syndrome, or toxic epidermal necrolysis may occur. Systemic terbinafine therapy for onychomycosis should be postponed until after pregnancy is complete.

Agents Active Against Microsporidia and Pneumocystis

Microsporidia are spore-forming unicellular eukaryotic organisms that were once thought to be parasites but are now classified as fungi (Field and Milner, 2015). They can cause several disease syndromes, including diarrhea in immunocompromised individuals.

Albendazole

Intestinal infections with most microsporidia are treated with albendazole, an inhibitor of α -tubulin polymerization (see Chemotherapy of Helminth Infections, Chapter 55) (Anane and Attouchi, 2010).

Fumagillin

Fumagillin is an acyclic polyene macrolide produced by the fungus *A. fumigatus*. Fumagillin and its synthetic analogue TNP-470 are toxic to microsporidia.

Immunocompromised individuals with intestinal microsporidiosis due to *Enterocytozoon bienersi* (which does not respond as well to albendazole) can be treated successfully with fumagillin (Didier et al., 2005; Rex and Stevens, 2014; Szumowski and Troemel, 2015). For the treatment of intestinal microsporidiosis caused by *E. bienersi*, fumagillin is used at a dose of 20 mg orally three times daily for 2 weeks (Medical-Letter, 2013; Molina et al., 2002; Rex and Stevens, 2014). Fumagillin is used topically to treat keratoconjunctivitis caused by *Encephalitozoon hellem* at a dose of 3–10 mg/mL in a balanced salt suspension. Adverse effects of fumagillin may include abdominal cramps, nausea, vomiting, and diarrhea. Reversible thrombocytopenia and neutropenia also have been reported (Anane and Attouchi, 2010). Fumagillin is not approved for use in humans in the U.S.

Pentamidine

Pneumocystis jiroveci is another fungus that, until recently, was classified as a protozoan parasite. It is the causative agent of PJP, formerly known as PCP. Pentamidine is one of several drugs or drug combinations used to treat or prevent PJP, which is a major cause of mortality in

immunocompromised individuals, including patients with AIDS. Note, however, that *trimethoprim-sulfamethoxazole* is the drug of choice for the treatment and prevention of PJP (see Chapter 56).

Therapy for PJP. Pentamidine as therapy for PJP is reserved for two indications:

- as a 4 mg/kg single daily intravenous dose for 21 days to treat severe PJP in individuals who cannot tolerate trimethoprim-sulfamethoxazole and are not candidates for alternative agent; and
- as a “salvage” agent for individuals with PJP who fail to respond to trimethoprim-sulfamethoxazole (pentamidine may be less effective than the combination of clindamycin and primaquine or atovaquone for this indication) (Gilroy and Bennett, 2011; Rex and Stevens, 2014).

Prophylaxis. Pentamidine administered as an aerosol preparation is used to prevent PJP in at-risk individuals who cannot tolerate trimethoprim-sulfamethoxazole, such as patients with severe bone marrow suppression. For prophylaxis, pentamidine isethionate is given monthly as a 300-mg dose in a 5%–10% nebulized solution over 30–45 min (Gilroy and Bennett, 2011). Aerosolized pentamidine has several disadvantages, including its failure to treat any extrapulmonary sites of *Pneumocystis*, the lack of efficacy against any other potential opportunistic pathogens, and a risk for pneumothorax (Rex and Stevens, 2014).

Topical Antifungal Agents

Topical agents are useful for the treatment of many superficial fungal infections, such as those confined to the stratum corneum, squamous mucosa, or cornea. Examples of infections that respond to topical therapy include dermatophytosis (ringworm), candidiasis, tinea versicolor, piedra, tinea nigra, and fungal keratitis. Preferred formulations for cutaneous application usually are creams or solutions. Ointments are inconvenient and can be too occlusive to the skin, particularly if the affected area is a macerated, fissured, or intertriginous lesion. Antifungal powders, whether applied by shake containers or aerosols, are useful only for lesions of the feet, groin, and similar intertriginous areas. With few exceptions, topical administration of antifungal agents usually is not successful for mycoses of the nails (onychomycosis) and hair (tinea capitis) and should not be used for the treatment of subcutaneous mycoses, such as sporotrichosis and chromoblastomycosis. Regardless of formulation, penetration of topical drugs into hyperkeratotic lesions often is poor. Removal of thick, infected keratin is sometimes a useful adjunct to therapy.

Topical Imidazoles and Triazoles

The imidazoles and triazoles are closely related classes of drugs that are synthetic antifungal agents used both topically and systemically. Indications for their topical use include ringworm, tinea versicolor, and mucocutaneous candidiasis. Resistance to imidazoles or triazoles is rare amongst the fungi that cause ringworm. Selection of one of these agents for topical use should be based on cost and availability because in vitro fungal susceptibility testing does not correlate with clinical responses. The mechanism of action of the azole antifungals was discussed previously in this chapter.

Modes of Administration

Cutaneous Application. The preparations for cutaneous use described in the following material are effective for tinea corporis, tinea pedis, tinea cruris, tinea versicolor, and cutaneous candidiasis. They should be applied twice a day for 3–6 weeks. The cutaneous formulations are not suitable for oral, vaginal, or ocular use.

Vaginal Application. Vaginal creams, suppositories, and tablets for vaginal candidiasis are all used once a day for 1–7 days, preferably at bedtime to facilitate retention. None is useful in trichomoniasis. Most vaginal creams are administered in 5-g amounts. Three vaginal formulations—clotrimazole tablets, miconazole suppositories, and terconazole cream—come in both low- and high-dose preparations. A shorter

duration of therapy is recommended for the higher dose of each. These preparations are administered for 3–7 days. Approximately 3%–10% of the vaginal dose is absorbed. Although some imidazoles are teratogenic in rodents, no adverse effects on the human fetus have been attributed to the vaginal use of imidazoles or triazoles. The most common side effect is vaginal burning or itching. A male sexual partner may experience mild penile irritation.

Oral Use. Use of the oral troche of clotrimazole is properly considered as topical therapy. The only indication for this 10-mg troche is oropharyngeal candidiasis. Antifungal activity is due entirely to the local concentration of the drug; there is no systemic effect.

Individual Agents

Clotrimazole

Absorption of clotrimazole is less than 0.5% after application to the intact skin; from the vagina, it is 3%–10%. Fungicidal concentrations remain in the vagina for as long as 3 days after application of the drug. In adults, an oral dose of 200 mg/d will give rise initially to plasma concentrations of 0.2–0.35 µg/mL, followed by a progressive decline.

In a small fraction of patients, clotrimazole on the skin may cause skin irritation, stinging sensations, erythema, edema, vesication, desquamation, pruritus, or urticaria. When applied to the vagina, about 1.6% of patients experience a mild burning sensation. In rare instances, lower abdominal cramps, a slight increase in urinary frequency, or skin rash may occur. Occasionally, a patient's sexual partner may experience penile or urethral irritation. Oral clotrimazole troches cause GI irritation in about 5% of patients.

Therapeutic Uses. Clotrimazole is available as a 1% cream, lotion, powder, aerosol solution, and solution; 1% or 2% vaginal cream; vaginal tablets of 100, 200, or 500 mg; and 10-mg troches. On the skin, applications are made twice a day. For the vagina, the standard regimens are one 100-mg tablet once a day at bedtime for 7 days, one 200-mg tablet daily for 3 days, one 500-mg tablet inserted only once, or 5 g of cream once a day for 3 days (2% cream) or 7 days (1% cream). For oropharyngeal candidiasis, troches are to be dissolved slowly in the mouth five times a day for 14 days.

Topical clotrimazole cures dermatophyte infections in 60%–100% of cases. The cure rates in cutaneous candidiasis are 80%–100%. In vulvovaginal candidiasis, the cure rate is usually greater than 80% when the 7-day regimen is used. A 3-day regimen of 200 mg once a day appears to be similarly effective, as does single-dose treatment (500 mg). Recurrences are common after all regimens. The cure rate with oral troches for oral and pharyngeal candidiasis may be as high as 100% in the immunocompetent host.

Econazole

Econazole is the deschloro- derivative of miconazole. Econazole readily penetrates the stratum corneum and achieves effective concentrations at the level of the middermis. Approximately 3% of recipients experience local erythema, burning, stinging, or itching. Econazole nitrate is available as a water-miscible cream (1%) to be applied twice a day.

Efinaconazole

Efinaconazole is an azoleamine derivative with excellent in vitro activity against *T. rubrum* and *T. mentagrophytes*. It is available as a 10% topical solution for the treatment of onychomycosis.

Miconazole

Miconazole readily penetrates the stratum corneum of the skin and persists for more than 4 days after application. Adverse effects from topical application to the vagina include burning, itching, or irritation in about 7% of recipients, as well as infrequent pelvic cramps (0.2%), headache, hives, or skin rash. Irritation, burning, and maceration are rare after cutaneous application. Miconazole is considered safe for use during pregnancy, although some experts advocate avoiding vaginal use during the first trimester.

Therapeutic Uses. Miconazole nitrate is available as a 2% cream, ointment, lotion, powder, gel, aerosol powder, and aerosol solution. To avoid

maceration, only the lotion should be applied to intertriginous areas. Miconazole is available as a 2% and 4% vaginal cream and as 100-, 200-, or 1200-mg vaginal suppositories to be applied high in the vagina at bedtime for 7, 3, or 1 days, respectively.

In the treatment of tinea pedis, tinea cruris, and tinea versicolor, the cure rate exceeds 90%. In the treatment of vulvovaginal candidiasis, the mycologic cure rate at the end of 1 month is about 80%–95%. Pruritus sometimes is relieved after a single application. Some vaginal infections caused by *C. glabrata* also respond to this drug.

Luliconazole

Luliconazole is available as a 1% cream and is effective for the topical treatment of interdigital tinea pedis, tinea cruris, and tinea corporis caused by susceptible organisms. It should be applied to the affected area once daily for 2 weeks.

Terconazole and Butoconazole

Terconazole is a ketal triazole. The 80-mg vaginal suppository is inserted at bedtime for 3 days; the 0.4% vaginal cream is used for 7 days and the 0.8% cream for 3 days. Clinical efficacy and patient acceptance of both preparations are at least as good as for clotrimazole in patients with vaginal candidiasis.

Butoconazole is an imidazole that is pharmacologically comparable to clotrimazole. Butoconazole nitrate is available as a 2% vaginal cream; it is used at bedtime in nonpregnant females. Because of the slower response during pregnancy, a 6-day course is recommended (during the second and third trimester).

Tioconazole

Tioconazole is an imidazole marketed for treatment of *Candida* vulvovaginitis. A single 4.6-g dose of ointment (300 mg of drug) is given at bedtime.

Oxiconazole, Sulconazole, and Sertaconazole

The imidazole derivatives oxiconazole, sulconazole, and sertaconazole are used for the topical treatment of infections caused by the common pathogenic dermatophytes. Oxiconazole nitrate is available as a 1% cream and lotion; sulconazole nitrate is supplied as a 1% solution or cream. Sertaconazole is a 2% cream marketed for tinea pedis.

Ketoconazole

The imidazole ketoconazole is available as a 0.5% cream, foam, gel, and shampoo for common skin dermatophyte infections, for tinea versicolor, and for seborrheic dermatitis.

Structurally Diverse Antifungal Agents

Ciclopirox Olamine

Ciclopirox olamine has broad-spectrum antifungal activity. It is fungicidal to *C. albicans*, *E. floccosum*, *M. canis*, *T. mentagrophytes*, and *T. rubrum*. It also inhibits the growth of *Malassezia furfur*. Ciclopirox appears to chelate trivalent metal cations and thereby inhibits metal-dependent enzymes required for degradation of peroxides within the fungal cell (Subissi et al., 2010). After application to the skin, it penetrates the epidermis to reach the dermis, but even under occlusion, less than 1.5% is absorbed into the systemic circulation. Furthermore, because the $t_{1/2}$ is 1.7 h, no systemic accumulation occurs. The drug penetrates hair follicles and sebaceous glands. It can sometimes cause hypersensitivity. It is available as a 0.77% cream, gel, suspension, and lotion for the treatment of cutaneous candidiasis and for tinea corporis, cruris, pedis, and versicolor. An 8% nail lacquer is available for onychomycosis. Cure rates in the dermatomycoses and candidal infections are 81%–94%. No topical toxicity has been noted.

Ciclopirox 0.77% gel and 1% shampoo are also used for the treatment of seborrheic dermatitis of the scalp. An 8% topical solution is an effective treatment of mild-to-moderate superficial white onychomycosis.

Haloprogin

Haloprogin is a halogenated phenolic ether. It is fungicidal to various species of *Epidermophyton*, *Pityrosporum*, *Microsporum*, *Trichophyton*, and *Candida*. During treatment with this drug, irritation, pruritus, burning sensations, vesiculation, increased maceration, and “sensitization”

(or exacerbation of the lesion) occasionally occur, especially on the foot if occlusive footwear is worn. Haloprogin is poorly absorbed through the skin; it is metabolized to trichlorophenol in the patient. However, systemic toxicity from topical application appears to be low. Haloprogin cream or solution is applied twice a day for 2–4 weeks. Its principal use is against tinea pedis, for which the cure rate is about 80%; it is thus approximately equal in efficacy to tolnaftate. It also is used against tinea cruris, tinea corporis, tinea manuum, and tinea versicolor. Haloprogin is no longer available in the U.S.

Tolnaftate

Tolnaftate is a thiocarbamate that is effective in the treatment of most cutaneous mycoses caused by *T. rubrum*, *T. mentagrophytes*, *Trichophyton tonsurans*, *E. floccosum*, *M. canis*, *M. audouinii*, *Microsporum gypseum*, and *M. furfur*, but it is ineffective against *Candida*. In tinea pedis, the cure rate is about 80%, compared with about 95% for miconazole. Tolnaftate is available in a 1% concentration as a cream, gel, powder, aerosol powder, topical solution, or a topical aerosol liquid. The preparations are applied locally twice a day. Pruritus is usually relieved in 24–72 h. Involution of interdigital lesions caused by susceptible fungi is very often complete in 7–21 days. Toxic or allergic reactions to tolinaftate have not been reported.

Naftifine

Naftifine is a synthetic allylamine that inhibits squalene-2,3-epoxidase, a key enzyme in the fungal biosynthesis of ergosterol. The drug has broad-spectrum fungicidal activity in vitro. Naftifine hydrochloride is available as a 1% cream or gel. It is effective for the topical treatment of tinea cruris and tinea corporis; twice-daily application is recommended. The drug is well tolerated, although local irritation has been observed in 3% of treated patients. Allergic contact dermatitis also has been reported. Naftifine also may be efficacious for cutaneous candidiasis and tinea versicolor, although the drug is not approved for these uses.

Terbinafine

Like naftifine, terbinafine is an allylamine that targets ergosterol biosynthesis. Terbinafine 1% cream or spray, applied twice daily, is effective in tinea corporis, tinea cruris, and tinea pedis. Terbinafine is less active against *Candida* species and *Malassezia furfur*, but the cream also can be used in cutaneous candidiasis and tinea versicolor.

Butenafine

Butenafine hydrochloride is a benzylamine derivative with a mechanism of action similar to that of terbinafine and naftifine. Its spectrum of antifungal activity and use also are similar to those of the allylamines.

Tavaborole

Tavaborole is an oxaborole antifungal indicated for the topical treatment of onychomycosis of the toenails. The drug inhibits fungal leucyl-tRNA synthetase, thereby inhibiting protein synthesis and ultimately causing fungal cell death.

Nystatin

Nystatin, a tetraene macrolide produced by *Streptomyces noursei*, is structurally similar to amphotericin B and acts through the same mechanism of action. The drug is not absorbed from the GI tract, skin, or vagina. Nystatin is useful only for candidiasis and is supplied in preparations intended for cutaneous, vaginal, or oral administration for this purpose. Infections of the nails and hyperkeratinized or crusted skin lesions do not respond. Powders are preferred for moist lesions such as diaper rash and are applied two to three times daily. Creams or ointments are used twice daily. Combinations of nystatin with antibacterial agents or corticosteroids also are available.

Allergic reactions to nystatin are uncommon. Although vaginal tablets of nystatin are well tolerated, imidazoles or triazoles are more effective agents than nystatin for vaginal candidiasis. Nystatin suspension is usually effective for oral candidiasis of the immunocompetent host and is widely used in neonates and infants for oral thrush. Patients should be instructed to swish the drug around in the mouth and then swallow; otherwise, the patient may expectorate the bitter liquid and

fail to treat the infected mucosa in the posterior pharynx or esophagus. Other than the bitter taste and occasional complaints of nausea, adverse effects are uncommon.

Undecylenic Acid

Undecylenic acid is 10-undecenoic acid, an 11-carbon unsaturated compound. It is primarily fungistatic, although fungicidal activity may be observed with long exposure to high concentrations of the agent. The drug is active against a variety of fungi, including those that cause ringworm. Undecylenic acid is available in a cream, powder, spray powder, soap, and liquid. Zinc undecylenate is marketed in combination with other ingredients. The zinc provides an astringent action that aids in the suppression of inflammation. Compounded undecylenic acid ointment contains both undecylenic acid (~5%) and zinc undecylenate (~20%). Calcium undecylenate is available as a powder.

Undecylenic acid preparations are used in the treatment of various dermatomycoses, especially tinea pedis. Concentrations of the acid as high as 10%, as well as those of the acid and salt in the compounded ointment, may be applied to the skin. These preparations are usually not irritating to tissue, and sensitization to them is uncommon. This agent retards fungal growth in tinea pedis, but the infection frequently

persists despite intensive treatment with preparations of the acid and the zinc salt. At best, the clinical “cure” rate is about 50%, which is much lower than that obtained with the imidazoles, haloprogin, or tolnaftate. Efficacy in the treatment of tinea capitis is marginal, and the drug is no longer used for that purpose. Undecylenic acid preparations also are approved for use in the treatment of diaper rash, tinea cruris, and other minor dermatologic conditions.

Benzoic and Salicylic Acids

An ointment containing benzoic and salicylic acids in a ratio of 2:1 (usually 6% and 3%) is known as Whitfield ointment. It combines the fungistatic action of benzoate with the keratolytic action of salicylate and is used mainly in the treatment of tinea pedis. Because benzoic acid is only fungistatic, eradication of the infection occurs only after the infected stratum corneum is shed; thus, continuous medication is required for several weeks to months. The salicylic acid accelerates desquamation. The ointment also is sometimes used to treat tinea capitis. Mild irritation may occur at the site of application.

Drugs	Therapeutic Uses	Clinical Pharmacology and Tips
Polyenes: Interact with ergosterol in the fungal cell membrane		
Amphotericin B deoxycholate (C-AMB)	<ul style="list-style-type: none"> Invasive candidiasis Invasive aspergillosis Blastomycosis Histoplasmosis Coccidioidomycosis Cryptococcosis Mucormycosis Sporotrichosis Empirical therapy in the immunocompromised host 	<ul style="list-style-type: none"> Associated with significant nephrotoxicity, including azotemia, renal tubular acidosis, and hypochromic, normocytic anemia Associated with acute reactions, including infusion-related fever and chills C-AMB is better tolerated by premature neonates than by older children and adults
Amphotericin B colloidal dispersion (ABCD) (not available in the U.S.)		<ul style="list-style-type: none"> All three amphotericin B lipid formulations are less nephrotoxic than C-AMB. Infusion-related reactions are highest with ABCD and lowest with L-AMB.
Liposomal amphotericin B (L-AMB)		
Amphotericin B lipid complex (ABLC)		
Pyrimidines: Disrupt fungal RNA and DNA synthesis		
Flucytosine	<ul style="list-style-type: none"> Cryptococcosis (with amphotericin B) 	<ul style="list-style-type: none"> Has broad activity but emergence of resistance limits usefulness as single-agent therapy ↓ Dosage in patients with ↓ renal function Toxicity more frequent in patients with AIDS or azotemia Flucytosine may depress bone marrow, lead to leukopenia and thrombocytopenia
Imidazoles and Triazoles: Inhibit ergosterol biosynthesis		
Ketoconazole		
Itraconazole	<ul style="list-style-type: none"> Invasive aspergillosis Blastomycosis Coccidioidomycosis Histoplasmosis Pseudallescheriasis Sporotrichosis Ringworm Onychomycosis 	<ul style="list-style-type: none"> Substrate for and potent inhibitor of CYP3A4 Hepatotoxic Contraindicated in pregnancy and in women considering becoming pregnant

Drug Facts For Your Personal Formulary: Antifungal Agents (continued)

Drugs	Therapeutic Uses	Clinical Pharmacology and Tips
Imidazoles and Triazoles: Inhibit ergosterol biosynthesis		
Fluconazole	<ul style="list-style-type: none"> Invasive candidiasis Cryptococcosis Coccidioidomycosis Prophylaxis and empirical therapy in immunocompromised host 	<ul style="list-style-type: none"> Plasma concentrations are essentially the same whether the drug is given orally or intravenously. Concentrations in CSF = 50%–90% of C_p Inhibitor of CYP3A4 and CYP2C9 Contraindicated during pregnancy
Voriconazole	<ul style="list-style-type: none"> Invasive aspergillosis Invasive candidiasis Pseudallescheriasis 	<ul style="list-style-type: none"> Oral bioavailability is 96%. Monitor C_p; serum levels of 1 to 5 mg/L maximize efficacy and minimize toxicity Metabolized by and inhibits CYPs (2C19 > 2C9 > 3A4) Can prolong the QTc interval Transient visual or auditory hallucinations are frequent after the first dose. Contraindicated in pregnancy
Posaconazole	<ul style="list-style-type: none"> Oropharyngeal candidiasis Prophylaxis in the immunocompromised host against aspergillosis and candidiasis 	<ul style="list-style-type: none"> Oral bioavailability enhanced by food Drugs that ↓ gastric acid ↓ posaconazole exposure Inhibits CYP3A4 Can prolong the QTc interval Adverse effects: headache and GI disorders
Isavuconazole (isavuconazonium prodrug)	<ul style="list-style-type: none"> Invasive aspergillosis Mucormycosis 	<ul style="list-style-type: none"> Oral bioavailability is 98%. Substrate of and inhibitor of CYP3A4 Does not appear to prolong QTc
Echinocandins: Inhibit 1,3-β-D-glucan synthesis in the fungal cell wall		
Caspofungin	<ul style="list-style-type: none"> Invasive candidiasis Empirical therapy in the immunocompromised host 	<ul style="list-style-type: none"> ↓ Dose in moderate hepatic impairment
Micafungin	<ul style="list-style-type: none"> Invasive candidiasis Prophylaxis in the immunocompromised host 	<ul style="list-style-type: none"> Reduction of micafungin dose in moderate hepatic failure is not required.
Anidulafungin	<ul style="list-style-type: none"> Invasive candidiasis 	<ul style="list-style-type: none"> No dose adjustment is needed for hepatic or renal failure.
Griseofulvin: Inhibits microtubule function, disrupts assembly of the mitotic spindle		
Griseofulvin	<ul style="list-style-type: none"> Ringworm Onychomycosis 	<ul style="list-style-type: none"> Absorption is reduced by barbiturates Induces hepatic CYPs
Allylamines: Inhibit fungal squalene epoxidase and reduce ergosterol biosynthesis		
Terbinafine	<ul style="list-style-type: none"> Ringworm Onychomycosis 	<ul style="list-style-type: none"> Bioavailability is ~40% due to first-pass metabolism in the liver. The drug accumulates in skin, nails, and fat. The initial $t_{1/2}$ is ~12 h but extends to 200–400 h at steady state.
Agents Active Against Microsporidia and <i>Pneumocystis</i>		
Albendazole	<ul style="list-style-type: none"> Microsporidia infection 	<ul style="list-style-type: none"> Anthelmintic Inhibitor of α-tubulin polymerization
Fumagillin	<ul style="list-style-type: none"> Microsporidia infection 	<ul style="list-style-type: none"> Used in immunocompromised individuals with intestinal microsporidiosis due to <i>Enterocytozoon bieneusi</i> unresponsive to albendazole Not approved for human use in the U.S.
Trimethoprim-sulfamethoxazole	<ul style="list-style-type: none"> <i>Pneumocystis jiroveci</i> pneumonia 	<ul style="list-style-type: none"> See Chapter 56
Pentamidine	<ul style="list-style-type: none"> <i>Pneumocystis jiroveci</i> pneumonia 	<ul style="list-style-type: none"> Prophylaxis use to prevent PJP in at-risk individuals who cannot tolerate trimethoprim-sulfamethoxazole
Topical Antifungal Agents		
Imidazoles and Triazoles Clotrimazole, miconazole, ketoconazole, etc.	<ul style="list-style-type: none"> Dermatophytosis (ringworm), candidiasis, tinea versicolor, piedra, tinea nigra, and fungal keratitis 	<ul style="list-style-type: none"> Available for cutaneous application as creams or solutions Some are available as vaginal creams or suppositories or as oral troches
Tavaborole	Toenail onychomycosis due to <i>T. rubrum</i> or <i>T. mentagrophytes</i>	<ul style="list-style-type: none"> Apply daily for 48 weeks

Chapter 62

Antiviral Agents (Nonretroviral)

Edward P. Acosta

VIRAL REPLICATION AND DRUG TARGETS

ANTIHERPESVIRUS AGENTS

- Acyclovir and Valacyclovir
- Cidofovir
- Famciclovir and Penciclovir
- Ganciclovir and Valganciclovir
- Foscarnet
- Fomivirsen
- Docosanol

- Idoxuridine
- Trifluridine

ANTI-INFLUENZA AGENTS

- Amantadine and Rimantadine
- Oseltamivir
- Zanamivir
- Peramivir
- Interferon

Most antivirals currently available in the U.S. have been developed and approved in the last 25 years. This flurry of activity was driven by successes in rational drug design and approval that began with the antiherpesvirus nucleoside analogue acyclovir (Elion, 1986), whose discovery and development resulted in the awarding of a Nobel Prize to Gertrude Elion and George Hitchings in 1988. Because viruses are obligatory intracellular microorganisms and rely on host biosynthetic machinery to reproduce, there were doubts about the possibility of developing antiviral drugs with selective toxicity, but those doubts have long been erased. Viruses are now obvious targets for effective antimicrobial chemotherapy, and it is certain that the number of available agents in this category will continue to increase. Indeed, the recent development of agents that target the viral protein NS5A has revolutionized treatment of infections of HVB and HVC, and these agents are now allotted a chapter of their own, Chapter 63. Chapter 64 describes chemotherapy for retroviruses. This present chapter covers antiviral agents for nonretroviral infections other than HVB and HVC.

RNA polymerase, which directs the synthesis of more viral mRNA and genomic RNA. Most RNA viruses complete their replication in the host cell cytoplasm, but some, such as influenza, are transcribed in the host cell nucleus. Examples of RNA viruses include rubella virus (German measles); rhabdoviruses (rabies); picornaviruses (poliomyelitis, meningitis, colds, hepatitis A); arenaviruses (meningitis, Lassa fever); flaviviruses (West Nile meningoencephalitis, yellow fever, hepatitis C, Zika virus); orthomyxoviruses (influenza); paramyxoviruses (measles, mumps); and coronaviruses (colds, SARS). Retroviruses are RNA viruses that include HIV; chemotherapy for retroviruses is described in Chapter 64. Pharmacotherapy of viral hepatitis is covered separately in Chapter 63.

Table 62–2 summarizes currently approved drugs for nonretroviral infections, excluding those for viral hepatitis. Their pharmacological properties are presented in the material that follows, class by class, as listed in the table.

Viral Replication and Drug Targets

Viruses are simple microorganisms that consist of either double- or single-stranded DNA or RNA enclosed in a protein coat called a *capsid*. Some viruses also possess a lipid envelope derived from the infected host cell, which, like the capsid, may contain antigenic glycoproteins. Effective antiviral agents inhibit virus-specific replicative events or preferentially inhibit *virus-directed rather than host cell-directed* nucleic acid or protein synthesis (Table 62–1). Host cell molecules that are essential to viral replication also offer targets for intervention. Figure 62–1 gives a schematic diagram of the replicative cycle of typical DNA and RNA viruses with the sites of anti-viral drugs indicated.

DNA viruses include poxviruses (smallpox), herpesviruses (chickenpox, shingles, oral and genital herpes); adenoviruses (conjunctivitis, sore throat); hepadnaviruses (HBV); and papillomaviruses (warts). Most DNA viruses enter the host cell nucleus, where the viral DNA is transcribed into mRNA by host cell polymerase; mRNA is translated in the usual host cell fashion into virus-specific proteins. Poxviruses are an exception; they carry their own RNA polymerase and replicate in the host cell cytoplasm.

For RNA viruses, the replication strategy either relies on enzymes in the virion to synthesize mRNA or has the viral RNA serving as its own mRNA. The mRNA is translated into various viral proteins, including

Antiherpesvirus Agents

Herpes simplex virus type 1 typically causes diseases of the mouth, face, skin, esophagus, or brain. HSV-2 usually causes infections of the genitals, rectum, skin, hands, or meninges. Both cause serious infections in neonates. Agents used in treating HSV work by several mechanisms to inhibit viral DNA replication in the host cell (Figure 62–1; Table 62–1).

Acyclovir and Valacyclovir

Acyclovir is an acyclic guanine nucleoside analogue that lacks the 2' and 3' positions normally supplied by ribose. Valacyclovir is the L-valyl ester pro-drug of acyclovir. Acyclovir is the prototype of a group of antiviral agents that are nucleoside congeners (see Figure 62–2) that are phosphorylated intracellularly by a viral kinase and subsequently by host cell enzymes to become inhibitors of viral DNA synthesis. Related agents include penciclovir and ganciclovir.

Mechanisms of Action and Resistance

Acyclovir inhibits viral DNA synthesis via a mechanism outlined in Figure 62–3. Its selectivity of action depends on interaction with HSV TK (*thymidine kinase*) and *DNA polymerase*. The initial phosphorylation of acyclovir is facilitated by HSV TK and thus occurs only in cells infected with the virus. The affinity of acyclovir for HSV TK is about 200 times

Abbreviations

ADME: absorption, distribution, metabolism, excretion
AIDS: acquired immune deficiency syndrome
AUC: area under the curve
CAPD: chronic ambulatory peritoneal dialysis
CDC: Centers for Disease Control and Prevention
cDNA: complementary DNA
CL_{cr}: creatinine clearance
CMV: cytomegalovirus
CNS: central nervous system
C_p: plasma concentration (of a drug, usually)
cRNA: complementary RNA
CSF: cerebrospinal fluid
CYP: cytochrome P450 isozyme
DNAp: DNA polymerase
EBV: Epstein-Barr virus
EIND: emergency investigational new drug
FDA: Food and Drug Administration
G-CSF: granulocyte colony-stimulating factor
GI: gastrointestinal
HBV: hepatitis B virus
HCV: hepatitis c virus
HHV-6: human herpesvirus 6
HIV: human immunodeficiency virus
HSV: herpes simplex virus
IFN: interferon
mRNA: messenger RNA
NSAID: nonsteroidal anti-inflammatory drug
RNAp: RNA polymerase
RNP: ribonuclear protein
SARS: severe acute respiratory syndrome
TK: thymidine kinase
vRNA: viral RNA
VZV: varicella zoster virus

greater than for the mammalian enzyme. Cellular enzymes convert the monophosphate to acyclovir triphosphate, which competes for endogenous dGTP. The immunosuppressive agent mycophenolate mofetil (see Chapter 35) potentiates the antiherpes activity of acyclovir and related agents by depleting intracellular dGTP pools. Acyclovir triphosphate competitively inhibits viral DNA polymerases and, to a much lesser extent, cellular DNA polymerases. Acyclovir triphosphate also is incorporated into viral DNA, where it acts as a chain terminator because of the lack of a 3'-hydroxyl group. By a mechanism termed *suicide inactivation*, the terminated DNA template containing acyclovir binds the viral DNA polymerase and leads to its irreversible inactivation.

Acyclovir resistance in HSV can result from impaired production of viral TK, altered TK substrate specificity (e.g., phosphorylation of thymidine but not acyclovir), or altered viral DNA polymerase. Alterations in viral enzymes are caused by point mutations and base insertions or deletions in the corresponding genes. Resistant variants are present in native virus populations and in isolates from treated patients. The most common resistance mechanism in clinical HSV isolates is absent or deficient viral TK activity; viral DNA polymerase mutants are rare. Phenotypic resistance typically is defined by in vitro inhibitory concentrations of more than 2–3 µg/mL, which predict failure of therapy in immunocompromised patients. Acyclovir resistance in VZV isolates is caused by mutations in VZV TK and less often by mutations in viral DNA polymerase.

TABLE 62-1 ■ STAGES OF VIRUS REPLICATION AND POSSIBLE TARGETS OF ACTION OF ANTIVIRAL AGENTS

STAGE OF REPLICATION	CLASSES OF SELECTIVE INHIBITORS
Cell entry Attachment Penetration	Soluble receptor decoys, antireceptor antibodies, fusion protein inhibitors
Uncoating Release of viral genome	Ion channel blockers, capsid stabilizers
Transcription of viral genome ^a Transcription of viral mRNA Replication of viral genome	Inhibitors of viral DNA polymerase, RNA polymerase, reverse transcriptase, helicase, primase, or integrase
Translation of viral proteins Regulatory proteins (early) Structural proteins (late)	Interferons, antisense oligonucleotides, ribozymes, Inhibitors of regulatory proteins
Posttranslational modifications Proteolytic cleavage Myristoylation, glycosylation	Protease inhibitors
Assembly of virion components	Interferons, assembly protein inhibitors
Release Budding, cell lysis	Neuraminidase inhibitors, antiviral antibodies, cytotoxic lymphocytes

^aDepends on specific replication strategy of virus, but virus-specified enzyme required for part of process.

ADME

The oral bioavailability of acyclovir is about 10%–30% and decreases with increasing dose (Wagstaff et al., 1994). Delivery of an oral dose can be enhanced by administration of the prodrug form, valacyclovir. Valacyclovir is an esterified version with higher bioavailability (55%–70%) than acyclovir (Steingrimsdottir et al., 2000); deesterification occurs rapidly and nearly completely following oral administration. Unlike acyclovir, valacyclovir is a substrate for intestinal and renal peptide transporters. Acyclovir distributes widely in body fluids, including vesicular fluid, aqueous humor, and CSF. Compared with plasma, salivary concentrations are low, and concentrations in vaginal secretion vary widely. Acyclovir is concentrated in breast milk, amniotic fluid, and placenta. Newborn plasma levels are similar to maternal ones. Percutaneous absorption of acyclovir after topical administration is low. Renal excretion of unmetabolized acyclovir by glomerular filtration and tubular secretion is the principal route of elimination. The elimination $t_{1/2}$ of acyclovir is about 2.5 h (range 1.5–6 h) in adults with normal renal function. In neonates, the elimination $t_{1/2}$ of acyclovir is about 4 h and increases to 20 h in anuric patients.

Therapeutic Uses

Acyclovir's clinical use is limited to herpesviruses. Acyclovir is most active against HSV-1 (effective C_p range: 0.02–0.9 µg/mL), approximately half as active against HSV-2 (0.03–2.2 µg/mL), a tenth as potent against VZV (0.8–4.0 µg/mL) and EBV, and least active against CMV (generally > 20 µg/mL) and HHV-6. Uninfected mammalian cell growth generally is unaffected by high acyclovir concentrations (> 50 µg/mL).

Figure 62-1 Replicative cycles of DNA (A) and RNA (B) viruses. The replicative cycles of herpesvirus (A) and influenza (B) are examples of DNA-encoded and RNA-encoded viruses, respectively. Sites of action of antiviral agents also are shown. The symbol \rightarrow indicates a block to virus growth. **A.** Replicative cycles of herpes simplex virus, a DNA virus, and the probable sites of action of antiviral agents. Herpesvirus replication is a regulated multistep process. After infection, a small number of immediate-early genes are transcribed; these genes encode proteins that regulate their own synthesis and are responsible for synthesis of early genes involved in genome replication, such as TKs, DNA polymerases, and so on. After DNA replication, the bulk of the herpesvirus genes (called late genes) are expressed and encode proteins that either are incorporated into or aid in the assembly of progeny virions. **B.** Replicative cycles of influenza, an RNA virus, and the loci for effects of antiviral agents. The mammalian cell shown is an airway epithelial cell. The M2 protein of influenza virus allows an influx of hydrogen ions into the virion interior, which in turn promotes dissociation of the RNP segments and release into the cytoplasm (uncoating). Influenza virus mRNA synthesis requires a primer cleared from cellular mRNA and used by the viral RNAP complex. The neuraminidase inhibitors zanamivir and oseltamivir specifically inhibit release of progeny virus.

In immunocompetent persons, the clinical benefits of acyclovir and valacyclovir are greater in initial HSV infections than in recurrent ones. These drugs are particularly useful in immunocompromised patients because these individuals experience both more frequent and more severe HSV and VZV infections. Because VZV is less susceptible than HSV to acyclovir, higher doses must be used for treating VZV infections. Oral valacyclovir is as effective as oral acyclovir in HSV infections and more effective for treating herpes zoster. Acyclovir is ineffective therapeutically in established CMV infections, but ganciclovir is effective for CMV prophylaxis in immunocompromised patients. EBV-related oral hairy leukoplakia may improve with acyclovir.

Oral acyclovir in conjunction with systemic corticosteroids appears beneficial in treating Bell palsy; valacyclovir is ineffective in acute vestibular neuritis.

Herpes Simplex Virus Infections. In initial genital HSV infections, oral acyclovir (200 mg five times daily or 400 mg three times daily for 7–10 days) and valacyclovir (1000 mg twice daily for 7–10 days) are associated with significant reductions in virus shedding, symptoms, and time to healing (Kimberlin and Rouse, 2004). Intravenous acyclovir (5 mg/kg every 8 h) has similar effects in patients hospitalized with severe primary genital HSV infections. Topical acyclovir is much less effective than systemic

TABLE 62-2 ■ NOMENCLATURE OF ANTIVIRAL AGENTS

GENERIC NAME	OTHER NAMES	DOSAGE FORMS AVAILABLE
Antitherpesvirus agents		
Acyclovir	ACV, acycloguanosine	IV, O, T, ophth ^a
Cidofovir	HPMPC, CDV	IV
Famciclovir	FCV	O
Foscarnet	PFA, phosphonoformate	IV, O ^a
Fomivirsena	ISIS 2922	Intravitreal
Ganciclovir	GCV, DHPG	IV, O, intravitreal
Idoxuridine	IDUR	Ophth
Penciclovir	PCV	T, IV ^a
Trifluridine	TFT, trifluorothymidine	Ophth
Valacyclovir		O
Valganciclovir		O
Anti-influenza agents		
Amantadine		O
Oseltamivir	GS4104	O
Peramivir	BCX 1812	IV
Rimantadine		O
Zanamivir	GC167	Inhalation
Other antiviral agents		
Ribavirin		O, inhalation, IV
Telbivudine		O
Tenofovir disoproxil fumarate	TDF	O
Imiquimod		Topical

^aNot currently approved for use in the U.S.
O, oral; ophth, ophthalmic; IV, intravenous; T, topical.

administration. None of these regimens reproducibly reduces the risk of recurrent genital lesions. Acyclovir (200 mg five times daily or 400 mg three times daily for 5 days or 800 mg three times daily for 2 days) or valacyclovir (500 mg twice daily for 3 or 5 days) shortens the manifestations of recurrent genital HSV episodes by 1–2 days. Frequently recurring genital herpes can be suppressed effectively with chronic oral acyclovir (400 mg twice daily or 200 mg three times daily) or with valacyclovir (500 mg or, for very frequent recurrences, 1000 mg once daily). During use, the rate of clinical recurrences decreases by about 90%, and subclinical shedding is markedly reduced, although not eliminated. Valacyclovir suppression

of genital herpes reduces the risk of transmitting infection to a susceptible partner by about 50% over an 8-month period (Corey et al., 2004). Chronic suppression may be useful in those with disabling recurrences of herpetic whitlow or HSV-related erythema multiforme.

Oral acyclovir is effective in primary herpetic gingivostomatitis (600 mg/m² four times daily for 10 days in children) but provides only modest clinical benefit in recurrent orolabial herpes. Short-term, high-dose valacyclovir (2 g twice over 1 day) shortens the duration of recurrent orolabial herpes by about 1 day (Elish et al., 2004). The FDA has approved an acyclovir/hydrocortisone combination (Lipsovir) for early treatment of recurrent herpes cold sores. Topical acyclovir cream is modestly effective in recurrent labial (Spruance et al., 2002) and genital herpes simplex virus infections. Preexposure acyclovir prophylaxis (400 mg twice daily for 1 week) reduces the overall risk of recurrence by 73% in those with sun-induced recurrences of HSV infections. Acyclovir during the last month of pregnancy reduces the likelihood of viral shedding and the frequency of cesarean delivery in women with primary or recurrent genital herpes (Corey and Wald, 2009).

In immunocompromised patients with mucocutaneous HSV infection, intravenous acyclovir (250 mg/m² every 8 h for 7 days) shortens healing time, duration of pain, and the period of virus shedding. Oral acyclovir (800 mg five times per day) and valacyclovir (1000 mg twice daily) for 5–10 days are also effective. Recurrences are common after cessation of therapy and may require long-term suppression. In those with very localized labial or facial HSV infections, topical acyclovir may provide some benefit. Intravenous acyclovir may be beneficial in visceraally disseminating HSV in immunocompromised patients and in patients with HSV-infected burn wounds.

Systemic acyclovir prophylaxis is highly effective in preventing mucocutaneous HSV infections in seropositive patients undergoing immunosuppression. Intravenous acyclovir (250 mg/m² every 8–12 h) begun prior to transplantation and continuing for several weeks prevents HSV disease in bone marrow transplant recipients. For patients who can tolerate oral medications, oral acyclovir (400 mg five times daily) is effective, and long-term oral acyclovir (200–400 mg three times daily for 6 months) also reduces the risk of VZV infection (Steer et al., 2000). In HSV encephalitis, acyclovir (10 mg/kg every 8 h for a minimum of 10 days) reduces mortality by more than 50% and improves overall neurologic outcome compared with vidarabine. Higher doses (15–20 mg/kg every 8 h) and prolonged treatment (up to 21 days) are recommended by many experts. Intravenous acyclovir (20 mg/kg every 8 h for 21 days) is more effective than lower doses in visceraally invasive neonatal HSV infections (Kimberlin et al., 2001). In neonates and immunosuppressed patients and, rarely, in previously healthy persons, relapses of encephalitis following acyclovir may occur. The value of continuing long-term suppression with valacyclovir after completing intravenous acyclovir is under study.

An ophthalmic formulation of acyclovir (not available in the U.S.) is at least as effective as topical vidarabine or trifluridine in herpetic keratoconjunctivitis.

Infection owing to resistant HSV is rare in immunocompetent persons; however, in immunocompromised hosts, acyclovir-resistant HSV

Figure 62-2 Chemical structures of some antiherpes drugs. Many antiherpes agents are nucleoside congeners that are phosphorylated sequentially by viral and host kinases to become triphosphate inhibitors of viral DNA synthesis (see Figure 62-3). Foscarnet is a pyrophosphate analogue that selectively blocks the pyrophosphate binding site on viral DNA polymerases, thereby inhibiting chain elongation.

A. DNA synthesis with mammalian DNA polymerase (insensitive to acyclovir)**B. DNA synthesis in host cell by herpes simplex DNA polymerase (sensitive to acyclovir)**

Figure 62-3 Acyclovir inhibits DNA synthesis by HSV DNA polymerase. After penetrating the membrane of a susceptible mammalian host cell, an HSV virion releases its capsid, which delivers viral DNA into the host cell, initiating viral DNA synthesis. Acyclovir, a guanine analogue, inhibits viral but not mammalian DNA polymerase. **A.** DNA synthesis with mammalian DNA polymerase (insensitive to acyclovir). In the presence of acyclovir, human DNA synthesis proceeds normally. Here, mammalian DNA polymerase removes pyrophosphate (PP_i) from dGTP and uses dGTP to add a dGMP to the 3' end of a growing nucleic acid polymer, the guanine base pairing with a cytosine and dGMP's 5'PO₄ bonding to the 3'OH group on the ribose of the preceding base, thymine. A 3'OH on the sugar of the added dGMP is available to form a 3'-5' bond with the next nucleotide added. **B.** DNA synthesis in host cell by HSV DNA polymerase (sensitive to acyclovir). The guanine analogue acyclovir inhibits viral DNA polymerase by acting as a terminal substrate, but to do so, acyclovir must be phosphorylated to acyclovir triphosphate. The first phosphate group is added by the HSV TK, which has an affinity for acyclovir that is about 200 times that of the mammalian enzyme for acyclovir. Host cell enzymes add the second and third phosphates, producing acyclovir triphosphate, which concentrates 40- to 100-fold in HSV-infected cells over the concentrations in uninfected cells. Thus, acyclovir triphosphate competes well for endogenous dGTP. HSV DNA polymerase cleaves PP_i from acyclovir triphosphate and adds acyclovir monophosphate to the 3' end of the growing DNA strand. Acyclovir lacks a hydroxyl group in the 3' position (indeed, it lacks that 3' position), and further addition to the polymer by HSV DNA polymerase is not possible. Furthermore, a viral exonuclease activity associated with viral DNA polymerase cannot remove the acyclovir moiety. Compare the actions of acyclovir to those of ganciclovir and penciclovir, which have 3'OH groups, and to foscarnet, which binds avidly at the PP_i cleavage site of HSV DNA polymerase, preventing cleavage of PP_i from nucleoside triphosphates.

isolates can cause extensive mucocutaneous disease and, rarely, meningoencephalitis, pneumonitis, or visceral disease. Resistant HSV can be recovered from 4% to 7% of immunocompromised patients receiving acyclovir treatment. Recurrences after cessation of acyclovir usually are due to sensitive virus but may be due to acyclovir-resistant virus in patients with AIDS. In patients with progressive disease, intravenous foscarnet therapy is effective, and vidarabine is considered only when all other therapies have failed (Chilukuri and Rosen, 2003).

Untoward Effects

Acyclovir generally is well tolerated. Chronic acyclovir suppression of genital herpes has been used safely for up to 10 years. No excess frequency of congenital abnormalities has been recognized in infants born to women exposed to acyclovir during pregnancy (Ratanajamit et al., 2003). Topical acyclovir in a polyethylene glycol base may cause mucosal

irritation and transient burning when applied to genital lesions. Oral acyclovir has been associated infrequently with nausea, diarrhea, rash, or headache and very rarely with renal insufficiency or neurotoxicity. Valacyclovir also may be associated with headache, nausea, diarrhea, nephrotoxicity, and CNS symptoms (confusion, hallucinations). Uncommon side effects include severe thrombocytopenic syndromes, sometimes fatal, in immunocompromised patients. Acyclovir has been associated with neutropenia in neonates. The principal dose-limiting toxicities of intravenous acyclovir are renal insufficiency and CNS side effects. Nephrotoxicity usually resolves with drug cessation and volume expansion. Hemodialysis may be useful in severe cases. Severe somnolence and lethargy may occur with combinations of zidovudine (see Chapter 59) and acyclovir. Concomitant cyclosporine and probably other nephrotoxic agents enhance the risk of nephrotoxicity. Probenecid decreases the acyclovir renal clearance and prolongs the elimination $t_{1/2}$. Acyclovir may decrease

Cidofovir

Cidofovir is a cytidine nucleotide analogue with inhibitory activity against human herpes, papilloma, polyoma, pox, and adenoviruses.

Because cidofovir is a phosphonate that is phosphorylated by cellular but not viral enzymes, it inhibits acyclovir-resistant TK-deficient or TK-altered HSV or VZV strains, ganciclovir-resistant CMV strains with UL97 mutations (but not those with DNA polymerase mutations), and some foscarnet-resistant CMV strains. Cidofovir synergistically inhibits CMV replication in combination with ganciclovir or foscarnet.

Mechanisms of Action and Resistance

Cidofovir inhibits viral DNA synthesis by slowing and eventually terminating chain elongation. Cidofovir is metabolized to its active diphosphate form by cellular enzymes; the levels of phosphorylated metabolites are similar in infected and uninfected cells. The diphosphate acts as both a competitive inhibitor with respect to dCTP and as an alternative substrate for viral DNA polymerase.

Cidofovir resistance in CMV is due to mutations in viral DNA polymerase. Low-level resistance to cidofovir develops in up to about 30% of patients with retinitis by 3 months of therapy. Highly ganciclovir-resistant CMV isolates that possess DNA polymerase and UL97 kinase mutations are resistant to cidofovir, and prior ganciclovir therapy may select for cidofovir resistance. Some foscarnet-resistant CMV isolates show cross-resistance to cidofovir, and triple-drug-resistant variants with DNA polymerase mutations occur.

ADME

Cidofovir has very low oral bioavailability. Penetration into the CSF is low. Topical cidofovir gel may result in low plasma concentrations ($<0.5 \mu\text{g/mL}$) in patients with large mucocutaneous lesions. Plasma levels after intravenous dosing decline in a biphasic pattern with a terminal $t_{1/2}$ that averages 2.6 h. The active form, cidofovir diphosphate, has a prolonged intracellular $t_{1/2}$ and competitively inhibits CMV and HSV DNA polymerases at concentrations one-eighth to one six-hundredth of those required to inhibit human DNA polymerases (Hitchcock et al., 1996). A phosphocholine metabolite also has a long intracellular $t_{1/2}$ (about 87 h) and may serve as an intracellular reservoir of drug. The prolonged intracellular $t_{1/2}$ of cidofovir diphosphate allows infrequent (weekly or biweekly) dosing regimens. Cidofovir is cleared by the kidney via glomerular filtration and tubular secretion. Over 90% of the dose is recovered unchanged in the urine. Probenecid blocks tubular transport of cidofovir and reduces renal clearance and associated nephrotoxicity. Elimination relates linearly to creatinine clearance; the $t_{1/2}$ increases to 32.5 h in patients on CAPD. Hemodialysis removes more than 50% of the administered dose.

Therapeutic Uses

Intravenous cidofovir is approved for the treatment of CMV retinitis in HIV-infected patients. Intravenous cidofovir has been used for treating acyclovir-resistant mucocutaneous HSV infection, adenovirus disease in transplant recipients, and extensive molluscum contagiosum in HIV patients. Reduced doses without probenecid may be beneficial in BK virus nephropathy in patients with a renal transplant. Topical cidofovir gel eliminates virus shedding and lesions in some HIV-infected patients with acyclovir-resistant mucocutaneous HSV infections and has been used in treating anogenital warts and molluscum contagiosum in immunocompromised patients and cervical intraepithelial neoplasia in women. Intralesional cidofovir induces remissions in adults and children with respiratory papillomatosis.

Untoward Effects

Nephrotoxicity is the principal dose-limiting side effect of intravenous cidofovir. Concomitant oral probenecid and saline prehydration reduce the risk of renal toxicity; however, probenecid alters renal clearance of many agents, albeit not of cidofovir. For example, probenecid alters zidovudine pharmacokinetics such that zidovudine doses should be reduced

when probenecid is present, as should the doses of other drugs whose renal secretion probenecid inhibits (e.g., β -lactam antibiotics, NSAIDs, acyclovir, lorazepam, furosemide, methotrexate, theophylline, and rifampin). On maintenance doses of 5 mg/kg every 2 weeks, up to 50% of patients develop proteinuria, 10%–15% show an elevated serum creatinine concentration, and 15%–20% develop neutropenia. Anterior uveitis that is responsive to topical corticosteroids and cycloplegia occurs commonly, and low intraocular pressure occurs infrequently with intravenous cidofovir. Administration with food and pretreatment with antiemetics, antihistamines, or acetaminophen may improve tolerance. Concurrent nephrotoxic agents are contraindicated, and at least 7 days should elapse before initiation of cidofovir treatment is recommended after prior exposure to aminoglycosides, intravenous pentamidine, amphotericin B, foscarnet, NSAID, or contrast dye. Cidofovir and oral ganciclovir are poorly tolerated in combination at full doses.

Topical application of cidofovir is associated with dose-related application site reactions (e.g., burning, pain, and pruritus) in up to one-third of patients and occasionally ulceration. Cidofovir is considered a potential human carcinogen. It may cause infertility and is classified as pregnancy category C.

Famciclovir and Penciclovir

Famciclovir is the diacetyl ester prodrug of 6-deoxy penciclovir and lacks intrinsic antiviral activity. Penciclovir is an acyclic guanine nucleoside analogue. Penciclovir is similar to acyclovir in its spectrum of activity and potency against HSV and VZV. It also is inhibitory for HBV.

Mechanisms of Action and Resistance

Penciclovir is an inhibitor of viral DNA synthesis. In HSV- or VZV-infected cells, penciclovir is phosphorylated initially by viral TK. Penciclovir triphosphate is a competitive inhibitor of viral DNA polymerase (see Figure 62-3). Although penciclovir triphosphate is approximately a one-hundredth as potent as acyclovir triphosphate in inhibiting viral DNA polymerase, it is present in infected cells at much higher concentrations and for more prolonged periods. The prolonged intracellular $t_{1/2}$ of penciclovir triphosphate, 7–20 h, is associated with prolonged antiviral effects. Because penciclovir has a 3'-hydroxyl group, it is not an obligate chain terminator but does inhibit DNA elongation. Resistance during clinical use is low. TK-deficient, acyclovir-resistant herpesviruses are cross-resistant to penciclovir.

ADME

Oral penciclovir has low ($<5\%$) bioavailability. In contrast, famciclovir is well absorbed orally (bioavailability $\sim 75\%$) and is converted rapidly to penciclovir by deacetylation of the side chain and oxidation of the purine ring during and following absorption. Food slows absorption but does not reduce overall bioavailability. The plasma elimination $t_{1/2}$ of penciclovir averages about 2 h, and more than 90% is excreted unchanged in the urine. Following oral famciclovir administration, nonrenal clearance accounts for about 10% of each dose, primarily through fecal excretion, but penciclovir (60% of dose) and its 6-deoxy precursor ($<10\%$ of dose) are eliminated primarily in the urine. The plasma $t_{1/2}$ averages 9.9 h in renal insufficiency ($\text{Cl}_{\text{cr}} < 30 \text{ mL/min}$); hemodialysis efficiently removes penciclovir.

Therapeutic Uses

Oral famciclovir, topical penciclovir, and intravenous penciclovir are approved for managing HSV and VZV infections.

Oral famciclovir (250 mg three times a day for 7–10 days) is as effective as acyclovir in treating first-episode genital herpes (Kimberlin and Rouse, 2004). In patients with recurrent genital HSV, patient-initiated famciclovir treatment (125 or 250 mg twice daily for 5 days) reduces healing time and symptoms by about 1 day. Famciclovir (250 mg twice daily for up to 1 year) is effective for suppression of recurrent genital HSV, but single daily doses are less effective. Higher doses (500 mg twice daily) reduce HSV recurrences in HIV-infected persons. Intravenous penciclovir (5 mg/kg every 8 or 12 h for 7 days) (not available in the U.S.) is comparable to intravenous acyclovir for treating mucocutaneous HSV infections in

immunocompromised hosts. In immunocompetent persons with recurrent orolabial HSV, topical 1% penciclovir cream (applied every 2 h while awake for 4 days) shortens healing time and symptoms by about 1 day (Raborn et al., 2002).

In immunocompetent adults with herpes zoster of 3 days' duration or less, famciclovir (500 mg three times a day for 10 days) is at least as effective as acyclovir (800 mg five times daily) in reducing healing time and zoster-associated pain, particularly in those 50 years or older. Famciclovir is comparable with valacyclovir in treating zoster and reducing associated pain in older adults (Tyring et al., 2000). Famciclovir (500 mg three times a day for 7–10 days) also is comparable with high-dose oral acyclovir in treating zoster in immunocompromised patients and in those with ophthalmic zoster (Tyring et al., 2001).

Famciclovir is associated with dose-related reductions in HBV DNA and transaminase levels in patients with chronic HBV hepatitis but is less effective than lamivudine (Lai et al., 2002). Famciclovir is also ineffective in treating lamivudine-resistant HBV infections owing to emergence of multiply resistant variants.

Untoward Effects

Oral famciclovir is associated with headache, diarrhea, and nausea. Urticaria, rash, and hallucinations or confusional states (predominantly in the elderly) have been reported. Topical penciclovir (~1%) rarely is associated with local reactions. The short-term tolerance of famciclovir is comparable with that of acyclovir. Penciclovir is mutagenic at high concentrations. Long-term administration (1 year) does not affect spermatogenesis in men. Safety during pregnancy has not been established.

Ganciclovir and Valganciclovir

Ganciclovir is an acyclic guanine nucleoside analogue that is similar in structure to acyclovir. Valganciclovir is the L-valyl ester prodrug of ganciclovir. Ganciclovir has inhibitory activity against all herpesviruses and is especially active against CMV.

Mechanisms of Action and Resistance

Ganciclovir inhibits viral DNA synthesis. It is monophosphorylated intracellularly by viral TK during HSV infection and by a viral phosphotransferase encoded by the UL97 gene during CMV infection. Ganciclovir diphosphate and ganciclovir triphosphate are formed by host enzymes. At least 10-fold higher concentrations of ganciclovir triphosphate are present in CMV-infected than in uninfected cells. The triphosphate is a competitive inhibitor of dGTP incorporation into DNA and preferentially inhibits viral rather than host cellular DNA polymerases. Incorporation into viral DNA causes eventual cessation of DNA chain elongation (see Figures 62–1A and 62–3).

Cytomegalovirus can become resistant to ganciclovir by either of two mechanisms: reduced intracellular ganciclovir phosphorylation owing to mutations in the viral phosphotransferase and mutations in viral DNA polymerase. Highly resistant variants with both mutations are cross-resistant to cidofovir and variably to foscarnet. Ganciclovir also is much less active against acyclovir-resistant TK-deficient HSV strains.

ADME

The oral bioavailability of ganciclovir is low, only 6%–9% following ingestion with food. On the other hand, oral doses of the prodrug valganciclovir are well absorbed and hydrolyzed rapidly to ganciclovir; thus, valganciclovir provides greater bioavailability of the ganciclovir moiety, about 60%. Food further increases the bioavailability of valganciclovir by about 25%. Following intravenous administration of ganciclovir, vitreous fluid levels are similar to or higher than those in plasma and decline with a $t_{1/2}$ of 23–26 h. Intraocular sustained-release ganciclovir implants provide vitreous levels of about 4.1 $\mu\text{g/mL}$. The plasma elimination $t_{1/2}$ is about 2–4 h. Intracellular ganciclovir triphosphate concentrations are 10-fold higher than those of acyclovir triphosphate and decline much more slowly, with an intracellular elimination $t_{1/2}$ longer than 24 h. These differences may account in part for ganciclovir's greater anti-CMV activity and provide the rationale for single daily doses in suppressing human CMV infections.

Over 90% of ganciclovir is eliminated unchanged by renal excretion. Plasma $t_{1/2}$ increases in patients with severe renal insufficiency.

Therapeutic Uses

In CMV retinitis, initial induction treatment (5 mg/kg IV every 12 h for 10–21 days) is associated with improvement or stabilization in about 85% of patients (Faulds and Heel, 1990). Reduced viral excretion is usually evident by 1 week, and funduscopic improvement is seen by 2 weeks. Because of the high risk of relapse, patients with AIDS with retinitis require suppressive therapy with high doses of ganciclovir (5 mg/kg/d). Oral ganciclovir (1000 mg three times daily) is effective for suppression of retinitis after initial intravenous treatment but has been replaced in practice by oral valganciclovir. Oral valganciclovir (900 mg twice daily for 21 days of initial treatment) is comparable with intravenous dosing for initial control and sustained suppression (900 mg daily) of CMV retinitis (Schreiber et al., 2009). Intravitreal ganciclovir injections have been used in some patients, and an intraocular sustained-release ganciclovir implant is more effective than systemic dosing in suppressing retinitis progression.

Ganciclovir therapy (5 mg/kg every 12 h for 14–21 days) may benefit other CMV syndromes in patients with AIDS or recipients of solid-organ transplants (Kotton et al., 2010). Ganciclovir has been used for both prophylaxis and preemptive therapy of CMV infections in transplant recipients (Schreiber et al., 2009).

A ganciclovir ophthalmic gel formulation (Zirgan) is effective in treating HSV keratitis (Colin et al., 1997). Oral ganciclovir also reduces HBV DNA levels and aminotransferase levels in chronic hepatitis B virus infection (Hadziyannis et al., 1999), but the drug is not approved for this indication.

Untoward Effects

Myelosuppression is the principal dose-limiting toxicity of ganciclovir. Neutropenia occurs in about 15%–40% of patients and is observed most commonly during the second week of treatment and usually is reversible within 1 week of drug cessation. Persistent fatal neutropenia has occurred. Recombinant G-CSF (filgrastim, lenograstim) may be useful in treating ganciclovir-induced neutropenia (see Chapter 41). Thrombocytopenia occurs in 5%–20% of patients. Zidovudine and probably other cytotoxic agents increase the risk of myelosuppression, as do nephrotoxic agents that impair ganciclovir excretion. Probenecid and possibly acyclovir reduce renal clearance of ganciclovir. Oral ganciclovir increases the absorption and peak plasma concentrations of didanosine by approximately 2-fold and that of zidovudine by about 20%. CNS side effects (5%–15%) range in severity from headache to behavioral changes to convulsions and coma. About one-third of patients must interrupt or prematurely stop intravenous ganciclovir therapy because of bone marrow or CNS toxicity. Infusion-related phlebitis, azotemia, anemia, rash, fever, liver function test abnormalities, nausea or vomiting, and eosinophilia also have been described. Ganciclovir is classified as pregnancy category C (risk not ruled out).

Foscarnet

Foscarnet (trisodium phosphonoformate) is an inorganic pyrophosphate analogue that is inhibitory for all herpesviruses and HIV.

Mechanisms of Action and Resistance

Foscarnet inhibits viral nucleic acid synthesis by interacting directly at HSV DNA polymerase or HIV reverse transcriptase (see Figures 62–1A and 62–3). Foscarnet reversibly blocks the pyrophosphate binding site of the viral DNA polymerase, inhibiting cleavage of pyrophosphate from deoxynucleotide triphosphates and thereby inhibiting chain elongation (deoxynucleotide triphosphate + $\text{DNA}_n \rightarrow$ diphosphate + DNA_{n+1}). Foscarnet has about 100-fold greater inhibitory effects against herpesvirus DNA polymerases than against cellular DNA polymerase α . Herpesviruses resistant to foscarnet have point mutations in the viral DNA polymerase.

ADME

Foscarnet is poorly soluble in aqueous solutions and requires large volumes for administration; in addition, the drug's oral bioavailability is low.

1112 Vitreous levels approximate those in plasma; CSF levels average 66% of those in plasma at steady state. Over 80% of foscarnet is excreted unchanged in the urine. Dose adjustments are necessary for small decreases in renal function. Plasma elimination has initial bimodal half-lives totaling 4–8 h and a prolonged terminal elimination $t_{1/2}$ of 3–4 days. Sequestration in bone with gradual release accounts for the fate of an estimated 10%–20% of a given dose. Foscarnet is cleared efficiently by hemodialysis (~50% of a dose).

Therapeutic Uses

Intravenous foscarnet is effective for treatment of CMV retinitis, including ganciclovir-resistant infections, other types of CMV infection, and acyclovir-resistant HSV and VZV infections.

In CMV retinitis in patients with AIDS, foscarnet (60 mg/kg every 8 h or 90 mg/kg every 12 h for 14–21 days followed by chronic maintenance at 90 to 120 mg/kg every day in one dose) is associated with clinical stabilization in about 90% of patients. In CMV retinitis in patients with AIDS, foscarnet (60 mg/kg every 8 h or 90 mg/kg every 12 h for 14–21 days followed by chronic maintenance at 90 to 120 mg/kg every day in one dose) is associated with clinical stabilization in about 90% of patients. When used for preemptive therapy of CMV viremia in bone marrow transplant recipients, foscarnet (60 mg/kg every 12 h for 2 weeks followed by 90 mg/kg daily for 2 weeks) is as effective as intravenous ganciclovir and causes less neutropenia (Reusser et al., 2002). When used for CMV infections, foscarnet may reduce the risk of Kaposi sarcoma in HIV-infected patients. Intravitreal injections of foscarnet also have been used. In acyclovir-resistant mucocutaneous HSV infections, lower doses of foscarnet (40 mg/kg every 8 h for ≥ 7 days) are associated with cessation of viral shedding and with complete healing of lesions in about three-quarters of patients. Foscarnet also appears to be effective in acyclovir-resistant VZV infections. Topical foscarnet cream is ineffective in treating recurrent genital HSV in immunocompetent persons but appears to be useful in chronic acyclovir-resistant infections in immunocompromised patients.

Untoward Effects

Major dose-limiting toxicities are nephrotoxicity and symptomatic hypocalcemia. Increases in serum creatinine occur in up to one-half of patients but are generally reversible after cessation. High doses, rapid infusion, dehydration, prior renal insufficiency, and concurrent nephrotoxic drugs are risk factors. Saline loading may reduce the risk of nephrotoxicity. Foscarnet is highly ionized at physiological pH, and metabolic abnormalities are very common. These include increases or decreases in Ca^{2+} and phosphate, hypomagnesemia, and hypokalemia. Concomitant intravenous pentamidine administration increases the risk of symptomatic hypocalcemia. CNS side effects include headache (25%), tremor, irritability, seizures, and hallucinosis. Other reported side effects are generalized rash, fever, nausea or emesis, anemia, leukopenia, abnormal liver function tests, electrocardiographic changes, infusion-related thrombophlebitis, and painful genital ulcerations. Topical foscarnet may cause local irritation and ulceration, and oral foscarnet may cause GI disturbance. Preclinical studies indicate that high foscarnet concentrations are mutagenic. Safety in pregnancy or childhood is uncertain.

Fomivirsen

Fomivirsen, a 21-base phosphorothioate oligonucleotide, provides antisense therapy. The drug is complementary to the mRNA sequence for the major immediate-early transcriptional region of CMV and inhibits CMV replication through sequence-specific and nonspecific mechanisms, including inhibition of virus binding to cells. Fomivirsen is active against CMV strains resistant to ganciclovir, foscarnet, and cidofovir. Fomivirsen is given by intravitreal injection in the treatment of CMV retinitis for patients intolerant of or unresponsive to other therapies. Following injection, it is cleared slowly from the vitreous ($t_{1/2} \sim 55$ h) through distribution to the retina and probable exonuclease digestion. In HIV-infected patients with refractory, sight-threatening CMV retinitis, fomivirsen

injections (330 μg weekly for 3 weeks and then every 2 weeks or on days 1 and 15 followed by monthly) significantly delay time to retinitis progression. Ocular side effects include iritis in up to one-quarter of patients, which can be managed with topical corticosteroids; vitritis; cataracts; and increases in intraocular pressure in 15%–20% of patients. Recent cidofovir use may increase the risk of inflammatory reactions. *This drug is no longer available in the U.S.*

Docosanol

Docosanol is a long-chain saturated alcohol that is approved as an over-the-counter 10% cream for the treatment of recurrent orolabial herpes. Docosanol inhibits the in vitro replication of many lipid-enveloped viruses, including HSV. It does not inactivate HSV directly but appears to block fusion between the cellular and viral envelope membranes and inhibits viral entry into the cell. Topical treatment beginning within 12 h of prodromal symptoms or lesion onset reduces healing time by about 1 day and is well tolerated. Treatment initiation at papular or later stages provides no benefit.

Idoxuridine

Idoxuridine is an iodinated thymidine analogue that inhibits the in vitro replication of various DNA viruses, including herpesviruses and poxviruses. Idoxuridine lacks selectivity, in that low concentrations inhibit the growth of uninfected cells. The triphosphate inhibits viral DNA synthesis and is incorporated into both viral and cellular DNA. In the U.S., idoxuridine is approved only for topical (ophthalmic) treatment of HSV keratitis. Idoxuridine formulated in dimethylsulfoxide is available outside the U.S. for topical treatment of herpes labialis, genitalis, and zoster. Adverse reactions include pain, pruritus, inflammation, and edema of the eye or lids; allergic reactions are rare.

Trifluridine

Trifluridine is a fluorinated pyrimidine nucleoside that has in vitro inhibitory activity against HSV types 1 and 2, CMV, vaccinia, and to a lesser extent, certain adenoviruses. Trifluridine inhibits replication of herpesviruses, including acyclovir-resistant strains, and also inhibits cellular DNA synthesis at relatively low concentrations. Trifluridine monophosphate irreversibly inhibits thymidylate synthase, and trifluridine triphosphate is a competitive inhibitor of thymidine triphosphate incorporation into DNA; trifluridine is incorporated into viral and cellular DNA. Trifluridine-resistant HSV has been described.

Trifluridine currently is used for treatment of primary keratoconjunctivitis and recurrent epithelial keratitis owing to HSV types 1 and 2. Topical trifluridine is more active than idoxuridine and comparable with vidarabine in HSV ocular infections. Adverse reactions include discomfort on instillation and palpebral edema. Hypersensitivity reactions and irritation are uncommon. Topical trifluridine also appears to be effective in some patients with acyclovir-resistant HSV cutaneous infections.

Anti-influenza Agents

Recently, there has been concern about the possibility of new influenza pandemics stemming from small but severe outbreaks of H5N1 avian influenza and the novel 2009 influenza A H1N1, thought to be of swine origin. Five drugs are currently approved for the treatment and prevention of influenza virus infection: the adamantane antivirals, amantadine and rimantadine; oseltamivir; zanamivir; and peramivir. Resistance to these drugs has arisen as a consequence of their overuse, including in veterinary applications. Development of resistance and the spread of resistant viruses are major challenges in the chemotherapy and chemoprophylaxis of influenza and are likely to drive future recommendations for use of these drugs in global populations. The CDC annually issues recommendations for influenza vaccinations and comments on effective medications (CDC, 2016).

Amantadine and Rimantadine

Amantadine and its derivative rimantadine are uniquely configured tricyclic amines. Rimantadine has $\text{H}_3\text{C}-\text{CH}-\text{NH}_2$ in place of the $-\text{NH}_2$ group.

AMANTADINE

Mechanisms of Action and Resistance

Amantadine and rimantadine inhibit an early step in viral replication, probably viral uncoating; for some strains, they also have an effect on a late step in viral assembly, probably mediated through altering hemagglutinin processing. The primary locus of action is the influenza A virus M2 protein, an integral membrane protein that functions as an ion channel. By interfering with this function of the M2 protein, the drugs inhibit the acid-mediated dissociation of the ribonucleoprotein complex early in replication and potentiate acidic pH-induced conformational changes in hemagglutinin during its intracellular transport later in replication. Resistance to these drugs results from a mutation in the RNA sequence encoding for the M2 protein transmembrane domain; resistant isolates typically appear in the treated patient within 2–3 days of starting therapy.

ADME

Table 62–3 summarizes important pharmacokinetics properties of these antiviral agents. The two adamantanes differ in several respects. Amantadine is excreted largely unmetabolized in the urine ($t_{1/2}$ of elimination is ~12–18 h in young adults, increasing up to twice that in the elderly and even more in those with renal impairment). By contrast, elimination of rimantadine depends on hepatic function; the drug is subject to

phase 1 and phase 2 reactions prior to renal excretion of metabolites (elimination $t_{1/2}$ ~24–36 h; 60%–90% is excreted in the urine as metabolites). The elderly require only one-half the weight-adjusted dose of amantadine needed for young adults. Amantadine is excreted in breast milk. Rimantadine concentrations in nasal mucus average 50% higher than those in plasma.

Therapeutic Uses

Although both drugs are useful for the prevention and treatment of infections caused by influenza A virus, vaccination against influenza is a more cost-effective means of reducing disease burden. Amantadine and rimantadine are active only against susceptible influenza A viruses (not influenza B); rimantadine is 4- to 10-fold more active than amantadine. Virtually all H3N2 strains of influenza circulating worldwide are resistant to these drugs.

Seasonal prophylaxis with either amantadine or rimantadine (a total of 200 mg/d in one or two divided doses in young adults) is about 70%–90% protective against influenza A illness. These agents are efficacious in preventing nosocomial influenza and in curtailing nosocomial outbreaks during pandemic influenza. Doses of 100 mg/d are better tolerated and still appear to be protective against influenzal illness. Seasonal prophylaxis is an alternative in high-risk patients, if the influenza vaccine cannot be administered or may be ineffective (i.e., in immunocompromised patients). Prophylaxis should be started as soon as influenza is identified in a community or region and should be continued throughout the period of risk (usually 4–8 weeks) because any protective effects are lost several days after cessation of therapy. Alternatively, the drugs can be started in conjunction with immunization and continued for 2 weeks until protective immune responses develop.

The amantadines are effective against influenza A H1N1 if treatment is initiated within 2 days of the onset of symptoms (Schmidt, 2004). In uncomplicated influenza A illness of adults, early amantadine or rimantadine treatment (200 mg/d for 5 days) reduces the duration of fever and systemic complaints by 1–2 days, speeds functional recovery, and sometimes decreases the duration of virus shedding. The usual regimen in children (≥ 1 year of age) is 5 mg/kg/d, up to 150 mg, administered once or twice daily. Resistant variants have been recovered from about 30% of treated children or outpatient adults by the fifth day of therapy.

TABLE 62–3 ■ PHARMACOLOGICAL CHARACTERISTICS OF ANTIVIRALS FOR INFLUENZA

^e% of parent drug.

^fTypes of influenza.

The most common side effects related to amantadine and rimantadine are minor dose-related CNS and GI effects: nervousness, light-headedness, difficulty concentrating, insomnia, loss of appetite, and nausea. CNS side effects (5%–33%) occur in patients treated with amantadine at doses of 200 mg/d but are significantly less frequent with rimantadine. The neurotoxic effects of amantadine appear to be increased by concomitant ingestion of antihistamines and psychotropic or anticholinergic drugs, especially in the elderly. At comparable doses of 100 mg/d, rimantadine is significantly better tolerated in nursing home residents than amantadine. High amantadine plasma concentrations (1.0–5.0 µg/mL) have been associated with serious neurotoxic reactions, including delirium, hallucinosis, seizures, coma, and cardiac arrhythmias. Exacerbations of preexisting seizure disorders and psychiatric symptoms may occur with amantadine and possibly with rimantadine. Both drugs are considered pregnancy category C (risk not ruled out; see Appendix I).

Oseltamivir

Oseltamivir carboxylate is a transition-state analogue of sialic acid that is a potent selective inhibitor of the neuraminidases of influenza A and B virus. Oseltamivir phosphate is an ethyl ester prodrug that lacks antiviral activity. Oseltamivir carboxylate has an antiviral spectrum and potency similar to that of zanamivir: It inhibits amantadine- and rimantadine-resistant influenza A viruses and some zanamivir-resistant variants.

Mechanisms of Action and Resistance

Influenza neuraminidase cleaves terminal sialic acid residues and destroys the receptors recognized by viral hemagglutinin, which are present on the cell surface, in progeny virions, and in respiratory secretions. This enzymatic action is essential for release of virus from infected cells. Interaction of oseltamivir carboxylate with the neuraminidase causes a conformational change within the enzyme's active site and inhibits its activity. Inhibition of neuraminidase activity leads to viral aggregation at the cell surface and reduced virus spread within the respiratory tract. Influenza variants selected in vitro for resistance to oseltamivir carboxylate contain hemagglutinin or neuraminidase mutations. Seasonal influenza A (H1N1) has become virtually 100% resistant to oseltamivir worldwide (Moscona, 2009; Schirmer and Holodniy, 2009). Importantly, novel H1N1 (nH1N1 or swine influenza) remains susceptible to oseltamivir.

ADME

Table 62–3 summarizes important pharmacokinetics properties of oseltamivir carboxylate. Oral oseltamivir phosphate is absorbed rapidly and cleaved by esterases in the GI tract and liver to the active carboxylate. Food does not decrease bioavailability but reduces the risk of GI intolerance. Bronchoalveolar lavage levels in animals and middle ear fluid and sinus concentrations in humans are comparable with plasma levels. Probenecid doubles the plasma $t_{1/2}$ of the carboxylate, which indicates tubular secretion by the anionic pathway. Children younger than 2 years exhibit age-related changes in oseltamivir carboxylate clearance and total drug exposure (Kimberlin et al., 2009).

Therapeutic Uses

Oral oseltamivir is effective in the treatment and prevention of influenza A and B virus infections. Treatment of previously healthy adults (75 mg twice daily for 5 days) or children 1–12 years of age (weight-adjusted dosing) with acute influenza reduces illness duration by about 1–2 days, speeds functional recovery, and reduces the risk of complications leading to antibiotic use by 40%–50%. Treatment reduces by about 50% the risk of subsequent hospitalization in adults (Kaiser et al., 2003). When used for prophylaxis during the typical influenza season, oseltamivir (75 mg once daily) is effective (~70%–90%) in reducing the likelihood of influenza illness in both unimmunized working adults and in immunized nursing home residents; short-term use protects against influenza in household contacts (Schirmer and Holodniy, 2009).

Untoward Effects

Oral oseltamivir is associated with nausea, abdominal discomfort, and, less often, emesis. GI complaints typically resolve in 1–2 days despite

continued dosing and are preventable by administration with food. An increased frequency of headache was reported in one prophylaxis study in elderly adults. Neither the phosphate nor the carboxylate form interacts with CYPs in vitro. Oseltamivir does not appear to impair fertility, but safety in pregnancy is uncertain (pregnancy category C).

Zanamivir

Zanamivir is a sialic acid analogue that potently and specifically inhibits the neuraminidases of influenza A and B viruses. Zanamivir inhibits in vitro replication of influenza A and B viruses, including amantadine- and rimantadine-resistant strains and several oseltamivir-resistant variants.

Mechanisms of Action and Resistance

Zanamivir inhibits viral neuraminidase and thus causes viral aggregation at the cell surface and reduced spread of virus within the respiratory tract. In vitro selection of viruses resistant to zanamivir is associated with mutations in the viral hemagglutinin or neuraminidase. Hemagglutinin variants are cross-resistant to other neuraminidase inhibitors. Neuraminidase variants contain mutations in the enzyme active site that diminish binding of zanamivir, but the altered enzymes show reduced activity or stability. Zanamivir-resistant variants usually have decreased infectivity in animals.

ADME

Table 62–3 summarizes important pharmacokinetics properties of zanamivir. Oral bioavailability of zanamivir is less than 5%, and the commercial form is delivered by oral inhalation of dry powder in a lactose carrier. The proprietary inhaler device is breath actuated and requires a cooperative patient. Following inhalation of the dry powder, about 15% is deposited in the lower respiratory tract and about 80% in the oropharynx. Overall bioavailability is 4%–17%.

Depending on the strain, zanamivir competitively inhibits influenza neuraminidase activity at concentrations of about 0.2–3 ng/mL but affects neuraminidases from other pathogens and mammalian sources only at 106-fold higher concentrations. Zanamivir inhibits in vitro replication of influenza A and B viruses, including amantadine- and rimantadine-resistant strains and several oseltamivir-resistant variants. It is active after topical administration in animal influenza models.

Therapeutic Uses

Inhaled zanamivir is effective for the prevention and treatment of influenza A and B virus infections. Early zanamivir treatment (10 mg [two inhalations] twice daily for 5 days) of febrile influenza in ambulatory adults and children 5 years or older shortens the time to illness resolution by 1–3 days and in adults reduces by 40% the risk of lower respiratory tract complications that require use of antibiotics. Once-daily inhaled zanamivir is highly protective against community-acquired influenza illness, and when given for 10 days, it protects against household transmission. Intravenous zanamivir ($t_{1/2} \sim 1.7$ h) is available in the U.S. as an EIND and in the E.U. on a compassionate use basis for life-threatening, resistant influenza.

Untoward Effects

Orally inhaled zanamivir generally is well tolerated in ambulatory adults and children with influenza. Wheezing and bronchospasm have been reported in some influenza-infected patients without known airway disease, and acute deteriorations in lung function, including fatal outcomes, have occurred in those with underlying asthma or chronic obstructive airway disease. Zanamivir is not generally recommended for treatment of patients with underlying airway disease because of the risk of serious adverse events. Preclinical studies of zanamivir revealed no evidence of mutagenic, teratogenic, or oncogenic effects (pregnancy risk not ruled out). No clinically significant drug interactions have been recognized to date. Zanamivir does not diminish the immune response to injected influenza vaccine.

Peramivir

Peramivir is a recently FDA-approved inhibitor of influenza virus neuraminidase, indicated for the treatment of acute uncomplicated influenza in patients 18 years and older who have been symptomatic for no

more than 2 days. While peramivir was in clinical development, the FDA authorized its emergency use for treatment of pandemic 2009 A/H1N1 in certain adult and pediatric patients (FDA, 2009).

Mechanisms of Action and Resistance

Peramivir has a mechanism of action similar to that of other neuraminidase inhibitors. Neuraminidase resistance can occur as the result of point mutations in either the neuraminidase or hemagglutinin genes or both. Structurally, peramivir differs somewhat from others in the class via a substitution resulting in multiple binding site interactions, which confers some activity against cross-resistant viruses. Antiviral resistance is currently low to the three available neuraminidase inhibitors amongst circulating influenza viruses. This will likely change with each influenza season. In general, cross-resistance across these agents exists. The degree of cross-resistance depends on the viral strain and which point mutations occur.

ADME

Peramivir is not significantly metabolized in humans. It is not a substrate for CYPs or a substrate or inhibitor of P-glycoprotein. The elimination half-life following intravenous administration of 600 mg as a single dose is approximately 20 h. The major route of clearance is via renal excretion. Approximately 90% of total clearance is unchanged peramivir. Negligible accumulation was observed after multiple dosing. Following a 600-mg dose infused over 30 min, the end-of-infusion C_{\max} was 46.8 $\mu\text{g}/\text{mL}$, and the $\text{AUC}_{0-\infty}$ was 102.7 $\mu\text{g}\cdot\text{h}/\text{mL}$. Dosing should be adjusted in patients with altered creatinine clearance. A single 200-mg dose should be administered for those with an estimated creatinine clearance (CL_{cr} , Cockcroft-Gault) between 30 and 49 mL/min, and 100 mg for a CL_{cr} of 10–29 mL/min. No clinically significant drug interactions have been recognized to date.

Therapeutic Uses

Peramivir is administered as a single 600-mg dose, administered via intravenous infusion over 15–30 min. A phase II clinical trial demonstrated that intravenous peramivir (300 or 600 mg as a single-dose infusion) reduced the time to alleviation of symptoms, from 82 h (placebo) to 59 h (treatment with 600 mg peramivir) (Kohn et al., 2010). A phase III trial demonstrated that peramivir (300 or 600 mg) was comparable in extent of symptom relief to oral oseltamivir (75 mg twice a day for 5 days) in patients with seasonal influenza A or B, and with comparable rates of adverse events (Kohn et al., 2011). At present, peramivir's primary use may be limited to patients with acute, uncomplicated influenza who cannot absorb or for other reasons cannot take oral agents. Further studies are needed regarding the use of peramivir in severely ill hospitalized patients and in the pediatric population.

Untoward Effects

The most common adverse event (>2%) is diarrhea. Hypersensitivity reactions (e.g., Stevens-Johnson syndrome and erythema multiforme) have occurred, and treated patients with influenza may be at increased risk for neuropsychiatric events such as hallucinations, delirium, and abnormal behavior. Frequency and severity of adverse effects (peramivir 300 mg

or 600 mg) are comparable to those with oseltamivir (75 mg twice daily for 5 days) (Kohn et al., 2011). Patients receiving 600 mg peramivir or oseltamivir had decreased neutrophil counts (10.4% vs. 9.3%), diarrhea (8.2% vs. 7.4%), and vomiting (1.6% vs. 4.1%), respectively.

Interferon

Interferons are potent cytokines that possess antiviral, immunomodulatory, and antiproliferative activities (see Chapter 35). Three major classes of human IFNs with significant antiviral activity are α , β , and γ . Clinically used recombinant α -IFNs are nonglycosylated proteins of about 19,500 Da, the pegylated forms predominating in the U.S. market. The mechanism of action, ADME, untoward effects, and therapeutic uses of IFNs are covered in Chapter 63. Recombinant, natural, and pegylated IFNs currently are approved in the U.S. for treatment of condyloma acuminatum, chronic HCV infection, chronic HBV infection, Kaposi sarcoma in HIV-infected patients, other malignancies, and multiple sclerosis. In addition, IFNs have been granted orphan drug status for a variety of rare disease states, including idiopathic pulmonary fibrosis, laryngeal papillomatosis, juvenile rheumatoid arthritis, and infections associated with chronic granulomatous disease.

Papillomavirus

In refractory condylomata acuminata (genital warts), intralesional injection of various natural and recombinant IFNs is associated with complete clearance of injected warts in 36%–62% of patients, but other treatments are preferred. Relapse occurs in 20%–30% of patients. Verruca vulgaris may respond to intralesional IFN- α . Intramuscular or subcutaneous administration is associated with some regression in wart size but greater toxicity. Systemic IFN may provide adjunctive benefit in recurrent juvenile laryngeal papillomatosis and in treating laryngeal disease in older patients.

Other Viruses

Interferons have been shown to have virological and clinical effects in various herpesvirus infections, including genital HSV infections, localized herpes zoster infection of cancer patients or of older adults, and CMV infections of renal transplant patients. However, IFN generally is associated with more side effects and inferior clinical benefits compared with conventional antiviral therapies. Topically applied IFN and trifluridine combinations appear active in acyclovir-resistant mucocutaneous HSV infections. In HIV-infected persons, IFNs have been associated with antiretroviral effects. In advanced infection, however, the combination of zidovudine and IFN is associated with only transient benefit and excessive hematological toxicity. IFN- α (3 million units thrice weekly) is effective for treatment of HIV-related thrombocytopenia that is resistant to zidovudine therapy.

Interferon has broad-spectrum antiviral activity against respiratory viruses other than adenovirus. However, prophylactic intranasal IFN- α is protective only against rhinovirus colds, and chronic use is limited by the occurrence of nasal side effects. Intranasal IFN is therapeutically ineffective in established rhinovirus colds.

Drug Facts for Your Personal Formulary: *Antiviral Agents for Herpes Virus and Influenza*

Drugs	Therapeutic Uses	Clinical Pharmacology and Tips
ANTIHERPES AGENTS		
Guanine nucleoside analogues		
Acyclovir Valacyclovir (Val, an ester prodrug form of acyclovir)	<ul style="list-style-type: none"> Clinical use limited to herpes viruses Efficacy against: HSV-1 > HSV-2 > VZV > EBV > CMV = -6 	<ul style="list-style-type: none"> Acyclovir has low bioavailability (~20%); Val has bioavailability ~ 70% Concentrates in breast milk Clearance via renal excretion of acyclovir, requires good kidney function; $t_{1/2}$ prolonged in neonates and anuric patients Safely used long term (10 years)
Cidofovir	<ul style="list-style-type: none"> Active against human herpes, papilloma, polyoma, pox, adenoviruses 	<ul style="list-style-type: none"> Low oral bioavailability Plasma $t_{1/2}$ ~ 2.6 h, but active diphosphate metabolite has long $t_{1/2}$ in cells, as does a phosphocholine metabolite ($t_{1/2}$ = 86 h) Major risk: nephrotoxicity, reduced by oral probenecid and saline prehydration (beware interactions of probenecid and other medicines)
Famciclovir (Fam), a prodrug form, rapidly converted to penciclovir (Pen)	<ul style="list-style-type: none"> Penciclovir similar to acyclovir against HSV and VZV; also inhibits HBV 	<ul style="list-style-type: none"> Oral bioavailabilities: Pen, < 5%; Fam, ~ 75% Food reduces rate but not extent of Pen absorption Safety in pregnancy not established
Valganciclovir (Val), a prodrug valyl ester of ganciclovir (Gan)	<ul style="list-style-type: none"> Gan has inhibitory activity against all herpesviruses, especially CMV 	<ul style="list-style-type: none"> Gan less active against acyclovir-resistant TK-deficient HSV strains Active triphosphate form has long cellular $t_{1/2}$ IV administration gives good levels in vitreous with long dwell time ($t_{1/2}$ ~ 25 h) Major adverse effects: myelosuppression, neutropenia Risk in pregnancy not ruled out
Pyrophosphate analogue		
Foscarnet	<ul style="list-style-type: none"> Active against all herpesviruses and HIV 	<ul style="list-style-type: none"> Poorly soluble in water; requires large volumes Adverse effects: nephrotoxicity, hypocalcemia Safety in pregnancy and childhood uncertain
Other agents		
Fomivirsen (antisense oligonucleotide)	<ul style="list-style-type: none"> Inhibits CMV replication 	<ul style="list-style-type: none"> No longer available in the U.S.
Docosanol (long-chain alcohol)	<ul style="list-style-type: none"> 10% cream for labial herpes 	<ul style="list-style-type: none"> Treatment initiation at papular or later stages provides no benefit
Idoxuridine (iodinated thymidine analogue)	<ul style="list-style-type: none"> Ophthalmic HSV keratitis (in the U.S.) 	<ul style="list-style-type: none"> Averse effects: pain, pruritus, inflammation, edema of eye/eyelid
Trifluridine (trifluoropyrimidine nucleoside)	<ul style="list-style-type: none"> Ocular herpes; 1° keratoconjunctivitis, recurrent epithelial keratitis from HSV1/2; for external use 	<ul style="list-style-type: none"> More active than idoxuridine and comparable to vidarabine in HSV ocular infections Triphosphate form incorporated into host and viral DNA, so not used systemically
ANTI-INFLUENZA AGENTS		
Inhibitors of viral M2 protein function		
Amantadine (Ama) Rimantadine (Rima)	<ul style="list-style-type: none"> Active only against susceptible influenza A viruses (not B) Seasonal prophylaxis against influenza A (70%–90% protective) 	<ul style="list-style-type: none"> Rima 4- to 10-fold more active than Ama Resistant isolates appear after 2–3 days of therapy Virtually all H3N2 strains of influenza are resistant to these drugs Vaccination is more cost-effective
Inhibitors of viral neuraminidase (see PK data in Table 62–3)		
Oseltamivir	<ul style="list-style-type: none"> Treatment and prevention of influenza A and B 	<ul style="list-style-type: none"> Probenecid doubles plasma $t_{1/2}$
Zanamivir	<ul style="list-style-type: none"> Treatment and prevention of influenza A and B 	<ul style="list-style-type: none"> Inhalable formulation IV formulation available as EIND No clinically significant drug interactions
Peramivir	<ul style="list-style-type: none"> Treatment of acute uncomplicated flu in patients ≥ 18 years and symptomatic ≤ 2 days 	<ul style="list-style-type: none"> Supplied as IV infusion; for patients who cannot absorb or oral agents Comparable in efficacy and adverse effects to oseltamivir No clinically significant drug interactions reported
CYTOKINES		
Interferon (recombinant α -IFNs; natural and pegylated IFNs)	<ul style="list-style-type: none"> Treatment of condyloma acuminatum, chronic HCV and HBV infection, Kaposi sarcoma (in patients with HIV, other malignancies, multiple sclerosis) 	<ul style="list-style-type: none"> See Chapter 63

Hepatitis viruses cause inflammation and necrosis of the liver. Hepatitis A and E, which are transmitted via the fecal-oral route, are typically self-limiting, although a small percentage (1%–2%) of those infected will develop fulminant hepatic failure. HBV, HCV, and hepatitis D viruses, however, are transmitted parenterally. Hepatitis B and C may or may not cause symptoms of acute infection, but both may progress to chronic infection. Individuals with chronic hepatitis B or C infection are at risk for cirrhosis, liver failure, and hepatocellular carcinoma. There are two notable differences between HBV and HCV. *First*, HBV is a vaccine-preventable illness, whereas there is no vaccine available to prevent HCV. *Second*, HCV can be cured with effective treatment, whereas the current treatments for HBV are not completely curative. The hepatitis D virus is defective and requires the presence of the HBV to propagate. Individuals coinfect with hepatitis B and D are at greater risk for cirrhosis and hepatocellular carcinoma compared with individuals with only hepatitis B infection, but fortunately only about 5% of individuals with HBV are coinfect with hepatitis D.

There are no antiviral therapies available for the treatment of hepatitis A and E viruses. At this time, the only drug available to treat hepatitis D is pegIFN- α , and it is successful in only 20%–35% of patients (Durantel and Zoulim, 2016). A number of drugs are available for the treatment of hepatitis B and C. Indeed, the RdRp (NS5B), the NS5A replication complex, and the NS3 protease of HCV have been fruitful targets for drug development over the past decade. We now have a growing number of DAAs that inhibit HCV RdRp, the NS3 protease, and NS5A. These DAAs, often used in oral combination therapies, have revolutionized the treatment of HCV, have good safety profiles, and provide well-tolerated and very effective treatments for HCV infection. Available therapies for HBV include IFN and nucleoside and nucleotide analogues. Several agents are in various stages of clinical development for the treatment of HBV. Therapeutic strategies for these two chronic viral infections, hepatitis B and C, are very different and are described separately in this chapter.

Several agents employed against hepatitis viruses, including IFN, ribavirin, and the nucleoside/nucleotide analogues lamivudine, emtricitabine, and tenofovir, are also used to treat other conditions, described in Chapters 64 (Antiretroviral Agents and Treatment of HIV Infection) and 69 (Ocular Pharmacology).

Assessing the stage and severity of liver disease is an important aspect of treating individuals with chronic viral hepatitis. Individuals with cirrhosis require additional monitoring for potential complications (e.g., varices and hepatocellular carcinoma) and the approach to treatment differs in cirrhotics and decompensated cirrhotics compared to individuals without significant liver fibrosis. Cirrhosis can be diagnosed with histologic, radiographic, or laboratory tests. However, decompensated

cirrhosis (also known as end-stage liver disease) is a clinical diagnosis based on the presence of variceal hemorrhage, ascites, jaundice, or hepatic encephalopathy. Decompensated cirrhosis carries a high risk of mortality (median survival 2 years), and these individuals should be evaluated for liver transplantation.

The urgency for liver transplantation in individuals with decompensated cirrhosis is determined using the MELD score. A MELD score is calculated based on a patient's bilirubin, INR, and serum creatinine. Individuals with higher MELD scores have a higher risk for mortality and a more urgent need for transplantation. Cirrhosis may also be categorized based on the Child Pugh score. The Child Pugh score accounts for bilirubin, albumin, and INR values and the presence/absence of ascites and encephalopathy. Higher scores are associated with more advanced disease: mild hepatic impairment (Child Pugh category A; score of 5–6), moderate hepatic impairment (Child Pugh category B; score of 7–9), and severe hepatic impairment (Child Pugh category C; score of 10–15). Individuals with Child Pugh B and C scores have decompensated cirrhosis. Familiarity with MELD and Child Pugh scoring and the diagnoses of compensated versus decompensated cirrhosis is helpful for understanding the pharmacologic basis of hepatitis B and C treatment.

Hepatitis B Virus

HBV Overview

Worldwide, an estimated 2 billion people have been infected with HBV and approximately 240 million have chronic disease (WHO, 2015). Areas with the highest HBV endemicity are sub-Saharan Africa and countries in the WHO Western-Pacific region (e.g., China) (Schweitzer et al., 2015). In these regions, HBV is most likely acquired perinatally. Those infected at birth have a 90% risk of progressing to chronic disease; otherwise, the risk of chronic HBV disease in adults is 5% (Tong and Revell, 2016). The lifetime risk of developing cirrhosis, liver failure, or hepatocellular carcinoma in individuals with HBV is 15%–40% (Lin et al., 2016). There are about 686,000 HBV-related deaths annually, which makes HBV the leading cause of liver-related deaths worldwide (WHO, 2016).

Genetic Heterogeneity of HBV

There are 10 described HBV genotypes (A–J) and at least 35 subtypes with distinct geographical distributions (Tong and Revell, 2016). Genotype A is most frequent in North America and Africa, genotypes B and C are dominant throughout East Asia and are primarily transmitted via the perinatal route, and genotype D is most common in Southern Europe and India.

2–5(A): 2′–5′-oligoadenylate

AASLD: American Association for the Study of Liver Diseases

ADME: absorption, distribution, metabolism, excretion

ALT: alanine aminotransferase

anti-HB: hepatitis B surface antibody

AST: aspartate aminotransferase

AUC_{ss}: area under the plasma concentration-time curve at steady state

BCRP: breast cancer resistance protein

BMD: bone mineral density

cccDNA: covalently closed circular DNA

C_{max}, C_{Pmax}: maximal blood or plasma concentration

C_p: plasma concentration

CPss: plasma concentration at steady state

CSF: cerebrospinal fluid

CYP: cytochrome P450

DAA: direct-acting antiviral

dATP: deoxyadenosine triphosphate

DCV/SOF: daclatasvir/sofosbuvir fixed-dose combination

dNTP: deoxynucleotide triphosphate

EBR: elbasvir

eGFR: estimated glomerular filtration rate

eIF-2: eukaryotic initiation factor

ESRD: end-stage renal disease

FDA: Food and Drug Administration

GTP: guanosine triphosphate

GZR: grazoprevir

HBeAg: hepatitis B e antigen

HBsAg: hepatitis B surface antigen

HINT1: histidine triad nucleotide-binding protein 1

IFN: interferon

INR: international normalized ratio

LBAT: liver bile acid transporter

LDV/SOF: ledipasvir/sofosbuvir fixed-dose combination

MELD: model for end-stage liver disease

MHC: major histocompatibility complex

MRP: multidrug resistance protein

MU: million units

NTCP: Na⁺/taurocholate cotransporter

ORF: open reading frame

PEG: polyethylene glycol

pegIFN: pegylated interferon

Pgp: P-glycoprotein

PPI: proton pump inhibitor

PrO: paritaprevir/ritonavir-boosted, ombitasvir combination

PrOD: paritaprevir/ritonavir-boosted, ombitasvir, dasabuvir combination

RAV: resistance-associated variant

RdRp: RNA-dependent RNA polymerase

RT: reverse transcriptase

SIM/SOF: simeprevir and sofosbuvir coadministered

SOF: sofosbuvir

SVR: sustained virologic response

TAF: tenofovir alafenamide fumarate

TDF: tenofovir disoproxil fumarate

VEL/SOF: fixed-dose combination of VEL and SOF

VEL: velpatasvir

WHO: World Health Organization

Genotype E is largely restricted to sub-Saharan Africa, while genotypes F and H cocirculate in indigenous peoples of South America. Genotypes I and J have been described in only three individuals and one individual, respectively.

Genotypes have relevance for the clinical manifestation of infection and the response to antiviral therapy. Clinically relevant features of HBV genotypes include the rate and durability of HBeAg (loss or seroconversion; A and D > B and C), the risk of developing aggressive HBeAg(–) chronic hepatitis B (C and D > A), spontaneous HBeAg loss (B > C), cirrhosis (C), hepatocellular carcinoma (C in Asians, F in Alaska Natives), and response to antivirals (A and B > C and D).

HBV Genome and Life Cycle

Hepatitis B virus is a small, enveloped, partially double-stranded DNA virus approximately 3200 kb in length. The virus is composed of a nucleocapsid core (HBcAg, core antigen) surrounded by an outer lipoprotein envelope containing the surface antigen (HBsAg). HBV is compact and contains four overlapping ORF. ORF C encodes the nucleocapsid protein and HBeAg, ORF P encodes the polymerase and terminal protein, ORF S/pre-S encodes three envelope proteins, and ORF X encodes the regulatory X protein.

Figure 63–1 depicts the HBV life cycle (Brahmania et al., 2016; Lin et al., 2016; Tong and Revill, 2016). HBV virus binds to the NTCP (SLC10A1; also called LBAT) on the surface of the hepatocytes. Virus is taken up into the hepatocyte, where it is uncoated. The partially double-stranded DNA is brought into the host cell's nucleus. The partial double strand is then repaired to form cccDNA. The cccDNA is not eliminated by available treatments; thus, a complete cure is not currently possible. cccDNA complexes with host proteins to form a minichromosome that becomes a template for the transcription of the various virally derived RNAs. These RNAs are transported to the cytoplasm, and some of the smaller RNAs are then made into various viral proteins, including the envelope protein. These proteins can actually be released without any genetic material (known as subviral particles). Filamentous and spherical HBsAg particles are produced in 3–4 log excess over virions (complete virus particles). These subvirus particles are thought to contribute to immune tolerance and T-cell exhaustion by increasing the amount of antigen that is circulating. The larger pregenomic RNA is used to form the HBcAg protein, which is also encapsidated. In the capsid, HBV is reverse transcribed to make more HBV DNA, and then the virus becomes bound to proteins and released as a virion.

Some patients develop mutations in the HBV genome that prevent HBeAg formation despite active HBV replication; this condition is known as HBeAg(–) disease.

HBV Drug Targets and Treatment Approach

Hepatitis B virus is a dynamic condition. Individuals with chronic infection can pass through several phases of disease throughout their lifetimes. At present, treatment is typically reserved for individuals with high levels of circulating HBV DNA and alanine aminotransferase elevations, those with cirrhosis, or for prevention of reactivation of disease in those receiving immunosuppressive therapies (e.g., chemotherapy) (Terrault et al., 2016). When treatment is necessary, the approach to HBV therapy in children and adults is similar, but most children have normal alanine aminotransferase levels and do not require treatment.

Current HBV therapies cannot achieve a complete cure, and only a small proportion (~10%) of patients achieve a functional cure. A functional cure is defined as undetectable HBV DNA with seroconversion from HBsAg to the anti-HBs. This is analogous to a resolved acute infection, but cccDNA persists, which can lead to reactivation of the disease. Existing treatment options include pegIFN-α, which has nonspecific antiviral and immunomodulatory effects, or the nucleoside/-tide analogues (Figure 63–2) adefovir, entecavir, lamivudine, telbivudine, and tenofovir, which inhibit the HBV polymerase. IFN treatment is finite (48–52 weeks), whereas individuals may require lifelong treatment with nucleoside/-tide analogues. Entecavir and TDF are the preferred nucleoside/-tide therapies due to

Figure 63–1 *Hepatitis B life cycle.* Not all steps in the hepatitis B viral life cycle have been completely elucidated. The figure represents our current understanding. For further details, consult the following references: Brahmania et al., 2016; Liang et al., 2015; and Tong and Revill, 2016.

Figure 63–2 *Chemical structures of nucleos(t)ide analogs used to treat Hepatitis B.*

1122 their potency, good tolerability, and low potential for the development of resistance (Martin et al., 2015). Considerations in selecting between the preferred therapies for HBV include the severity of liver disease, patient willingness, prior treatment, side effects, HBV genotype/serotype, comorbidities, and cost.

Because a functional cure occurs in only a small number of patients with current agents, and a complete cure is not possible, treatment goals with either pegIFN- α or nucleoside/-tide analogues are to suppress HBV DNA replication and promote seroconversion from HBeAg to anti-HBe, which in turn will slow the progression of liver disease; reduce the risk for complications, including hepatocellular carcinoma; and prolong survival (Liang et al., 2015).

Clinical Implications of HBV Resistance

Hepatitis B virus replicates at a high rate. The viral-polymerase also lacks proofreading capability. These conditions result in the generation of a large number of viral mutations. Mutations that confer a replication advantage are preferentially selected under pressure from antiviral therapy. Mutations in the reverse transcriptase/polymerase domain confer resistance to nucleoside analogues.

Lamivudine has the lowest genetic barrier to the development of resistance. After 4 years of treatment with lamivudine, 71% of patients have developed the M204V/I mutation, which renders this drug ineffective. Twenty-two percent of individuals treated with telbivudine develop this mutation after 2 years of therapy. With adefovir, about 29% of patients have developed an N236T mutation after 5 years of treatment. Resistance has not been reported with TDF. The rate of resistance with entecavir is 1% or less after 5 years in treatment-naïve individuals, whereas in those with preexisting M204V/I mutation, the prevalence of resistance is much higher, 51% after 5 years (Bhattacharya and Thio, 2010; Ghany and Doo, 2009).

The emergence of resistance has important clinical consequences. Resistance leads to therapeutic failure and a rapid resurgence of viral replication. This resurgence in HBV replication may predispose patients to hepatic decompensation. For this reason, monotherapy with lamivudine, adefovir, or telbivudine is not recommended for the treatment of hepatitis B (Terrault et al., 2016a). Individuals taking these drugs require frequent monitoring of HBV DNA and counseling on the importance of excellent adherence to the daily therapy.

Hepatic Impairment: Implications for HBV Treatment

Prolonged suppression of HBV DNA production prevents disease progression in individuals with cirrhosis and aids reversal of liver damage. Although IFN can be used in individuals with compensated cirrhosis, it is contraindicated in those with decompensated cirrhosis. Nucleos(t)ide analogue therapy is the treatment of choice for decompensated disease (Martin et al., 2015). In general, nucleos(t)ide analogue treatment improves liver function and increases the 5-year survival rate in individuals with decompensated cirrhosis from 14%–35% to 55%–86% (Honda et al., 2015). It may also prevent the need for liver transplantation.

The nucleoside/-tide analogues of choice for the treatment of decompensated cirrhosis are entecavir and TDF. Both agents require adjustments for renal impairment. TDF has been associated with nephrotoxicity, and entecavir has been associated with lactic acidosis in this population, so careful monitoring is imperative. Also, a combination of nucleoside/-tide analogues may be needed to improve efficacy in those with preexisting viral resistance. All nucleoside/-tide analogues carry a black-box warning for the risk of lactic acidosis, a risk that may be greater in individuals with advanced liver disease.

Pharmacotherapy of HBV Infection

Practice guidelines are available from several authorities on the treatment of HBV (Martin et al., 2015; Terrault et al., 2016; WHO, 2015). A description of current HBV therapies follows and a summary of the therapeutic uses and clinical pharmacology of these drugs is provided at the chapter's end.

Interferons

Interferons are potent cytokines that possess antiviral, immunomodulatory, and antiproliferative effects (Chapter 35). These proteins are synthesized by host cells in response to various inducers and, in turn, cause biochemical changes leading to an antiviral state in cells. Three major classes of human IFNs with significant antiviral activity currently are recognized: α (>18 individual species), β , and γ . Clinically used recombinant α -IFNs are nonglycosylated proteins of about 19,500 Da. Attachment of IFN proteins to large inert PEG molecules (pegylation) slows absorption, decreases clearance, and provides higher and more prolonged serum concentrations that enable once-weekly dosing. PegIFN- α is a first-line agent for the treatment of HBV.

Mechanisms of Action and Resistance. IFN- α may be produced by nearly all cells in response to viral infection and a variety of other stimuli, including double-stranded RNA and certain cytokines (e.g., interleukin 1, interleukin 2, and tumor necrosis factor). IFN- α exhibits antiviral and antiproliferative actions, stimulates the cytotoxic activity of lymphocytes, natural killer cells, and macrophages, and upregulates expression of class I MHC antigens and other surface markers. In addition, IFNs downregulate production of a number of cellular proteins, which may be an equally important mediator of the pharmacological benefit of IFNs (Teijaro, 2016).

Following binding to specific cellular receptors, IFNs activate the Jak-STAT signal transduction pathway and lead to the nuclear translocation of a cellular protein complex that binds to genes containing an IFN-specific response element. This, in turn, leads to synthesis of over two dozen proteins that contribute to viral resistance mediated at different stages of viral penetration.

Inhibition of protein synthesis is the major inhibitory effect for many viruses. IFN-induced proteins include 2–5(A) synthetase and a protein kinase, either of which can inhibit protein synthesis in the presence of double-stranded RNA. The 2–5(A) synthetase produces adenylate oligomers that activate a latent cellular endoribonuclease (RNase L) to cleave both cellular and viral single-stranded RNAs. The protein kinase selectively phosphorylates and inactivates a protein involved in protein synthesis, eIF-2. IFN-induced protein kinase also may be an important effector of apoptosis. In addition, IFN induces a phosphodiesterase that cleaves a portion of transfer RNA and thus prevents peptide elongation. A given virus may be inhibited at several steps, and the principal inhibitory effect differs amongst virus families.

Complex interactions exist between IFNs and other parts of the immune system, so IFNs may ameliorate viral infections by exerting direct antiviral effects or by modifying the immune response to infection. For example, IFN-induced expression of MHC antigens may contribute to the antiviral actions of IFN by enhancing the lytic effects of cytotoxic T lymphocytes. Conversely, IFNs may mediate some of the systemic symptoms associated with viral infections and contribute to immunologically mediated tissue damage in certain viral diseases.

Host genetics may predict IFN responsiveness. Single-nucleotide polymorphisms (rs12979860 and rs12980275) on or near the *IL-28B* gene on chromosome 19 have been associated with decreased responsiveness to IFN therapy with hepatitis C treatment (Sonneveld et al., 2012). Data are conflicting on whether *IL-28B* genetics are associated with response to IFN in individuals with HBV (Martin et al., 2015). This gene encodes IFN- λ -3. INF- λ enhances and sustains effects of INF- α on viral replication.

ADME. Oral administration of IFN- α does not result in detectable IFN levels in serum or increases in 2–5(A) synthetase activity in peripheral blood mononuclear cells (used as a marker of IFN's biologic activity). After intramuscular or subcutaneous injection of IFN- α , absorption exceeds 80%. Pegylated IFN- α is dosed subcutaneously once per week. The dose of pegIFN- α 2a is 180 μ g and should be reduced for patients with Cl_{Cr} less than 30 mL/min. Plasma levels are dose related, peaking at 4–8 h and returning to baseline by 18–36 h. Levels of 2–5(A) synthetase in peripheral blood mononuclear cells show increases beginning at 6 h and lasting through 4 days after a single injection. An antiviral state in peripheral blood mononuclear cells peaks at 24 h and decreases slowly

to baseline by 6 days after injection. After systemic administration, low levels of IFN are detected in respiratory secretions, CSF, eye, and brain.

Two pegIFNs are available commercially: pegINF- α 2a and pegINF- α 2b. PegINF- α 2b has a straight-chain 12,000-Da type of PEG that increases the plasma $t_{1/2}$ from 2–3 to 30–54 h. PegINF- α 2a consists of an ester derivative of a branched-chain 40,000-Da PEG bonded to IFN- α 2A and has a plasma $t_{1/2}$ of about 80–90 h. For pegINF- α 2a, peak serum concentrations occur up to 120 h after dosing and remain detectable throughout the weekly dosing interval; steady-state levels occur 5–8 weeks after initiation of weekly dosing. For pegINF- α 2A, dose-related maximum plasma concentrations occur at 15–44 h after dosing and decline by 96–168 h. Increasing PEG size is associated with longer $t_{1/2}$ and less renal clearance. About 30% of pegINF- α 2b is cleared by the kidneys; the remainder is cleared by both the liver and cellular degradation of IFN-receptor complexes. PegINF- α 2a is cleared by the liver and kidney. Patients with ESRD require dose reductions of both pegINF products.

Therapeutic Uses. Nonpegylated forms of IFN may be used in certain clinical scenarios, but in the U.S., use of pegINF- α predominates. PegINF- α 2a is FDA-approved for the treatment of hepatitis B and C. Its use in hepatitis C has largely been replaced by all oral DAA agents (see further discussion). However, it remains a preferred agent for the treatment of HBV in individuals with ongoing HBV DNA replication and liver inflammation. IFNs are contraindicated in patients with advanced liver disease because they can precipitate clinical deterioration and increase the risk of bacterial infections.

Unlike nucleoside/-tide analogues, which may require lifelong administration for the treatment of hepatitis B, IFN (or pegINF) treatment is finite. Plasma HBV DNA and polymerase activity decline promptly with α -IFN (pegINF- α) in most patients, but complete disappearance is sustained in only about one-third of patients. The advantage of α -IFN (pegINF- α) compared with nucleoside/-tide analogues, besides the finite treatment duration, is the higher rate of HBeAg loss (~32%–36%) and HBsAg loss (~4%–11%) with pegINF- α (Terrault et al., 2016). However, not all patients respond to α -IFN, and there are significant toxicities associated with this therapy.

Low pretherapy serum HBV DNA levels and high aminotransferase levels are predictors of response. In addition, individuals with genotypes A and B are more likely to respond to α -IFN than genotypes C or D. Responses with seroconversion to anti-HBe usually are associated with aminotransferase elevations and often a hepatitis-like illness during the second or third month of therapy, likely related to immune clearance of infected hepatocytes.

Untoward Effects. Injection of recombinant IFN doses of 1 to 2 MU or more usually is associated with an acute influenza-like syndrome beginning several hours after injection. Symptoms include fever, chills, headache, myalgia, arthralgia, nausea, vomiting, and diarrhea. Fever usually resolves within 12 h. Tolerance develops gradually in most patients. Febrile responses can be moderated by pretreatment with antipyretics.

The principal dose-limiting toxicities of systemic IFN are depression, myelosuppression with granulocytopenia and thrombocytopenia; neurotoxicity manifested by somnolence, confusion, behavioral disturbance, and rarely, seizures; debilitating neurasthenia; autoimmune disorders, including thyroiditis and hypothyroidism; and uncommonly, cardiovascular effects with hypotension and tachycardia. Elevations in hepatic enzymes and triglycerides, alopecia, proteinuria and azotemia, interstitial nephritis, autoantibody formation, pneumonia, and hepatotoxicity may occur. Alopecia and personality change are common in IFN-treated children (Sokal et al., 1998). The development of serum-neutralizing antibodies to exogenous IFNs may be associated infrequently with loss of clinical responsiveness. IFN may impair fertility, and safety during pregnancy is not established. IFNs can increase the hematological toxicity of drugs such as zidovudine and ribavirin and may increase the neurotoxicity and cardiotoxic effects of other drugs. Thyroid function and hepatic enzymes should be monitored during IFN therapy.

Pegylated IFNs are generally better tolerated than standard IFNs, although the frequencies of fever, nausea, injection site inflammation,

and neutropenia may be somewhat higher. Laboratory abnormalities, including severe neutropenia and the need for dose modifications, are higher in HIV-coinfected persons.

Pediatric and Geriatric Uses. Interferon- α 2b is approved for children 1 year or older. The dose is 6 million IU/m² thrice weekly. PegINF- α 2a is not approved for children with HBV but is approved for treatment of children 5 years or older with HCV. Thus, the guidelines of the AASLD state that providers may consider using this drug in children with HBV (Terrault et al., 2016). The dose of pegINF- α 2a in children with chronic HCV is 180 μ g/1.73 m² \times body surface area once weekly. PegINF- α 2a contains benzyl alcohol, which has been associated with neurologic toxicities in infants and neonates.

Elderly patients may experience more toxicities from IFN treatment, and dose adjustments are necessary in renal impairment.

Entecavir

Entecavir is a guanosine analogue. Entecavir inhibited HBV DNA synthesis (50% reduction, EC_{50}) at a concentration of 0.004 μ M in human HepG2 cells transfected with wild-type HBV. The median EC_{50} value for entecavir against lamivudine-resistant HBV was 0.026 μ M (range 0.010–0.059 μ M).

Mechanisms of Action and Resistance. Entecavir requires intracellular phosphorylation. Entecavir triphosphate competes with endogenous deoxyguanosine triphosphate and inhibits all three activities of the HBV polymerase (reverse transcriptase):

- base priming
- reverse transcription of the negative strand from the pregenomic messenger RNA
- synthesis of the positive strand of HBV DNA

Entecavir triphosphate is a weak inhibitor of cellular DNA polymerases α , β , and δ and mitochondrial DNA polymerase γ .

Susceptibility to entecavir is reduced with lamivudine and telbivudine resistance. In cell-based assays, 8- to 30-fold reductions in entecavir susceptibility were observed for lamivudine-resistant strains. In patients with preexisting lamivudine resistance, entecavir resistance emerged in 7% and 43% after 1 and 4 years, respectively.

Entecavir monotherapy in HIV/HBV-coinfected patients, including antiretroviral therapy-naïve patients, has significant anti-HIV activity and can result in the development of the M184V variant (Sasadeusz et al., 2008). Thus, entecavir should only be used in combination with fully suppressive antiretroviral therapy in individuals with HIV/HBV coinfection.

ADME. The recommended dose for nucleoside-treatment-naïve adults without decompensated cirrhosis is 0.5 mg once daily. For adults with lamivudine or telbivudine resistance or for those with decompensated cirrhosis, the dose is 1 mg once daily. The dose must be reduced for individuals with CrCl less than 50 mL/min. Time to peak C_p occurs in 0.5–1.5 h. Steady state is reached after 6–10 days of once-daily dosing. The tablet and oral solution can be used interchangeably. Administration with food decreases C_{max} by 44%–46% and AUC by 18%–20%; thus, entecavir should be administered on an empty stomach.

Entecavir is extensively distributed in tissues and binds slightly (13%) to serum proteins. It is primarily eliminated unchanged in the kidney, probably by both glomerular filtration and net tubular secretion. Entecavir exhibits biphasic elimination, with a terminal $t_{1/2}$ of 128–149 h. Dose reductions are needed for patients with Cl_{Cr} less than 50 mL/min, typically by extension of the dosing interval.

Therapeutic Uses. Entecavir is FDA approved for the treatment of chronic HBV infection in adults and children 2 years or older with evidence of active viral replication and evidence of either persistent elevations in serum aminotransferases or histologically active disease. Entecavir is considered a first-line agent for HBV because of its potency, durability, and low genetic barrier to the development of resistance (Terrault et al., 2016). In HBeAg-positive individuals, 61% are virologically suppressed, 22%–25% have HBeAg loss, 68%–81% normalize ALT, and 4%–5% have HBsAg loss after 2–3 years of continuous entecavir treatment. In HBeAg-negative individuals, 90%–91% are virologically suppressed and

1124 78%–88% normalize ALT after 2–3 years of entecavir treatment, but fewer than 1% have HBsAg loss at 1 year. Entecavir use reduces the risk of hepatocellular carcinoma relative to untreated historical controls. Few studies have shown a benefit to combination treatment of HBV; however, one study found that in individuals with HBV DNA of 10^8 or greater, the combination of entecavir and TDF was superior to entecavir alone (Lok et al., 2012). Nucleoside/-tide combination therapy may also be used in the case of decompensated cirrhosis and in individuals with virologic breakthrough on entecavir or TDF. The safety of entecavir in pregnancy is unknown.

Untoward Effects. Severe acute exacerbations of HBV have been reported in patients who have discontinued anti-HBV therapy, including entecavir. Hepatic function should be monitored closely with both clinical and laboratory follow-up for at least several months in patients who discontinue anti-HBV therapy. There is a potential for development of resistance to nucleoside reverse transcriptase inhibitors in HBV/HIV coinfection, especially if HIV is not being treated. Lactic acidosis and severe hepatomegaly with steatosis may occur in patients with decompensated cirrhosis receiving entecavir. More common adverse reactions include headache, fatigue, dizziness, and nausea (Sasadeusz et al., 2008).

Pediatric and Geriatric Uses. Entecavir oral solution is approved in children older than 2 years and dosing is weight based up to 30 kg. Entecavir exposures following a single 1-mg dose were 29% higher in elderly versus young HBV-seronegative volunteers. This difference is likely explained by declines in renal function with age.

Tenofovir

Tenofovir, an acyclic nucleoside phosphonate, is available in two different prodrug formulations, TDF and TAF. TAF is described separately in a following discussion. With TDF, cellular esterases cleave the diester, yielding tenofovir in plasma, which enters cells and is subsequently phosphorylated by cellular kinases to tenofovir diphosphate (Figure 64–4). The drug has activity against both HIV-1 and HBV. In cell cultures in vitro, the EC_{50} for tenofovir against HBV ranges from 0.14 to 1.5 μ M.

Mechanisms of Action and Resistance. The mechanism of action of tenofovir is presented in Chapter 64. Tenofovir has not been associated with the development of resistance when used as monotherapy for the treatment of HBV.

ADME. The TDF dose is 300 mg once daily; the dose is reduced in patients with renal impairment. The bioavailability of tenofovir is approximately 25%. Tenofovir exposures are increased 40% with a high-fat meal. Binding to plasma proteins is negligible (<8%). Tenofovir is not metabolized by CYP enzymes. The $t_{1/2}$ of tenofovir in plasma is 17 h, and the $t_{1/2}$ of the active form of the drug, tenofovir diphosphate, is 6-days and 17 days in peripheral blood and red blood cells, respectively. Tenofovir pharmacokinetics are not altered in hepatic impairment, but plasma exposures rise as Cl_{Cr} drops, becoming 2.8- and 7.3-fold higher in those with Cl_{Cr} of 30–49 mL/min and 12–29 mL/min compared to those with Cl_{Cr} greater than 80 mL/min. Doses should be reduced in those with $CrCl$ below 50 mL/min. Roughly 10% of the dose is removed by a 4-h hemodialysis session.

Therapeutic Uses. TDF is approved for the treatment of HBV infection in individuals 2 years or older. Due to its safety, efficacy, and resistance profile, TDF is a preferred agent for the treatment of HBV. In HBeAg-positive individuals, 76% are virologically suppressed, 21% have conversion from HBeAg to anti-HBe, 68% normalize ALT, and 8% have HBsAg loss after 3 years of continuous TDF treatment. In HBeAg-negative individuals, 93% are virologically suppressed and 76% normalize ALT after 2–3 years of treatment, but none have HBsAg loss at 1 year (Terrault et al., 2016).

Few studies have shown a benefit to combination treatment of HBV; however, one study found that in individuals with HBV DNA 10^8 or greater, the combination of entecavir and TDF was superior to entecavir alone (Lok et al., 2012). Nucleos(t)ide combination therapy may also be used in the case of decompensated cirrhosis and in individuals with virologic breakthrough on entecavir or TDF. TDF has a pregnancy category of B,

although a study found that infants born to HIV-infected women receiving TDF had 12% lower bone mineral density compared to infants born to women receiving other antiretroviral agents. HIV-infected individuals are generally treated with tenofovir and emtricitabine. Emtricitabine is a cytidine analog with activity against HIV and HBV. Refer to Chapter 64 for additional information about emtricitabine.

Untoward Effects and Drug Interactions. Tenofovir has a low potential for interactions but is not devoid of interactions. Tenofovir is a substrate for several membrane transporters, including OAT1 and MRP4, and TDF is a substrate for Pgp and BCRP and thus tenofovir may be affected by drugs that inhibit or induce these transporters. Some HCV therapies (e.g., sofosbuvir, ledipasvir, and velpatasvir) increase tenofovir exposures; patients receiving such combinations require more frequent renal monitoring.

Pediatric and Geriatric Uses. Primary considerations in treating the elderly with TDF are the bone and renal toxicities; a thorough study of TDF in the geriatric population has not been published. TDF has been studied in children and is approved for those 2 years or older. The dose of TDF in children is 8 mg/kg, with a maximum of 300 mg daily.

Adefovir

Adefovir dipivoxil is a diester prodrug of adefovir, an acyclic phosphonate nucleotide analogue of adenosine monophosphate. Inhibitory concentrations of adefovir against HBV range from 0.2 to 1.2 μ M in cell culture.

Mechanisms of Action and Resistance. Adefovir dipivoxil enters cells and is deesterified to adefovir. Adefovir is converted by cellular enzymes to the diphosphate, which acts as a competitive inhibitor of viral DNA polymerases and reverse transcriptases with respect to dATP and also serves as a chain terminator of viral DNA synthesis (Kundy, 1999).

Resistance to adefovir emerges in about 29% of patients after 5 years of treatment. The development of viral resistance may increase the risk of hepatic decompensation. Thus, adefovir, lamivudine, and telbivudine are not recommended for the treatment of HBV.

ADME. The adefovir dipivoxil dose is 10 mg once daily but must be reduced for those with renal impairment. The parent compound has low oral bioavailability (<12%), whereas the dipivoxil prodrug is absorbed rapidly and hydrolyzed by esterases in the intestine, liver, and blood to adefovir, providing a bioavailability of about 30%–60%. Food does not affect bioavailability. Adefovir is scantily protein bound (<5%) and has a volume of distribution of about 0.4 L/kg.

The drug is eliminated unchanged by the kidney through a combination of glomerular filtration and tubular secretion. After oral administration of adefovir dipivoxil, about 30%–45% of the dose is recovered within 24 h; the serum $t_{1/2}$ of elimination is 5–7.5 h. The intracellular $t_{1/2}$ of the active diphosphate form in vitro ranges from 5 to 18 h, although typically the half-lives are much longer in vivo. Dose reductions are recommended for Cl_{Cr} values below 50 mL/min. Adefovir is removed by hemodialysis, but the effects of peritoneal dialysis or severe hepatic insufficiency on pharmacokinetics are unknown.

Therapeutic Uses. Adefovir dipivoxil is approved for treatment of chronic HBV infections in individuals 12 years and older. However, adefovir dipivoxil is not a preferred agent for the treatment of HBV because it is associated with the development of viral resistance and nephrotoxicity.

Untoward Effects and Drug Interactions. Adefovir dipivoxil causes dose-related nephrotoxicity and tubular dysfunction, manifested by azotemia and hypophosphatemia, acidosis, glycosuria, and proteinuria, which usually are reversible months after discontinuation. Other adverse effects include headache, abdominal discomfort, diarrhea, and asthenia. Adverse events lead to premature discontinuation in about 2% of patients. After 2 years of dosing, the risk of serum creatinine levels rising above 0.5 mg/dL is approximately 2% but is higher in those with preexisting renal insufficiency. Acute, sometimes severe, exacerbations of hepatitis can occur in patients stopping adefovir or other anti-HBV therapies.

Close monitoring is necessary, and resumption of antiviral therapy may be required in some patients.

No clinically important drug interactions have been recognized to date, although drugs that reduce renal function or compete for active tubular secretion could decrease adefovir clearance. Ibuprofen increases adefovir exposure modestly. An increased risk of lactic acidosis and steatosis may exist when adefovir is used in conjunction with other nucleoside analogues or antiretroviral agents. Adefovir is transported efficiently by renal tubular OAT1.

Adefovir is genotoxic, and high doses cause hepatotoxicity, lymphoid toxicity, and renal tubular nephropathy in animals. The diphosphate's inhibitory effects on renal adenyl cyclase may contribute to nephrotoxicity (Shoshani et al., 1999). Adefovir dipivoxil is not associated with reproductive toxicity, although high intravenous doses of adefovir cause maternal and embryotoxicity with fetal malformations in rats (pregnancy category C).

Pediatric and Geriatric Uses. Adefovir should be avoided in elderly patients due to the risk for nephrotoxicity. This drug is approved in children 12 years or older at the same dose as that used in adults.

Lamivudine

Lamivudine, the (–)-enantiomer of 2',3'-dideoxy-3'-thiacytidine, is a nucleoside analogue that inhibits HIV reverse transcriptase and HBV DNA polymerase. Details of its *mechanism of action*, *ADME*, and *drug interaction potential* are described in Chapter 64. Lamivudine inhibits HBV replication in vitro by 50% at concentrations of 4–7 ng/mL.

Mechanisms of Action and Resistance. Cellular enzymes convert lamivudine to the triphosphate, which competitively inhibits HBV DNA polymerase and causes chain termination.

After 5 years of treatment, approximately 71% of patients develop resistance to lamivudine. Point mutations in the YMDD motif of HBV DNA polymerase result in a 40- to 104-fold reduction in the in vitro susceptibility (Ono et al., 2001). Lamivudine resistance confers cross-resistance to related agents, such as emtricitabine. Lamivudine-resistant HBV retains susceptibility to tenofovir and partially to adefovir and entecavir. Lamivudine resistance is associated with elevated HBV DNA levels, decreased likelihood of HBeAg loss or seroconversion, hepatitis exacerbations, and progressive fibrosis and graft loss in transplant recipients.

Therapeutic Uses. Lamivudine is approved for the treatment of chronic HBV hepatitis in adults and children 2 years or older. However, lamivudine is not a preferred agent for the treatment of HBV because it is associated with a high rate of viral resistance. Nonetheless, lamivudine is still used in many parts of the world because it is cheaper than other therapies.

The lamivudine dose is 100 mg once daily. In adults, doses of 100 mg/d for 1 year cause suppression of HBV DNA levels, normalization of aminotransferase levels in 41% or more of patients, and reductions in hepatic inflammation in more than 50% of patients. Seroconversion with antibody to HBeAg occurs in fewer than 20% of recipients at 1 year. In children 2–17 years of age, lamivudine (3 mg/kg/d to a maximum of 100 mg/d for 1 year) is associated with normalization of aminotransferase levels in about one-half and seroconversion to anti-HBe in about one-fifth of cases (Jonas et al., 2002). If resistant variants do not emerge, prolonged therapy is associated with sustained suppression of HBV DNA, continued histological improvement, and an increased proportion of patients experiencing a loss of HBeAg and undetectable HBV DNA. Prolonged therapy is associated with an approximate halving of the risk of clinical progression and development of hepatocellular carcinoma in those with advanced fibrosis or cirrhosis (Liaw et al., 2004). However, the frequency of lamivudine-resistant variants increases progressively with continued drug administration. Consider dose reduction for patients with renal impairment.

Untoward Effects. At the doses used for chronic HBV infection, lamivudine generally is well tolerated. Aminotransferase rises after therapy occur in lamivudine recipients, and flares in posttreatment

aminotransferase elevations (>500 IU/mL) occur in about 15% of patients after cessation.

Pediatric and Geriatric Uses. The dose of lamivudine for use in children 2–17 years old is 3 mg/kg/d to a maximum of 100 mg/d. Lamivudine is not associated with increased toxicities in the elderly.

Telbivudine

Telbivudine is a synthetic thymidine nucleoside analogue with activity against HBV DNA polymerase. In a cell culture model, the EC_{50} for inhibition of viral DNA synthesis by telbivudine was 0.2 μ M. The U.S. manufacturer has ceased producing telbivudine.

Mechanisms of Action and Resistance. Telbivudine is phosphorylated by cellular kinases to the active triphosphate form, telbivudine 5'-triphosphate, which inhibits HBV DNA polymerase (reverse transcriptase) by competing with the natural substrate, thymidine 5'-triphosphate. Incorporation of telbivudine 5'-triphosphate into viral DNA causes chain termination.

Resistance to telbivudine emerges in about 22% of patients after 2 years of treatment. The development of viral resistance may increase the risk for hepatic decompensation. Thus, this drug, along with lamivudine and adefovir, is not recommended for the treatment of HBV.

ADME. The standard telbivudine dose is 600 mg once daily. The bioavailability of telbivudine is 68% (Zhou et al., 2006), and the drug is widely distributed into tissues. Food does not affect the pharmacokinetics of telbivudine. The drug is eliminated unchanged in the urine. Telbivudine concentrations decline biexponentially with an elimination $t_{1/2}$ of 40–49 h. Patients with moderate-to-severe renal dysfunction and those undergoing hemodialysis require dose adjustments.

Therapeutic Uses. Telbivudine is indicated for the treatment of chronic HBV in adult patients (≥ 16 years) with evidence of viral replication and either evidence of persistent elevations in serum aminotransferases (ALT or AST) or histologically active disease. Although telbivudine has superior efficacy compared with lamivudine and adefovir, its use is associated with the development of resistance. Thus, telbivudine is not a preferred agent for the treatment of HBV.

Untoward Effects and Drug Interactions. Telbivudine is generally well tolerated and safe. The most common adverse events resulting in telbivudine discontinuation included increased creatine kinase, nausea, diarrhea, fatigue, myalgia, and myopathy. Elevations of creatine kinase activity, mostly asymptomatic grade 3–4, are more common in telbivudine-treated than in lamivudine-treated patients after 2 years of therapy. The risk of peripheral neuropathy is increased when telbivudine is used with INF- α , so this combination should be avoided.

Pediatric and Geriatric Uses. Telbivudine is not approved for children younger than 16 years. The primary consideration in treating geriatric patients with telbivudine is renal function.

Tenofovir Alafenamide

A different prodrug of tenofovir, TAF, is a phosphonate ester of tenofovir (Ray et al., 2016).

Mechanisms of Action and Resistance. The active ingredient of TAF is tenofovir, an inhibitor of HBV reverse transcriptase and HIV-1 reverse transcriptase. TAF is relatively more stable in the plasma than TDF; it is taken up into cells (e.g., hepatocytes), where it is deesterified, concentrated, and phosphorylated to tenofovir diphosphate. Tenofovir diphosphate is a competitive inhibitor of reverse transcriptase, competing with the physiological substrate dATP; when incorporated into DNA, the drug results in chain termination.

ADME. The dose of TAF for hepatitis B is 25 mg once daily. Plasma concentrations of tenofovir when administered as TAF are 90% less than when administered as TDF. The renal adverse effects of tenofovir are mediated through uptake by OAT1 in the kidney. TAF is not a substrate for OAT1, so less tenofovir is delivered to the kidneys, and there is less renal toxicity with this agent. However, TAF is preferentially taken up by several cell types, including peripheral blood mononuclear cells, and cellular

1126 concentrations of the active form, tenofovir diphosphate, are actually higher than those achieved with TDF.

Therapeutic Uses. TAF is used at a daily dose of 25 mg to treat HBV. Two studies have found TAF noninferior to TDF in terms of suppressed HBV DNA after 48 weeks of treatment with smaller declines in bone mineral density and eGFR.

Untoward Effects and Drug Interactions. TAF has similar efficacy to TDF with fewer adverse effects on BMD and kidney function (Cl_{CR} , eGFR, proteinuria). Common side effects of tenofovir include nausea, rash, diarrhea, depression, and weakness. HBV “flare up” can result from sudden discontinuation of the drug.

Investigational Agents

Current therapies provide a functional cure (i.e., a cure that mimics naturally acquired immunity off therapy) in a minority of patients, and none provides a complete cure because cccDNA persists in cells. Thus, hepatitis B disease is an area ripe for drug development. There are currently more than 30 compounds in development for the treatment of hepatitis B (Brahmania et al., 2016). Although most are in the early stages of development, there is tremendous promise for the treatment of this virus.

Hepatitis C Virus

HCV Overview

Two percent of the world’s population—approximately 150 million people—are infected with HCV. Africa and Central and East Asia have the highest prevalence of HCV. The majority of individuals infected with HCV, about 85%, will develop chronic infection, which may progress to cirrhosis (WHO, 2016). Approximately 6% of cirrhotic individuals will develop symptoms of decompensated liver disease (e.g., ascites, hepatic

encephalopathy, or variceal bleeding) each year, and 4% will develop hepatocellular carcinoma. These long-term complications carry a high risk of mortality and generally occur more than 20 years after infection (Freeman et al., 2001). There are approximately 700,000 HCV-related deaths annually. Without effective treatment, this number is expected to increase over the next 20 years. HCV is the leading indication for liver transplantation (Chinnadurai et al., 2012).

Genetic Heterogeneity of HCV

Hepatitis C virus exhibits remarkable within- and between-subject genetic heterogeneity, which is a major obstacle to the development of a universal treatment and a universal preventive vaccine. Six HCV genotypes have been identified. HCV strains belonging to different genotypes differ at 30%–35% of nucleotide sites (Messina et al., 2015). Within each genotype, HCV is further classified into subtypes that differ at fewer than 15% of nucleotide sites. Amongst genotypes, transmissibility does not seem to differ, whereas the rate of disease progression and response to treatment with current therapies does differ. Globally, genotype 1 is most prevalent (Messina et al., 2015), followed by genotype 3. Genotypes 2, 4, and 6 together account for 25% of those living with HCV. Within the U.S., 75% of HCV isolates are genotype 1a or 1b, and the remainder are primarily genotype 2 or 3 (Zein et al., 1996). Individuals with subtype 1a tend to have higher relapse rates with certain HCV treatments compared with individuals with subtype 1b.

The HCV Genome and Life Cycle

The HCV genome consists of a positive-sense, single-stranded RNA, about 9600 nucleotides long, which encodes three structural proteins (core, E1, and E2); the ion channel protein p7; and six nonstructural proteins (NS2, NS3, NS4A, NS4B, NS5A, and NS5B) (Tang and Grise, 2009). HCV replicates entirely within the cytoplasm (Figure 63–3); it does not

Figure 63–3 Hepatitis C life cycle. Not all steps in the hepatitis C viral life cycle have been completely elucidated. This figure represents our current understanding. For further details, consult the following references: Ciesek and Manns, 2011; Dubuisson and Cosset, 2014; and Holmes and Thompson, 2015.

establish latency, and it is curable. Cure of HCV is synonymous with achieving an SVR. SVR is defined as having no measurable HCV RNA in the blood following the cessation of treatment. With current therapies, SVR is assessed 12 weeks following treatment cessation. Achieving SVR decreases the progression of liver disease and reduces liver-related and all-cause mortality.

HCV Drug Targets and Treatment Approach

For many years, HCV was treated with a prolonged regimen of subcutaneously administered IFN- α (or pegIFN- α) with or without the purine nucleoside analogue ribavirin. SVR rates with this therapy were low, and tolerability was poor. Now, several antivirals that directly target various steps in the HCV life cycle (so-called DAAs) are the mainstay of HCV treatment. DAAs are administered orally, have few side effects, are taken for a period of 8, 12, or 24 weeks, and achieve SVR rates of at least 90% in most patient populations. Use of pegIFN- α for the treatment of HCV has largely been replaced by DAAs, although ribavirin is still used in combination with DAAs to improve SVR rates in certain clinical scenarios.

Detailed knowledge of the HCV life cycle and the structures of HCV proteins has permitted development of targeted inhibitors of HCV replication and revolutionized pharmacotherapy of HCV infection. Available DAAs target three major sites in the HCV life cycle: the NS3 protease, the NS5B polymerase, and NS5A (Figure 63–3) (Ciesek and Manns, 2011; Dubuisson and Cosset, 2014; Holmes and Thompson, 2015). Inhibition of the NS3 protease prevents the cleavage of the viral polyprotein and formation of the replication complex. The NS5B enzyme is essential for HCV replication as it catalyzes the synthesis of the complementary minus-strand RNA and subsequent genomic plus-strand RNA. There are two types of NS5B RdRp inhibitors: nucleotide and nonnucleoside inhibitors. The nucleotide inhibitors are active site inhibitors, whereas the nonnucleoside inhibitors are allosteric inhibitors. Another target, NS5A, encodes a protein that appears essential to the replication machinery of HCV and critical in the assembly of new infectious viral particles (Gish and Meanwell, 2011). However, the specific functions of this protein have not been established.

Clinical Implications of HCV Resistance

On average, almost a trillion HCV particles are produced in an infected individual each day (Neumann et al., 1998). The HCV NS5B polymerase enzyme lacks a proofreading function and has relatively poor fidelity (Brown, 2009); therefore, there is a continuous generation of a large variety of spontaneous viral mutations. Thus, even untreated persons have HCV genomes that harbor preexisting RAVs. These naturally occurring RAVs may affect the chances of achieving a cure with DAA treatment.

The likelihood that a DAA will select for and allow outgrowth of viral populations carrying RAVs during treatment depends on several factors,

including the DAA's genetic barrier to resistance (the number and type of base-pair mutations needed to result in amino acid substitutions that confer resistance), the level of drug exposure(s), and the viral fitness (replicative capacity) of the RAV (Lontok et al., 2015). Nucleotide NS5B polymerase inhibitors have a high genetic barrier to resistance; three or more RAVs are required for full resistance. In contrast, the nonnucleoside NS5B polymerase inhibitors, NS3 protease inhibitors, and NS5A inhibitors generally have a low genetic barrier to the development of resistance; that is, only one or two amino acid substitutions result in lack of drug efficacy. For drugs in these classes, there is swift emergence of RAVs during monotherapy. Thus, as with HIV treatment, HCV treatment requires a combination of agents to optimize viral suppression and protect against the development of resistance. Data are emerging on the impact of treatment-emergent NS5A RAVs on the likelihood of achieving SVR with current therapies. NS5A RAVs have been shown to persist for several years after treatment cessation, and some NS5A inhibitors suffer from broad cross-resistance at key positions (Q30R, L31M/V, Y93H/N).

Hepatic Impairment: Implications for HCV Treatment

The vast majority of HCV-infected individuals have at least a 90% chance of achieving SVR with current therapies. There are some groups, however, such as those with decompensated cirrhosis, who have lower rates of SVR. Treating those with decompensated cirrhosis and achieving SVR have been shown to improve MELD scores and reverse fibrosis, but benefits are not immediate. Data are needed to demonstrate the long-term benefits of achieving SVR in those with decompensated disease.

Studies indicated the optimal time to treat HCV is early in the course of illness. The risk of developing decompensated cirrhosis or hepatocellular carcinoma, requiring a liver transplant, or dying from HCV-related complications is significantly lower in those treated with minimal fibrosis compared to those treated once bridging fibrosis or cirrhosis has developed. Treating all patients early in the course of disease is challenging, however, because many patients with HCV are unaware of their disease. Others are aware of their disease and wish to be treated but cannot access the DAAs. Many payers are prioritizing those with more advanced disease for treatment because of the cost of the DAAs.

Pharmacotherapy of HCV

A description of current DAA therapies follows, and a summary of the therapeutic uses and clinical pharmacology of these drugs is provided in the Drug Facts table at the end of this chapter. The HCV field is rapidly evolving. Up-to-date information on testing, managing, and treating HCV can be found in guidelines from the AASLD and Infectious Diseases Society of America (<http://www.hcvguidelines.org>). An important aspect of treating HCV is identification and management of drug-drug

TABLE 63–1 ■ DAACLATASVIR (DCV) DOSING WITH INDUCERS AND INHIBITORS OF CYP3A4

STRONG CYP3A INHIBITORS	MODERATE CYP3A INHIBITORS	STRONG CYP3A INDUCERS	MODERATE CYP3A INDUCERS
Decrease DCV Dose to 30 mg	Standard DCV Dose, 60 mg	DCV Contraindicated	Increase DCV Dose to 90 mg
Ritonavir-boosted atazanavir	Ritonavir-boosted darunavir	Rifamycins	Bosentan
Clarithromycin	Ritonavir-boosted lopinavir	St. John's Wort	Dexamethasone
Itraconazole	Ciprofloxacin	Antiepileptics	Efavirenz
Ketoconazole	Diltiazem		Etravirine
Nefazodone	Erythromycin		Modafinil

Posaconazole	Fosamprenavir		Rifapentine
Telithromycin	Verapamil		
Voriconazole			

1128 interactions with DAAs (see, for instance, Table 63–1). The University of Liverpool offers a free, comprehensive, and reliable web-based drug interactions resource (available at <http://www.hep-druginteractions.org>).

Sofosbuvir

Sofosbuvir is a prodrug based on a uridine analogue. In cells, sofosbuvir is metabolized to an active form (known as GS-461203) that competes with uridine triphosphate for incorporation into HCV RNA by NS5B polymerase.

Mechanisms of Action and Resistance. Sofosbuvir is a prodrug, a 5' monophosphorylated uridine analogue on which the charges of the phosphate group are masked by groups that are readily removed in the cell. The active drug, generated in the host mammalian cell, inhibits HCV RNA polymerase. Figure 63–4 shows the cellular pharmacology of sofosbuvir.

Sofosbuvir provides a high barrier to the development of resistance, but the S282T RAV has been reported in patients who relapsed to sofosbuvir-based treatment. L159F, V321A, and C316N/H/F have also been observed (Lontok et al., 2015).

ADME. The dose of sofosbuvir is 400 mg taken once daily. The absolute bioavailability of sofosbuvir is estimated to be at least 80% based on recovery of sofosbuvir and its primary metabolite, GS-331007, following administration of a radiolabeled dose. A high-fat meal increases sofosbuvir's AUC by 67%–91%, but, based on the drug's high therapeutic index, the increased exposure is not thought to increase the likelihood of toxicities (Kirby et al., 2015). Sofosbuvir exhibits time-independent, near-linear pharmacokinetics across a range of doses. Sofosbuvir is 63% protein bound, whereas protein binding of the deesterified GS-331007 is minimal.

The primary metabolic route of sofosbuvir is hydrolysis to GS-331007. GS-331007 lacks antiviral activity and cannot be rephosphorylated. The majority of a sofosbuvir dose is converted to GS-331007 and eliminated in the urine via a combination of tubular secretion and glomerular filtration. Sofosbuvir AUC is increased 2.3-fold and 2.5-fold in patients with moderate and severe hepatic impairment (i.e., Child Pugh B and C), respectively, but GS-331007 AUC is unchanged. No dose adjustment is needed for this population; available data suggest sofosbuvir is safe and effective in individuals with decompensated cirrhosis when combined with appropriate DAAs (Charlton et al., 2015; Manns et al., 2015; Poordad et al., 2015).

Figure 63–4 Cellular pharmacology of sofosbuvir. Some nucleoside analogues act as antiviral agents in infected cells, but first they must cross the plasma membrane and then be phosphorylated, starting at the 5' position, a slow reaction catalyzed by nucleoside kinase. Use of a monophosphorylated nucleoside avoids the slow nucleoside kinase reaction, but the charge on the phosphate groups would greatly slow passage of the molecule across the plasma membrane. Sofosbuvir circumvents these issues by having a phosphate (red ellipse) at the 5' position of the nucleoside analogue (blue ellipse), but masking the two negative charges of the phosphate group with adducts that cellular esterases/amidases can readily remove. Sofosbuvir crosses the plasma membrane rapidly. The carboxyl ester moiety is hydrolyzed by CatA or hCE1. HINT1 catalyzes the phosphoramidate cleavage, yielding the monophosphate form, retained in the cell by ion trapping. Subsequent phosphorylation occurs via the pyrimidine nucleotide biosynthetic pathway. The triphosphate (GS-461203) is the active form responsible for the antiviral activity of sofosbuvir. GS-461203 acts as a defective dNTP substrate and inhibits HBV RNA polymerase (NS5B); it may also act as a chain terminator. Dephosphorylation of GS-461203 yields a uridine analogue metabolite, GS-331007, that cannot be readily rephosphorylated, lacks antiviral activity, and exits the cell. Most (90%) of the drug-related material measured in plasma is GS-331007. UMP-CMPK, uridine/cytidine monophosphate kinase; NDPK, nucleoside diphosphate kinase; CatA, cathepsin A; hCE1, human carboxylesterase 1.

In contrast, sofosbuvir and GS-331007 pharmacokinetics are affected by renal impairment. Sofosbuvir and GS-331007 AUC increased about 60% in those with eGFR 50–80 mL/min/1.73 m² and 2-fold in those with eGFR 30–50 mL/min/1.73 m². These exposures were safe and tolerated in prior studies, but significant increases in exposure are noted in patients with severe renal impairment (eGFR < 30 mL/min/1.73 m²) and ESRD requiring dialysis. Thus, sofosbuvir should not be used in patients with eGFR of less than 30 mL/min/1.73 m² or those with ESRD until more data are available on the safety and appropriate dosing of this drug in this population (Kirby et al., 2015). Sofosbuvir's AUC is 60% higher in HCV-infected persons, and GS-331007 AUC is 39% lower compared with HCV-seronegative volunteers. The mechanism for this is unclear. The median terminal half-lives of sofosbuvir and GS-331007 are 0.4 and 27 h, respectively.

Therapeutic Uses. The NS5B polymerase region is well conserved across genotypes. Thus, sofosbuvir is active against all HCV genotypes. In individuals with genotype 1 HCV, 7 days of sofosbuvir monotherapy reduces HCV RNA by 4.65 logs (Lawitz et al., 2013). Sofosbuvir is used in combination with other DAAs, including the NS3/4A protease inhibitor simeprevir, the purine nucleoside analogue ribavirin, and the NS5A inhibitors daclatasvir, ledipasvir, or velpatasvir. The efficacy and tolerability of sofosbuvir in these combination therapies are described in subsequent sections.

Untoward Effects and Drug Interactions. There are no hallmark toxicities associated with sofosbuvir use. Side effects observed when sofosbuvir is administered as part of combination DAA treatment are described in the material that follows with the concomitant antiviral.

Sofosbuvir is not a CYP substrate, inhibitor, or inducer and therefore has a low potential for drug interactions. However, sofosbuvir is a substrate for the efflux transporters Pgp and BCRP and should not be used with potent inducers of these transporters (e.g., rifampin, St. John's wort, phenytoin, carbamazepine). Sofosbuvir-containing DAA treatments have been associated with bradycardia, the requirement for pacemaker insertion, and fatal cardiac arrest in patients taking amiodarone. The mechanism(s) for this is unclear, but the interaction appears to be more pharmacodynamic rather than pharmacokinetic in nature (Regan et al., 2016). If the combination cannot be avoided, cardiac monitoring in an inpatient setting is advised for the first 48 h of sofosbuvir-based treatment, with daily heart rate monitoring for an additional 2 weeks.

Pediatric and Geriatric Uses. Sofosbuvir is not currently approved in children, but studies are ongoing. There are limited data on the use of DAAs in older patients. Ninety individuals 65 years or older received sofosbuvir in clinical trials. Response rates in these 90 individuals and in patients less than age 65 were similar. Because sofosbuvir is renally cleared, renal function is the primary consideration in treating the geriatric population with sofosbuvir.

Ribavirin

Ribavirin, a purine nucleoside analogue with a modified base and D-ribose sugar, inhibits the replication of a wide range of RNA and DNA viruses, including orthomyxo-, paramyxo-, arena-, bunya-, and flaviviruses in vitro.

Mechanisms of Action and Resistance. Host cell enzymes phosphorylate ribavirin to mono-, di-, and triphosphate derivatives. The exact mechanism(s) of action of ribavirin or its phosphorylated derivatives in vivo are unknown, but several immunomodulatory and antiviral effects have been observed in vitro, including (1) inhibiting the HCV RdRp, (2) depleting GTP (and thus nucleic acid synthesis in general) through inhibition of inosine 5'-monophosphate dehydrogenase, (3) enhancing viral mutagenesis, (4) converting the T-helper cell phenotype from 2 to 1, (4) inducing IFN-stimulated genes, and (5) modulating natural killer cell response. Ribavirin may select for HCV resistance mutations in vitro, but this has not been observed in vivo.

ADME. For the treatment of HCV, oral ribavirin dosing is weight based. Individuals weighing less than 75 kg receive 1000 mg daily in two divided doses. Individuals weighing at least 75 kg receive 1200 mg daily in two

divided doses. Dose reductions are necessary for those with renal impairment, and individuals with renal impairment or decompensated cirrhosis may have difficulty tolerating 1000 or 1200 mg of ribavirin.

With aerosol administration, levels in respiratory secretions are very high but variable. Some systemic absorption occurs with aerosol administration (C_p after 3–4 days of dosing < 8% of C_{ps} seen with oral dosing). When administered orally, bioavailability averages 50%. Food increases plasma levels substantially. Ribavirin is a substrate for equilibrative and concentrative nucleoside uptake transporters (ENT1 [SLC29A1], CNT2 [SLC28A2], and CNT3 [SLC28A3]) and thus is widely distributed throughout the body. The half-lives of the mono-, di-, and triphosphate derivatives in red blood cells and peripheral blood mononuclear cells mirror the plasma $t_{1/2}$ of parent ribavirin (7–10 days) (Wu et al., 2015). Hepatic metabolism (deribosylation and hydrolysis to a triazole carboxamide) and renal excretion of ribavirin and its metabolites are the principal routes of elimination. The dose of ribavirin should be reduced in patients with renal impairment. Even with a reduced dose, patients with renal impairment have difficulty tolerating ribavirin.

Therapeutic Uses. Ribavirin can be administered orally and intravenously and by inhalation. The aerosolized form of ribavirin is used in the treatment of a variety of respiratory viruses, including respiratory syncytial virus. Intravenous ribavirin has been used to treat hemorrhagic fever and severe influenza. Additional information on the use of aerosolized and intravenous ribavirin can be found in Chapter 64. Oral ribavirin is used in combination with DAAs for the treatment of chronic HCV infection in certain scenarios (e.g., in combination with sofosbuvir for genotype 2 disease, with sofosbuvir and ledipasvir, daclatasvir, or velpatasvir in the setting of decompensated cirrhosis, with grazoprevir/elbasvir in individuals with genotype 1a HCV and preexisting NS5A RAVs, and with ritonavir-boosted paritaprevir and ombitasvir with or without dasabuvir in patients with genotype 1a or 4 disease). The efficacy of ribavirin in combinations with these DAAs is described in subsequent sections.

Untoward Effects and Drug Interactions. Aerosolized ribavirin may cause conjunctival irritation, rash, transient wheezing, and occasional reversible deterioration in pulmonary function. When used in conjunction with mechanical ventilation, equipment modifications and frequent monitoring are required to prevent plugging of valves and tubing with ribavirin. Healthcare workers should use techniques to reduce environmental exposure. Pregnant women should not directly care for patients receiving ribavirin aerosol (FDA pregnancy category X). Bolus intravenous infusion may cause rigors. Systemic ribavirin causes dose-related reversible hemolytic anemia, with associated increases in reticulocyte counts and in serum bilirubin, iron, and uric acid concentrations. The ribavirin dose is often reduced when hemoglobin decreases to less than 10 g/dL or declines by more than 3 g/dL and discontinued if hemoglobin becomes less than 8.5 g/dL.

Anemia occurs in 5%–11% of patients receiving ribavirin in combination with DAAs (clinical trials of mostly noncirrhotic subjects); 18%–40% of patients postliver transplant or with decompensated cirrhosis receiving ribavirin with DAAs experienced anemia, many receiving ribavirin doses lower than the typical 1000–1200 mg daily. Two polymorphisms in the gene encoding inosine triphosphatase protect against ribavirin-induced hemolytic anemia; the frequency of the protective alleles in the general population is about 10%.

Other ribavirin toxicities include fatigue, cough, rash, and pruritus. Preclinical studies indicated that ribavirin is teratogenic, embryotoxic, oncogenic, and possibly gonadotoxic. Ribavirin is present in higher amounts in sperm than plasma. Thus, ribavirin is contraindicated in men and women who are attempting conception and for up to 6 months following cessation of treatment. Ribavirin has minimal drug interactions but should not be used with the HIV nucleoside analogue didanosine. Ribavirin increases formation of the triphosphorylated form of didanosine, which raises the risk of mitochondrial toxicity (see Chapter 64).

Pediatric and Geriatric Uses. Ribavirin is indicated for the treatment of HCV in children 5 years and older. Doses range from 400 to 1200 mg daily depending on body weight, administered in two divided doses.

1130 Specific pharmacokinetic evaluations for ribavirin in the elderly have not been performed. As with sofosbuvir, the primary consideration in treating older individuals with ribavirin is renal function. The dose of ribavirin should be reduced in those with an eGFR less than or equal to 50 mL/min/1.73 m².

Ledipasvir

Ledipasvir, an NS5A inhibitor, is available only as part of a fixed-dose combination tablet with the NS5B nucleotide polymerase inhibitor, sofosbuvir (LDV/SOF).

Mechanisms of Action and Resistance. Ledipasvir is an inhibitor of NS5A. Baseline NS5A RAVs were detected in 16% of the 2144 participants in the phase 2 and 3 studies of LDV/SOF (Sarrazin et al., 2016). For treatment-naïve patients, the presence of baseline NS5A RAVs does not reduce the likelihood of achieving SVR, but treatment-experienced patients with baseline NS5As RAVs achieve lower SVR rates compared with treatment-experienced patients with no baseline RAVs. NS5A RAVs are detected in the majority of patients who fail to respond to LDV/SOF treatment. These NS5A RAVs persist for at least 2 years and may affect the success of future HCV treatments.

ADME. Ledipasvir, 90 mg, is available as part of a fixed-dose combination tablet with sofosbuvir (German et al., 2016). This tablet is administered once daily without regard to meals. LDV/SOF should not be used in individuals with an eGFR less than 30 mL/min/1.73 m².

Ledipasvir absorption is pH dependent. Concomitant use of antacids, H₂ receptor antagonists, and PPIs is problematic. The bioavailability of ledipasvir in humans is unknown (30%–50% in rats, monkey, and dogs). Ledipasvir concentrations are similar when given fasted versus a high-fat (1000 kcal) meal. Ledipasvir is greater than 99.8% bound to human plasma proteins. Ledipasvir is primarily eliminated unchanged in the feces. Approximately 30% is metabolized via uncertain pathways. Ledipasvir pharmacokinetics are not significantly altered by hepatic or renal impairment, but because the drug is coformulated with sofosbuvir, limitations on use in those with renal impairment apply. The $t_{1/2}$ of ledipasvir is 47 h. Ledipasvir AUC and C_{pmax} are 24% and 32% lower in HCV-infected subjects, respectively, compared with HCV-seronegative volunteers.

Therapeutic Uses. LDV/SOF is FDA approved for individuals with HCV (genotype 1, 4, 5, and 6 disease), individuals coinfecting with HIV, and those with decompensated cirrhosis. In vitro, ledipasvir has limited activity against genotype 3; its activity against genotype 2 is reduced by the highly present L31M RAV; thus, LDV/SOF is not recommended for this genotype.

The SVR rates with 12 weeks of LDV/SOF therapy were 96% and 99% in clinical trials of HCV treatment-naïve patients and 95% in treatment-experienced patients without cirrhosis. Treatment-experienced individuals with cirrhosis should be treated for either 24 weeks with LDV/SOF or 12 weeks with LDV/SOF plus ribavirin to improve the likelihood of achieving a cure. LDV/SOF for 12 weeks achieved an SVR rate of 95% in two studies with a small number of individuals with genotype 4 disease. SVR was 93% in 44 patients with genotypes 5 and 96% in 25 patients with genotype 6 receiving 12 weeks of LDV/SOF.

Treatment of individuals with HIV/HCV coinfection yielded similarly high SVRs. In treating patients with decompensated cirrhosis, ribavirin is added to LDV/SOF treatment to increase SVR rates, usually at a ribavirin dose of 600 mg daily due to poor tolerability of ribavirin in this patient population.

Untoward Effects and Drug Interactions. Amongst patients receiving 12 weeks of LDV/SOF in phase III clinical trials, 13%–14% reported fatigue and headache. The addition of ribavirin to LDV/SOF in cirrhotic patients increased the number and frequency of adverse effects.

Ledipasvir relies on an acidic environment for optimal absorption; thus, gastric acid modifiers should be used with caution. In one large cohort, use of PPIs was found to be an independent predictor of relapse to LDV/SOF treatment (Terrault et al., 2016b). If gastric acid modifiers must be used, temporal separation is necessary with antacids (by 4 h); H₂

blocker and PPI doses should not exceed the equivalent of 40 mg famotidine twice daily and 20 mg omeprazole once daily. The omeprazole must be administered simultaneously with LDV/SOF in the fasted state. Like sofosbuvir, ledipasvir is a substrate for Pgp and BCRP and thus cannot be used with potent inducers of these transporters. The CYP3A inducer efavirenz reduces ledipasvir concentrations by 30%, and the pharmacokinetic enhancer cobicistat increases ledipasvir concentrations by 2-fold; given the rather high therapeutic index of ledipasvir, these changes are not expected to have clinical relevance. Ledipasvir inhibits Pgp and BCRP and may increase the concentrations of rosuvastatin via inhibition of BCRP; thus, this combination is not recommended. Ledipasvir increases the exposure to tenofovir, which may increase the risk of renal toxicity in HIV-infected individuals taking TDF with a boosting agent such as ritonavir or cobicistat. Use of TAF instead of TDF is an option for patients taking an antiretroviral regimen, which includes ritonavir or cobicistat (MacBrayne and Kiser, 2016).

Pediatric and Geriatric Uses. A pharmacokinetic trial of LDV/SOF is ongoing in 200 children ages 3–18 years (NCT02249182). The SVR rate was 98% in 100 adolescents ages 12–17 years receiving the FDA-approved adult dose of LDV/SOF with good tolerability. Age is not associated with ledipasvir exposures in population pharmacokinetic analyses over the range of 18 to 80 years. No differences in safety or efficacy have been observed between individuals 65 years and older and younger patients.

Daclatasvir

Daclatasvir is an NS5A inhibitor.

Mechanism of Action and Resistance. Daclatasvir binds to the N-terminus of NS5A and inhibits both viral RNA replication and virion assembly. The Y93H RAV is detected in most patients who fail DCV/SOF treatment. This variant has been shown to persist for several years after treatment cessation. The optimal re-treatment strategy for patients who fail with NS5A RAVs is under investigation.

ADME. Daclatasvir is available as 30-mg and 60-mg tablets. The standard dose of daclatasvir is 60 mg, but the dose should be reduced to 30 mg with strong CYP3A inhibitors and increased to 90 mg with moderate CYP3A inducers (Table 63–1). The absolute bioavailability of daclatasvir is 67%. A high-fat, high-calorie meal reduces daclatasvir exposure by 23%, but a low-fat meal has no effect. The drug is approved for administration without regard to meals. Daclatasvir is highly protein bound (99%).

Daclatasvir is metabolized by CYP3A and is therefore susceptible to the effects of potent inhibitors and inducers of this enzyme, but the drug itself does not appear to inhibit or induce any CYPs. Daclatasvir is a substrate for Pgp. Daclatasvir inhibits Pgp, BCRP, and OATP1B1/3 and thus may increase exposures of drugs that are substrates for these transporters. Total exposure to daclatasvir is about 37% lower in patients with Child Pugh B and C decompensated cirrhosis, but unbound concentrations are unchanged, and no dose adjustment is needed in such patients. Daclatasvir AUC increases in those with ESRD; with an eGFR of 15–29 mL/min/1.73 m², AUC is roughly doubled. Given the high therapeutic index of daclatasvir, this change is unlikely to have clinical relevance. However, since daclatasvir is given with sofosbuvir, the restrictions in those with eGFR less than 30 mL/min/1.73 m² still apply. The half-life of daclatasvir is 12–15 h. Daclatasvir pharmacokinetics are similar in HCV-seropositive and -seronegative individuals.

Therapeutic Uses. Daclatasvir is FDA-approved for use in combination with sofosbuvir in those with genotype 3 disease, in individuals with HIV coinfection regardless of HCV genotype, and in persons with advanced liver disease (Keating, 2016). It is rarely used in the U.S., however, because there are coformulated and cheaper alternatives. In Japan, daclatasvir is also approved in combination with the HCV NS3/4A protease inhibitor asunaprevir; this combination is not available in the U.S.

The SVR rates are 86%–90% in treatment-naïve and treatment-experienced individuals receiving 12 weeks of DCV/SOF. Lower SVR rates occur in those with cirrhosis (63%). Thus, cirrhotic patients with genotype 3 disease may benefit from the addition of ribavirin. In HIV-coinfecting

individuals with HCV genotypes 1–4, 96% achieved SVR with 12 weeks of daclatasvir and sofosbuvir administration. In a group of individuals primarily (75%) infected with HCV genotype 1 with advanced liver disease and with Child Pugh A ($n = 12$), B ($n = 32$), and C ($n = 16$) cirrhosis, 92%, 94%, and 56%, respectively, achieved SVR with 12 weeks of DCV/SOF plus ribavirin treatment.

Untoward Effects and Drug Interactions. Daclatasvir is well tolerated. The most commonly reported adverse events in genotype 3 patients receiving DCV/SOF were headache and fatigue (14% each). HIV-coinfected patients reported fatigue (17%), nausea (13%), and headache (11%). When combined with ribavirin in patients with advanced cirrhosis, the most common adverse effects were anemia (20%), fatigue (18%), nausea (17%), and headache (15%).

Daclatasvir is primarily a victim rather than a perpetrator in drug-drug interactions (Garimella et al., 2016). Daclatasvir cannot be used with potent CYP3A inducers but may be used with moderate inducers, if the daclatasvir dose is increased from 60 to 90 mg. The daclatasvir dose must be reduced from 60 to 30 mg with potent CYP3A inhibitors. Table 63–1 lists some comedications necessitating a daclatasvir dose modification.

Pediatric and Geriatric Uses. Daclatasvir has not been evaluated in children or the elderly. Age was not significantly associated with daclatasvir pharmacokinetics in population modeling over the range 18–79 years; no unique safety concerns were evident in those over 65 years of age, and SVR rates were comparable in older and younger subjects in trials.

Simeprevir

Simeprevir is an inhibitor of the HCV NS3 protease. Simeprevir is a noncovalent peptidomimetic with a macrocyclic structure.

Mechanisms of Action and Resistance. Simeprevir is an inhibitor of the HCV NS3 protease. Inhibition of the NS3 protease prevents cleavage of the viral replication complex (NS4A-NS4B, NS4B-NS5A, and NS5A-NS5B) and thus prevents the formation of viral RNA. Patients that fail to respond to SIM/SOF therapy typically have either the R155K or D168E treatment-emergent RAVs (Sanford, 2015). The limited available data indicate that patients who fail a SIM/SOF-based regimen can be successfully re-treated with an NS5A-containing therapy.

Cirrhotic persons with the preexisting Q80K mutation have an SVR of 74% compared with 92% in those without the Q80K mutation. It is presently unclear whether extending the SIM/SOF treatment duration to 24 weeks would improve SVR rates in cirrhotics or if this regimen should be avoided in individuals with this preexisting RAV.

ADME. Simeprevir is dosed as a single 150-mg tablet taken once daily with food. Individuals of East Asian ancestry exhibit higher plasma simeprevir exposures, presumably due to a lower expression of the hepatic uptake transporter, OATP1B1. Thus, 100 mg of simeprevir is approved in Japan.

The bioavailability of simeprevir is 62%. Food increases simeprevir AUC by about 65%; thus, it is recommended to take this agent with food. Simeprevir is 99.9% protein bound (primarily to albumin) and exhibits more than dose proportional increases in AUC and C_{max} . Simeprevir exposures are increased in patients with hepatic impairment (2- to 5-fold at Child Pugh B and C stages). There are reports of hepatic decompensation, hepatic failure, and death in patients with advanced liver disease receiving simeprevir; thus, it should be avoided in patients with decompensated cirrhosis. Because simeprevir is used with sofosbuvir, the same restrictions on use in those with eGFR less than 30 mL/min/1.73 m² apply. The terminal elimination half-life of simeprevir is 10–13 h in HCV-uninfected individuals and 41 h in HCV-infected subjects. Plasma exposures of simeprevir are 2- to 3-fold higher in HCV-infected individuals compared to HCV-seronegative subjects.

Therapeutic Uses. The combination SIM/SOF is used for the treatment of HCV-infected individuals with genotype 1 or 4. SVR is achieved in 97% of noncirrhotic, treatment-naïve, and experienced individuals receiving 12 weeks of SIM/SOF (Kwo et al., 2016); in cirrhotic patients, the SVR rate is lower (83%), and a preexisting NS3 RAV is associated with a higher rate of relapse in cirrhotic patients (Lawitz et al., 2016b).

Untoward Effects and Drug Interactions. The most common adverse effects from SIM/SOF are headache, fatigue, and nausea (11%–20%). Simeprevir contains a sulfonamide moiety and can cause photosensitivity, rash, and itching, more so in cirrhotic patients (5%, 16%, and 14%, respectively) receiving SIM/SOF. Simeprevir may elevate bilirubin levels. Higher simeprevir exposures have been associated with an increased frequency of the dermatologic events and bilirubin elevation.

Simeprevir is metabolized by CYP3A and should not be used with moderate or strong inducers or inhibitors of this enzyme. Simeprevir is a substrate for Pgp, MRP2, BCRP, OATP1B1/3, and OATP2B1. In terms of its ability to act as a perpetrator in interactions, simeprevir is a mild inhibitor of CYP1A2 and intestinal CYP3A and thus may increase the exposures of drugs metabolized by these enzymes. Simeprevir is also an inhibitor of the hepatic transporters OATP1B1, NTCP, Pgp, MRP2, and BSEP (see Chapter 5).

Pediatric and Geriatric Uses. Simeprevir has not been specifically studied in children or in the geriatric population. Age was not significantly associated with simeprevir pharmacokinetics in population modeling over the range 18–73 years.

Velpatasvir

Velpatasvir is an NS5A inhibitor available as part of a fixed dose combination product with sofosbuvir (SOF/VEL).

Mechanism of Action and Resistance. Baseline RAVs do not appear to influence the likelihood of achieving SVR with SOF/VEL except in cirrhotic patients with genotype 3 disease where the SVR rate was 73% compared with 93% in those without baseline RAVs (Feld et al., 2015; Foster et al., 2015).

ADME. SOF/VEL is a fixed-dose combination tablet containing 400 mg of sofosbuvir and 100 mg of VEL taken once daily. As with ledipasvir, VEL absorption is pH dependent, and gastric acid modifiers require special dosing considerations with this agent; food has little effect on VEL's absorption. VEL is greater than 99.5% protein bound. VEL is predominantly excreted in feces as parent and metabolite; less than 1% of a dose appears in urine. VEL AUC changes only modestly (–17% to +14%) with moderate and severe hepatic impairment. In patients with severe renal impairment (eGFR < 30 mL/min/1.73 m²), the AUC of VEL increases by 50%. Because VEL is used with sofosbuvir, the same limitations on use in those with eGFR less than 30 mL/min/1.73 m² apply. The VEL $t_{1/2}$ is 15 h. VEL AUC and C_{max} are reduced by ~40% in HCV-infected individuals compared with healthy volunteers.

Therapeutic Uses. SOF/VEL is the only currently available DAA combination therapy that is approved for the treatment of all HCV genotypes (1–6). SVR rates were 99% in patients with genotypes 1, 2, 4, 5, and 6 and 95% in genotype 3 patients with 12 weeks of VEL/SOF in trials. In decompensated patients, 83% achieved SVR with SOF/VEL for 12 weeks, 94% achieved SVR with SOF/VEL plus ribavirin, and 86% achieved SVR with 24 weeks of SOF/VEL.

Untoward Effects and Drug Interactions. The most common adverse reactions with SOF/VEL are headache (22%), fatigue (15%), nausea (9%), asthenia (5%), and insomnia (5%). When ribavirin is given with SOF/VEL to patients with decompensated cirrhosis, adverse events are more frequent: fatigue (32%), anemia (26%), nausea (15%), headache (11%), insomnia (11%), and diarrhea (10%).

Velpatasvir has a pharmacologic profile similar to that of ledipasvir but is subject to more CYP3A-mediated interactions. As with LDV, antacids should be separated by 4 h, and H₂ blocker doses should not exceed the equivalent of 40 mg twice daily, and PPI doses should not exceed the equivalent of 20 mg daily. The timing of the PPI in relation to SOF/VEL is important. SOF/VEL should be taken with food 4 h prior to a PPI dose. VEL is a substrate for CYP3A4, 2C8, and 2B6 but has not been shown to inhibit any CYPs. VEL is a substrate for and weak inhibitor of Pgp and a weak inhibitor of BCRP and OATP1B1/3. There are some notable drug interactions with VEL (Mogalian et al., 2016): The pravastatin (an OATP1B1 substrate) AUC increases 35% and rosuvastatin (an OATP1B1

and BCRP substrate) AUC increases about 170% when coadministered with VEL in healthy volunteers; digoxin (a Pgp substrate) AUC increases 34%. Single-dose rifampin, which acts as an OATP1B1 inhibitor, increases VEL AUC by 47%. However, multiple doses of rifampin, which induces CYP metabolism and transporter expression, reduces the AUC of VEL by about 82%. Single-dose cyclosporine (a mixed OATP/Pgp/MRP2 inhibitor) doubles the VEL AUC. Ketoconazole (CYP3A inhibitor) increases the VEL AUC by 70%. Efavirenz reduces the VEL AUC by 50%, and this combination should be avoided.

Pediatric and Geriatric Uses. SOF/VEL has not been evaluated in children. Twelve percent of participants in phase III trials (156 subjects) were age 65 or older. No differences in efficacy or safety were observed in this group compared with those less than 65 years.

Ritonavir-Boosted Paritaprevir, Ombitasvir, With or Without Dasabuvir

Ombitasvir is an NS5A inhibitor. Dasabuvir is a nonnucleoside NS5B polymerase inhibitor. Paritaprevir is an NS3 protease inhibitor. Ritonavir is an inhibitor of CYP3A and is used as a pharmacokinetic enhancer to increase the exposures and decrease the dosing frequency for paritaprevir. Ritonavir has no activity against HCV. For more information on the clinical pharmacology of ritonavir, refer to Chapter 64.

Mechanism of Action and Resistance. Ombitasvir and paritaprevir inhibit NS5A and the NS3 protease, respectively. Dasabuvir binds non-competitively to the palm I site outside the NS5B polymerase active site, producing a conformational change in NS5B before the elongation complex is formed (Eltahla et al., 2015). Ribavirin is administered in combination with these DAAs in patients with genotype 1a disease to increase the likelihood of achieving SVR.

The SVR rates are not statistically different between patients with pre-existing NS3, NS5A, and NS5B RAVs to those without preexisting RAVs. The most prevalent treatment-emergent RAVs in patients with genotype 1a were R155K and D168V in NS3, M28T and Q30R in NS5A, and S556G in NS5B. In a trial, in which 21 individuals (95% genotype 1a) failed to achieve SVR on PrOD, 96% still had detectable NS5A RAVs at 2 years. The approach to re-treatment of patients who have failed NS5A-based therapy is not clear, but a small study of 15 patients showed 93% of individuals could be cured with PrOD plus sofosbuvir for 12 to 24 weeks. Results from a number of phase II and phase III trials provide useful information on the clinical application of DAAs and PrO/PrOD therapy (Eltahla et al., 2015; Hussaini, 2016; Krishnan et al., 2015).

ADME. Ritonavir-boosted paritaprevir and ombitasvir are coformulated. These agents are administered as two tablets once daily for a total daily dose of 100 mg ritonavir, 150 mg paritaprevir, and 25 mg ombitasvir. Dasabuvir is administered as one 250-mg tablet taken twice daily. These medications should be administered with a meal; moderate, and high-fat meals increase exposures of all four. On this regimen, accumulation is minimal for ombitasvir and dasabuvir and approximately 1.5- to 2-fold for ritonavir and paritaprevir. Protein binding is high (about 99%) for all four drugs. Ombitasvir is primarily metabolized by amide hydrolysis followed by oxidative metabolism. Paritaprevir is metabolized by CYP3A, ritonavir primarily by CYP3A and to a lesser extent by CYP2D6. Dasabuvir is metabolized primarily by CYP2C8 and to a lesser extent by CYP3A. Paritaprevir exposures are increased 62% and 945% in individuals with Child Pugh B and C cirrhosis, respectively.

Due to reports of hepatic decompensation, hepatic failure, and death in patients with advanced liver disease receiving PrOD, this combination should not be administered to patients with decompensated cirrhosis. Ombitasvir pharmacokinetics are not significantly altered in renal impairment, but to the extent that renal impairment may affect hepatic function, paritaprevir, dasabuvir, and ritonavir exposures will increase with worsening renal function. PrOD has been studied in noncirrhotic, HCV-infected individuals with eGFR less than 30 mL/min/1.73 m²; high cure rates were achieved, but ribavirin was difficult to tolerate in the genotype 1a individuals, 65% of whom developed anemia. The plasma half-lives of PrOD components are as follows: ombitasvir about 23 h; paritaprevir,

5.5 h; ritonavir, 4 h; and dasabuvir, 5.8 h. There are inconsistent results on differences in pharmacokinetics of PrOD in HCV-seropositive versus -HCV-seronegative individuals; some studies indicated a decrease in exposures in HCV-seropositive persons, while others indicated no difference.

Therapeutic Uses. The PrOD combination is FDA-approved for the treatment of HCV genotype 1. PrOD is administered for 12 weeks to patients with genotype 1b regardless of cirrhosis status. However, in individuals with genotype 1a, ribavirin is used with PrOD in a 12-week regimen to increase the rate of SVR (from 90% to 97%). Treatment should be extended to 24 weeks in patients with genotype 1a with cirrhosis because it increases the rate of SVR from 91% to 96%.

Ritonavir-boosted paritaprevir and ombitasvir is used with ribavirin, but without dasabuvir, for 12 weeks for the treatment of individuals with genotype 4 disease.

The SVR rates are similar in individuals with HIV coinfection to those seen in individuals with HCV monoinfection. The primary consideration in the treatment of HIV-coinfected individuals with PrOD or PrO is avoidance of drug interactions. Efavirenz, rilpivirine, and regimens containing cobicistat or ritonavir can be problematic with this therapy (MacBrayne and Kiser, 2016).

Untoward Effects and Drug Interactions. The most commonly reported clinical adverse effects with PrOD include nausea (8%), pruritis (7%), insomnia (5%), and asthenia (4%). The frequency of these effects doubles with the addition of ribavirin.

The PrOD combination acts as both a victim and a perpetrator in a number of clinically significant drug interactions. The ritonavir booster prolongs the dwell time of paritaprevir but may necessitate lowering the dose of any concomitant agent that CYP3A4 also metabolizes. CYP2C8 metabolizes dasabuvir (as does CYP3A4 to a lesser degree); thus, inhibitors of CYP2C8 may elevate dasabuvir blood levels and are contraindicated during PrOD therapy. Ethinyl-estradiol-containing contraceptives will elevate hepatic enzymes and should be avoided with PrOD or PrO therapy; progestin-containing contraceptives may be used. Vigilance is required in the identification, management, and avoidance of interactions with PrO and PrOD therapy for HCV. Refer to the product labeling and consult the Internet (<http://www.hep-druginteractions.org>) for up-to-date information on drug interactions with this DAA combination.

Pediatric and Geriatric Uses. A study of PrOD is ongoing in children (NCT02486406). Approximately 8% of patients in clinical trials of PrOD were age 65 or older. No differences in safety or efficacy were observed between these subjects and younger subjects.

Grazoprevir/Elbasvir

Grazoprevir is an NS3/4A protease inhibitor; elbasvir is an NS5A inhibitor. These drugs are available in a single fixed-dose combination tablet.

Mechanism of Action and Resistance. Grazoprevir and elbasvir are inhibitors of the NS3 and NS5A viral enzymes, respectively. In trials, pre-existing NS3 RAVs were detected in 57% and 19% of individuals with genotype 1a and 1b, respectively, but the presence of preexisting NS3 RAVs does not reduce the likelihood of high SVR rates. The presence of preexisting NS5A RAVs did reduce SVR rates in genotype 1a patients. SVR rates were 58% and 68% in genotype 1a treatment-naïve and treatment-experienced patients, respectively, with preexisting NS5A RAVs. Adding ribavirin and extending the treatment duration greatly increases SVR rates in patients with preexisting NS5A RAVs.

ADME. GZR/EBR is dosed as a single 100-mg/50-mg fixed-dose combination tablet taken once daily without regard to meals, although a high-fat meal will increase the AUC and C_{max} of grazoprevir by 1.5- and 2.8-fold. The bioavailability of elbasvir is 30%; that of grazoprevir ranges from 10% to 40%. The $t_{1/2}$ of grazoprevir is about 30 h. Elbasvir has a $t_{1/2}$ of 23 h. Less than 1% of grazoprevir and elbasvir are renally eliminated. Both drugs are extensively (~99%) bound. Grazoprevir exposures are increased 62% in those with mild (Child-Pugh A) and 388% in those with moderate (Child Pugh B) hepatic impairment relative to those with no hepatic impairment. Total concentrations of elbasvir are 24% and 14% lower in patients with

mild and moderate hepatic insufficiency, respectively, likely a reflection of reduced serum protein levels. Grazoprevir and elbasvir pharmacokinetics in individuals with ESRD on hemodialysis are comparable to individuals without hepatic impairment. The AUCs of grazoprevir and elbasvir are increased, however, by 65% and 86%, respectively, in those with eGFR less than 30 mL/min/1.73 m² not receiving dialysis. As with other hepatically metabolized DAAs, this increase may be due to accumulation of uremic toxins, parathyroid hormone, or cytokines that can impair hepatic metabolism. The grazoprevir AUCs are 1.2- to 2.1-fold higher in HCV-infected individuals compared with HCV-uninfected individuals. There are no differences in elbasvir pharmacokinetics in HCV-seropositive versus seronegative individuals.

Therapeutic Uses. Grazoprevir/elbasvir is FDA approved for HCV genotypes 1 and 4, in individuals with HIV coinfection, and in those with renal impairment. Compared with prior HCV NS3 protease inhibitors, grazoprevir has activity against more genotypes and a higher barrier to the development of resistance.

Based on clinical trials, 95% of treatment-naïve individuals with primarily genotype 1 disease will achieve SVR after 12 weeks of GZR/EBR (SVR rates: 92% with genotype 1a, 99% with genotype 1b, 100% with genotype 4, and 80% with genotype 6). There are no differences in response between cirrhotics and noncirrhotics, but lower SVR rates (58% vs. 99%) are observed in patients with preexisting NS5A RAVs. Thus, NS5A resistance testing needs to be performed for individuals with genotype 1a before starting GZR/EBR. In genotype 1a individuals with preexisting NS5A RAVs, adding ribavirin and treating for an additional 4 weeks for a total of 16 weeks improves SVR rates. SVR rates are similar in patients with HIV coinfection, but drug interactions with antiretroviral therapy are an important consideration in this population (AASLD/IDSA, 2016).

The combination GZR/EBR has a particular niche in the treatment of HCV-infected patients with impaired renal function. In a trial of individuals (14% cirrhotic) with eGFR less than 30 mL/min/1.73 m² (76% of whom were hemodialysis dependent), the SVR after 12 weeks of treatment was 94%. The percentage of patients reporting any adverse event (~75%) was

similar to studies of GZR/EBR in patients without renal impairment. More serious events occurred in these patients (15% vs. 3%), but many were not considered related to GZR/EBR treatment (Roth et al., 2015).

Untoward Effects and Drug Interactions. The most common side effects with GZR/EBR are headache (17%), fatigue (16%), and nausea (9%–15%). Higher exposures of grazoprevir are associated with liver function test elevations. Grazoprevir may increase bilirubin concentrations through inhibition of OATP1B1.

Grazoprevir is a substrate for CYP3A4, Pgp, and OATP1B1. OATP1B1 inhibitors and moderate/strong CYP3A and Pgp inducers (including efavirenz) are not recommended for coadministration with GZR/EBR. Elbasvir is a substrate for CYP3A4 and Pgp and an inhibitor of BCRP and Pgp.

Pediatric and Geriatric Uses. GZR/EBR has not been studied in children, and no dedicated studies have been performed in older patients. No age effect was observed in elbasvir pharmacokinetics in young (22–45 years) versus elderly (65–78 years) males; elderly females had a 33% higher elbasvir AUC compared with elderly men even after adjustment for body weight.

Investigational Agents and the Future for Treatment of HCV

Several agents are still in clinical development for the treatment of hepatitis C, including combination therapies such as sofosbuvir + velpatasvir + voxilaprevir (Lawitz et al., 2016a), glecaprevir + pibrentasvir (Gane et al., 2016), and MK-3682 + grazoprevir + ruzasvir. However, compared with 10 years ago, drug development has slowed. For those individuals able to access therapy, currently available agents achieve cure in most (but not all) patient populations. The remaining challenges for this disease are testing and diagnosis, linkage to care, increasing access to these expensive therapies, and management of special patient populations, including cirrhotic individuals with genotype 3 disease, individuals with decompensated cirrhosis, and those who fail DAA treatment.

Drug Facts for Your Personal Formulary: Viral Hepatitis (HBV/HCV)

Drugs	Therapeutic Uses	Clinical Pharmacology and Tips
Hepatitis B Therapy		
Pegylated interferon alfa	<ul style="list-style-type: none"> Preferred agent Approved for adult patients with compensated liver disease and evidence of viral replication and liver inflammation Administered SC weekly for 48–52 weeks 	<ul style="list-style-type: none"> Adverse reactions (>40%): fatigue/asthenia, pyrexia, myalgia, and headache May cause fatal neuropsychiatric, autoimmune, ischemic, and infectious disorders Frequent hematologic monitoring required Contraindicated in advanced liver disease and in pregnancy
Entecavir	<ul style="list-style-type: none"> Preferred agent Approved for individuals ≥ 2 years old Indefinite treatment for patients with cirrhosis 	<ul style="list-style-type: none"> Use higher dose for decompensated cirrhosis and patients with lamivudine or telbivudine resistance Take on an empty stomach Monitor for lactic acidosis in decompensated cirrhosis Adverse reactions (≥3%): headache, fatigue, dizziness, nausea
Tenofovir disoproxil fumarate	<ul style="list-style-type: none"> Preferred agent Approved for individuals ≥ 2 years old Indefinite treatment for patients with cirrhosis 	<ul style="list-style-type: none"> Dose reduction in renal impairment Monitor renal function May decrease bone mineral density Adverse reactions (≥10%) in decompensated cirrhosis: abdominal pain, nausea, insomnia, pruritus, vomiting, dizziness, and pyrexia
Adefovir Lamivudine Telbivudine	<ul style="list-style-type: none"> Alternative agents due to high incidence of HBV resistance with monotherapy Indefinite treatment for patients with cirrhosis 	<ul style="list-style-type: none"> Dose adjust for renal impairment Abrupt discontinuation causes hepatitis flares Common adverse reactions: <ul style="list-style-type: none"> <i>Adefovir</i>: asthenia and impaired renal function <i>Lamivudine</i>: ear, nose, and throat infections; sore throat; and diarrhea <i>Telbivudine</i>: increased CK, nausea, diarrhea, fatigue, myalgia, and myopathy

- Entry Inhibitors
- Integrase Inhibitors
- Future Treatment Guidelines

The pharmacotherapy of HIV infection is a rapidly moving field. Three-drug combinations are the current minimum standard of care for this infection, so available agents and formulations constitute several thousand possible regimens. Knowing the essential features of the pathophysiology of this disease and how chemotherapeutic agents affect the virus and the host is critical in developing a rational approach to therapy. Unique features of this drug class include the need for lifelong administration to control virus replication and the possibility of rapid emergence of permanent drug resistance if these agents are not used properly.

Pathogenesis of HIV-Related Disease

Human immunodeficiency viruses are lentiviruses, a family of retroviruses evolved to establish chronic persistent infection with gradual onset of clinical symptoms. Replication is constant following infection, and although some infected cells may harbor nonreplicating virus for years, in the absence of treatment there generally is no true period of viral latency following infection (Deeks et al., 2015). Humans and nonhuman primates are the only natural hosts for these viruses.

There are two major families of HIV. Most of the epidemic involves HIV-1; HIV-2 is more closely related to SIV and is concentrated in western Africa. HIV-1 is genetically diverse, with at least five distinct subfamilies or clades. HIV-1 and HIV-2 have similar sensitivity to most antiretroviral drugs, although the NNRTIs are HIV-1 specific and have no activity against HIV-2.

Virus Structure

HIV is a typical retrovirus with a small RNA genome of 9300 base pairs. Two copies of the genome are contained in a nucleocapsid core surrounded by a lipid bilayer, or envelope that is derived from the host cell plasma membrane (Figure 64–1). The viral genome encodes three major open reading frames: *gag* encodes a polyprotein that is processed to release the major structural proteins of the virus; *pol* overlaps *gag* and encodes three important enzyme activities (an RNA-dependent DNA polymerase or reverse transcriptase with RNAase activity, protease, and the viral integrase); and *env* encodes the large transmembrane envelope protein responsible for cell binding and entry. Several small genes encode regulatory proteins that enhance virion production or combat host defenses. These include *tat*, *rev*, *nef*, and *vpr*.

Virus Life Cycle

Understanding the HIV life cycle (Figure 64–1) is crucial to understanding the rational therapy of HIV infection. HIV tropism is controlled by the envelope protein gp160 (*env*). The major target for *env* binding is the CD4

receptor present on lymphocytes and macrophages, although cell entry also requires binding to a coreceptor, generally the chemokine receptors CCR5 or CXCR4. CCR5 is present on macrophage lineage cells. Most infected individuals harbor predominantly the CCR5-tropic virus; HIV with this tropism is responsible for nearly all naturally acquired infections. A shift from CCR5 to CXCR4 utilization is associated with advancing disease, and the increased affinity of HIV-1 for CXCR4 allows infection of T-lymphocyte lines. A phenotypic switch from CCR5 to CXCR4 heralds accelerated loss of CD4⁺ helper T cells and increased risk of immunosuppression. Whether coreceptor switch is a cause or a consequence of advancing disease is still unknown, but it is possible to develop clinical AIDS without this switch (Deeks et al., 2015).

The gp41 domain of *env* controls the fusion of the virus lipid bilayer with that of the host cell. Following fusion, full-length viral RNA enters the cytoplasm, where it undergoes replication to a short-lived RNA-DNA duplex; the original RNA is degraded by the RNase H activity of reverse transcriptase to allow creation of a full-length double-stranded DNA copy of the virus. Because the HIV reverse transcriptase is error prone and lacks a proofreading function, mutation is frequent and occurs at about three bases of every full-length (9300-base-pair) replication (Coffin, 1995). Virus-derived DNA is transported into the nucleus, where it is integrated into a host chromosome by the viral integrase in a random or quasi-random location (Greene and Peterlin, 2002).

Following integration, the virus may remain quiescent, not producing RNA or protein but replicating as the cell divides. When a cell that harbors the viral DNA is activated, viral RNA and proteins are produced. Structural proteins assemble around full-length genomic RNA to form a nucleocapsid. The envelope and structural proteins assemble at the cell surface, concentrating in cholesterol-rich lipid rafts. The nucleocapsid cores are directed to these sites and bud through the cell membrane, creating new enveloped HIV particles containing two complete single-stranded RNA genomes. Reverse transcriptase is incorporated into virus particles so replication can begin immediately after the virus enters a new cell.

How the Virus Causes Disease

Sexual acquisition of HIV infection is likely mediated by one or, at most, a handful of infectious virus particles. Soon after infection, there is a rapid burst of replication peaking at 2–4 weeks, with 10⁹ cells or more becoming infected. This peak is associated with a transient dip in the number of peripheral CD4⁺ (helper) T lymphocytes. As a result of new host immune responses and target cell depletion, the number of infectious virions as reflected by the plasma HIV RNA concentration (also known as viral load) declines to a quasi-steady state. This set point reflects the interplay between host immunity and the pathogenicity of the infecting virus

Abbreviations

ABC:	abacavir
ADME:	absorption, distribution, metabolism, excretion
AIDS:	acquired immunodeficiency syndrome
5'-AMP:	adenosine 5'-monophosphate
AUC:	area under plasma concentration-time curve
cDNA:	complementary DNA
CL_{cr}:	creatinine clearance
CMP:	cytidine monophosphate
CNS:	central nervous system
CSF:	cerebrospinal fluid
CYP:	cytochrome P450
dCMP:	deoxycytidine monophosphate
ddC:	dideoxycytidine
ddI:	didanosine
DF:	disoproxil fumarate
DRESS:	drug reaction with eosinophilia and systemic symptoms
d4T:	stavudine
eCL_{cr}:	estimated creatinine clearance
env:	envelope protein gp160
FDA:	Food and Drug Administration
FTC:	emtricitabine
GI:	gastrointestinal
HBV:	hepatitis B virus
HIV:	human immunodeficiency virus
HTLV:	human T-cell lymphotropic virus
IMP:	inosine 5'-monophosphate
InSTI:	integrase strand transfer inhibitor
IRIS:	immune reconstitution inflammatory syndrome
LTR:	long terminal repeat
NDP:	nucleoside diphosphate
NNRTI:	nonnucleoside reverse transcriptase inhibitor
NRTI:	nucleos(t)ide reverse transcriptase inhibitor
OATP:	organic anion-transporting polypeptide
PI:	protease inhibitor
PK:	pharmacokinetic
PRPP:	phosphoribosyl pyrophosphate
QT_c:	corrected cardiac QT interval
RNase H:	ribonuclease H
RT:	reverse transcriptase
SIV:	simian immunodeficiency virus
t_{1/2}:	half-life of elimination
TAF:	tenofovir alafenamide
TAM:	thymidine analogue mutation
3TC:	lamivudine
TDF:	tenofovir disoproxil fumarate
vRNA:	viral RNA
ZDV:	zidovudine

(Coffin, 1995). In the average infected individual, several billion infectious virus particles are produced every few days.

Eventually, the host CD4⁺ T-lymphocyte count begins a steady decline, accompanied by a rise in the plasma HIV RNA concentration. Once the peripheral CD4 cell count falls below 200 cells/mm³, there is an increasing risk of opportunistic diseases and, ultimately, death. Sexual acquisition of CCR5-tropic HIV-1 is associated with a median time to clinical AIDS of 8–10 years if the patient is not treated. Some patients, termed long-term nonprogressors, can harbor HIV for more than two decades without significant decline in peripheral CD4 cell count or clinical immunosuppression; this may reflect a combination of favorable host immunogenetics and immune responses.

An important question relevant to treatment is whether HIV disease is a consequence of CD4⁺ lymphocyte depletion alone. Most natural history data suggest that this is true. Regardless, successful therapy is based on inhibition of HIV replication; interventions designed specifically to boost the host immune response without exerting a direct antiviral effect have had no reliable clinical benefit (Deeks et al., 2015).

Principles of HIV Chemotherapy

Current treatment assumes that all aspects of disease derive from the direct toxic effects of HIV on host cells, mainly CD4⁺ T lymphocytes. *The goal of therapy is to suppress virus replication as much as possible for as long as possible.* The current standard of care is to use at least three drugs simultaneously for the entire duration of treatment (Department of Health and Human Services, 2016).

Two large randomized clinical trials found substantial clinical benefit from initiating antiretroviral therapy regardless of baseline CD4 count (INSIGHT START Study Group, 2015; TEMPRANO ANRS 12136 Study Group, 2015); thus, the current global standard of care is to offer treatment to all infected individuals whenever possible (World Health Organization, 2015). Increasing evidence also confirms the value of antiretroviral therapy in preventing transmission of the virus from person to person (Cohen et al., 2011).

Drug resistance remains a key problem. There is a high likelihood that all untreated infected individuals harbor viruses with single-amino-acid mutations that confer some degree of resistance to every known antiretroviral drug because of the high mutation rate of HIV and the tremendous number of infectious virions (Coffin, 1995). Thus, a combination of active agents is required to prevent drug resistance, analogous to strategies employed in the treatment of tuberculosis (see Chapter 60). Prolonged drug holidays may allow the virus to replicate anew, increasing the risk of drug resistance and disease progression; such breaks in treatment are associated with increased morbidity and mortality and are not generally recommended (Lawrence et al., 2003).

The expected outcome of initial therapy in a previously untreated patient is an undetectable viral load (plasma HIV RNA < 50 copies/mL) within 24 weeks of starting treatment. Mathematical models of HIV replication suggest that three is the minimum number of agents required to guarantee effective long-term suppression of HIV replication without resistance (Muller and Bonhoeffer, 2003). However, earlier models may not adequately predict the effects of newer and more potent antiretrovirals.

In treatment-naïve patients, a regimen containing a nonnucleoside plus two NRTIs is as effective as a regimen containing an additional nucleoside (Shafer et al., 2003), indicating the equivalence of these three-drug and four-drug regimens. Four or more drugs may be used simultaneously in patients harboring drug-resistant virus, but the number of agents a patient can take is limited by toxicity and inconvenience.

Failure of an antiretroviral regimen is defined as a persistent increase in plasma HIV RNA concentrations in a patient with previously undetectable virus, despite continued treatment with that regimen. This indicates resistance to one or more drugs in the regimen and necessitates a change in treatment. The selection of new agents is therefore informed by the patient's treatment history and viral resistance testing. Treatment failure generally requires implementation of a completely new combination of drugs (Department of Health and Human Services, 2016). Adding a single active agent to a failing regimen is functional monotherapy if the patient is resistant to all other drugs in the regimen. The risk of failing a regimen also depends on the percentage of prescribed doses taken during a given period of treatment.

As antiretroviral therapy becomes more effective and easier to take, long-term toxicity of these drugs is of greater importance. Fortunately, several approved antiretroviral agents (lamivudine, emtricitabine, raltegravir, possibly dolutegravir) have essentially no clinically significant short-term or long-term toxicities. A potential concern that applies to all PIs and NNRTIs is clinically significant pharmacokinetic drug interactions. Most agents in these two drug classes can act as inhibitors

Figure 64-1 Replicative cycle of HIV-1 showing the sites of action of available antiretroviral agents. Available antiretroviral agents are shown in red. In this figure, gp120 + gp41 indicates extracellular and intracellular domains, respectively, of envelope glycoprotein.

and/or inducers of hepatic CYPs, other drug-metabolizing enzymes, and drug transporters (Piscitelli and Gallicano, 2001; see also Chapter 5). An increasingly recognized complication of initiating antiretroviral therapy is accelerated inflammatory reaction to overt or subclinical opportunistic infections or malignancies. This immune reconstitution inflammatory syndrome (IRIS) is most commonly seen when initiating therapy in individuals with low CD4 counts or advanced HIV disease. Infections commonly associated with IRIS include tuberculosis and other mycobacterial diseases, cryptococcosis, hepatitis virus infections, and *Pneumocystis pneumonia* (Manabe et al., 2007).

Drugs Used to Treat HIV Infection

Nucleoside and Nucleotide Reverse Transcriptase Inhibitors

Overview

HIV-encoded, RNA-dependent DNA polymerase, also called reverse transcriptase, converts viral RNA into proviral DNA, which is then incorporated into a host cell chromosome. Available inhibitors of this enzyme are either nucleoside/nucleotide analogues or nonnucleoside inhibitors (Table 64-1). NRTIs prevent infection of susceptible cells but do not eradicate the virus from cells that already harbor integrated proviral DNA. Nearly all patients starting antiretroviral treatment do so with at least one agent from this class. Figure 64-2 shows the mechanism of action of NRTIs, which involves phosphorylation by host cells to the active inhibitory form. All but one of the drugs in this class (see structures in Figure 64-3) are nucleosides that must be triphosphorylated at the 5'-hydroxyl to exert activity. The sole exception, tenofovir, is a nucleotide monophosphate analogue that requires two additional phosphates to acquire full activity. These compounds inhibit both HIV-1 and HIV-2, and several have broad-spectrum activity against other human and animal retroviruses; emtricitabine, lamivudine, and tenofovir are active against HBV, and tenofovir also has activity against herpesviruses (see Chapter 63).

The selective toxicity of these drugs depends on their ability to inhibit the HIV reverse transcriptase without inhibiting host cell DNA

polymerases. Although the intracellular triphosphates for all these drugs have low affinity for human DNA polymerase α and polymerase β , some do inhibit human DNA polymerase γ , which is the mitochondrial enzyme. As a result, the important toxicities common to this class of drugs result in part from the inhibition of mitochondrial DNA synthesis (Lee et al., 2003). These toxicities include anemia, granulocytopenia, myopathy, peripheral neuropathy, and pancreatitis. Lactic acidosis with or without hepatomegaly and hepatic steatosis is a rare but potentially fatal complication seen with stavudine, zidovudine, and didanosine. Phosphorylated emtricitabine, lamivudine, and tenofovir have low affinity for DNA polymerase γ and are largely devoid of mitochondrial toxicity.

Table 64-2 summarizes the pharmacokinetic properties of NRTIs approved for treating HIV infection. A notable pharmacological feature of these agents is the formation of the intracellular nucleoside di- or triphosphate, which is the active form. Figure 64-4 shows the cellular routes that catalyze the activation of NRTIs. In general, the phosphorylated anabolites are eliminated from cells much more gradually than the parent drug is eliminated from the plasma. As a result, available NRTIs are dosed once or twice daily. These drugs are not major substrates for hepatic CYPs. Pharmacokinetic drug interactions involving tenofovir and PIs are likely explained by inhibition of OATP drug transporters (Chapman et al., 2003; see Chapter 5). High-level resistance to NRTIs, especially thymidine analogues, occurs slowly by comparison to NNTRIs and first-generation PIs. High-level resistance can occur rapidly with lamivudine and emtricitabine. Cross-resistance is common but often confined to drugs having similar chemical structures. Several nucleoside analogues have favorable safety and tolerability profiles and are useful in suppressing the emergence of HIV isolates resistant to the more potent drugs in combination regimens (Kuritzkes, 2011).

Zidovudine

Zidovudine is a synthetic thymidine analogue (Figure 64-3) with potent activity against a broad spectrum of retroviruses, including HIV-1, HIV-2, and HTLVs I and II. Zidovudine is active in lymphoblastic and monocytic cell lines but has no impact on cells already infected with HIV. Zidovudine appears to be more active in activated than in resting lymphocytes because

TABLE 64-1 ■ ANTIRETROVIRAL AGENTS APPROVED FOR USE IN THE U.S.

GENERIC NAME	ABBREVIATION; Chemical Name
Nucleoside/Nucleotide Reverse Transcriptase Inhibitors	
Zidovudine ^a	ZDV; azidothymidine (AZT)
Didanosine	ddI; dideoxyinosine
Stavudine	d4T; didehydrodeoxythymidine
Zalcitabine ^b	DDC; dideoxycytidine
Lamivudine ^a	3TC; dideoxythiacytidine
Abacavir ^a	ABC; amino-cyclopropylamino-purinylicyclopentenylmethanol
Tenofovir disoproxil ^{a,c}	TDF; TAF; phosphono-methoxypropyladenine (PMPA)
Tenofovir alafenamide ^{a,c}	
Emtricitabine ^a	FTC; fluorooxathiolanyl cytosine
Nonnucleoside Reverse Transcriptase Inhibitors	
Nevirapine	NVP
Efavirenz ^a	EFV
Delavirdine	DLV

Elvitegravir ^a	EVG
Dolutegravir ^a	DTG

^aA number of fixed-dose coformulations are available: zidovudine + lamivudine; zidovudine + lamivudine + abacavir; abacavir + lamivudine; tenofovir + emtricitabine; tenofovir + efavirenz + emtricitabine; emtricitabine + rilpivirine + tenofovir disoproxil fumarate; cobicistat + elvitegravir + emtricitabine + tenofovir disoproxil fumarate; lamivudine + raltegravir.

^bNo longer marketed worldwide.

^cTenofovir disoproxil fumarate is a nucleotide prodrug of the nucleoside tenofovir.

^dLopinavir is available only as part of a fixed-dose coformulation with ritonavir.

the phosphorylating enzyme, thymidine kinase, is S-phase specific (Cihlar and Ray, 2010). Zidovudine is FDA-approved for the treatment of adults and children with HIV infection and for preventing mother-to-child transmission; it also was previously recommended for postexposure prophylaxis in HIV-exposed healthcare workers. Zidovudine is marketed in

oral tablets, capsules, and solution as well as a solution for intravenous injection. Zidovudine is available in coformulated tablets with lamivudine or with lamivudine and abacavir.

Mechanisms of Action and Resistance. Intracellular zidovudine is phosphorylated to zidovudine 5'-triphosphate. Zidovudine-triphosphate terminates the elongation of proviral DNA because it is incorporated by reverse transcriptase into nascent DNA but lacks a 3'-hydroxyl group. The monophosphate competitively inhibits cellular thymidylate kinase, and this may reduce the amount of intracellular thymidine triphosphate formed. Zidovudine-triphosphate only weakly inhibits cellular DNA polymerase α but is a more potent inhibitor of mitochondrial polymerase γ . Because the conversion of zidovudine-monophosphate to diphosphate is inefficient, high concentrations of the monophosphate accumulate inside cells and may serve as a precursor depot for formation of triphosphate. As a consequence, there is little correlation between extracellular concentrations of parent drug and intracellular concentrations of triphosphate, and higher plasma concentrations of zidovudine do not increase intracellular triphosphate concentrations proportionately.

Resistance to zidovudine is associated with mutations at reverse transcriptase codons 41, 44, 67, 70, 210, 215, and 219. These mutations are referred to as TAMs because of their ability to confer cross-resistance to other thymidine analogues, such as stavudine. The M184V substitution in the reverse transcriptase gene associated with the use of lamivudine or emtricitabine greatly restores sensitivity to zidovudine (Kuritzkes, 2011). The combination of zidovudine and lamivudine produces greater long-term suppression of plasma HIV RNA than does zidovudine alone.

ADME. Zidovudine is absorbed rapidly and reaches peak plasma concentrations within 1 h. Table 64-2 summarizes the drug's pharmacokinetic profile, which is not altered significantly during pregnancy; drug concentrations in the newborn approach those of the mother. Parent drug crosses the blood-brain barrier relatively well and also is detectable in breast milk, semen, and fetal tissue.

Untoward Effects and Drug Interactions. Patients initiating zidovudine treatment often complain of fatigue, malaise, myalgia, nausea, anorexia, headache, and insomnia; these symptoms usually resolve within a few weeks. Erythrocytic macrocytosis is seen in about 90% of patients but usually is not associated with anemia. Chronic zidovudine administration has been associated with nail hyperpigmentation. Skeletal muscle myopathy can occur and is associated with depletion of mitochondrial DNA, most likely as a consequence of inhibition of DNA polymerase γ . Serious hepatic toxicity, with or without steatosis and lactic acidosis, is rare but can be fatal.

Probenecid, fluconazole, atovaquone, and valproic acid may increase plasma concentrations of zidovudine, probably through inhibition of glucuronosyl transferases. Zidovudine is neither substrate nor inhibitor of CYPs. Zidovudine can cause bone marrow suppression and should be used cautiously in patients with preexisting anemia or granulocytopenia and in those taking other marrow-suppressive drugs. Stavudine and zidovudine compete for intracellular phosphorylation and should not be used concomitantly.

Stavudine

Stavudine is a synthetic thymidine analogue that is active in vitro against HIV-1 and HIV-2. Stavudine is approved for use in HIV-infected adults and children, including neonates. This drug is no longer widely prescribed because of the availability of agents with less toxicity.

Mechanisms of Action and Resistance. Intracellular stavudine is sequentially phosphorylated to form stavudine 5'-triphosphate. Like zidovudine, stavudine is most potent in activated cells, probably because thymidine kinase, which produces the monophosphate, is an S-phase-specific enzyme. Stavudine resistance is seen most frequently with mutations at reverse transcriptase codons 41, 44, 67, 70, 210, 215, and 219, which are mutations associated with zidovudine resistance. Resistance mutations for stavudine appear to accumulate slowly. Cross-resistance to multiple nucleoside analogues has been reported following prolonged therapy (Martin et al., 2010).

Figure 64-2 Mechanism of NRTIs. Zidovudine is depicted; Table 64-1 lists other agents in the NRTI class. Nucleoside and nucleotide analogues must enter cells and be phosphorylated to generate synthetic substrates for reverse transcriptase. The fully phosphorylated analogues block replication of the viral genome both by competitively inhibiting incorporation of native nucleotides and by terminating elongation of nascent proviral DNA because they lack a 3'-hydroxyl group.

ADME. Table 64-2 summarizes the agent's pharmacokinetic data. Stavudine is well absorbed and reaches peak plasma concentrations within 1 h; bioavailability is not affected by food. The drug penetrates well into the CSF, achieving concentrations that are about 40% of those in plasma. Placental concentrations of stavudine are about half those of zidovudine. The drug undergoes active tubular secretion, and renal elimination accounts for about 40% of parent drug; thus, the dose should be adjusted in patients with renal insufficiency.

Untoward Effects and Drug Interactions. The most common serious toxicity of stavudine is peripheral neuropathy. Although this may reflect mitochondrial toxicity, stavudine is a less-potent inhibitor of DNA

polymerase γ than either didanosine or zalcitabine, suggesting that other mechanisms may be involved. Stavudine is also associated with a progressive motor neuropathy characterized by weakness and in some cases respiratory failure, similar to Guillain-Barré syndrome.

Lactic acidosis and hepatic steatosis are associated with stavudine use and may be more common when stavudine and didanosine are combined. Acute pancreatitis is not highly associated with stavudine but is more common when stavudine is combined with didanosine than when didanosine is given alone. Of all nucleoside analogues, stavudine use is associated most strongly with fat wasting (lipoatrophy). Stavudine has fallen out of favor largely because of this toxicity.

^bParameters reported for the stavudine capsule formulation.

^cParameters reported for the didanosine chewable tablet formulation.

^dReported values for oral tenofovir disoproxil fumarate.

Stavudine is mainly renally cleared and is not subject to metabolic drug interactions. The incidence and severity of peripheral neuropathy may be increased when stavudine is combined with other neuropathic medications; thus, drugs such as ethambutol, isoniazid, phenytoin, and vincristine should be avoided. Combining stavudine with didanosine leads to increased risk and severity of peripheral neuropathy and potentially fatal pancreatitis; therefore, these two drugs should not be used together. Stavudine and zidovudine compete for intracellular phosphorylation and should not be used concomitantly (Martin et al., 2010).

Lamivudine

Lamivudine is a cytidine analogue reverse transcriptase inhibitor that is active against HIV-1, HIV-2, and HBV. Lamivudine is approved for HIV

in adults and children 3 months or older. Lamivudine has been effective in combination with other antiretroviral drugs in both treatment-naïve and experienced patients and is a common component of therapy, given its safety, convenience, and efficacy (Cihlar and Ray, 2010). Lamivudine is also approved for treatment of chronic hepatitis B.

Mechanisms of Action and Resistance. Lamivudine enters cells by passive diffusion and is sequentially phosphorylated to lamivudine 5'-triphosphate, which is the active anabolite. Lamivudine has low affinity for human DNA polymerases, explaining its low toxicity to the host. High-level resistance to lamivudine occurs with single-amino-acid substitutions, M184V or M184I. These mutations can reduce in vitro sensitivity to lamivudine as much as 1000-fold. The M184V mutation

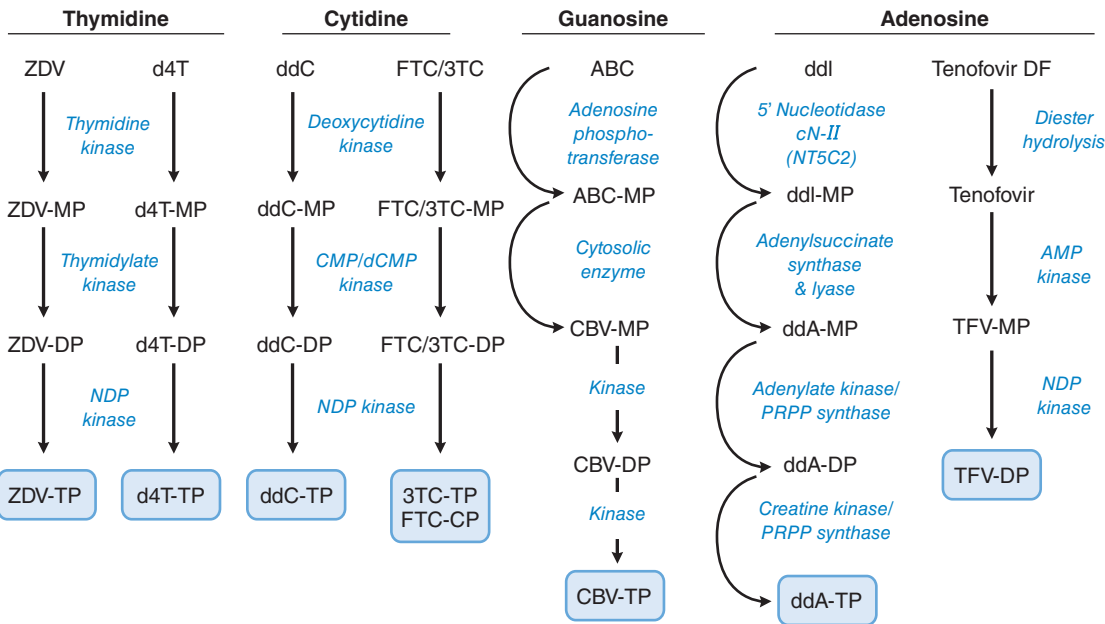

Figure 64-4 Intracellular activation of nucleoside analogue reverse transcriptase inhibitors. Drugs and phosphorylated anabolites are abbreviated; the enzymes responsible for each conversion are spelled out. The active antiretroviral anabolite for each drug is shown in the blue box. (Adapted with permission from Khoo SH, et al. Pharmacology. In: Boucher CAB, Galasso GAJ, eds. *Practical Guidelines in Antiviral Therapy*. Elsevier, New York, 2002, 13–35. Copyright © Elsevier.) MP, monophosphate; DP, diphosphate; TP, triphosphate.

restores zidovudine susceptibility in zidovudine-resistant HIV and also partially restores tenofovir susceptibility in tenofovir-resistant HIV harboring the K65R mutation (Kuritzkes, 2011). This effect may contribute to the sustained virologic benefits of zidovudine and lamivudine combination therapy.

ADME. Table 64–2 summarizes the pharmacokinetic parameters for this drug. Lamivudine is excreted primarily unchanged in the urine; dose adjustment is recommended for patients with a creatinine clearance less than 50 mL/min. Lamivudine freely crosses the placenta into the fetal circulation.

Untoward Effects and Precautions. Lamivudine is one of the least-toxic antiretroviral drugs. Neutropenia, headache, and nausea have been reported at higher-than-recommended doses. Pancreatitis has been reported in pediatric patients. Because lamivudine also has activity against HBV, caution is warranted in using this drug in patients coinfecting with HBV or in HBV-endemic areas: Abrupt discontinuation of lamivudine may be associated with a rebound of HBV replication and exacerbation of hepatitis.

Abacavir

Abacavir, a synthetic purine analogue, is approved for the treatment of HIV-1 infection, in combination with other antiretroviral agents. Abacavir is available in a coformulation with zidovudine and lamivudine for twice-daily dosing and in a coformulation with lamivudine, or lamivudine and dolutegravir, for once-daily dosing. Abacavir is approved for use in adult and pediatric patients 3 months or older, with dosing in the latter based on body weight.

Mechanisms of Action and Resistance. Abacavir is the only approved antiretroviral that is active as a guanosine analogue. It is sequentially phosphorylated in the host cell to carbovir 5′-triphosphate, which terminates the elongation of proviral DNA because it is incorporated by reverse transcriptase into nascent DNA but lacks a 3′-hydroxyl group (Cihlar and Ray, 2010). Clinical resistance to abacavir is associated with four specific substitutions: K65R, L74V, Y115F, and M184V. In combination, these substitutions can reduce susceptibility by up to 10-fold. K65R confers cross-resistance to all nucleosides except zidovudine. An alternate pathway for abacavir resistance involves mutations at codons 41, 210, and 215 (Kuritzkes, 2011).

ADME. Table 64–2 summarizes the pharmacokinetic parameters for this agent. The presence of food does not affect the oral bioavailability of abacavir. Abacavir is neither a substrate nor an inhibitor of CYPs. Its CSF/plasma AUC ratio is about 0.3.

Untoward Effects and Drug Interactions. The most important adverse effect of abacavir is a unique and potentially fatal hypersensitivity syndrome characterized by fever, abdominal pain, and other GI complaints; a mild maculopapular rash; and malaise or fatigue. Respiratory complaints (cough, pharyngitis, dyspnea); musculoskeletal complaints; headache; and paresthesias are less common. The presence of concurrent fever, abdominal pain, and rash within 6 weeks of starting abacavir is diagnostic and necessitates immediate discontinuation of the drug. Once discontinued for hypersensitivity, abacavir must never be restarted. The hypersensitivity syndrome (2%–9% of patients) results from a genetically mediated immune response linked to both the HLA-B*5701 locus and the M493T allele in the heat-shock locus Hsp70-Hom. The *Hsp* gene is implicated in antigen presentation, and this haplotype is associated with aberrant tumor necrosis factor α release after exposure of human lymphocytes to abacavir ex vivo (White et al., 2015). Abacavir should not be used in anyone known to carry the HLA-B*5701 locus (approximately 10% of Caucasians).

Abacavir is not associated with any clinically significant pharmacokinetic drug interactions. However, a large dose of ethanol (0.7 g/kg) increases the abacavir plasma AUC by 41% and prolongs the elimination $t_{1/2}$ by 26%, possibly owing to competition for alcohol dehydrogenase, which produces the dehydro- metabolite of the drug (see Table 64–2).

Tenofovir

Tenofovir is a derivative of 5′-AMP that lacks a complete ribose ring; it is the only nucleotide analogue currently marketed for the treatment of

HIV infection. Tenofovir is available as the disoproxil or alafenamide prodrugs, which substantially improve oral absorption. Tenofovir is active against HIV-1, HIV-2, and HBV. TDF is FDA-approved for treating HIV infection in adults and children older than 2 years in combination with other antiretroviral agents and for the treatment of chronic hepatitis B in adults and children older than 12. It is also approved for HIV preexposure prophylaxis (in combination with emtricitabine) in adults at high risk of acquiring the infection. A new tenofovir oral prodrug, TAF, is FDA-approved for the treatment of HIV and HBV. Its advantages over TDF include lower dose and less renal and bone toxicity (Sax et al., 2015); it is currently available in coformulation with elvitegravir, cobicistat, and emtricitabine; rilpivirine and emtricitabine; or emtricitabine.

Mechanisms of Action and Resistance. Tenofovir disoproxil is hydrolyzed rapidly to tenofovir, which is phosphorylated by cellular kinases to its active metabolite, tenofovir diphosphate, which is actually a triphosphate: The parent drug is a monophosphate (Figure 64–3) (Cihlar and Ray, 2010). The disposition of oral tenofovir alafenamide is similar, but it circulates largely as the uncleaved prodrug, which is taken up into cells and then converted to the parent nucleotide; as a consequence, circulating concentrations of tenofovir, which may contribute to renal toxicity, are much lower than produced by the disoproxil fumarate prodrug. Tenofovir diphosphate is a competitive inhibitor of viral reverse transcriptases and is incorporated into HIV DNA to cause chain termination because it has an incomplete ribose ring. Although tenofovir diphosphate has broad-spectrum activity against viral DNA polymerases, it has low affinity for human DNA polymerase α , polymerase β , and polymerase γ , which is the basis for its selective toxicity.

Specific resistance occurs with a K65R substitution that has been associated with clinical failure of tenofovir-containing regimens. Tenofovir sensitivity and virologic efficacy also are reduced in patients harboring HIV isolates with high-level resistance to zidovudine or stavudine. The M184V mutation associated with lamivudine or emtricitabine resistance partially restores susceptibility in tenofovir-resistant HIV harboring the K65R mutation (Kuritzkes, 2011).

ADME. Table 64–2 shows pharmacokinetic data for tenofovir. Following an intravenous dose, 70%–80% of the drug is recovered unchanged in the urine; thus, doses should be decreased in those with renal insufficiency. Tenofovir is not known to inhibit or induce CYPs.

Untoward Effects and Drug Interactions. Tenofovir generally is well tolerated, with few significant symptoms reported except for flatulence. Rare episodes of acute renal failure and Fanconi syndrome have been reported, and this drug should be used with caution in patients with pre-existing renal disease. Tenofovir use is associated with small declines in eCL_{Cr} after months of treatment in some patients; because the dose needs to be reduced in renal insufficiency, renal function (creatinine and phosphorus) should be monitored regularly. Because tenofovir also has activity against HBV, caution is warranted in using this drug in patients coinfecting with HBV: Abrupt discontinuation of tenofovir may be associated with a rebound of HBV replication and exacerbation of hepatitis. Tenofovir can increase the AUC of didanosine, and the two drugs should not be used together (Cihlar and Ray, 2010).

Tenofovir plasma concentrations are increased by 30%–50% if combined with the pharmacokinetic enhancers ritonavir or cobicistat due to inhibition of renal drug transporters. Similar effects are seen with the HBV NS5A inhibitors ledipasvir and velpatasvir (see Chapter 63). These combinations are generally well tolerated, without producing significant renal injury. However, acute renal insufficiency has been reported when TDF is combined with the oral nonsteroidal diclofenac.

Emtricitabine

Emtricitabine is a cytidine analogue that is chemically related to lamivudine and shares many of its properties. Emtricitabine is active against HIV-1, HIV-2, and HBV. The drug is FDA-approved for treating HIV infection in adults, children, and infants, in combination with other antiretroviral agents, and is available coformulated with tenofovir with or without efavirenz or with tenofovir, elvitegravir, and cobicistat. Emtricitabine is also

1144 approved for HIV preexposure prophylaxis (in combination with tenofovir) in adults at high risk of acquiring the infection.

Mechanisms of Action and Resistance. Emtricitabine enters cells by passive diffusion and is sequentially phosphorylated to its active metabolite, emtricitabine 5'-triphosphate. High-level resistance to emtricitabine occurs with the same mutations affecting lamivudine (mainly M184I/V), although these appear to occur less frequently with emtricitabine. The M184V mutation restores sensitivity to zidovudine in zidovudine-resistant HIV and partially restores sensitivity to tenofovir in tenofovir-resistant HIV harboring the K65R mutation (Kuritzkes, 2011). The same K65R mutation confers resistance to emtricitabine and the other cytidine analogue lamivudine, as well as didanosine, stavudine, and abacavir.

ADME. Table 64-2 summarizes pharmacokinetic data for emtricitabine. Orally administered drug is absorbed rapidly and well; the drug can be taken without regard to meals. Emtricitabine is excreted primarily unchanged in the urine; thus, the dose should be reduced in patients with CL_{Cr} below 50 mL/min.

Untoward Effects and Drug Interactions. Emtricitabine is one of the least-toxic antiretroviral drugs and has few significant adverse effects (Cihlar and Ray, 2010). Prolonged exposure has been associated with hyperpigmentation of the skin, especially in sun-exposed areas. Because emtricitabine also has in vitro activity against HBV, caution is warranted in using this drug in patients coinfecting with HBV and in regions with high HBV seroprevalence; abrupt discontinuation of emtricitabine may be associated with a rebound of HBV replication and exacerbation of hepatitis.

Emtricitabine is not metabolized to a significant extent by CYPs, and it is not susceptible to known metabolic drug interactions.

Didanosine

Didanosine (2',3'-dideoxyinosine) is a purine nucleoside analogue that is active against HIV-1, HIV-2, and other retroviruses, including HTLV-1. The drug is FDA-approved for adults and children with HIV infection in combination with other antiretroviral agents. Didanosine is no longer widely prescribed because of the availability of agents with less toxicity (Martin et al., 2010).

Mechanisms of Action and Resistance. Didanosine enters cells via a nucleoside transporter and is sequentially phosphorylated by cellular enzymes to the triphosphate, the active anabolite that functions as an antiviral adenosine analogue. Resistance to didanosine is associated with mutations at reverse transcriptase codons 65 and 74. The L74V substitution, which reduces susceptibility 5- to 26-fold in vitro, is seen most commonly in patients failing to respond to didanosine (Kuritzkes, 2011). Other nucleoside analogue mutations, including TAMs, can contribute to didanosine resistance even though the drug does not appear to select for these mutations *de novo*. The reverse transcriptase insertion mutations at codon 69 produce cross-resistance to all current nucleoside analogues, including didanosine.

ADME. Table 64-2 summarizes major pharmacokinetic parameters for didanosine. The drug is acid labile and thus is administered with an antacid buffer. Food decreases didanosine bioavailability; all formulations of didanosine must be administered at least 30 min before or 2 h after eating. This complicates dosing of didanosine in combination with antiretroviral drugs that must be given with food, as is the case for most HIV PIs. Didanosine is excreted by glomerular filtration and tubular secretion; doses therefore must be adjusted in patients with renal insufficiency.

Untoward Effects and Drug Interactions. The most serious toxicities associated with didanosine include peripheral neuropathy and pancreatitis, both of which are thought to be a consequence of mitochondrial toxicity. Didanosine should be avoided in patients with a history of pancreatitis or neuropathy. Patients complain of pain, numbness, and tingling in the affected extremities. If the drug is stopped as soon as symptoms appear, the neuropathy should improve or resolve. However, irreversible neuropathy can occur with continued use. Retinal changes and optic neuritis also have been reported. Coadministration of other drugs that cause

pancreatitis or neuropathy (i.e., stavudine) will increase the risk and severity of these symptoms. Ethambutol, isoniazid, vincristine, cisplatin, and pentamidine should be avoided. Serious hepatic toxicity occurs rarely but can be fatal (Martin et al., 2010). Other reported adverse effects include elevated hepatic transaminases, headache, and asymptomatic hyperuricemia; noncirrhotic portal hypertension can occur years after exposure to didanosine.

Buffering agents included in didanosine formulations can interfere with the bioavailability of some coadministered drugs because of altered pH or chelation with cations in the buffer. For example, didanosine greatly reduces the AUCs of ciprofloxacin and indinavir; concentrations of ketoconazole and itraconazole, whose absorption is pH dependent, also are diminished. These interactions generally can be avoided by separating administration of didanosine from that of other agents by at least 2 h after or 6 h before the interacting drug. The enteric-coated formulation of didanosine does not alter ciprofloxacin or indinavir absorption. Didanosine is excreted renally, and shared renal excretory mechanisms provide a basis for interactions with oral ganciclovir, allopurinol, and tenofovir. Methadone decreases the didanosine AUC by about 60%.

Nonnucleoside Reverse Transcriptase Inhibitors

Overview

The NNRTIs include a variety of chemical substrates that bind to a hydrophobic pocket in the p66 subunit of the HIV-1 reverse transcriptase, in a site distant from the active site (Figure 64-5). These compounds induce a conformational change in the 3-dimensional structure of the enzyme that greatly reduces its activity, and thus they act as noncompetitive inhibitors. Because the binding site for NNRTIs is virus-strain specific, the approved agents are active against HIV-1 but not HIV-2 or other retroviruses and should not be used to treat HIV-2 infection. These compounds also have no activity against host cell DNA polymerases (de Bethune, 2010). The five approved NNRTIs are nevirapine, efavirenz, etravirine, rilpivirine, and delavirdine. Table 64-3 summarizes their pharmacokinetic properties.

Agents in this class share a number of properties. All approved NNRTIs are eliminated from the body by hepatic metabolism. Efavirenz, etravirine, and nevirapine are moderately potent inducers of hepatic drug-metabolizing enzymes, including CYP3A4; delavirdine is mainly a CYP3A4 inhibitor. Pharmacokinetic drug interactions are thus an important consideration with this class of compounds. All NNRTIs except etravirine and rilpivirine are susceptible to high-level drug resistance caused by single-amino-acid changes in the NNRTI-binding pocket (usually in codons 103 or 181; Kuritzkes, 2011). Exposure to even a single dose of nevirapine in the absence of other antiretroviral drugs is associated with resistance mutations in up to one-third of patients (Eshleman et al., 2004). These agents are potent and highly effective but should be combined with other active agents to avoid resistance. *NNRTIs should never be used as single agents in monotherapy or as the sole addition to a failing regimen.*

The use of efavirenz or nevirapine in combination with other antiretroviral drugs is associated with favorable long-term suppression of viremia and elevation of CD4⁺ lymphocyte counts. Rashes occur frequently with all NNRTIs, usually during the first 4 weeks of therapy. Rare cases of potentially fatal DRESS or Stevens-Johnson syndrome have been reported with nevirapine, efavirenz, rilpivirine, and etravirine. Fat accumulation can be seen after long-term use of NNRTIs, and fatal hepatitis has been associated with nevirapine use (de Bethune, 2010).

Nevirapine

Nevirapine is a dipyrindodiazepinone NNRTI with potent activity against HIV-1. The drug is FDA-approved for the treatment of HIV-1 infection in adults and children in combination with other antiretroviral agents. Nevirapine is approved for use in infants and children 15 days old or older, with dosing based on body surface area. Single-dose nevirapine was used widely in pregnant HIV-infected women to prevent mother-to-child transmission, but this practice is declining as more pregnant HIV-infected women are being placed on permanent multidrug antiretroviral regimens (de Bethune, 2010).

Figure 64–5 Mechanism of NNRTIs.

ADME. Table 64–3 summarizes the pharmacokinetic data for this agent. The drug readily crosses the placenta and has been found in breast milk. Nevirapine is a moderate inducer of CYPs and induces its own metabolism. To compensate for this, the drug should be initiated at a dose of 200 mg once daily for 14 days, with the dose then increased to 200 mg twice daily if no adverse reactions have occurred.

Untoward Effects and Drug Interactions. The most frequent adverse events associated with nevirapine are rash (in ~ 16% of patients) and pruritus. In most patients, the rash resolves with continued administration of drug; administration of glucocorticoids may cause a more severe rash. Life-threatening Stevens-Johnson syndrome is rare but occurs in up to 0.3% of recipients. Clinical hepatitis occurs in up to 1% of patients. Severe and fatal hepatitis has been associated with nevirapine use, and this may be more common in women with CD4 counts greater than 250 cells/mm³, especially during pregnancy (de Bethune, 2010). Other reported side effects include fever, fatigue, headache, somnolence, and nausea.

Because nevirapine induces CYP3A4, this drug may lower plasma concentrations of coadministered CYP3A4 substrates. Methadone withdrawal has been reported in patients receiving nevirapine, presumably as a consequence of enhanced methadone clearance. Plasma ethinyl estradiol and norethindrone concentrations decrease by 20% with nevirapine; alternative methods of birth control are advised.

Efavirenz

Efavirenz (see structure in Figure 64–5) is an NNRTI with potent activity against HIV-1. The drug should be used only in combination with other effective agents and should not be added as the sole new agent to a failing regimen. Efavirenz has been used widely because of its convenience, effectiveness, and long-term tolerability. Especially popular is the once-daily, single-pill coformulation of efavirenz, TDF, and emtricitabine. Efavirenz plus two NRTIs was a preferred regimen for naïve patients, but it is being replaced in many parts of the world by regimens with better tolerability. A 400-mg daily dose of efavirenz may be equally efficacious and better tolerated than the standard 600-mg dose (ENCORE1 Study Group, 2014).

TABLE 64–3 ■ PHARMACOKINETIC PROPERTIES OF NONNUCLEOSIDE REVERSE TRANSCRIPTASE INHIBITORS^a

PARAMETER	NEVIRAPINE ^b	EFAVIRENZ ^b	ETRAVIRINE
Oral bioavailability, %	90–93	50	NR
Effect of meals on AUC	↔	↑ 17%–28%	↑ 33%–102%

Inhibition of CYP3A	No	Yes	No

$t_{1/2}$, half-life of elimination; ↑, increase; ↓, decrease; ↔, no effect; NR, not reported.

^aReported mean values in adults with normal renal and hepatic function.

^bValues at steady state after multiple oral doses.

1146 Efavirenz can be safely combined with rifampin and is useful in patients also being treated for tuberculosis. Efavirenz is approved for adult and pediatric patients 3 years and older and weighing at least 10 kg.

ADME. Table 64–3 summarizes the pharmacokinetic data for this agent. Efavirenz is well absorbed from the GI tract, but there is diminished absorption of the drug with increasing doses. Bioavailability (AUC) is increased by 22% with a high-fat meal. Efavirenz is more than 99% bound to plasma proteins and, as a consequence, has a low CSF-to plasma ratio of 0.01. The drug should be taken initially on an empty stomach at bedtime to reduce side effects. The long elimination $t_{1/2}$ permits once-daily dosing.

Untoward Effects and Drug Interactions. The most important adverse effects of efavirenz involve the CNS. Up to 53% of patients report some CNS or psychiatric side effects, but fewer than 5% discontinue the drug for this reason. Patients commonly report dizziness, impaired concentration, dysphoria, vivid or disturbing dreams, and insomnia. CNS side effects generally become more tolerable and resolve within the first 4 weeks of therapy. Rash occurs frequently with efavirenz (27%), usually in the first few weeks of treatment, resolving spontaneously and rarely requiring drug discontinuation. Life-threatening skin eruptions such as Stevens-Johnson syndrome are rare (de Bethune, 2010). Other side effects reported with efavirenz include headache, increased hepatic transaminases, and elevated serum cholesterol. Efavirenz is the only antiretroviral drug that is teratogenic in primates, but careful clinical studies suggested that it is no more teratogenic in humans than other antiretroviral drugs (Ford et al., 2014).

Efavirenz is a moderate inducer of hepatic enzymes, especially CYP3A4, but also a weak to moderate CYP inhibitor. Efavirenz decreases concentrations of phenobarbital, phenytoin, and carbamazepine; the methadone AUC is reduced by 33%–66% at steady state. Efavirenz reduces the rifabutin AUC by about 38%. Efavirenz has a variable effect on HIV PIs: Indinavir, saquinavir, and amprenavir concentrations are reduced; ritonavir and nelfinavir concentrations are increased. Drugs that induce CYPs 2B6 or 3A4 (e.g., phenobarbital, phenytoin, and carbamazepine) would be expected to increase the clearance of efavirenz and should be avoided (de Bethune, 2010).

Rilpivirine

Rilpivirine is a diarylpyrimidine NNRTI with potent activity against HIV-1; Table 64–3 presents some of the drug's pharmacokinetic values. The drug should be used only in combination with other effective agents and should not be added as the sole new agent to a failing regimen. Rilpivirine has the best side-effect profile of available NNRTIs and has few or no CNS side effects compared to efavirenz. Rilpivirine retains efficacy against many HIV strains that are resistant to efavirenz and other earlier NNRTIs. However, higher concentrations of rilpivirine are associated with prolongation of the QTc interval and, at the approved dose of 25 mg per day, is less effective than efavirenz in patients with baseline viral load greater than 100,000 copies/mL or CD4 count below 200 cells/mm³ (Sharma and Saravolatz, 2013). Failure of a rilpivirine-containing regimen generally results in resistance that precludes the use of other NNRTIs. Rilpivirine is approved for adult and pediatric patients 12 years of age and older and weighing at least 35 kg. Rilpivirine is also available as a once-daily, single-tablet coformulation with TDF and emtricitabine or tenofovir alafenamide and emtricitabine.

ADME. Table 64–3 summarizes the pharmacokinetic data for rilpivirine. Absorption of rilpivirine is both food and pH dependent. Bioavailability (AUC) is decreased by 40% in the fasted state or by 50% with a high-protein, low-fat meal; the drug should only be given with food and not with high-protein, low-fat supplements. Rilpivirine should not be given with proton pump inhibitors, and H₂ receptor antagonists should be administered 12 h before or 4 h after dosing (Sharma and Saravolatz, 2013). The long elimination $t_{1/2}$ permits once-daily dosing.

Untoward Effects and Drug Interactions. Rash (<5%) occurs less frequently with rilpivirine than with other NNRTIs. Although CNS adverse effects are much less common with rilpivirine than with efavirenz, depressive symptoms have been reported, including in pediatric and adolescent patients. Elevated hepatic transaminases may occur, especially in those with underlying HBV or hepatitis C virus infection. Rilpivirine is considered pregnancy category B by the FDA.

Rilpivirine concentrations can be reduced by coadministered CYP inducers, and this drug should not be given with rifampin; anticonvulsants such as carbamazepine, phenobarbital, or phenytoin; or any products containing St. John's wort. At the 25-mg daily dose, rilpivirine is not a clinically significant inhibitor or inducer of hepatic enzymes. Because rilpivirine can prolong the QTc in a concentration-dependent fashion, caution is advised when combining this drug with any known CYP3A4 inhibitors or other drugs that can increase rilpivirine concentrations or with other drugs known to prolong the QTc.

Etravirine

Etravirine is a diarylpyrimidine NNRTI that is active against HIV-1. The drug is unique in its ability to inhibit reverse transcriptase that is resistant to other NNRTIs. Etravirine appears to have conformational and positional flexibility in the NNRTI-binding pocket that allow it to inhibit the function of the HIV-1 reverse transcriptase in the presence of common NNRTI resistance mutations (de Bethune, 2010). Etravirine is approved for use only in treatment-experienced adults and children 6 years or older with viral strains resistant to another NNRTI. NNRTI-experienced patients should not receive etravirine plus NRTIs alone.

ADME. Table 64–3 summarizes the pharmacokinetic data for this agent. Food increases the etravirine AUC by about 50%; thus, the drug should be administered with food. Methyl- and dimethyl-hydroxylated metabolites are produced in the liver primarily by CYPs 3A4, 2C9, and 2C19, accounting for most of the elimination of this drug.

Untoward Effects and Drug Interactions. The only notable side effect of etravirine is rash (17% vs. placebo value of 9%), usually occurring within a few weeks of starting therapy and resolving within 1–3 weeks. Severe rash, including Stevens-Johnson syndrome and toxic epidermal necrolysis, have been reported (de Bethune, 2010).

Etravirine is an inducer of CYP3A4 and glucuronosyl transferases and an inhibitor of CYPs 2C9 and 2C19; it can therefore be involved in a number of clinically significant pharmacokinetic drug interactions. Etravirine can be combined with darunavir/ritonavir, lopinavir/ritonavir, and saquinavir/ritonavir without the need for dose adjustments. The dose of maraviroc should be doubled when these two drugs are combined. Etravirine should not be administered with tipranavir/ritonavir, fosamprenavir/ritonavir, or atazanavir/ritonavir in the absence of better data to guide dosing. Etravirine should not be combined with other NNRTIs. Unlike other NNRTIs, etravirine does not appear to alter the clearance of methadone.

Delavirdine

Delavirdine is a bisheteroaryl piperazine NNRTI that selectively inhibits HIV-1. This agent shares resistance mutations with efavirenz and nevirapine.

ADME. Delavirdine is rarely used because it has to be dosed thrice daily (de Bethune, 2010). The drug is well absorbed, especially at acidic pH (pH < 2). Antacids, histamine H₂ receptor antagonists, proton pump inhibitors, and achlorhydria can decrease its absorption. The drug can be administered irrespective of concurrent food.

Untoward Effects and Drug Interactions. The most common side effect of delavirdine is rash (18%–36%), usually in the first few weeks of treatment and often resolving despite continued therapy. Severe dermatitis, including erythema multiforme and Stevens-Johnson syndrome, is rare. Elevated hepatic transaminases and hepatic failure also have been reported, as has neutropenia (rare). Delavirdine is both a substrate for and an inhibitor of CYP3A4 and can alter the metabolism of other CYP3A4 substrates. Delavirdine increases the plasma concentrations of most HIV PIs.

HIV Protease Inhibitors

Overview

The HIV PIs are peptide-like chemicals that competitively inhibit the action of the virus aspartyl protease (Figure 64–6). This protease is a homodimer consisting of two 99-amino-acid monomers; each monomer contributes an aspartic acid residue that is essential for catalysis. The preferred cleavage site for this enzyme is the N-terminal side of proline

Figure 64-6 Mechanism of action of an HIV PI. Shown here is a phenylalanine-proline target peptide sequence (in blue) for the protease enzyme (in golden brown) with chemical structures of the native amino acids (in lower box) to emphasize homology of their structures to that of saquinavir (at top).

residues, especially between phenylalanine and proline. Human aspartyl proteases (i.e., renin, pepsin, gastricsin, and cathepsins D and E) contain only one polypeptide chain and are not significantly inhibited by HIV PIs (Wensing et al., 2010).

Table 64-4 summarizes pharmacokinetic data for these agents. Clearance is mainly through hepatic oxidative metabolism. All except nelfinavir are metabolized predominantly by CYP3A4 (and nelfinavir's major metabolite is cleared by CYP3A4). All approved HIV PIs have the potential for metabolic drug interactions. Most of these drugs inhibit CYP3A4 at clinically achieved concentrations, although the magnitude of inhibition varies greatly, with ritonavir by far the most potent. It is now a common practice to combine HIV PIs with a low dose of ritonavir or cobicistat to take advantage of either drug's remarkable capacity to inhibit CYP3A4 metabolism.

"Boosting" PIs With a CYP Inhibitor. The metabolic clearance of HIV PIs is inhibited by cobicistat, a ritonavir analogue that lacks antiretroviral activity and that was developed for exclusive use as a pharmacokinetic enhancer (Sherman et al., 2015). Cobicistat is a potent and selective inhibitor of CYP 3A4 but is better tolerated than ritonavir and is not a CYP enzyme inducer. Doses of ritonavir of 100 or 200 mg once or twice daily, or cobicistat 150 mg daily, are sufficient to inhibit CYP3A4 and increase ("boost") the concentrations of most concurrently administered CYP3A4 substrates. The enhanced pharmacokinetic profile of HIV PIs administered with ritonavir or cobicistat reflects inhibition of both first-pass and

systemic clearance, resulting in improved oral bioavailability and a longer elimination $t_{1/2}$ of the coadministered drug. This allows a reduction in both drug dose and dosing frequency while increasing systemic concentrations. Combinations of either atazanavir, darunavir, fosamprenavir, lopinavir with ritonavir, or cobicistat with atazanavir or darunavir are approved for once-daily administration.

Other Shared Properties of PIs. Most HIV PIs are substrates for the P-glycoprotein efflux pump (see Chapter 5). These agents generally penetrate less well into semen than do NRTIs and NNRTIs. HIV PIs have high interindividual serum concentration variability that may reflect differential activity of intestinal and hepatic CYPs. The speed with which HIV develops resistance to unboosted PIs is intermediate between that of nucleoside analogues and NNRTIs. Initial (primary) resistance mutations in the enzymatic active site confer only a 3- to 5-fold drop in sensitivity to most drugs; these are followed by secondary mutations often distant from the active site that compensate for the reduction in proteolytic efficiency. Accumulation of secondary resistance mutations increases the likelihood of cross-resistance to other PIs. This relatively favorable resistance profile makes HIV PIs attractive agents for use as second-line therapy in patients who have failed previous antiretroviral regimens (Wensing et al., 2010).

Gastrointestinal side effects, including nausea, vomiting, and diarrhea, were common with older HIV PIs but are much less likely to occur with the newer drugs atazanavir and darunavir.

TABLE 64-4 ■ PHARMACOKINETIC PROPERTIES OF HIV-1 PROTEASE INHIBITORS^a

^aReported mean values in adults with normal renal and hepatic function.

^bParameters reported for the saquinavir soft-gel capsule formulation.

^cValues for lopinavir, tipranavir, and darunavir reflect coadministration with ritonavir.

Saquinavir

Saquinavir is a peptidomimetic hydroxyethylamine that inhibits replication of both HIV-1 and HIV-2 (Figure 64–6). Typical of HIV PIs, high-level resistance requires accumulation of multiple resistance mutations. The drug is available as a hard-gelatin capsule. When combined with ritonavir and nucleoside analogues, saquinavir produces viral load reductions comparable with those of other HIV PI regimens (Wensing et al., 2010).

ADME. See Table 64–4 for the pharmacokinetic profile of this agent. Fractional oral bioavailability is low owing mainly to first-pass metabolism, so this drug should always be given in combination with ritonavir. Low doses of ritonavir increase the saquinavir steady-state AUC by 20- to 30-fold. Substances that inhibit intestinal but not hepatic CYP3A4 (e.g., grapefruit juice) can increase the saquinavir AUC by about 3-fold.

Untoward Effects and Drug Interactions. The most frequent side effects of saquinavir are GI: nausea, vomiting, diarrhea, and abdominal discomfort. Most side effects of saquinavir are mild and short lived, although long-term use is associated with lipodystrophy.

Saquinavir clearance is increased with CYP3A4 induction. Coadministration of inducers of CYP3A4 such as rifampin, phenytoin, or carbamazepine lowers saquinavir concentrations and should be avoided. The effect of nevirapine or efavirenz on saquinavir may be reversed with ritonavir.

Ritonavir

Ritonavir is a peptidomimetic HIV PI designed to complement the C2 axis of symmetry of the enzyme active site. Ritonavir is active against both HIV-1 and HIV-2 (perhaps slightly less active against HIV-2). Ritonavir is mostly used as a pharmacokinetic enhancer (CYP3A4 inhibitor); the low doses used for this purpose are not known to induce ritonavir resistance mutations. The drug is used infrequently as the sole PI in combination regimens because of GI toxicity (Wensing et al., 2010).

ADME. Table 64–4 summarizes the pharmacokinetic profile of this agent. Interindividual variability in pharmacokinetics is high, with variability exceeding 6-fold in trough concentrations amongst patients given 600 mg of ritonavir every 12 h as capsules.

Untoward Effects and Drug Interactions. The major side effects of ritonavir are GI and include dose-dependent nausea, vomiting, diarrhea, anorexia, abdominal pain, and taste perversion. GI toxicity may be reduced if the drug is taken with meals. Peripheral and perioral paresthesias can occur at the therapeutic dose of 600 mg twice daily. These side effects generally abate within a few weeks of starting therapy. Ritonavir also causes dose-dependent elevations in serum total cholesterol and triglycerides, as well as other signs of lipodystrophy.

Ritonavir is one of the most potent known inhibitors of CYP3A4. Thus, ritonavir must be used with caution in combination with any CYP3A4 substrate and should not be combined with drugs that have a narrow therapeutic index, such as midazolam, triazolam, fentanyl, and ergot derivatives. Ritonavir is a mixed competitive and irreversible inhibitor of CYP3A4; its effects can persist for 2–3 days after the drug is discontinued (Washington et al., 2003). Ritonavir is also a weak inhibitor of CYP2D6. Potent inducers of CYP3A4 activity such as rifampin may lower ritonavir concentrations and should be avoided or the dosages adjusted. Capsule and solution formulations of ritonavir contain alcohol and should not be administered with disulfiram or metronidazole. Ritonavir is also a moderate inducer of CYP3A4, glucuronosyl-S-transferase, and possibly other hepatic enzymes and drug transport proteins. The concentrations of some drugs therefore will be decreased in the presence of ritonavir. Ritonavir reduces the ethinyl estradiol AUC by 40%; thus, alternative forms of contraception should be used.

Use of Ritonavir as a CYP3A4 Inhibitor. Ritonavir inhibits the metabolism of all current HIV PIs and is frequently used in combination with most of these drugs (with the exception of nelfinavir) to enhance their pharmacokinetic profiles and allow a reduction in their doses and dosing frequencies. Ritonavir also overcomes the deleterious effect of food on indinavir bioavailability. Low doses of ritonavir (100 or 200 mg once or

twice daily) are just as effective at inhibiting CYP3A4 and are much better tolerated than the 600-mg twice-daily dose (Wensing et al., 2010).

Fosamprenavir

Fosamprenavir is a phosphonoxy prodrug of amprenavir that has increased water solubility and improved oral bioavailability. Fosamprenavir is as effective, and generally better tolerated, than amprenavir, and as a result, amprenavir is no longer marketed (Wensing et al., 2010). The drug is active against both HIV-1 and HIV-2. Fosamprenavir has long-term virologic benefit in treatment-naïve and treatment-experienced patients, with or without ritonavir, in combination with nucleoside analogues. Twice-daily fosamprenavir/ritonavir produces virologic outcomes equivalent to lopinavir/ritonavir in both treatment-naïve and treatment-experienced patients. Fosamprenavir is approved for use in treatment-naïve pediatric patients 2 years or older and treatment-experienced patients 6 or more years of age, at a dose of 30 mg/kg twice daily or 18 mg/kg plus ritonavir 3 mg/kg twice daily. Amprenavir's primary resistance mutation occurs at HIV protease codon 50. Primary resistance occurs less frequently at codon 84.

ADME. Table 64–4 summarizes the pharmacokinetic profile of this agent. The phosphorylated prodrug is about 2000 times more water soluble than amprenavir. Fosamprenavir is dephosphorylated rapidly to amprenavir in the intestinal mucosa (Wensing et al., 2010). Meals have no significant effect on fosamprenavir pharmacokinetics.

Untoward Effects and Drug Interactions. The most common adverse effects involve the GI tract and include diarrhea, nausea, and vomiting. Hyperglycemia, fatigue, paresthesias, and headache also have been reported. Fosamprenavir can produce skin eruptions; moderate-to-severe rash (in up to 8% of recipients) may occur within 2 weeks of starting therapy. Fosamprenavir has fewer effects on plasma lipid profiles than lopinavir-based regimens.

Inducers of hepatic CYP3A4 activity (e.g., rifampin and efavirenz) may lower plasma amprenavir concentrations. Because amprenavir is both an inhibitor and inducer of CYP3A4, pharmacokinetic drug interactions can occur and may be unpredictable, especially if the drug is given without ritonavir.

Lopinavir

Lopinavir is structurally similar to ritonavir but is 3- to 10-fold more potent against HIV-1. This agent is active against both HIV-1 and HIV-2. Lopinavir is available only in coformulation with low doses of ritonavir used as a CYP3A4 inhibitor. Lopinavir has antiretroviral activity comparable with that of other potent HIV PIs and better than that of nelfinavir. Lopinavir also has considerable and sustained antiretroviral activity in patients who have failed previous HIV PI-containing regimens (Wensing et al., 2010).

Treatment-naïve patients who fail a first regimen containing lopinavir generally do not have detectable HIV protease mutations but may have genetic resistance to the other drugs in the regimen (Wensing et al., 2010). For treatment-experienced patients, accumulation of four or more HIV PI resistance mutations is associated with a reduced likelihood of virus suppression after starting lopinavir.

ADME. Table 64–4 summarizes the pharmacokinetic profile of this agent. The adult lopinavir/ritonavir dose is 400/100 mg (2 tablets) twice daily, or 800/200 mg (4 tablets) once daily. Lopinavir/ritonavir should not be dosed once daily in treatment-experienced patients. Lopinavir/ritonavir is approved for use in pediatric patients 14 days or older, with dosing based on either weight or body surface area. A pediatric tablet formulation is available for use in children more than 6 months of age. Lopinavir is absorbed rapidly after oral administration. Food has a minimal effect on bioavailability. Although the tablets contain lopinavir/ritonavir in a fixed 4:1 ratio, the observed plasma concentration ratio for these two drugs following oral administration is nearly 20:1, reflecting the sensitivity of lopinavir to the inhibitory effect of ritonavir on CYP3A4. Both lopinavir and ritonavir are highly bound to plasma proteins, mainly to α 1-acid glycoprotein, and have a low fractional penetration into CSF and semen.

1150 Untoward Effects and Drug Interactions. The most common adverse events reported with the lopinavir/ritonavir coformulation are GI: loose stools, diarrhea, nausea, and vomiting. Laboratory abnormalities include elevated total cholesterol and triglycerides. It is unclear whether these side effects are due to ritonavir, lopinavir, or both.

Concomitant administration of agents that induce CYP3A4, such as rifampin, may lower plasma lopinavir concentrations considerably. St. John's wort is a known inducer of CYP3A4, leading to lower concentrations of lopinavir and possible loss of antiviral effectiveness. Coadministration of other antiretrovirals that can induce CYP3A4 (e.g., amprenavir, nevirapine, or efavirenz) may require increasing the dose of lopinavir. The liquid formulation of lopinavir contains 42% ethanol and should not be administered with disulfiram or metronidazole. Ritonavir is also a moderate CYP inducer at the dose employed in the coformulation and can adversely decrease concentrations of some coadministered drugs (e.g., oral contraceptives). There is no direct proof that lopinavir is a CYP inducer in vivo; however, concentrations of some coadministered drugs (e.g., amprenavir and phenytoin) are lower with the lopinavir/ritonavir coformulation than would have been expected with low-dose ritonavir alone.

Atazanavir

Atazanavir is an azapeptide PI that is active against both HIV-1 and HIV-2. A coformulation with cobicistat (EVOTAZ) is also available.

Therapeutic Use. Atazanavir, with or without ritonavir, is approved for treatment of adults and pediatric patients more than 3 months of age and weighing at least 5 kg; in the pediatric population, dosing is based on weight. In treatment-experienced adult patients, atazanavir 400 mg once daily without ritonavir was inferior to the lopinavir/ritonavir coformulation given twice daily. The combination of atazanavir and low-dose ritonavir had a similar viral load effect as the lopinavir/ritonavir coformulation in one study, suggesting that this drug should be combined with ritonavir or cobicistat in treatment-experienced patients and perhaps in treatment-naïve patients with high baseline viral loads. The primary atazanavir resistance mutation occurs at HIV protease codon 50 and confers about 9-fold decreased susceptibility. High-level resistance is more likely if five or more additional mutations are present (Wensing et al., 2010).

ADME. Table 64–4 summarizes the pharmacokinetic profile of this agent. Atazanavir is absorbed rapidly after oral administration. A light meal increases the AUC; thus, the drug should be administered with food. Absorption is pH dependent, and proton pump inhibitors or other acid-reducing agents substantially reduce atazanavir concentrations after oral dosing (Wensing et al., 2010). The mean elimination $t_{1/2}$ of atazanavir increases with dose, from 7 h at the standard 400-mg once-daily dose to nearly 10 h at a dose of 600 mg. The atazanavir dose is 400 mg once daily in adults if given without a pharmacokinetic enhancer (ritonavir or cobicistat) and 300 mg if given with ritonavir 100 mg or cobicistat 150 mg. The drug is present in CSF at less than 3% of plasma concentrations but has excellent penetration into seminal fluid.

Untoward Effects and Drug Interactions. Atazanavir frequently causes unconjugated hyperbilirubinemia, although this is not associated with hepatotoxicity. Postmarketing reports include hepatic adverse reactions of cholecystitis, cholelithiasis, cholestasis, and other hepatic function abnormalities. Atazanavir can precipitate in urine, causing increased risk of kidney stones. Other side effects reported with atazanavir include diarrhea and nausea, mainly during the first few weeks of therapy. Overall, 6% of patients discontinue atazanavir because of side effects during 48 weeks of treatment. Patients treated with atazanavir have significantly lower fasting triglyceride and cholesterol concentrations than patients treated with nelfinavir, lopinavir, or efavirenz.

Because atazanavir is metabolized by CYP3A4, concomitant administration of agents that induce CYP3A4 (e.g., rifampin) is contraindicated. Atazanavir is also a moderate inhibitor of CYP3A4 and may alter plasma concentrations of other CYP3A4 substrates. Atazanavir is a moderate UGT1A1 inhibitor and increases the raltegravir AUC by 41%–72%. Ritonavir significantly increases the atazanavir AUC and reduces atazanavir systemic clearance. Concomitantly administered proton pump

inhibitors reduce atazanavir concentrations substantially. Proton pump inhibitors and H_2 receptor antagonists should be avoided in patients receiving atazanavir without ritonavir (Wensing et al., 2010).

Darunavir

Darunavir is a nonpeptidic PI that is active against both HIV-1 and HIV-2. Darunavir binds tightly but reversibly to the active site of HIV protease but has also been shown to prevent protease dimerization. At least three darunavir-associated resistance mutations are required to confer resistance (Wensing et al., 2010). Darunavir in combination with ritonavir is approved for use in HIV-infected adults and children more than 3 years old. A coformulation with cobicistat is also available.

DARUNAVIR

ADME. Table 64–4 presents some pharmacokinetic data on this agent. Darunavir/ritonavir can be used as a once-daily (800-/100-mg) regimen with nucleosides in treatment-naïve adults or as a twice-daily (600-/100-mg) regimen in treatment-experienced adults with at least one darunavir-associated resistance mutation; this drug should be taken with food. Pediatric dosing is based on body weight. Darunavir is absorbed rapidly after oral administration with ritonavir, with peak concentrations occurring after 2–4 h. Ritonavir increases darunavir bioavailability by up to 14-fold. When combined with ritonavir, the mean elimination $t_{1/2}$ of darunavir is about 15 h, and the AUC is increased by an order of magnitude.

Untoward Effects and Drug Interactions. Because darunavir must be combined with cobicistat or a low dose of ritonavir, drug administration can be accompanied by all of the side effects caused by those agents, including drug interactions and GI complaints in up to 20% of patients taking ritonavir. Darunavir, like fosamprenavir, contains a sulfa moiety, and rash has been reported in up to 10% of recipients. Darunavir/ritonavir is associated with increases in plasma triglycerides and cholesterol, although the magnitude of increase is lower than that seen with lopinavir/ritonavir. Darunavir has been associated with episodes of hepatotoxicity.

Because darunavir is metabolized by CYP3A4, concomitant administration of agents that induce CYP3A4 (e.g., rifampin) is contraindicated. The drug interaction profiles of darunavir/ritonavir or darunavir/cobicistat are dominated by those expected with the pharmacokinetic enhancer. Darunavir/ritonavir 600/100 twice daily increases the maraviroc AUC by 340%; the maraviroc dose should be reduced to 150 mg twice daily when combined with darunavir (Wensing et al., 2010).

Indinavir

Indinavir, a peptidomimetic HIV PI, lacks significant advantages over other HIV PIs and is no longer widely prescribed because of problems with nephrolithiasis and other nephrotoxicities (Wensing et al., 2010).

ADME. Table 64–4 summarizes the pharmacokinetic profile of indinavir. The drug is absorbed rapidly after oral administration, with peak concentrations achieved in about 1 h. High-calorie, high-fat meals reduce the C_p by 75%; thus, indinavir must be taken with ritonavir or while fasting or with a light low-fat meal. Indinavir has the lowest protein binding of the HIV PIs; as a consequence, indinavir has higher fractional CSF penetration than other drugs in this class. The short $t_{1/2}$ of indinavir makes thrice-daily (every 8 h) dosing necessary unless the drug is combined with ritonavir, which reduces indinavir clearance, allowing twice-daily dosing regardless of meals.

Untoward Effects and Drug Interactions. A unique adverse effect of indinavir is crystalluria and nephrolithiasis, stemming from the poor solubility of the drug (lower at pH 7.4 than at pH 3.5). Nephrolithiasis occurs in about 3% of patients. Patients must drink sufficient fluids to maintain dilute urine and prevent renal complications. Risk of nephrolithiasis is related to higher plasma drug concentrations. Patients taking indinavir should drink at least 2 L of water daily to prevent renal complications. This is especially problematic for those who live in warm climates. Because indinavir solubility decreases at higher pH, antacids or other buffering agents should not be taken at the same time. Didanosine formulations containing an antacid buffer should not be taken within 2 h before or 1 h after indinavir. This agent is metabolized by CYP3A4 and is a moderately potent CYP3A4 inhibitor; thus, indinavir should not be coadministered with other CYP3A4 substrates that have narrow therapeutic indices.

Indinavir frequently causes unconjugated hyperbilirubinemia. This is generally asymptomatic and not associated with serious long-term sequelae. Indinavir has been associated with hyperglycemia and can induce insulin resistance. Dermatologic complications have been reported, including hair loss, dry skin, dry and cracked lips, and ingrown toenails.

Nelfinavir

Nelfinavir is a nonpeptidic PI that is active against both HIV-1 and HIV-2. Nelfinavir is approved for the treatment of HIV infection in adults and children in combination with other antiretroviral drugs. Long-term virologic suppression with nelfinavir-based combination regimens is significantly inferior to lopinavir/ritonavir, atazanavir, or efavirenz-based regimens. Nelfinavir is rarely used because of the availability of better tolerated and more efficacious PIs (Wensing et al., 2010).

The primary nelfinavir resistance mutation (D30N) is unique to this drug and results in a 7-fold decrease in susceptibility. Isolates with only this mutation retain full sensitivity to other HIV PIs. Less commonly, a primary resistance mutation occurs at position 90, which can confer cross-resistance. Secondary resistance mutations can accumulate, and these are associated with further resistance to nelfinavir, as well as cross-resistance to other HIV PIs.

ADME. The pharmacokinetic profile of this agent appears in Table 64-4. A moderate-fat meal increases the AUC 2- to 3-fold; higher concentrations are achieved with high-fat meals. Intraindividual and interindividual variabilities in plasma nelfinavir concentrations are large as a consequence of variable absorption. Nelfinavir is the only HIV PI whose pharmacokinetics are not substantially improved with ritonavir. Its major hydroxy-t-butylamide metabolite, M8, the only known active metabolite of any HIV PI, is formed by CYP2C19; its antiretroviral activity rivals that of the parent drug. Nelfinavir induces its own metabolism.

Untoward Effects and Drug Interactions. The most important side effects of nelfinavir are diarrhea and loose stools, which resolve in most patients within the first 4 weeks of therapy. Otherwise, nelfinavir is generally well tolerated. It has been associated with glucose intolerance, elevated cholesterol levels, and elevated triglycerides.

Because nelfinavir is metabolized by CYPs 2C19 and 3A4, concomitant administration of agents that induce these enzymes may be contraindicated (as with rifampin) or may necessitate an increased nelfinavir dose (as with rifabutin). Nelfinavir is a moderate inhibitor of CYP3A4 and may alter plasma concentrations of other CYP3A4 substrates. Nelfinavir also induces hepatic drug-metabolizing enzymes, reducing the AUC of ethinyl estradiol (↓ 47%) and norethindrone (↓ 18%). Combination oral contraceptives therefore should not be used as the sole form of contraception in patients taking nelfinavir. Nelfinavir reduces the zidovudine AUC by 35%.

Tipranavir

Tipranavir is a nonpeptidic PI that is active against both HIV-1 and HIV-2. Tipranavir is approved for use only in treatment-experienced adult and pediatric patients whose HIV is resistant to one or more PIs. Combining tipranavir/ritonavir with at least one other active antiretroviral drug, usually enfuvirtide, greatly improves virologic responses.

Tipranavir/ritonavir is approved for use in adults and pediatric patients more than 2 years of age, with pediatric dosing based on weight or body surface area. Because most HIV strains sensitive to tipranavir are also sensitive to darunavir, darunavir is preferred for most treatment-experienced patients because of its better tolerability and toxicity profile (Wensing et al., 2010).

ADME. Table 64-4 summarizes the pharmacokinetic profile of this agent. Tipranavir must be administered with ritonavir because of poor oral bioavailability. The recommended regimen of tipranavir/ritonavir 500/200 mg twice daily includes a ritonavir dose higher than that of other boosted HIV PIs; lower doses of ritonavir should not be used. Food does not alter pharmacokinetics in the presence of ritonavir but may reduce GI side effects.

Untoward Effects and Drug Interactions. Tipranavir use has been associated rarely with fatal hepatotoxicity and also with intracranial hemorrhage (including fatalities) and bleeding episodes in patients with hemophilia. The drug has anticoagulant properties in vitro and in animal models that are potentiated by vitamin E. Tipranavir is more likely to cause elevation in lipids and triglycerides than other boosted PIs, possibly due to the higher dose of ritonavir with which it is administered. Tipranavir contains a sulfa moiety, and about 10% of treated patients report a transient rash. The current formulation contains a high amount of vitamin E; patients should not take supplements containing this vitamin.

Like ritonavir, tipranavir is a substrate, inhibitor, and inducer of CYP enzymes. Tipranavir/ritonavir reduces the concentrations (AUC) of all coadministered PIs by 44%–76% and should not be administered with any of these agents. This reflects the combined effect of the increased ritonavir dose, as well as tipranavir's unique capacity amongst PIs to induce expression of the P-glycoprotein drug transporter.

Entry Inhibitors

The two drugs available in this class, enfuvirtide and maraviroc, have different mechanisms of action (see Figure 64-1). Enfuvirtide inhibits fusion of the viral and cell membranes mediated by gp41 and CD4 interactions. Maraviroc is a chemokine receptor antagonist and binds to the host cell CCR5 receptor to block binding of viral gp120 (Tilton and Doms, 2010).

Maraviroc

Maraviroc blocks the binding of the HIV outer envelope protein gp120 to the CCR5 chemokine receptor (Figure 64-7). Maraviroc is approved for use in HIV-infected adults who have baseline evidence of predominantly CCR5-tropic virus. The drug has no activity against viruses that are CXCR4-tropic or dual-tropic (Tilton and Doms, 2010). Maraviroc retains activity against viruses that have become resistant to antiretroviral agents of other classes because of its unique mechanism of action.

HIV can develop resistance to this drug through two distinct pathways. A patient starting maraviroc therapy with HIV that is predominantly CCR5-tropic may experience a shift in tropism to CXCR4- or dual/mixed tropism predominance. This is especially likely in patients harboring low-level but undetected CXCR4- or dual/mixed-tropic virus prior to initiation of maraviroc. Alternatively, HIV can retain its CCR5-tropism but gain resistance to the drug through specific mutations in the V3 loop of gp120 that allow virus binding in the presence of inhibitor (Kuritzkes, 2011).

ADME. Maraviroc is the only antiretroviral drug approved at three different starting doses, depending on concomitant medications. When combined with most CYP3A inhibitors, the starting dose is 150 mg twice daily; when combined with most CYP3A inducers, the starting dose is 600 mg twice daily; for other concomitant medications, the starting dose is 300 mg twice daily. Once-daily maraviroc has been studied, but is not FDA-approved. The oral bioavailability of maraviroc, 23%–33%, is dose dependent. Food decreases bioavailability, but there are no food requirements for drug administration.

Untoward Effects and Drug Interactions. Maraviroc is generally well tolerated, but can cause dose- and concentration-dependent orthostatic

Figure 64–7 Mechanism of action of the HIV entry inhibitor maraviroc.

hypotension. Although one case of serious hepatotoxicity with allergic features has been reported, significant (grade 3 or 4) hepatotoxicity was no more frequent with maraviroc than with placebo in controlled trials.

Maraviroc is a CYP3A4 substrate and susceptible to pharmacokinetic drug interactions involving CYP3A4 inhibitors or inducers. Maraviroc itself is not a CYP inhibitor or inducer in vivo, although high-dose maraviroc (600 mg daily) can increase concentrations of the CYP2D6 substrate debrisoquine.

Enfuvirtide

Enfuvirtide is a 36-amino-acid synthetic peptide that is not active against HIV-2 but is broadly effective against laboratory and clinical isolates of HIV-1. Enfuvirtide is FDA-approved for use only in treatment-experienced adults and children more than 6 years of age who have evidence of HIV replication despite ongoing antiretroviral therapy. The drug's cost and route of administration (subcutaneous injection twice daily) limit its use to those with no other treatment options (Tilton and Doms, 2010).

Mechanisms of Action and Resistance. The amino acid sequence of enfuvirtide derives from the transmembrane gp41 region of HIV-1 that is involved in fusion of the virus membrane lipid bilayer with that of the host cell membrane. The peptide blocks the interaction between the N36 and C34 sequences of the gp41 glycoprotein by binding to a hydrophobic groove in the N36 coil. This prevents formation of a six-helix bundle critical for membrane fusion and viral entry into the host cell (Tilton and Doms, 2010). Enfuvirtide inhibits infection of CD4⁺ cells by free virus particles. Enfuvirtide retains activity against viruses that have become resistant to antiretroviral agents of other classes. HIV can develop resistance to this drug through specific mutations in the enfuvirtide-binding domain of gp41.

ADME. Enfuvirtide is the only approved antiretroviral drug that must be administered parenterally. The bioavailability of subcutaneous enfuvirtide is 84% compared with an intravenous dose. Pharmacokinetics of the subcutaneous drug are not affected by site of injection. The major route of elimination for enfuvirtide has not been determined. The mean elimination $t_{1/2}$ of parenteral drug is 3.8 h, necessitating twice-daily administration, which may create adherence issues for the patient.

Untoward Effects and Drug Interactions. The most prominent adverse effects of enfuvirtide are injection-site reactions. Most patients (98%) develop local side effects, including pain, erythema, and induration at the site of injection; 80% of patients develop nodules or cysts. Use of enfuvirtide has been associated with a higher incidence of lymphadenopathy and pneumonia. Enfuvirtide is not known to alter the concentrations of any coadministered drugs.

Integrase Inhibitors

Overview

Chromosomal integration is a defining characteristic of retrovirus life cycles and allows viral DNA to remain in the host cell nucleus for a prolonged period of inactivity or latency (Figure 64–1). Because human DNA is not known to undergo excision/reintegration, this process is an excellent target for selective antiviral intervention. The HIV integrase inhibitors prevent formation of covalent bonds between host and viral DNA—a process known as strand transfer—presumably by interfering with essential divalent cations in the enzyme's catalytic core (see Figure 64–8). In clinical trials, HIV integrase inhibitors produce a more rapid decline in plasma viral RNA over the first 3–4 months of therapy than other antiretroviral agents and are generally better tolerated than comparator agents (Hicks and Gulick, 2009).

Raltegravir

Raltegravir blocks the catalytic activity of the HIV-encoded integrase, preventing integration of viral DNA into the host chromosome (Figure 64–8). Raltegravir has potent activity against both HIV-1 and HIV-2. Because of its unique mechanism of action, this agent retains activity against viruses that have become resistant to antiretroviral agents of other classes. Raltegravir is approved for use in HIV-infected adults and children more than 4 weeks of age. A 1200 mg once-daily oral formulation was recently approved, eliminating the need for twice daily dosing.

ADME. Peak concentrations of raltegravir occur about 1 h after oral dosing. Elimination is biphasic, with an α -phase $t_{1/2}$ of about 1 h and a terminal β phase $t_{1/2}$ of about 12 h, with the α phase predominating. The pharmacokinetics of raltegravir are highly variable. Moderate- and high-fat meals

Figure 64–8 Mechanism of action of the HIV integrase inhibitor raltegravir.

increase raltegravir's AUC by as much as 2-fold; a low-fat meal decreases AUC modestly (\downarrow 46%); however, there are no food requirements for raltegravir administration. The drug is 83% protein bound in human plasma. Raltegravir is eliminated mainly via glucuronidation by UGT1A1 (Hicks and Gulick, 2009).

Untoward Effects and Drug Interactions. Raltegravir generally is well tolerated, with little clinical toxicity. The most common complaints are headache, nausea, asthenia, and fatigue, which are also associated with coadministered NRTIs. Creatine kinase elevations, myopathy, and rhabdomyolysis have been reported, as has exacerbation of depression, but their relationship to raltegravir use is not clear (Hicks and Gulick, 2009). Raltegravir is rarely associated with DRESS (Ripamonti et al., 2014).

As a UGT1A1 substrate, raltegravir is susceptible to pharmacokinetic drug interactions involving inhibitors or inducers of this enzyme. Atazanavir, a moderate UGT1A1 inhibitor, increases the raltegravir AUC (41%–72%). Tenofovir increases the raltegravir AUC by 49%, but the mechanism for this interaction is unknown. When raltegravir is combined with the CYP inducer rifampin, the raltegravir dose should be doubled to 800 mg twice daily. Raltegravir has little effect on the pharmacokinetics of the usual coadministered drugs. Because the mechanism of action of HIV integrase strand transfer inhibitors involves chelation with a divalent cation (Mg^{2+}) in the enzyme active site, chelation of divalent cations may occur in the GI tract following oral administration. It is therefore necessary to give magnesium- or aluminum-containing antacids and sucralfate 6 h before or 2 h after raltegravir. Administration of calcium and iron-containing supplements should also be separated from raltegravir by at least 2 h.

Elvitegravir

Elvitegravir blocks the catalytic activity of the HIV-encoded integrase, preventing integration of viral DNA into the host chromosome for both HIV-1 and HIV-2. Elvitegravir retains activity against viruses that have become resistant to antiretroviral agents of other classes, but shares cross-resistance with mutations affecting the HIV integrase inhibitor raltegravir (Johnson and Saravolatz, 2014). Elvitegravir is available only in single-tablet, once-daily coformulations with cobicistat, emtricitabine, and tenofovir disoproxil fumarate (STRIBILD) or tenofovir alafenamide (GENVOYA). These coformulations are approved for use in HIV-infected adults and children more than 12 years of age.

A Note on Cobicistat. Cobicistat selectively inhibits CYP3A4 with potency similar to that of ritonavir but without anti-HIV activity (Sherman et al., 2015). Additional potential advantages compared to ritonavir include greater specificity for CYP 3A4, better tolerability, reduced impact on plasma lipids, and lack of P450 enzyme induction. However, cobicistat can inhibit some drug transport proteins and blocks the tubular transport of creatinine, resulting in a small but reversible increase in serum

creatinine. Cobicistat is available only in coformulation with elvitegravir, atazanavir, or darunavir.

ADME. Peak concentrations of elvitegravir occur about 4 h after oral dosing. The plasma $t_{1/2}$ of elvitegravir (administered as STRIBILD) is approximately 13 h. Because light or high-fat meals increase the AUC of elvitegravir by 34% or 87%, respectively, elvitegravir coformulations should be given with food. The drug is largely (98%–99%) protein bound in human plasma. Unlike raltegravir and dolutegravir, elvitegravir is eliminated mainly by CYP 3A4, thus explaining the substantial pharmacokinetic benefit of combining it with cobicistat. Elvitegravir coformulations should not be given to patients with baseline estimated creatinine clearance below 70 mL/min (for STRIBILD) or 30 mL/min (for GENVOYA) because of potential effects on the NRTI components of the tablet (Johnson and Saravolatz, 2014).

Untoward Effects and Drug Interactions. Like other HIV integrase inhibitors, elvitegravir is well tolerated. In clinical trials, the only side effects reported in more than 10% of elvitegravir recipients were nausea and diarrhea; fewer than 1% of patients discontinued treatment due to adverse drug effects.

Although elvitegravir by itself is not likely to cause clinically significant drug-drug interactions, the impact of the coformulations with other drugs is dominated by the effects of cobicistat, which is a potent inhibitor of CYP 3A4 and a weak inhibitor of CYP 2D6. Caution is warranted in administering elvitegravir coformulations with other CYP 3A4 substrates with low therapeutic indices or with CYP 3A4 inducers that could lower concentrations of cobicistat or elvitegravir. This includes rifamycins and St. John's wort. As with raltegravir, elvitegravir coformulations are subject to similar restrictions for coadministration of oral divalent cations (Mg^{2+} , Al^{3+} , Ca^{2+} , Fe^{2+}). Because tenofovir plus emtricitabine is effective suppressive therapy for chronic HBV infection (see Chapter 63), these coformulations may be used in patients coinfecting with HIV-HBV, but they should not be discontinued abruptly because of the risk of rebound HBV replication and acute liver damage.

Dolutegravir

Dolutegravir blocks the catalytic activity of the HIV-encoded integrase of HIV-1 and HIV-2, preventing integration of viral DNA into the host chromosome. Dolutegravir retains activity against viruses that have become resistant to antiretroviral agents of other classes and also remains active against some viruses that are resistant to raltegravir or elvitegravir. Dolutegravir is approved for use in HIV-infected adults and children more than 12 years of age and weighing at least 40 kg. Dolutegravir is also available as a single-tablet, once-daily coformulation with abacavir and lamivudine. Given its high efficacy, tolerability, and convenience, dolutegravir is increasingly popular as a starting agent in

1154 treatment-naïve HIV-infected patients in high-income countries (Osterholzer and Goldman, 2014).

ADME. Peak concentrations of dolutegravir occur 3–4 h after oral dosing, which may be done without regard to concurrent food. The drug is 99% protein bound in human plasma; its plasma elimination $t_{1/2}$ is about 12 h. Like raltegravir, dolutegravir is eliminated mainly by UGT1A1. Subjects with UGT1A1 slow metabolism genotypes had a 32% lower clearance of dolutegravir and 46% higher AUC, although this is not thought to have clinical significance (Osterholzer and Goldman, 2014).

Untoward Effects and Drug Interactions. Like other HIV integrase inhibitors, dolutegravir is well tolerated. Hypersensitivity reactions, including rash and organ dysfunction, have been reported rarely (<1% of recipients). Because dolutegravir inhibits the renal organic cation transporter OCT2, it causes small increases in serum creatinine (0.1–0.2 mg/dL) that persist during therapy but are immediately reversible once the drug is stopped.

Dolutegravir has low potential to cause clinically significant drug-drug interactions. Its capacity to inhibit the renal organic cation transporter OCT2 likely explains its effects to double concentrations of metformin. Dolutegravir is susceptible to decreases in plasma concentrations caused by inducers of drug-metabolizing enzymes and should not be coadministered with efavirine, nevirapine, or St. John's wort. For some enzyme inducers such as rifampin, efavirenz, and ritonavir-boosted HIV PIs, the dolutegravir dose can be increased from 50 mg once daily to 50 mg twice daily to counter this effect (Dooley et al., 2013). Similar to other HIV integrase inhibitors, dolutegravir should be taken 2 h before or 6 h after cation-containing antacids or laxatives, sucralose, or oral supplements containing Fe^{2+} or Ca^{2+} . However, supplements containing Fe^{2+} or Ca^{2+} can be taken at the same time as dolutegravir if given with food (Osterholzer and Goldman, 2014). Lamivudine is no longer considered adequate suppressive therapy for chronic HBV infection; therefore, the coformulation of dolutegravir with abacavir and lamivudine should not be considered adequate treatment of HBV in coinfecting patients (see Chapter 63). If a patient is coinfecting with HBV or becomes infected during treatment, abrupt discontinuation of dolutegravir/abacavir/lamivudine may result in rebound HBV replication and acute liver damage. The dolutegravir/abacavir/lamivudine combination should not be given to patients who are known to carry the HLA-B*5701 allele because of the risk of abacavir hypersensitivity.

Future Treatment Guidelines

Several expert panels issue periodic recommendations for use of antiretroviral drugs for treatment-naïve and treatment-experienced adults and children. In the U.S., the Panel on Clinical Practices for Treatment of HIV Infection issues updated guidelines approximately every 6 months; their most recent guidelines can be accessed online (<http://www.aidsinfo.nih.gov/Guidelines>) (Department of Health and Human Services, 2016).

Treatment recommendations compare various regimens currently available for treatment-naïve patients and also address when to change therapy in individuals who are failing their current regimen. The specific drugs recommended may change as new choices become available and clinical research data accumulate. Selection of drugs in the developed world will be driven by genotypic and phenotypic resistance testing. However, future treatment guidelines will likely continue to be driven by three principles:

- Use of combination therapy to prevent the emergence of resistant virus
- Emphasis on regimen convenience, tolerability, and adherence in order to chronically suppress HIV replication
- Realization of the need for lifelong treatment under most circumstances

Treatment guidelines are not sufficient to dictate all aspects of patient management. Prescribers of antiretroviral therapy must maintain a comprehensive and current fund of knowledge regarding this disease and its pharmacotherapy. Because the treatment of HIV infection is a long-lived and complex affair, and because mistakes can have dire and irreversible consequences for the patient, the prescribing of these drugs should be limited to those with specialized training. Prescribers should also be aware that several additional antiretroviral agents are in advanced clinical development and could alter treatment possibilities. These include the NNRTI doravirine and the integrase strand transfer inhibitor (INSTI), cabotegravir and bictegravir (Flexner and Saag, 2013). Experimentally, cabotegravir has been formulated in nanoparticles having a $t_{1/2}$ of 3 weeks, raising the possibility of a sustained-release formulation that would deliver the drug for several months.

Acknowledgment: Stephen P. Raffanti and David W. Haas contributed to this chapter in an earlier edition of this book. We have retained some of their text in the current edition.

Drug Facts for Your Personal Formulary: Antiretroviral Agents and Treatment of HIV Infection

Drug	Therapeutic Use	Clinical Pharmacology and Tips
Nucleoside/Nucleotide Reverse Transcriptase Inhibitors (phosphorylated to active form to prevent infection of susceptible cells; do not eradicate virus from cells with integrated proviral DNA): Active against HIV-1 and HIV-2 and in some cases HBV		
Zidovudine (AZT) (thymidine analogue)	<ul style="list-style-type: none">• HIV in adults and children• Preventing mother-to-child transmission	<ul style="list-style-type: none">• Adverse effects: bone marrow (anemia, neutropenia) and muscle toxicity (myopathy); inhibits mitochondrial DNA polymerase γ• Do not use with stavudine
Stavudine (d4T)	<ul style="list-style-type: none">• HIV in adults and children	<ul style="list-style-type: none">• Adverse effects: sensory neuropathy and lipoatrophy• Do not use with zidovudine• Avoid use because of long-term and potentially irreversible toxicities
Lamivudine	<ul style="list-style-type: none">• HIV in adults and children ≥ 3 months• Chronic hepatitis B (adults, children)	<ul style="list-style-type: none">• Essentially nontoxic
Abacavir (only guanosine analogue antiretroviral)	<ul style="list-style-type: none">• HIV in adults and children• Not active against HBV	<ul style="list-style-type: none">• Bioavailability not affected by food• Adverse effects: hypersensitivity syndrome (fever, abdominal pain, rash), associated with HLA B*5701 genotype; discontinue drug immediately and never use again as this is potentially fatal

Nucleoside/Nucleotide Reverse Transcriptase Inhibitors (phosphorylated to active form to prevent infection of susceptible cells; do not eradicate virus from cells with integrated proviral DNA): Active against HIV-1 and HIV-2 and in some cases HBV (continued)		
Tenofovir (5'-AMP derivative; supplied as prodrugs: TDF or TAF)	<ul style="list-style-type: none"> HIV infection (adults, children > 2 years, in combination with other antiretrovirals) Chronic hepatitis B (adults, children > 12 years) HIV preexposure prophylaxis (with emtricitabine) in adults at high risk of infection 	<ul style="list-style-type: none"> Nephrotoxicity: small decreases in estimated creatinine clearance are common; Fanconi syndrome rare Decreases in bone mineral density with chronic use
Emtricitabine	<ul style="list-style-type: none"> HIV infection (adults, children, in combination with other antiretrovirals) Chronic hepatitis B (adults, children) HIV preexposure prophylaxis (with tenofovir) in adults at high risk of infection 	<ul style="list-style-type: none"> Generally nontoxic
Didanosine	<ul style="list-style-type: none"> HIV infection in adults and children 	<ul style="list-style-type: none"> Adverse effects: sensory neuropathy and pancreatitis Avoid use because of long-term and potentially irreversible toxicities
Nonnucleoside Reverse Transcriptase Inhibitors: Do not require metabolic activation; HIV-1 specific and not active against HIV-2		
Nevirapine	<ul style="list-style-type: none"> HIV-1 infection in infants, children, and adults Single-dose prevention of mother-to-child transmission 	<ul style="list-style-type: none"> Autoinducer of metabolism Commonly produces rash that usually resolves with continued treatment Can rarely produce life-threatening skin eruptions such as Stevens-Johnson syndrome Rarely produces life-threatening hepatitis
Efavirenz	<ul style="list-style-type: none"> HIV-1 infection in children ≥ 3 years and adults 	<ul style="list-style-type: none"> Commonly causes CNS toxicity that usually resolves with continued treatment but can be severe enough to warrant discontinuation Moderate hepatic enzyme inducer
Rilpivirine	<ul style="list-style-type: none"> HIV-1 infection in children > 12 years and adults 	<ul style="list-style-type: none"> Must be given with food Avoid proton pump inhibitors because of reduced absorption May cause prolonged QTc interval if concentrations are too high
Etravirine	<ul style="list-style-type: none"> Treatment-experienced adults and children ≥ 6 years 	<ul style="list-style-type: none"> Commonly produces rash that usually resolves with continued treatment Can rarely produce life-threatening skin eruptions such as Stevens-Johnson syndrome Moderate inducer of hepatic enzymes
Delavirdine	<ul style="list-style-type: none"> Adults with HIV infection 	<ul style="list-style-type: none"> Rash commonly and rarely Stevens-Johnson syndrome Rarely used because of the requirement for thrice-daily dosing
Protease Inhibitors: Active against HIV-1 and HIV-2; generally used as second-line agents in treatment-experienced patients		
Saquinavir	<ul style="list-style-type: none"> Second-line treatment of HIV in adults and children 	<ul style="list-style-type: none"> Rarely used because of better-tolerated alternative PIs
Ritonavir	<ul style="list-style-type: none"> Used only as a PK-boosting agent in combination with other PIs 	<ul style="list-style-type: none"> Commonly causes nausea Associated with elevated cholesterol and triglycerides at higher doses Potent inhibitor of CYP3A4 Moderate hepatic enzyme inducer
Fosamprenavir	<ul style="list-style-type: none"> HIV-infected adults, treatment-naïve children ≥ 2 years and treatment-experienced children ≥ 6 years 	<ul style="list-style-type: none"> Adverse effects: diarrhea, nausea, and vomiting Occasional skin rashes

Atazanavir	<ul style="list-style-type: none"> Treatment-naïve or -experienced HIV-infected adults and children ≥ 3 months 	<ul style="list-style-type: none"> Usually combined with ritonavir or cobicistat Can be given without a PK booster at a higher dose of 400 mg Absorption reduced with proton pump inhibitors and H₂ blockers Commonly causes unconjugated hyperbilirubinemia Can cause nephrolithiasis and cholelithiasis
Darunavir	<ul style="list-style-type: none"> Treatment-naïve or -experienced HIV-infected adults and children > 3 years 	<ul style="list-style-type: none"> Must be combined with ritonavir or cobicistat May cause transient rash Better tolerated than other PIs

Drug Facts for Your Personal Formulary: *Antiretroviral Agents and Treatment of HIV Infection (continued)*

Drug	Therapeutic Use	Clinical Pharmacology and Tips
Protease Inhibitors: Active against HIV-1 and HIV-2; generally used as second-line agents in treatment-experienced patients		
Indinavir	• Treatment-naïve or -experienced HIV-infected adults and children	• Must be taken with ritonavir or while fasting • Adverse effects: crystalluria and nephrolithiasis • Rarely used because of the availability of better-tolerated PIs
Nelfinavir	• Treatment-naïve or -experienced HIV-infected adults and children	• The only PI that does not benefit from PK boosting • Must be taken with food • Adverse effects: diarrhea and other GI toxicity • Rarely used because of the availability of better-tolerated PIs
Tipranavir	• Treatment-experienced HIV-infected adults and children ≥ 2 years, generally those who have failed all other PIs	• Toxicity: rare but potentially fatal hepatotoxicity; rare but potentially fatal bleeding diathesis, including intracranial hemorrhage • Rarely used because of the availability of better-tolerated PIs
Entry Inhibitors: Generally reserved for second-line or salvage therapy		
Maraviroc	• Treatment-naïve or -experienced HIV-infected adults who have evidence of predominantly CCR5-tropic virus	• CYP3A4 substrate susceptible to drug interactions with other antiretrovirals • Adverse effect: dose- and concentration-dependent orthostatic hypotension
Enfuvirtide	• Treatment-experienced HIV-infected adults and children > 6 years • Generally reserved for those with no other treatment options	• Injected subcutaneously twice daily • Adverse effects: injection site reactions and subcutaneous nodules are common • Not active against HIV-2
Integrase Inhibitors: Widely used in treatment-naïve patients because of excellent tolerability, safety, and antiretroviral activity		
Raltegravir	• HIV-infected adults and children > 4 weeks of age	• Given twice daily without the need for a PK boosting agent • Reduced bioavailability if given concurrently with divalent cations • Generally well tolerated
Elvitegravir	• HIV-infected adults and children > 12 years of age	• Requires cobicistat as a PK booster • Should be taken with food • Reduced bioavailability if given concurrently with divalent cations • Generally well tolerated
Dolutegravir	• HIV-infected adults and children > 12 years of age	• Given once daily without the need for a PK-boosting agent • Reduced bioavailability if given concurrently with divalent cations • Generally well tolerated

ACHIEVING THERAPEUTIC INTEGRATION AND EFFICACY

A CAUTIONARY NOTE

Cancer pharmacology has changed dramatically during the recent past with the improved understanding of cancer biology and an ever-expanding set of newly developed drugs that target vulnerabilities in individual cancers. Effective early treatments have been developed for some fatal malignancies, including testicular cancer, lymphomas, and leukemia. Also, adjuvant chemotherapy and hormonal therapy can extend overall survival and prevent disease recurrence following surgical resection of localized breast, colorectal, and lung cancers. Chemotherapy is also employed as part of the multimodal treatment of locally advanced head and neck, breast, lung, and esophageal cancers; soft-tissue sarcomas; and pediatric solid tumors, thereby allowing for surgery that is more limited with favorable outcomes (Chabner and Roberts, 2005). In the past 5 years, the ability to harness the power of the immune system in the treatment of cancer has brought about a paradigm shift whereby some of the most feared diseases, such as melanoma and lung cancer and even late-stage metastatic disease, can be eradicated. For some cancers, response rates are surprisingly high: 87% in Hodgkin lymphoma even in heavily pretreated patients (Ansell et al., 2015), and 50% in patients with metastatic melanoma treated with combinations of PD-1 and CTLA4 immune checkpoint antibodies. Immune checkpoint inhibitors are currently approved for the treatment of bladder cancer, Hodgkin lymphoma, kidney cancer, lung cancer, and melanoma; more approvals are anticipated in the near future based on several hundred ongoing clinical trials.

Despite these major therapeutic successes, few categories of medication have a narrower therapeutic index and greater potential for causing harmful effects than anticancer drugs. A thorough understanding of their mechanisms of action, including clinical pharmacokinetics, drug interactions, and adverse effects, is essential for their safe and effective use. Anticancer drugs are quite varied in structure and mechanism of action. The group includes alkylating agents; antimetabolite analogues of folic acid, pyrimidine, and purine; natural products; hormones and hormone antagonists; and a variety of small-molecule drugs and antibodies directed at specific molecular targets, such as extracellular receptors, intracellular kinases, or the checkpoints of immune surveillance. Figure 65-1 depicts the cellular targets of these drugs, and Chapters 66–68 provide information on the different classes of drugs.

Anticancer drugs are increasingly used in a variety of nonmalignant diseases and have become treatment standards, for example, for autoimmune diseases (rituximab); rheumatoid arthritis (methotrexate and cyclophosphamide); Crohn disease (6-mercaptopurine); organ transplantation (methotrexate and azathioprine); sickle cell anemia (hydroxyurea); psoriasis (methotrexate); and wet macular degeneration (ranibizumab and aflibercept).

The Cell Cycle

An understanding of the cell cycle is essential for the rational use of anti-cancer drugs (Figure 65-2). Many cytotoxic agents act by damaging DNA. Their toxicity is greatest during S phase, the DNA synthetic phase of the cell cycle. Other agents, such as the vinca alkaloids and taxanes, block the formation of a functional mitotic spindle in the M phase. These agents are most effective on cells entering mitosis, the most vulnerable phase of the cell cycle. Accordingly, human cancers most susceptible to chemotherapy are those having a high percentage of proliferating cells. Normal tissues that proliferate rapidly (bone marrow, hair follicles, and intestinal epithelium) are thus also susceptible to damage from cytotoxic drugs. Slowly growing tumors with a small growth fraction (e.g., carcinomas of the colon or NSCLC) are less responsive to cell cycle-specific drugs.

Although cells from different tumors display differences in the duration of their transit through the cell cycle and in the fraction of cells in active proliferation, all cells display a similar pattern of cell cycle progression (Figure 65-2):

- A phase that precedes DNA synthesis (G_1)
- A DNA synthesis phase (S)
- An interval following the termination of DNA synthesis (G_2)
- The mitotic phase (M) in which the cell, containing a double complement of DNA, divides into two daughter G_1 cells
- A probability of moving into a quiescent state (G_0) and failing to move forward for long periods of time

At each transition point in the cell cycle, specific proteins, such as *p53* and *chk-1* and 2, monitor the integrity of DNA and, on detection of DNA damage, may initiate DNA repair processes or, in the presence of massive damage, direct cells down a pathway of cell death (apoptosis). Some anti-cancer drugs act at specific phases in the cell cycle, mainly at the S and M phases; other drugs are cytotoxic at any point in the cell cycle and are termed *cell cycle phase nonspecific*.

Each transition point in the cell cycle requires the activation of specific CDKs, which, in their active forms, couple with corresponding regulatory proteins called *cyclins*. The proliferative impact of CDKs is, in turn, dampened by inhibitory proteins such as $p16^{INK4A}$, a tumor suppressor named for its molecular mass (protein of 16 kDa) and inhibition of CDK4. Tumor cells often exhibit changes in cell cycle regulation that lead to relentless proliferation (e.g., mutations or loss of $p16^{INK4A}$ or of other inhibitory components of the so-called retinoblastoma pathway, enhanced cyclin or enhanced CDK activity).

Abbreviations

ABL: Abelson murine leukemia viral oncogene homolog
ALK: anaplastic lymphoma kinase
ALL: acute lymphoblastic leukemia
ATRA: all-*trans* retinoic acid
BCR: breakpoint cluster region
BRAF: B-Raf proto-oncogene ser/thr protein kinase
BRCA: breast cancer tumor suppressor
CAR(T): chimeric antigen receptor T cell
CDK: cyclin-dependent kinase
ctDNA: cell-free mutant tumor DNA
CTLA4: cytotoxic T lymphocyte-associated protein 4
EGF(R): epidermal growth factor (receptor) [HER1, ErbB-1]
ER: estrogen receptor
FDA: Food and Drug Administration
GI: gastrointestinal
HER1: human EGFR (ErbB-1)
HER2: receptor tyrosine-protein kinase erbB-2
MEK: mitogen-activated protein kinase kinase
MHC: major histocompatibility class (protein)
NCCN: National Comprehensive Cancer Network
NSCLC: non-small cell lung cancer
PARP: poly(ADP-ribose) polymerase
PD-1: programmed cell death 1
PD-L1: programmed cell death 1 ligand 1
PR: progesterone receptor
RAR: retinoic acid receptor
VEGF: vascular endothelial growth factor

The CDK family consists of over 20 serine/threonine protein kinases that have been amongst the first pathway targets pursued for the treatment of cancer. However, different tissue selectivities and distinct cell cycle-specific activity periods of the various CDKs provide a challenge for the development of CDK inhibitors. CDK4/6 have become attractive targets because they control cell cycle progression from the G₁ to the S phase. Interaction of cyclin D with CDK4/6 enhances phosphorylation and inactivation of the retinoblastoma (Rb) protein, followed by the transcription of factors that control transition into the S phase. CDK4/6 inhibition will thus cause a G₁ arrest in susceptible cells that utilize this pathway. The CDK4/6 inhibitor palbociclib was recently approved for the treatment of breast cancer (see Chapter 67).

Because of the central importance of DNA to the identity and functionality of a cell, elaborate mechanisms ("cell cycle checkpoints") have evolved to monitor DNA integrity. If a cell possesses normal checkpoint function, drug-induced DNA damage will activate apoptosis when the cell reaches the G₁/S or G₂/M boundary. However, if the p53 gene product or other checkpoint proteins are mutated or absent or the checkpoint function fails, damaged cells will not divert to the apoptotic pathway but will proceed through the S phase and mitosis. The cell progeny will then emerge as a mutated and potentially drug-resistant subpopulation (see Figure 65-3A).

Cancer Evolution and Drug Discovery

The rapidly expanding knowledge of cancer biology and the ability to analyze cancer genome alterations in thousands of patient samples have led to a better understanding of the molecular evolution of cancer and the discovery of cancer-specific drug targets: growth factor receptors, intracellular signaling pathways, epigenetic processes, tumor vascularity, DNA repair defects, cell death pathways, and immune escape mechanisms (Hanahan and Weinberg, 2011). Human malignancies are a highly diverse

Figure 65-1 Mechanisms and sites of action of some of the drugs used in the treatment of cancer.

Figure 65-2 Cell cycle specificity of drugs used in the treatment of cancer.

group of diseases that vary even within defined classifications such as organ of origin (lung, breast, prostate, colon, etc.), histology, or molecular marker. Also, the tumor cell population constituting a given cancer at the time of diagnosis has evolved over many years from a few precursor cells that accumulated mutations over time, generating heterogeneity within the primary tumor and at metastatic sites (Figure 65-3).

Clinically detectable cancer lesions represent approximately 1 g of tumor tissue or 10^9 cells and can contain a multitude of subpopulations and a wide variety of genetic alterations (see legend of Figure 65-3). The dynamic evolution of individual cancer genomes and the implications for the development of therapies was established from the analyses of specimens from diverse cancers (Yates and Campbell, 2012). This dynamic was exemplified in a detailed analysis of a series of multiple parallel biopsies from different sites in patients with metastatic melanoma during treatment with inhibitors of BRAF. The genomic analysis of the biopsies revealed complex and distinct evolutionary branching architectures due to the selection of drug-resistant subpopulations during treatment (Shi et al., 2014).

Nevertheless, in many tumors, proliferation and survival of the majority of subpopulations depends on a shared (ancestral) constitutive activity of a single growth factor pathway, or so-called oncogene addiction. Inhibition of that pathway leads to cell death of the sensitive populations. Thus, imatinib attacks the unique and specific *bcr-abl* translocation in chronic myelocytic leukemia. Imatinib also inhibits *c-kit* and produces extended control of GI stromal tumors that express a mutated and constitutively activated form of *c-kit*. Monoclonal antibodies effectively inhibit tumor-associated antigens such as the amplified *HER2* receptor in breast cancer cells (Slamon et al., 2001). Protein kinase inhibitors targeting mutant EGFR or mutant ALK in lung cancers improve disease outcomes over the use of conventional chemotherapy.

These examples emphasize that new strategies for drug discovery and development, and advances in patient care, will result from new knowledge of cancer biology. One response to the oncogene addiction paradigm has been to group cancers by shared vulnerabilities and include patients in so-called basket trials that evaluate a drug based on its target rather than particular disease entities and consider sensitivity and resistance to treatments in that context.

However, in the foreseeable future, targeted drugs and cytotoxics will continue to be used in combination. For instance, cytotoxics in combination with monoclonal antibodies such as trastuzumab or bevacizumab improve efficacy. At the same time, the toxicities of cytotoxic drugs have become more manageable with the development of better antiemesis

Figure 65-3 Evolution of treatment resistance; mutational load of human cancers. **A. Treatment resistance.** Cancers accumulate mutations during their evolution. Cancer cell subpopulations are selected based on their growth capacity, adaptation to the tumor microenvironment at the primary or metastatic site, and the evasion of immune surveillance. Drug treatment will add evolutionary pressure and select for resistant subpopulations. Differently colored dots indicate tumor subpopulations of different genetic makeup. **B. Mutational load.** Data are median number of somatic mutations per million bases plus or minus the range observed for some major human cancers. Note that the ordinate is a logarithmic scale. In 7042 cancer specimens between 100 and 1,000,000 mutations were detected per tumor specimen, with a 30- to 1000-fold range amongst individual specimens from a single cancer type (see original data in Alexandrov et al., 2013). A typical mutation burden of 10 somatic mutations per megabase (= 30,000 per genome of 3×10^9 base pairs) results in approximately 150 mutations in amino acid sequences that can alter protein function, drug sensitivity, and antigenicity. Such data have been analyzed in terms of the likelihood of formation of specific neoantigens that permit the immune system to distinguish between tumor and normal cells and are putative factors of importance in cancer immunotherapy (Schumacher and Schreiber, 2015). Adeno, adenocarcinoma; SCC, squamous cell carcinoma; SCLC, small cell lung cancer.

1164 medications (see Chapter 50) and with granulocyte colony-stimulating factor to restore bone marrow function (see Chapters 41 and 67).

Finally, targeted drugs are helping to overcome resistance to chemotherapeutic agents by normalizing blood flow, promoting apoptosis, and inhibiting prosurvival signals from growth factor pathways. Tumor angiogenesis leads to increased interstitial pressure and diminishes delivery of drugs to tumor cells; inhibitors of angiogenesis (e.g., bevacizumab) normalize blood flow and interstitial pressure, improve drug delivery, and can thus synergize with cytotoxic drugs in the treatment of lung, colon, and other cancers. It is also thought that the combination of cytotoxic drugs or pathway inhibitors can induce tumor cell death and antigen release and thus enhance responses to immune checkpoint inhibitors or other immune modulators. This concept is part of a recommendation for the treatment of patients with melanoma (Kaufman et al., 2013) and should be relevant for a range of cancers (Sharma and Allison, 2015). The ongoing development of activating and inhibitory drugs for additional immune checkpoint pathways (Anderson et al., 2016) will provide new options for drug combinations. One challenge in immunotherapy is the highly variable responses of the immune systems of individual patients that govern the success of the treatment.

Drug Resistance

Resistance remains the major obstacle to successful cancer treatment. Resistance results from a variety of molecular changes that can defeat the best-designed treatments. Mechanisms of drug resistance include poor drug absorption and delivery; genetically determined variability in drug transport, activation, and clearance; and mutations, amplifications, or deletions in drug targets (Holohan et al., 2013). The resistance process is best understood for pathway-targeted drugs. Tumors developing resistance to *bcr-abl* inhibitors and to inhibitors of the EGFR typically express mutations in the target enzyme. Cells exhibiting drug-resistant mutations preexist in a patient's tumor prior to drug treatment and are selected by drug exposure (see Figure 65-3A). Resistance to inhibitors of the EGFR may also develop through expression of an alternative receptor, *c-met*, which bypasses EGFR blockade and stimulates proliferation (Engelman et al., 2007). Defects in recognition of DNA breaks and overexpression of specific repair enzymes may contribute to resistance to cytotoxic drugs, and a loss of apoptotic pathways can lead to resistance to both cytotoxic and pathway-targeted drugs.

Resistance to immune checkpoint inhibitory drugs appears to follow patterns that are distinct from those of other anticancer drugs, as evidenced by their efficacy in some heavily pretreated patients. Combinations of therapies with pathway-targeted drugs as well as cytotoxic agents need to be evaluated to design effective combinations (Hughes et al., 2016). Finally, T cells carrying chimeric antigen receptors (CARs) can be directed against cancer cells that express specific antigens. CARs are engineered to contain an antigen recognition domain of a monoclonal antibody in the extracellular portion and intracellular signaling domains capable of activating T cells independently of the physiological pathway of antigen presentation by an MHC molecule (see Figures 67-3, 35-2, and 35-4). CD19-targeted CAR T cells reached a 70%–90% response rate in patients with previously treated, relapsed B-cell leukemias (Khalil et al., 2016), indicating a lack of cross-resistance with conventional therapies. This result is consistent with the requirement for effective combination therapies, that is, complementary mechanisms of action and no overlap in major toxicities.

Molecular Testing to Select Appropriate Drugs

Clinical trials and patient treatments increasingly employ results from biomarker analysis to identify patients likely to benefit from particular treatments and individuals at the greatest risk of toxicity. Some of the tests have been approved by the FDA as “companion diagnostics” in conjunction with specific drug therapies (see Table 65-1). Pretreatment testing of tumor specimens is standard practice in selecting patients for antihormonal therapy of breast cancer and for treatment with antibodies such as trastuzumab (anti-HER2). Detection of a mutated *KRAS* gene indicates that the tumor of a patient with colorectal cancer will not respond to anti-EGFR antibodies; in patients with lung cancers and EGFR mutations, treatment with erlotinib, gefitinib, or afatinib results in response rates of 70%, and in patients with ALK translocations, the response rates are similar for treatment with the ALK inhibitors crizotinib and ceritinib. A T790M “gatekeeper” mutation in EGFR (Kobayashi et al., 2005) accounts for about 60% of acquired resistance to first- and second-generation inhibitors but is sensitive to osimertinib, a third-generation EGFR inhibitor (Thomas et al., 2015). Overall, introduction of molecular analysis and appropriate choice of pathway-targeted inhibitors in the treatment of NSCLC has increased median survival of patients from less than 1 year to about 3 years.

TABLE 65-1 ■ DIAGNOSTIC TESTS OF CANCER SPECIMENS TO GUIDE TREATMENT DECISIONS

MOLECULAR MARKER	TARGET: drugs	INDICATION	CHAPTER LOCATION
ALK translocation	ALK: alectinib, ceritinib, crizotinib	NSCLC	67
BRAF V600 mutation	BRAF: dabrafenib, vemurafenib	Melanoma	67
BRAF V600 mutation	MEK: trametinib	Melanoma	67
BRCA mutation	PARP: olaparib	Ovarian cancer	67
EGFR deletion of exon 19 or L858R mutation ^a	EGFR: afatinib, erlotinib, gefitinib	NSCLC	67
EGFR T790M mutation ^a	EGFR: osimertinib	NSCLC	67
HER2 overexpression	HER2: trastuzumab, pertuzumab; lapatinib	Breast cancer	67
KRAS wild type	EGFR: cetuximab, panitumumab	Colorectal cancer	67
Hormone receptor expression (ER and PR)	Various: antiestrogens (tamoxifen, raloxifene, fulvestrant) or aromatase inhibitors (anastrozole, letrozole, exemestane)	Breast cancer	68
Risk of recurrence score (expression of a defined panel of genes)	Chemotherapy	Breast cancer	66

FDA-approved tests: www.fda.gov “List of cleared or approved companion diagnostic devices”.

^aAlso detectable as circulating tumor DNA (ctDNA) in blood samples.

Inherited differences in protein sequence polymorphisms or levels of RNA expression can also influence toxicity and antitumor response. For example, tandem repeats in the promoter region of the gene encoding thymidylate synthase, the target of 5-fluorouracil, determine the level of expression of the enzyme. Increased numbers of repeats are associated with increased gene expression, a lower incidence of toxicity, and a decreased rate of response in patients with colorectal cancer (Pullarkat et al., 2001). Polymorphisms of the dihydropyrimidine dehydrogenase gene, the product of which is responsible for degradation of 5-fluorouracil, are associated with decreased enzyme activity and a significant risk of overwhelming drug toxicity, particularly in the rare individual homozygous for the polymorphic genes (Van Kuilenburg et al., 2002).

Gene expression profiling, in which the levels of messenger RNA from thousands of genes are surveyed using gene arrays, has revealed tumor profiles that are highly associated with poor outcomes and warrant adjuvant chemotherapy (Sotiriou and Puszta, 2009). As an alternative to this broad analysis, small sets of informative genes can be identified and used clinically. One example is a set of 21 genes used in the analysis of samples from patients with early stage breast cancer. Based on the known association between the expression pattern of the 21 genes and disease outcomes, the analysis of patient samples can predict the risk of disease relapse. Thus, one can identify the patients at a high risk who will benefit from adjuvant chemotherapy (Paik et al., 2004).

Molecular Analysis and Tumor Heterogeneity

One of the caveats to conclusions drawn from the molecular analysis of tumor specimens is the dynamic evolution of cancers outlined previously (see Figure 65–3). Clinically important mutations in subclones may be missed due to geographically inadequate sampling and may provide the wrong guidance to treatment decisions. Response to treatment of different subpopulations presents a further challenge and would require multiple-site, longitudinal sampling (Shi et al., 2014).

Liquid Biopsies

More recent technology advances have made it possible to measure circulating, ctDNA in blood samples from patients with cancer (“liquid biopsies”) and to follow changes in the abundance of mutant *KRAS* during colon cancer treatment (Diehl et al., 2008). The analysis of ctDNA has also shown that during antiestrogen therapy of breast cancer the appearance of mutant estrogen receptor coincides with subsequent resistance to aromatase inhibitor treatment (Schiavon et al., 2015). Furthermore, mutant *KRAS* DNA in the circulation was increased during the treatment of patients with colon cancer with EGFR antibodies but surprisingly reverted to baseline values after cessation of the treatment. This observation demonstrates the dynamic evolution of cancer subpopulations during drug treatment (Siravegna et al., 2015). The FDA recently approved a test for the presence of mutant *EGFR* DNA in blood samples of patients with NSCLC to select candidates for treatment with erlotinib and thus circumvent the need for a tissue biopsy. The incorporation of liquid biopsies into future treatment monitoring could provide additional molecular insights into drug efficacy and the onset of resistance.

Achieving Therapeutic Integration and Efficacy

The clinical benefit of cytotoxic drugs has primarily been measured by radiological assessment of drug effects on tumor size. Pathway-targeted agents, however, may slow or halt tumor growth, so their effects may be measured in the assessment of time to disease progression; however, for

some immune checkpoint inhibitors, tumor lesions may initially increase in size due to cytotoxic lymphocyte infiltration. Thus, one of the great challenges is to assess efficacy and adjust drug regimens to achieve a therapeutic but nontoxic outcome. Treatment of patients with cancer requires a skillful interdigitation of pharmacotherapy with other modalities of treatment (e.g., surgery and irradiation). Each treatment modality carries its own risks and benefits, with the potential for both antagonistic and synergistic interactions between modalities, particularly between drugs and irradiation.

Individual patient characteristics determine the choice of modalities. Not all patients can tolerate drugs, and not all drug regimens are appropriate for a given patient. Renal and hepatic function, bone marrow reserve, general performance status, and concurrent medical problems all come into consideration in making a therapeutic plan. Other less-quantifiable considerations, such as the natural history of the tumor, the patient’s willingness to undergo difficult and potentially dangerous treatments, and the patient’s physical and emotional tolerance for adverse effects enter the equation, with the goal of balancing the likely long-term gains and risks in the individual patient. In particular, the long-term adverse effects of cytotoxic drugs have been related to the induction of cellular senescence in different organs that can adversely affect organ function and the overall well-being of patients long after completion of the treatments (Childs et al., 2015). The choice of treatment regimen should take all of this into account. Finally, in terminally ill patients, the treatment choices must be weighed carefully; the maximal length and highest quality of life may be achieved with palliative care rather than standard chemotherapy (Temel et al., 2010).

A Cautionary Note

Although advances in drug discovery and molecular profiling of tumors offer great promise for improving the outcomes of cancer treatment, a final word of caution regarding all treatment regimen deserves emphasis: *The pharmacokinetics and toxicities of cancer drugs vary amongst individual patients.* It is imperative to recognize toxicities early, to alter doses or discontinue offending medication to relieve symptoms and reduce risk, and to provide vigorous supportive care. Toxicities affecting the heart, lungs, nervous system, or kidneys may be irreversible if recognized late in their course, leading to permanent organ damage or death. Fortunately, such toxicities can be minimized by early recognition and by adherence to standardized protocols and to the guidelines for each drug’s use.

A Note on Treatment Regimens

Cancer treatment regimens change to reflect continuous advances in basic and clinical science: new drugs, both small molecules and biologicals; improved methods of targeting and timing of drug delivery; agents with altered pharmacokinetic properties and selectivities; the use of rational multidrug combinations; and greater knowledge of the basic cell biology of tumorigenesis, metastasis, and immune function, amongst other advances. As a consequence, this chapter and the three that follow presents relatively few detailed treatment regimens; rather, we refer the reader to the web-based resources of the U.S. FDA and the NCCN. Table 67–1 provides examples that illustrate the complexities of current therapeutic regimens for two cancers.

Acknowledgment: Paul Calabresi and Bruce A. Chabner contributed to this chapter in recent editions of this book. We have retained some of their text in the current edition.

Chapter 66

Cytotoxic Drugs

Anton Wellstein, Giuseppe Giaccone,
Michael B. Atkins, and Edward A. Sausville

I. ALKYLATING AGENTS AND PLATINUM COORDINATION COMPLEXES

ACTIONS COMMON TO ALKYLATING DRUGS

- Structure-Activity Relationships
- General Pharmacological Actions
- Mechanisms of Resistance to Alkylating Drugs
- Adverse Effects of Alkylating Drugs

CLINICAL PHARMACOLOGY OF NITROGEN MUSTARDS

- Mechlorethamine
- Cyclophosphamide
- Ifosfamide
- Melphalan
- Chlorambucil
- Bendamustine

ETHYLENEIMINES AND METHYLMELAMINES

- Altretamine
- Thiotepa

ALKYL SULFONATES

- Busulfan

NITROSOUREAS

- Carmustine (BCNU)
- Streptozocin

TRIAZENES

- Dacarbazine (DTIC)
- Temozolomide

METHYLHYDRAZINES

- Procarbazine

PLATINUM COORDINATION COMPLEXES

- Mechanisms of Action
- Resistance to Platinum Analogues
- Cisplatin
- Carboplatin
- Oxaliplatin

II. ANTIMETABOLITES

FOLIC ACID ANALOGUES

- Mechanism of Action
- Selective Toxicity; Rescue
- Cellular Entry and Retention
- Newer Congeners
- Mechanisms of Resistance to Antifolates

PYRIMIDINE ANALOGUES

- Cellular Actions of Pyrimidine Antimetabolites

- Fluorouracil, Floxuridine, Capecitabine
- Trifluridine

CYTIDINE ANALOGUES

- Cytarabine (Cytosine Arabinoside; Ara-C)
- Azacitidine (5-Azacytidine); Decitabine
- Gemcitabine

PURINE ANALOGUES

- 6-Thiopurine Analogues
- Fludarabine Phosphate
- Cladribine
- Clofarabine (2-Chloro-2'-fluoro-arabinosyladenine)
- Nelarabine (6-Methoxy-arabinosyl-guanine)
- Pentostatin (2'-Deoxycoformycin)

III. NATURAL PRODUCTS

MICROTUBULE-DAMAGING AGENTS

- Vinca Alkaloids
- Eribulin
- Taxanes
- Estramustine
- Epothilones

CAMPTOTHECIN ANALOGUES

- Chemistry
- Mechanism of Action
- Mechanisms of Resistance
- Topotecan
- Irinotecan

ANTIBIOTICS

- Dactinomycin (Actinomycin D)
- Anthracyclines and Anthracenediones

EPIPODOPHYLLOTOXINS

- Podophyllotoxin Derivatives
- Etoposide
- Teniposide

DRUGS OF DIVERSE MECHANISMS OF ACTION

- Bleomycin
- Mitomycin
- Mitotane
- Trabectedin
- L-Asparaginase
- Hydroxyurea
- Retinoids
- Arsenic Trioxide

- ABC:** ATP-binding cassette
ABVD: doxorubicin (*adriamycin*), *bleomycin*, *vinblastine*, *dacarbazine*
ADA: adenosine deaminase
ADME: absorption, distribution, metabolism, excretion
ALL: acute lymphoblastic leukemia
AML: acute myeloid leukemia; acute myelocytic leukemia
APL: acute promyelocytic leukemia
Ara-C: cytarabine, cytosine arabinoside
Ara-U: ara-uridine
ARDS: acute respiratory distress syndrome
L-ASP: L-asparaginase
ATO: arsenic trioxide
ATRA: all-*trans* retinoic acid
BCNU: carmustine [1,3-*bis*-(2-chloroethyl)-1-nitrosourea]
BCRP: breast cancer resistance protein
CCNU: 1-(2-chloroethyl)-3-cyclohexyl-1-nitrosourea (lomustine)
2CdA: 2-chlorodeoxyadenosine (cladribine)
CDK: cyclin-dependent kinase
C/EBP: CCAAT/enhancer binding protein
CHOP: cyclophosphamide, doxorubicin (*H*), vincristine (*O*) and prednisone
CL_{cr}: creatinine clearance
CLL: chronic lymphocytic leukemia
CML: chronic myelocytic leukemia; chronic myelogenous leukemia
CNT1: concentrative nucleoside transporter 1
CTCL: cutaneous T-cell lymphoma
dCK: deoxycytidine kinase
dCTP: deoxycytidine 5'-triphosphate
DDD: dichlorodiphenyldichloroethane
dFdC: 2',2'-difluorodeoxycytidine, gemcitabine
5'-dFdU: 5'-deoxyfluorodeoxyuridine
DHFR: dihydrofolate reductase
dNTP: deoxynucleotide triphosphate
DPD: dihydropyrimidine dehydrogenase
dTMP/TTP: deoxythymidine monophosphate/triphosphate
dUMP/FdUMP: deoxyuridine monophosphate/fluoro dUMP
ENT1: equilibrative nucleoside transporter 1
FdUMP: deoxynucleotide, fluorodeoxyuridine monophosphate
FH₂Glu_n/FH₄Glu_n: dihydro-/tetrahydrofolate polyglutamates
FOLFIRINOX: FOLFOX plus irinotecan
FOLFOX: *folinic* acid, 5FU and *oxaliplatin*
5FU: 5-fluorouracil
FUdR: fluorodeoxyuridine
G-CSF: granulocyte colony-stimulating factor
GI: gastrointestinal
GSH: glutathione
GST: glutathione S-transferase
Hb: hemoglobin
HbF: fetal hemoglobin
HDAC: histone deacetylase
HDM-L: high-dose MTX with leucovorin rescue
HGPRT: hypoxanthine guanine phosphoribosyl transferase
HMG: high-mobility group
HMM: hexamethylmelamine
HSV: herpes simplex virus
5HT: serotonin, 5-hydroxytryptamine
HU: hydroxyurea
IMP: inosine monophosphate
Jak2: Janus kinase 2
MAO: monoamine oxidase
MDS: myelodysplastic syndrome
MESNA: 2-*mercaptoethanesulfonate-Na*⁺
methyl-CCNU: semustine
MGMT: O⁶-alkyl, methyl guanine methyltransferase
MLL: mixed-lineage leukemia
MM: multiple myeloma
MMR: mismatch repair
MOPP: nitrogen *mustard*, *oncovin* (vincristine), *procarbazine*, and *prednisone*
6MP: 6-mercaptopurine
MRP: multidrug resistance-associated protein
MSH6: mutator S homologue 6
MTA: pemetrexed
MTIC: methyl-triazeno-imidazole-carboxamide
mTOR: mammalian target of rapamycin
MTX: methotrexate
Nab-paclitaxel: albumin-bound nanoparticle solution of paclitaxel
NCCN: National Comprehensive Cancer Network
NER: nucleotide excision repair
NHL: non-Hodgkin lymphoma
NSAID: nonsteroidal anti-inflammatory drug
PG: polyglutamate
Pgp: P-glycoprotein
PI3K: phosphoinositide 3-kinase
PML: promyelocytic leukemia
PN: peripheral neuropathy
PRPP: 5-phosphoribosyl-1-pyrophosphate
PVC: procarbazine, vincristine and CCNU
RAR: retinoic acid receptor
RNR: ribonucleoside diphosphate reductase
ROS: reactive oxygen species
SCC: squamous cell carcinoma
SHMT: serine hydroxymethyltransferase
TEM: triethylenemelamine
TEPA: triethylenephosphoramidate
6TG: 6-thioguanine
THF: tetrahydrofolate
T-IMP: 6-thioinosine-5'-monophosphate
6-thioGMP: 6-thioguanosine-5'-monophosphate
Thiotepa: triethylenethiophosphoramidate
TMP: thymidine monophosphate
TPMT: thiopurine methyltransferase
TS: thymidylate synthase
TTP: thymidine triphosphate
VOD: veno-occlusive disease
XPG: xeroderma pigmentosum endonuclease G

A Note on Treatment Regimens

Cancer treatment regimens change to reflect continuous advances in basic and clinical science: new drugs, both small molecules and biologicals; improved methods of targeting and timing of drug delivery; agents with altered pharmacokinetic properties and selectivities; the use of rational multidrug combinations; and greater knowledge of the basic cell biology of tumorigenesis, metastasis, and immune function, amongst other advances. As a consequence, this chapter presents relatively few detailed treatment regimens; rather, we refer the reader to the web-based resources of the U.S. FDA and the NCCN. Table 67–1 provides two examples of therapeutic regimens that illustrate the complexity of current cancer drug therapy.

I. Alkylating Agents and Platinum Coordination Complexes

HISTORY Alkylating Anticancer Drugs

The discovery and initial development of alkylating anticancer drugs are based on observations of the effects of chemical warfare in World War I (Chabner and Roberts, 2005). The pervasively toxic sulfur mustard gas that caused topical burns to skin, eyes, lungs, and mucosa also caused aplasia of the bone marrow and lymphoid tissue and ulceration of the GI tract (Krumbhaar, 1919). In 1942, Louis Goodman and Alfred Gilman, the originators of this text, demonstrated the activity of nitrogen mustards against mouse lymphoma. Their clinical studies of intravenous nitrogen mustards in patients with lymphoma launched the modern era of cancer chemotherapy (Gilman and Philips, 1946).

Actions Common to Alkylating Drugs

Six major types of alkylating agents are used in the chemotherapy of cancer: *nitrogen mustards*, *ethyleneimines*, *alkyl sulfonates*, *nitrosoureas*, *triazenes*, and *methylhydrazines*. Because of similarities in their mechanisms of action and resistance, *platinum complexes* are also discussed with classical alkylating agents, even though they do not alkylate DNA but instead form covalent metal adducts with DNA.

The chemotherapeutic alkylating agents have in common the property of forming highly reactive carbonium ion intermediates. These reactive intermediates covalently link to sites of high electron density, such as phosphates, amines, sulfhydryl, and hydroxyl groups. Their chemotherapeutic and cytotoxic effects are directly related to the alkylation of reactive amines, oxygens, or phosphates on DNA. The N7 atom of guanine is

A

Activation

Nucleophilic attack of unstable aziridine ring by electron donor

(–SH of protein, –N– of protein or DNA base, =O of DNA base or phosphate)

Figure 66–1 Mechanism of action of alkylating agents of mechlorethamine, a prototypic nitrogen mustard. **A.** Activation reaction. **B.** Alkylation of N7 of guanine. With bifunctional drugs such as nitrogen mustards (see Figure 66–2), the second 2-chloroethyl side chain can undergo a similar activation cross-link of two nucleic acid chains or a nucleic acid to a protein.

particularly susceptible to the formation of a covalent bond with bifunctional alkylating agents and may represent the key target that determines their biological effects (Figure 66–1). Other atoms in the purine and pyrimidine bases of DNA, including N1 and N3 of the adenine ring, N3 of cytosine, and O6 of guanine, react with these agents, as do the amino and sulfhydryl groups of proteins and the sulfhydryls of glutathione. The general mechanisms of alkylating agents on DNA are illustrated in Figure 66–1 using mechlorethamine (nitrogen mustard).

With the bifunctional alkylating agents such as nitrogen mustard and its derivatives that are used therapeutically (Figure 66–2), the second 2-chloroethyl side chain can undergo a similar cyclization reaction and alkylate a second guanine residue or another nucleophilic moiety, resulting in the cross-linking of two nucleic acid chains or the linking of a nucleic acid to a protein, alterations that cause a major disruption in nucleic acid function. Any of these effects can contribute to both the mutagenic and the cytotoxic effects of alkylating agents. The extreme cytotoxicity of the bifunctional alkylators correlates closely with interstrand cross-linkage of DNA.

Figure 66–2 Nitrogen mustards employed in therapy.

The ultimate cause of cell death related to DNA damage is not known. Specific cellular responses include cell-cycle arrest and attempts to repair DNA. The specific repair enzyme complex utilized will depend on two factors: the chemistry of the adduct formed and the repair capacity of the cell involved. The process of recognizing and repairing DNA generally requires an intact NER complex but may differ with each drug and with each tumor. Alternatively, recognition of extensively damaged DNA by p53 can trigger apoptosis. However, faulty DNA damage repair mechanisms and mutations of p53 can lead to resistance to alkylating drugs (Kastan, 1999).

Structure-Activity Relationships

Although alkylating agents share the capacity to alkylate biologically important molecules, modification of the basic backbone structure changes reactivity, lipophilicity, active transport across biological membranes, sites of macromolecular attack, and mechanisms of DNA repair, all of which determine drug activity in vivo. For several of the most valuable agents (e.g., cyclophosphamide, ifosfamide), the active alkylating moieties are generated in vivo through hepatic metabolism (Figure 66-3).

The newest (2008) approved alkylating agent, **bendamustine**, has the typical chloroethyl reactive groups in nitrogen mustard (M) attached to a benzimidazole backbone. The unique properties and activity of this drug may derive from this purine-like structure; the agent produces slowly repaired DNA cross-links, lacks cross-resistance with other classical alkylators (Leoni et al., 2008), and is approved for treatment of CLL and large-cell lymphomas refractory to standard alkylators.

One class of alkylating agents transfers methyl rather than ethyl groups to DNA: The *triazene* derivative 5-(3,3-dimethyl-1-triazeno)-imidazole-4-carboxamide, usually called *dacarbazine* or DTIC, is prototypical of methylating agents. Dacarbazine requires initial activation by hepatic CYPs through an *N*-demethylation reaction. In the target cell, spontaneous cleavage of the metabolite, MTIC, yields an alkylating moiety, a methyl diazonium ion. A related triazene, temozolomide, undergoes spontaneous, nonenzymatic activation to MTIC. It is able to cross the blood-brain barrier and has been shown to have significant activity against gliomas.

The *nitrosoureas*, which include compounds such as 1,3-bis-(2-chloroethyl)-1-nitrosourea (carmustine [BCNU]), 1-(2-chloroethyl)-3-cyclohexyl-1-nitrosourea (lomustine [CCNU]), and its methyl derivative (semustine [methyl-CCNU]), as well as the antibiotic streptozocin (streptozotocin), exert their cytotoxicity through the spontaneous breakdown to an alkylating intermediate, the 2-chloroethyl diazonium ion. As with the nitrogen mustards, interstrand DNA cross-linking appears to be the primary lesion responsible for the cytotoxicity of nitrosoureas. The reactions of the nitrosoureas with macromolecules are shown in Figure 66-4. The use of nitrosoureas is presently limited to brain tumors due to their lipophilicity.

Stable ethyleneimine derivatives have antitumor activity; TEM and thiotepa have been used clinically. In standard doses, thiotepa produces little toxicity other than myelosuppression; it is used for high-dose chemotherapy regimens in transplants for hematological malignancies, in which it causes both mucosal and CNS toxicity. Altretamine (HMM) is chemically similar to TEM and has been used to treat ovarian cancer. The methylmelamines are *N*-demethylated by hepatic microsomes with the release of formaldehyde; there is a direct relationship between the degree of the demethylation and their antitumor activity in model systems.

Figure 66-3 Activation and metabolism of cyclophosphamide. Cyclophosphamide is activated (hydroxylated) by CYP2B, with subsequent transport of the activated intermediate to sites of action. The selectivity of cyclophosphamide against certain malignant tissues may result in part from the capacity of normal tissues to degrade the activated intermediates via aldehyde dehydrogenase, glutathione transferase, and other pathways. Ifosfamide is structurally similar to cyclophosphamide (see Figure 66-2); whereas cyclophosphamide has two chloroethyl groups on the exocyclic nitrogen atom, one of the 2-chloroethyl groups of ifosfamide is on the cyclic phosphoramidate nitrogen of the oxazaphosphorine ring. Ifosfamide is activated by hepatic CYP3A4 and proceeds more slowly than activation of cyclophosphamide, with greater production of dechlorinated metabolites and chloroacetaldehyde. These differences in metabolism likely account for the higher doses of ifosfamide required for equitoxic effects, the greater neurotoxicity of ifosfamide, and perhaps differences in the antitumor spectra of cyclophosphamide and ifosfamide.

Esters of alkane sulfonic acids alkylate DNA through the release of methyl radicals. Busulfan is of value in high-dose chemotherapy.

General Pharmacological Actions

Cytotoxic Actions

The capacity of alkylating agents to interfere with DNA integrity and function and to induce cell death in rapidly proliferating tissues provides the basis for their therapeutic and toxic properties. Acute effects manifest primarily against rapidly proliferating tissues; however, certain alkylating agents may have damaging effects on tissues with normally low mitotic indices (e.g., liver, kidney, and mature lymphocytes); effects in these tissues usually are delayed. Lethality of DNA alkylation depends on the recognition of the adduct, the creation of DNA strand breaks by repair enzymes, and an intact apoptotic response. In nondividing cells, DNA damage activates a checkpoint that depends on the presence of a normal p53 gene. Cells thus blocked in the G₁/S interface either repair DNA alkylation or undergo apoptosis. Malignant cells with mutant or absent p53 fail to suspend cell-cycle progression, do not undergo apoptosis, and can exhibit resistance to these drugs.

Figure 66-4 Generation of alkylating and carbamylating intermediates from carmustine (BCNU). The 2-chloroethyl diazonium ion, a strong electrophile, can alkylate guanine, cytidine, and adenine bases. Displacement of the halogen atom can then lead to interstrand or intrastrand cross-linking of DNA. The formation of cross-links after the initial alkylation reaction proceeds slowly and can be reversed by the DNA repair enzyme MGMT, which displaces the chloroethyl adduct from its binding to guanine in a suicide reaction. The same enzyme, when expressed in human gliomas, produces resistance to nitrosoureas and to other methylating agents, including dacarbazine, temozolomide, and procarbazine.

Distinction Between Mono- and Bi-functional Agents

Although DNA is the ultimate target of all alkylating agents, there is a crucial distinction between the bifunctional agents, in which cytotoxic effects predominate, and the monofunctional methylating agents (procarbazine, temozolomide), which have greater capacity for mutagenesis and carcinogenesis. This suggests that the cross-linking of DNA strands represents a much greater threat to cellular survival than do other effects, such as single-base alkylation and the resulting depurination and single-chain scission. Conversely, simple methylation may be bypassed by DNA polymerases, leading to mispairing reactions that permanently modify a DNA sequence. These new sequences are transmitted to subsequent generations and may result in mutagenesis or carcinogenesis. Some methylating agents, such as procarbazine, are highly carcinogenic.

Adduct recognition systems and DNA repair systems play important roles in removing adducts and thereby determine the selectivity of action against particular cell types and the acquisition of resistance to alkylating agents. Alkylation of a single strand of DNA (monoadducts) is repaired by the NER pathway. The less frequent cross-links require participation of nonhomologous end joining, an error-prone pathway, or the error-free homologous recombination pathway. After drug infusion in humans, monoadducts appear rapidly and peak within 2 h of drug exposure, while cross-links peak at 8 h. The $t_{1/2}$ for repair of adducts varies amongst normal tissues and tumors; in peripheral blood mononuclear cells, both monoadducts and cross-links disappear with a $t_{1/2}$ of 12–16 h.

The repair process depends on the presence and accurate functioning of multiple proteins. Their absence or mutation, as in Fanconi anemia or ataxia telangiectasia, leads to extreme sensitivity to DNA cross-linking agents such as mitomycin, cisplatin, or classical alkylators. Other repair enzymes are specific for removing methyl and ethyl adducts from the O6 of guanine (methyl guanine methyltransferase [MGMT]) and for repair of alkylation of the N3 of adenine and N7 of guanine (3-methyladenine-DNA glycosylase). High expression of MGMT protects cells from cytotoxic effects of nitrosoureas and methylating agents and confers drug resistance, while methylation and silencing of the gene in brain tumors are

associated with clinical response to BCNU and temozolomide (Hegi et al., 2008). Bendamustine differs from classical chloroethyl alkylators in activating base excision repair, rather than the more complex double-strand break repair or MGMT. It impairs physiological arrest of adduct-containing cells at mitotic checkpoints, leads to mitotic catastrophe rather than apoptosis, and does not require an intact p53 to cause cytotoxicity.

Recognition of DNA adducts is an essential step in promoting attempts at repair and ultimately leading to apoptosis. The Fanconi pathway, consisting of 12 proteins, recognizes adducts and signals the need for repair of a broad array of DNA-damaging drugs and irradiation. Absence or inactivation of components of this pathway leads to increased sensitivity to DNA damage. Conversely, for the methylating drugs, nitrosoureas, cisplatin and carboplatin, and thiopurine analogues, the MMR pathway is essential for cytotoxicity, causing strand breaks at sites of adduct formation, creating mispairing of thymine residues, and triggering apoptosis.

Mechanisms of Resistance to Alkylating Drugs

Resistance to an alkylating agent develops rapidly when it is used as a single agent. Specific biochemical changes implicated in the development of resistance include the following:

- decreased permeation of actively transported drugs (e.g., mechlorethamine and melphalan)
- increased intracellular concentrations of nucleophilic substances, principally thiols such as glutathione, which can conjugate with and detoxify electrophilic intermediates
- increased activity of DNA repair pathways, which may differ for the various alkylating agents
- increased rates of metabolic degradation of the activated forms of cyclophosphamide and ifosfamide to their inactive keto and carboxy metabolites by aldehyde dehydrogenase (see Figure 66-3) and detoxification of most alkylating intermediates by glutathione transferases
- loss of ability to recognize adducts formed by nitrosoureas and methylating agents, as the result of defective MMR protein capability, confers resistance, as does defective checkpoint function, for virtually all alkylating drugs
- impaired apoptotic pathways, with overexpression of bcl-2 as an example, confer resistance

Adverse Effects of Alkylating Drugs

Alkylating agents differ in their patterns of the tissue specificity and severity of their adverse effects, which are summarized next.

Marrow

Most alkylating agents cause dose-limiting toxicity to marrow cells and, to a lesser extent, intestinal mucosa. Most alkylating agents (i.e., melphalan, chlorambucil, cyclophosphamide, and ifosfamide) cause myelosuppression, with a nadir of the peripheral blood granulocyte count at 6–10 days and recovery in 14–21 days. Cyclophosphamide has lesser effects on peripheral blood platelet counts than do the other agents. Busulfan suppresses all blood elements, particularly stem cells, and may produce a prolonged and cumulative myelosuppression lasting months or even years. For this reason, it is used as a preparative regimen in allogeneic bone marrow transplantation. Carmustine and other chloroethyl-nitrosoureas cause delayed and prolonged suppression of both platelets and granulocytes, reaching a nadir 4–6 weeks after drug administration and reversing slowly thereafter. Both cellular and humoral immunity are suppressed by alkylating agents, which have, therefore, been used to treat various autoimmune diseases. Immunosuppression is reversible at usual doses, but opportunistic infections may occur with extended treatment.

Mucosa, Hair Follicles

Alkylating agents are highly toxic to dividing mucosal cells and to hair follicles, leading to oral mucosal ulceration, intestinal denudation, and alopecia. Mucosal effects are particularly damaging in high-dose chemotherapy protocols associated with bone marrow transplantation, as they predispose to bacterial sepsis arising from the GI tract. In these protocols,

TABLE 66-1 ■ DOSE-LIMITING EXTRAMEDULLARY TOXICITIES OF SINGLE ALKYLATING AGENTS

DRUG	MTD, ^a mg/m ²	FOLD INCREASE OVER STANDARD DOSE	MAJOR ORGAN TOXICITIES
Cyclophosphamide	7000	7	Cardiac, hepatic VOD
Ifosfamide	16,000	2.7	Renal, CNS, hepatic VOD
Thiotepa	1000	18	GI, CNS, hepatic VOD
Melphalan	180	5.6	GI, hepatic VOD
Busulfan	640	9	GI, hepatic VOD
Carmustine (BCNU)	1050	5.3	Lung, hepatic VOD
Cisplatin	200	2	PN, renal
Carboplatin	2000	5	Renal, PN, hepatic VOD

^aMaximum tolerated dose (cumulative) in treatment protocols.

cyclophosphamide, melphalan, and thiotepa have the advantage of causing less mucosal damage than the other agents. In high-dose protocols, however, other toxicities become limiting (Table 66-1).

Nervous System

Nausea and vomiting commonly follow administration of nitrogen mustard or BCNU. Ifosfamide is the most neurotoxic of the alkylating agents and may produce altered mental status, coma, generalized seizures, and cerebellar ataxia. These side effects result from the release of chloroacetaldehyde from the phosphate-linked chloroethyl side chain of ifosfamide. High-dose busulfan can cause seizures; in addition, it accelerates the clearance of phenytoin, an antiseizure medication.

Other Organs

All alkylating agents, including temozolomide, have caused pulmonary fibrosis, usually several months after treatment. In high-dose regimens, particularly those employing busulfan or BCNU, vascular endothelial damage may precipitate veno-occlusive disease (VOD) of the liver (Table 66-1), an often-fatal side effect that is successfully reversed by *defibrotide*. Defibrotide is an oligonucleotide mixture with profibrinolytic properties that is FDA-approved for the treatment of adult and pediatric patients with hepatic VOD. The nitrosoureas and ifosfamide, after multiple cycles of therapy, may lead to renal failure. Cyclophosphamide and ifosfamide release a nephrotoxic and urotoxic metabolite, acrolein, which causes severe hemorrhagic cystitis in high-dose regimens. This adverse effect can be prevented by coadministration of MESNA, which conjugates acrolein in urine. Ifosfamide in high doses for transplant causes a chronic, and often irreversible, renal toxicity; its nephrotoxicity correlates with the total dose of drug received and increases in frequency in children younger than 5 years. The syndrome may be due to chloroacetaldehyde or acrolein excreted in the urine.

The more unstable alkylating agents (e.g., mechlorethamine and the nitrosoureas) have strong vesicant properties, damage veins with repeated use, and, if extravasated, produce ulceration. All alkylating agents have toxic effects on the male and female reproductive systems, causing an often-permanent amenorrhea, particularly in perimenopausal women, and an irreversible azoospermia in men.

Leukemogenesis

Alkylating agents have a high capacity to induce leukemia. Acute non-lymphocytic leukemia, induced by treatment, is often associated with a higher incidence of p53 mutations, partial or total deletions of

chromosome 5 or 7, and reduced response to chemotherapy. Incidence peaks about 4 years after therapy and may affect up to 5% of patients treated on regimens containing alkylating drugs. Leukemia often is preceded by a period of neutropenia or anemia and by bone marrow morphology consistent with myelodysplasia. Melphalan, the nitrosoureas, and the methylating agent procarbazine have the greatest propensity to cause leukemia, which is less common after cyclophosphamide.

Clinical Pharmacology of Nitrogen Mustards

Mechlorethamine

Mechlorethamine HCl was the first clinically used nitrogen mustard and is the most reactive of the drugs in this class. It is used topically for treatment of CTCL as a solution that is rapidly mixed and applied to affected areas. It has been largely replaced by cyclophosphamide, melphalan, and other more stable alkylating agents.

Cyclophosphamide

ADME

Cyclophosphamide is well-absorbed orally and is activated to the 4-hydroxy intermediate (see Figure 66-3). Its rate of metabolic activation exhibits significant interpatient variability and increases with successive doses in high-dose regimens but appears to be saturable at concentrations of the parent compound greater than 150 μ M. 4-Hydroxycyclophosphamide may be oxidized further by aldehyde oxidase, either in liver or in tumor tissue, to inactive metabolites. 4-Hydroxycyclophosphamide and its tautomer, aldophosphamide, travel in the circulation to tumor cells, where aldophosphamide cleaves spontaneously, generating stoichiometric amounts of phosphoramidate mustard and acrolein. Phosphoramidate mustard is responsible for antitumor effects, while acrolein causes hemorrhagic cystitis often seen during therapy with cyclophosphamide.

Pretreatment with CYP inducers such as phenobarbital enhances the rate of activation of the azoxyphosphorenes but does not alter total exposure to active metabolites over time and does not affect toxicity or efficacy. Cyclophosphamide can be used in full doses in patients with renal dysfunction because it is eliminated by hepatic metabolism. Patients with significant hepatic dysfunction should receive reduced doses. Maximal plasma concentrations are achieved about 1 h after oral administration; the $t_{1/2}$ of parent drug in plasma is about 7 h.

Therapeutic Uses

Cyclophosphamide is administered orally or intravenously. Recommended doses vary widely, and standard protocols for determining the schedule and doses of cyclophosphamide in combination with other chemotherapeutic agents should be consulted. The neutrophil nadir of 500–1000 cells/mm³ generally serves as a lower limit for dosage adjustments in prolonged therapy.

The clinical spectrum of activity for cyclophosphamide is broad. It is an essential component of many effective drug combinations for non-Hodgkin lymphomas, other lymphoid malignancies, breast and ovarian cancers, and solid tumors in children. Complete remissions and presumed cures have been reported when cyclophosphamide was given as a single agent for Burkitt lymphoma. It frequently is used in combination with doxorubicin and a taxane as adjuvant therapy after surgery for breast cancer. Because of its potent immunosuppressive properties, cyclophosphamide has been used to treat autoimmune disorders, including Wegener granulomatosis, rheumatoid arthritis, and the nephrotic syndrome. Caution is advised when the drug is considered for nonneoplastic conditions, not only because of its toxic effects but also because of its potential for inducing premature menopause, sterility, teratogenic effects, and leukemia.

Adverse Effects

Phosphoramidate mustard is responsible for antitumor effects, while acrolein causes hemorrhagic cystitis often seen during therapy with

cyclophosphamide. Patients should receive vigorous intravenous hydration during high-dose treatment. Brisk hematuria in a patient receiving daily oral therapy should lead to immediate drug discontinuation. Refractory bladder hemorrhage can become life-threatening and may require cystectomy for control of bleeding. Inappropriate secretion of antidiuretic hormone has been observed (usually at doses greater than 50 mg/kg) and can lead to water intoxication because these patients usually are vigorously hydrated. In addition to the cystitis (counteracted by MESNA and diuresis), GI, pulmonary, renal, hepatic, and cardiac toxicities (hemorrhagic myocardial necrosis) may occur after high-dose therapy with total doses greater than 200 mg/kg.

Ifosfamide

Ifosfamide is an analogue of cyclophosphamide. Severe urinary tract and CNS toxicity initially limited the use of ifosfamide, but adequate hydration and coadministration of MESNA have reduced its bladder toxicity. CNS toxicity is handled with methylene blue.

ADME

Ifosfamide has a plasma elimination $t_{1/2}$ ~1.5 h after doses of 3.8–5 g/m² and a somewhat shorter $t_{1/2}$ at lower doses; its pharmacokinetics are highly variable due to variable rates of hepatic metabolism (see legend to Figure 66–3).

Therapeutic Uses

Ifosfamide is approved for treatment of patients with relapsed germ cell testicular cancer and is frequently used for first-time treatment of pediatric or adult patients with sarcomas. It is a common component of high-dose chemotherapy regimens with bone marrow or stem cell rescue. In nonmyeloablative regimens, ifosfamide is infused intravenously over at least 30 min at a dose of 1.2 g/m²/d or less for 5 days. Intravenous MESNA is given as bolus injections in a dose equal to 20% of the ifosfamide dose concomitantly and an additional 20% again 4 and 8 h later, for a total MESNA dose of 60% of the ifosfamide dose. Alternatively, MESNA may be given concomitantly in a single dose equal to the ifosfamide dose. Patients also should receive at least 2 L of oral or intravenous fluid daily. Treatment cycles are repeated every 3–4 weeks.

Adverse Effects

Ifosfamide has a similar toxicity profile as cyclophosphamide, although it causes greater platelet suppression, neurotoxicity, nephrotoxicity, and urothelial damage. In high-dose regimens (i.e., total doses of 12–14 g/m²), it may cause severe neurological toxicity, including hallucinations, coma, and death, with symptoms appearing 12 h to 7 days after beginning the ifosfamide infusion. This toxicity may result from a metabolite, chloroacetaldehyde. Ifosfamide also causes nausea, vomiting, anorexia, leukopenia, nephrotoxicity, and VOD of the liver.

Melphalan

The alkylating agent melphalan primarily is used to treat multiple myeloma and, less commonly, in high-dose chemotherapy with marrow transplantation. The general pharmacological and cytotoxic actions of melphalan are similar to those of other bifunctional alkylators. The drug is not a vesicant.

ADME

Oral melphalan is absorbed in an inconsistent manner and, for most indications, is given as an intravenous infusion. The drug has a plasma $t_{1/2}$ of about 45–90 min; 10%–15% of an administered dose is excreted unchanged in the urine. Patients with decreased renal function may develop unexpectedly severe myelosuppression.

Therapeutic Uses and Adverse Effects

Melphalan for multiple myeloma is administered orally for 4–7 days every 28 days, with dexamethasone or thalidomide. Treatment is repeated at 4-week intervals based on response and tolerance. Dosage adjustments should be based on blood cell counts. Melphalan also may be used in myeloablative regimens followed by bone marrow or peripheral blood stem cell reconstitution. The toxicity of melphalan is mostly hematological

and is similar to that of other alkylating agents. Nausea and vomiting are less frequent. The drug causes less alopecia and, rarely, renal or hepatic dysfunction.

Chlorambucil

The cytotoxic effects of chlorambucil on the bone marrow, lymphoid organs, and epithelial tissues are similar to those observed with other nitrogen mustards. As an orally administered agent, chlorambucil is well tolerated in small daily doses and provides flexible titration of blood counts. Nausea and vomiting may result from single oral doses of 20 mg or greater.

ADME

Oral absorption of chlorambucil is adequate and reliable. The drug has a $t_{1/2}$ in plasma of about 1.5 h and is hydrolyzed to inactive products.

Therapeutic Uses and Adverse Effects

Chlorambucil is almost exclusively used in treating CLL. In treating CLL, chlorambucil is given once daily and continued for 3–6 weeks. With a fall in the peripheral total leukocyte count or clinical improvement, the dosage is titrated to maintain neutrophils and platelets at acceptable levels. Maintenance therapy often is required to maintain clinical response. Chlorambucil treatment may continue for months or years, achieving its effects gradually and often without significant toxicity to a compromised bone marrow. Marked hypoplasia of the bone marrow may be induced with excessive doses, but the myelosuppressive effects are moderate, gradual, and rapidly reversible. GI discomfort, azoospermia, amenorrhea, pulmonary fibrosis, seizures, dermatitis, and hepatotoxicity rarely may be encountered. A marked increase in the incidence of AML and other tumors has been noted in the treatment of polycythemia vera and in patients with breast cancer receiving chlorambucil as adjuvant chemotherapy.

Bendamustine

Bendamustine is approved for treatment of CLL and non-Hodgkin lymphoma. Bendamustine is given as a 30-min intravenous infusion on days 1 and 2 of a 28-day cycle. Lower doses may be indicated in heavily pretreated patients. Bendamustine is rapidly degraded through sulfhydryl interaction and adduct formation with macromolecules; less than 5% of the parent drug is excreted in the urine intact. *N*-Demethylation and oxidation produce metabolites that have antitumor activity, but less than that of the parent molecule. The parent drug has a plasma $t_{1/2}$ of about 30 min. The clinical toxicity pattern of bendamustine is typical of alkylators, with a rapidly reversible myelosuppression and mucositis, both generally tolerable.

Ethyleneimines and Methylmelamines

Although nitrogen mustards containing chloroethyl groups constitute the most widely used class of alkylating agents, other alkylators such as ethyleneimines with greater chemical stability and well-defined activity in specific types of cancer have value in clinical practice.

Altretamine

Altretamine is structurally similar to triethylenemelamine (TEM). Its precise mechanism of cytotoxicity is unknown, although it can alkylate DNA and proteins. It is a palliative treatment of patients with persistent or recurrent ovarian cancer following cisplatin-based combination therapy. The usual dosage of altretamine as a single agent in ovarian cancer is 260 mg/m²/d in four divided doses, for 14 or 21 consecutive days out of a 28-day cycle, for up to 12 cycles.

ADME

Altretamine is well absorbed from the GI tract; its elimination $t_{1/2}$ is 4–10 h. The drug undergoes rapid demethylation in the liver; the principal metabolites are pentamethylmelamine and tetramethyl melamine.

The main toxicities of altretamine are myelosuppression and neurotoxicity. Altretamine causes both peripheral and central neurotoxicity (ataxia, depression, confusion, drowsiness, hallucinations, dizziness, and vertigo). Neurological symptoms abate on discontinuation of therapy. Peripheral blood counts and a neurological examination should be performed prior to the initiation of each course of therapy. Therapy should be interrupted for at least 14 days and subsequently restarted at a lower dosage if the white cell count falls to less than 2000 cells/mm³ or the platelet count falls to less than 75,000 cells/mm³ or if neurotoxic or intolerable GI symptoms occur. If neurological symptoms fail to stabilize on the reduced-dose schedule, altretamine should be discontinued. Nausea and vomiting also are common side effects and may be dose limiting. Renal dysfunction may necessitate discontinuing the drug. Other rare adverse effects include rashes, alopecia, and hepatic toxicity. Severe, life-threatening orthostatic hypotension may develop in patients who receive MAO inhibitors, amitriptyline, imipramine, or phenelzine concurrently with altretamine.

Thiotepa

Thiotepa consists of three ethyleneimine groups stabilized by attachment to the nucleophilic thiophosphoryl base. Its current use is primarily for high-dose chemotherapy regimens. Hepatic CYPs rapidly convert thiotepa to its desulfurated primary metabolite, TEPA. Both thiotepa and TEPA form DNA cross-links.

ADME

Within hours of thiotepa administration, TEPA becomes the predominant form of the drug present in plasma. The parent compound has a plasma $t_{1/2}$ of 1.2–2 h; TEPA has a longer $t_{1/2}$, 3–24 h. Thiotepa pharmacokinetics essentially are the same in children as in adults at conventional doses (≤ 80 mg/m²), and drug and metabolite $t_{1/2}$ are unchanged in children receiving high-dose therapy of 300 mg/m²/d for 3 days. Less than 10% of the administered drug appears in urine as the parent drug or the primary metabolite.

Adverse Effects

Toxicities include myelosuppression and, to a lesser extent, mucositis. Myelosuppression tends to develop somewhat later than with cyclophosphamide, with leukopenic nadirs at 2 weeks and platelet nadirs at 3 weeks. In high doses, thiotepa may cause neurotoxic symptoms, including coma and seizures.

Alkyl Sulfonates

Busulfan

Busulfan exerts few pharmacological actions other than myelosuppression at conventional doses and, prior to the advent of imatinib mesylate, was a standard agent for patients in the chronic phase of myelocytic leukemia and caused a severe and prolonged pancytopenia in some patients. Busulfan now is primarily used in high-dose regimens, in which pulmonary fibrosis, GI mucosal damage, and hepatic VOD are important toxicities.

ADME

Busulfan is well absorbed after oral administration and has a plasma $t_{1/2}$ of 2–3 h. The drug is conjugated to GSH by GSTA1A and further metabolized by CYP-dependent pathways; its major urinary metabolite is methane sulfonic acid. In high doses, children less than 18 years of age clear the drug two to four times faster than adults and tolerate higher doses. Busulfan clearance varies considerably amongst patients. VOD is associated with high AUC (>1500 $\mu\text{M} \times \text{min}$) and slow clearance, leading to recommendations for dose adjustment based on drug-level monitoring.

A target steady-state concentration of 600–900 ng/mL in plasma in adults or AUC < 1000 $\mu\text{M} \times \text{min}$ in children achieves an appropriate balance between toxicity and therapeutic benefit.

Therapeutic Uses

In treating CML, the initial oral dose of busulfan varies with the total leukocyte count and the severity of the disease; daily doses are adjusted to subsequent hematological and clinical responses, with the aim of reducing the total leukocyte count to 10,000 cells/mm³ or less. A decrease in the leukocyte count usually is not seen during the first 10–15 days of treatment, and the leukocyte count may actually increase during this period. Because the leukocyte count may fall for more than 1 month after discontinuing the drug, it is recommended that busulfan be withdrawn when the total leukocyte count has declined to about 15,000 cells/mm³. A normal leukocyte count usually is achieved within 12–20 weeks. During remission, daily treatment resumes when the total leukocyte count reaches about 50,000 cells/mm³.

In high-dose therapy, anticonvulsants must be used concomitantly to protect against acute CNS toxicities, including tonic-clonic seizures that may occur several hours after each dose. Although phenytoin is a frequent choice, phenytoin induces the GSTs that metabolize busulfan, reducing its AUC by about 20%. In patients requiring concomitant antiseizure medication, non-enzyme-inducing benzodiazepines such as lorazepam and clonazepam are recommended as an alternative to phenytoin. If phenytoin is used concurrently, plasma busulfan levels should be monitored and the busulfan dose adjusted accordingly.

Adverse Effects

The toxic effects of busulfan are related to its myelosuppressive properties; prolonged thrombocytopenia may occur. Occasionally, patients experience nausea, vomiting, and diarrhea. Long-term use leads to impotence, sterility, amenorrhea, and fetal malformation. Rarely, patients develop asthenia and hypotension. High-dose busulfan causes VOD of the liver in 10% or fewer of patients, as well as seizures, hemorrhagic cystitis, permanent alopecia, and cataracts. The coincidence of VOD and hepatotoxicity is increased by its coadministration with drugs that inhibit CYPs, including imidazoles and metronidazole, possibly through inhibition of the clearance of busulfan or its toxic metabolites.

Nitrosoureas

The nitrosoureas have an important role in the treatment of brain tumors and find occasional use in treating lymphomas and in high-dose regimens with bone marrow reconstitution. They function as bifunctional alkylating agents but differ from conventional nitrogen mustards in both pharmacological and toxicological properties.

Carmustine (BCNU) and lomustine (CCNU, not discussed in detail) are highly lipophilic and thus readily cross the blood-brain barrier, an important property in the treatment of brain tumors. Unfortunately, with the exception of streptozocin, nitrosoureas cause profound and delayed myelosuppression, with recovery 4–6 weeks after a single dose. Long-term treatment with the nitrosoureas, especially semustine (methyl-CCNU), has resulted in renal failure. As with other alkylating agents, the nitrosoureas are highly carcinogenic and mutagenic. They generate both alkylating and carbamylating moieties (see Figure 66–4).

Carmustine (BCNU)

Carmustine's major action is its alkylation of DNA at the O6-guanine position, an adduct repaired by MGMT. Methylation of the MGMT promoter inhibits its expression in about 30% of primary gliomas and is associated with sensitivity to nitrosoureas. In high doses with bone marrow rescue, carmustine produces hepatic VOD, pulmonary fibrosis, renal failure, and secondary leukemia.

ADME

Carmustine is unstable in aqueous solution and in body fluids. After intravenous infusion, it disappears from the plasma with a highly variable $t_{1/2}$ of 15–90 min or more. Approximately 30%–80% of the drug appears in the urine within 24 h as degradation products. The alkylating metabolites

enter rapidly into the CSF, and their concentrations in the CSF reach 15%–30% of the concurrent plasma values.

Therapeutic Uses

Carmustine (BCNU) is administered intravenously over 1–2 h and repeated every 6 weeks. Because of its ability to cross the blood-brain barrier, carmustine has been used in the treatment of malignant gliomas. An implantable carmustine wafer is available for use as an adjunct to surgery for recurrent glioblastoma multiforme.

Streptozocin

Streptozocin (or streptozotocin) has a methylnitrosourea moiety attached to the 2-carbon of glucose. It has a high affinity for cells of the islets of Langerhans and causes diabetes in experimental animals.

ADME

Streptozocin is rapidly degraded following intravenous administration. The $t_{1/2}$ of the drug is about 15 min. Only 10%–20% of a dose is recovered intact in the urine.

Therapeutic Uses

Streptozocin is used in the treatment of human pancreatic islet cell carcinoma and carcinoid tumors. It is administered intravenously once daily for 5 days; this course is repeated every 6 weeks. Alternatively, a higher dose can be given weekly for 2 weeks, and the weekly dose then can be increased as tolerated.

Adverse Effects

Nausea is frequent. Mild, reversible renal or hepatic toxicity occurs in approximately two-thirds of cases; in fewer than 10% of patients, renal toxicity may be cumulative with each dose and may lead to irreversible renal failure. Streptozocin should not be given with other nephrotoxic drugs. Hematological toxicities (anemia, leukopenia, thrombocytopenia) occur in 20% of patients.

Triazines

Dacarbazine (DTIC)

Dacarbazine functions as a methylating agent after metabolic activation to the monomethyl triazeno metabolite MTIC. It kills cells in all phases of the cell cycle. Resistance has been ascribed to the removal of methyl groups from the O6-guanine bases in DNA by MGMT.

ADME

Dacarbazine is administered intravenously. After an initial rapid phase ($t_{1/2}$ of about 20 min), dacarbazine is cleared from plasma with a terminal $t_{1/2}$ of about 5 h. The $t_{1/2}$ is prolonged in the presence of hepatic or renal disease. Almost 50% of the compound is excreted intact in the urine by tubular secretion.

Therapeutic Uses

The primary clinical indication for dacarbazine is in the chemotherapy of Hodgkin disease. In combination with other drugs for Hodgkin disease, dacarbazine is given on day 1 and 15 and repeated every 4 weeks for up to 6 cycles (see NCCN). It is modestly effective against malignant melanoma and adult sarcomas. Dacarbazine for malignant melanoma is given for a 10-day period, repeated every 28 days; alternatively, it can be given daily for 5 days and repeated every 3 weeks. Extravasation of the drug may cause tissue damage and severe pain. Its use in patients with melanoma has largely been replaced by immune checkpoint inhibitors and agents targeting the typically activated mitogen-activated protein kinase pathway (see Chapter 67).

Adverse Effects

Dacarbazine induces nausea and vomiting in more than 90% of patients; vomiting usually develops 1–3 h after treatment and may last up to 12 h. Myelosuppression, with both leukopenia and thrombocytopenia, is mild and readily reversible within 1–2 weeks. A flu-like syndrome may occur.

Hepatotoxicity, alopecia, facial flushing, neurotoxicity, and dermatological reactions are less common adverse effects.

Temozolomide

Temozolomide is the standard agent, in combination with radiation therapy, for patients with malignant glioma and astrocytoma. Temozolomide, like dacarbazine, forms the methylating metabolite MTIC and kills cells in all phases of the cell cycle. It is more active in MGMT deficient tumors.

ADME

Temozolomide is administered orally and has a bioavailability approaching 100%. Plasma levels of the parent drug decline with a $t_{1/2}$ of 1–2 h. The primary active metabolite MTIC reaches a maximum plasma concentration (150 ng/mL) 90 min after a dose and declines with a $t_{1/2}$ of 2 h. Little intact drug is recovered in the urine, the primary urinary metabolite being the inactive imidazole carboxamide.

Adverse Effects

The toxicities of temozolomide mirror those of DTIC. Hematological monitoring is necessary to guide dosing adjustments.

Methylhydrazines

Procarbazine

Procarbazine is used in malignant brain tumors and in combination regimens for patients with Hodgkin disease.

Mechanisms of Action

The antineoplastic activity of procarbazine results from its conversion by CYP-mediated hepatic oxidative metabolism to highly reactive alkylating species that methylate DNA. Activated procarbazine can produce chromosomal damage, including chromatid breaks and translocations, consistent with its mutagenic and carcinogenic actions. Resistance to procarbazine develops rapidly when it is used as a single agent; one mechanism of resistance results from increased expression of MGMT, which repairs methylation of guanine.

ADME

The pharmacokinetic behavior of procarbazine has not been thoroughly defined. The drug is extensively metabolized by CYPs to azo, methylazoxy, and benzylazoxy intermediates, which are found in the plasma and yield the alkylating metabolites in tumor cells. In patients with brain cancer, the concurrent use of antiepileptic drugs that induce hepatic CYPs does not significantly alter the pharmacokinetics of the parent drug.

Therapeutic Uses

Procarbazine is used in combination regimens such as MOPP for Hodgkin disease. It is also used in treating gliomas as part of the PVC (procarbazine, vincristine and CCNU) regimen.

Adverse Effects

The most common toxic effects include leukopenia and thrombocytopenia, which begin during the second week of therapy and reverse within 2 weeks off treatment. GI symptoms such as mild nausea and vomiting occur in most patients; diarrhea and rash are noted in 5%–10% of cases. Behavioral disturbances also have been reported. Because procarbazine augments sedative effects, the concomitant use of CNS depressants should be avoided. The drug is a weak MAO inhibitor; it blocks the metabolism of catecholamines, sympathomimetics, and dietary tyramine and thus may provoke hypertension in patients concurrently exposed to these. Procarbazine has disulfiram-like actions; therefore, the ingestion of alcohol should be avoided. The drug is highly carcinogenic, mutagenic, and teratogenic and is associated with a 5%–10% risk of acute leukemia in patients treated with MOPP. The highest risk is for patients who also receive radiation therapy. Procarbazine is a potent immunosuppressive agent. It causes infertility, particularly in males.

Platinum coordination complexes have broad antineoplastic activity and have become the foundation for treatment of ovarian, head and neck, bladder, esophagus, lung, and colon cancers. Although cisplatin and other platinum complexes do not form carbonium ion intermediates like other alkylating agents or formally alkylate DNA, they covalently bind to nucleophilic sites on DNA and share many pharmacological attributes with alkylators.

Mechanisms of Action

Cisplatin, carboplatin, and oxaliplatin enter cells by the high-affinity Cu²⁺ transporter CTR1 (SLC31A1, a member of the solute carrier family; see Chapter 5) and in doing so contribute to the degradation of the transporter. The compounds are actively extruded from cells by ATP7A and ATP7B copper exporters and by MRP1; variable expression of these transporters may contribute to clinical resistance, along with a variety of other proteins and epigenetic phenomena (Shen et al., 2012). Inside the cell, the chloride, cyclohexane, or oxalate ligands of the analogues are displaced by water molecules, yielding a positively charged molecule that reacts with nucleophilic sites on DNA and proteins.

Aquation of cisplatin is favored at the low concentrations of Cl[−] inside the cell and in the urine. High concentrations of Cl[−] stabilize the drug, explaining the effectiveness of Cl[−] diuresis in preventing nephrotoxicity. The activated platinum complexes can react with electron-rich regions, such as sulfhydryls, and with various sites on DNA, forming both intrastrand and interstrand cross-links. The DNA-platinum adducts inhibit replication and transcription, lead to single- and double-stranded breaks and miscoding, and if recognized by p53 and other checkpoint proteins, cause induction of apoptosis. Adduct formation is an important predictor of clinical response (Reed et al., 1998). The analogues differ in the conformation of their adducts and the effects of adduct on DNA structure and function. Oxaliplatin and carboplatin are slower to form adducts. The oxaliplatin adducts are bulkier and less readily repaired, create a different pattern of distortion of the DNA helix, and differ from cisplatin adducts in the pattern of hydrogen bonding to adjacent segments of DNA (Sharma et al., 2007).

Unlike the other platinum analogues, oxaliplatin exhibits a cytotoxicity that does not depend on an active MMR system, which may explain its greater activity in colorectal cancer. It also seems less dependent on the presence of HMG proteins that are required by the other platinum derivatives. Testicular cancers have a high concentration of HMG proteins and are quite sensitive to cisplatin. Basal-type breast cancers, such as those with *BRCA1* and *BRCA2* mutations, lack *HER2* amplification and hormone-receptor expression and appear to be uniquely susceptible to cisplatin through their upregulation of apoptotic pathways governed by p63 and p73 (Deyoung and Ellisen, 2007). The cell cycle specificity of cisplatin differs amongst cell types; the effects of cross-linking are most pronounced during the S phase. The platinum analogues are mutagenic, teratogenic, and carcinogenic. Cisplatin- or carboplatin-based chemotherapy for ovarian cancer is associated with a 4-fold increased risk of developing secondary leukemia.

Resistance to Platinum Analogues

Resistance to the platinum analogues likely is multifactorial; the compounds differ in their degree of cross-resistance. Carboplatin shares

cross-resistance with cisplatin in most experimental tumors, while oxaliplatin does not.

A number of factors influence sensitivity to platinum analogues in experimental cells, including intracellular drug accumulation and intracellular levels of glutathione and other sulfhydryls, such as metallothionein, that bind to and inactivate the drug and rates of repair of DNA adducts. Repair of platinum-DNA adducts requires participation of the NER pathway. Inhibition or loss of NER increases sensitivity to cisplatin in patients with ovarian cancer, while overexpression of NER components is associated with poor response to cisplatin- or oxaliplatin-based therapy in lung, colon, and gastric cancer (Paré et al., 2008).

Resistance to cisplatin, but not oxaliplatin, appears to be partly mediated through loss of function in the MMR proteins. In the absence of effective repair of DNA-platinum adducts, sensitive cells cannot replicate or transcribe affected portions of the DNA strand. Some DNA polymerases can bypass adducts, possibly contributing to resistance. Overexpression of copper efflux transporters ATP7A and ATP7B correlates with poor survival after cisplatin-based therapy for ovarian cancer (Shen et al., 2012).

Cisplatin

ADME

Cisplatin is given only intravenously. To prevent renal toxicity, it is important to establish a chloride diuresis by the infusion of 1–2 L of normal saline prior to treatment. The appropriate amount of cisplatin then is diluted in a solution containing dextrose, saline, and mannitol and administered intravenously over 4–6 h. Because aluminum inactivates cisplatin, the drug should not come in contact with needles or other infusion equipment that contain aluminum during its preparation or administration. After intravenous administration, cisplatin has an initial plasma elimination $t_{1/2}$ of 25–50 min; concentrations of total (bound and unbound) drug fall thereafter, with a $t_{1/2}$ of 24 h or more. More than 90% of the platinum in the blood is covalently bound to plasma proteins. High concentrations of cisplatin are found in the kidney, liver, intestine, and testes; cisplatin penetrates poorly into the CNS. Only a small portion of the drug is excreted by the kidney during the first 6 h; by 24 h, up to 25% is excreted, and by 5 days, up to 43% of the administered dose is recovered in the urine, mostly covalently bound to protein and peptides. Biliary or intestinal excretion of cisplatin is minimal.

Therapeutic Uses

Cisplatin, in combination with bleomycin, etoposide, or with ifosfamide and vinblastine, cures 90% of patients with testicular cancer. Used with paclitaxel, cisplatin or carboplatin induces complete response in the majority of patients with carcinoma of the ovary. Cisplatin produces responses in cancers of the bladder, head and neck, cervix, and endometrium; all forms of carcinoma of the lung; anal and rectal carcinomas; and neoplasms of childhood. The drug also sensitizes cells to radiation therapy and enhances control of locally advanced lung, esophageal, and head and neck tumors when given with irradiation.

Adverse Effects

Cisplatin-induced nephrotoxicity has been largely ameliorated by forced pretreatment hydration and chloride diuresis. Amifostine, a thiophosphate cytoprotective agent, reduces renal toxicity associated with repeated administration of cisplatin. Ototoxicity caused by cisplatin is unaffected by diuresis and is manifested by tinnitus and high-frequency hearing loss. Marked nausea and vomiting occur in almost all patients and usually can be controlled with 5HT₃ receptor antagonists, neurokinin (NK₁) receptor antagonists (e.g., *aprepitant*), and high-dose corticosteroids.

At higher doses or after multiple cycles of treatment, cisplatin causes a progressive peripheral motor and sensory neuropathy that may worsen after discontinuation of the drug and may be aggravated by subsequent or simultaneous treatment with taxanes or other neurotoxic drugs. Cisplatin causes mild-to-moderate myelosuppression, with transient

leukopenia and thrombocytopenia. Anemia may become prominent after multiple cycles of treatment. Electrolyte disturbances, including hypomagnesemia, hypocalcemia, hypokalemia, and hypophosphatemia, are common. Hypocalcemia and hypomagnesemia secondary to tubular damage and renal electrolyte wasting may produce tetany if untreated. Routine measurement of Mg^{2+} concentrations in plasma is recommended. Hyperuricemia, hemolytic anemia, and cardiac abnormalities are rare side effects. Anaphylactic-like reactions, characterized by facial edema, bronchoconstriction, tachycardia, and hypotension, may occur within minutes after administration and should be treated by intravenous injection of epinephrine and with corticosteroids or antihistamines. Cisplatin has been associated with the development of AML, usually 4 years or more after treatment.

Carboplatin

The mechanisms of action and resistance and the spectrum of clinical activity of carboplatin are similar to cisplatin. However, the two drugs differ significantly in their chemical, pharmacokinetic, and toxicological properties.

ADME

Because carboplatin is much less reactive than cisplatin, the majority of drug in plasma remains in its parent form, unbound to proteins. Most drug is eliminated via renal excretion, with a $t_{1/2}$ of about 2 h. A small fraction of platinum binds irreversibly to plasma proteins and disappears slowly, with a $t_{1/2}$ of 5 days or more.

Therapeutic Uses

Carboplatin and cisplatin are equally effective in the treatment of patients with suboptimally debulked ovarian cancer, non-small cell lung cancer, and extensive-stage small cell lung cancer; however, carboplatin may be less effective than cisplatin in the treatment of patients with germ cell, head and neck, and esophageal cancers. Carboplatin is an effective alternative for responsive tumors in patients unable to tolerate cisplatin because of impaired renal function, refractory nausea, significant hearing impairment, or neuropathy, but doses must be adjusted for renal function. In addition, it may be used in high-dose therapy with bone marrow or peripheral stem cell rescue. Carboplatin is administered as an intravenous infusion over at least 15 min and is given once every 21–28 days; the overall dose of carboplatin should be adjusted in proportion to the reduction in creatinine clearance for patients with $CL_{Cr} < 60$ mL/min and use the Calvert formula for adjustment (Calvert et al., 1989).

Adverse Effects

Carboplatin is relatively well tolerated clinically, causing less nausea, neurotoxicity, ototoxicity, and nephrotoxicity than cisplatin. The dose-limiting toxicity of carboplatin is myelosuppression, primarily thrombocytopenia. It may cause a hypersensitivity reaction; in patients with a mild reaction, premedication, graded doses of drug, and more prolonged infusion lead to desensitization.

Oxaliplatin

ADME

Oxaliplatin has a short $t_{1/2}$ in plasma, probably as a result of its rapid uptake by tissues and its reactivity; the initial $t_{1/2}$ is about 17 min. No dose adjustment is required for hepatic dysfunction or for patients with a $CL_{Cr} \geq 20$ mL/min.

Therapeutic Uses

Oxaliplatin exhibits a range of antitumor activity (colorectal and gastric cancer) that differs from other platinum agents. Oxaliplatin's effectiveness in colorectal cancer is perhaps due to its MMR- and HMG-independent effects. It also suppresses expression of TS, the target enzyme of 5FU action, which may promote synergy of these two drugs (Fischel et al., 2002). In combination with 5FU, it is approved for treatment of patients with colorectal cancer.

Adverse Effects

The dose-limiting toxicity of oxaliplatin is peripheral neuropathy. An acute form, often triggered by exposure to cold liquids, manifests as paresthesias or dysesthesias in the upper and lower extremities, mouth, and throat. A second type relates to cumulative dose and has features similar to cisplatin neuropathy; 75% of patients receiving a cumulative dose of 1560 mg/m² experience some progressive sensory neurotoxicity, with dysesthesias, ataxia, and numbness of the extremities. Hematological toxicity is mild to moderate, except for rare immune-mediated cytopenias; nausea is well controlled with 5HT₃ receptor antagonists. Oxaliplatin may cause leukemia and pulmonary fibrosis months to years after administration. Oxaliplatin may cause an acute allergic response with urticaria, hypotension, and bronchoconstriction.

II. Antimetabolites

Folic Acid Analogues

Folic acid is an essential dietary factor that is converted by enzymatic reduction to FH_4 cofactors that provide methyl groups for the synthesis of precursors of DNA (thymidylate and purines) and RNA (purines) (Wilson et al., 2014). Folic acid analogues such as MTX interfere with FH_4 metabolism (Figure 66–5), reducing the cellular capacity for one-carbon transfer and methylation reactions in the synthesis of purine ribonucleotides and TMP, thereby inhibiting DNA replication.

HISTORY Antifolate Chemotherapy

Antifolate chemotherapy produced the first striking, although temporary, remissions in leukemia (Farber et al., 1948) and the first cure of a solid tumor, choriocarcinoma (Berlin et al., 1963). Interest in folate antagonists further increased with the development of curative combination therapy for childhood acute lymphocytic leukemia; in this therapy, MTX played a critical role in both systemic treatment and intrathecal therapy. Introduction of high-dose regimens with “rescue” of host toxicity by the reduced folate leucovorin (folinic acid, citrovorum factor, 5-formyl tetrahydrofolate, N^5 -formyl FH_4) further extended the effectiveness of this drug to both systemic and CNS lymphomas, osteogenic sarcoma, and leukemias. Recognition that MTX, an inhibitor of DHFR, also directly inhibits the folate-dependent enzymes of de novo purine synthesis and thymidylate synthesis led to development of antifolate analogues that specifically target these other folate-dependent enzymes. New congeners have greater capacity for transport into tumor cells (*pralatrexate*) and exert their primary inhibitory effect on TS (*raltitrexed*), early steps in purine biosynthesis (*lometrexol*), or both (the multitargeted antifolate *pemetrexed*).

Mechanism of Action

The primary target of folic analogs, such as MTX, is the enzyme DHFR (see Figure 66–6). To function as a cofactor in one-carbon transfer reactions, folate must be reduced by DHFR to FH_4 . Inhibitors such as MTX, with a high affinity for DHFR (K_i about 0.01–0.2 nM), cause partial depletion of N^5 -¹⁰ methylene FH_4 and N^{10} formyl FH_4 cofactors that are required for the synthesis of thymidylate and purines. In addition, MTX, like cellular folates, undergoes addition of a series of polyglutamates (MTX-PGs) in both normal and tumor cells (Figure 66–5). These PGs constitute intracellular storage forms of folates and folate analogues that dramatically increase inhibitory potency of the analogue for additional sites, including TS and two early enzymes in the purine biosynthetic pathway. The FH_2 PGs that accumulate in cells behind the blocked DHFR reaction also act as inhibitors of TS and other enzymes (see Figure 66–6) (Allegra et al., 1987b).

Figure 66–5 Folic acid, metabolic intermediates, and MTX. The shading identifies common structural features and areas of modification. Yellow highlights indicate sites modified by DHFR to FH_2 (DHF) and to FH_4 (THF); red atoms and bonds indicate metabolic intermediates that serve as single-carbon donors (see pathways in Figure 66–6).

Selective Toxicity; Rescue

As with most antimetabolites, MTX is only partially selective for tumor cells and kills rapidly dividing normal cells, such as those of the intestinal epithelium and bone marrow. Folate antagonists kill cells during the S phase of the cell cycle and are most effective when cells are proliferating rapidly. The toxic effects of MTX may be terminated by administering leucovorin, a fully reduced folate coenzyme that replenishes the intracellular pool of FH_4 cofactors (see Figure 66–6).

Cellular Entry and Retention

Because folic acid and many of its analogues are polar, they cross the blood-brain barrier poorly and require specific transport mechanisms to enter mammalian cells. Three inward folate transport systems are found on mammalian cells:

1. A folate receptor, which has high affinity for folic acid but much lower ability to transport MTX and other analogues
2. The reduced folate transporter, the major transit protein for MTX, raltitrexed, pemetrexed, and most analogues
3. A transporter that is active at low pH

The reduced folate transporter is highly expressed in the hyperdiploid subtype of ALL, which has extreme sensitivity to MTX (Pui et al., 2004). Once in the cell, additional glutamyl residues are added to the molecule by the enzyme folylpolyglutamate synthetase. Because these higher PGs are strongly charged and cross cellular membranes poorly, polyglutamation serves as a mechanism of ion trapping within the cell. The polyglutamation may also account for the prolonged retention of MTX in chorionic epithelium (where it is a potent abortifacient); in tumors derived from this tissue, such as choriocarcinoma cells; and in normal tissues subject to cumulative drug toxicity, such as liver. Polyglutamyl folates and analogues have substantially greater affinity than the monoglutamate form for folate-dependent enzymes that are required for purine and thymidylate synthesis and have at least equal affinity for DHFR.

Newer Congeners

New folate antagonists that are better substrates for the reduced folate carrier have been identified. In efforts to bypass the obligatory membrane transport system and to facilitate penetration of the blood-brain barrier, lipid-soluble folate antagonists also have been synthesized. Trimetrexate, a lipid-soluble analogue that lacks a terminal glutamate, has modest

Figure 66–6 Folate metabolism and the actions of 5FU, MTX, and MTX polyglutamates. **A.** Thymidylate synthesis (for composition of folates, see Figure 66–5). **B.** De novo purine synthesis. GAR transformylase provides the C8 and AICAR transformylase the C2 in the purine ring biosynthesis (see Figure 66–1 for numbering of purine ring atoms). AICAR, aminoimidazole carboxamide; dUMP, deoxyuridine monophosphate; FH_2Glu_n , dihydrofolate polyglutamate; FH_4Glu_n , tetrahydrofolate polyglutamate; GAR, glycylamide ribonucleotide; IMP, inosine monophosphate; PRPP, 5-phosphoribosyl-1-pyrophosphate; TMP, thymidine monophosphate.

antitumor activity, primarily in combination with leucovorin rescue. However, it is beneficial in the treatment of *Pneumocystis jiroveci* (*Pneumocystis carinii*) pneumonia, for which leucovorin provides differential rescue of the host but not the parasite (Allegra et al., 1987a). The most important recent folate analogue, MTA or pemetrexed, is a pyrrole-pyrimidine structure. It is avidly transported into cells via the reduced folate carrier and is converted to PGs that inhibit TS and glycine amide ribonucleotide transformylase, as well as DHFR. It has activity against ovarian cancer, mesothelioma, and adenocarcinomas of the lung. Pemetrexed and its PGs have a somewhat different spectrum of biochemical actions. Like MTX, pemetrexed inhibits DHFR, but as a PG, it even more potently inhibits TS and GART (Figure 66–6). Unlike MTX, it produces little change in the pool of reduced folates, indicating that the distal sites of inhibition (TS and GART) predominate. Its pattern of deoxynucleotide depletion also differs; it causes a greater fall in TTP than in other triphosphates. Like MTX, it induces p53 and cell-cycle arrest, but this effect does not depend on induction of p21. A newer congener, pralatrexate, is more effectively taken up and polyglutamated than MTX and is approved for treatment of CTCL.

Mechanisms of Resistance to Antifolates

Resistance to MTX can involve alterations in each known step in MTX action, including

- Impaired transport of MTX into cells
- Production of altered forms of DHFR that have decreased affinity for the inhibitor
- Increased concentrations of intracellular DHFR through gene amplification or altered gene regulation
- Decreased ability to synthesize MTX-PGs
- Increased expression of a drug efflux transporter of the MRP class (see Chapter 5)

The DHFR levels in leukemic cells increase within 24 h after treatment of patients with MTX, probably as a result of induction of DHFR synthesis. Unbound DHFR protein may bind to its own message and reduce its own translation, while the DHFR-MTX complex is ineffective in blocking DHFR translation. With longer periods of drug exposure, tumor cell populations emerge that contain markedly increased levels of DHFR. These cells contain multiple gene copies of DHFR either in mitotically unstable double-minute chromosomes (extrachromosomal elements) or in stably integrated, homogeneously staining chromosomal regions or amplicons (Schimke et al., 1978). Similar gene amplification target proteins have been implicated in the resistance to other antitumor agents, including 5FU and pentostatin (2'-deoxycytosine) and observed in patients with lung cancer (Curt et al., 1985).

High doses of MTX may permit entry of the drug into transport-defective cells and may permit the intracellular accumulation of MTX in concentrations that inactivate high levels of DHFR. The understanding of resistance to pemetrexed is incomplete. In various cell lines, resistance seems to arise from loss of influx transport, TS amplification, changes in purine biosynthetic pathways, or loss of polyglutamation.

ADME

Methotrexate is readily absorbed from the GI tract at doses of less than 25 mg/m²; larger doses are absorbed incompletely and are routinely administered intravenously. After intravenous administration, the drug disappears from plasma in a triphasic fashion. The rapid distribution phase is followed by a second phase, which reflects renal clearance ($t_{1/2}$ of about 2–3 h). A third phase has a $t_{1/2}$ of about 8–10 h. This terminal phase of disappearance, if prolonged by renal failure, may be responsible for major toxic effects of the drug on the bone marrow, GI epithelium, and skin. Distribution of MTX into body spaces, such as the pleural or peritoneal cavity, occurs slowly. However, if such spaces are expanded (e.g., by ascites or pleural effusion), they may act as a site of storage and slow release of the drug, resulting in prolonged elevation of plasma concentrations and more severe bone marrow toxicity.

Approximately 50% of MTX binds to plasma proteins and may be displaced from plasma albumin by myriad drugs, including sulfonamides, salicylates, tetracycline, chloramphenicol, and phenytoin; caution should be used if these drugs are given concomitantly. Up to 90% of a given dose of MTX is excreted unchanged in the urine, mostly within the first 8–12 h. Metabolism of MTX usually is minimal. After high doses, however, metabolites are readily detectable; these include 7-hydroxy-MTX, which is potentially nephrotoxic. Renal excretion of MTX occurs through a combination of glomerular filtration and active tubular secretion. Therefore, the concurrent use of drugs that reduce renal blood flow (e.g., NSAIDs), that are nephrotoxic (e.g., cisplatin), or that are weak organic acids (e.g., aspirin) can delay drug excretion and lead to severe myelosuppression. In patients with renal insufficiency, the dose should be adjusted in proportion to decreases in renal function, and high-dose regimens should be avoided. Concentrations of MTX in CSF are only 3% of those in the systemic circulation at steady state; hence, neoplastic cells in the CNS probably are not killed by standard dosage regimens. When high doses of MTX are given, cytotoxic concentrations of MTX reach the CNS beyond the blood-brain barrier. MTX is retained in the form of PGs for long periods (e.g., weeks in the kidneys, several months in the liver).

Pharmacogenetics may influence the response to antifolates and their toxicity. The C677T substitution in methylenetetrahydrofolate reductase reduces the activity of the enzyme that generates N⁵-¹⁰ methylene FH₄, the cofactor for TS, and thereby increases MTX toxicity (Pullarkat et al., 2001). The presence of this polymorphism in leukemic cells confers increased sensitivity to MTX and might also modulate the toxicity and therapeutic effect of pemetrexed, a predominant TS inhibitor. Likewise, polymorphisms in the promoter region of TS affect its expression and, by altering the intracellular levels of TS, modulate the response and toxicity of both antifolates and fluoropyrimidines (Pui et al., 2004).

Therapeutic Uses

Methotrexate is a critical drug in the management of childhood ALL. High-dose MTX is of great value in remission induction and consolidation and in the maintenance of remissions in this highly curable disease. A 6- to 24-h infusion of relatively large doses of MTX may be employed every 2–4 weeks but only when leucovorin rescue follows within 24 h of the MTX infusion. For maintenance therapy, it is administered at a lower dose, orally every week. Outcome of treatment in children correlates inversely with the rate of drug clearance. During MTX infusion, high steady-state levels are associated with a lower leukemia relapse rate. Methotrexate is of limited value in adults with AML, except for treatment and prevention of leukemic meningitis.

The intrathecal administration of MTX has been employed for treatment or prophylaxis of meningeal leukemia or lymphoma and for treatment of meningeal carcinomatosis. This route of administration achieves high concentrations of MTX in the CSF and also is effective in patients whose systemic disease has become resistant to MTX. The treatment is repeated every 4 days until malignant cells no longer are evident in the CSF. Leucovorin may be administered to counteract the potential toxicity of MTX that escapes into the systemic circulation, although this generally is not necessary. Because MTX administered into the lumbar space distributes poorly over the cerebral convexities, the drug may be given via an intraventricular catheter system in the treatment of active intrathecal disease. MTX is of established value in choriocarcinoma and related trophoblastic tumors of women; cure is achieved in about 75% of advanced cases treated sequentially with MTX and dactinomycin and in more than 90% when early diagnosis is made. For choriocarcinoma, MTX is administered intramuscularly every other day for four doses, alternating with leucovorin. Courses are repeated at 3-week intervals, toxicity permitting, and urinary β -human chorionic gonadotropin titers are used as a guide for persistence of disease.

Beneficial effects also are observed in the combination therapy of Burkitt and other non-Hodgkin lymphomas. MTX is a component of regimens for carcinomas of the breast, head and neck, ovary, and bladder. HDM-L is a standard agent for adjuvant therapy of osteosarcoma and produces a high complete response rate in CNS lymphomas. The administration

1180 of HDM-L has the potential for renal toxicity, probably related to the precipitation of the drug, a weak acid, in the acidic tubular fluid. Thus, vigorous hydration and alkalinization of urine pH are required prior to drug administration. If MTX values measured 48 h after drug administration are 1 μM or higher, higher doses (100 mg/m²) of leucovorin must be given until the plasma concentration of MTX falls to less than 50 nM. With appropriate hydration and urine alkalinization, and in patients with normal renal function, the incidence of nephrotoxicity following HDM-L is less than 2%. In patients who become oliguric, intermittent hemodialysis is ineffective in reducing MTX levels. Continuous-flow hemodialysis can eliminate MTX at about 50% of the clearance rate in patients with intact renal function. Alternatively, a MTX-cleaving enzyme, *glucarpidase*, is FDA approved for the treatment of MTX toxicity. *Glucarpidase* is a recombinant bacterial carboxypeptidase G2 that converts MTX into glutamate and 2,4-diamino-N(10)-methylpteroic acid. These metabolites are less toxic and are excreted by the liver. MTX concentrations in plasma fall by 99% or more within 5–15 min following enzyme administration. However, systemically administered carboxypeptidase G2 has little effect on MTX levels in the CSF.

Methotrexate is used in the treatment of severe, disabling psoriasis (see Chapter 70) orally for 5 days, followed by a rest period of at least 2 days, or intravenously weekly. It also is used at low dosage to induce remission in refractory rheumatoid arthritis. MTX inhibits cell-mediated immune reactions and is employed to suppress graft-versus-host disease in allogeneic bone marrow and organ transplantation and for the treatment of dermatomyositis, Wegener granulomatosis, and Crohn disease (see Chapters 38 and 51). MTX is also used as an abortifacient, generally in combination with a prostaglandin (see Chapter 44).

Adverse Effects

The primary toxicities of antifolates are on the bone marrow and the intestinal epithelium. Patients may be at risk for spontaneous hemorrhage or life-threatening infection and may require prophylactic transfusion of platelets and broad-spectrum antibiotics if febrile. Side effects usually reverse completely within 2 weeks, but prolonged myelosuppression may occur in patients with compromised renal function who have delayed drug excretion. The dosage of MTX (and likely pemetrexed) must be reduced in proportion to any reduction in creatinine clearance. Additional toxicities of MTX include alopecia, dermatitis, an allergic interstitial pneumonitis, nephrotoxicity (after high-dose therapy), defective oogenesis or spermatogenesis, abortion, and teratogenesis. Low-dose MTX may lead to cirrhosis after long-term continuous treatment, as in patients with psoriasis. Intrathecal administration of MTX often causes meningismus and an inflammatory response in the CSF. Seizures, coma, and death may occur rarely. Note that leucovorin does not reverse neurotoxicity.

Pemetrexed toxicity mirrors that of MTX, with the additional feature of a prominent erythematous and pruritic rash in 40% of patients. Dexamethasone, 4 mg twice daily on days –1, 0, and +1, markedly diminishes this toxicity. Unpredictably severe myelosuppression with pemetrexed, seen especially in patients with preexisting homocystinemia, largely is eliminated by concurrent administration of low dosages of folic acid, 350–1000 mg/d, beginning 1–2 weeks prior to pemetrexed and continuing while the drug is administered. Patients should receive intramuscular vitamin B₁₂ (1 mg) with the first dose of pemetrexed to correct possible B₁₂ deficiency. These small doses of folate and B₁₂ do not compromise the therapeutic effect.

Pyrimidine Analogues

The pyrimidine antimetabolites encompass a diverse group of drugs that inhibit RNA and DNA function. The fluoropyrimidines and certain purine analogues (6MP and 6TG) inhibit the synthesis of essential precursors of DNA. Others, such as the cytidine and adenosine nucleoside analogues, become incorporated into DNA and block its further elongation and function (Wilson et al., 2014). Other inhibitory effects of these analogues may contribute to their cytotoxicity and their capacity to induce differentiation.

Cellular Actions of Pyrimidine Antimetabolites

Four bases (Figure 66–7) form DNA: two pyrimidines (thymine and cytosine) and two purines (guanine and adenine). RNA differs in that it incorporates uracil instead of thymine as one of its bases. Strategies for inhibiting DNA synthesis are based on the ability to create analogues of these precursors that readily enter tumor cells and become activated intracellularly. As an example, the pyrimidine analog 5FU is converted to an FdUMP, which in turn blocks TS, an enzyme required for the physiological conversion of dUMP to dTMP, a component of DNA (see Figure 66–6). Other analogues incorporate into DNA itself and thereby block its function (Wilson et al., 2014).

Cells can make the purine and pyrimidine bases *de novo* and convert them to their active triphosphates (dNTPs), providing substrates for DNA polymerase. Alternatively, cells can salvage free bases or their deoxynucleosides from the bloodstream. Thus, cells can take up uracil, guanine, and their analogues and convert them to (deoxy)nucleotides by the addition of deoxyribose and phosphate groups. Antitumor analogues of these bases (5FU, 6TG) can be formulated as simple substituted bases. Other bases, including cytosine, thymine, and adenine, and their analogues can only be used as deoxynucleosides, which are readily transported into cells and activated to deoxynucleotides by intracellular kinase. Thus, cytarabine (cytosine arabinoside; Ara-C), gemcitabine, 5-azacytidine, and adenosine analogues (cladribine) (Figures 66–7 and 66–8) are nucleosides readily taken up by cells, converted to nucleotides, and incorporated into DNA.

Fludarabine phosphate, a nucleotide, is dephosphorylated rapidly in plasma, releasing the nucleoside that is readily taken up by cells. Analogues may differ from the physiological bases in a variety of ways: by altering in the purine or pyrimidine ring; by altering the sugar attached

to the base, as in the arabinoside, Ara-C; or by altering both the base and sugar, as in fludarabine phosphate (see Figure 66-7). These alterations produce inhibitory effects on vital enzymatic pathways and prevent DNA synthesis.

Fluorouracil, Floxuridine, Capecitabine

Fluorouracil is available as 5FU, as the derivative FdUR (not often used in clinical practice), and as a prodrug, capecitabine, which is ultimately converted to 5FU.

Mechanisms of Action

5-Fluorouracil requires enzymatic conversion (ribosylation and phosphorylation) to the nucleotide form to exert its cytotoxic activity. As the triphosphate FUTP, the drug is incorporated into RNA. Alternative reactions can produce the deoxy derivative FdUMP; FdUMP inhibits TS and blocks the synthesis of dTTP, a necessary constituent of DNA (Figure 66-6). The folate cofactor, 5,10-methylene FH_4 , and FdUMP form a covalently bound ternary complex with TS. The physiological complex of TS-folate-dUMP progresses to the synthesis of thymidylate by transfer of the methylene group and two hydrogen atoms from folate to dUMP, but this reaction is blocked in the inhibited complex of TS-FdUMP-folate by the stability of the fluorine carbon bond on FdUMP; sustained inhibition of the enzyme results.

5-Fluorouracil is incorporated into both RNA and DNA. In 5FU-treated cells, both FdUTP and dUTP (which accumulates behind the blocked TS reaction) incorporate into DNA in place of the depleted physiological TTP. Presumably, such incorporation into DNA calls into action the excision-repair process, which can lead to DNA strand breakage because DNA repair requires TTP, which is lacking as a result of TS inhibition. 5FU incorporation into RNA also causes toxicity as the result of major effects on both the processing and the functions of RNA.

Mechanisms of Resistance

Resistance to the cytotoxic effects of 5FU or FdUR has been ascribed to loss or decreased activity of the enzymes necessary for activation of 5FU, amplification of TS, mutation of TS to a form that is not inhibited by

FdUMP, and high levels of the degradative enzymes dihydrouracil dehydrogenase and thymidine phosphorylase. TS levels are finely controlled by an autoregulatory feedback mechanism wherein the unbound enzyme interacts with and inhibits the translational efficiency of its own mRNA, which provides for the rapid TS modulation needed for cellular division. When TS is bound to FdUMP, inhibition of translation is relieved and levels of free TS rise, restoring thymidylate synthesis. Thus, TS autoregulation may be an important mechanism by which malignant cells become insensitive to the effects of 5FU.

Combination With Leucovorin

Some malignant cells appear to have insufficient concentrations of 5,10-methylene FH_4 and thus cannot form maximal levels of the inhibited ternary complex with TS. Addition of exogenous folate in the form of leucovorin increases formation of the complex and enhances responses to 5FU. A number of other agents have been combined with 5FU in attempts to enhance the cytotoxic activity through biochemical modulation. MTX, by inhibiting purine synthesis and increasing cellular pools of PRPP, enhances the activation of 5FU and increases antitumor activity of 5FU when given prior to but not following 5FU. The combination of cisplatin and 5FU has yielded impressive responses in tumors of the upper aerodigestive tract, but the molecular basis of their interaction is unclear. A combination with oxaliplatin, which downregulates TS expression, is commonly used with 5FU and leucovorin for treating patients with metastatic colorectal cancer; the combination is abbreviated as FOLFOX. Addition of irinotecan (see discussion that follows) is abbreviated as FOLFIRINOX and used in the treatment of patients with colorectal or pancreatic cancer. A most important interaction is the enhancement of irradiation by fluoropyrimidines, the basis for which is unclear. 5FU with simultaneous irradiation cures patients with anal cancer and enhances local tumor control in patients with head, neck, cervical, rectal, gastroesophageal, and pancreatic cancer.

ADME

5-Fluorouracil is administered parenterally because absorption after oral ingestion of the drug is unpredictable and incomplete. 5FU is inactivated

1182 by reduction of the pyrimidine ring in a reaction carried out by DPD, which is found in liver, intestinal mucosa, tumor cells, and other tissues. Inherited deficiency of this enzyme leads to greatly increased sensitivity to the drug (Milano et al., 1999). DPD deficiency can be detected by either enzymatic or molecular assays using peripheral white blood cells or by determining the plasma ratio of 5FU to its metabolite, 5-fluoro-5,6-dihydrouracil.

Plasma clearance is rapid ($t_{1/2}$ about 10–20 min). Only 5%–10% of a single intravenous dose of 5FU is excreted intact in the urine. The dose does not have to be modified in patients with hepatic dysfunction, presumably because of sufficient degradation of the drug at extrahepatic sites. 5FU enters the CSF in minimal amounts.

Therapeutic Uses

5-Fluorouracil. 5-Fluorouracil produces partial responses in 10%–20% of patients with metastatic colon carcinomas, upper GI tract carcinomas, and breast carcinomas but rarely is used as a single agent. 5FU in combination with leucovorin and oxaliplatin or irinotecan (FOLFOX or FOLFIRINOX) in adjuvant therapy is associated with a survival advantage for patients with colorectal cancers. For average-risk patients in good nutritional status with adequate hematopoietic function, the dosage regimen employs leucovorin once each week for 6 of 8 weeks. Other regimens use daily doses for 5 days, repeated in monthly cycles. When used with leucovorin, doses of daily 5FU for 5 days must be reduced because of mucositis and diarrhea. 5FU increasingly is used as a biweekly infusion, a schedule that has less overall toxicity as well as superior response rates and progression-free survival for patients with metastatic colon cancer.

Floxuridine. Fluorodeoxyuridine is converted directly to FdUMP by thymidine kinase. The drug is administered primarily by continuous infusion into the hepatic artery for treatment of patients with metastatic carcinoma of the colon or following resection of hepatic metastases; the response rate of intrahepatic infusion (40%–50%) is twice that of intravenous administration. Intrahepatic arterial infusion for 14–21 days causes minimal systemic toxicity; however, there is a significant risk of biliary sclerosis if this route is used for multiple cycles of therapy. Treatment should be discontinued at the earliest manifestation of toxicity (usually stomatitis or diarrhea) because the maximal effects of bone marrow suppression and gut toxicity will not be evident until days 7–14.

Capecitabine. Capecitabine, an orally administered prodrug of 5FU, is approved for the treatment of patients with (1) metastatic breast cancer who have not responded to a regimen of paclitaxel and an anthracycline; (2) metastatic breast cancer when used in combination with docetaxel in patients who have had a prior anthracycline-containing regimen; and (3) metastatic colorectal cancer.

The recommended dosage is given in two divided doses with food, for 2 weeks, followed by a rest period of 1 week. Capecitabine is well absorbed orally. It is rapidly deesterified and deaminated, yielding high plasma concentrations of an inactive prodrug 5'-dFdU, which disappears with a $t_{1/2}$ of about 1 h. The conversion of 5'-dFdU to 5FU by thymidine phosphorylase occurs in liver tissues, peripheral tissues, and tumors. 5FU levels are less than 10% of those of 5'-dFdU, reaching a maximum of 0.3 mg/L or 1 μ M at 2 h. Liver dysfunction delays the conversion of the parent compound to 5'-dFdU and 5FU, but there is no consistent effect on toxicity.

Combination Therapy. Higher response rates are seen when 5FU or capecitabine is used in combination with other agents (e.g., with cisplatin in head and neck cancer, with oxaliplatin or irinotecan in colon cancer). The combination of 5FU and oxaliplatin or irinotecan has become the standard first-line treatment of patients with metastatic colorectal cancer (FOLFOX and FOLFIRINOX). The use of 5FU in combination regimens has improved survival in the adjuvant treatment of breast cancer and, with oxaliplatin and leucovorin, of colorectal cancer. 5FU also is a potent radiation sensitizer. Beneficial effects have been reported when combined with irradiation as primary treatment of patients with locally advanced cancers of the esophagus, stomach, pancreas, cervix, anus, and head and neck. 5FU is effective in the topical treatment of premalignant keratoses of the skin and multiple superficial basal cell carcinomas.

Adverse Effects

The clinical manifestations of toxicity caused by 5FU and floxuridine are similar. The earliest untoward symptoms during a course of therapy are anorexia and nausea, followed by stomatitis and diarrhea, reliable warning signs that a sufficient dose has been administered. Mucosal ulcerations occur throughout the GI tract and may lead to fulminant diarrhea, shock, and death, particularly in patients who are DPD deficient. The major toxic effects of bolus-dose regimens result from the myelosuppressive action of 5FU. The nadir of leukopenia usually occurs 9–14 days after the first injection of drug. Thrombocytopenia and anemia also may occur, as may loss of hair (occasionally progressing to total alopecia), nail changes, dermatitis, and increased pigmentation and atrophy of the skin. Hand-foot syndrome, a particularly prominent adverse effect of capecitabine, consists of erythema, desquamation, pain, and sensitivity to touch of the palms and soles. Acute chest pain with evidence of ischemia in the electrocardiogram may result from coronary artery vasospasms during or shortly after 5FU infusion. In general, myelosuppression, mucositis, and diarrhea occur less often with infusional than with bolus regimens, while hand-foot syndrome occurs more often with infusional than with bolus regimens. The significant risk of toxicity with fluoropyrimidines requires close supervision by physicians familiar with the drug's effects and possible hazards.

Capecitabine causes a similar spectrum of toxicities as 5FU (diarrhea, myelosuppression), but the hand-foot syndrome occurs more frequently and may require dose reduction or cessation of therapy.

Trifluridine

Trifluridine is a trifluoro nucleoside analogue of FdUR (see Figure 66–8). It is used in eye drops for the treatment of HSV and in a fixed combination with *tipiracil*, a thymidine phosphorylase inhibitor, for the treatment of patients with metastatic colorectal cancers who have previously received other standard combination treatments that included FOLFIRINOX. *Trifluridine* and *tipiracil* are formulated together in a single tablet with *tipiracil* added to prevent rapid breakdown of trifluridine. The trifluridine mechanism of action mimics that of 5FU (Davidson et al., 2016).

Cytidine Analogues

Cytarabine (Cytosine Arabinoside; Ara-C)

Cytarabine is the most important antimetabolite used in the therapy of AML; it is the single most effective agent for induction of remission in this disease.

Mechanisms of Action

Cytarabine is an analogue of 2'-deoxycytidine; the 2'-hydroxyl in a position *trans* to the 3'-hydroxyl of the sugar (see Figures 66–7 and 66–8) hinders rotation of the pyrimidine base around the nucleoside bond and interferes with base pairing. The drug enters cells via ENT1 (or SLC29A1). It is then converted to its active form, the 5'-monophosphate ribonucleotide, by dCK, an enzyme that shows polymorphic expression amongst patients (see discussion that follows). Ara-CMP then reacts with deoxynucleotide kinases to form diphosphate and triphosphates (Ara-CDP and Ara-CTP). Ara-CTP competes with dCTP for incorporation into DNA by DNA polymerases. The incorporated Ara-CMP residue is a potent inhibitor of DNA polymerase, in both replication and repair synthesis, and blocks the further elongation of the nascent DNA molecule. If DNA breaks are not repaired, apoptosis ensues. Ara-C cytotoxicity correlates with the total Ara-C incorporated into DNA; incorporation of about 5 molecules of Ara-C per 10⁴ bases of DNA decreases cellular clonogenicity by about 50% (Kufe et al., 1984).

In infants and adults with ALL and t(4;11) MLL translocation, high-dose Ara-C is particularly effective; in these patients, the nucleoside transporter ENT1 is highly expressed, and its expression correlates with sensitivity to Ara-C (Pui et al., 2004). At extracellular drug concentrations greater than 10 μ M (levels achievable with high-dose Ara-C), the nucleoside transporter no longer limits drug accumulation, and intracellular metabolism to a triphosphate becomes rate limiting. Patients with particular

subtypes of AML derive benefit from high-dose Ara-C treatment; these types include t(8;21), inv(16), t(9;16), and del(16). Approximately 20% of patients with AML have leukemic cells with a *KRAS* mutation, and these patients seem to derive greater benefit from high-dose Ara-C regimens than do patients with wild-type *KRAS*.

Mechanisms of Resistance

Response to Ara-C is strongly influenced by the relative activities of anabolic and catabolic enzymes that determine the proportion of drug converted to Ara-CTP. The rate-limiting activating enzyme dCK produces Ara-CMP. It is opposed by the degradative enzyme, cytidine deaminase, which converts Ara-C to a nontoxic metabolite, Ara-U. Cytidine deaminase activity is high in many normal tissues, including intestinal mucosa, liver, and neutrophils, but lower in AML cells and other human tumors. A second degradative enzyme, dCMP deaminase, converts Ara-CMP to the inactive metabolite Ara-UMP. Increased synthesis and retention of Ara-CTP in leukemic cells lead to a longer duration of complete remission in patients with AML. The capacity of cells to transport Ara-C also may affect response. Clinical studies have implicated a loss of dCK as the primary mechanism of resistance to Ara-C in AML.

ADME

Due to the presence of high concentrations of cytidine deaminase in the GI mucosa and liver, only about 20% of the drug reaches the circulation after oral Ara-C administration; thus, the drug must be given intravenously. Peak concentrations of 2–50 μM are measurable in plasma after intravenous injection of 30–300 mg/m^2 but fall rapidly ($t_{1/2} \approx 10$ min). Less than 10% of the injected dose is excreted unchanged in the urine within 12–24 h; most appears as the inactive deaminated product, Ara-U. Higher concentrations of Ara-C are found in CSF after continuous infusion than after rapid intravenous injection but are 10% or less of concentrations in plasma. After intrathecal administration of the drug at a dose of 50 mg/m^2 , deamination proceeds slowly, with a $t_{1/2}$ of 3–4 h, and peak concentrations of 1–2 μM are achieved. CSF concentrations remain above the threshold for cytotoxicity (0.4 μM) for 24 h or longer. A depot liposomal formulation of Ara-C provides sustained release into the CSF. After a standard dose, liposomal Ara-C remains above cytotoxic levels for an average of 12 days, thus avoiding the need for frequent lumbar punctures.

Therapeutic Uses

Continuous inhibition of DNA synthesis for a duration equivalent to at least one cell cycle or 24 h is necessary to expose most tumor cells during the S phase of the cell cycle. The optimal interval between bolus doses of Ara-C is about 8–12 h, a schedule that maintains intracellular concentrations of Ara-CTP at inhibitory levels during a multiday cycle of treatment. In general, children tolerate higher doses than adults. The intrathecal administration of liposomal cytarabine every 2 weeks seems equally effective as the regimen every 4 days with the standard drug. Ara-C is indicated for induction and maintenance of remission in AML and is useful in the treatment of patients with other leukemias, such as ALL, CML in the blast phase, APL, and high-grade lymphomas. Because drug concentration in plasma rapidly falls below the level needed to saturate transport and intracellular activation, clinicians have employed high-dose regimens every 12 h for 3–4 days to achieve 20–50 times higher serum levels, with improved results in remission induction and consolidation for AML. Injection of the liposomal formulation is indicated for the intrathecal treatment of lymphomatous meningitis.

Adverse Effects

Cytarabine is myelosuppressive and can produce acute, severe leukopenia, thrombocytopenia, and anemia with striking megaloblastic changes. Other toxic manifestations include GI disturbances, stomatitis, conjunctivitis, reversible hepatic enzyme elevations, noncardiogenic pulmonary edema, and dermatitis. The onset of dyspnea, fever, and pulmonary infiltrates on chest computed tomographic scans may follow 1–2 weeks after high-dose Ara-C and may be fatal in 10%–20% of patients, especially in patients being treated for relapsed leukemia. No specific therapy, other than Ara-C discontinuation, is indicated. Intrathecal Ara-C, either the free drug or the liposomal preparation, may cause arachnoiditis, seizures, delirium, myelopathy,

or coma, especially if given concomitantly with systemic high-dose MTX or systemic Ara-C. Cerebellar toxicity, manifesting as ataxia and slurred speech, and cerebral toxicity (seizures, dementia, and coma) may follow intrathecal administration or high-dose systemic administration, especially in patients older than 40 years or patients with poor renal function.

Azacitidine (5-Azacytidine); Decitabine

5-Azacytidine (Figure 66–7) and decitabine (2'-deoxy-5-azacytidine; Figure 66–8) have antileukemic activity and induce differentiation by inhibiting DNA cytosine methyltransferase activity. Both drugs are approved for treatment of myelodysplasia, for which they induce normalization of bone marrow in 15%–20% of patients and reduce the transfusion requirement in one-third of patients. 5-Azacytidine improves survival.

Mechanism of Action

The aza-nucleosides enter cells by ENT1 (SLC29A1). The drugs incorporate into DNA, where they become covalently bound to the DNA methyltransferase, depleting intracellular enzyme and leading to global demethylation of DNA that results in tumor cell differentiation and apoptosis. Decitabine also induces double-strand DNA breaks, perhaps as a consequence of the effort to repair the protein-DNA adduct.

ADME

After subcutaneous administration, 5-azacytidine undergoes rapid deamination by cytidine deaminase (plasma $t_{1/2} \sim 20$ –40 min). Due to the formation of intracellular nucleotides that become incorporated into DNA, the effects of the aza-nucleosides persist for many hours.

Therapeutic Use

The usual treatment regimen for 5-azacytidine in patients with MDS is daily for 7 days every 28 days, while decitabine is given intravenously every day for 5 days every 4 weeks. Best responses may become apparent only after two to five courses of treatment.

Adverse Effects

The major toxicities of the aza-nucleosides include myelosuppression and mild GI symptoms. 5-Azacytidine produces severe nausea and vomiting when given intravenously in large doses (150–200 $\text{mg}/\text{m}^2/\text{d}$ for 5 days).

Gemcitabine

Gemcitabine, a difluoro analogue of deoxycytidine (dFdC; see Figure 66–8), is used for patients with metastatic pancreatic; non-squamous, non-small cell lung; ovarian; and bladder cancer.

Mechanism of Action

Gemcitabine enters cells via three distinct nucleoside transporters: ENT1 (SLC29A1; the major route); CNT1 (SLC28A1); and a nucleobase transporter found in malignant mesothelioma cells. Intracellularly, dCK phosphorylates gemcitabine to the monophosphate (dFdCMP), which is converted to di- and triphosphates (dFdCDP and dFdCTP, respectively). Although gemcitabine's anabolism and effects on DNA in general mimic those of cytarabine, there are distinct differences in kinetics of inhibition, additional enzymatic sites of action, different effects of incorporation into DNA, and a distinct spectrum of clinical activity. Unlike that of cytarabine, the cytotoxicity of gemcitabine is not confined to the S phase of the cell cycle. The cytotoxic activity may reflect several actions on DNA synthesis. dFdCTP competes with dCTP as a weak inhibitor of DNA polymerase. dFdCDP is a stoichiometric inhibitor of RNR, resulting in depletion of deoxyribonucleotide pools necessary for DNA synthesis. Incorporation of dFdCTP into DNA causes DNA strand termination (Heinemann et al., 1988) and appears resistant to repair. The capacity of cells to incorporate dFdCTP into DNA is critical for gemcitabine-induced apoptosis. Gemcitabine is inactivated by cytidine deaminase, which is found both in tumor cells and throughout the body.

ADME

Gemcitabine is administered as an intravenous infusion. The pharmacokinetics of the parent compound are largely determined by deamination in liver, plasma, and other organs, and the predominant urinary elimination product is dFdU. In patients with significant renal dysfunction, dFdU and

1184 its triphosphate accumulate to high and potentially toxic levels. Gemcitabine has a short plasma $t_{1/2}$ (~15 min); women and elderly patients clear the drug more slowly.

Therapeutic Uses

The standard dosing schedule for gemcitabine is an intravenous infusion on days 1, 8, and 15 of each 21- to 28-day cycle, depending on the indication. Conversion of gemcitabine to dFdCMP by dCK is saturated at infusion rates of about 10 mg/m²/min. To increase dFdCTP formation, the duration of infusion at this maximum concentration has been extended to 100–150 min at a fixed rate of 10 mg/min. The 150-min infusion produces a higher level of dFdCTP within peripheral blood mononuclear cells and increases the degree of myelosuppression. The inhibition of DNA repair by gemcitabine may increase cytotoxicity of other agents, particularly platinum compounds, and with radiation therapy.

Adverse Effects

The principal toxicity is myelosuppression. Longer duration infusions lead to greater myelosuppression and hepatic toxicity. Nonhematological toxicities include a flu-like syndrome, asthenia, and rarely a posterior leukoencephalopathy syndrome. Mild, reversible elevation in liver transaminases may occur in 40% or more of patients. Interstitial pneumonitis, at times progressing to ARDS, may occur within the first two cycles of treatment and usually responds to corticosteroids. Rarely, patients treated for many months may develop a slowly progressive hemolytic uremic syndrome, necessitating drug discontinuation. Gemcitabine is a very potent radiosensitizer and should not be used with radiotherapy.

Purine Analogues

The pioneering studies of Hitchings and Elion identified analogues of naturally occurring purine bases with antileukemic and immunosuppressant properties. Figure 66–9 shows structural formulas of several purine analogues, with adenosine for comparison. Other purine analogues that have valuable roles in leukemia and lymphoid malignancies include cladribine (standard therapy of hairy cell leukemia), fludarabine phosphate (standard treatment of CLL), nelarabine (pediatric ALL), and clofarabine (T-cell leukemia/lymphoma). The apparent selectivity of these agents may relate to their effective uptake, activation, and apoptotic effects in lymphoid tissue.

6-Thiopurine Analogues

6-Mercaptopurine and 6TG are approved agents for human leukemias and function as analogues of the natural purines hypoxanthine and guanine. The substitution of sulfur for oxygen on C6 of the purine ring creates compounds that are readily transported into cells, including activated malignant cells. Nucleotides formed from 6MP and 6TG inhibit *de novo* purine synthesis and also become incorporated into nucleic acids (Figure 51–5).

Mechanism of Action

Hypoxanthine guanine phosphoribosyl transferase converts 6TG and 6MP to the ribonucleotides 6-thioGMP and 6-thioIMP (T-IMP), respectively. Because T-IMP is a poor substrate for guanylyl kinase (the enzyme that converts GMP to GDP), T-IMP accumulates intracellularly. T-IMP inhibits the new formation of ribosyl-5-phosphate, as well as conversion of IMP to adenine and guanine nucleotides. The most important point of attack seems to be the reaction of glutamine and PRPP to form ribosyl-5-phosphate, the first committed step in the *de novo* pathway. 6TG nucleotide is incorporated into DNA, where it induces strand breaks and base mispairing.

Mechanisms of Resistance

The most common mechanism of 6MP resistance observed *in vitro* is deficiency or complete lack of the activating enzyme HGPRT or increased alkaline phosphatase activity. Other mechanisms for resistance include

- decreased drug uptake or increased efflux due to active transporters;
- alteration in allosteric inhibition of ribosylamine 5-phosphate synthase; and
- impaired recognition of DNA breaks and mismatches due to loss of a component (MSH6) of MMR system (Karran and Attard, 2008).

Figure 66–9 Adenosine and various purine analogues.

ADME and Toxicity

Absorption of oral mercaptopurine is incomplete (10%–50%); the drug is subject to first-pass metabolism by xanthine oxidase in the liver. Food or oral antibiotics decrease absorption. Oral bioavailability is increased when mercaptopurine is combined with high-dose MTX. After an intravenous dose, the $t_{1/2}$ of the drug is about 50 min in adults due to rapid metabolic degradation by xanthine oxidase and by TPMT. Restricted brain distribution of mercaptopurine results from an efficient efflux transport system in the blood-brain barrier. In addition to the HGPRT-catalyzed anabolism of mercaptopurine, there are two other pathways for its metabolism. The first involves methylation of the sulfhydryl group and subsequent oxidation of the methylated derivatives. Activity of the enzyme TPMT reflects the inheritance of polymorphic alleles; up to 15% of the Caucasian population has decreased enzyme activity. Low levels of erythrocyte TPMT activity are associated with increased drug toxicity in individual patients and a lower risk of relapse. In patients with autoimmune disease treated with mercaptopurine, those with polymorphic alleles may experience bone marrow aplasia and life-threatening toxicity. Testing for these polymorphisms prior to treatment is recommended in this patient population.

A relatively large percentage of the administered sulfur appears in the urine as inorganic sulfate. The second major pathway for 6MP metabolism involves its oxidation by xanthine oxidase to 6-thiourate, an inactive metabolite. Oral doses of 6MP should be reduced by 75% in patients receiving the xanthine oxidase inhibitor allopurinol; no dose adjustment is required for intravenous dosing.

Therapeutic Uses

In the maintenance therapy of ALL, an initial daily oral dose of 6MP is adjusted according to white blood cell and platelet counts. The combination of MTX and 6MP appears to be synergistic. By inhibiting the earliest steps in purine synthesis, MTX elevates the intracellular concentration of PRPP, a cofactor required for 6MP activation.

Adverse Effects

The principal toxicity of 6MP is myelosuppression. Thrombocytopenia, granulocytopenia, or anemia may not become apparent for several weeks. Dose reduction usually results in prompt recovery, although myelosuppression may be severe and prolonged in patients with a polymorphism affecting TPMT. Anorexia, nausea, or vomiting is seen in about 25% of adults, but stomatitis and diarrhea are rare; manifestations of GI effects are less frequent in children than in adults. Jaundice and hepatic enzyme elevations occur in up to one-third of adult patients treated with 6MP and usually resolve on discontinuation of therapy. 6MP and its derivative azathioprine predispose to opportunistic infection (e.g., reactivation of hepatitis B, fungal infection, and *Pneumocystis pneumonia*) and an increased incidence of squamous cell malignancies of the skin. 6MP is teratogenic during the first trimester of pregnancy, and AML has been reported after prolonged 6MP therapy for Crohn disease.

Fludarabine Phosphate

Fludarabine phosphate is a fluorinated, deamination-resistant, phosphorylated analogue of the antiviral agent vidarabine (9- β -D-arabinofuranosyl-adenine). It is active in CLL and low-grade lymphomas and is also effective as a potent immunosuppressant.

Mechanisms of Action and Resistance

The drug is dephosphorylated extracellularly to the nucleoside fludarabine, which enters the cell and is rephosphorylated by dCK to the active triphosphate. This antimetabolite inhibits DNA polymerase, DNA primase, DNA ligase, and RNR and becomes incorporated into DNA and RNA. The nucleotide is an effective chain terminator when incorporated into DNA (Kamiya et al., 1996). Incorporation of fludarabine into RNA inhibits RNA function, RNA processing, and mRNA translation.

In experimental tumors, resistance to fludarabine is associated with decreased activity of dCK (the enzyme that phosphorylates the drug), increased drug efflux, and increased RNR activity. Its mechanism of immunosuppression and paradoxical stimulation of autoimmunity stems from the particular susceptibility of lymphoid cells to purine analogues and the specific effects on the CD4⁺ subset of T cells, as well as its inhibition of regulatory T-cell responses.

ADME

Fludarabine phosphate is administered both intravenously and orally and is rapidly converted to fludarabine in the plasma. The median time to reach maximal concentrations of drug in plasma after oral administration is 1.5 h, and oral bioavailability averages 55%–60%. The $t_{1/2}$ of fludarabine in plasma is about 10 h. The compound is eliminated primarily by renal excretion.

Therapeutic Uses

Fludarabine phosphate is approved for intravenous and oral use and is equally active by both routes. The recommended dose interval is daily for 5 days and may be repeated every 4 weeks. Gradual improvement in CLL usually occurs within two to three cycles. Dosage should be reduced in patients with renal impairment in proportion to the reduction in CL_{CR} . Fludarabine phosphate is highly active alone or with rituximab and cyclophosphamide for the treatment of patients with CLL; overall response rates in previously untreated patients approximate 80%, and the duration of response averages 22 months. The synergy of fludarabine with alkylators

may stem from the observation that it blocks the repair of double-strand DNA breaks and interstrand cross-links induced by alkylating agents. It also is effective in follicular B-cell lymphomas refractory to standard therapy. It is increasingly used as a potent immunosuppressive agent in nonmyeloablative allogeneic bone marrow transplantation.

Adverse Effects

Oral and intravenous therapy cause myelosuppression in about 50% of patients, nausea and vomiting in a minor fraction, and, uncommonly, chills and fever, malaise, anorexia, peripheral neuropathy, and weakness. Lymphopenia and thrombocytopenia and cumulative side effects are expected. Depletion of CD4⁺ T cells with therapy predisposes to opportunistic infections. Tumor lysis syndrome, a rare complication, occurs primarily in previously untreated patients with CLL. Altered mental status, seizures, optic neuritis, and coma have been observed at higher doses and in older patients. Autoimmune events may occur after fludarabine treatment. Patients with CLL may develop an acute hemolytic anemia or pure red cell aplasia during or following fludarabine treatment. Prolonged cytopenias, probably mediated by autoimmunity, also complicate fludarabine treatment. Myelodysplasia and acute leukemias may arise as late complications. Pneumonitis is an occasional side effect and responds to corticosteroids. In patients with compromised renal function, the initial doses should be reduced in proportion to the reduction in CL_{CR} .

Cladribine

Cladribine is an ADA-resistant purine analogue that has potent and curative activity in hairy cell leukemia, CLL, and low-grade lymphomas.

Mechanisms of Action and Resistance

Cladribine enters cells via active nucleoside transport. After phosphorylation by dCK and conversion to cladribine triphosphate, it is incorporated into DNA. It produces DNA strand breaks and depletion of NAD and ATP, leading to apoptosis. It is a potent inhibitor of RNR. The drug does not require cell division to be cytotoxic. Resistance is associated with loss of the activating enzyme dCK; increased expression of RNR; or increased active efflux by ABCG2 or other members of the ABC family of transporters.

ADME

Cladribine is absorbed orally (55%) but is routinely administered intravenously. It is excreted by the kidneys, with a terminal $t_{1/2}$ in plasma of 6.7 h. Cladribine crosses the blood-brain barrier and reaches CSF concentrations of about 25% of those seen in plasma. Doses should be adjusted for renal dysfunction.

Therapeutic Uses

Cladribine is administered daily for 7 days by continuous intravenous infusion. It is the drug of choice in hairy cell leukemia. Eighty percent of patients achieve a complete response after a single course of therapy. The drug also is active in CLL; low-grade lymphomas; Langerhans cell histiocytosis; CTCLs, including mycosis fungoides and the Sézary syndrome; and Waldenström macroglobulinemia.

Adverse Effects

The major dose-limiting toxicity of cladribine is myelosuppression. Cumulative thrombocytopenia may occur with repeated courses. Opportunistic infections are common and correlate with decreased CD4⁺ cell counts. Other toxic effects include nausea, infections, high fever, headache, fatigue, skin rashes, and tumor lysis syndrome.

Clofarabine (2-Chloro-2'-fluoro-arabinosyladenine)

The analogue clofarabine (2-chloro-2'-fluoro-arabinosyladenine) incorporates the 2-chloro, glycosylase-resistant substituent of cladribine and a 2'-fluoro-arabinosyl substitution, which adds stability and enhances uptake and phosphorylation. The resulting compound is approved for the treatment of pediatric ALL after failure of two prior therapies. Clofarabine produces complete remissions in 20%–30% of these patients.

1186 It has activity in pediatric and adult AML and in myelodysplasia. The uptake and metabolic activation of clofarabine in tumor cells follow the same path as cladribine and the other purine nucleosides, although clofarabine is more readily phosphorylated by dCK. Clofarabine triphosphate has a long intracellular $t_{1/2}$ (24 h). It incorporates into DNA, where it terminates DNA synthesis and leads to apoptosis; clofarabine also inhibits RNR.

Therapeutic Uses and Adverse Effects

In children, clofarabine is administered as a 2-h infusion daily for 5 days. The primary elimination $t_{1/2}$ in plasma is 6.5 h. Most of the drug is excreted unchanged in the urine. Doses should be adjusted according to reductions in CL_{Cr} . The primary toxicities are myelosuppression; a clinical syndrome of hypotension, tachypnea, pulmonary edema, organ dysfunction, and fever, all suggestive of capillary leak syndrome and cytokine release that necessitate immediate discontinuation of the drug; elevated hepatic enzymes and increased bilirubin; nausea, vomiting, and diarrhea; and hypokalemia and hypophosphatemia.

Nelarabine (6-Methoxy-arabinosyl-guanine)

Nelarabine (6-methoxy-arabinosyl-guanine) is the only guanine nucleoside in clinical use. It has selective activity against acute T-cell leukemia (20% complete responses) and the closely related T-cell lymphoblastic lymphoma and is approved for use in patients with relapsed/refractory disease. Its basic mechanism of action closely resembles that of the other purine nucleosides, in that it is incorporated into DNA and terminates DNA synthesis.

ADME

Following infusion, the parent methoxy compound is rapidly activated in blood and tissues by ADA-mediated cleavage of the methyl group, yielding the phosphorylase resistant Ara-G, which has a plasma $t_{1/2}$ of 3 h. The active metabolite is transported into tumor cells, where it is activated by dCK to Ara-GTP, which incorporates into DNA and terminates DNA synthesis. The drug and its metabolite Ara-G are primarily eliminated by metabolism to guanine, and a smaller fraction is eliminated by renal excretion of Ara-G. The drug should be used with close clinical monitoring in patients with severe renal impairment ($CL_{Cr} < 50$ mg/mL). Adults are given a 2-h infusion on days 1, 3, and 5 of a 21-day cycle, and children are given a lower dose for 5 days, repeated every 21 days.

Adverse Effects

The adverse effects include myelosuppression and liver function test abnormalities, as well as infrequent serious neurological sequelae, such as seizures, delirium, somnolence, peripheral neuropathy, or Guillain-Barré syndrome. Neurological adverse effects may not be reversible.

Pentostatin (2'-Deoxycoformycin)

Pentostatin (2'-deoxycoformycin; see Figure 66-9), a transition-state analogue of the intermediate in the ADA reaction, potently inhibits ADA. Its effects mimic the phenotype of genetic ADA deficiency (severe immunodeficiency affecting T-cell and B-cell functions).

Mechanism of Action

Inhibition of ADA by pentostatin leads to accumulation of intracellular adenosine and deoxyadenosine nucleotides, which can block DNA synthesis by inhibiting RNR. Deoxyadenosine also inactivates S-adenosyl homocysteine hydrolase. The resulting accumulation of S-adenosyl homocysteine is particularly toxic to lymphocytes. Pentostatin also can inhibit RNA synthesis, and its triphosphate derivative is incorporated into DNA, resulting in strand breakage. Although the precise mechanism of cytotoxicity is not known, it is probable that the imbalance in purine nucleotide pools accounts for its antineoplastic effect in hairy cell leukemia and T-cell lymphomas.

ADME

Pentostatin is administered intravenously every other week and has a mean terminal $t_{1/2}$ of 5.7 h. After hydration with 500–1000 mL of 5% dextrose in half-normal (0.45%) saline, the drug is administered by rapid intravenous injection or by infusion over a period of 30 min or less, followed by an additional 500 mL of fluids. The drug is eliminated almost

entirely by renal excretion. Proportional reduction of dosage is recommended in patients with renal impairment as measured by reduced CL_{Cr} .

Therapeutic Use

Pentostatin is effective in producing complete remissions (58%) and partial responses (28%) in patients with hairy cell leukemia. It largely has been superseded by cladribine (see previous discussion). Toxic manifestations include myelosuppression, GI symptoms, skin rashes, and abnormal liver function studies. Depletion of normal T cells occurs, and neutropenic fever and opportunistic infections may result. Immunosuppression may persist for several years after discontinuation. At high doses, major renal and neurological complications are encountered. Pentostatin in combination with fludarabine phosphate may result in severe or even fatal pulmonary toxicity.

III. Natural Products

Microtubule-Damaging Agents

Vinca Alkaloids

Purified alkaloids from the periwinkle plant, including *vinblastine* and *vincristine*, were amongst the earliest clinical agents for the treatment of patients with leukemias, lymphomas, and testicular cancer. A closely related derivative, *vinorelbine*, has activity against lung and breast cancer.

Basic structure of vinca alkaloids

Mechanism of Action

The vinca alkaloids are cell-cycle-specific agents and, in common with other drugs, such as colchicine, podophyllotoxin, the taxanes, and the epothilones, block cells in mitosis. The biological activities of the vincas can be explained by their ability to bind specifically to β -tubulin and to block its polymerization with α -tubulin into microtubules (Akhmanova and Steinmetz, 2015). The mitotic spindle cannot form, duplicated chromosomes cannot align along the division plate, and cell division arrests in metaphase. Cells blocked in mitosis undergo changes characteristic of apoptosis. Microtubules are found in high concentration in the brain and contribute to other cellular functions, such as movement, phagocytosis, and axonal transport. Adverse effects of the vinca alkaloids, such as their neurotoxicity, may relate to disruption of these functions.

Resistance

Despite their structural similarity, the individual vinca alkaloids have unique patterns of clinical efficacy (see discussion that follows). However, in most experimental systems, they share cross-resistance. Their antitumor effects are blocked by multidrug resistance mediated by Pgp, which confers resistance to a broad range of agents (vinca alkaloids, epipodophyllotoxins, anthracyclines, and taxanes). Pgp, also known as MDR1, ABCB1, and CD243, is an ATP-dependent efflux pump with broad substrate specificity that provides a cellular defense mechanism against potentially harmful substances. Chromosomal abnormalities consistent with gene amplification and markedly increased levels of Pgp have been

observed in resistant cells in culture. Other membrane transporters, such as the MRP and the closely related BCRP, may contribute to resistance. Other forms of resistance to vinca alkaloids stem from mutations in β -tubulin or in the relative expression of isoforms of β -tubulin that prevent the inhibitors from effectively binding to their target.

Adverse Effects

The limited myelosuppressive activity of vincristine makes it a valuable component of several combination therapy regimens for leukemia and lymphoma, while the lack of severe neurotoxicity of vinblastine is a decided advantage in lymphomas and in combination with cisplatin against testicular cancer. Vinorelbine, which causes mild neurotoxicity and myelosuppression, has an intermediate toxicity profile.

ADME

Hepatic CYPs extensively metabolize all three drugs, and the metabolites are excreted in the bile. Only a small fraction of a dose (<15%) is found unchanged in the urine. In patients with hepatic dysfunction (bilirubin > 3 mg/dL), a 50%–75% reduction in dose of any of the vinca alkaloids is advisable. The elimination $t_{1/2}$ is 20 h for vincristine, 23 h for vinblastine, and 24 h for vinorelbine.

Vinblastine

Therapeutic Uses. Vinblastine sulfate is given intravenously; special precautions must be taken against subcutaneous extravasation, which may cause painful irritation and ulceration. The drug should not be injected into an extremity with impaired circulation. After a single dose, myelosuppression reaches its maximum in 7–10 days. If a moderate level of leukopenia (~ 3000 cells/mm³) is not attained, the weekly dose may be increased gradually. For testicular cancer, vinblastine is administered every 3 weeks. Doses should be reduced by 50% for patients with plasma bilirubin > 1.5 mg/dL. Vinblastine is used with bleomycin and cisplatin in the curative therapy of patients with metastatic testicular cancer, although it has been mainly supplanted by etoposide (see further discussion) or ifosfamide (see previous material). It is a component of the standard curative ABVD regimen for Hodgkin lymphoma. Vinblastine also is active against Kaposi sarcoma, neuroblastoma, Langerhans cell histiocytosis, bladder cancer, carcinoma of the breast, and choriocarcinoma.

Adverse Effects. Maximal leukopenia occurs within 7–10 days, after which recovery ensues within 7 days. Other toxic effects of vinblastine include mild neurological manifestations. GI disturbances, including nausea, vomiting, anorexia, and diarrhea, may be encountered. The syndrome of inappropriate secretion of antidiuretic hormone has been reported. Loss of hair, stomatitis, and dermatitis occur infrequently. Extravasation during injection may lead to cellulitis and phlebitis.

Vincristine

Therapeutic Uses. Vincristine is a standard component of regimens for treating pediatric patients with leukemias, lymphomas, and solid tumors, such as Wilms tumor, neuroblastoma, and rhabdomyosarcoma. In large-cell non-Hodgkin lymphomas, vincristine remains an important agent, particularly when used in the CHOP regimen. Vincristine with glucocorticoids is the treatment of choice to induce remissions in patients with childhood leukemia and in combination with alkylating agents and anthracycline for those with pediatric sarcomas. The common intravenous dosage for vincristine is 2 mg/m² of body surface area at weekly or longer intervals. Vincristine is tolerated better by children than by adults, who may experience severe, progressive neurological toxicity and require lowering of the dose. Administration of the drug more frequently than every 7 days or at higher doses increases the toxic manifestations without proportional improvement in the response rate. Precautions also should be used to avoid extravasation during intravenous administration. Doses should be reduced for patients with elevated plasma bilirubin.

Adverse Effects. The clinical toxicity of vincristine is mostly neurological. Severe neurological manifestations may be reversed by suspending therapy or reducing the dosage at the first sign of motor dysfunction. Severe constipation, sometimes resulting in colicky abdominal pain and obstruction, may be prevented by laxatives and hydrophilic (bulk-forming) agents

and usually is a problem only with doses greater than 2 mg/m². Reversible alopecia occurs in about 20% of patients. Modest leukopenia may occur. Thrombocytopenia, anemia, and the syndrome of inappropriate secretion of antidiuretic hormone are less common. Inadvertent injection of vincristine into the CSF causes a devastating and often-fatal irreversible coma and seizures.

Vinorelbine

Vinorelbine has activity against non-small cell lung cancer and breast cancer. Vinorelbine is administered in normal saline as an intravenous infusion over 6–10 min. When used alone, it is given at doses of 30 mg/m² either weekly or for 2 of every 3 weeks. When used with cisplatin for the treatment of non-small cell lung cancer, it is given at doses of 25 mg/m² either weekly or for 3 of every 4 weeks. A lower dose (20–25 mg/m²) may be required for patients who have received prior chemotherapy and for hematological toxicity. The primary adverse effect of vinorelbine is granulocytopenia, with only modest thrombocytopenia and less neurotoxicity than other vinca alkaloids. Vinorelbine may cause allergic reactions and mild, reversible changes in liver enzymes. Doses should be reduced in patients with elevated plasma bilirubin.

Eribulin

Eribulin is a synthetic analogue of halichondrin, a poly-ether macrolide, originally isolated from the Pacific marine sponge *Halichondria okadai*. The drug binds to the vinca alkaloid site on β -tubulin and inhibits microtubule assembly. Eribulin is a poorer substrate than other microtubule disruptors for the Pgp efflux pump and is effective in drug-resistant tumors that overexpress Pgp. Eribulin is approved for the treatment of patients with drug-resistant metastatic breast cancer and liposarcoma. Adverse effects overlap with those of the vinca alkaloids and include neutropenia, neuropathies, and GI toxicities.

Taxanes

Paclitaxel was first isolated from the bark of the Western yew tree. *Paclitaxel* and its semisynthetic congeners *docetaxel* and *cabazitaxel*, exhibit unique pharmacological properties as inhibitors of mitosis. These taxanes differ from the vinca alkaloids and colchicine derivatives in that they bind to a different site on β -tubulin and promote rather than inhibit microtubule formation (Figure 66–10), stabilizing tubulin-GDP (Akhmanova and Steinmetz, 2015). The taxanes have a central role in the therapy of patients with ovarian, breast, lung, GI, genitourinary, prostate, and head and neck cancers.

Core structure of taxanes

Figure 66-10 Inhibitors of microtubular function.

Mechanism of Action

Paclitaxel binds to the β -tubulin subunit on the inner surface of microtubules and antagonizes their disassembly (Figure 66-10), with the result that bundles of microtubules and aberrant structures derived from microtubules appear in the mitotic phase of the cell cycle. Arrest in mitosis follows. Cell death occurs by apoptosis and depends on both drug concentration and duration of drug exposure. Drugs that block cell-cycle progression prior to mitosis antagonize the toxic effects of taxanes.

Drug interactions have been noted. The sequence of cisplatin preceding paclitaxel decreases paclitaxel clearance and produces greater toxicity than the opposite schedule. Paclitaxel decreases doxorubicin clearance and enhances its cardiotoxicity; docetaxel has no apparent effect on anthracycline pharmacokinetics.

Resistance to taxanes can be a result of decreased cellular drug accumulation due to increased expression of membrane-bound efflux proteins, including MRP1 and Pgp. Cabazitaxel is a poor substrate for Pgp and may therefore be useful for treating multidrug-resistant tumors. Other mechanisms of resistance may include an increase in *survivin*, an anti-apoptotic factor; an increase in α -*aurora kinase*, which promotes completion of mitosis; an upregulation of the β III-isoform of tubulin that lacks taxane-binding capacity; or a direct alteration of the drug target by mutation.

ADME

Paclitaxel has limited water solubility and is administered in a vehicle of 50% ethanol and 50% polyethoxylated castor oil. Hepatic CYPs (primarily CYP2C8, secondarily CYP3A4) extensively metabolize the drug. The primary metabolite is 6-OH paclitaxel, which is inactive; multiple additional hydroxylation products are found in plasma; less than 10% of a dose is excreted in the urine intact. Dose reductions in patients with abnormal hepatic function have been suggested, and 50%–75% of doses of taxanes should be used in the presence of hepatic metastases larger than 2 cm in size or in patients with abnormal serum bilirubin. Drugs that induce CYP2C8 or CYP3A4, such as phenytoin and phenobarbital, or those that inhibit these CYPs, such as antifungal imidazoles, significantly alter drug clearance and toxicity.

Paclitaxel clearance is nonlinear and decreases with increasing dose or dose rate; the plasma $t_{1/2}$ is 10–14 h. The critical plasma concentration for myelosuppression depends on the duration of exposure but likely is 50–100 nM. Paclitaxel clearance is markedly delayed by cyclosporine A and other drugs that inhibit Pgp.

An albumin-bound nanoparticle solution for infusion (nab-paclitaxel) is soluble in aqueous solutions. This form of paclitaxel has increased cellular uptake via an albumin-specific mechanism. Nab-paclitaxel achieves a higher serum concentration than paclitaxel, but the increased clearance of nab-paclitaxel results in a similar systemic drug exposure. It is somewhat less neurotoxic than paclitaxel and is approved for metastatic non-small cell lung cancer. Like the other taxanes, nab-paclitaxel should not be given to patients with an absolute neutrophil count below 1500 cells/mm³.

Docetaxel, somewhat more soluble than paclitaxel, is administered intravenously in an emulsifier (polysorbate 80). Docetaxel pharmacokinetics are similar to those of paclitaxel, with an elimination $t_{1/2}$ of about 12 h. Clearance is primarily through CYP3A4- and CYP3A5-mediated hydroxylation, leading to inactive metabolites.

Therapeutic Uses

The taxanes have become central components of regimens for treating patients with metastatic ovarian, breast, lung, GI, genitourinary, and head

and neck cancers. These drugs are administered once weekly or once every 3 weeks. Cabazitaxel is a poor substrate for Pgp and is approved for hormone-refractory metastatic prostate cancer previously treated with a docetaxel-containing regimen.

Adverse Effects

Paclitaxel exerts its primary toxic effects on the bone marrow. Neutropenia usually occurs 8–11 days after a dose and reverses rapidly by days 15–21. Used with G-CSF, high doses over 24 h are well tolerated, and peripheral neuropathy becomes dose limiting. Many patients experience myalgias after receiving paclitaxel. In high-dose schedules, or with prolonged use, a stocking-glove sensory neuropathy can be disabling, particularly in patients with underlying diabetic neuropathy or concurrent cisplatin therapy. Mucositis is prominent in 72- or 96-h infusions and in the weekly schedule. Hypersensitivity reactions can occur in patients receiving paclitaxel infusions of short duration (1–6 h) but are largely averted by pretreatment with dexamethasone, diphenhydramine, and histamine H₂ receptor antagonists. Premedication is not necessary with 96-h infusions. Many patients experience asymptomatic bradycardia; occasional episodes of silent ventricular tachycardia also occur and resolve spontaneously during 3- or 24-h infusions. Nab-paclitaxel produces increased rates of peripheral neuropathy compared to the original cremophor-delivered paclitaxel but rarely causes hypersensitivity reactions.

Docetaxel causes greater degrees of neutropenia than paclitaxel but less peripheral neuropathy and asthenia and less frequent hypersensitivity. Fluid retention is a progressive problem with multiple cycles of docetaxel therapy, leading to peripheral edema, pleural and peritoneal fluid, and pulmonary edema in extreme cases. Oral dexamethasone, begun 1 day prior to drug infusion and continuing for 3 days, greatly ameliorates fluid retention. In rare cases, docetaxel may cause progressive interstitial pneumonitis and respiratory failure if the drug is not discontinued.

Estramustine

Estramustine combines estradiol and normustine (nornitrogen mustard) through a carbamate link. Although the intent of the combination was to enhance the uptake of the alkylating agent into estradiol-sensitive prostate cancer cells, estramustine does not function in vivo as an alkylating agent; rather, it binds to β -tubulin and microtubule-associated proteins, causing microtubule disassembly and antimetabolic actions.

Therapeutic Use

Estramustine is used solely for the treatment of patients with metastatic or locally advanced hormone-refractory prostate cancer.

ADME

Following oral administration, at least 75% of a dose of estramustine phosphate is absorbed from the GI tract and rapidly dephosphorylated. The drug undergoes extensive first-pass metabolism by hepatic CYPs to an active 17-keto derivative, estromustine, and to multiple inactive products; the active drug forms accumulate in the prostate. Some hydrolysis of the carbamate linkage occurs in the liver, releasing estradiol, estrone, and the normustine group. Estramustine and estromustine have plasma half-lives of 10 and 14 h, respectively, and are excreted as inactive metabolites, mainly in the feces.

Adverse Effects, Drug Interactions

In addition to myelosuppression, estramustine also possesses estrogenic side effects (gynecomastia, impotence, elevated risk of thrombosis, and fluid retention); hypercalcemia; acute attacks of porphyria; impaired glucose tolerance; and hypersensitivity reactions, including angioedema. Estramustine inhibits the clearance of taxanes.

Epothilones

The epothilones are polyketides discovered as cytotoxic metabolites from a strain of *Sorangium cellulosum*, a myxobacterium isolated from soil on the bank of the Zambezi River in southern Africa (Gerth et al., 1996). One of these, *ixabepilone*, is approved for breast cancer treatment; others are under development (Lee and Swain, 2008).

Ixabepilone

Mechanism of Action; Resistance. Epothilones bind to a β -tubulin site distinct from that of taxanes and trigger microtubule nucleation at multiple sites away from the centriole. This dysfunctional microtubule stabilization triggers cell-cycle arrest at the G_2 -M interface and apoptosis. In vitro studies suggested that ixabepilone is less susceptible to Pgp-mediated export and multidrug resistance than taxanes. Mechanisms implicated in epothilone resistance include mutation of the β -tubulin binding site and upregulation of isoforms of β -tubulin.

ADME. Ixabepilone is administered intravenously. Because of its minimal aqueous solubility, it is delivered in the solubilizing agent cremophor (polyoxyethylated castor oil/ethanol), which has been implicated as the cause of infusion reactions; such reactions are infrequent when administration is preceded by premedication with H_1 and H_2 antagonists. The drug is cleared by hepatic CYPs and has a plasma $t_{1/2}$ of 52 h.

Therapeutic Uses. In patients with metastatic breast cancer resistant to or pretreated with anthracyclines and resistant to taxanes, ixabepilone plus capecitabine provides an improved progression-free survival of 1.6 months compared to capecitabine alone. Ixabepilone also is indicated as monotherapy for metastatic breast cancer in patients who have previously progressed through treatment with anthracyclines, taxanes, and capecitabine. Ixabepilone (~ 40 mg/m²) is administered as monotherapy or in combination with capecitabine over 3 h every 3 weeks. Patients should be premedicated with both an H_1 and an H_2 antagonist before receiving ixabepilone to minimize hypersensitivity reactions. In patients with mild-to-moderate hepatic dysfunction who receive ixabepilone monotherapy, lower starting doses are recommended due to delayed drug clearance.

Adverse Effects. Epothilones have toxicities similar to those of the taxanes: neutropenia, peripheral sensory neuropathy, fatigue, diarrhea, and asthenia.

Camptothecin Analogues

The camptothecins are potent, cytotoxic antineoplastic agents that target the nuclear enzyme *topoisomerase I*. The lead compound in this class, camptothecin, was isolated from the tree *Camptotheca acuminata*. Irinotecan and topotecan, currently the only camptothecin analogues approved for clinical use, have activity in colorectal, ovarian, and small cell lung cancer.

Chemistry

All camptothecins have a fused five-ring backbone that includes a labile lactone ring (Figure 66–11). The hydroxyl group and S conformation of the chiral center at C20 in the lactone ring are required for biological activity. Appropriate substitutions on the A and B rings of the quinoline

	<u>C-10</u>	<u>C-9</u>	<u>C-7</u>
Camptothecin	H	H	H
Topotecan	OH	(CH ₃) ₂ NHCH ₂	H
Irinotecan		H	CH ₂ CH ₃
SN-38	OH	H	CH ₂ CH ₃

Figure 66–11 Camptothecin and its analogues.

subunit enhance water solubility and increase potency for inhibiting topoisomerase I. Topotecan is a semisynthetic molecule with a basic dimethylamino group that increases its water solubility. Irinotecan (CPT-11) differs from topotecan in that it is a prodrug. The carbamate bond between the camptothecin moiety and the dibasic bis-piperidine side chain at position C10 (which makes the molecule water soluble) is cleaved by a carboxylesterase to form the active metabolite SN-38 (see Figure 6–6).

Mechanism of Action

The DNA topoisomerases are nuclear enzymes that reduce torsional stress in supercoiled DNA, allowing selected regions of DNA to become sufficiently untangled to permit replication, repair, and transcription. Two classes of topoisomerase (I and II) mediate DNA strand breakage and resealing. Camptothecin analogues inhibit the function of topoisomerase I; other drugs, such as anthracyclines, epipodophyllotoxins, and acridines, inhibit topoisomerase II. The camptothecins bind to and stabilize the normally transient DNA–topoisomerase I cleavable complex. Although the initial cleavage action of topoisomerase I is not affected, the religation step is inhibited, leading to the accumulation of single-stranded breaks in DNA. These lesions are reversible and not by themselves toxic to the cell. However, the collision of a DNA replication fork with this cleaved strand of DNA causes an irreversible double-strand DNA break, ultimately leading to cell death.

Camptothecins are *S phase-specific drugs* because ongoing DNA synthesis is necessary for cytotoxicity. This has important clinical implications. *S phase-specific* cytotoxic agents generally require prolonged exposures of tumor cells to drug concentrations above a minimum threshold for optimal therapeutic efficacy. In fact, low-dose, protracted administration of camptothecin analogues have less toxicity, and equal or greater antitumor activity, than shorter, more intense courses.

Mechanisms of Resistance

Decreased intracellular drug accumulation may underlie resistance. Topotecan, but not irinotecan, is a substrate for Pgp; however, compared with other substrates, such as etoposide or doxorubicin, topotecan is a relatively poor substrate. Nonetheless, the BCRP/xenobiotic exporter ABCG2/BCRP is overexpressed in cultured cells that have become resistant to irinotecan after exposure to camptothecins. Cell lines that lack carboxylesterase activity demonstrate resistance to irinotecan, but the liver and red blood cells may have sufficient carboxylesterase activity to convert irinotecan to the active metabolite SN-38. Camptothecin resistance also may result from decreased expression or mutation of topoisomerase I. A transient downregulation of topoisomerase I has been demonstrated following prolonged exposure to camptothecins in vitro and in vivo. Mutations leading to reduced topoisomerase I enzyme catalytic activity or DNA-binding affinity have been associated with experimental camptothecin resistance. Finally, exposure of cells to topoisomerase I–targeted agents upregulates topoisomerase II, an alternative enzyme for DNA strand passage.

Topotecan

ADME

Topotecan is approved for intravenous administration. An oral dosage form in development has a bioavailability of 30%–40% in patients with cancer. Topotecan exhibits linear pharmacokinetics, and it is rapidly eliminated from systemic circulation with a $t_{1/2}$ of about 3.5–4.1 h. Only 20%–35% of the total drug in plasma is found to be in the active lactone form. Within 24 h, 30%–40% of the administered dose appears in the urine. Doses should be reduced in proportion to reductions in CL_{CR} . Hepatic metabolism appears to be a relatively minor route of drug elimination. Plasma protein binding of topotecan is low (7%–35%), which may explain its relatively greater CNS penetration.

Therapeutic Uses

Topotecan is indicated for previously treated patients with ovarian and small cell lung cancer. Significant hematological toxicity limits its use in combination with other active agents in these diseases (e.g., cisplatin). The recommended dosing regimen of topotecan for ovarian cancer and small

1190 cell lung cancer is a 30-min infusion for 5 consecutive days every 3 weeks. For the treatment of patients with cervical cancer in conjunction with cisplatin, topotecan is administered on days 1, 2, and 3, repeated every 21 days. The dose of topotecan should be reduced in patients with moderate renal dysfunction (CL_{Cr} of 20–40 mL/min); topotecan should not be administered to patients with severe renal impairment ($CL_{Cr} < 20$ mL/min). Hepatic dysfunction does not alter topotecan clearance and toxicity. A baseline neutrophil count greater than 1500 cells/mm³ and a platelet count above 100,000 is necessary prior to topotecan administration.

Adverse Effects

The dose-limiting toxicity with all dosing schedules is neutropenia, with or without thrombocytopenia. The incidence of severe neutropenia at 1.5 mg/m² daily for 5 days every 3 weeks may be as high as 81%, with a 26% incidence of febrile neutropenia. In patients with hematological malignancies, GI side effects such as mucositis and diarrhea become dose limiting. Other less common and generally mild topotecan-related toxicities include nausea and vomiting, elevated liver transaminases, fever, fatigue, and rash.

Irinotecan

ADME

The conversion of irinotecan to its active metabolite SN-38 is mediated predominantly by carboxylesterases in the liver (see Figures 6–6 and 6–7). Although SN-38 can be measured in plasma shortly after beginning an intravenous infusion of irinotecan, the AUC of SN-38 is only about 4% of the AUC of irinotecan, suggesting that only a relatively small fraction of the dose is ultimately converted to the active form of the drug. Irinotecan exhibits linear pharmacokinetics. In comparison to topotecan, a relatively large fraction of both irinotecan and SN-38 are present in plasma as the biologically active intact lactone form. The $t_{1/2}$ of SN-38 is 11.5 h, three times that of topotecan. CSF penetration of SN-38 in humans has not been characterized.

In contrast to topotecan, hepatic metabolism of irinotecan and SN-38 represents an important route of elimination for both. Oxidative metabolites have been identified in plasma, all of which result from CYP3A-mediated reactions directed at the bis-piperidine side chain. These metabolites are not significantly converted to SN-38. The total body clearance of irinotecan was found to be two times greater in patients with brain cancer taking antiepileptic drugs that induce hepatic CYPs.

UGT1A1 glucuronidates the hydroxyl group at position C10 (resulting from cleavage of the bispiperidine promoiety), producing the inactive glucuronide metabolite SN-38G (see Figures 6–6 and 6–7). Biliary excretion appears to be the primary elimination route of irinotecan, SN-38, and metabolites, although urinary excretion also contributes (14%–37%). The extent of SN-38 glucuronidation inversely correlates with the risk of severe diarrhea after irinotecan therapy. UGT1A1 polymorphisms associated with familial hyperbilirubinemia syndromes may have a major impact on the clinical use of irinotecan. In patients treated with irinotecan, there is a positive correlation between baseline serum unconjugated bilirubin concentration and both severity of neutropenia and the AUC of irinotecan and SN-38. Severe irinotecan toxicity has been observed in patients with cancer with Gilbert syndrome, presumably due to decreased glucuronidation of SN-38. In patients with the syndrome, elevated levels of unconjugated bilirubin in the bloodstream are due to reduced activity of glucuronyltransferase. The presence of bacterial glucuronidase in the intestinal lumen potentially can contribute to irinotecan's GI toxicity by releasing unconjugated SN-38 from the inactive glucuronide metabolite.

Therapeutic Uses

Single-agent dosage of irinotecan is by weekly infusion for 4 of 6 weeks, with a higher dose given every 3 weeks. In patients with advanced colorectal cancer, irinotecan is used as first-line therapy in combination with fluoropyrimidines or as a single agent or in combination with cetuximab following failure of a 5FU/oxaliplatin regimen. It also has activity in small cell lung cancer. A irinotecan liposome injection in combination with 5FU and leucovorin was recently approved by the FDA for treatment of

metastatic pancreatic cancer after disease progression following gemcitabine therapy.

Adverse Effects

The dose-limiting toxicity with all dosing schedules is delayed diarrhea (35%), with or without neutropenia. An intensive regimen of loperamide (see Chapter 49) reduces this incidence by more than half. However, once severe diarrhea occurs, standard doses of antidiarrheal agents tend to be ineffective. Diarrhea generally resolves within a week and, unless associated with fever and neutropenia, rarely is fatal.

The second most common irinotecan-associated toxicity is myelosuppression. Severe neutropenia occurs in 14%–47% of the patients treated with a schedule of administration every 3 weeks and is less frequently encountered amongst patients treated with the weekly schedule. Febrile neutropenia is observed in 3% of patients and may be fatal, particularly when associated with concomitant diarrhea. A cholinergic syndrome resulting from the inhibition of acetylcholinesterase activity by irinotecan may occur within the first 24 h after irinotecan administration. Symptoms include acute diarrhea, diaphoresis, hypersalivation, abdominal cramps, visual accommodation disturbances, lacrimation, rhinorrhea, and, less often, asymptomatic bradycardia. These effects are short lasting and respond within minutes to atropine. Other common toxicities include nausea and vomiting, fatigue, vasodilation or skin flushing, mucositis, elevation in liver transaminases, and alopecia. There have been case reports of dyspnea and interstitial pneumonitis associated with irinotecan therapy.

Antibiotics

Dactinomycin (Actinomycin D)

Actinomycins are chromopeptides isolated from *Streptomyces* soil bacteria. Most contain the same chromophore, the planar phenoxazone actinosin, which is responsible for their yellow-red color. The differences amongst naturally occurring actinomycins are confined to variations in the structure of the amino acids of the peptide side chains. Actinomycin D has beneficial effects in the treatment of solid tumors in children and choriocarcinoma in adult women.

Mechanism of Action

The capacity of actinomycins to bind to double-helical DNA is responsible for their biological activity and cytotoxicity. The planar phenoxazone ring intercalates between adjacent guanine-cytosine base pairs of DNA, while the polypeptide chains extend along the minor groove of the helix, resulting in a dactinomycin-DNA complex with stability sufficient to block the transcription of DNA by RNA polymerase. The DNA-dependent RNA polymerases are much more sensitive to the effects of dactinomycin than are the DNA polymerases. In addition, dactinomycin causes single-strand breaks in DNA, possibly through a free-radical intermediate or as a result of the action of topoisomerase II. Dactinomycin inhibits rapidly proliferating cells of normal and neoplastic origin and is amongst the most potent antitumor agents known.

ADME

Dactinomycin is administered by intravenous injection. Metabolism of the drug is minimal. The drug is excreted in both bile and urine and disappears from plasma with a terminal $t_{1/2}$ of 36 h. Dactinomycin does not cross the blood-brain barrier.

Therapeutic Uses

Dactinomycin is given intravenously for 5 days, usually in the range of 10–15 µg/kg. If no manifestations of toxicity are encountered, additional courses may be given at intervals of 2–4 weeks, although weekly maintenance doses have been used. The main clinical use of dactinomycin is in the treatment of rhabdomyosarcoma and Wilms tumor in children, where it is curative in combination with primary surgery, radiotherapy, and other drugs, particularly vincristine and cyclophosphamide. Ewing, Kaposi, and soft-tissue sarcomas also respond. Dactinomycin and MTX form a curative therapy for choriocarcinoma.

Adverse Effects

Toxic manifestations include anorexia, nausea, and vomiting, usually beginning a few hours after administration. Hematopoietic suppression with pancytopenia may occur in the first week after completion of therapy. Proctitis, diarrhea, glossitis, cheilitis, and ulcerations of the oral mucosa are common; dermatological manifestations include alopecia, as well as erythema, desquamation, and increased inflammation and pigmentation in areas previously or concomitantly subjected to X-ray radiation. Severe injury may occur as a result of local drug extravasation; the drug is extremely corrosive to soft tissues.

Anthracyclines and Anthracenediones

Anthracyclines are derived from the fungus *Streptomyces peucetius* var. *caesius*. *Idarubicin* and *epirubicin* are analogues of the naturally produced anthracyclines *doxorubicin* and *daunorubicin*, differing only slightly in chemical structure, but having somewhat distinct patterns of clinical activity. Daunorubicin and idarubicin primarily have been used in acute leukemias, whereas doxorubicin and epirubicin display broader activity against solid tumors. These agents, which possess the potential for generating free radicals, cause an unusual and often-irreversible cardiomyopathy, the occurrence of which is related to the total dose of the drug. The structurally similar agent *mitoxantrone* has less cardiotoxicity and is useful against prostate cancer and AML and in high-dose chemotherapy.

	DOXORUBICIN	DAUNORUBICIN	EPIRUBICIN	IDARUBICIN
R ₁ =	OCH ₃	OCH ₃	OCH ₃	H
R ₂ =	H	H	OH	H
R ₃ =	OH	OH	H	OH
R ₄ =	OH	H	OH	H

Mechanisms of Action and Resistance

Anthracyclines and anthracenediones can intercalate with DNA, directly affecting transcription and replication. More important is their capacity to form a heterotrimeric complex with topoisomerase II and DNA. Topoisomerase II produces double-strand breaks at the 3'-phosphate backbone, allowing strand passage and uncoiling of supercoiled DNA. Following strand passage, topoisomerase II religates the DNA strands; this enzymatic function is essential for DNA replication and repair. Formation of the ternary complex with anthracyclines or with etoposide inhibits the religation of the broken DNA strands, leading to apoptosis. Defects in DNA double-strand break repair sensitize cells to damage by these drugs, while altered DNA damage-sensing and DNA repair capacity may contribute to resistance.

The quinone moieties of anthracyclines can form radical intermediates that react with O₂ to produce superoxide anion radicals, which can generate H₂O₂ and •OH that attack DNA and oxidize DNA bases, leading to apoptosis (Serrano et al., 1999). The production of free radicals is significantly stimulated by the interaction of doxorubicin with iron. Enzymatic defenses such as superoxide dismutase and catalase protect cells against the toxicity of the anthracyclines, and these defenses can be augmented by exogenous antioxidants such as α-tocopherol or by the iron chelator dexrazoxane, which protects against cardiac toxicity. Multidrug resistance is observed in tumor cell populations exposed to anthracyclines. Anthracyclines also are exported from tumor cells by members of the MRP transporter family and by ABCG2 (BCRP). Other biochemical

changes in resistant cells include increased glutathione peroxidase activity, decreased activity or mutation of topoisomerase II, and enhanced ability to repair DNA strand breaks.

ADME

Daunorubicin, doxorubicin, epirubicin, and idarubicin are administered intravenously and are cleared by a complex pattern of hepatic metabolism and biliary excretion. Each anthracycline is converted to an active alcohol intermediate that plays a variable role in the therapeutic activity. The plasma disappearance curves for doxorubicin and daunorubicin are multiphasic, with a terminal $t_{1/2}$ of 30 h. Idarubicin has a $t_{1/2}$ of 15 h, and its active metabolite, idarubicinol, has a $t_{1/2}$ of 40 h. The drugs rapidly enter the heart, kidneys, lungs, liver, and spleen; they do not cross the blood-brain barrier. Clearance is delayed in the presence of hepatic dysfunction; at least a 50% initial reduction in dose should be considered in patients with elevated serum bilirubin levels.

Idarubicin and Daunorubicin

Therapeutic Use. Idarubicin (~12 mg/m²/d for 3 days) is administered by slow intravenous injection (10–15 min) to avoid extravasation. Treatment is for 3 days. Idarubicin has less cardiotoxicity than the other anthracyclines. Daunorubicin (also named daunomycin or rubidomycin) is administered (at 24–45 mg/m²/d) intravenously for 3 days, with care to prevent extravasation. Total doses greater than 1000 mg/m² are associated with a high risk of cardiotoxicity. Daunorubicin may impart a red color to the urine. Daunorubicin and idarubicin are used in the treatment of patients with AML in combination with Ara-C.

Adverse Effects. Toxic effects of daunorubicin and idarubicin include bone marrow depression, stomatitis, alopecia, GI disturbances, rash, and cardiac toxicity. Cardiac toxicity of anthracyclines can be acute or chronic and is described in detail next for doxorubicin.

Doxorubicin

Therapeutic Uses. The dose (60–75 mg/m²) is administered as a single rapid intravenous infusion that is repeated after 21 days. A doxorubicin liposomal product is available for treatment of AIDS-related Kaposi sarcoma and is given intravenously in a dose of 20 mg/m² over 60 min and repeated every 3 weeks. The liposomal formulation also is approved for ovarian cancer for treatment at a dose of 50 mg/m² every 4 weeks and as a treatment of multiple myeloma (in conjunction with bortezomib), where it is given as a 30-mg/m² dose on day 4 of each 21-day cycle. Patients should be advised that the drug may impart a red color to the urine. Doxorubicin is effective in malignant lymphomas. In combination with cyclophosphamide, vinca alkaloids, and other agents, it is an important ingredient for the successful treatment of lymphomas. It is a valuable component of various regimens of chemotherapy for adjuvant and metastatic carcinoma of the breast. The drug also is beneficial in pediatric and adult sarcomas, including osteogenic, Ewing, and soft-tissue sarcomas.

Adverse Effects. Toxicities of doxorubicin are similar to those of daunorubicin. Myelosuppression is a major dose-limiting complication, with maximal leukopenia usually occurring during the second week of therapy and recovering by the fourth week; thrombocytopenia and anemia follow a similar pattern but usually are less pronounced. Stomatitis, mucositis, diarrhea, and alopecia are common but reversible. Erythematous streaking near the site of infusion ("flare") is a benign local allergic reaction and should not be confused with extravasation. Facial flushing, conjunctivitis, and lacrimation may occur rarely. The drug may produce severe local toxicity in irradiated tissues (e.g., the skin, heart, lung, esophagus, and GI mucosa) even when the two therapies are not administered concomitantly.

Cardiomyopathy is the most important long-term toxicity (Rochette et al., 2015) and may take two forms:

- **An acute form, characterized by abnormal electrocardiographic changes, including ST- and T-wave alterations and arrhythmias.** This is brief and rarely a serious problem. An acute reversible reduction in ejection fraction is observed in some patients in the 24 h after a single dose, and plasma troponin T may increase in a minority of patients in

the first few days following drug administration (Lipshultz et al., 2004). Acute myocardial damage, the “pericarditis-myocarditis syndrome,” may begin in the days following drug infusion and is characterized by severe disturbances in impulse conduction and frank congestive heart failure, often associated with pericardial effusion.

- **Chronic, cumulative, dose-related toxicity (usually total doses of $\geq 550 \text{ mg/m}^2$) progressing to congestive heart failure.** The mortality rate in patients with congestive failure approaches 50%. The risk of cardiomyopathy increases markedly with dose; estimates run as high as 20% at total doses of 550 mg/m^2 (a total dose limit of 300 mg/m^2 is advised for pediatric cases). These total dosages should be exceeded only under exceptional circumstances or with the concomitant use of dexrazoxane, a cardioprotective iron-chelating agent (Swain et al., 1997). Cardiac irradiation, administration of high doses of cyclophosphamide or another anthracycline, or concomitant trastuzumab increases the risk of cardiotoxicity (Slamon et al., 2001). Late-onset cardiac toxicity, with congestive heart failure years after treatment, may occur in both pediatric and adult populations. In children treated with anthracyclines, there is a 3- to 10-fold elevated risk of arrhythmias, congestive heart failure, and sudden death in adult life. Concomitant administration of dexrazoxane may reduce troponin T elevations and avert later cardiotoxicity (Lipshultz et al., 2004).

Epirubicin

The anthracycline epirubicin is indicated as a component of adjunctive therapy for treatment of breast cancer. It is administered intravenously in doses of $100\text{--}120 \text{ mg/m}^2$ every 3–4 weeks. Total doses greater than 900 mg/m^2 sharply increase the risk of cardiotoxicity. Its toxicity profile is the same as that of doxorubicin.

Valrubicin

Valrubicin is a semisynthetic analogue of doxorubicin used exclusively for intravesicular treatment of bladder cancer. Once a week for 6 weeks, 800 mg are instilled into the bladder. Less than 10% of instilled drug is absorbed systemically. Side effects relate to bladder irritation.

Mitoxantrone

Mitoxantrone is a synthetic anthracenedione derivative topoisomerase II inhibitor that is approved for use in AML, prostate cancer, and late-stage, secondary progressive multiple sclerosis. Mitoxantrone has limited ability to produce quinone-type free radicals and causes less cardiac toxicity than does doxorubicin. It produces acute myelosuppression, cardiac toxicity, and mucositis as its major toxicities; the drug also causes nausea, vomiting, and alopecia, although less than doxorubicin. Mitoxantrone is administered by intravenous infusion. To induce remission in acute nonlymphocytic leukemia in adults, the drug is given in a daily dose of 12 mg/m^2 for 3 days with cytarabine. It also is used in advanced hormone-resistant prostate cancer in a dose of $12\text{--}14 \text{ mg/m}^2$ every 21 days.

Epipodophyllotoxins

Podophyllotoxin Derivatives

Two synthetic derivatives of podophyllotoxins have significant therapeutic activity in pediatric leukemia, small cell carcinomas of the lung, testicular tumors, Hodgkin disease, and large cell lymphomas. These derivatives are etoposide (VP-16-213) and teniposide (VM-26). Although podophyllotoxin binds to tubulin, etoposide and teniposide have no effect on microtubular structure or function at usual concentrations.

Mechanisms of Action and Resistance

Etoposide and teniposide form ternary complexes with topoisomerase II and DNA and prevent resealing of the break that normally follows topoisomerase binding to DNA. The enzyme remains bound to the free end of the broken DNA strand, leading to an accumulation of DNA breaks and cell death. Cells in the S and G_2 phases of the cell cycle are most sensitive to etoposide and teniposide. Resistant cells demonstrate (1) amplification of the *MDR1* gene that encodes the Pgp drug efflux transporter, (2) mutation

or decreased expression of topoisomerase II, or (3) mutations of the p53 tumor suppressor gene, a required component of the apoptotic pathway (Lowe et al., 1993).

Etoposide

ADME

Oral administration of etoposide results in variable absorption that averages about 50%. After intravenous injection, there is a biphasic pattern of clearance with a terminal $t_{1/2}$ of about 6–8 h in patients with normal renal function. Approximately 40% of an administered dose is excreted intact in the urine. In patients with compromised renal function, dosage should be reduced in proportion to the reduction in CL_{CR} . In patients with advanced liver disease, increased toxicity may result from a low serum albumin (decreased drug binding) and elevated bilirubin (which displaces etoposide from albumin); guidelines for dose reduction in this circumstance have not been defined. Drug concentrations in the CSF average 1%–10% of those in plasma.

Therapeutic Uses

The intravenous dose of etoposide for testicular cancer in combination therapy (with bleomycin and cisplatin) is $50\text{--}100 \text{ mg/m}^2$ for 5 days or 100 mg/m^2 on alternate days for three doses. For small cell carcinoma of the lung, the dosage in combination therapy (with cisplatin) is $100\text{--}200 \text{ mg/m}^2/\text{d}$ intravenously for 3 days. Cycles of therapy usually are repeated every 3–4 weeks. After relapse, oral administration of $50 \text{ mg/m}^2/\text{d}$ for 21 days is one treatment option. When given intravenously, the drug should be administered slowly over a 30- to 60-min period to avoid hypotension and bronchospasm, which likely result from the additives used to dissolve etoposide.

Etoposide is also active against non-Hodgkin lymphomas, acute nonlymphocytic leukemia, and Kaposi sarcoma associated with AIDS. Etoposide has a favorable toxicity profile for dose escalation in that its primary acute toxicity is myelosuppression. In combination with ifosfamide and carboplatin, it frequently is used for high-dose chemotherapy in total doses of $1500\text{--}2000 \text{ mg/m}^2$.

Adverse Effects

The dose-limiting toxicity of etoposide is leukopenia (nadir at 10–14 days, recovery by 3 weeks). Thrombocytopenia occurs less often and usually is not severe. Nausea, vomiting, stomatitis, and diarrhea complicate treatment in about 15% of patients. Alopecia is common but reversible. Hepatic toxicity is particularly evident after high-dose treatment. For both etoposide and teniposide, toxicity increases in patients with decreased serum albumin, an effect related to decreased protein binding of the drug.

A disturbing complication of etoposide therapy is the development of an unusual form of acute nonlymphocytic leukemia with a translocation in chromosome 11q23. At this locus is a gene (the MLL gene) that regulates the proliferation of pluripotent stem cells. The leukemic cells have the cytological appearance of acute monocytic or monomyelocytic leukemia. Another distinguishing feature of etoposide-related leukemia is the short time interval between the end of treatment and the onset of leukemia (1–3 years), compared to the 4- to 5-year interval for secondary leukemias related to alkylating agents, and the absence of a myelodysplastic period preceding leukemia (Pui et al., 1995). Patients receiving weekly or twice-weekly doses of etoposide, with cumulative doses greater than 2000 mg/m^2 , seem to be at higher risk of leukemia.

Teniposide

Teniposide is administered intravenously. It has a multiphasic pattern of clearance from plasma: After distribution, a $t_{1/2}$ of 4 h and another $t_{1/2}$ of 10–40 h are observed. Approximately 45% of the drug is excreted in the urine; in contrast to etoposide, as much as 80% is recovered as metabolites. Anticonvulsants such as phenytoin increase the hepatic metabolism of teniposide and reduce systemic exposure. Dosage need not be reduced for patients with impaired renal function. Less than 1% of the drug crosses the blood-brain barrier. Teniposide is available for treatment of refractory ALL in children and is synergistic with cytarabine. Teniposide is administered

by intravenous infusion for 5 days or twice weekly. The drug has limited utility and is given primarily for acute leukemia in children and monocytic leukemia in infants, as well as glioblastoma, neuroblastoma, and brain metastases from small cell carcinomas of the lung. Myelosuppression, nausea, and vomiting are its primary toxic effects.

Drugs of Diverse Mechanisms of Action

Bleomycin

The bleomycins, a unusual group of DNA-cleaving antibiotics, are fermentation products of *Streptomyces verticillus*, comprising a family of peptide polyketides. The drug currently employed clinically is a mixture of two copper-chelating peptides, bleomycins A₂ and B₂, that differ only in their terminal amino acid. Because their toxicities do not overlap with those of other cytotoxic drugs and because of their unique mechanism of action, bleomycin maintains an important role in treating Hodgkin disease and testicular cancer.

Mechanisms of Action and Resistance

Bleomycin's cytotoxicity results from its capacity to cause oxidative damage to the deoxyribose of thymidylate and other nucleotides, leading to single- and double-stranded breaks in DNA; the exact mechanism is unresolved. Bleomycin causes accumulation of cells in the G₂ phase of the cell cycle, and many of these cells display chromosomal aberrations, including chromatid breaks, gaps, fragments, and translocations. Bleomycin cleaves DNA by generating free radicals. In the presence of O₂ and a reducing agent, the metal-drug complex becomes activated and functions as a ferrous oxidase, transferring electrons from Fe²⁺ to molecular oxygen to produce oxygen radicals. Metalbleomycin complexes can be activated by reaction with the flavin enzyme, NADPH-CYP450 reductase. Bleomycin binds to DNA, and the activated complex generates free radicals that are responsible for abstraction of a proton at the 3' position of the deoxyribose backbone of the DNA chain, opening the deoxyribose ring and generating a strand break in DNA. An excess of breaks generates cell death.

Bleomycin is degraded by a specific hydrolase found in various normal tissues, including liver. Hydrolase activity is low in skin and lung, perhaps contributing to the serious toxicity. Some bleomycin-resistant cells contain high levels of hydrolase activity. In other cell lines, resistance has been attributed to decreased uptake, repair of strand breaks, or drug inactivation by thiols or thiol-rich proteins.

ADME

Bleomycin is administered intravenously, intramuscularly, or subcutaneously or instilled into the bladder for local treatment of bladder cancer. Having a high molecular mass, bleomycin crosses the blood-brain barrier poorly. The elimination $t_{1/2}$ is about 3 h. About two-thirds of the drug is excreted intact in the urine. Concentrations in plasma are greatly elevated in patients with renal impairment, and doses of bleomycin should be reduced in the presence of a CL_{Cr} less than 60 mL/min.

Therapeutic Uses

Bleomycin is given weekly or twice weekly by the intravenous, intramuscular, or subcutaneous route. A test dose of 2 units or less is recommended for patients with lymphoma. Myriad regimens are employed clinically, with bleomycin doses expressed in units. Total courses exceeding 250 mg should be given with caution, and usually only in high-risk testicular cancer treatment, because of a marked increase in the risk of pulmonary toxicity. Bleomycin also may be instilled into the pleural cavity in doses of 5–60 mg to ablate the pleural space in patients with malignant effusions. Bleomycin is highly effective against germ cell tumors of the testis and ovary. In testicular cancer, it is curative when used with cisplatin and vinblastine or cisplatin and etoposide. It is a component of the standard curative ABVD regimen for Hodgkin disease.

Adverse Effects

Because bleomycin causes little myelosuppression, it has significant advantages in combination with other cytotoxic drugs. However, it does cause a constellation of cutaneous toxicities, including hyperpigmentation,

hyperkeratosis, erythema, even ulceration, and rarely, Raynaud phenomenon. Skin lesions may recur when patients are treated with other antineoplastic drugs. Rarely, bleomycin causes a flagellate dermatitis consisting of bands of pruritic erythema on the arms, back, scalp, and hands; this rash responds readily to topical corticosteroids.

The most serious adverse reaction to bleomycin is pulmonary toxicity, which begins with a dry cough, fine rales, and diffuse basilar infiltrates on X-ray and may progress to life-threatening pulmonary fibrosis. Approximately 5%–10% of patients receiving bleomycin develop clinically apparent pulmonary toxicity, and about 1% die of this complication. Most who recover experience a significant improvement in pulmonary function, but fibrosis may be irreversible. Pulmonary function tests are not of predictive value for detecting early onset of this complication. The risk of pulmonary toxicity is related to total dose, with a significant increase in risk in total doses greater than 250 mg and in patients more than 40 years of age, in those with a CL_{Cr} less than 80 mL/min, and in those with underlying pulmonary disease; single doses of 30 mg/m² or more also are associated with an increased risk of pulmonary toxicity. Administration of high O₂ concentrations during anesthesia or respiratory therapy may aggravate or precipitate pulmonary toxicity in patients previously treated with the drug. There is no known specific therapy for bleomycin lung injury except for symptomatic management and standard pulmonary care. Steroids are of variable benefit, with greatest effectiveness in the earliest inflammatory stages of the lesion.

Other toxic reactions to bleomycin include hyperthermia, headache, nausea and vomiting, and a peculiar acute fulminant reaction observed in patients with lymphomas. This reaction is characterized by profound hyperthermia, hypotension, and sustained cardiorespiratory collapse; it does not appear to be a classical anaphylactic reaction and may be related to release of an endogenous pyrogen. This reaction has occurred in about 1% of patients with lymphomas or testicular cancer.

Mitomycin

Mitomycin has limited clinical utility, having been replaced by less toxic and more effective drugs, with the exception of the use in patients with anal cancers, for which it is potentially curative.

MITOMYCIN

Mechanisms of Action and Resistance

After intracellular enzymatic or spontaneous chemical alteration, mitomycin becomes a bifunctional or trifunctional alkylating agent. The drug inhibits DNA synthesis and cross-links DNA at the N6 position of adenine and at the O6 and N7 positions of guanine. Attempts to repair DNA lead to strand breaks. Mitomycin is a potent radiosensitizer, teratogen, and carcinogen in rodents. Resistance has been ascribed to deficient activation, intracellular inactivation of the reduced Q form, and Pgp-mediated drug efflux.

ADME

Mitomycin is administered intravenously. It has a $t_{1/2}$ of 25–90 min. The drug distributes widely throughout the body but is not detected in the CNS. Inactivation occurs by hepatic metabolism or chemical conjugation with sulphydryls. Less than 10% of the active drug is excreted in the urine or the bile.

Therapeutic Uses

Mitomycin is administered as a single bolus (6–20 mg/m²) every 6–8 weeks. Dosage should be modified based on hematological recovery. Mitomycin also may be used by direct instillation into the bladder to treat superficial transitional cell carcinomas. Mitomycin is used in combination with

1194 5FU and cisplatin for the treatment of anal cancer. Mitomycin is used off label (as an extemporaneously compounded eye drop) as an adjunct to surgery to inhibit wound healing and reduce scarring.

Adverse Effects

The major toxic effect is myelosuppression, characterized by marked leukopenia and thrombocytopenia; after higher doses, maximal suppression may be delayed and cumulative, with recovery only after 6–8 weeks of pancytopenia. Nausea, vomiting, diarrhea, stomatitis, rash, fever, and malaise also are observed. Patients who have received more than 50 mg/m² total dose may acutely develop hemolysis, neurological abnormalities, interstitial pneumonia, and glomerular damage resulting in renal failure. The incidence of renal failure increases to 28% in patients who receive total doses of 70 mg/m² or more. There is no effective treatment of the disorder. It must be recognized early, and mitomycin must be discontinued immediately. Mitomycin causes interstitial pulmonary fibrosis; total doses greater than 30 mg/m² have infrequently led to congestive heart failure. Mitomycin may potentiate the cardiotoxicity of doxorubicin.

Mitotane

Mitotane (*o,p'*-DDD), a compound chemically similar to the insecticides DDT and DDD, is used in the treatment of adrenal cortex carcinoma. The mechanism of action of mitotane has not been elucidated, but its relatively selective destruction of adrenocortical cells, normal or neoplastic, is well established. Administration of the drug causes a rapid reduction in the levels of adrenocorticosteroids and their metabolites in blood and urine, a response that is useful in both guiding dosage and following the course of hyperadrenocorticism (Cushing syndrome) resulting from an adrenal tumor or adrenal hyperplasia. It does not damage other organs.

ADME

Approximately 40% of mitotane is absorbed after oral administration. Plasma concentrations of mitotane are still measurable for 6–9 weeks following discontinuation of therapy. Although the drug is found in all tissues, fat is the primary site of storage. A water-soluble metabolite of mitotane found in the urine constitutes 25% of an oral or parenteral dose. About 60% of an oral dose is excreted unchanged in the stool.

Therapeutic Uses

Mitotane initial daily oral doses are 2–6 g, usually in three or four divided portions. The maximal tolerated dose may vary from 2 to 16 g/d. Treatment should continue for at least 3 months; if beneficial effects are observed, therapy should be maintained indefinitely. Spironolactone should not be administered concomitantly because it interferes with the adrenal suppression produced by mitotane. Treatment with mitotane is indicated for the palliation of inoperable adrenocortical carcinoma, producing symptomatic benefit in 30%–50% of such patients.

Adverse Effects

Although the administration of mitotane produces anorexia and nausea in most patients, somnolence and lethargy in about 34%, and dermatitis in 15%–20%, these effects do not contraindicate the use of the drug at lower doses. Because this drug damages the adrenal cortex, administration of replacement doses of adrenocorticosteroids is necessary.

Trabectedin

Trabectedin is derived from the marine invertebrate tunicate *Ecteinascidin turbinata*. Trabectedin is an alkylating drug that binds to the minor groove

of DNA, allowing the alkylation of the N2 position of guanine and bending the helix toward the major groove. The bulky DNA adduct is recognized by the transcription-coupled nucleotide excision-repair (NER) complex, and these proteins initiate attempts to repair the damaged strand, converting the adduct to a double-stranded break. Trabectedin has particular cytotoxic effects on cells that lack components of the Fanconi anemia complex or those that lack the ability to repair double-strand DNA breaks through homologous recombination (Soares et al., 2007). Unlike cisplatin and other DNA adduct-forming drugs, the activity of trabectedin requires the presence of intact components of NER, including XPG, which may be important for initiation of single breaks and attempts at adduct removal.

ADME

Trabectedin is administered as a 24-h infusion of 1.3 mg/m² every 3 weeks. It is administered with dexamethasone, 4 mg twice daily, starting 24 h before drug infusion to diminish hepatic toxicity. The drug is slowly cleared by CYP3A4, with a plasma $t_{1/2}$ of about 24–40 h.

Therapeutic Uses

Trabectedin is approved for the treatment of patients with unresectable or metastatic liposarcoma or leiomyosarcoma after an anthracycline-containing regimen and is under study as an orphan drug for the treatment of patients with ovarian and pancreatic cancer.

Adverse Effects

Without dexamethasone pretreatment, trabectedin causes significant hepatic enzyme elevations and fatigue in at least one-third of patients. With the steroid, the increases in transaminase are less pronounced and rapidly reversible. Other toxicities include mild myelosuppression and, rarely, rhabdomyolysis.

L-Asparaginase

Malignant lymphoid cells depend on exogenous sources of L-asparagine. Thus, L-asparaginase (L-ASP) has become a standard agent for treating ALL.

Mechanism of Action

Most normal tissues synthesize L-asparagine in amounts sufficient for protein synthesis, but lymphocytic leukemias lack adequate amounts of asparagine synthase and derive the required amino acid from plasma. L-ASP, by catalyzing the hydrolysis of circulating asparagine to aspartic acid and ammonia, deprives these malignant cells of asparagine, leading to cell death. L-ASP is used in combination with other agents, including MTX, doxorubicin, vincristine, and prednisone, for the treatment of ALL and high-grade lymphomas. Resistance arises through induction of asparagine synthetase in tumor cells.

ADME and Therapeutic Use

Asparaginase is given intramuscularly or intravenously. After intravenous administration, *Escherichia coli*-derived L-ASP has a clearance rate from plasma of 0.035 mL/min/kg, a volume of distribution that approximates the volume of plasma in humans, and a $t_{1/2}$ of 1 day. The enzyme is given in doses of 6000–10,000 IU every third day for 3–4 weeks. Pegaspargase, a preparation in which the enzyme is conjugated to 5000-Da units of monomethoxy polyethylene glycol, has a much longer plasma $t_{1/2}$ (6–7 days); it is administered intramuscularly every 14 days, producing rapid and complete depletion of plasma and tumor cell asparagine for 21 days in most patients. Pegaspargase has much reduced immunogenicity (<20% of patients develop antibodies) and has been approved for first-line ALL therapy.

Intermittent dosage regimens and longer durations of treatment increase the risk of inducing hypersensitivity. In hypersensitive patients, neutralizing antibodies inactivate L-ASP. Not all patients with neutralizing antibodies experience clinical hypersensitivity, although the enzyme may be inactivated and therapy may be ineffective. In previously untreated ALL, pegaspargase produces more rapid clearance of lymphoblasts from bone marrow than does the *E. coli* preparation and circumvents the rapid antibody-mediated clearance seen with *E. coli*

enzyme in relapsed patients. Asparaginase preparations only partially deplete CSF asparagine.

Adverse Effects

The L-ASP toxicities result from its antigenicity as a foreign protein and its inhibition of protein synthesis. Hypersensitivity reactions, including urticaria and full-blown anaphylaxis, occur in 5%–20% of patients and may be fatal. In these patients, pegaspargase is a safe and effective alternative. So-called silent enzyme inactivation by antibodies occurs in a higher percentage of patients than overt hypersensitivity and may be associated with a negative clinical outcome, especially in high-risk patients with ALL.

Other toxicities result from inhibition of protein synthesis in normal tissues (e.g., hyperglycemia due to insulin deficiency, clotting abnormalities due to deficient clotting factors, hypertriglyceridemia due to effects on lipoprotein production, hypoalbuminemia). Pancreatitis also has been observed. The clotting problems may take the form of spontaneous thrombosis or, less frequently, hemorrhagic episodes. Brain magnetic resonance imaging studies should be considered in patients treated with L-ASP who present with seizures, headache, or altered mental status. Intracranial hemorrhage in the first week of L-ASP treatment is an infrequent but devastating complication. L-ASP also suppresses immune function. L-ASP terminates the antitumor activity of MTX when given shortly after the antimetabolite. By lowering serum albumin concentrations, L-ASP may decrease protein binding and accelerate plasma clearance of other drugs.

Hydroxyurea

Hydroxyurea inhibits RNR and has unique and diverse biological effects as an antileukemic drug, radiation sensitizer, and an inducer of HbF in patients with sickle cell disease. It is orally administered, and its toxicity is modest and limited to myelosuppression.

Mechanisms of Action and Resistance

Hydroxyurea inhibits the enzyme ribonucleotide reductase (RNR), which catalyzes the reductive conversion of ribonucleotides to deoxyribonucleotides, a rate-limiting step in the biosynthesis of DNA. HU binds iron molecules that are essential for activation of a tyrosyl radical in the catalytic subunit of RNR. The drug is specific for the S phase of the cell cycle, during which RNR concentrations are maximal. HU produces arrest at or near the G₁-S interface through both p53-dependent and -independent mechanisms. Because cells are highly sensitive to irradiation at the G₁-S boundary, HU and irradiation cause synergistic antitumor effects. Through depletion of deoxynucleotides, HU potentiates the antiproliferative effects of DNA-damaging agents such as cisplatin, alkylating agents, or topoisomerase II inhibitors and facilitates the incorporation of antimetabolites such as Ara-C, gemcitabine, and fludarabine into DNA. It also promotes degradation of the p21 cell-cycle checkpoint and thereby enhances the effects of HDAC inhibitors in vitro (Kramer et al., 2008).

Hydroxyurea is the primary drug for improving control of sickle cell (HbS) disease in adults and for inducing HbF in patients with thalassemia HbC and HbC/S. It reduces vaso-occlusive events, painful crises, hospitalizations, and the need for blood transfusions in patients with sickle cell disease. The mechanism of stimulated HbF production is uncertain. HU stimulates NO production, causing nitrosylation of low-molecular-weight GTPases, a process that stimulates γ -globin production in erythroid precursors. Another property of HU that may be therapeutically relevant is its capacity to reduce L-selectin expression and thereby to reduce adhesion of red cells and neutrophils to vascular endothelium. Also, by suppressing the production of neutrophils, it decreases their contribution to vascular occlusion. Tumor cells become resistant to HU through increased synthesis of the catalytic subunit of RNR, thereby restoring enzyme activity.

ADME

The oral bioavailability of HU is 80%–100%; comparable plasma concentrations are seen after oral or intravenous dosing. HU disappears from plasma with a $t_{1/2}$ of 3.5–4.5 h. The drug readily crosses the blood-brain barrier; significant quantities appear in human breast milk. From 40% to 80% of the drug is recovered in the urine within 12 h after administration. It is advisable to modify initial doses for patients with renal dysfunction.

Therapeutic Uses

In cancer treatment, HU is used alone or in combination with other drugs with two dosage schedules: (1) intermittent therapy administered orally as a single dose (~80 mg/kg) every third day or (2) continuous therapy administered as a single daily dose (20–30 mg/kg). In patients with essential thrombocythemia and in sickle cell disease, HU is given in a daily dose of 15 mg/kg, adjusting that dose upward or downward according to blood counts. The neutrophil count responds within 1–2 weeks to discontinuation of the drug. In treating subjects with sickle cell and related diseases, a neutrophil count of at least 2500 cells/mL should be maintained. Treatment typically is continued for 6 weeks to determine effectiveness; if satisfactory results are obtained, therapy can be continued indefinitely, although leukocyte counts at weekly intervals are advisable.

The principal use of HU has been as a myelosuppressive agent in various myeloproliferative syndromes, particularly CML, polycythemia vera, myeloid metaplasia, and essential thrombocythosis, for controlling high platelet or white cell counts. Many of the myeloproliferative syndromes harbor activating mutations of *Jak2*, a gene that is downregulated by HU. In essential thrombocythemia, it is the drug of choice for patients with a platelet count greater than 1.5 million cells/mm³ or with a history of arterial or venous thrombosis. In CML, HU has been largely replaced by imatinib (see Chapter 67). HU is a potent radiosensitizer as a consequence of its inhibition of RNR and has been incorporated into several treatment regimens with concurrent irradiation (i.e., cervical carcinoma, primary brain tumors, head and neck cancer, non-small cell lung cancer).

Adverse Effects

Leukopenia, anemia, and occasionally thrombocytopenia are the major toxic effects; recovery of the bone marrow is prompt if the drug is discontinued for a few days. Other adverse reactions include a desquamative interstitial pneumonitis, GI disturbances, mild dermatological reactions, and, more rarely, stomatitis, alopecia, and neurological manifestations. Increased skin and fingernail pigmentation may occur, as well as painful leg ulcers, especially in elderly patients or in those with renal dysfunction. HU does not increase the risk of secondary leukemia in patients with myeloproliferative disorders or sickle cell disease. It is a potent teratogen in animals and should not be used in women with childbearing potential.

Retinoids

One of the hallmarks of malignant transformation is a block in differentiation. A number of chemical entities (vitamin D and its analogues, retinoids, benzamides and other inhibitors of HDAC [see Chapter 67], various cytotoxic and biological agents, and inhibitors of DNA methylation) can induce differentiation in tumor cell lines. The most important of these for cancer treatment are retinoids, in particular tretinoin (ATRA), which induces a high rate of complete remission in patients with APL as a single agent and, in combination with anthracyclines, cures most patients with this disease. The biology and pharmacology of retinoids are discussed in detail in Chapter 70.

Tretinoin (ATRA)

Mechanism of Action. Under physiological conditions, the RARA dimerizes with the retinoid X receptor to form a complex that binds ATRA tightly. ATRA binding displaces a repressor from the transcriptional complex and alters the expression of genes that control differentiation of cells of multiple lineages. Most APLs are characterized by a chromosomal translocation of the RARA gene on chr17 and fusion with the PML on

1196 chr15 that is denoted as t(15;17)(q22;q12). In APL cells, physiological concentrations of retinoid are inadequate to displace the repressor, but pharmacological concentrations are effective in activating the differentiation program and in promoting degradation of the PML-RARA fusion protein (Collins, 2008). The PML gene encodes a transcription factor important in inhibiting proliferation and promoting myeloid differentiation. The oncogenic PML-RARA gene produces a protein that binds retinoids with much decreased affinity, lacks PML regulatory function, and fails to upregulate transcription factors (C/EBP and PU.1) that promote myeloid differentiation. ATRA also binds and activates RAR- γ and thereby promotes stem cell renewal, and this action may help restore normal bone marrow renewal. Resistance to ATRA arises by further mutation of the fusion gene, abolishing ATRA binding; by induction of the CYP26A1; or by loss of expression of the PML-RARA fusion gene.

Tretinoin

ADME and Therapeutic Use. Oral administration of ATRA is 45 mg/m²/d until 30 days after remission is achieved (maximum course of therapy is 90 days). ATRA as a single agent reverses the hemorrhagic diathesis associated with APL and induces a high rate of temporary remission. ATRA in combination with an anthracycline induces remission with 80% or greater relapse-free long-term survival.

ATRA is cleared by a CYP3A4-mediated elimination with a $t_{1/2}$ of less than 1 h. Treatment with inducers of CYP3A4 leads to more rapid drug disappearance and resistance to ATRA. Inhibitors of CYPs, such as antifungal imidazoles, block ATRA degradation and may lead to hypercalcemia and renal failure, which respond to diuresis, bisphosphonates, and ATRA discontinuation. Corticosteroids and chemotherapy sharply decrease the occurrence of “retinoic acid syndrome,” which is characterized by fever, dyspnea, weight gain, pulmonary infiltrates, and pleural or pericardial effusions. When used as a single agent for remission induction, especially in patients with more than 5000 leukemic cells/mm³ in the peripheral blood, ATRA induces an outpouring of cytokines and mature-appearing neutrophils of leukemic origin. These cells express high concentrations of integrins and other adhesion molecules on their surface and clog small vessels in the pulmonary circulation, leading to significant morbidity in 15%–20% of patients. The syndrome of respiratory distress, pleural and pericardial effusions, and mental status changes may have a fatal outcome. Retinoids also cause dry skin, cheilitis, reversible hepatic enzyme abnormalities, bone tenderness, pseudotumor cerebri, hypercalcemia, and hyperlipidemia.

Arsenic Trioxide

Arsenic trioxide (As₂O₃), known as ATO, is a highly effective treatment of relapsed APL, producing complete responses in more than 85% of such patients. The chemistry and toxicity of arsenic are considered in Chapter 71.

ARSENIC TRIOXIDE

Mechanism of Action

The basis for ATO's antitumor activity remains uncertain. APL cells have high levels of ROS and are quite sensitive to further ROS induction. ATO inhibits thioredoxin reductase and thereby generates ROS. It inactivates glutathione and other sulfhydryls that scavenge ROS and thereby aggravates ROS damage. Cells exposed to ATO also upregulate p53, Jun kinase, and caspases associated with the intrinsic pathway of apoptosis and downregulate antiapoptotic proteins such as bcl-2 (Figure 13–15). ATO's cytotoxic effects are antagonized by cell survival signals emanating from activation of components of the PI3 kinase cell survival pathway, including PKB, S6 kinase, and mTOR (Figures 3–16 and 67–4). ATO also induces differentiation of leukemic cell lines in experimental and human leukemias.

ADME

Arsenic trioxide is well absorbed orally but in cancer treatment is administered as a 2-h daily intravenous infusion in dosages of 0.15 mg/kg/d for up to 60 days, until remission is documented. The drug enters cells via one of several glucose transporters. The primary mechanism of elimination is through enzymatic methylation. Multiple methylated metabolites (Figure 71–9) form rapidly and are excreted in urine. Less than 20% of administered drug is excreted unchanged in the urine. No dose reductions are indicated for hepatic or renal dysfunction.

Adverse Effects

Pharmacological doses of ATO are well tolerated. Patients may experience reversible side effects, including hyperglycemia, hepatic enzyme elevations, fatigue, dysesthesias, and light-headedness. Fewer than 10% of patients experience a leukocyte maturation syndrome similar to that seen with ATRA, including pulmonary distress, effusions, and mental status changes. Oxygen, corticosteroids, and temporary discontinuation of ATO lead to full reversal of this syndrome. Lengthening of the QT interval on the electrocardiogram occurs in 40% of patients, but rarely do patients develop torsade de pointes. Simultaneous treatment with other QT-prolonging drugs should be avoided. Monitoring of serum electrolytes and repletion of serum K⁺ in patients with hypokalemia are precautionary measures in patients receiving ATO therapy. In patients exhibiting a significantly prolonged QT (>470 ms), treatment should be suspended, K⁺ supplemented, and therapy resumed only if the QT returns to normal.

Drug Facts for Your Personal Formulary: *Cytotoxic Drugs*

Drug	Therapeutic Use	Clinical Pharmacology and Tips
Section I: Alkylating Agents and Platinum Coordination Complexes		
Mechanism of action: covalent modification of DNA. Adverse effects of all alkylating drugs: myelosuppression and immunosuppression; toxicity to dividing mucosal cells and hair follicles (e.g., oral mucosal ulceration, intestinal denudation, alopecia); delayed pulmonary fibrosis; reproductive system toxicity (premature menopause, sterility); and leukemogenesis (up to 5%, highest for melphalan, procarbazine, nitrosoureas).		
Nitrogen Mustards: DNA alkylation		
Mecllorethamine	<ul style="list-style-type: none"> Hodgkin lymphoma Topical: cutaneous T-cell lymphoma 	<ul style="list-style-type: none"> Vascular damage during injection due to vesicant properties
Cyclophosphamide	<ul style="list-style-type: none"> Acute and chronic lymphocytic leukemia; Hodgkin lymphoma; non-Hodgkin lymphoma; multiple myeloma; neuroblastoma; breast, ovary, Wilms tumor; soft-tissue sarcoma Autoimmune disease (Wegener granulomatosis, rheumatoid arthritis, nephrotic syndrome) 	<ul style="list-style-type: none"> Oral or intravenous administration Active alkylating moieties generated through hepatic metabolism Nephrotoxic and urotoxic metabolite, acrolein; severe hemorrhagic cystitis in high-dose regimens; prevented by MESNA Provide vigorous hydration during high-dose treatment Elimination not affected by renal dysfunction; reduce dose in patients with hepatic dysfunction
Ifosfamide	<ul style="list-style-type: none"> Germ cell testicular cancer Pediatric and adult sarcoma High-dose chemotherapy with bone marrow rescue 	<ul style="list-style-type: none"> See cyclophosphamide Can cause neurotoxicity (including seizures) Methylene blue treatment of CNS toxicity possibly useful
Melphalan	<ul style="list-style-type: none"> Multiple myeloma 	<ul style="list-style-type: none"> Oral and intravenous administration
Chlorambucil	<ul style="list-style-type: none"> Chronic lymphocytic leukemia 	<ul style="list-style-type: none"> Oral administration
Bendamustine	<ul style="list-style-type: none"> Non-Hodgkin lymphoma Chronic lymphocytic leukemia 	<ul style="list-style-type: none"> Lacks cross-resistance with other classical alkylators
Alkyl Sulfonate: DNA alkylation		
Busulfan	<ul style="list-style-type: none"> Chronic myelogenous leukemia High-dose chemotherapy regimen with bone marrow transplantation 	<ul style="list-style-type: none"> Oral administration Adverse effects: prolonged (up to years) pancytopenia; suppression of stem cells; seizures; ↑ clearance of phenytoin; hepatic VOD
Nitrosoureas: DNA alkylation		
Carmustine (BCNU)	<ul style="list-style-type: none"> Malignant gliomas Hodgkin lymphoma; non-Hodgkin lymphoma 	<ul style="list-style-type: none"> Vascular damage during injection due to vesicant properties Profound and delayed myelosuppression
Streptozocin (streptozotocin)	<ul style="list-style-type: none"> Malignant pancreatic insulinoma Carcinoid 	<ul style="list-style-type: none"> Frequent renal toxicity, sometimes renal failure
Methylhydrazine Derivatives: Monofunctional DNA alkylation		
Procarbazine (<i>N</i> -methylhydrazine, MIH)	<ul style="list-style-type: none"> Hodgkin lymphoma Gliomas 	<ul style="list-style-type: none"> Greater capacity for mutagenesis and carcinogenesis than bifunctional alkylators (e.g., cyclophosphamide)
Triazenes: Methyl transfer to DNA		
Dacarbazine (DTIC)	<ul style="list-style-type: none"> Hodgkin lymphoma; soft-tissue sarcomas Melanoma 	<ul style="list-style-type: none"> Intravenous administration Activation by hepatic CYPs Adverse effects: nausea, vomiting Rare hepatotoxicity and neurotoxicity
Temozolomide	<ul style="list-style-type: none"> Malignant gliomas 	<ul style="list-style-type: none"> Oral administration Combined with radiation therapy Greater capacity for mutagenesis and carcinogenesis than bifunctional alkylators; more active in MGMT-deficient tumors
Platinum Coordination Complexes: Form covalent metal adducts with DNA		
Cisplatin	<ul style="list-style-type: none"> Testicular, ovarian, bladder, esophageal, gastric, lung, head and neck, anal, and, breast cancer 	<ul style="list-style-type: none"> Intravenous administration Adverse effects: <ul style="list-style-type: none"> Nephrotoxicity (reduce by forced pretreatment hydration, diuresis, and use of <i>amifostine</i>) Ototoxicity (tinnitus, high-frequency hearing loss) Nausea and vomiting (antidote, <i>aprepitant</i>) Peripheral sensory and motor neuropathy (may worsen after discontinuation; may be aggravated by taxane treatment) Drug resistance due to loss of mismatch repair proteins

Drug Facts for Your Personal Formulary: *Cytotoxic Drugs (continued)*

Drug	Therapeutic Use	Clinical Pharmacology and Tips
Platinum Coordination Complexes: Form covalent metal adducts with DNA		
Carboplatin	<ul style="list-style-type: none"> Same as above 	<ul style="list-style-type: none"> Less nausea, neuro-, oto-, and nephrotoxicity than cisplatin Dose-limiting toxicity: myelosuppression May cause hypersensitivity reaction
Oxaliplatin	<ul style="list-style-type: none"> Colorectal, gastric, and pancreatic cancer 	<ul style="list-style-type: none"> Peripheral neuropathy is dose limiting Some nausea Efficacy not dependent on intact mismatch repair
Section II: Antimetabolites		
Folic Acid Analogues: Inhibit dihydrofolate reductase		
Methotrexate (amethopterin)	<ul style="list-style-type: none"> Acute lymphocytic leukemia; choriocarcinoma; breast, head and neck, ovary, bladder and lung cancers; osteogenic sarcoma Noncancer use: psoriasis, rheumatoid arthritis 	<ul style="list-style-type: none"> Oral, intravenous, or intramuscular administration Adverse effects: myelosuppression, GI toxicity Leucovorin can reverse toxic effects; used as "rescue" in high-dose therapy <i>Glucarpidase</i>, a methotrexate-cleaving enzyme, is approved to treat toxicity ↓ Dose in renal insufficiency
Pemetrexed	<ul style="list-style-type: none"> Mesothelioma, lung cancer 	<ul style="list-style-type: none"> Similar effects and side effects as methotrexate Attenuate toxicity with folate and Vit B12 supplementation
Pyrimidine Analogues		
5-Fluorouracil (5FU) <i>Thymidylate synthase inhibitor</i>	<ul style="list-style-type: none"> Breast, colon, esophageal, stomach, anal cancer In FOLFOX or FOLFIRINOX combination to treat pancreatic or colorectal cancer Combined with cisplatin in head and neck cancer Premalignant skin lesion (topical) 	<ul style="list-style-type: none"> Intravenous administration Nausea, mucositis, diarrhea, myelosuppression, hand-foot syndrome Combined with leucovorin to enhance efficacy Enhanced toxicity with DPD deficiency; may rescue with uridine
Capecitabine <i>Thymidylate synthase inhibitor</i>	<ul style="list-style-type: none"> Metastatic breast, colorectal cancer 	<ul style="list-style-type: none"> Orally administered prodrug of 5FU Similar adverse effects as 5FU; hand and foot syndrome more frequent than with 5FU
Cytarabine (cytosine arabinoside) <i>Interferes with base pairing in DNA; inhibits DNA polymerase</i>	<ul style="list-style-type: none"> Acute myelogenous and acute lymphocytic leukemia; non-Hodgkin lymphoma 	<ul style="list-style-type: none"> Intravenous administration Myelosuppressive; can cause acute, severe leukopenia, thrombocytopenia, anemia GI disturbances Noncardiogenic pulmonary edema Dermatitis
Gemcitabine (difluoro analogue of deoxycytidine) <i>Inhibits DNA polymerase; causes strand termination</i>	<ul style="list-style-type: none"> Pancreatic, ovarian, lung, bladder cancer 	<ul style="list-style-type: none"> Intravenous administration Female and elderly patients clear the drug more slowly Myelosuppression, hepatic toxicity Rare posterior leukoencephalopathy syndrome; sometimes interstitial pneumonitis Radiosensitizer; should be used with caution in radiotherapy
5-Azacytidine <i>Inhibits DNA cytosine methyltransferase</i>	<ul style="list-style-type: none"> Myelodysplasia 	<ul style="list-style-type: none"> Subcutaneous or intravenous administration Myelosuppression and mild GI symptoms After intravenous administration severe nausea possible
Purine Analogues and Related Inhibitors		
6-Mercaptopurine <i>Inhibits purine nucleotide synthesis and metabolism</i>	<ul style="list-style-type: none"> Acute lymphocytic and myelogenous leukemia; small cell non-Hodgkin lymphoma Noncancer: Crohn disease, ulcerative colitis 	<ul style="list-style-type: none"> Oral absorption incomplete, thus intravenous administration Reduce oral dose by 75% in patients receiving allopurinol; no adjustment needed for intravenous administration Myelosuppression; anorexia, nausea, vomiting; GI side effects less frequent in children than adults Secondary malignancy: SCC of the skin, AML
Fludarabine <i>A chain terminator when incorporated into DNA; inhibits RNA function and processing</i>	<ul style="list-style-type: none"> Chronic lymphocytic leukemia Follicular B-cell lymphoma Allogeneic bone marrow transplant 	<ul style="list-style-type: none"> Oral or intravenous administration Frequently myelosuppression Less frequent: nausea, vomiting; altered mental status; seizures Secondary myelodysplasia and acute leukemias Adjust dose for renal dysfunction

Purine Analogues and Related Inhibitors (continued)		
Cladribine <i>Incorporated into DNA, produces strand breaks; inhibits conversion of ribo- to deoxyribonucleotides</i>	<ul style="list-style-type: none"> • Hairy cell leukemia • Chronic lymphocytic leukemia • Low-grade lymphoma • CTCL, Waldenström macroglobulinemia 	<ul style="list-style-type: none"> • Intravenous administration • Adjust dose for renal dysfunction • Myelosuppression, opportunistic infections, nausea, high fever, tumor lysis syndrome
Clofarabine (mechanism as above)	<ul style="list-style-type: none"> • Acute myelogenous or lymphocytic leukemia 	<ul style="list-style-type: none"> • Intravenous administration • Adjust dose to creatinine clearance • Myelosuppression • Capillary leak syndrome: discontinue drug • Nausea, vomiting, diarrhea
Nelarabine <i>Incorporated into DNA, terminates DNA synthesis</i>	<ul style="list-style-type: none"> • T-cell leukemia, lymphoma 	<ul style="list-style-type: none"> • Intravenous administration • Myelosuppression; liver function abnormalities; infrequent neurologic sequelae
Pentostatin (2'-deoxycoformycin) <i>Inhibits adenosine deaminase; causes immunodeficiency (T and B cells)</i>	<ul style="list-style-type: none"> • Hairy cell leukemia; chronic lymphocytic leukemia; small cell non-Hodgkin lymphoma 	<ul style="list-style-type: none"> • Intravenous administration • Adjust dose for renal dysfunction • Myelosuppression, GI symptoms, skin rashes, opportunistic infections • Renal, neurologic, pulmonary toxicity

Section III: Natural Products

Vinca Alkaloids: Inhibit tubulin polymerization and microtubule formation

Vinblastine	<ul style="list-style-type: none"> • Hodgkin and non-Hodgkin lymphoma • Breast, bladder, lung, testicular cancer • Kaposi sarcoma, neuroblastoma • Part of ABVD combination with doxorubicin (adriamycin, bleomycin, dacarbazine) for Hodgkin lymphoma 	<ul style="list-style-type: none"> • Intravenous administration; extravasation causes irritation and ulceration • Reduce dose in patients with impaired liver function • Least neurotoxic Vinca alkaloid • Myelosuppressive • GI side effects nausea, vomiting, diarrhea • Vinca alkaloids are substrates of the Pgp efflux pump
Vinorelbine	<ul style="list-style-type: none"> • Breast cancer • Non-small cell lung cancer 	<ul style="list-style-type: none"> • Intravenous administration • Reduce dose in patients with impaired liver function • Intermediate neurotoxicity amongst the Vinca alkaloids • Myelosuppressive (granulocytopenia)
Vincristine	<ul style="list-style-type: none"> • Acute lymphocytic leukemia; neuroblastoma; Wilms tumor; rhabdomyosarcoma; Hodgkin and non-Hodgkin lymphoma • part of CHOP regimen: cyclophosphamide, doxorubicin (H), vincristine (O), prednisone 	<ul style="list-style-type: none"> • Intravenous administration; extravasation causes irritation and ulceration • Reduce dose in patients with impaired liver function • Least myelosuppressive Vinca alkaloid • Dose-limiting neurotoxicity • Better tolerated by children than adults
Eribulin	<ul style="list-style-type: none"> • Breast cancer, liposarcoma 	<ul style="list-style-type: none"> • Side effects overlap with vinca but less sensitive to extrusion by Pgp

Taxanes: Stabilize microtubules, inhibit depolymerization

Paclitaxel	<ul style="list-style-type: none"> • Ovarian, breast, lung, prostate, bladder, head and neck cancer 	<ul style="list-style-type: none"> • Intravenous administration • Metabolized by hepatic CYPs, ↓ dose in patients with hepatic dysfunction • Substrate of Pgp efflux pump • Myelosuppressive, alleviated by G-CSF • Peripheral neuropathy is dose limiting • Mucositis
Docetaxel	<ul style="list-style-type: none"> • Same as above 	<ul style="list-style-type: none"> • No effect on doxorubicin clearance • Pharmacokinetics similar to paclitaxel's • ↓ Neutropenia, ↓ neuropathy than paclitaxel

Camptothecins: Inhibit topoisomerase I; DNA religation is inhibited: accumulation of single-strand breaks

Topotecan	<ul style="list-style-type: none"> • Ovarian cancer; small cell lung cancer 	<ul style="list-style-type: none"> • Intravenous or oral administration • Reduce dose in patients with renal dysfunction • Neutropenia, GI side effects, nausea, vomiting • Substrate for Pgp
Irinotecan	<ul style="list-style-type: none"> • Colorectal cancer, small cell lung cancer • Part of FOLFIRI or FOLFIRINOX combination for GI tumors 	<ul style="list-style-type: none"> • Intravenous administration • Prodrug activated in the liver; CYP substrate • Diarrhea and neutropenia • Acetylcholinesterase inhibition results in cholinergic syndrome: treat with atropine

Antibiotics

Dactinomycin (actinomycin D) <i>Intercalates between GC base pairs of DNA</i>	<ul style="list-style-type: none"> • Wilms tumor; rhabdomyosarcoma; Ewing, Kaposi, and other sarcoma; choriocarcinoma 	<ul style="list-style-type: none"> • Intravenous administration; severe injury on extravasation • Nausea, vomiting; myelosuppression; GI side effects; erythema, inflammation of the skin
--	--	---

Drug Facts for Your Personal Formulary: Cytotoxic Drugs (continued)

Drug	Therapeutic Use	Clinical Pharmacology and Tips
Anthracyclines and Anthracenediones: Inhibit topoisomerase II and intercalate DNA		
Daunorubicin (daunomycin, rubidomycin)	<ul style="list-style-type: none"> Acute myelogenous and acute lymphocytic leukemia 	<ul style="list-style-type: none"> Intravenous administration Impart a red color to the urine Myelosuppression, GI side effects Most important long-term side effect is cardiotoxicity, including tachycardia, arrhythmias, congestive heart failure Alopecia
Doxorubicin	<ul style="list-style-type: none"> Soft-tissue, osteogenic, and other sarcoma; Hodgkin and non-Hodgkin lymphoma; acute leukemia; breast, genitourinary, thyroid, and stomach cancer; neuroblastoma 	
Mitoxantrone (an anthracenedione)	<ul style="list-style-type: none"> Acute myelocytic leukemia; breast and prostate cancer 	<ul style="list-style-type: none"> Similar side effects as above Less cardiotoxic
Epipodophyllotoxins: Inhibit topoisomerase II and religation of cleaved DNA strand		
Etoposide	<ul style="list-style-type: none"> Testicular and lung cancer; Hodgkin lymphoma; non-Hodgkin lymphomas; acute myelogenous leukemia; Kaposi sarcoma 	<ul style="list-style-type: none"> Oral and intravenous administration Reduce dose in patients with renal dysfunction Leukopenia, GI side effects; hepatic toxicity after high doses Secondary leukemia
Teniposide	<ul style="list-style-type: none"> Acute lymphoblastic leukemia in children; glioblastoma, neuroblastoma 	<ul style="list-style-type: none"> Intravenous administration Myelosuppression, nausea, vomiting
Drugs With Diverse Mechanism of Action		
Bleomycin <i>Binds to DNA, generates free radicals, and induces DNA cleavage via deoxyribose ring damage</i>	<ul style="list-style-type: none"> Testicular cancer; Hodgkin and non-Hodgkin lymphoma; local treatment of bladder cancer Part of the ABVD regimen (doxorubicin [Adriamycin], Bleomycin, Vinblastine, and Dacarbazine) 	<ul style="list-style-type: none"> IV, IM or SC administration; instilled into bladder Reduce dose in patients with renal dysfunction Most serious: pulmonary toxicity Cutaneous toxicity (erythema, ulcerations) Less myelosuppression than other cytotoxics
L-Asparaginase <i>Hydrolyzes asparagine; deprives leukemia cells that lack asparagine synthase</i>	<ul style="list-style-type: none"> Acute lymphocytic leukemia 	<ul style="list-style-type: none"> IV and IM administration Hypersensitivity reactions, anaphylaxis Hyperglycemia, clotting abnormalities
Hydroxyurea <i>Inhibits RNR (conversion of ribo- to deoxyribonucleotides)</i>	<ul style="list-style-type: none"> Chronic myelogenous leukemia; polycythemia vera; essential thrombocytosis; sickle cell disease in adults 	<ul style="list-style-type: none"> Oral administration Reduce dose in patients with renal dysfunction Myelosuppression; some GI side effects
Tretinoin (all-trans retinoic acid) <i>Promotes degradation of PML-RARA fusion protein</i>	<ul style="list-style-type: none"> Acute promyelocytic leukemia 	<ul style="list-style-type: none"> Oral administration CYP substrate Leukocyte maturation syndrome, pulmonary distress, effusions, fever, dyspnea Dry skin, cheilitis Hypercalcemia and renal failure
Arsenic trioxide <i>Inhibits thioredoxin and generates reactive oxygen species</i>	<ul style="list-style-type: none"> Acute promyelocytic leukemia 	<ul style="list-style-type: none"> Oral or intravenous administration Leukocyte maturation syndrome as above with ATRA QT prolongation; rare torsade de pointes

^aFor drugs that are subject to hepatic metabolism by CYP enzymes, drug exposure of a patient can be affected by coadministration of inhibitors or inducers of CYP3A4 and can then reduce efficacy or increase side effects.

^bEmbryo-fetal toxicity: Consider that all of these drugs can cause fetal harm. Advise women of the potential risk to a fetus and to avoid pregnancy while taking the drug and for 1 month after cessation of therapy. Advise men to avoid fathering a child during the same time period. Avoid lactation during therapies.

Chapter 67

Pathway-Targeted Therapies: Monoclonal Antibodies, Protein Kinase Inhibitors, and Various Small Molecules

Anton Wellstein, Giuseppe Giaccone, Michael B. Atkins, and Edward A. Sausville

I. GROWTH FACTORS AND RECEPTORS IN CANCER CELLS

INHIBITORS OF EGFR FUNCTION

HER2/NEU INHIBITORS

INHIBITORS OF PDGF RECEPTOR

HEDGEHOG PATHWAY INHIBITORS

II. INTRACELLULAR PROTEIN KINASES IN CANCER CELLS

INHIBITORS OF RAF KINASE: VEMURAFENIB, DABRAFENIB

INHIBITORS OF MEK: TRAMETINIB, COBIMETINIB

INHIBITORS OF JAK1 AND JAK2

CYCLIN-DEPENDENT KINASE 4/6 INHIBITORS

BRUTON TYROSINE KINASE INHIBITOR

INHIBITORS OF THE BCR-ABL KINASE

INHIBITORS OF ALK

INHIBITORS OF THE PI3K/AKT/mTOR PATHWAY

MULTIKINASE INHIBITORS

III. TUMOR ANGIOGENESIS

INHIBITION OF VEGF AND THE VEGFR PATHWAY

ANTIANGIOGENIC SMALL-MOLECULE KINASE INHIBITORS

IV. TARGETING THE IMMUNE SYSTEM

IMMUNE CHECKPOINT INHIBITORS

INHIBITORS OF CTLA4

INHIBITORS OF PD-1

ANTAGONISTS OF PD-1 LIGAND 1

COMBINATION OF ANTI-PD-1 AND ANTI-CTLA-4

CYTOKINES TO STIMULATE IMMUNE RESPONSES

CANCER VACCINES

CHIMERIC ANTIGEN RECEPTOR T CELLS

FUTURE CHALLENGES OF IMMUNOTHERAPY

V. OTHER TARGETS

INHIBITORS OF POLY(ADP-RIBOSE) POLYMERASE

BCL2 INHIBITORS

THALIDOMIDE AND LENALIDOMIDE

PROTEASOME INHIBITORS

CD20 INHIBITORS

OTHER CELL SURFACE TARGETS FOR MONOCLONAL ANTIBODIES

MONOCLONAL ANTIBODY-CYTOTOXIN CONJUGATES

CYTOKINES AND GROWTH FACTORS

INHIBITORS OF HISTONE DEACETYLASE

- ABC:** ATP-binding cassette
ABL: Abelson murine leukemia viral oncogene homolog
ADCC: antibody-dependent cellular cytotoxicity
AI: aromatase inhibitor
ALK: anaplastic lymphoma kinase
ALL: acute lymphoblastic leukemia
AML: acute myelocytic leukemia
APC: antigen-presenting cell
aPTT: activated partial thromboplastin time
AUC: area under the curve
AXL: TAM family receptor tyrosine
BCC: basal cell carcinoma
BCL: B-cell lymphoma
BCR: breakpoint cluster region (chr22)
BCRP: breast cancer resistance protein
BH3: BCL2 homology domain 3
BIM: BCL2-like protein 11
BRCA: breast cancer susceptibility gene
BRK: breast tumor kinase, PTK6
BTk: Bruton tyrosine kinase
CAR(T): chimeric antigen receptor T cells
CDC: complement-dependent cytotoxicity
CDK: cyclin-dependent kinase
CLL: chronic lymphocytic leukemia
cMET: mesenchymal-epithelial transition receptor tyrosine kinase
CML: chronic myelocytic leukemia
CRL4-CRBN: cullin-ring ubiquitin ligase cereblon complex
CTLA-4: cytotoxic T lymphocyte-associated protein 4
cuSCC: cutaneous squamous cell carcinoma
CXCR4: C-X-C chemokine receptor 4
EGF(R): epidermal growth factor (receptor) = HER1
EML4: echinoderm microtubule-associated protein-like 4
EPH: ephrin
ER: estrogen receptor
FADD: fas-associated protein with death domain
FGF: fibroblast growth factor
FGFR: fibroblast growth factor receptor
FIP1L1: factor interacting with poly (A) polymerase
FKBP12: immunophilin-binding protein for tacrolimus (FK506)
FL: follicular B-cell non-Hodgkin lymphoma
FLT4: fms-related tyrosine kinase 4 = VEGFR3
FMO3: flavin containing monooxygenase 3
FOLFIRI: folinic acid (leucovorin), 5-fluorouracil, irinotecan
FOLFOX: folinic acid (leucovorin), 5-fluorouracil, oxaliplatin
5FU: 5-fluorouracil
GAP: GTPase-activating protein
G-CSF: granulocyte colony-stimulating factor
GIST: gastrointestinal stromal tumor
GM-CSF: granulocyte-macrophage colony-stimulating factor
HDAC: histone deacetylase
HER1: human epidermal growth factor receptor = EGFR
HGF(R): hepatocyte growth factor (receptor) = cMET
HIF-1: hypoxia inducible factor 1
HL: Hodgkin lymphoma
HNSCC: head and neck squamous cell carcinoma
HSC: hematopoietic stem cell
IFN: interferon
IGF1R: insulin-like growth factor 1 receptor
IkB: inhibitor of nuclear factor kappa B
IL: interleukin
IL-2R: interleukin 2 receptor
INR: international normalized ratio
ITK: inducible T cell kinase
JC: John Cunningham
KDR: kinase insert domain receptor = VEGFR2
KIT: feline sarcoma virus oncogene homolog
LCK: lymphocyte specific kinase
LVEF: left ventricular ejection fraction
MCL: mantle cell lymphoma
mCRC: metastatic colorectal cancer
MDS: myelodysplastic syndrome
MET: mesenchymal-epithelial transition factor (= HGFR)
MHC: major histocompatibility complex protein
MKK: mitogen-activated protein kinase kinase (= MEK)
MM: multiple myeloma
MMAE: monomethyl auristatin E
mTOR: mammalian target of rapamycin
NCCN: National Comprehensive Cancer Network
NER: nucleotide excision repair
NET: neuroendocrine tumor
NHL: non-Hodgkin lymphoma
NK: natural killer
NPM: nucleophosmin (gene)
NRAS: neuroblastoma RAS virus homolog
NSCLC: non-small cell lung cancer
OATP: organic anion-transporting polypeptide
PAP: prostate acidic phosphatase
PARP1: poly(ADP-ribose) polymerase
PD-1: programmed cell death 1
PDGF: platelet-derived growth factor
PDGFR: platelet-derived growth factor receptor
PD-L1: programmed cell death 1 ligand 1
Pgp: P-glycoprotein
PML: promyelocytic leukemia
PNET: peripheral neuroendocrine tumors
PPES: palmar-plantar erythrodysesthesia syndrome
PPI: proton pump inhibitor
PTEN: phosphatase and tensin homolog
RA: 13-cis-retinoic acid
Rb: retinoblastoma (protein)
RCC: renal cell carcinoma
ROS1: orphan receptor tyrosine kinase
SCC: squamous cell carcinoma
SCLC: small cell lung cancer
SDF: stromal cell-derived factor
S6K1: ribosomal protein S6 kinase β 1
SLL: small lymphocytic lymphoma
STS: soft-tissue sarcoma
TCR: T cell receptor
TIE: tyrosine kinase with Ig and EGF domains
TIL: tumor-infiltrating lymphocyte
TKI: tyrosine kinase inhibitor
TNF: tumor necrosis factor
TRADD: tumor necrosis factor receptor death domain
TRAIL: TNF-related apoptosis inducing ligand
TSC: tuberous sclerosis complex
VEGF: vascular endothelial growth factor
VEGFR: vascular endothelial growth factor receptor
WM: Waldenström macroglobulinemia

A Note on Treatment Regimens

Cancer treatment regimens change to reflect continuous advances in basic and clinical science: new drugs, both small molecules and biologicals; improved methods of targeting and timing of drug delivery; agents with altered pharmacokinetic properties and selectivities; the use of rational multidrug combinations; and greater knowledge of the basic cell biology of tumorigenesis, metastasis, and immune function, amongst other advances. As a consequence, this chapter presents relatively few detailed treatment regimens; rather, we refer the reader to the web-based resources of the U.S. FDA and the NCCN. Table 67–1 provides two examples of therapeutic regimens that illustrate the complexity of current cancer drug therapy.

Development of targeted therapies for treating cancer relies on the continuing process of discovery of molecular changes that drive malignant progression of human cancers. A rapidly growing number of drugs are being developed to block oncogenic pathways that lead to dysregulated cancer cell growth and survival. Targeted therapy may be combined with classical cytotoxic cancer drugs described in Chapter 66 for improved efficacy. Growth factor receptors and downstream signaling molecules are amongst the most actively explored targets for cancer drug discovery. The drivers of cancer growth are oncogenic pathways in malignant cells themselves (e.g., mutant receptors and kinases), the reaction of the tumor microenvironment (e.g., angiogenesis), and the escape of malignant cells from the host's immune surveillance (Hanahan and Weinberg, 2011). The discussion of drugs in this chapter is organized into sections focusing on these drivers of cancer growth:

- I. Growth factors and receptors in cancer cells
- II. Intracellular kinases in cancer cells
- III. Tumor-host interactions reflected in aberrant tumor angiogenesis
- IV. Restoring immune recognition of cancer cells
- V. Other drugs and targets that control cancer cell behavior

The primary tools for targeting oncogenic pathways are *monoclonal antibodies* that recognize cell surface or shed antigens (e.g., growth factor receptors or receptor ligands) and *small molecules* that can enter cells and engage intracellular targets, many of them kinases. These two classes of drugs have very different pharmacological properties (see Box).

I. Growth Factors and Receptors in Cancer Cells**Inhibitors of Epidermal Growth Factor Receptor (EGFR) Function****Background**

The EGFR belongs to the ErbB family of transmembrane receptor tyrosine kinases also known as ErbB1 or HER1 (*human EGFR 1*). EGFR is essential for the growth and differentiation of epithelial cells. Ligand binding to the extracellular domain of EGFR family members causes receptor dimerization and stimulates the protein tyrosine kinase activity of the intracellular domain, resulting in autophosphorylation of several Tyr residues located in the C-terminal tail of the receptor monomers. These phosphotyrosines provide interaction sites for a variety of adapter proteins, resulting in stimulation of signaling pathways, including MAPK, PI3K/Akt, and STAT pathways (see Figure 67–1).

Two separate classes of drugs that target the EGFR pathway are important in the therapy of solid tumors: protein tyrosine kinase inhibitors and inhibitors of extracellular ligand binding. EGFR TKIs (*erlotinib*, *gefitinib*, *afatinib*, *osimertinib*) bind to the intracellular kinase domain and inhibit the enzymatic function of an EGFR. Monoclonal antibodies (*cetuximab*,

Two Classes of Pathway-Targeted Cancer Drugs

1. Monoclonal Antibodies: Monoclonal antibodies kill tumor cells by blocking cell surface receptor function, by recruiting immune cells and complement to the antigen-antibody complex, and by modulating immune cell function. Also, they may be armed to carry toxins or radionuclides to the cells of interest, thereby enhancing their cytotoxic effects. A monoclonal antibody is generally specific for a single antigen, such as an epitope in a growth factor receptor; has a long plasma $t_{1/2}$; and requires only intermittent parenteral administration.

The Naming of Monoclonal Antibodies: Monoclonal antibody names end with the syllable “mab” preceded by “mu” for fully human protein sequence, “zu” for human protein with the antigen-binding region from a mouse antibody, “xi” for a chimera consisting of human constant and mouse variable antibody domains, and “o” for entirely mouse protein sequences (Hansel et al., 2010; see Figures 34–6 and 34–7).

2. Small Molecules: Small molecules may attack the same targets as monoclonal antibodies but can exert their effect by entering cells. Small molecules often inhibit multiple enzymes with different selectivities and thus are likely to have a broader spectrum of targets and produce a broader spectrum of desired effects, off-target effects, and adverse effects than monoclonal antibodies. Many small-molecule drugs have elimination half-lives of 12 to 24 h and typically require at least daily oral administration. For small-molecule drugs that are metabolized by hepatic CYPs, the concomitant use of strong CYP inhibitors (e.g., ketoconazole, nefazodone, clarithromycin, gemfibrozil, cobicistat) or inducers (e.g., rifampin, phenytoin, carbamazepine, phenobarbital, St John's wort) can lead to increased adverse effects due to reduced drug elimination or to reduced efficacy due to accelerated clearance. The small-molecule inhibitors mentioned in this chapter, mostly protein kinase inhibitors, end with the syllable “ib.” More than 130 novel TKIs are currently being evaluated in different clinical phases (Neul et al., 2016).

panitumumab, *nectinumab*) recognize the extracellular domain of the EGFR, inhibit ligand-induced signaling, and can elicit an immune response. In epithelial cancers, overexpression of the EGFR is a common finding, and mutational activation of the EGFR (e.g., in 10%–40% of NSCLCs) creates a dependence on EGFR signaling. The most common EGFR mutations are in-frame deletions in exon 19 or leucine-to-arginine point mutations (L858R) in exon 21 that cause conformational changes and constitutive activation of the kinase. First- (*erlotinib*, *gefitinib*) and second- (*afatinib*) generation drugs are available that inhibit EGFR kinase activity driven by these mutations. Resistant cancer cell subpopulations that emerge during treatment with first- and second-generation inhibitors are usually sensitive to the third-generation inhibitor *osimertinib* (Figure 67–1).

Protein Tyrosine Kinase Inhibitors of EGFR**Erlotinib**

Mechanism of Action. Erlotinib is a reversible inhibitor of the EGFR tyrosine kinase, competitively inhibiting ATP binding at the active site of the kinase. Erlotinib has an IC_{50} of 2 nM for EGFR kinase activity. By comparison, for many protein kinases, the K_d for ATP at the substrate site is in the range of 20 μ M.

ADME. Erlotinib is about 60% absorbed after oral administration. Peak plasma levels occur after 4 h. Erlotinib has a $t_{1/2}$ of 36 h and is metabolized by CYP3A4 and to a lesser extent by CYPs 1A2 and 1A1.

Therapeutic Uses. Erlotinib is approved for treatment of patients with advanced or metastatic NSCLC after failure of platinum-based treatment. In newly diagnosed NSCLC, erlotinib is approved in patients with EGFR mutations only (Figure 67–1). Erlotinib in combination with gemcitabine is also approved for the treatment of patients with locally advanced, unresectable, or metastatic pancreatic cancer.

TABLE 67-1 ■ CANCER TREATMENT REGIMENS: COMPLEXITIES AND RESOURCES

In treating cancers, the selection of the most appropriate treatment(s), dose, and dose intervals as well as the management of adverse effects requires specialized knowledge and a team effort. In addition, cancer treatment regimens are undergoing frequent updates due to findings in ongoing clinical trials. The availability of drugs with new mechanisms of action (e.g., immune checkpoint inhibitors), good target selectivity (e.g., kinase inhibitors), efficacy in specific cancers, and different adverse effect profiles permits the use of new drug combinations and regimens. The chapters on the pharmacotherapy of cancer focus on mechanism of action, ADME, and adverse effects, with less emphasis on treatment regimens. There are several excellent sources of up-to-date treatment information. The U.S. FDA provides authoritative information on approved drugs online (<http://www.accessdata.fda.gov/scripts/cder/daf/>). Detailed treatment guidelines for most cancers are available from the NCCN, an alliance of cancer centers that establishes evidence-based guidelines for cancer treatment. The NCCN guidelines are continuously updated to reflect new information that may alter clinical practice. The guidelines can be accessed online (https://www.nccn.org/professionals/physician_gls/f_guidelines.asp).

This table provides examples that illustrate the complexities of current treatment for two cancers: HER2+ breast cancer and advanced colorectal cancer.

SAMPLE TREATMENT REGIMENS	
SUMMARY	DRUGS, SCHEDULE, AND DOSING
HER2-Positive Breast Cancer	
Doxorubicin and cyclophosphamide (= AC) followed by paclitaxel, trastuzumab, and pertuzumab	<p>Day 1: Doxorubicin 60 mg/m² IV</p> <p>Day 1: Cyclophosphamide 600 mg/m² IV</p> <p>Repeat cycle every 21 days for 4 cycles</p> <p>Followed by</p> <p>Day 1: Pertuzumab 840 mg IV followed by 420 mg IV</p> <p>Day 1: Trastuzumab 8 mg/kg IV followed by 6 mg/kg IV</p> <p>Days 1, 8, and 15: Paclitaxel 80 mg/m² IV</p> <p>Repeat cycle every 21 days for 4 cycles</p> <p>Day 1: Trastuzumab 6 mg/kg IV</p> <p>Repeat cycle every 21 days to complete 1 year of trastuzumab therapy</p> <p>Cardiac monitoring at baseline and 3-month intervals</p>
Advanced or Metastatic Colorectal Cancer RAS wild-type	
Oxaliplatin, leucovorin, 5FU (= FOLFOX) plus cetuximab	<p>Day 1: Oxaliplatin 85 mg/m² IV over 2 h</p> <p>Day 1: Leucovorin 400 mg/m² IV over 2 h</p> <p>Days 1–3: 5FU 400 mg/m² IV bolus on day 1, then 1200 mg/m²/d × 2 days (total 2400 mg/m² over 46–48 h) IV continuous infusion</p> <p>Repeat cycle every 2 weeks, plus</p> <p>Cetuximab 400 mg/m² IV over 2 h for the first infusion, then 250 mg/m² IV over 60 min weekly.</p> <p>OR</p> <p>Day 1: Cetuximab 500 mg/m² IV over 2 h every 2 weeks</p>

Source: Adapted from NCCN.

Adverse Effects and Drug Interactions. The most common adverse reactions (≥20%) are rash, diarrhea, anorexia, fatigue, dyspnea, nail disorders, nausea, and vomiting. Serious adverse reactions include severe rash (>10%). Fatal interstitial lung disease occurs with a frequency of 0.7%–2.5%, and fatal hepatic failure has been reported, particularly in patients with baseline hepatic dysfunction. Other rare but serious toxicities include GI perforation, renal failure, arterial thrombosis, microangiopathic hemolytic anemia, hand-foot skin reaction, and corneal perforation or ulceration. Erlotinib therapy may cause rare cases of Stevens-Johnson syndrome/toxic epidermal necrolysis.

Concurrent use of proton pump inhibitors decreases the bioavailability of erlotinib by 50%. Plasma levels can vary due to drug interactions with inducers or inhibitors of CYP3A4. Patients using warfarin may experience poorer extrinsic coagulation (elevated INR) while taking erlotinib. Smoking accelerates metabolic clearance of erlotinib and may decrease its antitumor effects.

Gefitinib

Mechanism of Action. Gefitinib inhibits the EGFR tyrosine kinase by competitive blockade of ATP binding with an IC₅₀ of 20–60 nM for the kinase activity.

ADME. Oral bioavailability is about 60%; peak plasma concentrations are achieved within 3–7 h. Absorption of gefitinib is not significantly altered by food but is reduced by drugs that cause elevations in gastric pH. Metabolism of gefitinib is predominantly via CYP3A4, with a terminal *t*_{1/2} of 41 h. Inducers of CYP3A4 activity decrease gefitinib plasma concentrations and efficacy; conversely, CYP3A4 inhibitors increase plasma concentrations.

Therapeutic Uses. Gefitinib is approved for treatment of patients with metastatic NSCLC with EGFR mutations (Figure 67-1).

Adverse Effects and Drug Interactions. Diarrhea and skin reactions occur in more than 20% of patients. In addition to pustular/papular rash,

Figure 67-1 Targeting the EGFR in cancer. The extracellular portion of the EGFR contains the binding domains for growth factors that include EGF, TGF- α , and amphiregulin. Ligand binding to extracellular domains I and III induces conformational change and receptor dimerization through domains II and IV and activates intracellular signaling by cross-phosphorylation. The monoclonal antibodies cetuximab and panitumumab recognize the growth factor-binding domain and prevent ligand binding. The intracellular portion contains the tyrosine kinase activity and a C-terminal tail that recruits intracellular substrates after phosphorylation (see Chapter 3). EGFR mutations enhance downstream signaling, which provides a growth and survival advantage for cancer cells and confers sensitivity to treatment with TKIs gefitinib, erlotinib, and afatinib. The most common activating mutations are in-frame deletions in exon 19 (del 19) between E746 and A750 (~45%) and a missense mutation in exon 21 that leads to an L858R substitution (~40%). Lung cancers with these mutations are initially sensitive to the TKIs mentioned. Resistance develops, however, most commonly via the T790M substitution found in about 50% of resistant tumors. TKIs such as osimertinib have been developed for the treatment of cancers with the T790M mutation. Genotype screening for mutations in the EGFR is used to select patients who will receive TKIs and help predict which patients with lung cancer may respond best to some therapies. Numbers shown are amino acid positions in the EGFR protein.

other side effects include dry skin, nausea, vomiting, pruritus, anorexia, and fatigue. Most adverse effects occur within the first month of therapy and are manageable with medications. Asymptomatic increases in liver transaminases may necessitate discontinuation of therapy. Respiratory compromise and interstitial lung disease, especially in patients with prior radiation, occurs in fewer than 2% of patients but may have a fatal outcome. Inducers and inhibitors of CYP3A4 will alter plasma concentrations. Patients using warfarin should be monitored for poorer extrinsic coagulation (elevated INR) while taking gefitinib.

Afatinib

Mechanism of Action. Afatinib is a second-generation, orally bioavailable, *irreversible* inhibitor of EGFR (HER1) and HER2 receptor kinases with IC_{50} values of 0.5 and 14 nM, respectively.

ADME. The elimination $t_{1/2}$ of afatinib is 37 h after repeat dosing in patients with cancer. In patients with severe renal impairment, a dose reduction is recommended. Afatinib is a substrate of Pgp and coadministration of Pgp-modulating drugs can alter effective drug concentrations of afatinib.

Therapeutic Uses. Afatinib is approved for the first-line treatment of patients with metastatic NSCLC with EGFR mutations (see Figure 67-1)

and patients with metastatic squamous NSCLC that have progressed subsequent to platinum-based chemotherapy.

Adverse Effects and Drug Interactions. Most common adverse effects are diarrhea and skin rash/acneiform dermatitis, stomatitis, as well as hand-foot skin reactions. Also observed are interstitial lung disease, liver function abnormalities, and left ventricular dysfunction.

Resistance to Gefitinib, Erlotinib, and Afatinib

The majority of tumors with activating mutations in the EGFR initially respond to these kinase inhibitors of the first (*gefitinib*, *erlotinib*) and second generation (*afatinib*). Eventually, however, the tumors progress. Approximately 60% of NSCLC acquire a second EGFR mutation in the so-called EGFR gatekeeper residue T790M (see Figure 67-1) that prevents binding of these inhibitors to the kinase domain. *Osimertinib*, a third-generation inhibitor designed to recognize the T790M-mutant EGFR, is described next. Other mechanisms of resistance include mutational activation of downstream signaling molecules such as KRAS or activation of parallel signaling pathways, for example, through MET amplification, *MLL4-ALK* translocation (see Figure 67-2), and small cell lung cancer transformation. ALK and MET kinase inhibitors are described in material that follows (Smit and Baas, 2015).

Osimertinib

Mechanism of Action. Osimertinib is a third-generation, orally bioavailable, *irreversible* inhibitor of T790M-mutant EGFR, with an IC_{50} value of 10 nM. The T790M gatekeeper mutation is often acquired after prior treatment with other EGFR kinase inhibitors (see previous discussion). Very sensitive detection methods can identify the presence of T790M in up to 30% of untreated patients, suggesting preexisting resistant subpopulations (see Chapter 65, Figure 65-3).

ADME. The mean $t_{1/2}$ of osimertinib is 48 h. Osimertinib is a substrate of CYP3A. The drug is primarily eliminated in the feces and to a lesser extent in the urine. Concurrent administration of inducers of CYP3A4 may necessitate an increase in the dose.

Therapeutic Uses. Osimertinib is approved for metastatic NSCLC that has progressed after prior EGFR TKI treatment and is positive for the EGFR T790M mutation. Genotyping of tumor biopsies for the T790M mutation is required after resistance develops. Recent studies have shown that noninvasive genotyping of DNA shed from tumor cells into the bloodstream may be feasible after extracting cell-free DNA from patient serum samples (Oxnard et al., 2016). Response rates are greater than 60% in patients with metastatic NSCLC. However, with osimertinib treatment acquired resistance occurs, most commonly manifested by the appearance of a third mutation, C797S. The mutation of Cys⁷⁹⁷ to Ser⁷⁹⁷ prevents formation of the potency-conferring covalent bond of the inhibitor (Thress et al., 2015). Inhibitors of C797S-mutant EGFR are under development for combination treatment with an EGFR-targeted antibody (Jia et al., 2016).

Adverse Effects and Drug Interactions. The most common adverse effects after osimertinib treatment are diarrhea and skin rash; however, these are much less common and severe than for first- and second-generation inhibitors, presumably because the activity on wild-type EGFR is limited with third-generation inhibitors. Also observed are interstitial lung disease, QTc prolongation, and left ventricular dysfunction.

Antibody Inhibitors of EGFRs

Cetuximab

Mechanism of Action. Cetuximab is a recombinant, chimeric human/mouse IgG₁ antibody that binds to the extracellular domain III of EGFR (Figure 67-1) and prevents ligand-dependent signaling and receptor dimerization, thereby blocking cell growth and survival signals. Cetuximab can also mediate ADCC against tumor cells that express high levels of EGFR.

ADME. Cetuximab exhibits nonlinear pharmacokinetics. A single loading dose of cetuximab intravenously is followed by weekly

Figure 67-2 Cancer cell signaling pathway and drug targets. Extracellular binding of agonist ligands to transmembrane growth factor receptors causes receptor dimerization and activation of a C-terminal protein kinase that initiates intracellular signaling cascades that regulate gene expression and control cancer cell proliferation, apoptosis, metabolism, and metastasis. Crosstalk between cancer cells and the host stroma (including the vasculature and immune cells) is modulated through the release of angiogenic factors and the expression of immune checkpoint proteins. Cancer cell signaling can be altered through increased expression of receptors (e.g., HER2) or ligands, activating mutations in receptors (e.g., ALK, EGFR, FGFR) or in intracellular kinases (e.g., RAS, RAF, MEK, PI3K, AKT, JAK), gene translocations resulting in activated fusion proteins (e.g., bcr-abl, EML4-ALK), and the loss of function of a pathway (e.g., the PTEN phosphatase) through mutation, gene deletion, or promoter methylation. Inhibitors are shown acting on three different cells: a cancer cell, an endothelial cell, and a T cell. Antibodies (green) are shown at their extracellular protein targets. Small-molecule inhibitors (in blue) are depicted adjacent to their intracellular target proteins. Proteins within red ellipses provide activating signals, those in green ellipses, inhibitory signals. Starbursts (★) indicate signaling components in which mutations are common. Figure 67-4 describes mTOR signaling and its inhibition in more detail (see also Figure 35-2). Figure 67-6 describes Jak-STAT signaling in greater detail.

maintenance doses for the duration of treatment. Following intravenous administration, steady-state levels are achieved by the third weekly infusion. The volume of distribution approximates the intravascular space. The half-life of cetuximab is about 5 days.

Therapeutic Uses. Antibodies targeting EGFR show a different spectrum of antitumor activity than EGFR TKIs, in part due to the additional ADCC of antibodies toward tumor cells. Cetuximab and related antibodies are used to treat patients with *metastatic colon cancers* and *HNSCC*.

In colon cancer, cetuximab enhances the effectiveness of chemotherapy in patients with *KRAS* wild-type but not *KRAS*-mutant tumors (Van Cutsem et al., 2009). A combination of cetuximab with FOLFIRI (see Chapter 66) is typically used to treat patients with *KRAS* wild-type tumors that express EGFR. Cetuximab is also used as a single agent in patients who cannot tolerate irinotecan-based therapy and in patients with cancers that are resistant to oxaliplatin, irinotecan, and 5FU.

In HNSCC, cetuximab is used in combination with radiation or with platinum complex-based chemotherapy (e.g., cisplatin; see Chapter 66) for locally or regionally advanced HNSCC. Cetuximab is also indicated as a monotherapy for patients with metastatic or recurrent HNSCC who fail platinum-based chemotherapy.

Adverse Effects. Antibodies targeting EGFR have an adverse effect profile similar to that of first-generation EGFR protein tyrosine kinase inhibitors. Acneiform rash in the majority of patients, pruritus, nail changes, headache, and less frequently diarrhea are the most common adverse reactions. Rare but serious adverse effects include infusion reactions (~3% of patients), cardiopulmonary arrest (2%–3%), interstitial lung disease, and serum electrolyte imbalances, including hypomagnesemia. During

pregnancy, cetuximab may be transmitted to the developing fetus and has the potential to cause fetal harm.

Other EGFR Antibodies

Panitumumab

Panitumumab is a recombinant, fully humanized IgG_{2k} antibody that binds to the extracellular domain III of the EGFR and prevents ligand-dependent signaling. It is FDA approved for the treatment of EGFR-expressing mCRC in combination with chemotherapy and as monotherapy after disease progression following chemotherapy regimens containing fluoropyrimidine, oxaliplatin, and irinotecan (Saltz et al., 2006). Although panitumumab effectively inhibits EGFR signaling similarly to cetuximab, it is less effective at triggering cellular immune mechanisms that may be crucial for effective therapy of HNSCC (Trivedi et al., 2016).

ADME; Adverse Effects. Panitumumab exhibits nonlinear pharmacokinetic characteristics. Following intravenous administration every 2 weeks, steady-state levels are achieved by the third infusion. The mean $t_{1/2}$ is 7.5 days. **Adverse effects** of panitumumab are similar to those of cetuximab and include rash and dermatological toxicity, infusion reactions, pulmonary fibrosis, and electrolyte abnormalities.

Necitumumab

Necitumumab is a recombinant human IgG₁ monoclonal antibody that binds to the extracellular domain of the EGFR. It is approved for first-line treatment of patients with metastatic, squamous NSCLC in combination with gemcitabine and cisplatin. Necitumumab is administered intravenously every 3 weeks prior to chemotherapy. Adverse effects are similar to those of cetuximab.

HER2/Neu Inhibitors

Human epidermal growth factor receptor 2 (also named Neu or ErbB2) is a member of the HER family, which includes also EGFR (HER1), HER3, and HER4 (Figure 67–2). The fixed conformation of the extracellular domain of HER2 resembles the ligand-activated state of the other HER family members and explains its unique function as a coreceptor that does not require ligand activation. In addition, due to this conformation, the overexpression of wild-type HER2 is sufficient to activate the intracellular tyrosine kinase and oncogenic signaling even in the absence of activating mutations, coreceptors, or ligands. Overexpression of HER2 is found in 20% to 30% of human breast cancers due to gene amplification on chromosome 17 and results in more aggressive tumors, lower response rates to hormonal therapies, and higher risk of disease recurrence after treatment.

HISTORY EGFR/HER Pathway-Targeted Cancer Therapy

The discovery and analysis of the EGFR (= HER1) in 1984 revealed a remarkable homology of its protein kinase domain to an oncogenic protein in the avian erythroblastosis retrovirus, v-erb. This oncogenic protein was the second one isolated from v-erb, resulting in erbB as an alternate name for HER gene family members. The HER2 gene was discovered based on its homology to v-erbB in human breast cancer and its oncogenic function in rat *neural* tumors, hence the name HER2/ErbB2/Neu (King et al., 1985; Schechter et al., 1985). The association of HER2 overexpression with poor prognosis in breast cancer (Slamon et al., 1987) provided the impetus for the development of HER2-targeted antibodies and a new concept in the treatment of HER2-positive breast cancers. *Trastuzumab* was the first anti-HER2 monoclonal antibody developed based on these discoveries; it was approved in the U.S. in 1998 and in Europe in 2000 for the treatment of patients with HER2-positive breast cancers. A small molecule kinase inhibitor of EGFR (HER1), *gefitinib* was approved in 1998 in the U.S. and in 2000 in Europe. A monoclonal antibody targeting EGFR, *cetuximab*, was approved in Switzerland in 2003 and in the U.S. in 2004.

Trastuzumab

Mechanism of Action

Trastuzumab is a humanized IgG1 monoclonal antibody that binds to the extracellular domain IV of HER2 (Figure 67–2), inhibiting hetero- and homodimerization and signal transduction. In addition, binding of trastuzumab to HER2 overexpressing cells can induce antibody-dependent, immune cell-mediated cytotoxicity. HER2 protein overexpression or gene amplification are predictive of response to HER2-targeted therapies (Wolff et al., 2013).

ADME

Trastuzumab has dose-dependent pharmacokinetics with a mean $t_{1/2}$ of 5.8 days on a weekly maintenance dose with alternative dosing every 3 weeks. Steady-state levels are achieved between 16 and 32 weeks.

Therapeutic Uses

Trastuzumab is approved for HER2-overexpressing breast and gastric cancer. It is used in combination with cytotoxic chemotherapeutics such as taxanes as initial treatment or as a single agent following relapse of disease after cytotoxic chemotherapy (Chapter 66).

Adverse Effects and Precautions

Acute adverse effects after infusion of trastuzumab are typical for monoclonal antibodies and can include fever, chills, nausea, dyspnea, and rashes. The most serious toxicity of trastuzumab is heart failure. Cardiotoxicity is caused by interruption of HER2/4 heterodimer signaling in cardiomyocytes, signaling that is essential for the maintenance of contractile

function. The cardiotoxic potential was predicted from gene inactivation studies (“knockouts”) in mice, which showed that mice lacking HER2, HER4, or HER ligands developed dilated cardiomyopathy and heart failure. Thus, baseline electrocardiogram and cardiac ejection fraction measurement should be obtained before initiating treatment with trastuzumab to rule out underlying heart disease. Clinical monitoring for symptoms of congestive heart failure as well as periodic determination of LVEF during and after the course of therapy is recommended. When trastuzumab is used as a single agent, fewer than 5% of patients will experience a decrease in LVEF, and about 1% will have clinical signs of congestive failure. However, left ventricular dysfunction occurs in up to 20% of patients who receive a combination of doxorubicin and trastuzumab, reflecting the added cardiotoxicity of doxorubicin. In contrast, the risk of cardiac toxicity is greatly reduced with the recommended combination of trastuzumab with taxanes.

Pertuzumab

Mechanism of Action

Pertuzumab is a humanized monoclonal antibody directed against the extracellular receptor dimerization domain II of HER2 that is distinct from domain IV targeted by trastuzumab (Figure 67–2). Pertuzumab prevents ligand-dependent heterodimerization of other HER family members with HER2 and thus inhibits ligand-induced signaling, cell growth, and survival. In addition to the inhibition of receptor heterodimerization, binding of pertuzumab to HER2 overexpressing cells can induce antibody-dependent, immune cell-mediated cytotoxicity.

ADME

The median half-life of pertuzumab is 18 days; after an initial loading dose, maintenance doses are administered every 3 weeks.

Therapeutic Use

Preclinical studies with HER2-overexpressing human tumor cells grown as xenograft tumors in mice showed that the combination of pertuzumab and trastuzumab enhanced antitumor activity. In patients with HER2-positive metastatic breast cancer, the addition of pertuzumab to trastuzumab and docetaxel increases the median overall survival by 15.7 months (Swain et al., 2015). Use of pertuzumab is approved for the treatment of patients with HER2-positive, locally advanced, inflammatory, or early stage breast cancer in combination with trastuzumab and docetaxel.

Adverse Effects

Cardiotoxicity is similar to that of trastuzumab, and combinations with cardiotoxic anthracyclines are not indicated (Slamon et al., 2001). On the other hand, the combination of pertuzumab and trastuzumab does not cause any increase in cardiac toxicity (Swain et al., 2015). Based on its mechanism of action, pertuzumab can cause fetal harm when administered to a pregnant woman, and this risk should be weighed against the potential benefit.

Lapatinib

Mechanism of Action; ADME

Lapatinib is an orally bioavailable, small-molecule inhibitor of the EGFR and HER2 tyrosine kinases with an IC_{50} of about 10 nM. Lapatinib is metabolized by CYP3A4 with a plasma $t_{1/2}$ of 14 h. Concurrent administration of inducers and inhibitors of CYP3A4 may necessitate adjustment of the dose.

Therapeutic Uses; Adverse Effects

Lapatinib in combination with capecitabine is approved for the treatment of patients with metastatic HER2-positive and trastuzumab-refractory breast cancer. Lapatinib is also used in combination with the aromatase inhibitor letrozole (see Chapter 68) to treat postmenopausal women with hormone receptor-positive, metastatic breast cancer that overexpresses HER2. Frequent adverse effects include acneiform rash, diarrhea, cramping, and exacerbation of gastroesophageal reflux. When lapatinib is

1210 combined with capecitabine, diarrhea is worsened. Cardiac toxicity appears less pronounced than with trastuzumab, although lapatinib should be used with caution in combination with cardiotoxic drugs: A dose-dependent prolongation of the QT interval has been reported; thus, careful monitoring of patients with heart disease is recommended.

Neratinib

Neratinib is an orally bioavailable, *irreversible* inhibitor of the HER2 and EGFR protein tyrosine kinase with IC_{50} values of 59 nM and 92 nM, respectively. Addition of neratinib to standard chemotherapy that includes trastuzumab in patients with HER2-positive breast cancers has shown some efficacy. Diarrhea was the most common and frequent adverse effect, with grade 3 or 4 in over one-third of patients (Park et al., 2016).

Inhibitors of Platelet-Derived Growth Factor Receptor (PDGFR)

Signaling by the PDGFR plays a significant part in mesenchymal biology, including stem cell growth, and is involved in oncogenesis through aberrant cancer cell signaling, modulation of the tumor microenvironment, and facilitation of angiogenesis and metastasis. Small-molecule protein kinase inhibitors, including *imatinib* (see discussion below), have been used in the treatment of patients with GISTs that carry mutations in KIT or PDGFRA (Figure 67–2). The addition of the anti-PDGFR monoclonal antibody *olatumab* to *doxorubicin* treatment (see Chapter 66) improves overall survival of patients with STS (Judson and van der Graaf, 2016).

Olatumab

Mechanism of Action

Olatumab is a human IgG1 monoclonal antibody that binds to PDGFRA and blocks ligand-mediated receptor activation (Tap et al., 2016).

Therapeutic Uses

Olatumab is indicated, in combination with doxorubicin, for the treatment of adult patients with STS with a histologic subtype for which an anthracycline-containing regimen is appropriate and which is not amenable to curative treatment with radiotherapy or surgery. Recent studies showed that addition of olatumab to doxorubicin doubled median survival of patients with metastatic STS to 26 months (Judson and van der Graaf, 2016).

Adverse Effects

The most common ($\geq 20\%$) adverse effects of treatment with olatumab are nausea, fatigue, neutropenia, musculoskeletal pain, inflammation of the mucous membranes (mucositis), alopecia, vomiting, diarrhea, decreased appetite, abdominal pain, neuropathy, and headache. Laboratory abnormalities are lymphopenia, neutropenia, thrombocytopenia, hyperglycemia, elevated aPTT, hypokalemia, and hypophosphatemia. Other adverse effects include infusion-related reactions (low blood pressure, fever, chills, rashes) and embryo-fetal harm.

Hedgehog Pathway Inhibitors

The hedgehog signaling pathway was discovered by genetic studies in fruit flies: Mutations resulting in stubby and hairy *Drosophila melanogaster* larvae inspired the naming of the signaling pathway as “hedgehog” or Hh, which is the name of the pathway’s polypeptide ligand. Mammals have three hedgehog homologs. The hedgehog pathway controls embryonic cell differentiation in tissues of different species through distinct gradients of hedgehog signaling proteins that are key regulators during development. In adults, hedgehog signaling plays roles in stem cell regulation and tissue regeneration. BCC of the skin is one of several cancers associated with the dysregulation of this pathway.

Vismodegib is a first-in-class hedgehog signaling pathway inhibitor approved for the treatment of adult patients with BCC. It acts as a competitive antagonist of the SMO (“smoothened hedgehog”) receptor in the hedgehog signaling pathway. Vismodegib is indicated for patients with metastatic or relapsed BCC. The drug is also undergoing clinical trials in other cancers. Common adverse effects include GI disorders (nausea, vomiting, diarrhea, constipation), muscle spasms, fatigue, hair loss, and dysgeusia (distortion of the sense of taste). These adverse effects are mostly mild to moderate. Vismodegib can cause embryo-fetal death and severe birth defects and must not be used during pregnancy.

Sonidegib is a hedgehog pathway inhibitor that binds to and inhibits SMO receptor signal transduction similar to *vismodegib*. Sonidegib is indicated for the treatment of patients with locally advanced BCC that has recurred following surgery or radiation therapy. Adverse effects are similar to those of vismodegib.

II. Intracellular Protein Kinases in Cancer Cells

HISTORY The RAS-RAF-MEK-ERK Pathway

HRAS and *KRAS*, named after Harvey and Kirsten *rat* sarcoma viruses and discovered in the early 1980s, were the first oncogenes discovered in human tumors. These oncogenes were found to be mutated and constitutively active in approximately 20% of all cancers and in up to 90% in specific cancers (pancreatic adenocarcinoma). *NRAS* was identified in human neuroblastoma. The first *RAF* gene was identified from a murine retrovirus named “rapidly accelerated fibrosarcoma” due to its oncogenic effects. Following the discovery of the first human *RAF* gene, (*RAF-1*, also named *cRAF* = normal cellular *RAF*), the *RAF* genes *ARAF* and *BRAF* were identified; their gene products are ser/thr protein kinases. The signaling cascade of RAS-RAF-MEK-ERK was established by the early 1990s. This pathway plays a central role in cell proliferation and differentiation and is activated in many human cancers (Figure 67–2). Mutations in *RAF* genes can lead to one (*BRAF*) or two (*cRAF*, *BRAF*) changes in amino acids, rendering these gene products oncogenic and resulting in continuous cell proliferation and the development of cancer. Activating mutations of *BRAF* were detected in melanoma and other tumors in 2002. A small-molecule inhibitor targeting mutated *BRAF*, *vemurafenib*, was shown to be effective in melanoma in 2010 and approved by the FDA in 2011; the first inhibitor of MEK, *trametinib*, was approved in 2013.

Inhibitors of RAF Kinase: Vemurafenib, Dabrafenib

BRAF belongs to the *RAF*/mil family of serine/threonine protein kinases and plays a role in regulating signaling via MAPK (or ERK) (Figure 67–2).

In melanoma, MAPK signaling can be constitutively activated through alterations in membrane receptors or through mutations of *RAS* or *BRAF*. *BRAF* mutations confer constitutive activation of the kinase pathway independent of *RAS* activation. *BRAF* is mutated in about 55% of melanomas, and 90% of these mutations display a substitution of valine to glutamic acid (V600E) or to lysine (V600K), which results in constitutive protein kinase activation (Vultur and Herlyn, 2013). Approximately 8% of other cancers, colon cancer and NSCLC amongst them, also carry an activating mutation in *BRAF*. The *BRAF* inhibitors *vemurafenib* and *dabrafenib* are superior to traditional chemotherapy in improving survival in patients with mutant *BRAF* melanoma and are discussed in the material that follows. In patients with *BRAF*-mutant lung or colon cancers, only the lung cancer patients show a therapeutic benefit. This finding indicates that colon cancers do not depend on the activated mutant *BRAF* as a necessary oncogenic driver.

Vemurafenib

Mechanism of Action

Vemurafenib is an orally bioavailable inhibitor of mutated BRAF (V600E). The name *vemurafenib* is derived from the target, that is, **V600E mutated BRAF**. Vemurafenib also is effective against the less common BRAF V600K mutation. Melanoma cells lacking these mutations are not inhibited by vemurafenib.

ADME

Following oral administration, the elimination half-life for vemurafenib is 57 h.

Vemurafenib is a substrate of CYP3A4 and a substrate and an inhibitor of the Pgp exporter. Vemurafenib can increase concentrations of CYP1A2 substrates. Thus, concomitant use with the centrally acting α_2 adrenergic receptor agonist tizanidine, which has a narrow therapeutic window and is used as a muscle relaxant, should be avoided.

Therapeutic Uses

Vemurafenib is FDA approved for the treatment of patients with metastatic melanoma harboring activating BRAF (V600E/K) mutations. It is not indicated for the treatment of patients with melanoma carrying wild-type BRAF.

Adverse Effects

The most common adverse effects (30%–60% of patients) are cutaneous events. Arthralgia, fatigue, and nausea are also observed but at a lower frequency. cuSCCs and keratoacanthomas that may need surgical removal appear in more than 20% of patients. The median time to the first appearance of these skin lesions is 7 to 8 weeks and is caused by a paradoxical stimulation of wild-type BRAF. Increased photosensitivity reactions can be prevented with sunblock. QT prolongation has been observed, necessitating controlling for risk factors and monitoring ECG and electrolytes.

Drug Resistance

Melanoma is one of the most aggressive malignancies, with a high mutation rate that renders these tumors highly heterogeneous and thus prone to the quick development of resistance to drug treatments. After the initial response of melanoma lesions to treatment with vemurafenib, resistant cancer cell subpopulations are selected, typically in less than 6 months. Constitutively active mutant NRAS; downstream mutations in MEK; overexpression of the growth receptor PDGFR-B; activation of parallel pathways such as PI3K/Akt, mTOR, and STAT3 signaling; or stromal cell secretion of HGF can drive this drug resistance (Chapman et al., 2011). Combination treatment with a MEK inhibitor (*trametinib*, *cobimetinib*) that acts downstream of BRAF (Figure 67–2) can delay development of resistance to single-agent BRAF inhibitors (Robert et al., 2015).

Dabrafenib

Mechanism of Action

Dabrafenib is an orally bioavailable, small-molecule inhibitor of mutated forms of BRAF kinases. Dabrafenib can inhibit the proliferation of tumor cells that contain a constitutively active mutated BRAF with in vitro IC_{50} values of 0.65, 0.5, and 1.84 nM for the V600E, V600K, and V600D mutations, respectively. At about 5-fold higher concentrations, dabrafenib also inhibits wild-type BRAF and cRAF (IC_{50} values of 3.2 and 5.0 nM, respectively). Dabrafenib, in combination with trametinib (see discussion that follows), is approved for the treatment of patients with unresectable or metastatic melanoma and NSCLC with BRAF mutations. The drug is not indicated for the treatment of patients with wild-type BRAF melanoma.

ADME

The mean terminal half-life of dabrafenib is 8 h after oral administration.

Dabrafenib is metabolized primarily by CYP2C8 and CYP3A4. Patients should be monitored closely for adverse reactions and for loss of efficacy if treated with drugs that induce CYP2C8 and CYP3A4 activity.

Therapeutic Uses

Dabrafenib was FDA approved as a single-agent treatment of patients with BRAF V600E mutation-positive advanced melanoma in 2013. Resistance to dabrafenib and other BRAF inhibitors occurs within about 6 months, but a combination with the MEK inhibitor trametinib can delay the development of resistance (see discussion that follows). Thus, the FDA has approved the combination of dabrafenib and trametinib for the treatment of patients with BRAF V600E/K-mutant metastatic melanoma and BRAF V600E-mutant NSCLC.

Adverse Effects and Drug Interactions

Adverse effects, in order of decreasing frequency, are hyperkeratosis, headache, pyrexia, arthralgia, papilloma, alopecia, and PPES. An increased incidence of cuSCC is expected in about 10% of patients, with a median time of 2 months to the first diagnosis. About one-third of those patients develop more than one lesion with continued administration of dabrafenib. With the dabrafenib-trametinib combination, the appearance of cuSCC is delayed to a median time of 7 months and occurs in only 3% of patients. Most common adverse reactions ($\geq 20\%$) for dabrafenib in combination with trametinib are pyrexia, rash, chills, headache, arthralgia, and cough. Cardiomyopathy has also been reported.

Inhibitors of MEK: Trametinib, Cobimetinib

The MKKs or MEKs are serine-threonine kinases that act downstream of RAF. They provide additional targets for the inhibition of the RAS-RAF-MEK-ERK pathway that is frequently activated in cancer and controls cell survival, differentiation, and growth (Figure 67–2).

Trametinib

Trametinib was the first inhibitor of the MEK family to be FDA approved.

Mechanism of Action

Trametinib is an orally bioavailable, reversible, allosteric inhibitor of ATP binding to the MEK1/2 kinases. Trametinib inhibits MEK1/2 kinase activities with an IC_{50} of about 2 nM.

ADME

Bioavailability of oral trametinib is 72% and is reduced if taken with a high-calorie meal. Peak plasma concentrations are achieved 1.5 h post-dose. The drug has a relatively long half-life of 4 to 5 days. Trametinib is not a substrate of CYP enzymes and mild renal or hepatic impairment does not affect exposure to the drug significantly.

Therapeutic Uses

The FDA approved trametinib as a monotherapy for patients with mutant BRAF V600E/K melanoma due to improved survival relative to standard therapy. Trametinib in combination with the BRAF inhibitor dabrafenib is also approved for mutant V600E/K metastatic melanoma and mutant V600E metastatic NSCLC. Trametinib treatment lacks efficacy in patients who received prior treatment with BRAF inhibitors. This suggests that resistance to BRAF and MEK inhibitors involves similar mechanisms (Kim et al., 2013).

Adverse Effects

The most frequent adverse effects are cutaneous rash, acneiform dermatitis, and diarrhea. Fatigue, nausea, and lymphedema also occur. Serious grade 3–4 skin toxicity is found in 6% of patients. Other serious adverse effects are cardiomyopathy, hypertension, hemorrhage, interstitial lung disease, and ocular toxic effects. In contrast to the BRAF inhibitors, trametinib does not cause cuSCC. Because trametinib can cause fetal harm when administered to a pregnant woman, this risk must be weighed against the potential benefit.

Drug Resistance

Activation of alternative signaling pathways that include PI3K/Akt, mTOR, and STAT3 signaling can bypass MEK inhibition and result in drug-resistant tumors. Also, mutations in the allosteric binding pocket and activation loop of MEK1 can inhibit the binding of the inhibitor

1212 and cause resistance to trametinib. Resistance to single-agent trametinib occurs within 6 to 7 months of the initiation of treatment at a rate approaching 50%. As a strategy to overcome resistance, trametinib has been combined with the BRAF inhibitor *dabrafenib* for the treatment of patients with BRAF V600E/K-mutant metastatic melanoma (Flaherty et al., 2012). This combination has been approved by the FDA.

Cobimetinib

Mechanism of Action; ADME

Cobimetinib is an orally bioavailable, reversible inhibitor of MEK1/2 protein kinase activity with an IC_{50} of about 4nM. Its elimination half-life ranges from 1 to 3 days. Cobimetinib is a substrate for CYP3A, and concomitant treatment with inducers or inhibitors of CYP3A will reduce or increase the systemic exposure of patients.

Therapeutic Uses

A combination of cobimetinib and vemurafenib is FDA approved for the treatment of patients with unresectable or metastatic melanoma with a BRAF V600E/K mutation.

Adverse Effects

The most common adverse effects are diarrhea, photosensitivity reaction, nausea, pyrexia, and vomiting. Major hemorrhagic events can occur with cobimetinib; patients should be monitored for signs and symptoms of bleeding. The drug also increases the risk of cardiomyopathy. The safety in patients with decreased LVEF has not been established.

Other MEK Inhibitors

Under development are *binimetinib*, a MEK inhibitor being studied in patients with NRAS-mutant melanoma, and *encorafenib*, a BRAF inhibitor being used in combination with *binimetinib* for patients with BRAF-mutant melanoma.

Inhibitors of Jak1 and Jak2

Janus associated kinases (Jaks) mediate the signaling of cytokines and growth factors in hematopoiesis and immune function (see, for instance, Figure 35–2). Intracellular Jak signaling recruits STATs to cytokine membrane receptors (Figure 67–2). After STAT activation and subsequent localization to the nucleus, STATs modulate gene expression. Jak signaling is dysregulated in myelofibrosis and polycythemia vera, which prompted the development of Jak inhibitors. *Ruxolitinib* is the first drug in this class.

Ruxolitinib

Ruxolitinib

Mechanism of Action; ADME

Ruxolitinib is an orally bioavailable (95%) analogue of ATP that inhibits the protein kinase activities of Jak1 and Jak2 (IC_{50} value of 3 nM) and exhibits more than 100-fold selectivity for Jak1/2 over Jak3. The half-life of ruxolitinib is about 3 h; its metabolism is mainly via hepatic CYP3A4, with products excreted largely in the urine. In patients with renal or hepatic impairment, a dose reduction is recommended.

Therapeutic Uses

Ruxolitinib is indicated for the treatment of patients with polycythemia vera who have had an inadequate response to hydroxyurea and for the treatment of myelofibrosis.

Adverse Effects and Drug Interactions

The most common adverse reactions, thrombocytopenia and anemia, should be met with a dose reduction or discontinuation of treatment. Infections should be resolved before treatment with ruxolitinib. In a few patients, BCC or squamous cell skin carcinoma may occur, warranting periodic skin examinations during treatment. Strong CYP3A4 inhibitors (e.g., ketoconazole, fluconazole) increase exposure to ruxolitinib and prolong its half-life to 6 h. Due to the adverse hematopoietic effects, postpartum patients should discontinue nursing during drug treatment.

Cyclin-Dependent Kinase (CDK) 4/6 Inhibitors

The CDKs are a family of over 20 serine/threonine protein kinases that modulate intracellular signaling during cell cycle progression (Figure 67–2). Given their pivotal role in cellular proliferation, CDKs are prime targets for development of inhibitors. However, different tissue selectivity and distinct cell cycle-specific activity periods of different CDKs provide a challenge.

CDK4/6 are attractive targets because they control cell cycle progression from the G_0/G_1 to S phase. Interaction of cyclin D with CDK4/6 enhances phosphorylation of the Rb tumor suppressor protein, inactivating Rb and permitting the transcription of factors that control transition into the S phase. Inhibition of CDK4/6 will inhibit the phosphorylation and inactivation of Rb and cause a G_1 arrest in susceptible cells that utilize this pathway, thereby providing the rationale for the use of inhibitors of CDK4/6 (Figure 67–3). This cell cycle checkpoint is frequently compromised in cancers due to cyclin D amplification, loss of Rb function, or loss of negative regulators of CDK4/6, such as p16^{INK4A}, a tumor suppressor named for its molecular mass (it is a small protein of 16 kDa) and its capacity to inhibit CDK4. The class of CDK inhibitory drugs is identified by the syllable *ciclib* and includes *palbociclib*, discussed next.

Palbociclib

Mechanism of Action

Palbociclib is an orally bioavailable, small-molecule inhibitor of CDK4 and CDK6, with IC_{50} values of 11 and 16 nM, respectively, and without inhibitory activity against CDK1, 2, or 5.

Figure 67–3 CDK4 inhibitors: retinoblastoma protein, cyclin-dependent protein kinases, and the regulation of cell cycle progression. In quiescent and differentiated cells (in G_0 or in cells arrested in G_1), the Rb protein is active and interacts with a heterodimer of the transcription factor E2F and its dimerization partner DP1, repressing transcription of promoters regulated by E2F. As a cell begins a cycle of division, cyclins activate CDKs that phosphorylate Rb, disrupting the Rb-E2F/DP complexes and permitting accumulation of active E2F complexes that drive transcription. This cell cycle checkpoint is frequently compromised in cancers due to cyclin D amplification, loss of Rb function, or loss of negative regulators of CDK4/6. Hyperphosphorylation of Rb can occur via mutations in Rb or expression of viral oncoproteins targeting Rb, placing the cell in a state of extensive proliferation, with reduced capacity to exit the cell cycle. Inhibition of CDK4/6 can cause G_1 arrest in susceptible cells (Dyson, 2016). CDK inhibitors (in red lettering) are identified by the disyllabic suffix “ciclib.”

ADME

The mean plasma elimination $t_{1/2}$ is 29 h. Palbociclib is a substrate and an inhibitor of CYP3A; thus, doses of palbociclib or of substrates of CYP3A4 may need to be reduced when they are given concurrently, with special attention to coadministered agents with narrow therapeutic indices (see the Adverse Effects and Drug Interactions section). The sulfotransferase SUL2A1 also participates in palbociclib metabolism.

Therapeutic Uses

Palbociclib is the first CDK inhibitor approved by the FDA for the treatment of advanced or metastatic breast cancer that is ER positive and HER2 negative. Palbociclib is used in combination with letrozole, an aromatase inhibitor, as initial endocrine-based therapy in postmenopausal women or with the antiestrogen fulvestrant in women with disease progression after endocrine-based therapy. Letrozole and fulvestrant are described in Chapter 68. The inclusion of palbociclib with different endocrine-based treatments almost doubles the progression-free survival of patients (Cristofanilli et al., 2016; Finn et al., 2016).

Adverse Effects and Drug Interactions

The most common adverse effects of palbociclib are neutropenia, leukopenia, infections, stomatitis, fatigue, nausea, anemia, headache, diarrhea, and thrombocytopenia. The most common grades 3 and 4 adverse effects are neutropenia (>60%), leukopenia (~25%), and anemia (~5%). Patients should avoid breastfeeding while taking palbociclib. Letrozole and fulvestrant do not alter the pharmacokinetics of palbociclib.

Patients should avoid concomitant use of strong CYP3A inhibitors (e.g., clarithromycin, indinavir, itraconazole, ketoconazole, lopinavir/ritonavir, nefazodone, nelfinavir, posaconazole, ritonavir, saquinavir, telaprevir, telithromycin, and voriconazole). Coadministration of a strong CYP3A inhibitor (e.g., itraconazole) can markedly increase exposure to palbociclib (by 87% in healthy subjects). Patients should avoid grapefruit or grapefruit juice. If palbociclib coadministration with a strong CYP3A inhibitor cannot be avoided, reduce the dose of palbociclib.

Coadministration of a strong CYP3A inducer will decrease exposure to palbociclib. Thus, avoid concomitant use of phenytoin, rifampin, carbamazepine, enzalutamide, and St. John's Wort.

Palbociclib may increase exposure to coadministered CYP3A substrates with narrow therapeutic indices (e.g., midazolam, alfentanil, cyclosporine, dihydroergotamine, ergotamine, everolimus, fentanyl, pimezone, quinidine, sirolimus, and tacrolimus), requiring reduction of palbociclib dose.

Other Drugs That Target CDK4/6

Abemaciclib and **ribociclib** are CDK4/6 inhibitors with inhibitory profiles similar to that of *palbociclib*. These inhibitors are currently undergoing clinical trials in patients with breast cancer as well as a variety of other cancers. Ribociclib is FDA-approved for treating breast cancer. The major efficacy and adverse effects of these inhibitors appear to overlap. However, differences in the selectivity for the targeted kinases appear to result in different adverse effect profiles and possibly future uses of these inhibitors (O'Leary et al., 2016).

Bruton Tyrosine Kinase (BTK) Inhibitor

The BTK protein tyrosine kinase plays important roles in the function of B cells. The PH domain of BTK binds PIP3. BTK-PIP3 phosphorylates PLC, which hydrolyzes phosphatidylinositol, thereby activating the IP_3 - Ca^{2+} -PKC pathway in B cells.

Ibrutinib**Mechanism of Action**

Ibrutinib is an orally bioavailable, small-molecule inhibitor that inactivates BTK through covalent binding to cys^{481} near the ATP-binding domain.

ADME

Administration with food (vs. on an empty stomach) roughly doubles absorption. The elimination half-life of ibrutinib is 4 to 6 h. It is a substrate of CYP3A; CYP2D6 participates to a minor degree. Metabolites are

excreted mainly via the feces; renal excretion is minor. Hepatic impairment is likely to increase ibrutinib exposure. Ibrutinib is not a substrate for Pgp.

Therapeutic Uses

Ibrutinib inhibits malignant B-cell proliferation and is indicated for the treatment of patients with MCL who have received at least one prior therapy, CLL, SLL, and WM.

Adverse Effects and Drug Interactions

The most common adverse effect ($\geq 20\%$) in patients with B-cell malignancies are neutropenia, pyrexia, thrombocytopenia, hemorrhage, anemia, diarrhea, nausea, musculoskeletal pain, rash, and fatigue. The onset of hypertension has been observed within less than a month and up to 2 years after the start of ibrutinib treatment. Thus, blood pressure should be monitored and antihypertensive treatment initiated or modified. Atrial fibrillations are observed in up to 7% of patients; this requires monitoring and treatment. Second primary malignancies occur in up to 16% of patients, most of them nonmelanoma skin cancers.

Strong (e.g., azole antifungals) and moderate (e.g., diltiazem, erythromycin) CYP inhibitors will increase ibrutinib's AUC; thus, dose reduction is recommended when using CYP3A inhibitors concomitantly. The reverse is true for strong and moderate CYP inducers (e.g., rifampin, efavirenz), which will decrease ibrutinib exposure.

Ibrutinib is classified *pregnancy category D* (see Appendix I) and may cause fetal harm. Pregnant patients and those at risk for pregnancy should be apprised of the drug's hazardous potential.

Acalabrutinib is a second-generation, orally bioavailable, irreversible BTK inhibitor that shows higher selectivity for BTK versus other kinases (e.g., EGFR, ITK) than ibrutinib. Acalabrutinib appears to have less-frequent off-target toxicities. Acalabrutinib received orphan drug designation for the treatment of CLL in the U.S. and for CLL, SLL, MCL, or WM in Europe.

Inhibitors of the BCR-ABL Kinase

A single molecular event, the Philadelphia chromosome translocation $t(9;22)$, leads to expression of ABL and BCR. This fusion generates a constitutively active protein kinase, BCR-ABL, resulting in continuous and uncontrollable cell division. BCR-ABL drives the malignant phenotype of CML (Figure 67-2).

HISTORY BCR-ABL Kinase Inhibitors

Imatinib mesylate, originally named "sti 571" (signal transduction inhibitor 571), was the first protein kinase inhibitor designed to target a driver mutation in a cancer and to receive FDA approval. It was approved in 2001 under the name *Gleevec* and is now designated as an essential drug by the World Health Organization (WHO). Imatinib targets the BCR-ABL tyrosine kinase fusion protein that drives CML. Imatinib-resistant ABL mutations were uncovered in 2002 and led to the development of next-generation inhibitors *dasatinib* and *nilotinib*, which overcome the resistance.

Imatinib and the second-generation inhibitors *dasatinib* and *nilotinib* induce clinical and molecular remissions in more than 90% of patients with CML in the chronic phase of disease. Due to its inhibition of other kinases, imatinib is also effective in some other tumors, including GISTs (driven by a c-KIT mutation), hypereosinophilia syndrome, and dermatofibrosarcoma protuberans (all driven by activating mutations in the PDGFR; see Figure 67-2).

Imatinib, Dasatinib, and Nilotinib**Mechanisms of Action**

These are orally bioavailable, small-molecule kinase inhibitors. Imatinib was identified through high-throughput screening against the BCR-ABL kinase. Dasatinib, a second-generation BCR-ABL inhibitor, also inhibits

1214 the Src kinase, and unlike imatinib, it binds both the open (active) and closed (inactive) configurations of the BCR-ABL kinase. Nilotinib was designed to have increased potency and specificity compared to imatinib. Its structure overcomes mutations that cause imatinib resistance. Imatinib and nilotinib bind to a segment of the kinase domain that fixes the enzyme in a closed or nonfunctional state, in which the protein is unable to bind its substrate/phosphate donor, ATP. These three BCR-ABL kinase inhibitors differ in their inhibitory potencies, binding specificities, and susceptibility to resistance mutations in the target enzyme. Dasatinib ($IC_{50} \sim 1$ nM) and nilotinib ($IC_{50} \sim 20$ nM) inhibit BCR-ABL kinase more potently than imatinib ($IC_{50} \sim 100$ nM).

Mechanisms of Resistance

Resistance to these TKIs arises from point mutations in three separate segments of the kinase domain. The contact points between imatinib and the enzyme become sites of mutations in drug-resistant leukemic cells; these mutations prevent tight binding of the drug and lock the enzyme in its open configuration, in which it has access to substrate and is enzymatically active. Nilotinib retains inhibitory activity in the presence of most point mutations that confer resistance to imatinib. Other mutations affect the phosphate-binding region and the “activation loop” of the domain with varying degrees of associated resistance. Some mutations, such as those at amino acids 351 and 355, confer low levels of resistance to imatinib, possibly explaining the clinical response of some resistant tumors to dose escalation of imatinib.

Molecular studies have detected cells with resistance-mediating kinase mutations *prior* to initiation of therapy, particularly in patients with Ph⁺ ALL or CML in blast crisis. This finding indicates that drug-resistant cells arise through spontaneous mutation and expand under the selective pressure of drug exposure. Mechanisms other than BCR-ABL kinase mutations play a minor role in resistance to imatinib. Amplification of the wild-type kinase gene, leading to overexpression of the enzyme, has been identified in tumor samples from patients resistant to treatment. The *MDR* gene confers resistance experimentally but has not been implicated in clinical resistance. Ph⁻ clones lacking the BCR-ABL translocation and displaying the karyotype of myelodysplastic cells may emerge in patients receiving imatinib for CML; these may progress to MDS and AML. Their origin is unclear.

A comparison amongst secondary mutations in the EGFR, ABL, and KIT kinases following treatment with BCR-ABL kinase inhibitors shows striking differences: The T790M gatekeeper mutation in the EGFR (Figure 67–1) accounts for about 90% of secondary mutations. In contrast, secondary resistance mutations in ABL or KIT after treatment of CML or GIST with imatinib are found across the kinase domain and rarely at the analogous gatekeeper residue in ABL (T³¹⁵) or in KIT (T⁶⁷⁰).

ADME

Imatinib is well absorbed after oral administration and reaches maximal plasma concentrations within 2–4 h. The elimination $t_{1/2}$ of imatinib and its major active metabolite, the *N*-desmethyl derivative, are about 18 and 40 h, respectively. Food does not change the pharmacokinetic profile. Doses of more than 300 mg/d achieve trough levels of 1 μ M, which correspond to in vitro levels required to kill BCR-ABL-expressing cells. In the treatment of GISTs, higher doses may improve response rates. CYP3A4 is the major metabolizer of imatinib; thus, drugs that induce or interact with CYP3A4 can alter the pharmacokinetics of imatinib. Coadministration of imatinib and rifampin, an inducer of CYP3A4, lowers the plasma imatinib AUC by 70%. Imatinib, as a competitive CYP3A4 substrate, inhibits the metabolism of simvastatin and increases its plasma AUC by 3.5-fold.

Dasatinib. Oral dasatinib is well absorbed; its bioavailability is significantly reduced at neutral gastric pH (i.e., after antacids and H₂ blockers) but is unaffected by food. The plasma $t_{1/2}$ of dasatinib is 3–5 h. Dasatinib exhibits dose-proportional increases in AUC, and its clearance is constant over the dose range of 15–240 mg/d. Dasatinib is metabolized primarily by CYP3A4, with minor contributions by FMO3 and UGT. The major metabolite is equipotent to the parent drug but represents only 5% of the AUC. Plasma concentrations of dasatinib are affected by inducers and inhibitors of CYP3A4 in a similar fashion to imatinib.

Nilotinib. Approximately 30% of an oral dose of nilotinib is absorbed after administration, with peak concentrations in plasma 3 h after dosing. Unlike the other BCR-ABL inhibitors, nilotinib's bioavailability increases significantly in the presence of food. The drug has a plasma $t_{1/2}$ about 17 h, and plasma concentrations reach a steady state only after 8 days of daily dosing. Nilotinib is metabolized by CYP3A4, with predictable alteration by inducers, inhibitors, and competitors of CYP3A4. Nilotinib is a substrate and an inhibitor of Pgp.

Therapeutic Uses

These protein TKIs have efficacy in diseases in which ABL, *KIT*, or PDGFR have dominant roles in driving tumor growth, reflecting the presence of a mutation that results in constitutive activation of the kinase. Imatinib shows therapeutic benefits in patients with chronic-phase CML (BCR-ABL) or GIST and a subset of patients with mucosal or acral lentiginous melanoma (*KIT* mutation positive), chronic myelomonocytic leukemia (EVT6-PDGFR translocation), hypereosinophilia syndrome (FIP1L1-PDGR), and dermatofibrosarcoma protuberans (constitutive production of the ligand for PDGFR). It is the agent of choice for patients with metastatic GIST and is used as adjuvant therapy of *c-KIT*-positive GIST. Dasatinib is approved for patients with newly diagnosed CML with resistance to or intolerance of imatinib in both chronic and advanced phases of disease and for use combined with cytotoxic chemotherapy in patients with Ph⁺ ALL who are resistant or intolerant to prior therapies.

Adverse Effects

Imatinib, dasatinib, and nilotinib cause GI symptoms (diarrhea, nausea, and vomiting) that are usually readily controlled. All three drugs promote fluid retention, edema, and periorbital swelling. Myelosuppression occurs infrequently but may require transfusion support and dose reduction or discontinuation of the drug. These drugs can be associated with hepatotoxicity. Dasatinib may cause pleural effusions and pulmonary hypertension in a small subset of patients. Nilotinib and dasatinib may prolong the QT interval; nilotinib has been associated with cardiac and vascular events, including ischemia. Most nonhematological adverse reactions are self-limited and respond to dose adjustments. After the adverse reactions have resolved, the drug may be reinitiated and titrated back to effective doses.

Bosutinib

Bosutinib is another second-generation, orally bioavailable BCR-ABL kinase inhibitor ($IC_{50} = 1.2$ nM). Bosutinib also inhibits activity of Src ($IC_{50} = 1$ nM) and other members of the Src family. It is FDA approved for the treatment of patients with chronic, accelerated, or blast-phase Ph⁺ CML with resistance or intolerance to prior therapy. The most common adverse reactions (incidence greater than 20%) are diarrhea, nausea, thrombocytopenia, vomiting, abdominal pain, rash, anemia, pyrexia, and fatigue.

Ponatinib

Ponatinib is a third-generation BCR-ABL kinase inhibitor. Imatinib (first generation) lacks efficacy for the more advanced disease phases, and cells with mutations in the BCR-ABL tyrosine kinase domain are resistant. Second-generation inhibitors (nilotinib, dasatinib, bosutinib) were developed to address these weaknesses, although they do not inhibit the T315I mutant of BCR-ABL that is found in 15%–20% of patients with CML.

Mechanism of Action

Ponatinib is a third-generation, orally bioavailable kinase inhibitor that is active against the T315I mutant BCR-ABL and also is effective toward all other known BCR-ABL1 kinase mutants. IC_{50} values (nM) for different kinases are as follows: ABL, 0.37; PDGFR, 1.1; VEGFR2, 1.5; FGFR1, 2.2; and Src, 5.4.

ADME

Peak ponatinib concentrations are observed within 6 h and are unaffected by food or fasting. Drug solubility is pH dependent, with higher pH resulting in decreased solubility. Accordingly, drugs that affect gastric pH (such

as H_2 antagonists, antacids, and PPIs) may significantly alter ponatinib bioavailability. Ponatinib is highly (99%) bound to plasma proteins and is a weak substrate for Pgp and ABCG2 transporters. Metabolism is primarily via CYP3A4 and to lesser extents by CYPs 2C8, 2D6, and 3A511; esterases; and amidases. Coadministration of CYP3A inhibitors significantly increases ponatinib concentrations. The $t_{1/2}$ of ponatinib is about 24 h. Unmetabolized ponatinib is primarily excreted in the feces (87%), with a small portion (5%) in the urine.

Therapeutic Uses

Ponatinib is approved for resistant CML and Ph^+ ALL. Clinical cytogenetics measurements are a key tool for monitoring the response to therapy, reported as the percentage of Ph^+ karyotypes in 20 bone marrow metaphases (major cytogenetic response; MCyR). Ponatinib produces an overall 54% MCyR in patients with early-phase CML and a 70% MCyR in patients with early-phase CML with the T315I mutation. Because of ponatinib's potency and efficacy against all known BCR-ABL single mutants, trials are under way that may advance this therapy to a first-line treatment.

Adverse Effects

Arterial thrombosis and hepatotoxicity are major adverse effects; thus, appropriate precautions, dose reduction, monitoring, or discontinuation are recommended following arterial thrombotic or hepatotoxic events. Dose-limiting toxicities include elevated lipase or amylase levels and pancreatitis.

Inhibitors of Anaplastic Lymphoma Kinase (ALK)

ALK is a membrane monospan with an extracellular domain and an intracellular protein tyr kinase domain (Figure 67-2). The importance of this protein kinase in human cancers is the capacity of the *ALK* gene to form fusion genes that become oncogenic drivers. A 2;5 chromosomal translocation yields an oncogenic fusion gene in which a 3' portion of *ALK* (chromosome 2) contributes coding for the catalytic domain and is joined to a 5' region of the *NPM* gene. The extracellular and transmembrane sequences of ALK are absent in the *ALK-NPM* fusion gene, which is the oncogenic driver of malignant progression in anaplastic large cell lymphoma (ALCL). A similar translocation of the ALK kinase and fusion with *EML4* creates the oncogenic driver in a subset of NSCLC (Martelli et al., 2010), as shown in Figure 67-2. *ALK* also fuses with numerous additional 5' partners (Roskoski, 2017). *Alectinib*, *crizotinib*, and *ceritinib* are small-molecule inhibitors of ALK kinase that are used in the treatment of ALK translocation-positive cancers.

Crizotinib

Mechanism of Action

Crizotinib is an orally bioavailable inhibitor of receptor tyrosine kinases that include HGFR/cMET, ALK, and ROS1. IC_{50} values are 11 nM and 24 nM for HGFR/cMet and ALK, respectively.

ADME

Crizotinib is predominantly metabolized by CYP3A4/5 and shows a terminal half-life of 42 h. The typical dose of 250 mg twice daily is reduced to once daily in patients with severe renal impairment and a creatinine clearance below 30 mL/min.

Therapeutic Uses

Crizotinib is approved for the treatment of patients with locally advanced or metastatic NSCLC harboring ALK or ROS1 gene rearrangements (Figure 67-2) (Thomas et al., 2015). The *ROS1* gene product is a receptor tyr protein kinase that is structurally similar to ALK. *ROS1* also participates in gene translocations and the formation of oncogenic fusion genes that have a 1% incidence in lung cancers.

Adverse Effects

The most common adverse reactions are GI toxicity including nausea, diarrhea, and vomiting as well as hepatic, respiratory, and ocular toxicity and neuropathy. Also observed are QT prolongation and bradycardia.

Alectinib

Mechanism of Action

Alectinib is an orally bioavailable inhibitor of ALK kinase activity with an IC_{50} of 1.9 nM. Alectinib shows a higher selectivity for ALK than crizotinib and is active against mutant forms of ALK that are found in tumors resistant to crizotinib.

ADME

Alectinib has an elimination half-life of 33 h and is metabolized by CYP3A4. Coadministration of alectinib with CYP3A inhibitors or inducers will alter plasma concentrations.

Therapeutic Uses

Alectinib is approved for the treatment of patients with advanced or recurrent NSCLC harboring the ALK fusion gene (ALK^+). Patients with ALK^+ NSCLC who have progressed on treatment with crizotinib or are intolerant to crizotinib also qualify.

Adverse Effects

The most common adverse effects are fatigue, constipation, edema, and myalgia. Pneumonitis, GI toxicity, hepatotoxicity, bradycardia, and prolonged QT intervals are also observed (Katayama et al., 2015).

Ceritinib

Ceritinib is an orally bioavailable ALK inhibitor approved for the treatment of ALK^+ metastatic NSCLC that is unresponsive to crizotinib. Common adverse effects are GI toxicity and hepatotoxicity. Bradycardia and prolonged QT intervals also occur.

Inhibitors of the PI3K/Akt/mTOR Pathway

Background

Activation of PI3K and the consequent activation of signaling events through protein kinase B (Akt) and the mechanistic or mTOR pathway are important in cell growth and survival and in regulation of cell metabolism (Figures 67-2 and 67-5). Excessive signaling through the PI3K pathway is a frequent aberration in many human cancers; thus, this pathway is an attractive target in cancer therapy. There are three classes of PI3Ks: The class I PI3K enzymes are the most important in cancer. These isoforms are activated by receptor protein tyrosine kinases and GPCRs. The PI3K enzymes are heterodimers of a p85 regulatory subunit and a p110 catalytic subunit. The p110 subunit exists in four identified isoforms: α , β , γ , and δ . The α and β isoforms are ubiquitously expressed, whereas the γ and δ isoforms are predominantly expressed in cells of hematopoietic origin. The different catalytic subunits have distinct roles in normal and malignant B-cell function. PI3K α , containing the 110 α catalytic subunit, is the most frequently mutated PI3K in human cancer (Fruman and Rommel, 2014). In B-cell malignancies, the PI3K δ isoform is frequently activated. A recently approved PI3K δ inhibitor, *idelalisib*, is described in the next section. Currently, the mTORC1 inhibitors *sirolimus* (rapamycin), *everolimus*, and *temsirolimus* are approved for clinical use in different cancers and are described in the material that follows. Ongoing clinical trials are evaluating the safety and efficacy of pan-PI3K inhibitors, inhibitors of the PI3K α isoform, as well as inhibitors of AKT, PI3K/mTOR, and TORC1/TORC2.

PI3K δ Inhibitor: Idelalisib

The PI3K δ isoform is constitutively activated in many B-cell malignancies, and inhibition of this pathway can promote apoptosis in these cancer cells.

Mechanism of Action

Idelalisib is an orally bioavailable inhibitor of the PI3K δ isoform with an IC_{50} of about 8 nM. It is 40- to 300-fold more selective for the PI3K δ isoform than for the other isoforms.

ADME

Food does not affect absorption of idelalisib. The drug is metabolized by aldehyde oxidase, CYP3A, and UGT1A4, yielding an elimination half-life

1216 of 8.2 h. Idelalisib inhibits CYP3A and is a substrate of Pgp and of the efflux transporter BCRP/ABCG2 in vitro. Idelalisib increases plasma levels of midazolam (a CYP3A substrate) but does not affect plasma levels of digoxin (a Pgp substrate) or rosuvastatin (an OATP1B1/B3 substrate). Patients receiving strong CYP inhibitors may be at increased risk for idelalisib toxicity. Hepatic impairment increases systemic exposure, putting patients at risk for toxicity.

Clinical Use

Idelalisib is approved for the treatment of relapsed or refractory B-cell malignancies in patients who have received at least two prior systemic therapies. This includes CLL in combination with rituximab, FL, and SLL. Idelalisib is not indicated and is not recommended for first-line treatment.

Adverse Effects

Idelalisib may cause serious and sometimes-fatal adverse effects, including liver toxicity, diarrhea, colitis, pneumonitis, intestinal perforations, and skin toxicity. Patients taking idelalisib should avoid other hepatotoxic drugs. Other common side effects include fever, chills, cough, pneumonia, fatigue, nausea, abdominal pain, rash, hyperglycemia, and elevated levels of triglycerides and liver enzymes. Idelalisib may cause embryo-fetal toxicity. Breastfeeding during therapy is contraindicated because of the potential for adverse reactions in nursing infants.

mTOR Inhibitors: Rapamycin Analogues

Rapamycin (sirolimus) is a product from a strain of *Streptomyces* found on the Rapa Nui Easter Island. It inhibits a serine/threonine protein kinase in mammalian cells named mTOR. The PI3K/PKB(Akt)/mTOR pathway responds to a variety of signals from growth factors. The activation of the PI3K pathway is opposed by the phosphatase activity of the tumor suppressor, PTEN (Figure 67-2). Activating mutations and amplification of genes in the receptor-PI3K pathway, and loss of function alterations in PTEN, occur frequently in cancer cells, with the result that PI3K signaling is exaggerated, and cells exhibit enhanced survival. Rapamycin (sirolimus) and its congeners, the so-called rapalogs *temsirolimus* and *everolimus*, are first-line drugs in posttransplant immunosuppression (see Figure 35-2) and are used in coronary artery stents to prevent fibrotic growth. Rapalogs have been approved for the treatment of patients with renal cancer; NETs of the pancreas; NETs of GI tract or lung origin; anti-hormone refractory, hormone receptor-positive breast cancer; and for patients with TSC-related tumors.

Mechanism of Action

The rapamycins inhibit an enzyme complex, mTORC1, which occupies a downstream position in the PI3K pathway (Figure 67-4). mTOR forms the mTORC1 complex with a member of the FK506-binding protein family, FKBP12. The antitumor actions of the rapamycins result from their binding to FKBP12 and preventing activation of mTOR, as detailed in Figure 67-4 and its legend.

ADME

For renal cell cancer, *temsirolimus* is given in weekly intravenous doses of 25 mg; *temsirolimus* is metabolized by CYP3A4; the parent drug has a plasma $t_{1/2}$ of 30 h, but its primary active metabolite, sirolimus (rapamycin), has a $t_{1/2}$ of 53 h. Because sirolimus has equivalent activity as an inhibitor of mTORC1 and has a greater AUC, sirolimus is likely the more important contributor to antitumor action in patients. The concomitant use of strong CYP3A4 inhibitors or inducers should thus be avoided. Grapefruit juice may also increase plasma concentrations of the active metabolite sirolimus and should be avoided.

Everolimus is administered orally in doses of 10 mg/d and is metabolized by CYP3A4. *Everolimus* has a plasma $t_{1/2}$ of 30 h; on a weekly schedule at doses of 20 mg, it maintains inhibition of mTORC1 for 7 days in white blood cells. Both drugs are susceptible to interactions with other agents that affect CYP3A4 activity. For everolimus, the dose should be reduced for patients with moderate hepatic impairment; guidelines for dose reduction of *temsirolimus* in such patients have not been established. The drugs' pharmacokinetics do not depend on renal function, and hemodialysis does not hasten *temsirolimus* clearance.

Therapeutic Uses

Temsirolimus and *everolimus* are approved for treatment of patients with advanced renal cancer. *Temsirolimus* prolongs survival and delays disease progression in patients with advanced and poor- or intermediate-risk renal cancer, as compared to standard IFN- α treatment. *Everolimus*, as compared to placebo, prolongs survival in patients who had failed initial treatment with antiangiogenic drugs. mTOR inhibitors also have antitumor activity against MCLs. *Everolimus* is approved for the treatment of postmenopausal women with advanced hormone receptor-positive, HER2-negative breast cancer in combination with exemestane after failure of treatment with letrozole or anastrozole. Other indications are PNET and progressive, well-differentiated, non-functional NETs of GI or lung origin as well as TSC-related tumors.

Adverse Effects; Resistance

The rapamycin analogues cause similar patterns of adverse effects: a mild maculopapular rash, mucositis, anemia, and fatigue (30%–50%). A few patients will develop leukopenia or thrombocytopenia, effects that are reversed if therapy is discontinued. Less common side effects include hyperglycemia, hypertriglyceridemia, and, rarely, pulmonary infiltrates and interstitial lung disease. Pulmonary infiltrates emerge in 8% of patients receiving *everolimus* and in a smaller percentage of those treated with *temsirolimus*. If symptoms such as cough or shortness of breath develop or radiological changes progress, the drug should be discontinued. Prednisone may hasten the resolution of radiological changes and symptoms.

Resistance to mTOR inhibitors is incompletely understood but may arise through the action of a second mTOR complex, mTORC2, which is unaffected by rapamycins and which can upregulate Akt activity (Figure 67-4).

Multikinase Inhibitors

Selectivity of small-molecule protein kinase inhibitors for their targets is dependent on the similarity of the targeted site with sites in other kinases and the chemical composition of the inhibitor. Most inhibitors interact with the ATP-binding site of their target that is relatively conserved within a kinase family; thus, such inhibitors have only relative specificity and will cross-react at higher concentrations with closely related kinases. Nonetheless, inhibition of distantly related kinases is possible. The selectivity of inhibitors for a range of targets in the kinome is determined experimentally using assays with recombinant kinase proteins and in vivo using intact cells that express the kinases (Elkins et al., 2015). Inhibitors that target multiple kinase families within the clinically used dose range can be therapeutically efficacious and are discussed in the material that follows. In using drugs directed toward protein kinases, remember that the specificity of these agents is not absolute and that the inhibited kinases often serve important "normal" functions in the cell in addition to the pathologic functions being targeted.

Cabozantinib

Mechanism of Action

Cabozantinib is an orally bioavailable, small-molecule inhibitor of several tyrosine kinases; as ranked by the IC_{50} values (in nM) from in vitro assays, these protein kinases are VEGFR2, 0.035; MET, 1.3; RET, 4; KIT, 4.6; VEGFR, 3.6; AXL, 7; FLT3, 11.3; VEGFR1, 12; and TIE2, 14.3. These receptor tyrosine kinases control normal cellular function and pathologic processes that include maintenance of the tumor microenvironment, tumor angiogenesis, and metastatic spread.

ADME

The elimination half-life of cabozantinib is about 99 h. Cabozantinib is a substrate of CYP3A4; thus, the dose of cabozantinib should be reduced in patients with mild-to-moderate hepatic impairment as well as for concurrent administration of CYP3A4 inhibitors. Conversely, strong inducers of CYP3A4 will reduce exposure to the drug and necessitate increased dosage of cabozantinib unless the CYP inducers can be avoided.

Figure 67–4 *Caveat mTOR: effect of rapamycin on growth factor signaling.* The PI3K-mTOR pathway responds to extracellular signals, the metabolic and nutrient status, and the energy charge of the cell, transmitting signals downstream that drive maintenance and proliferation (Hall, 2016). mTOR activity appears to contribute to resistance to many targeted cancer therapies (Guri and Hall, 2016), and dysregulation of the pathway is implicated in diabetes, cancer, and other pathologies (Dibble and Cantley, 2015). In this simplified version of the PI3K-mTOR pathway, the green shapes show the action pathway from membrane receptor to the mTOR multiprotein complex, mTORC1. Substrates of the mTOR ser/thr protein kinase activity and integrated responses are shown in blue across the bottom of the figure. Red T bars represent inhibitory influence. Signaling through the pathway is initiated by agonist activation of membrane receptors such as IGF1R and stimulation of their tyr kinase activities, leading to activation of PI3K, which phosphorylates the inositol ring of the PIP₂ in the membrane to produce PIP₃. PIP₃ recruits to the membrane several proteins containing PH domains, including PKD1 and Akt. Akt, also known as PKB, phosphorylates TSC-2 (a subunit of TSC) at multiple sites. TSC is a GAP for Rheb. Phosphorylation of TSC inhibits its GAP activity, thereby reducing the GTPase activity of Rheb and increasing the fraction of Rheb in the GTP-liganded state. Rheb, in its GTP-liganded configuration, activates mTORC1. TSC phosphorylation and PIP₃ phosphorylation can be reversed by the phosphatase PTEN. mTORC1 phosphorylates substrates that mediate downstream effects; among them are the following:

- HIF-1, leading to increased angiogenesis. HIF-1 is overexpressed in many cancers.
- S6K1, enhancing protein synthesis. Dephospho S6K1 exists in a complex with eIF3; phosphorylation by mTOR dissociates the complex, freeing S6K1 to phosphorylate its targets that promote translation.
- 4EBP (eukaryotic initiation factor 4e binding protein), thereby enhancing translation. 4EBP is a repressor of mRNA translation via its inhibitory interaction with eukaryotic initiation factor 4E (eIF4E). The phosphorylation of 4EBP by mTOR reduces the capacity of 4EBP to inhibit eIF4E and slow translation.
- ULK1 (unc-51 like autophagy activating kinase 1), whose phosphorylation reduces autophagic activity. mTOR activity prevents ULK1 activation by disrupting its interaction with AMP-activated protein kinase (AMPK), a key promoter of autophagy.

Rapamycin (sirolimus) and the “rapalogs” *everolimus* and *temsirolimus* inhibit mTOR by associating with the intracellular protein FKBP12. The FKBP12-rapalog complex binds directly to mTOR and inhibits its functions in the multiprotein complex mTORC1. mTORC2 remains relatively unaffected by mTORC1 inhibitors and can respond by upregulating Akt activity.

Cabozantinib is indicated for the treatment of patients with advanced RCC who have received prior antiangiogenic therapy. Cabozantinib was also shown to produce superior efficacy to sunitinib in patients with treatment-naïve intermediate- or poor-risk metastatic renal cancer (Choueiri et al., 2016). Also, cabozantinib showed some efficacy in subgroups of patients with lung adenocarcinoma and MET exon 14 splice variants (Paik et al., 2015) and in patients with medullary thyroid cancer.

Adverse Effects

The most commonly reported ($\geq 25\%$) adverse reactions are diarrhea, fatigue, nausea, decreased appetite, PPES, hypertension, vomiting, weight loss, and constipation. Cabozantinib should not be administered to patients with a recent history of bleeding and should be discontinued in patients with GI perforations and fistulas. In the case of thrombotic events such as myocardial infarction, cerebral infarction, or other serious arterial thromboembolic events, treatment with cabozantinib should be discontinued. Blood pressure should be monitored regularly for the onset of hypertension. Due to the risk of fetal harm, women of childbearing age should use contraception during treatment and for 4 months thereafter. Although there are no specific data on this point, nursing mothers are advised to cease breastfeeding during treatment and for 4 months thereafter due to the potential for harm to the infant.

Vandetanib

Mechanism of Action; ADME

Vandetanib is an orally bioavailable, small-molecule multikinase inhibitor of VEGFRs, the EGFR/HER family, RET, BRK, TIE2, and members of the EPH receptor and SRC kinase families. These receptor tyrosine kinases are involved in both normal cellular functions and pathologic processes (Figure 67-2). Vandetanib is a substrate of CYP3A4. Its median elimination half-life is 19 days.

Therapeutic Uses

Vandetanib is indicated for the treatment of symptomatic or progressive medullary thyroid cancer that is unresectable, locally advanced, or metastatic. In patients with asymptomatic or slowly progressing disease, vandetanib is only indicated after careful consideration of the treatment-related risks.

Adverse Effects and Drug Interactions

The most common adverse effects ($>20\%$) are diarrhea/colitis, rash, acneiform dermatitis, hypertension, nausea, headache, upper respiratory tract infections, decreased appetite, and abdominal pain. Less common are QT prolongation, torsades de pointes, and sudden death. Vandetanib should not be used in patients with hepatic impairment or congenital long QT syndrome.

Midostaurin

Midostaurin is a small-molecule multikinase inhibitor with activity against mutant FLT3, a driver in AML. It is FDA-approved for combination chemotherapy of adults with newly diagnosed AML. Leukopenia, nausea, mucositis, diarrhea, and musculoskeletal pain are major adverse effects of treatment. Midostaurin was also approved for different forms of mast cell disorders.

III. Tumor Angiogenesis

Cancer cells secrete angiogenic factors that induce the formation of new blood vessels and guarantee the flow of nutrients to the tumor cells to permit growth and metastasis. Many tumor types overexpress these angiogenic factors, turning on an “angiogenic switch” whereby the tumor cells adopt an invasive phenotype favoring proliferation of endothelial cells and neovascularization. In 1971, Judah Folkman hypothesized that the growth of solid tumors was dependent on angiogenesis and that blockade of the effects of putative angiogenic factors would be a good treatment modality

for human cancers (Folkman, 1971). Folkman’s hypothesis proved to be correct and led to the characterization of a number of secreted angiogenic factors, including VEGF, FGF, TGF- β , and PDGF. Furthermore, inhibitors of these angiogenic factors have, indeed, become useful therapeutic agents against certain cancers. VEGF is a major driver of angiogenesis, and inhibitors of VEGF signaling comprise an important class of antitumor agents.

Inhibition VEGF and the VEGFR Pathway

Vascular endothelial growth factor initiates endothelial cell proliferation and vascular permeability when it binds to a member of the VEGFR family, a group of highly homologous receptors with intracellular tyrosine kinase domains; these receptors include VEGFR1 (FLT1), VEGFR2 (KDR), and VEGFR3 (FLT4) (Figure 67-2). The binding of VEGF to its receptors activates the intracellular VEGFR tyrosine kinase activity and initiates mitogenic and antiapoptotic signaling pathways (Nagy et al., 2007). Antibodies targeting VEGF, such as *bevacizumab*, sterically hinder the interaction of VEGF with its receptor. *Aflibercept* acts as a VEGF trap; it is a recombinant molecule that uses the VEGFR1-binding domain to sequester VEGF, basically acting as a “soluble decoy receptor” for VEGF. Several small-molecule drugs that inhibit the protein tyrosine kinase function of VEGFR (*pazopanib*, *sorafenib*, *sunitinib*, and *axitinib*) as well as monoclonal antibodies that target the receptor (*ramucirumab*) have been approved for clinical use. The inhibition of endothelial function by these different approaches results in a similar spectrum of adverse effects.

Bevacizumab

Mechanism of Action

Bevacizumab is a humanized monoclonal IgG1 antibody that binds to VEGF; the antibody contains the antigen-recognition domain of a murine antibody inserted into a human IgG1. Bevacizumab prevents the interaction of VEGF with its receptors on the surface of endothelial cells and inhibits receptor signaling that normally increases vascular permeability and angiogenesis. Bevacizumab delays progression of renal cell cancer and, in combination with cytotoxic chemotherapy, is approved in the treatment of patients with mCRC as well as NSCLC and glioblastoma.

ADME

Bevacizumab is administered intravenously as a 30- to 90-min infusion every 2 weeks in metastatic colon cancer and, in conjunction with combination chemotherapy, in metastatic NSCLC every 3 weeks with chemotherapy. The antibody has a plasma half-life of about 20 days (range 11 to 50 days).

Therapeutic Use in Cancer

Bevacizumab is indicated as treatment of various cancers, frequently in combination with other drugs. In metastatic colon cancer, bevacizumab combined with FOLFOX or FOLFIRI increases patient survival by about 5 months (Hurwitz et al., 2004). In NSCLC, a combination of bevacizumab with carboplatin and paclitaxel increases survival by about 2 months. Also approved are combinations of bevacizumab with cytotoxic chemotherapy in patients with cervical or ovarian cancer and a combination with IFN- α for the treatment of metastatic RCC. For glioblastoma, bevacizumab is approved as a single agent following prior therapy.

Other Therapeutic Uses: Wet Macular Degeneration

Vascular endothelial growth factor is an important mediator of pathologic vascular permeability. Intravitreal administration of anti-VEGF targeted therapy has become a standard treatment of wet macular degeneration (see also Chapter 69). *Bevacizumab* and a modified fragment of bevacizumab, *ranibizumab*, are used. Ranibizumab is derived from the bevacizumab IgG1 by deletion of the Fc domain and changes in six amino acids in the antigen-recognition domain to increase affinity for VEGF.

Because these drugs are administered by injection into the vitreous cavity of the eye, few systemic adverse effects are observed. A direct

comparison of intravitreal *bevacizumab*, *ranibizumab*, and *aflibercept* (the VEGF trap protein; see discussion that follows) in patients with diabetic macular edema showed that all three treatments improved vision, although *aflibercept* appeared more effective in patients with worse baseline levels of visual impairment (Wells et al., 2015).

Adverse Effects. Bevacizumab causes a wide range of serious class-related adverse effects that include hypertension, GI perforation, thromboembolic events, and hemorrhage. A major concern is the potential for vessel injury and bleeding in patients with lung cancer. Bevacizumab is contraindicated for patients with a history of hemoptysis, brain metastasis, or a bleeding diathesis. In appropriately selected patients, the predicted rate of life-threatening pulmonary hemorrhage is less than 2%, and for arterial thromboembolism (stroke; myocardial infarction) observed during treatments that include bevacizumab the predicted rate is less than 4%.

Other adverse effects characteristic of drugs that target the VEGF pathway include hypertension and proteinuria. A majority of patients require antihypertensive therapy, particularly those receiving higher doses and more prolonged treatment. Bevacizumab can be associated with congestive heart failure, probably secondary to hypertension, and with reversible posterior leukoencephalopathy in patients with poorly controlled hypertension. GI perforation, a potentially life-threatening complication, has been observed in up to 11% of patients with ovarian cancer. In patients with colon cancer, colonic perforation occurs infrequently during bevacizumab treatment but increases in frequency in patients with intact primary colonic tumors, peritoneal carcinomatosis, peptic ulcer disease, chemotherapy-associated colitis, diverticulitis, or prior abdominal radiation treatment. Perforation of the colon occurs in less than 1% of patients. Following colon cancer surgery, patients on bevacizumab have a higher rate (13% vs. 3.4%) of serious wound-healing complications. Because of the long $t_{1/2}$ of bevacizumab, elective surgery should be delayed for at least 4 weeks from the last dose of antibody, and treatment should not be resumed for at least 4 weeks after surgery.

Ramucirumab

Mechanism of Action

Ramucirumab is a human IgG1 monoclonal antibody that binds to VEGFR2, blocking the binding of VEGFR ligands and thereby inhibiting ligand-induced activity in endothelial cells.

ADME

Ramucirumab is administered intravenously every 2 to 3 weeks. Its mean half-life is 14 days.

Therapeutic Uses

Ramucirumab is used in combination with chemotherapy for the treatment of patients with mCRC with disease progression on or after prior therapy; as a single agent or in combination with paclitaxel for treatment of patients with advanced gastric adenocarcinoma with disease progression on or after prior chemotherapy; and in combination with docetaxel for treatment of patients with metastatic NSCLC with disease progression on or after chemotherapy.

Adverse Effects

The most common adverse effects are hypertension and diarrhea. Other severe adverse effects overlap with those of bevacizumab (anti-VEGF; see previous discussion): increased risk of hemorrhage, GI perforation, and impaired wound healing.

Aflibercept

Mechanism of Action

Ziv-aflibercept acts as a trap for VEGFR ligands. It is a recombinant fusion protein that contains the extracellular VEGF-binding domain of human VEGFR1/2 fused to the Fc portion of human IgG1. Ziv-aflibercept acts as a soluble receptor that binds to human VEGFR ligands with high affinity (K_d s of 0.5 to 40 pM), reducing their plasma concentrations to levels that are too low for significant activation of their cognate receptors.

ADME

The elimination half-life is about 6 days (range 4–7 days). Ziv-aflibercept is administered by intravenous infusion over 1 h every 2 weeks.

Therapeutic Uses

In combination with FOLFIRI, aflibercept is indicated for patients with mCRC that is resistant to or has progressed following an oxaliplatin-containing regimen.

Adverse Effects

The most common adverse effects are hypertension and diarrhea. Other severe adverse effects overlap with those of bevacizumab (anti-VEGF; see previous discussion): increased risk of hemorrhage, GI perforation, and impaired wound healing.

Antiangiogenic Small-Molecule Kinase Inhibitors

Sunitinib

Mechanism of Action

Sunitinib is a small-molecule, orally bioavailable inhibitor of multiple kinases, including VEGFR2.

ADME

The typical treatment cycle of sunitinib is 4 weeks on treatment followed by 2 weeks off. The dosage and schedule of sunitinib can be decreased in patients with adverse effects. More recently, a 2-week on/1-week off schedule has proven to be better tolerated and as effective as the original treatment schedule. Sunitinib is metabolized by CYP3A4 to produce an active metabolite, SU12662, the $t_{1/2}$ of which is 80–110 h; steady-state levels of the metabolite are reached after about 2 weeks of repeated administration of the parent drug. Further metabolism results in the formation of inactive products. The pharmacokinetics of sunitinib are not affected by food intake.

Therapeutic Uses

Sunitinib has activity in metastatic renal cell cancer, producing a higher response rate and a longer progression-free survival than seen with IFN or bevacizumab. Sunitinib is also approved for the treatment of pancreatic NETs and of GIST in patients who have developed resistance to imatinib as a consequence of *c-KIT* mutations. Specific *c-KIT* mutations correlate with the degree of response to sunitinib (e.g., patients with *c-KIT* exon 9 mutations have a response rate of 37%; patients with *c-KIT* exon 11 mutations have a 5% response rate).

Adverse Effects

The main adverse effects of sunitinib are shared by all antiangiogenic inhibitors: bleeding, hypertension, proteinuria, and, uncommonly, arterial thromboembolic events and intestinal perforation. However, because sunitinib is a multitargeted TKI, it has a broader adverse effect profile than bevacizumab. Fatigue affects 50%–70% of patients and may be disabling. Hypothyroidism occurs in 40%–60% of patients. Bone marrow suppression and diarrhea also are common side effects; severe neutropenia (neutrophils < 1000/mL) develops in 10% of patients. Less common side effects include hepatotoxicity, congestive heart failure and PPES. It is essential to check blood counts and thyroid function at regular intervals. Periodic echocardiograms also are recommended.

Sorafenib

Mechanism of Action and Therapeutic Use

Sorafenib, like *sunitinib*, is an orally bioavailable inhibitor of multiple protein kinases. Sorafenib is the only drug currently approved for treatment of patients with hepatocellular carcinoma. Sorafenib also is approved in patients with metastatic renal cell cancer, but sunitinib and pazopanib are generally preferred first-line therapies (see previous discussion and below).

ADME

Sorafenib is given orally every day without treatment breaks. Sorafenib is metabolized to inactive products by CYP3A4 with a $t_{1/2}$ of 20–27 h; with repeated administration, steady-state concentrations are reached within 1 week.

Sorafenib-treated patients can experience the vascular toxicities seen with other antiangiogenic medications described under *bevacizumab*. More common adverse effects include fatigue, nausea, diarrhea, anorexia, rash, and palmar-plantar erythrodysesthesias; uncommonly, bone marrow suppression, GI perforation, and cardiomyopathy occur.

Pazopanib

Pazopanib is a kinase inhibitor of VEGFR-1, -2, and -3 as well as FGFRs, KIT, LCK, PDGFR, and other kinases implicated in pathologic angiogenesis and cancer progression. Pazopanib is approved for the treatment of patients with advanced renal cell cancer and advanced STS after prior chemotherapy. It has less toxicity and equivalent efficacy to sunitinib in patients with treatment-naïve metastatic renal cancer and therefore has become the preferred first-line treatment of many patients. Pazopanib is orally bioavailable, metabolized mostly by CYP3A, and eliminated with a $t_{1/2}$ of 31 h. Major adverse effects include hypertension, thrombotic and hemorrhagic events, GI perforation, QT prolongation, and cardiomyopathy. Pazopanib carries a black-box warning: It can produce severe and life-threatening hepatotoxicity; as a consequence, pazopanib should not be used in elderly patients or those with preexisting liver function test abnormalities.

Other Receptor Kinase Inhibitors With Antiangiogenic Effects

Axitinib is a kinase inhibitor of VEGFR-1, -2, and -3 that are implicated in pathologic angiogenesis, tumor growth, and cancer progression. Axitinib is approved for the treatment of patients with advanced RCC after failure of one prior systemic therapy. Axitinib is orally bioavailable, metabolized mainly by CYP3A4/5, and eliminated with a variable $t_{1/2}$ of 2.5 to 6.1 h. Major adverse effects include hypertension, thrombotic and hemorrhagic events, and GI perforation similar to those of the anti-VEGF *bevacizumab* (see previous discussion).

Lenvatinib inhibits the protein kinase activities of VEGFR-1, -2, and -3 as well as FGFRs, PDGFR, and other kinases that are implicated in pathologic angiogenesis and cancer progression. Lenvatinib is approved for the treatment of patients with recurrent or metastatic differentiated thyroid cancer and in combination with everolimus for patients with advanced renal cell cancer. Lenvatinib is orally bioavailable, metabolized by CYP3A, and eliminated with a $t_{1/2}$ of 28 h. Major adverse effects include hypertension, thrombotic and hemorrhagic events, hepatotoxicity, GI perforation, and QT prolongation.

Regorafenib inhibits the protein kinase activities of RET, VEGFR1-3, KIT, PDGFR, FGFR1/2, TIE2, RAF1, BRAF, and ABL at concentrations that can be achieved clinically. Several of these kinases are implicated in pathologic angiogenesis and malignant progression. Regorafenib is approved for the treatment of patients with mCRC after previous chemotherapy, anti-VEGF therapy, or anti-EGFR therapy and for patients with locally advanced, unresectable, or metastatic GIST after imatinib or sunitinib. Regorafenib is orally bioavailable, metabolized mostly by CYP3A, and eliminated with a variable $t_{1/2}$ of about 28 h (range 14 to 58 h). Major adverse effects include hepatotoxicity, hypertension, thrombotic and hemorrhagic events, GI perforation, QT prolongation, and wound-healing complications. As expected for an agent metabolized by CYP3A4, strong inducers and strong inhibitors of CYP3A4 must be avoided (see *palbociclib*, previously discussed, for details).

of inhibitory signals that limit T-cell activation, so-called immune checkpoints. The discovery of receptors, ligands, and their function in the control of immune cell activity during the past two decades led to the development of clinically effective monoclonal antibodies that enable T cells to recognize and eradicate cancer cells with acceptable adverse effects (Figure 67-5).

HISTORY Immune Checkpoint Inhibitors

The discovery of the TCR and of costimulatory signal pathways in the period from 1982 to 1992 defined essential requirements for T-cell activation during antigen presentation: In addition to the antigen-TCR interaction, CD28 on T cells binds to B7 proteins on APCs (see Figure 67-5, see also Figures 35-2 and 35-4). The finding, in the mid-1990s, of coinhibitory molecules that can dampen T-cell activation revealed a potential mechanism for drugs to modulate immune checkpoints and alter anticancer immune activity. TCR activation induces expression of the inhibitory CTLA-4, a CD28 homolog with higher affinity for the B7 ligands than CD28. CTLA-4 inhibits T-cell activation to control autoimmune tissue damage. PD-1, another inhibitory molecule expressed on T cells after their activation, and PD-L1, the ligand for PD-1, were described in the early 2000s. It became obvious that T cells present in human tumors were being inhibited by factors in the tumor tissues: TILs harvested from patients and activated exogenously showed efficacy and paved the way for targeting immune inhibition. Improved survival of patients with metastatic melanoma after anti-CTLA-4 treatment led to FDA approval of ipilimumab in 2011; anti-PD-1 and anti-PD-L1 were approved in 2014. Clinical trials in multiple types of cancer have been ongoing since then and have led to the approval of immune checkpoint inhibitors for additional indications (Monteiro, 2015) described in this section.

Blocking immune checkpoints on cytotoxic T cells enables them to eradicate cancer cells that express antigens recognized by the T cells. Sustained eradication of metastatic melanoma in a significant number of patients was an impressive outcome of initial clinical trials with a monoclonal antibody, *ipilimumab*, which is an immune checkpoint inhibitor (Robert et al., 2013). Note that immune checkpoint inhibition is distinct from conventional approaches such as vaccination with a known antigen (to generate T cells that recognize cells expressing the antigen), nonspecific stimulation of T cells, or approaches using antigen-responsive T cells that express a specific chimeric antigen receptor (CAR). The different approaches are described next.

Mechanisms of T-Cell Activation

Antigen-mediated activation of T cells is initiated by engagement of the TCR with antigen presented on MHC protein on the surface of an APC, “signal 1.” In addition, engagement of CD28 costimulatory molecules on T cells is required for effective T-cell activation that includes cell proliferation, migration, and production of cytokines. This “signal 2” is provided by B7 surface proteins on APCs, for example, CD80 or CD86 (Figures 35-4 and 67-5). T-cell activation is tightly controlled by immune-suppressive cells and cytokines as well as by coinhibitory molecules present on T cells, such as *CTLA-4* or *PD-1* (Figure 67-5). CTLA-4 is expressed by activated CD4 and CD8 T cells and competes with costimulatory CD28 for binding to the B7 protein ligands. Binding of CTLA-4 to B7 proteins interrupts the initial CD28 costimulatory signals and serves as an early negative regulator of the T-cell activation responses, that is, an *immune checkpoint*. Additional control of T-cell activity is provided by later inhibitory signals through other molecules, such as PD-1 that binds the ligand PD-L1. PD-1 is mainly expressed by activated CD4 and CD8 T cells as well as APCs.

Blocking monoclonal antibodies to CTLA-4, PD-1, or PD-L1 are currently used to neutralize coinhibitory receptors during T-cell priming (CTLA-4), to maintain cancer antigen-specific T-cell function, and to provide a sustained T-cell response (PD-1) that includes increased production

IV. Targeting the Immune System

Immune Checkpoint Inhibitors

Recent striking successes of cancer immunotherapy have given credence to the long-held hope that the immune system may be unleashed to treat cancer. The conceptual breakthrough is based on the discovery

Figure 67-5 Targeting of immune checkpoints. Antigens shed from dead cancer cells are captured and processed by APCs. APCs travel to the regional lymph nodes and present the antigen bound to MHC to stimulate TCRs. Costimulatory signals leading to T-cell activation are provided by the interaction between CD28 on T cells and B7 on APCs. CTLA-4 is upregulated and limits T-cell activation (early coinhibition) by outcompeting CD28 for binding to B7. Activated T cells also upregulate PD-1 on their surface. Figure 35-4 shows additional details of T-cell activation. Activated effector T cells capable of killing cancer cells then traffic from the lymph node to the tumor site, where they recognize cancer cells by the interaction of the TCR with the MHC-neoantigen complex and kill cancer cells through cytolysis (release of perforin and granzyme). This triggers additional antigen release that can induce subsequent rounds of anticancer immunity. Release of IFN- γ upon TCR recognition of the MHC-neoantigen complex induces upregulation of PD-L1 on the surface of tumor cells. PD-L1 binds to PD-1 on the surface of activated T cells, dampening the immune response in the tumor microenvironment. T-cell checkpoint inhibitors can enhance T-cell priming through blockade of CTLA-4 (ipilimumab) or by T-cell activation in the tumor via blocking the PD-1/PD-L1 interaction with antibody ligands to PD-1 (nivolumab, pembrolizumab) or PD-L1 (atezolizumab). Antibodies that block inhibitory immune checkpoints allow a sustained T-cell response that also includes an increased production of cytokines and T-cell proliferation.

of cytokines such as TNF α , IFN- γ , and granzyme B. Antibodies that target different checkpoint molecules are discussed in the following material: *ipilimumab* (anti-CTLA-4), *atezolizumab* (anti-PD-L1), *nivolumab* and *pembrolizumab* (anti-PD-1).

Inhibitors of Cytotoxic T Lymphocyte–Associated Protein 4 (CTLA4)

The CTLA-4 is upregulated during the antigen priming of T cells and binds B7 on APCs to attenuate the T-cell response and thus reduce the risk for chronic autoimmune-dependent inflammation (Figure 67-5).

Ipilimumab

Ipilimumab is a fully human IgG1 monoclonal antibody that binds to CTLA-4 and is approved for the treatment of late-stage melanoma and under study for other cancers.

Mechanism of Action

Ipilimumab blocks the interaction of CTLA-4 with B7 ligands on APCs and thereby augments T-cell activation (Figure 67-5). Inhibition of CTLA-4 signaling can also inhibit regulatory T-cell function that dampens cytotoxic T-cell activity and thus increases the antitumor immune response further (Mellman et al., 2011).

ADME

Ipilimumab is administered intravenously and shows linear pharmacokinetics in the dose range of 0.3 to 10 mg/kg, with a terminal half-life of 15.4 days.

Therapeutic Uses

A pivotal 2010 trial in patients with metastatic melanoma showed improved median overall survival after ipilimumab treatment (Hodi et al., 2010). This trial led to FDA approval of ipilimumab for the treatment of metastatic melanoma. Further studies showed that some patients had clinical responses that lasted for 10 or more years (Schadendorf et al., 2015). The tumor response can take several months to manifest, and tumors may increase in size during this period, in part due to the evolving inflammatory reaction (Mellman et al., 2011). Current recommended dosing of ipilimumab is 3 mg/kg intravenously over 90 min every 3 weeks for a total of four doses for patients with metastatic disease and 10 mg/kg followed by 10 mg/kg every 12 weeks for up to 3 years or until documented disease recurrence or unacceptable toxicity for patients treated in the adjuvant setting.

Adverse Effects

Blockade of CTLA-4 compromises immune tolerance to some normal tissue antigens and provokes inflammatory toxicities, mostly in the skin, pituitary gland, intestine, and liver. The activation of T-cell responses by ipilimumab treatment leads to immune-related toxicities in the majority of patients (73.6%), with 18.6% reaching toxicity grade 3–4 toxicity (Callahan et al., 2016). Adverse effects on the skin (pruritus, rash, vitiligo) and GI tract (diarrhea, colitis) are the most frequent, whereas immune-mediated hepatitis, hypophysitis, and hypo- or hyperthyroidism are less frequent. Withholding treatment because of moderate adverse reactions until return to baseline and high-dose corticosteroids for severe immune-mediated reactions are recommended.

Other Drugs in This Class

Tremelimumab (formerly ticilimumab) is a fully human IgG2 monoclonal antibody that targets CTLA-4; it is under investigation in several clinical trials.

Inhibitors of Programmed Cell Death 1 (PD-1)

Activation of the PD-1 checkpoint pathway in T cells by PD-L1 or PD-L2 evokes a negative regulatory immune response and inactivates T cells (Figure 67-5). Tumor cells can exploit this pathway by presenting the PD-L1 ligand to tumor-infiltrating T cells and thus shield the tumor from T cell–mediated destruction. Presentation of PD-L1 to activated T cells results in T-cell exhaustion, whereas antibody-mediated blockade of PD-1 can restore or maintain T-cell antitumor response.

Nivolumab

Mechanism of Action

Nivolumab is a fully human monoclonal IgG4 antibody that blocks the interaction between PD-1 and its ligands.

ADME; Clinical Use

Nivolumab is administered as an intravenous infusion every 2 weeks until the time of disease progression or of unacceptable toxicity. The drug has an elimination half-life of 26.7 days. Nivolumab is FDA approved for the treatment of a variety of cancers, currently including advanced melanoma, previously treated advanced NSCLC, RCC, advanced head and neck cancer, and relapsed/refractory classical Hodgkin lymphoma. Quite strikingly, nivolumab provided an overall response rate of 87% in patients with

1222 Hodgkin lymphoma who had failed treatment with brentuximab vedotin (see discussion that follows). Nivolumab has significant clinical activity in a variety of heavily pretreated patients with solid tumors as well as patients with hematological malignancies. This is also true for the other anti-PD-1 monoclonal antibody, pembrolizumab.

Adverse Effects

The most common adverse effect of treatment in patients with melanoma is a rash (>20%); in patients with advanced squamous NSCLC, the adverse effects are fatigue, dyspnea, musculoskeletal pain, decreased appetite, cough, nausea, and constipation. Immune-mediated adverse reactions are much less common than with CTLA-4 antibodies; corticosteroids are recommended based on the severity of the reaction. For pneumonitis, colitis, hepatitis, nephritis and renal dysfunction, withhold treatment if the adverse effects are moderate and discontinue treatment if the effects are severe.

Pembrolizumab

Pembrolizumab (formerly called lambrolizumab or MK-3475) is a humanized monoclonal IgG4- κ isotype antibody that blocks interaction between PD-1 and its ligands. This humanized antibody has a mouse variable region grafted onto a human antibody framework and shows high affinity toward PD-1 receptors of humans and other primates but no appreciable affinity for mouse or rat PD-1.

The FDA has extended the approval for pembrolizumab to any cancer with mismatch repair (MMR) deficiency or high microsatellite instability (MSI-H). The defects in DNA repair lead to a higher mutation load and increased generation of mutant protein antigen by cancer cells that can activate the immune system. This first cancer tissue-agnostic approval extends immune checkpoint inhibitor treatment to subsets of patients with hereditary CRC due to Lynch syndrome (MSI-H) and up to 20% of patients with sporadic colon cancer. The frequency is less in endometrial, ovarian and pancreatic cancers and will require testing of each patient's tumor to assess suitability of the treatment.

ADME; Clinical Use

The recommended treatment schedule for pembrolizumab is 2 mg/kg (or a 200-mg flat dose) as an intravenous infusion over 30 min every 3 weeks. The elimination half-life is 26 days. In clinical trial, pembrolizumab demonstrated an overall response rate of 26% in patients with ipilimumab-pretreated and refractory advanced melanoma (Hamid et al., 2013; Robert et al., 2014). Pembrolizumab is more effective and less toxic than ipilimumab in patients with either treatment-naïve or BRAF inhibitor-pretreated melanoma. Pembrolizumab is currently approved for the treatment of patients with advanced melanoma, unresectable or metastatic melanoma in patients previously treated with ipilimumab, PD-L1-positive NSCLC (either prior to or after platinum-containing chemotherapy), and chemotherapy-refractory head and neck cancer. Significant antitumor activity has also been found relative to chemotherapy in patients with metastatic urothelial cancer, Merkel cell carcinoma, and Hodgkin lymphoma.

Adverse Effects

The most common adverse effects, experienced by more than 20% of patients, are fatigue, cough, nausea, pruritus, rash, decreased appetite, constipation, arthralgia, and diarrhea. An additional 10% of patients may experience complications with infections. Serious adverse events include immune-mediated inflammation, specifically pneumonitis, colitis, hepatitis, and hypophysitis and both hyper- and hypothyroidism. Withholding treatment and administration of systemic corticosteroids for grade 2⁺ or discontinuing treatment with more severe adverse effects is recommended. Because human IgG4 can cross the placenta, the benefit from pembrolizumab treatment should be balanced with the potential fetal risk in a pregnant woman.

Antagonists of PD-1 Ligand 1

Programmed cell death 1 has two ligands, PD-L1 and PD-L2, each with distinct expression profile. The PD-L1 ligand is expressed on APCs, T cells, B cells, and nonhematopoietic cells, which can include cancer cells

(Figure 67-5). Expression of PD-L2 is restricted to APCs, macrophages, myeloid dendritic cells, and mast cells. Clinical trial results are promising with drugs targeting PD-L1.

Atezolizumab

Mechanism of Action

Atezolizumab, also known as MPDL3280A, is a fully human IgG1 monoclonal antibody that blocks the interaction of PD-L1 with PD-1 and B7-H1. PD-L1 is expressed in many cancers and thus can suppress the activation of cytotoxic T cells that enter the tumor. Atezolizumab can remove this inhibitory effect and promote an effective antitumor response.

ADME

Atezolizumab is administered as an intravenous infusion over 60 min every 3 weeks. The terminal half-life is 27 days.

Clinical Use

Atezolizumab is indicated for conventional treatment-resistant metastatic NSCLC as well as locally advanced or metastatic urothelial cancer.

Adverse Effects

The most common adverse effects in 20% or more of patients with metastatic NSCLC are fatigue, decreased appetite, dyspnea, cough, nausea, musculoskeletal pain, and constipation. Patients with urothelial carcinoma may report urinary tract infection. Possible immune-related adverse effects include hepatitis, colitis, hypophysitis, thyroid disorders, adrenal insufficiency, type 1 diabetes mellitus, pancreatitis, myasthenia gravis, Guillain-Barré syndrome, and ocular inflammation; these may require discontinuation of treatment. Due to potential embryo-fetal toxicity, female patients should be advised accordingly.

Other Anti-PD-L1 Antibodies

Durvalumab (approved in 2017 for metastatic urothelial cancer) and *avelumab* (approved in 2017 for metastatic urothelial and Merkel cell cancer) are also being evaluated for efficacy toward cancers of the head and neck, stomach, lung, and ovary, as well as hepatocellular cancer.

Combination of Anti-PD-1 and Anti-CTLA4

Because anti-CTLA-4 and anti-PD-1 target distinct immune checkpoints during T-cell activation, preclinical studies have shown that concurrent targeting of CTLA-4 and PD-1 significantly improves therapeutic efficacy when compared to effects of single agents (Curran et al., 2010). In patients with advanced melanoma, the combination of ipilimumab and nivolumab produces a positive response in more than 50% of the patients with an acceptable level of adverse effects, although the combination therapy significantly increased the rate of rare but fatal myocarditis (combination 0.17%; nivolumab < 0.01%) (Johnson et al., 2016). The 1- and 2-year overall survival rates were 94% and 88%, respectively (Wolchok et al., 2013). Thus, combinations of immune checkpoint inhibitors with different targets may become the standard of care in various solid as well as hematologic malignancies (Mellman et al., 2016). Most important, combination immunotherapy will likely be more effective than most other forms of treatment of patients with metastatic disease (Restifo et al., 2016).

Cytokines to Stimulate Immune Responses

Interleukin 2

Of the 70 or so proteins and glycoproteins that are classified as cytokines, only IFN (Chapters 34 and 35) and IL-2 are in routine clinical use, often for actions against cancer.

Activated CD4⁺ T cells are the primary producers of IL-2. The functions of IL-2 are myriad; amongst other roles, IL-2 promotes the growth of T cells and NK cells, stimulates the proliferation of and antibody production by B cells, and drives the development of T_{reg} cells (mediators

of tolerance and suppression). As noted by Liao and colleagues (2013), “IL-2 has broad essential biological actions, not only driving T cell proliferation and modulating effector cell differentiation, but also limiting potentially dangerous autoimmune reactions.” This statement provides a general rationale for the clinical use of IL-2 and the likelihood that IL-2 administration might also engender adverse effects.

Mechanism of Action

Interleukin 2 stimulates the proliferation of activated T cells and the secretion of cytokines from NK cells and monocytes. IL-2 stimulation increases cytotoxic killing by T cells and NK cells.

Interleukin 2 is a 133-amino acid glycoprotein (molecular weight ~ 15 kDa) produced by activated T cells and NK cells; it promotes activated T-cell proliferation and enhanced killing by NK cells. Responsiveness depends on expression of the IL-2R. The receptor comprises three independently expressed membrane monospans, α , β , and γ , which can assemble in several combinations to produce working receptors of varying affinities. These monospans are variously expressed in lymphohematopoietic cells, lack C-terminal protein kinase activities, and transduce signals via coupling to Jak proteins (Figure 67-6). Nearly all types of tumor cells lack receptor expression and are unresponsive to IL-2.

ADME

Interleukin 2 (as recombinant IL-2, aldesleukin) is administered intravenously. The serum $t_{1/2}$ of IL-2 after intravenous administration has an α phase of about 13 min and a β phase of about 90 min. IL-2 is excreted in the urine as an inactive metabolite.

Therapeutic Uses

Aldesleukin possesses the biological activities of native human IL-2. The drug is approved for use in patients with metastatic renal cell cancer and metastatic melanoma. High-dose IL-2 produces an overall response rate of 15%–25% in patients with renal cell cancer; 8% achieve a complete response. In patients with metastatic melanoma, high-dose IL-2 induces an overall response rate of 16%–22%, and 6% achieve a complete response. In both instances, responses last a median of about 5 years. Low-dose IL-2 also produces responses, but few are complete responses, and the duration may be less than with high-dose IL-2.

Adverse Effects

Interleukin 2 toxicities are dominated by the capillary leak syndrome, in which intravascular fluid leaks into the extravascular space, producing hypotension, edema, respiratory difficulties, confusion, tachycardia, oliguric renal failure, and electrolyte problems. Symptoms include fever, chills, malaise, nausea, vomiting, and diarrhea. Laboratory abnormalities include thrombocytopenia, abnormal liver function tests, and neutropenia. Most patients develop a pruritic skin rash. Hypothyroidism may occur. Arrhythmias are a rare complication. These toxicities can be life threatening, yet nearly all are reversible within 24–48 h of discontinuing therapy. Patients should have normal renal and hepatic function before beginning therapy and should be closely supervised in an inpatient facility capable of care at the intensive care unit level during drug administration.

Figure 67-6 A pharmacologist's view of IL-2 receptors, their cellular signaling pathways, and their inhibition. **A. IL-2 receptors.** The IL-2 receptor has three components: an α chain, a 55-kDa protein (CD25) involved mainly in IL-2 binding; a β chain, a 75-kDa protein that binds to Jak1; and a γ chain, a 64-kDa protein that signals via Jak3. These components combine as shown to produce receptors of varying affinities and with different capacities for intracellular signaling. The γ chain is a component of many cytokine receptors (IL-2, IL-4, IL-7, IL-9, IL-15, and IL-21). Resting T cells have a low density of IL-2R α ; however, activation of the TCR (see Figure 35-2) and IL-2, itself, induce IL-2R α expression. IL-2R α can also be induced by a large variety of cytokines, viruses, and activators of PKC. The β and γ monospans are constitutively expressed on many lymphohematopoietic cells, and their expression can also be regulated. Tumor cells generally lack receptor expression and are unresponsive to IL-2. **B. IL-2 receptor signaling.** The formation of the quaternary complex of IL-2 and the α , β , and γ units of IL-2R suffice to activate intracellular signaling. The IL-2R monospans shown in A lack the protein tyr kinase activities common to many monospanning hormone receptors. Rather, these receptors respond to IL-2 binding at the extracellular domain by differentially recruiting Jak1 and Jak3 to their cytosolic domains, Jak1 at IL-2R β and Jak3 at IL-2R γ . Heterodimerization of β and γ cytosolic domains leads to activation of Jak1 and Jak3. The Jaks transactivate and also phosphorylate key tyrosines on IL-2R β . These phosphotyrosines (P) permit important protein-protein interactions that direct downstream signaling:

- Binding of an SHC adapter/scaffolding protein that is the platform for activation of the Ras-MAPK pathway and the PI3K pathway
 - Recruitment and phosphorylation of STAT5 (and to a lesser extent, STATs 1 and 3), leading to STAT-dependent gene regulation
- IL-2/IL-2R signaling can be therapeutically reduced by inhibitors that interact with IL-2R α , Jak1, and Jak3 (red boxes and T bars)

Cancer Vaccines

Vaccination against cancer antigens has shown little efficacy with the exception of two approaches that were approved by the FDA in 2010 (*sipuleucel-T*) and in 2015 (*T-VEC*).

Sipuleucel-T

Sipuleucel-T is a cell-based approach designed to induce an immune response against PAP, which is expressed in most prostate cancers. This autologous cellular immunotherapy is generated from a patient's peripheral blood cells, which are isolated by leukapheresis. The cells are exposed to a human recombinant protein, PAP-GM-CSF. APCs present amongst the blood cells are thought to take up and process PAP and direct the immune response toward the antigen. A patient receives the treated cells by infusion on three occasions at 2-week intervals. Treatment is approved for patients with minimally symptomatic, hormone-refractory, metastatic prostate cancer. Adverse effects include acute infusion reactions, which can be reduced by premedication with acetaminophen and antihistamine.

T-Vec

T-VEC (talimogene laherparepvec) is an oncolytic herpesvirus that replicates within tumors and expresses GM-CSF. Tumor antigens are released after virally induced cell death, and the presence of GM-CSF can promote an antitumor immune response. T-VEC is approved for the local treatment of unresectable cutaneous and nodal lesions in patients with melanoma. T-VEC may synergize with immune checkpoint inhibitor treatment. Adverse effects are influenza-like symptoms and injection site pain.

Chimeric Antigen Receptor T Cells

Treatment of patients with B-cell leukemias or lymphoma with receptor-engineered T cells has produced striking successes. CARs contain the antigen-binding domain of a monoclonal antibody to confer recognition of the targeted tumor antigen coupled to intracellular domains capable of activating T cells (Figure 67–7). When expressed in T cells, these CARs recognize cell surface antigens and activate T cells independent of antigen presentation by a MHC molecule as required for physiologic antigen presentation (see Figures 35–2 and 67–5). In initial studies, CAR-expressing T cells were targeted to NY-ESO-1, a tumor antigen of the cancer/testis family that is highly expressed on many poor-prognosis melanoma cells. The CAR T cells showed long-lasting efficacy (>3 years) in some patients with metastatic melanoma. CAR targeting CD19, a B-cell antigen, also resulted in striking efficacy in patients with B-cell leukemias (Klebanoff

Figure 67–7 Chimeric antigen receptor (CAR) T cell activation by a target antigen on cancer cells. T cells are harvested from a cancer patient and transduced with a CAR expression vector. Elements in a CAR: extracellular, single-chain antibody fragment of the variable domain (scFv) that recognizes the targeted antigen; intracellular co-stimulatory domain (e.g. from CD28); intracellular signaling domain of the TCR. CD19 is shown as an antigen example. APC-mediated stimulation of T cells is depicted for comparison (see figure 67–5).

et al., 2016). The approval of CD19 CAR-T cells (tisagenlecleucel-T; previously named CTL019) has been recommended, based on data showing >80% remissions of relapsed or refractory B cell ALL during treatment. Other CARs targeting CD22 and B-cell maturation antigen (BCMA) have shown efficacy and are currently under investigation.

Future Challenges of Immunotherapy

The potential for immunotherapies to augment conventional chemotherapy, pathway-targeted treatment, and radiotherapy will require detailed exploration and will be a common theme in the design of future clinical trials (Ebert et al., 2016; Hughes et al., 2016). The recent identification of multiple negative and positive immune-modulatory pathways that can be targeted is leading to development of new drugs that will require testing as monotherapy and combination with each other as well as with conventional treatments. This new class of cancer treatment presents a new set of adverse effects (e.g., fulminant myocarditis caused by a combination of immune checkpoint inhibitors; Johnson et al., 2016) that must be understood mechanistically before rational combination strategies can be developed.

V. Other Targets

Inhibitors of Poly (ADP-Ribose) Polymerase

DNA damage-repair genes are frequently inactivated in human cancer. PARP1 is the product of one such gene. PARP1 is a nuclear protein that transfers ADP-ribose from NAD⁺ to target proteins, and this poly (ADP-ribosylation) (or PARylation) of nuclear proteins by PARP1 plays a significant role in the DNA damage response (Tallis et al., 2014). Inactive PARP1 associates with chromatin and helps to create a compact chromatin structure in the nucleosome. DNA damage (e.g., strand breaks) mobilizes the enzyme, promoting PARP-mediated PARylation, with the result that chromatin relaxes in the area of damage. The mechanisms of relaxation are the PARylation of PARP1 itself, and of histones and other chromatin-associated proteins, resulting in their dissociation from DNA. PARylation produces branching chains up to 200 ADP-ribose units in length. These chains provide docking centers for the localized recruitment of PAR-binding factors and thence of DNA repair enzymes (e.g., DNA pol β , DNA ligase III) and proteins that help to maintain an inactive environment in the open chromatin region while repairs are made to the damaged DNA. The synthesis and degradation of PAR chains in vivo is tightly regulated, with the chains having half-lives measured in minutes (Wei and Yu, 2016). Excessive activation of PARP1 leads to depletion of the cellular pool of NAD⁺ and to cell death; teleologically, this could be viewed as a means of preserving genomic integrity by removing cells with heavily damaged DNA.

Deficient PARP1 activity leads to defective DNA repair. However, PARP-deficient cells are still able to carry out DNA repair through a different mechanism: homologous recombination. The protein machinery for homologous recombination repair includes the breast cancer susceptibility genes BRCA1 and BRCA2, suggesting that cells with diminished or absent BRCA1/2 function could be unusually susceptible to the inhibition of PARP activity. BRCA1/2 mutations predispose carriers to breast, ovarian, and other cancers that can be resistant to chemotherapy. BRCA-deficient cells are more dependent on PARP1 and base excision repair to maintain genomic integrity. BRCA1/2-deficient cancer cells are less able to carry out repair and ultimately die; inhibition of PARP could accelerate this process. It is noteworthy that PARPs catalyze PARylation of a number of proteins that regulate cellular processes beyond DNA damage repair; these extra-chromatin actions may contribute to the clinical efficacy and adverse effects of PARP inhibitors. Inhibitors of PARP are designed to compete with NAD⁺ at its binding site on the PARP enzyme. *Olaparib* and *rucaparib* are approved for the treatment of patients with advanced ovarian cancer.

Olaparib

Olaparib is an orally bioavailable inhibitor of PARP enzymes.

ADME

Olaparib is rapidly absorbed after oral administration and metabolized primarily by CYP3A4, yielding a $t_{1/2}$ of about 12 h. Drug exposure is increased or reduced when administered in combination with a CYP3A4 inhibitor or inducer, respectively.

Therapeutic Uses; Adverse Effects

Olaparib is EMA and FDA approved as monotherapy in patients with germline BRCA-mutated, advanced, ovarian cancer who have been treated with three or more prior lines of chemotherapy. Adverse effects include GI upset (nausea and vomiting) and loss of appetite; fatigue; muscle and joint pain; low blood cell counts and anemia; and occasionally leukemia. Potentially fatal MDS and pneumonitis have been observed.

Rucaparib

Rucaparib is a benzimidazole derivative that inhibits PARP1. Rucaparib is FDA approved for treatment of advanced ovarian cancer in patients exhibiting deleterious BRCA mutations who have been treated with at least two prior chemotherapies. The drug was approved in conjunction with the approval of a gene-sequencing test that detects BRCA1/2 mutations in patient tumor tissue.

Clinical Use; Adverse Effects

The drug is administered orally but should not be given until the patient has recovered from any hematological toxicity caused by previous chemotherapy. CYP2D6 metabolizes rucaparib, yielding a half-life of about 18 h. Adverse effects include GI upset and abdominal pain, fatigue, and decreased appetite. MDS and AML are rare but serious adverse effects (<1%). This agent may cause fetal harm and should not be administered to pregnant females or used by nursing mothers.

BCL2 Inhibitors

The BCL2 protein family comprises more than 20 proteins that govern mitochondrial outer membrane permeabilization and control programmed cell death (apoptosis). Proteins in this family can be either *pro*- or *anti*apoptotic depending on their content of BCL2 homology domains

(BH1 to 4). *Proapoptotic* proteins contain a BH3 domain that is necessary for dimerization with other proteins of the BCL2 family. *Antiapoptotic* proteins contain BH1 and BH2. The balance of these interacting proteins controls mitochondrial outer membrane permeabilization, cytochrome c release, and the activation of caspases that leads to apoptosis (Figure 67–8). BCL2 promotes cellular survival by inhibiting proapoptotic proteins like BIM, BAX, and BAK and is overexpressed in CLL and some other tumors where it can support tumor cell survival and resistance to cancer treatments.

Venetoclax

Mechanism of Action

Venetoclax is a first-in-class, orally bioavailable, small-molecule inhibitor of BCL2. It was designed as a BH3 mimetic that inhibits BCL2 interaction with the proapoptotic BH3-only family members, such as BIM, BID, and BAD. In vitro, venetoclax inhibits BCL2 action with an IC_{50} of less than 0.01 nM and with a selectivity of two to three orders of magnitude over other BCL2 family members. In the presence of venetoclax, BH3-only proteins can translocate to mitochondria and initiate BAX/BAK-dependent apoptosis. Overexpression of BCL2 occurs in CLL cells, where it supports tumor cell survival and resistance to chemotherapeutic agents. Thus, venetoclax helps restore apoptosis in these cells.

ADME; Therapeutic Use; Adverse Effects

Oral absorption is significantly improved 3- to 5-fold by administration with a meal. Venetoclax, a Pgp substrate, is metabolized by CYP3A4/5; concomitant use of CYP3A inhibitors or inducers and Pgp inhibitors should be avoided (see previous discussion of *palbociclib* for details). The elimination half-life is 18–26 h. Venetoclax is approved for the treatment of patients with CLL with a 17p deletion. The most common adverse effects are neutropenia, diarrhea, nausea, anemia, upper respiratory tract infection, thrombocytopenia, and fatigue. Venetoclax should not be administered during pregnancy or breastfeeding until further data are available.

Thalidomide and Lenalidomide

Thalidomide and lenalidomide have a most unusual history and a multiplicity of biological and immunological effects. Thalidomide originally was used for the treatment of pregnancy-associated morning sickness

Figure 67–8 BH3 mimetics enhance apoptosis. Permeability of the outer mitochondrial membrane to cytochrome c is regulated by proteins required for forming pores, including proapoptotic BAX and BAK. BAK and BAX are rendered inactive by binding to the BH3 domains of antiapoptotic proteins such as BCL2. BH3 mimetic drugs (*venetoclax*) target BCL2 and its interaction with BAX/BAK, reducing the inhibitory effect of BCL2 on apoptosis progression, enhancing cytochrome c release, and sensitizing the cell to apoptosis. Cancer cells may be resistant to apoptosis by overexpression of BCL2; BH3 mimetics such as *venetoclax* release the resultant blockade and promote apoptosis.

1226 but was withdrawn from the market due to teratogenicity and dysmelia (stunted limb growth). It reentered clinical practice for treatment of erythema nodosum leprosum (see Chapter 60). Further research revealed its antiangiogenic and immunomodulatory effects. At least four distinct mechanisms have been proposed to explain its antitumor activity, which are summarized in Figure 67–9 and enumerated in its legend.

Both thalidomide and lenalidomide possess potent activity in patients with newly diagnosed and heavily pretreated relapsed/refractory MM. Lenalidomide also is approved for its activity in the 5q– subset [or del(5q) subset] of MDS. A specific gene array profile identifies patients with MDS who lack the 5q– abnormality but respond to lenalidomide. A more recently added derivative of thalidomide is pomalidomide, approved for treatment of patients with MM resistant to lenalidomide.

Thalidomide

ADME

Thalidomide exists at physiological pH as a racemic mixture of cell-permeable and rapidly interconverting nonpolar S(–) and R(+) isomers. The R-enantiomer is associated with the teratogenic and biological activities, while the S accounts for the sedative properties of thalidomide. In treating MM, doses usually are escalated by 200 mg/d every 2 weeks until dose-limiting side effects (sedation, fatigue, constipation, or a sensory neuropathy) appear. With extended treatment, the neuropathy may necessitate dose reduction or discontinuation of treatment for a period of time. Thalidomide absorption from the GI tract is slow and highly variable. It distributes throughout most tissues and organs, without significant binding to plasma proteins. The enantiomers are eliminated with a $t_{1/2}$ of about 6 h, mainly due to spontaneous hydrolysis in all body fluids; the S-enantiomer is cleared more rapidly than the R-enantiomer. Thalidomide and its metabolites are excreted in the urine, while the nonabsorbed portion of the drug is excreted unchanged in feces. The inactive hydrolysis products undergo CYP-mediated metabolism. Longer plasma $t_{1/2}$ is reported at the highest doses (1200 mg daily). No dose adjustment is necessary in the presence of renal failure.

Lenalidomide

Lenalidomide constitutes the lead compound of immunomodulatory thalidomide derivatives. Lenalidomide induces the ubiquitination and degradation of target proteins by the E3 ubiquitin ligase CRL4CRBN (Fink and Ebert, 2015). Target proteins in MM cells are IKZF1/3, which are crucial for cell survival (Lu et al., 2014) (Figure 67–9). In MDS, casein kinase 1A1 is the target protein (Krönke et al., 2015). Cellular effects of lenalidomide include direct suppression of tumor cell growth in culture, T-cell and NK-cell activation, suppression of TNF α and other cytokines, antiangiogenesis, and promotion of HSC differentiation.

ADME

The standard dosage of lenalidomide is 25 mg/d for 21 days of a 28-day cycle. The drug is rapidly absorbed following oral administration, reaching peak plasma levels within 1.5 h. The $t_{1/2}$ of parent drug in plasma is 9 h. Approximately 70% of the orally administered dose of lenalidomide is excreted intact by the kidney. Dose adjustments to 10 mg/d for creatinine clearance of 30–50 mL/h and to the same dose every 2 days for creatinine clearance less than 30 mL/h are recommended for patients with renal failure.

Therapeutic Use

Lenalidomide exhibits potent antitumor activity in MM, MDS, and CLL; this agent causes fewer adverse effects and lacks the teratogenicity of thalidomide.

Adverse Effects of Thalidomide and Lenalidomide

Thalidomide is well tolerated at doses less than 200 mg daily. Common adverse effects are sedation and constipation. The most serious adverse effect is peripheral sensory neuropathy, which occurs in 10%–30% of patients with MM or other malignancies in a dose- and time-dependent manner. Thalidomide-related neuropathy is an asymmetrical, painful,

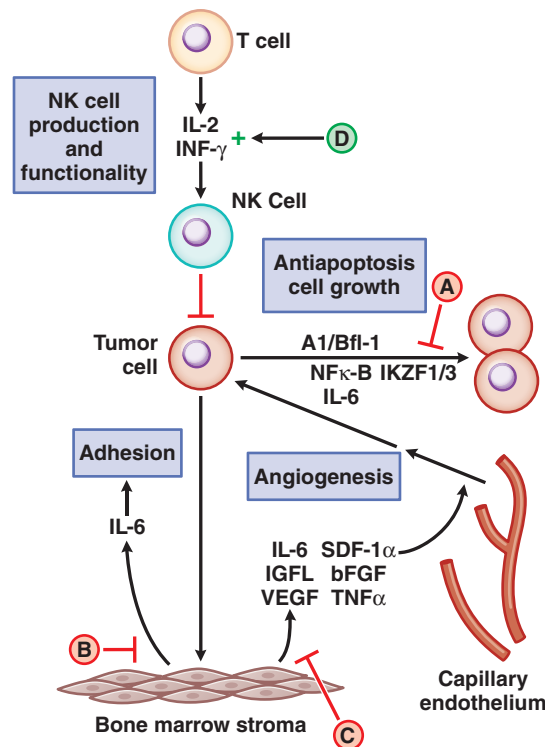

Figure 67–9 Overview of proposed mechanisms of antimyeloma activity of thalidomide and its derivatives. Some biological hallmarks of the malignant phenotype are indicated in blue boxes. The proposed sites of action for thalidomide (letters inside red and green circles) are hypothesized to also be operative for thalidomide derivatives. **A.** Direct anti-MM effect on tumor cells, including G₁ growth arrest or apoptosis, even against MM cells resistant to conventional therapy. This is due to the disruption of the antiapoptotic effect of BCL2 family members, blocking NF- κ B signaling, and inhibition of the production of IL-6. Mechanistic studies show that lenalidomide can kill MM cells by inducing E3 ubiquitin ligase CRL4CRBN-mediated ubiquitination and degradation of the crucial IKZF1 & 3 (zinc finger transcription factors). **B.** Inhibition of MM cell adhesion to bone marrow stromal cells partially due to the reduction of IL-6 release. **C.** Decreased angiogenesis due to the inhibition of cytokine and growth factor production and release. **D.** Enhanced T-cell production of cytokines, such as IL-2 and INF- γ , that increase the number and cytotoxic functionality of NK cells.

peripheral paresthesia with sensory loss, commonly presenting with numbness of toes and feet, muscle cramps, weakness, signs of pyramidal tract involvement, and carpal tunnel syndrome. Although symptoms improve on drug discontinuation, long-standing sensory loss may not reverse. Particular caution should be applied in patients with preexisting neuropathy (e.g., related to diabetes) or prior exposure to drugs that can cause peripheral neuropathy (e.g., vinca alkaloids, bortezomib). Thalidomide enhances the sedative effects of barbiturates and alcohol and the catatonic effects of chlorpromazine. Conversely, CNS stimulants (such as methamphetamine and methylphenidate) counteract the depressant effects of thalidomide.

Adverse effects of lenalidomide are less severe; it causes little sedation, constipation, or neuropathy. Lenalidomide depresses bone marrow function and is associated with significant leukopenia (20% of patients). Hepatotoxicity and renal dysfunction are rare. In some patients with CLL, lenalidomide causes dramatic lymph node swelling and tumor lysis (tumor flare reaction). Patients with renal dysfunction are prone to this reaction; thus, patients with CLL should be started at lower doses of 10 mg/d, with escalation as tolerated. Patients with CLL should receive pretreatment hydration and allopurinol to avoid the consequences of tumor swelling and tumor lysis. A negative interaction with rituximab, an anti-CD20 antibody, may result from lenalidomide's downregulation of CD20, an interaction that has clinical implications for their combined use in lymphoid malignancies.

Thalidomide and lenalidomide increase the risk for thromboembolic events, including deep vein thrombosis, stroke, and myocardial infarction, which occur with increased frequency in combination with glucocorticoids and with anthracyclines. Anticoagulation and antiplatelet medication reduce this risk and are indicated in patients with risk factors for clotting.

Pomalidomide

Pomalidomide, a thalidomide congener, is indicated for the treatment of patients with MM who have received at least two prior therapies including lenalidomide. Adverse effects are similar to those of thalidomide. Pomalidomide is contraindicated during pregnancy and in females who may become pregnant. As a consequence, this drug is available only under a pregnancy control system to ensure that recipients are not pregnant and are using effective birth control.

Proteasome Inhibitors

First Generation

Bortezomib is a first-generation inhibitor of proteasome-mediated protein degradation that has a central role in the treatment of MM.

Mechanism of Action

Bortezomib binds to the $\beta 5$ subunit of the 20S core of the 26S proteasome and reversibly inhibits its chymotrypsin-like activity. This event disrupts multiple intracellular signaling cascades, leading to apoptosis. An important consequence of proteasome inhibition is its effect on NF- κ B, a transcription factor that promotes cell damage response and cell survival. Most cellular NF- κ B is cytosolic and bound to I κ B; in this form, NF- κ B is restricted to the cytosol and cannot enter the nucleus to regulate transcription. In response to stress signals resulting from hypoxia, chemotherapy, and DNA damage, I κ B becomes ubiquitinated and then degraded via the proteasome. Its degradation releases NF- κ B, which enters the nucleus and transcriptionally activates a host of genes involved in cell survival (e.g., cell adhesion proteins, and proliferation (e.g., cyclin-D1) or antiapoptosis (e.g., cIAPs, BCL-2). NF- κ B is highly expressed in many human tumors, including MM, and may be a key factor in tumor cell survival in a hypoxic environment and during chemotherapy. Bortezomib blocks proteasomal degradation of I κ B, thereby preventing the transcriptional activity of NF- κ B and downregulating survival responses.

Bortezomib also disrupts the ubiquitin-proteasomal degradation of p21, p27, p53, and other key regulators of the cell cycle and initiators of apoptosis. Bortezomib activates the cell's stereotypical "unfolded protein response," in which abnormal protein conformation activates adaptive signaling pathways in the cell. The composite effect leads to irreversible commitment of MM cells to apoptosis.

ADME

The recommended starting dose of bortezomib is 1.3 mg/m² given as an intravenous bolus on days 1, 4, 8, and 11 of every 21-day cycle (with a 10-day rest period per cycle). At least 72 h should elapse between doses. Drug administration should be withheld until resolution of any grade 3 nonhematological toxicity or grade 4 hematological toxicity, and subsequent doses should be reduced 25%. The drug exhibits a terminal $t_{1/2}$ in plasma of 5.5 h. Peak proteasome inhibition reaches 60% within 1 h and declines thereafter, with a $t_{1/2}$ of about 24 h. Bortezomib clearance results from the deboronation of the parent compound (90%), followed by hydroxylation of the boron-free product by CYPs 3A4 and 2D6; administration of this drug with potent inducers or inhibitors/substrates of CYP3A4 requires caution. No dose adjustment is required for patients with renal dysfunction.

Therapeutic Uses

Bortezomib is used as initial therapy for patients with MM and as therapy for patients with MM after relapse from other drugs. It is also approved for treatment of patients with relapsed or refractory MCL. The drug is active in myeloma, including the induction of complete responses in up to 30% of patients when used in combination with other drugs (i.e., thalidomide, lenalidomide, liposomal doxorubicin, or dexamethasone).

Adverse Effects

Bortezomib toxicities include thrombocytopenia (28%), fatigue (12%), peripheral neuropathy (12%), neutropenia, anemia, vomiting, diarrhea, limb pain, dehydration, nausea, and weakness. Peripheral neuropathy, the most chronic of the toxicities, develops most frequently in patients with a prior history of neuropathy secondary to prior drug treatment (e.g., thalidomide) or diabetes or with prolonged use. Dose reductions or discontinuation of bortezomib ameliorates the neuropathic symptoms. Injection of bortezomib may precipitate hypotension, especially in volume-depleted patients, in those who have a history of syncope, or in patients taking antihypertensive medications. Cardiac toxicity is rare, but congestive heart failure and prolonged QT interval have been reported.

Second Generation

Carfilzomib is a second-generation selective proteasome inhibitor based on a tetrapeptide epoxyketone. It is FDA approved as a single agent or in combination with dexamethasone or lenalidomide plus dexamethasone for the treatment of patients with relapsed or refractory MM who have received at least one prior therapy. Frequent adverse effects (>20% of patients) include anemia, thrombocytopenia, diarrhea, dyspnea, and peripheral edema. There is a risk for cardiac, renal, pulmonary, and hepatic toxicity as well as hypertension.

Ixazomib is an orally bioavailable second-generation peptide analogue proteasome inhibitor that interacts with subunit beta type 5 (PSMB5) of the 20S proteasome complex. Ixazomib has an elimination half-life of 9.5 days and is approved for use in combination with lenalidomide and dexamethasone for the treatment of patients with MM after at least one prior therapy (Moreau et al., 2016). Ixazomib can cause diarrhea, peripheral neuropathy, and hepatotoxicity.

Omacetaxine. This agent's mechanisms of action include inhibition of protein translation by preventing the initial elongation step of protein synthesis, thereby depleting the cell of short-lived proteins. Omacetaxine is FDA approved for the treatment of patients with chronic or accelerated -phase CML with resistance or intolerance to two or more TKIs.

CD20 Inhibitors

CD20 is a cell surface antigen expressed on the surface of all B cells beginning with the pro-B cell stage through its terminal differentiation to plasma cells (see Chapters 34 and 35) and is expressed on about 90% of B-cell neoplasms.

Rituximab

Rituximab is a chimeric murine/human monoclonal IgG1 antibody that targets the CD20 B-cell surface antigen. On binding to CD20, rituximab mediates B-cell lysis through CDC and ADCC. In patients with NHL, administration of rituximab depletes circulating and tissue-based B cells within the first 3 weeks, with sustained depletion for 6 to 9 months post-treatment in a majority of patients. Median B-cell levels return to normal by 12 months.

ADME

The drug is administered by intravenous infusion both as a single agent and in combination with chemotherapy. Rituximab has a $t_{1/2}$ of about 22 days. As a single agent, it is given weekly for 4 weeks, with maintenance dosing every 3–6 months. In combination regimens, the drug may be administered every 3–4 weeks, with chemotherapy, for up to eight doses. The rate of infusion should be increased slowly to prevent serious hypersensitivity reactions. Pretreatment with antihistamines, acetaminophen, and glucocorticoids decreases the risk of hypersensitivity reactions. Patients with large numbers of circulating tumor cells (as in CLL) are at increased risk for tumor lysis syndrome; in these patients, the initial dose should be no more than 50 mg/m² on day 1 of treatment, and patients should receive standard tumor lysis prophylaxis.

Therapeutic Uses

Rituximab is approved as a single agent for relapsed indolent lymphomas and significantly enhances response and survival in combination with

1228 chemotherapy for the initial treatment of diffuse large BCL. Rituximab improves response rates when added to combination chemotherapy for other indolent B-cell NHLs, including CLL, MCL, WM, and marginal zone lymphomas. Maintenance of remission with rituximab delays time to progression and improves overall survival in indolent NHL. It is increasingly used for treatment of autoimmune diseases such as rheumatological disease, thrombotic thrombocytopenic purpura, autoimmune hemolytic anemias, cryoglobulin-induced renal disease, and multiple sclerosis.

Resistance and Adverse Effects

Resistance to rituximab may emerge through downregulation of CD20, impaired antibody-dependent cellular cytotoxicity, decreased complement activation, limited effects on signaling and induction of apoptosis, and inadequate blood levels. Polymorphisms in two of the receptors for the antibody Fc region responsible for complement activation may predict the clinical response to rituximab monotherapy in patients with follicular lymphoma but not in CLL. Rituximab infusion reactions can be life threatening, but with pretreatment, reactions are usually mild and limited to fever, chills, throat itching, urticaria, and mild hypotension. All respond to decreased infusion rates and antihistamines. Uncommonly, patients may develop severe mucocutaneous skin reactions, including Stevens-Johnson syndrome. Rituximab may cause reactivation of hepatitis B virus or rarely, JC virus (with progressive multifocal leukoencephalopathy). Hypogammaglobulinemia and autoimmune syndromes (idiopathic thrombocytopenic purpura, thrombotic thrombocytopenic purpura, autoimmune hemolytic anemia, pure red cell aplasia, and delayed neutropenia) may supervene 1–5 months after administration.

Ofatumumab

Ofatumumab is a second monoclonal antibody that binds to CD20 at sites on the major and minor extracellular loops of CD20, distinct from the site targeted by rituximab. Antibody binding results in B-cell lysis via CDC and ADCC. Ofatumumab is approved for treating patients with CLL after failure of fludarabine and alemtuzumab. A complex dosing scheme is used, beginning with small (300-mg) doses on day 1, followed by higher doses (up to 2 g/week) later. Ofatumumab's primary toxicities consist of immunosuppression and opportunistic infection, hypersensitivity reactions during antibody infusion, and myelosuppression. Blood counts should be monitored during treatment. Rarely, patients may develop reactivation of viral infections. The drug should not be administered to patients with active hepatitis B infection; liver function should be monitored in hepatitis B carriers.

Obinutuzumab

Obinutuzumab is a humanized monoclonal IgG1 antibody that recognizes the CD20 antigen expressed on the surface of B cells. On binding to CD20, obinutuzumab mediates B-cell lysis through CDC and ADCC. Obinutuzumab is approved for the treatment of treatment-naïve patients with CLL in combination with chemotherapy. Patients who receive this combination therapy are more likely to go into complete remission and have better overall survival than those receiving chlorambucil alone. In this study, they also compared patients treated with obinutuzumab and chlorambucil to patients who were treated with rituximab and chlorambucil. A comparison of patients with CLL given obinutuzumab-chlorambucil combination therapy versus rituximab-chlorambucil combination therapy showed that the obinutuzumab-chlorambucil combination provided higher rates of complete remission as well as longer progression-free survival. Cytopenias, fever, cough, and musculoskeletal disorders are frequent side effects.

Other Cell Surface Targets for Monoclonal Antibodies

Alemtuzumab

Alemtuzumab is a humanized IgG- κ monoclonal antibody that binds to CD52 antigen. CD52 is found on the surface of a subset of normal

neutrophils and on all B and T lymphocytes, on testicular elements and sperm, and on most BCLs and T-cell lymphomas. Consistently high levels of CD52 expression on lymphoid tumor cells and the lack of CD52 modulation with antibody binding make this antigen a potential target for unconjugated monoclonal antibodies. Alemtuzumab can induce tumor cell death through ADCC and CDC.

ADME

Alemtuzumab is administered intravenously in dosages of 30 mg/d, three times/week. Premedication with diphenhydramine and acetaminophen should precede drug infusion. Dosing should begin with a low-dose infusion, followed by an increased dose 2 days later and, if well tolerated, the highest dose 2 days later. The drug has an initial mean $t_{1/2}$ of 1 h, but after multiple doses, the $t_{1/2}$ extends to 12 days, and steady-state plasma levels are reached at approximately week 6 of treatment.

Therapeutic Uses

Alemtuzumab is approved as a single agent for the treatment of B-cell CLL. Clinical activity had been demonstrated in both B- and T-cell low-grade lymphomas and CLL, including patients with disease refractory to purine analogues. In chemotherapy-refractory CLL, overall response rates are about 40%, with complete responses of 6% in multiple series. Response rates in treatment-naïve patients with CLL are higher (overall response rates of 83% and complete responses of 24%). Alemtuzumab is also approved for the treatment of patients with relapsing forms of multiple sclerosis under a different label.

Adverse Effects

Serious toxicities include acute infusion reactions and depletion of normal neutrophils and T cells. Myelosuppression, with depletion of all blood lineages, occurs in the majority of patients and may represent either direct marrow toxicity or autoimmune responses. Immunosuppression leads to a significant risk of fungal, viral, and other opportunistic infections, particularly in patients who have previously received purine analogues. Patients should receive prophylaxis against *Pneumocystis carinii* and herpesvirus during treatment and for at least 2 months following therapy with alemtuzumab. Because reactivation of cytomegalovirus (CMV) infections may follow antibody use, patients should be monitored for symptoms and signs of viremia, hepatitis, and pneumonia. CD4⁺ T-cell counts may remain profoundly depleted (<200 cells/ μ L) for 1 year.

Dinutuximab

Dinutuximab is a monoclonal antibody that targets glycolipid GD2, expressed on neuroblastoma cells and on normal cells of neuroectodermal origin, including the CNS and peripheral nerves. It is approved in combination with GM-CSF, IL-2, and RA for high-risk neuroblastoma in pediatric patients. Dinutuximab can cause nerve damage and life-threatening infusion reactions.

Daratumumab

Daratumumab is a human IgG1 monoclonal antibody that binds to CD38 and inhibits the growth of CD38-expressing tumor cells by inducing immune-mediated tumor cell lysis through CDC and ADCC. The FDA has recently approved daratumumab for treatment of patients with MM in combination with lenalidomide or bortezomib and dexamethasone. The most frequent adverse effects are infusion reactions, neutropenia, thrombocytopenia, fatigue, nausea, diarrhea, muscle spasms, back pain, pyrexia, cough, dyspnea, peripheral edema, peripheral sensory neuropathy, and upper respiratory tract infection.

Elotuzumab

Elotuzumab is a humanized monoclonal IgG1 antibody that targets SLAMF7 (CD319). It is approved for the treatment of patients with MM who have received one to three prior therapies. Binding of elotuzumab to the antigen on myeloma cells induces ADCC-dependent tumor cell lysis. ADCC is enhanced by stimulation of the SLAMF7 pathway in NK cells by elotuzumab.

Blinatumomab

Blinatumomab is a bispecific antibody that recognizes sites on the surfaces of B cells and T cells, thereby enabling a patient's T cells to recognize malignant B cells. Blinatumomab binds simultaneously to CD3 (part of the TCR) on T cells and to CD19 on B cells. The drug links these two cell types and activates the T cell to exert cytotoxic activity on CD19⁺ target B cells. Blinatumomab is approved for the treatment of Philadelphia chromosome-negative relapsed or refractory B-cell precursor ALL. Major adverse effects are cytokine release syndrome, neurologic toxicities, neutropenic fever, and sepsis.

Monoclonal Antibody–Cytotoxin Conjugates

Gemtuzumab Ozogamicin

Mechanism of Action

Gemtuzumab ozogamicin is a humanized monoclonal antibody against CD33 covalently linked to a semisynthetic derivative of calicheamicin, a potent antitumor antibiotic. The CD33 antigen is present on most hematopoietic cells, on more than 80% of AMLs, and on most myeloid cells in patients with MDSs. However, other normal cell types lack CD33 expression, making this antigen attractive for targeted therapy. CD33 has no known biological function, although monoclonal antibody cross-linking inhibits normal and myeloid leukemia cell proliferation. Following its binding to CD33, gemtuzumab ozogamicin undergoes endocytosis; cleavage of calicheamicin from the antibody takes place within the lysosome. The potent toxin then enters the nucleus, binds in the minor groove of DNA, and causes double-strand DNA breaks and cell death.

ADME

The antibody conjugate produces a 30% complete response rate in relapsed AML when administered at a dose of 9 mg/m² for up to three doses at 2-week intervals. The $t_{1/2}$ of total and unconjugated calicheamicin are 41 and 143 h, respectively. Following a second dose, the $t_{1/2}$ of drug-antibody conjugate increases to 64 h. Most patients require two to three doses to achieve remission.

Therapeutic Use

The drug was initially approved for use in patients more than 60 years of age with AML in first relapse. However, the drug is not yet available, pending clinical trials to more precisely define a population with high likelihood of efficacy. Primary toxicities include myelosuppression in all patients treated and hepatocellular damage in 30%–40% of patients, manifested by hyperbilirubinemia and enzyme elevations. This agent also causes a syndrome that resembles hepatic veno-occlusive disease when patients subsequently undergo myeloablative therapy or when gemtuzumab ozogamicin follows high-dose chemotherapy.

Brentuximab Vedotin

Brentuximab vedotin is an anti-CD30 IgG1 monoclonal antibody linked with the microtubule-disrupting agent MMAE. CD30 is expressed on a number of malignant cells and is especially prevalent in Hodgkin and anaplastic lymphoma. Binding of the antibody to CD30-expressing cells is followed by internalization and the intracellular release of MMAE via proteolytic cleavage. MMAE disrupts the microtubule network, inducing cell cycle arrest and apoptotic cell death. MMAE is mostly metabolized by CYP3A, and coadministration with CYP3A4 inhibitors will increase exposure to the MMAE toxin. Coadministration with CYP3A4 inducers (e.g., rifampicin) reduces exposure. The most common adverse reactions are neutropenia, peripheral sensory neuropathy, fatigue, nausea, anemia, upper respiratory tract infection, diarrhea, pyrexia, rash, thrombocytopenia, cough, and vomiting.

Ado-trastuzumab Emtansine

Ado-trastuzumab-DM1 combines the HER2-targeted properties of trastuzumab with the antimicrotubule agent DM1 (derived from maytansine), allowing preferential intracellular drug delivery to HER2⁺ cells in the

treatment of HER⁺ breast cancer. The complex binds to the EGFR2 (HER2) and enters the cell by receptor-mediated endocytosis. The DM1 (emtansine) is released into the cytosol as the complex is cleaved by proteases in lysosomes. The DM1 disrupts microtubule-dependent events, causing mitotic arrest, disruption of intracellular trafficking, and apoptosis. The adverse effects of treatment include cardiac dysfunction as described for unconjugated trastuzumab. Hepatotoxicity is an additional risk.

Denileukin Diftitox

Denileukin diftotox is an immunotoxin made from the genetic recombination of IL-2 and the catalytically active fragment of diphtheria toxin. The high-affinity IL-2R has limited tissue expression and is an attractive target for an immunotoxin. Introduction of the diphtheria toxin fragment into cells leads to ADP-ribosylation and inactivation of eukaryotic elongation factor EF-2, inhibition of protein synthesis, and thence cell death.

ADME

Denileukin diftotox is administered by intravenous infusion over 30–60 min for 5 consecutive days every 21 days for eight cycles. The drug is quickly distributed and has a terminal $t_{1/2}$ of about 70 min. Denileukin diftotox clearance in later cycles of treatment accelerates by 2- to 3-fold as a result of development of antibodies, but serum levels exceed those required to produce cell death in IL-2R-expressing cell lines (1–10 ng/mL for > 90 min).

Therapeutic Uses

Denileukin diftotox is approved for the treatment of recurrent/refractory cutaneous T-cell lymphomas. Response rates of 30%–37% have been achieved, with a median response duration of 6.9 months. Patients with a history of hypersensitivity reactions to diphtheria toxin or IL-2 should not be treated. Significant toxicities include acute hypersensitivity reactions, a vascular leak syndrome, and constitutional toxicities; glucocorticoid premedication significantly decreases toxicity.

Radioimmunoconjugates

Radioimmunoconjugates provide targeted delivery of radionuclides to tumor cells. ¹³¹Iodine (¹³¹I) is a favored radioisotope because it is readily available, relatively inexpensive, and easily conjugated to a monoclonal antibody. The γ particles emitted by ¹³¹I can be used for both imaging and therapy, but protein-iodine conjugates have the drawback of releasing free ¹³¹I and ¹³¹I-tyrosine into the blood and thus present a health hazard to people in contact with the patient. The β -emitter ⁹⁰Y (yttrium) has emerged as an alternative to ¹³¹I, based on its higher energy and longer path length. Thus, it may be more effective in tumors with larger diameters. It also has a short $t_{1/2}$ and remains conjugated, even after endocytosis, providing a safer profile for outpatient use. Currently available radioimmunoconjugates consist of murine monoclonal antibodies against CD20 conjugated with ¹³¹I (tositumomab) or ⁹⁰Y (ibritumomab). Both drugs have shown response rates in relapsed lymphoma of 65%–80%. Adverse effects include antibody-related hypersensitivity, bone marrow suppression, and secondary leukemias. Both radioconjugates targeting CD20 on lymphomas have been approved; concerns over toxicity have limited their use.

Cytokines and Growth Factors

Colony-Stimulating Factors

Many agents used for cancer chemotherapy suppress the production of multiple types of hematopoietic cells, and bone marrow suppression can limit the delivery of chemotherapy on schedule and at prescribed doses. The availability of recombinant growth factors for erythrocytes (i.e., erythropoietin), granulocytes (i.e., G-CSF), and granulocytes and macrophages (i.e., GM-CSF) has advanced the ability to use combination therapy or high-dose cytotoxic therapy with diminished complications such as febrile neutropenia (see Chapter 66). Chapter 41 presents the basic pharmacology of hematopoietic growth factors.

Plerixafor is a small-molecule inhibitor of the CXCR4 chemokine receptor and is used in combination with G-CSF to mobilize HSC to the peripheral blood for collection and subsequent autologous transplantation in patients with NHL and MM. Plerixafor blocks binding of SDF-1 α to CXCR4. CXCR4 activity supports homing of HSCs to the bone marrow, and plerixafor mobilizes the release and entry of HSCs into the circulation. Combination of G-CSF with plerixafor increases the efficacy of HSC mobilization.

Inhibitors of Histone Deacetylase

Histone deacetylases are a class of enzymes that catalyze the removal of acetyl groups from acetylated lysine amino acids in histones, thereby altering the transcriptional activation of cellular genes. Thus, HDAC inhibitors produce a broad spectrum of epigenetic effects. HDACs can also deacetylate other proteins, including transcription factors. Overexpression of HDACs found in some cancers, or aberrant recruitment of HDACs to oncogenic transcription factors, can cause hypoacetylation of core nucleosomal histones. This hypoacetylation results in a condensed chromatin structure and repression of gene transcription. In contrast, inhibition of HDAC activity leads to the accumulation of acetyl groups on the histone lysine residues, an open chromatin structure, and activation of target genes that are selectively repressed in tumors. The result of HDAC inhibition can be differentiation with the emergence of a more normal cellular phenotype or cell cycle arrest with expression of endogenous regulators of cell cycle progression. Due to the diversity of the HDAC family of enzymes and their tissue distribution, HDAC inhibitors with different selectivity can induce a wide variety of cellular effects.

Panobinostat

Panobinostat is an orally bioavailable, nonselective pan-HDAC inhibitor. The inhibitory activity leads to apoptosis of malignant cells via multiple pathways. Panobinostat is approved for the treatment of patients with MM who have received at least two previous treatments, including bortezomib and an immunomodulatory agent.

ADME

The oral bioavailability is about 21%. Panobinostat is metabolized through CYP3A. It is recommended to avoid concomitant use with strong CYP3A4 inducers or inhibitors. Otherwise, dose adjustments will be necessary. The elimination half-life is approximately 37 h.

Adverse Effects

The most common adverse effects are diarrhea (severe in 25% of patients), fatigue, nausea, peripheral edema, decreased appetite, pyrexia, and vomiting. The most common nonhematologic laboratory abnormalities (incidence $\geq 40\%$) are hypophosphatemia, hypokalemia, hyponatremia, and increased creatinine. The common hematologic laboratory abnormalities (incidence $\geq 60\%$) are thrombocytopenia, lymphopenia, leukopenia, neutropenia, and anemia. Fatal cardiac ischemic events, severe arrhythmias, and ECG changes have occurred in patients receiving panobinostat. Arrhythmias may be exacerbated by electrolyte abnormalities. Avoid

concomitant use of antiarrhythmic or QT-prolonging drugs. Close cardiac monitoring during treatment is recommended.

Romidepsin

Romidepsin is an HDAC inhibitor used in the treatment of cutaneous and peripheral T-cell lymphoma. Romidepsin is a natural product obtained from the bacteria *Chromobacterium violaceum* and is sometimes referred to as depsipeptide. Romidepsin functions as a prodrug. Within cells, a zinc-binding thiol of the drug is reduced and interacts with a zinc atom in the binding pocket of HDAC to block its activity.

ADME

After intravenous administration, the major metabolism is through CYP3A4. Thus, it is recommended to monitor for toxicities related to increased romidepsin exposure when coadministering strong CYP3A4 inhibitors. Avoid use with rifampin and other strong CYP3A4 inducers. The terminal half-life is about 3 h.

Adverse Effects

The most commonly observed are nausea and vomiting, anemia, thrombocytopenia, and leukopenia as well as abnormal electrolyte levels and ECG changes.

Vorinostat

Vorinostat is a small-molecule, orally bioavailable HDAC inhibitor; it is also known as SAHA based on its chemical name *suberanilohydroxamic acid*.

Mechanism of Action

Vorinostat binds to the active site of HDACs and chelates zinc ions in the active site. The resulting inhibition of HDACs causes the accumulation of acetylated histones and other acetylated proteins, amongst which are transcription factors crucial for cell differentiation. Vorinostat inhibits the enzymatic activities of HDAC1, 2, 3 (class I) and HDAC6 (class II) at nanomolar concentrations ($IC_{50} < 100$ nM). In vitro, vorinostat induces cell cycle arrest or apoptosis of some cancer cells.

ADME

The absorption of vorinostat is slightly improved when taken with a meal. Metabolism is mostly through glucuronidation and hydrolysis. The elimination $t_{1/2}$ is about 2 h.

Therapeutic Use; Adverse Effects

Vorinostat is approved for the treatment of patients with cutaneous T-cell lymphoma with persistent or recurrent disease after two systemic therapies. The most common adverse reactions are diarrhea, fatigue, nausea, thrombocytopenia, anorexia, and dysgeusia. Patients with severe hepatic impairment should be excluded from treatment. Vorinostat is classified as pregnancy category D: evidence of risk.

Nilotinib	<ul style="list-style-type: none"> CML resistant to imatinib after prior therapy 	<ul style="list-style-type: none"> Adverse effects: diarrhea, nausea, vomiting, fluid retention, edema May ↑ QT interval; beware vascular events, including ischemia Rare myelosuppression, hepatotoxicity Bioavailability ↑ in the presence of food CYP3A4 and Pgp substrate Inhibitor of the Pgp
Bosutinib	<ul style="list-style-type: none"> CML with resistance to prior therapy 	<ul style="list-style-type: none"> Diarrhea, nausea, thrombocytopenia, vomiting, rash
Ponatinib	<ul style="list-style-type: none"> Resistant CML and Ph⁺ ALL 	<ul style="list-style-type: none"> Major adverse effects: thrombosis, hepatotoxicity, pancreatitis Absorption ↓ by elevated gastric pH (H₂ antagonists, antacids, PPIs) CYP3A4 substrate
Anaplastic Lymphoma Kinase Inhibitors		
Alectinib	<ul style="list-style-type: none"> Advanced NSCLC with gene rearrangement containing the ALK kinase fusion gene Advanced NSCLC with gene rearrangement containing the ALK kinase fusion gene and disease progression on crizotinib 	<ul style="list-style-type: none"> Fatigue, constipation, and edema, myalgia are common adverse effects Pneumonitis, GI and hepatic toxicity; bradycardia and prolonged QT intervals observed
Ceritinib, Crizotinib	<ul style="list-style-type: none"> As above 	<ul style="list-style-type: none"> As above
PI3K (Phosphatidylinositol-4,5-Bisphosphate 3-Kinase) Inhibitors		
Idelalisib	<ul style="list-style-type: none"> Relapsed or refractory B-cell malignancies: CLL (with rituximab), FL, SLL Not indicated for first-line treatment 	<ul style="list-style-type: none"> Serious and sometimes-fatal adverse effects: hepatotoxicity, colitis, pneumonitis, intestinal perforations, skin toxicity CYP3A substrate

mTOR (Mechanistic or Mammalian Target of Rapamycin) Inhibitors		
Temsirolimus	<ul style="list-style-type: none"> Renal cell carcinoma 	<ul style="list-style-type: none"> Adverse effects: frequent rash, mucositis, anemia, fatigue (30%–50%); rare leukopenia, thrombocytopenia, interstitial lung disease Metabolized to a longer-lived active metabolite (sirolimus) by CYP3A4; avoid CYP3A4 inhibitors, including grapefruit juice
Everolimus	<ul style="list-style-type: none"> Renal cell carcinoma Breast cancer: advanced ER positive, HER2 negative in combination with AI exemestane after failure of other AIs (letrozole, anastrozole) PNETs Progressive, well-differentiated, nonfunctional neuroendocrine GIST 	<ul style="list-style-type: none"> Adverse effects overlap with temsirolimus (see above) CYP3A4 substrate

Multikinase Inhibitors		
Cabozantinib	<ul style="list-style-type: none"> Advanced renal cell carcinoma Lung adenocarcinoma with <i>MET</i> gene alteration 	<ul style="list-style-type: none"> Diarrhea, fatigue, nausea, abdominal pain Hypertension: monitor blood pressure Not indicated in patients with recent bleeding history or thromboembolic event Discontinue in patients with GI perforation, fistulas CYP3A4 substrate; ↓ dose with hepatic impairment
Vandetanib	<ul style="list-style-type: none"> Progressing, locally advanced medullary thyroid cancer 	<ul style="list-style-type: none"> Diarrhea, colitis, rash QT interval prolongation, torsades des pointes, sudden death Do not use in patients with hepatic impairment, long QT syndrome CYP3A4 substrate

Section III: Inhibitors of Tumor Angiogenesis

Vascular Endothelial Growth Factor Inhibitors		
Bevacizumab (<i>humanized IgG1</i>)	<ul style="list-style-type: none"> Metastatic colorectal cancer combined with chemotherapy (FOLFOX or FOLFIRI) NSCLC combined with carboplatin and paclitaxel Ovarian cancer combined with chemotherapy Renal cell carcinoma combined with interferon α Glioblastoma following prior therapy 	<ul style="list-style-type: none"> Hypertension, related congestive heart failure: monitor blood pressure and treat hypertension Impaired wound healing: delay elective surgery for 1 month after the last dose; do not resume treatment for at least 1 month after surgery Spontaneous GI perforation
Ramucirumab (<i>fully human IgG1 to VEGFR2</i>)	<ul style="list-style-type: none"> Metastatic colorectal cancer, advanced gastric adenocarcinoma, and NSCLC with disease progression on or after prior therapy as a single drug or in combination with chemotherapy 	<ul style="list-style-type: none"> Hypertension, diarrhea Hemorrhage, GI perforations Impaired wound healing
Aflibercept (<i>extracellular domain of VEGFR1/2 fused to Fc portion of human IgG1</i>)	<ul style="list-style-type: none"> Metastatic colorectal cancer in combination with FOLFIRI chemotherapy following FOLFOX 	<ul style="list-style-type: none"> Soluble trap for VEGF receptor ligands Hypertension, diarrhea Increased risk of hemorrhage, GI perforation Impaired wound healing

Inhibitors of Intracellular Kinases Participating in Angiogenesis		
Sunitinib	<ul style="list-style-type: none"> VEGFR2 and multiple other kinases inhibited Metastatic renal cell cancer GIST after imatinib resistance Pancreatic neuroendocrine tumors 	<ul style="list-style-type: none"> Adverse effects shared with anti-VEGF: bleeding, hypertension, proteinuria (frequent); thromboembolism, GI perforations (rare) Adverse events distinct from anti-VEGF: <ul style="list-style-type: none"> Fatigue (50%–70%), hypothyroidism (40%–60%) Common: bone marrow suppression and diarrhea Less common: hepatotoxicity, congestive heart failure Check blood pressure, blood counts, and thyroid functions at regular intervals Elimination $t_{1/2}$ ~ 4 days: regimen in some cancers is 4 weeks on, 2 weeks off versus continuous daily administration for other cancers
Sorafenib	<ul style="list-style-type: none"> Hepatocellular carcinoma (currently the only approved drug) Metastatic renal cell cancer (however, sunitinib is the first choice) 	<ul style="list-style-type: none"> Adverse vascular effects match with those of sunitinib More common: fatigue, diarrhea, anorexia, rash Less common: bone marrow suppression, GI perforation, cardiomyopathy
Axitinib	<ul style="list-style-type: none"> Inhibition of VEGFR1–3 Advanced renal cell cancer after failure of prior systemic therapy 	<ul style="list-style-type: none"> Adverse effects overlap with those of anti-VEGF: hypertension, thrombotic and hemorrhagic events, GI perforation CYP3A4/5 substrate
Lenvatinib	<ul style="list-style-type: none"> Inhibition of VEGFR1–3, FGFRs, PDGFR Recurrent or metastatic differentiated thyroid cancer Renal cell cancer in combination with everolimus 	<ul style="list-style-type: none"> Adverse effects overlap with those of anti-VEGF: hypertension, thrombotic and hemorrhagic events, GI perforation In addition: hepatotoxicity, QT prolongation CYP3A substrate

Drug Facts for Your Personal Formulary: *Pathway-Targeted Therapies (continued)*

Drug	Therapeutic Use	Clinical Pharmacology and Tips
Pazopanib	<ul style="list-style-type: none"> Inhibition of VEGFR1–3, FGFRs, KIT, PDGFR Advanced renal cell carcinoma and advanced soft-tissue sarcoma after prior chemotherapy 	<ul style="list-style-type: none"> Adverse effects overlap with those of anti-VEGF: hypertension, thrombotic and hemorrhagic events, GI perforation In addition: hepatotoxicity, QT prolongation CYP3A substrate
Regorafenib	<ul style="list-style-type: none"> Inhibition of RET, VEGFR1, PDGFR, FGFR, TIE2, RAF1, BRAF, ABL Metastatic colorectal cancer after previous chemotherapy and anti-VEGF or anti-EGFR Advanced GIST after imatinib or sunitinib 	<ul style="list-style-type: none"> Major adverse effects: hepatotoxicity, hypertension, thrombotic and hemorrhagic events, GI perforation, and wound-healing complications CYP3A substrate

Section IV: Drugs Targeting the Immune System

Immune Checkpoint Inhibitors

Ipilimumab (<i>anti-CTLA-4 fully human IgG1</i>)	<ul style="list-style-type: none"> Metastatic melanoma as single agent or in combination with nivolumab (anti-PD1) Clinical trials with different cancers are ongoing 	<ul style="list-style-type: none"> Autoimmune inflammatory toxicities in majority of patients (>70%) Most frequent: skin (pruritus, rash, vitiligo), GI tract (diarrhea, colitis) Less frequent: hepatitis, pneumonitis, hypophysitis, hypo- or hyperthyroidism, myocarditis
Tremelimumab (<i>anti-CTLA-4 fully human IgG2</i>)	<ul style="list-style-type: none"> Clinical trials with different cancers are ongoing 	<ul style="list-style-type: none"> See above
Nivolumab (<i>anti-PD-1 fully human IgG4</i>)	<ul style="list-style-type: none"> Advanced melanoma that progressed after ipilimumab (anti-CTLA-4) Previously treated NSCLC Advanced renal cell carcinoma Relapsed/refractory Hodgkin lymphoma 	<ul style="list-style-type: none"> Adverse effects: rash, fatigue, dyspnea, musculoskeletal pain, decreased appetite, cough, nausea, constipation Immune-related serious adverse effects include pneumonitis, colitis, hepatitis, nephritis, renal dysfunction, hypophysitis, hypo- and hyperthyroidism
Pembrolizumab (<i>anti-PD-1 humanized IgG4</i>)	<ul style="list-style-type: none"> Advanced melanoma that progressed after ipilimumab (anti-CTLA-4) NSCLC that express PD-L1 and progressed under chemotherapy NSCLC with wild-type EGFR and ALK and disease progression after chemotherapy HNSCC with disease progression after chemotherapy 	<ul style="list-style-type: none"> Adverse effects: rash, fatigue, dyspnea, musculoskeletal pain, decreased appetite, cough, nausea, constipation Immune-related serious adverse effects include pneumonitis, colitis, hepatitis, nephritis, renal dysfunction, hypophysitis, hypo- and hyperthyroidism
Atezolizumab (<i>anti-PD-L1 fully human IgG1</i>)	<ul style="list-style-type: none"> NSCLC that is treatment resistant Urothelial cancer that is locally advanced or metastatic 	<ul style="list-style-type: none"> Adverse effects: fatigue, decreased appetite, dyspnea, cough, nausea, musculoskeletal pain, constipation In patients with urothelial cancer: urinary tract infections Immune-related pneumonitis, colitis, hepatitis, nephritis, renal dysfunction, hypo- and hyperthyroidism, hypophysitis, adrenal insufficiency, pancreatitis, Guillain-Barré syndrome, severe infections

Section V: Inhibitors of Other Targets

Poly(ADP-Ribose) Polymerase Inhibitor

Olaparib <i>PARP (poly (ADP-ribose) polymerase) inhibitor</i>	<ul style="list-style-type: none"> Ovarian cancer after three or more prior lines of treatment in patients with germline mutant BRCA 	<ul style="list-style-type: none"> Adverse effects: nausea, vomiting, loss of appetite, muscle and joint pain, anemia; leukemia (rare), potentially fatal myelodysplastic (rare) syndrome pneumonitis CYP3A4 substrate
---	---	--

BCL2 (Antiapoptotic Protein): Orally Available Inhibitor

Venetoclax	<ul style="list-style-type: none"> CLL with 17p deletion (poor prognosis) 	<ul style="list-style-type: none"> Neutropenia, thrombocytopenia, diarrhea, nausea Absorption ↑ 3- to 5-fold with a meal CYP3A substrate
------------	--	---

Thalidomide and Lenalidomide

Thalidomide	<ul style="list-style-type: none"> Newly diagnosed multiple myeloma Relapsed or refractory, pretreated multiple myeloma 	<ul style="list-style-type: none"> Most serious adverse effect: sensory neuropathy in 10%–30% of patients; may not be reversible after discontinuation of treatment; patients with preexisting neuropathy at higher risk Teratogenic; do not use in pregnancy Causes sedation, fatigue, constipation Sedation enhanced by alcohol, chlorpromazine, barbiturates; counteracted by methylphenidate or methamphetamine
-------------	---	---

Thalidomide and Lenalidomide (continued)		
Lenalidomide	<ul style="list-style-type: none"> Multiple myeloma Myelodysplastic syndrome (5q⁺ MDS) Chronic lymphocytic leukemia (CLL) 	<ul style="list-style-type: none"> Bone marrow function suppression and leukopenia (20% of patients), rare hepatic or renal toxicity Tumor lysis in some patients with CLL ⇒ lymph node swelling and tumor flare: start at lower dose in patients with CLL Downregulates CD20, a target for monoclonal antibody therapy In contrast to thalidomide: little neuropathy, sedation, or constipation; lack of teratogenicity Dose reduction recommended in patients with reduced renal function
Proteasome Inhibitors		
Bortezomib	<ul style="list-style-type: none"> Multiple myeloma: initial therapy and after relapse Mantle cell lymphoma: relapsed or refractory 	<ul style="list-style-type: none"> Thrombocytopenia (28%), fatigue (12%), peripheral neuropathy (12%) Neutropenia, anemia, vomiting, diarrhea, limb pain, weakness Rare: congestive heart failure and prolonged QT intervals Metabolized by CYP3A4; drug exposure of patient affected by coadministration of inhibitors or inducers of CYP3A4
Antibodies Targeting Cell Surface Antigens		
Rituximab (<i>chimeric murine/human IgG1 anti-CD20</i>)	<ul style="list-style-type: none"> Non-Hodgkin lymphoma Chronic lymphocytic leukemia Rheumatological and other autoimmune disease, including multiple sclerosis 	<ul style="list-style-type: none"> Infusion-related toxicity with fever, rash, and dyspnea; B-cell depletion; late-onset neutropenia risk of hypersensitivity reaction: use slow increase in infusion rate and antihistamines Rare: severe mucocutaneous skin reaction, including Stevens-Johnson syndrome Risk of tumor lysis syndrome in patients with high tumor burden in the circulation: use lower dose initially Reactivation of hepatitis B virus or JC polyoma virus
Ofatumumab (<i>fully human IgG1 anti-CD20</i>)	<ul style="list-style-type: none"> CLL after treatment failure 	<ul style="list-style-type: none"> Immunosuppression and opportunistic infections, hypersensitivity reaction during infusion and myelosuppression: monitor blood counts during treatment
Obinutuzumab (<i>humanized IgG1 anti-CD20</i>)	<ul style="list-style-type: none"> CLL in combination with chemotherapy 	<ul style="list-style-type: none"> Frequent adverse effects: cytopenia, fever, cough, musculoskeletal disorders
Alemtuzumab (<i>Campath or Lemtrada; humanized IgG1 anti-CD52</i>)	<ul style="list-style-type: none"> CLL (label: <i>Campath</i>) Multiple sclerosis (label: <i>Lemtrada</i>) 	<ul style="list-style-type: none"> Infusion-related toxicity, T-cell depletion with increased infection; myelosuppression with pancytopenia Antibiotic prophylaxis
Dinutuximab (<i>chimeric mouse/human anti-GD2</i>)	<ul style="list-style-type: none"> High-risk neuroblastoma 	<ul style="list-style-type: none"> Infusion reaction Nerve damage
Daratumumab (<i>human IgG1 anti-CD38</i>)	<ul style="list-style-type: none"> Multiple myeloma in combination with lenalidomide or bortezomib 	<ul style="list-style-type: none"> Infusion reactions Peripheral sensory neuropathy, upper respiratory tract infection
Elotuzumab (<i>humanized IgG1 anti-CD319</i>) (SLAMF7)	<ul style="list-style-type: none"> Multiple myeloma after one to three prior therapies 	<ul style="list-style-type: none"> Infusion reaction
Blinatumomab (<i>bispecific anti-CD19 and anti-CD3</i>)	<ul style="list-style-type: none"> Ph-negative relapsed or refractory B-cell precursor ALL 	<ul style="list-style-type: none"> Cytokine release syndrome, neurologic toxicity, neutropenic fever

Note: CYP3A4 substrate: For drugs that are subject to hepatic metabolism by CYP enzymes, drug exposure of a patient can be affected by coadministration of inhibitors or inducers of CYP3A4 and can then reduce efficacy or increase side effects.

Embryo-fetal toxicity: Consider that all of these drugs can cause fetal harm. Advise women of the potential risk to a fetus and to avoid pregnancy while taking the drug and for 1 month after cessation of therapy. Advise men to avoid fathering a child during the same time period. Avoid lactation during therapies.

Chapter 68

Hormones and Related Agents in the Therapy of Cancer

Claudine Isaacs, Anton Wellstein, and Anna T. Riegel

DRUGS THAT TARGET THE GLUCOCORTICOID RECEPTOR

ESTROGENS AND ANDROGENS IN CANCER

- Hormone Therapy of Breast Cancer
- Hormone Therapy of Prostate Cancer

A Note on Treatment Regimens

Cancer treatment regimens change to reflect continuous advances in basic and clinical science: new drugs, both small molecules and biologicals; improved methods of targeting and timing of drug delivery; agents with altered pharmacokinetic properties and selectivities; the use of rational multidrug combinations; and greater knowledge of the basic cell biology of tumorigenesis, metastasis, and immune function, amongst other advances. As a consequence, this chapter presents relatively few detailed treatment regimens; rather, we refer the reader to the web-based resources of the U.S. FDA and the NCCN. Table 67–1 provides the details and demonstrates the complexities of treatment of two cancers.

The growth of a number of cancers is hormone dependent or regulated by hormones. Glucocorticoids are used for their antiproliferative and lympholytic properties and to ameliorate untoward responses to other treatments. Estrogen and androgen antagonists, steroid synthesis inhibitors, and GnRH analogues and antagonists are all effective in extending survival and delaying or preventing tumor recurrence of both breast and prostate cancer. These molecules interrupt the stimulatory axis created by systemic pools of androgens and estrogens, inhibit hormone production or hormone binding to receptors, and ultimately block expression of genes that promote tumor growth and survival.

Drugs That Target the Glucocorticoid Receptor

The pharmacology, major therapeutic uses, and toxic effects of the glucocorticoids are discussed in Chapter 46. Only the applications of these drugs in the treatment of neoplastic disease are considered here.

Glucocorticoids act by binding to a specific GR that is a member of the nuclear receptor family of transcription factors. The GR translocates to the nucleus and induces complex gene expression changes (Chapter 46) that lead to antiproliferative and apoptotic responses in sensitive cells. Because of their lympholytic effects and their ability to suppress mitosis in lymphocytes, glucocorticoids are used as cytotoxic agents in the treatment of acute leukemia in children and malignant lymphoma in children and adults. In acute lymphoblastic or undifferentiated leukemia of childhood, glucocorticoids may produce prompt clinical improvement and objective hematological remissions in 30% of children. However, the duration of remission is brief. Remissions occur more rapidly with glucocorticoids than with antimetabolites, and there is no evidence of cross-resistance to unrelated agents. Thus, therapy is initiated with *prednisone* and *vincristine*, often followed by an anthracycline or *methotrexate*, and *L-asparaginase*. Glucocorticoids are a valuable component of curative regimens for other lymphoid malignancies, including Hodgkin disease, non-Hodgkin

lymphoma, multiple myeloma, and CLL. Glucocorticoids are extremely helpful in controlling autoimmune hemolytic anemia and thrombocytopenia associated with CLL.

A number of glucocorticoids are available and at equivalent dosages exert similar effects (see Chapter 46). Prednisone, for example, usually is administered orally in doses up to 100 mg for the first few days and gradually reduced to the lowest possible effective dose. Side effects of these agents include glucose intolerance, immunosuppression, osteoporosis, and psychosis (see Chapter 46). Dexamethasone is one of the preferred agents for remission induction in multiple myeloma, typically in combination with bortezomib, anthracyclines, or lenalidomide. Glucocorticoids, particularly dexamethasone, are used in conjunction with radiotherapy to reduce edema related to tumors in critical areas such as the superior mediastinum, brain, and spinal cord. Frequent lower doses (4–6 mg every 6 h) can have dramatic effects in restoring neurological function in patients with cerebral metastases, but these effects are temporary. However, acute changes in dexamethasone dosage can lead to a rapid recrudescence of symptoms. Dexamethasone should not be discontinued abruptly in patients receiving radiotherapy or chemotherapy for brain metastases. Dexamethasone is also frequently used as part of an antiemetic regimen in patients receiving chemotherapy.

Estrogens and Androgens in Cancer

The pharmacology of the estrogens and androgens is described in detail in Chapters 44 and 45. These agents are of value in certain cancers, most notably those of the prostate and breast, because these organs are dependent on hormones for their growth, function, and morphological integrity.

Hormone Therapy of Breast Cancer

Historically, high doses of estrogen have been recognized as effective treatment of breast cancer. More recent studies have suggested lower doses of estrogen can be effective in the management of endocrine-resistant disease (Ellis et al., 2009). The growth inhibitory effect of estrogens may be related to their ability to induce apoptosis in endocrine-resistant breast cancer (Jordan, 2015; Song and Santen, 2003). However, interruption of estrogen-induced signaling with antiestrogens such as tamoxifen and drugs that reduce estrogen production such as AIs and GnRH analogues have been found to be more effective and better tolerated. These drugs have largely replaced estrogens or androgens for the treatment of breast cancer.

The presence of the ER and PR in breast cancer tissue identifies the subset of hormone-receptor-positive (HR⁺) patients with a more than 60% likelihood of responding to hormonal therapy. The response rate to antiestrogen treatment is somewhat lower in the subset of patients with tumors that are ER⁺ or PR⁺ but also positive for human epidermal growth factor receptor HER2/neu amplification. In contrast, ER-negative and

ADME: absorption, distribution, metabolism, excretion
ADT: androgen deprivation therapy
AI: aromatase inhibitor
ALL: acute lymphoblastic leukemia
AR: androgen receptor
CDK: cyclin-dependent kinase
CLL: chronic lymphocytic leukemia
CRPC: castration-resistant prostate cancer
CYP: cytochrome P450
DHEA: dehydroepiandrosterone
ER: estrogen receptor
ERE: estrogen-response element
FDA: Food and Drug Administration
FSH: follicle-stimulating hormone
HL: Hodgkin lymphoma
HR: hormone receptor
GI: gastrointestinal
GnRH: gonadotropin-releasing hormone
GR: glucocorticoid receptor
HR: hormone receptor (i.e., ER⁺/PR⁺)
LH: luteinizing hormone
MM: multiple myeloma
mTOR: mechanistic target of rapamycin
NCCN: National Comprehensive Cancer Network
NHL: non-Hodgkin lymphoma
PR: progesterone receptor
PSA: prostate-specific antigen
SERD: selective estrogen receptor downregulator
SERM: selective estrogen receptor modulator

PR-negative carcinomas do not respond to hormonal therapy. In patients with metastatic cancer, responses to hormonal therapy may not be apparent clinically or by imaging for 8–12 weeks. The medication typically should be continued until the disease progresses or unwanted toxicities develop.

Antiestrogen approaches for the therapy of HR⁺ breast cancer include the use of SERMs, SERDs, and AIs (Table 68–1).

Drugs That Target the Estrogen Receptor

Selective Estrogen Receptor Modulators. The SERMs bind to the ER and exert either estrogenic or antiestrogenic effects, depending on the specific organ (Chapter 44). Tamoxifen is the most widely studied antiestrogenic drug used in the treatment of breast cancer. Tamoxifen also exerts estrogenic agonist effects on nonbreast tissues, which influences the overall therapeutic index of the drug. Therefore, several novel antiestrogen compounds that offer the potential for enhanced efficacy and reduced toxicity compared with tamoxifen have been developed. These novel antiestrogens can be divided into tamoxifen analogues (e.g., toremifene, droloxifene, idoxifene); “fixed-ring” compounds (e.g., raloxifene, bazedoxifene, lasofoxifene, arzoxifene, miproxifene, levormeloxifene); and the SERDs (e.g., fulvestrant), the latter also termed “pure antiestrogens” (Howell et al., 2004; McDonnell and Wardell, 2010).

Tamoxifen. Tamoxifen was developed as an oral contraceptive but instead was found to induce ovulation and to have antiproliferative effects on estrogen-dependent breast cancer cell lines (Jordan, 2006). Tamoxifen is prescribed for the adjuvant therapy of early-stage breast cancer (Early Breast Cancer Trialists’ Collaborative Group, 2011) and for the therapy of advanced breast cancer (Burstin et al., 2010). Tamoxifen and other SERMs such as raloxifene are also used for the prevention of breast cancer in high-risk patients such as those with a strong family history or prior nonmalignant breast pathology (Visvanathan et al., 2013). The uses,

pharmacology, and mechanism of action of raloxifene are discussed in Chapter 44.

- **Mechanism of Action.** Tamoxifen is a competitive inhibitor of estrogens (e.g., 17 β -estradiol), binding to the ER, and antagonizes estrogen-induced proliferation of human breast cancer. There are two subtypes of ERs: ER α and ER β , which have different tissue distributions and can either homo- or heterodimerize. Binding of estrogen and SERMs to the estrogen-binding sites of the ERs initiates a change in conformation of the ER, dissociation of the ER from heat-shock proteins, and ER dimerization. Dimerization facilitates the binding of the ER to specific DNA EREs in the vicinity of estrogen-regulated genes. Coregulator proteins interact with the liganded receptor to act as corepressors or coactivators of gene expression (Chapter 44). Elegant studies of the crystal structure of ER α bound to different ligands indicate that, when an ER agonist is bound to the ligand-binding domain of the ER, helix 12 enables recruitment of coactivators. Conversely, with an estrogen antagonist such as 4-hydroxytamoxifen bound to the ER, helix 12 is displaced, the binding of coactivators is disrupted, and subsequent estrogen-induced gene transcription is inhibited (Nettles and Greene, 2005). Differences in tissue distribution of the ER subtypes and the function and relative amounts of different transcriptional coregulator proteins likely explains the antagonist response to tamoxifen in ER⁺ breast cancer and partial agonist activities in noncancerous tissues. Organs displaying agonist effects of tamoxifen include the uterine endometrium (endometrial hypertrophy, vaginal bleeding, and endometrial cancer); the coagulation system (thromboembolism); bone metabolism (increase in bone mineral density, which can slow development of osteoporosis); and liver (tamoxifen lowers total serum cholesterol, low-density lipoprotein cholesterol, and lipoproteins and raises apolipoprotein A-I levels).
- **ADME.** Tamoxifen is readily absorbed following oral administration, with peak concentrations measurable after 3–7 h and steady-state levels reached at 4–6 weeks. Metabolism of tamoxifen is complex and principally involves CYPs 3A4/5, and 2D6 in the formation of *N*-desmethyl tamoxifen and CYP2D6 to form 4-hydroxytamoxifen, a more potent metabolite (Figure 68–1). Both metabolites can be further converted to 4-hydroxy-*N*-desmethyltamoxifen (endoxifen), which retains high affinity for the ER. The parent drug has a terminal $t_{1/2}$ of 7 days. After enterohepatic circulation, glucuronides and other metabolites are excreted in the stool; excretion in the urine is minimal. Polymorphisms in CYP2D6 that reduce its activity lead to lower plasma levels of the potent metabolites 4-OH tamoxifen and endoxifen, but whether this leads to inferior efficacy of tamoxifen treatment and higher risks of disease relapse is unclear (Hertz and Rae, 2016). While drugs that inhibit CYP2D6 activity, such as antidepressants, have been postulated to minimize tamoxifen activity in breast cancer, more recent studies do not suggest a clinically significant impact (Haque et al., 2016).
- **Therapeutic Uses.** Tamoxifen is given orally once per day. Tamoxifen is used for the treatment of women with ER⁺ metastatic breast cancer or following primary excision of an ER⁺ tumor as an adjuvant treatment to prevent recurrence and extend overall survival. For the adjuvant treatment of premenopausal women, tamoxifen is given for at least 5 years (Table 68–1). Tamoxifen may also be used for postmenopausal women, but AIs are preferred as they are associated with further reductions in the risk of recurrence (Early Breast Cancer Trialists’ Collaborative Group, 2015). Recent studies indicated that patients with breast cancer derive modest additional benefit, in terms of disease-free survival, overall survival, and decrease in contralateral breast cancer risk, if tamoxifen is taken for up to 10 years or AIs are continued for 5–10 years after completion of 5 years of tamoxifen (Davies et al., 2013; Goss et al., 2016). Of note, while taken for a finite time, Tamoxifen has been shown to have persisting long-term benefits (Ekholm et al., 2016). Tamoxifen may be taken as sole adjuvant therapy or after adjuvant chemotherapy (Table 68–1). Alternative or additional antiestrogen strategies in the adjuvant treatment of premenopausal women with ER⁺ breast cancer include oophorectomy or

suppression of ovarian function with GnRH analogues (Table 68-2) typically given in combination with either tamoxifen or an AI. These combinations used in premenopausal women further reduce estrogen stimulation of breast cancer and result in lower rates of disease recurrence in very young women and in patients receiving chemotherapy

(Francis et al., 2015). Some studies suggested improved response rates with these combinations in patients with metastatic disease. Tamoxifen also has shown effectiveness (a 40%–50% reduction in tumor incidence) in preventing breast cancer in women at increased risk (Fisher et al., 1998). In the preventive setting, tamoxifen reduces

Figure 68-1 Tamoxifen and its metabolites.

only ER⁺ tumors, not ER-negative tumors, and does not affect overall mortality.

- **Toxicity.** The common adverse reactions to tamoxifen include vasomotor symptoms (hot flashes), atrophy of the lining of the vagina, menstrual irregularities, vaginal bleeding and discharge, and pruritus vulvae and occur with increasing severity in postmenopausal women. Because of partial agonist activity, tamoxifen also increases the incidence of endometrial cancer by 2- to 3-fold, particularly in postmenopausal women who receive tamoxifen for more than 2 years. Tamoxifen slightly increases the risk of thromboembolic events, which increase with the age of a patient and also in the perioperative period. Hence, it often is advisable to temporarily halt tamoxifen prior to elective surgery. Tamoxifen can cause retinal deposits, decreased visual acuity, and cataracts, although these changes are uncommon.
- **Endocrine Resistance.** Initial or acquired resistance to endocrine therapies (tamoxifen or AIs) frequently occurs (Moy and Goss, 2006). Multiple mechanisms contribute to endocrine resistance in breast cancer (Clarke et al., 2015); these mechanisms include loss of ER expression, changes in coregulator expression, and hormone-independent activation of the ER by stress kinase or growth factor-activated cellular kinase pathways. In particular, cross talk between the ER and the HER2/neu pathway has been implicated in tamoxifen resistance. In a significant portion of metastatic breast cancers, estrogen-deprivation therapy can lead to selection of cancer cells expressing an ER with mutations that allow hormone-independent activation. Acquired ER mutations also contribute to endocrine-resistant breast cancer growth (Jeselsohn et al., 2015).

Toremifene. Toremifene is a triphenylethylene derivative of tamoxifen and has a similar pharmacological profile, clinical efficacy, and safety (Howell et al., 2004). Toremifene is used occasionally in the metastatic setting for the treatment of breast cancer in women with tumors that are ER⁺ or of unknown receptor status. In rare cases, toremifene can cause heart rhythm problems through prolongation of the QT interval.

Selective Estrogen Receptor Downregulators. The SERDS, also termed *pure antiestrogens*, include fulvestrant and a number of agents in experimental trials. SERDs, unlike SERMs, are devoid of any estrogen agonist activity.

Fulvestrant. Fulvestrant is currently the only FDA-approved SERD, either as a single agent or in combination with palbociclib, a CDK4/6 inhibitor (Chapter 67), for postmenopausal women with HR⁺ metastatic breast cancer that has progressed on antiestrogen therapy.

Mechanism of Action. Fulvestrant is a steroidal antiestrogen that binds to the ER with an affinity more than 100 times that of tamoxifen. The drug not only inhibits the binding of estrogen but also alters the receptor structure such that the receptor is targeted for proteasomal degradation; fulvestrant also may inhibit receptor dimerization. Unlike tamoxifen, which stabilizes or even increases ER expression, fulvestrant reduces the number of ER molecules in cells; as a consequence of this ER downregulation, the drug abolishes ER-mediated transcription of estrogen-dependent genes.

ADME. Fulvestrant is given intramuscularly with initial biweekly loading doses in the first month followed by once monthly injections thereafter. Using this dosing regimen, steady-state levels are achieved within the first month (Robertson et al., 2014) (Table 68-1). Peak plasma concentrations are reached about 7 days after intramuscular administration of fulvestrant and the plasma *t*_{1/2} is about 40 days. There is rapid distribution and extensive protein binding of this highly lipophilic drug. Various pathways, similar to those of steroid metabolism (oxidation, aromatic hydroxylation, and conjugation), metabolize fulvestrant. CYP3A4 appears to be the major CYP isoenzyme involved in the metabolism of fulvestrant. The putative metabolites possess no estrogenic activity, and only the 17-keto compound demonstrates a level of antiestrogenic activity (~22% that of fulvestrant). Less than 1% of the parent drug is excreted intact in the urine.

Therapeutic Uses. Fulvestrant is used in postmenopausal women as antiestrogen therapy of HR⁺ metastatic breast cancer after progression on first-line antiestrogen therapy such as tamoxifen or an AI. Fulvestrant is at least as effective in this setting as the third-generation AI anastrozole. Recently, the addition of a CDK4/6 inhibitor (Chapter 67) to fulvestrant

treatment has been shown to prolong disease-free survival (Turner et al., 2015).

Toxicity and Adverse Effects. Fulvestrant generally is well tolerated, the most common adverse effects being nausea, asthenia, pain, hot flashes, arthralgias, and headache. The risk of injection site reactions, seen in almost 10% patients, is reduced by giving the injection slowly.

Drugs That Decrease Estrogen Levels

Aromatase Inhibitors. Aromatase converts androgens to estrogens (e.g., androstenedione to estrone). AIs (Figure 68–2) block this enzymatic activity, thereby reducing estrogen production (Figure 67–3). AIs are now considered the standard of care for adjuvant treatment of postmenopausal women with ER⁺ breast cancer, either as initial therapy or after tamoxifen. (Dowsett et al., 2010). AIs are also approved in the initial treatment of metastatic HR⁺ breast cancer, often in combination with CDK4/6 inhibitors, and for disease that has progressed following tamoxifen treatment in postmenopausal women.

Aromatase (CYP19A1) is responsible for the conversion of adrenal androgens and gonadal androstenedione and testosterone to the estrogens estrone (E1) and estradiol (E2), respectively (Figure 68–3; reactions catalyzed by aromatase are noted by a green *A* beside the reaction arrow). In postmenopausal women, this conversion occurs in nonovarian tissues (fat, liver, muscle, brain, breast, and breast tumors) and is the primary source of circulating estrogens. In premenopausal women, estrogen is primarily produced in the ovaries. AIs increase gonadotropin production in premenopausal women, which reduces their ability to inhibit ovarian estrogen production. As a result, AIs are not effective in premenopausal women without additional ovarian suppression (e.g., with GnRH analogues; see the next section and Table 68–2). In postmenopausal women, AIs suppress most peripheral aromatase activity, leading to profound estrogen deprivation. AIs are classified as first, second, or third generation. In addition, they are further classified as type 1 (steroidal) or type 2 (nonsteroidal) AI according to their structure and mechanism of action (Figure 68–2). Type 1 inhibitors are steroidal analogues of androstenedione that bind covalently and irreversibly to the same site on the

aromatase molecule. Thus, they commonly are known as aromatase inactivators. Type 2 inhibitors are nonsteroidal and bind reversibly to the heme group of the enzyme, producing reversible inhibition.

Third-Generation Aromatase Inhibitors. First- and second-generation (e.g., aminoglutethimide, formestane) AIs are no longer used for breast cancer treatment because of their side effects. Third-generation inhibitors include the type 1 steroidal agent *exemestane* and the type 2 nonsteroidal imidazoles *anastrozole* and *letrozole*; they are approved for use in postmenopausal women (Brodie and Njar, 2000). Third-generation AIs are used as part of the treatment of early-stage and advanced breast cancer in postmenopausal women and for chemoprevention (Table 68–1). The type 1 and 2 AIs have similar clinical efficacy and toxicity profiles (Goss et al., 2013), and these are summarized for AIs using anastrozole as a prototype. For letrozole and exemestane, additional drug-specific information is given.

- **Anastrozole.** Anastrozole is a potent and selective triazole AI. Anastrozole, like letrozole, binds competitively and specifically to the heme of the CYP19. Daily administration of AIs reduces total body androgen aromatization by more than 95% after 1 month of treatment. AIs also reduce aromatization within large ER⁺ breast tumors.
- **ADME.** Anastrozole is absorbed rapidly after oral administration. Steady state is attained after 7 days of repeated dosing. Anastrozole is metabolized by *N*-dealkylation, hydroxylation, and glucuronidation. The main metabolite of anastrozole is a triazole. Less than 10% of the drug is excreted as the unmetabolized parent compound. The principal excretory pathway is via the liver and biliary tract. The elimination $t_{1/2}$ is about 50 h. The pharmacokinetics of anastrozole, which can be affected by drug interactions via the CYP system, are not altered by coadministration of tamoxifen or cimetidine.
- **Therapeutic Uses.** AIs are approved for up-front adjuvant hormonal therapy for 5–10 years or following prior tamoxifen in postmenopausal women with early-stage breast cancer and as treatment of advanced and metastatic breast cancer. In early-stage breast cancer, anastrozole is significantly more effective than tamoxifen in delaying time to

Figure 68–2 Aromatase and its inhibitors. Aromatase trihydroxylates the methyl group at C19, eliminating it as formate and aromatizing the A ring of the androgen substrate. Type 1 AIs are steroidal analogues of androstenedione that bind covalently and irreversibly to the steroid substrate site on the enzyme and are known as aromatase inactivators. Type 2 inhibitors are nonsteroidal, bind reversibly to the heme group of the enzyme, and produce reversible inhibition.

Figure 68-3 Steroid synthesis pathways. The shaded area contains the pathways used by the adrenal glands and gonads and clinically used agents that inhibit the pathways. Enzymes are labeled in green, inhibitors in red. Pertaining to this figure only, A, aromatase; 3 β , 3 β -hydroxysteroid dehydrogenase; 5 α R, 5 α -reductase; 11 β , 11 β -hydroxylase; 17, 20, C-17, 20-lyase (also CYP17); 17 α , 17 α -hydroxylase (CYP17); 17 β R, 17 β -reductase; 18, aldosterone synthase; 21, 21-hydroxylase.

tumor recurrence and decreasing the odds of a primary contralateral tumor. In advanced breast cancer, postmenopausal women with disease progression while taking tamoxifen showed a significant survival advantage with anastrozole versus megestrol acetate (see Progestins, next section). Additionally, in women with ER⁺ or PR⁺ metastatic breast cancer, anastrozole was significantly better than tamoxifen in median time to disease progression. AIs are used in premenopausal women combined with ovarian suppression, as adjuvant treatment of breast cancer in premenopausal women less than 35 years of age, and in women requiring chemotherapy, where AI use is associated with significant reduction in risk of recurrence.

- **Adverse Effects and Toxicity.** Most adverse effects are related to estrogen depletion. In postmenopausal women, compared to tamoxifen, anastrozole has been associated with a lower incidence of hot flashes, vaginal bleeding, vaginal discharge, endometrial cancer, ischemic cerebrovascular events, venous thromboembolic events, and deep venous thrombosis, including pulmonary embolism. Anastrozole is associated with a higher incidence of symptomatic arthralgias, vaginal dryness, and sexual dysfunction than tamoxifen. In addition, the estrogen depletion caused by AIs results in loss of bone mineral density. Compared with tamoxifen, treatment with anastrozole results in significantly lower bone mineral density in the lumbar spine and total hip and has been associated with increased fracture risk. Bisphosphonates (Chapter 48) prevent AI-induced loss of bone mineral density in postmenopausal women.
- **Letrozole.** The clinical uses and side-effect profile of the type 2 AI letrozole are similar to that detailed in the previous section for anastrozole (Table 68-1). Letrozole-specific information is as follows:
 - **ADME.** Letrozole is rapidly absorbed after oral administration, with a bioavailability of 99.9%. Steady-state plasma concentrations of letrozole are reached after 2–6 weeks of treatment. Following metabolism by CYP2A6 and CYP3A4, letrozole is eliminated as an inactive metabolite mainly via the kidneys and has a $t_{1/2}$ of about 41 h.
 - **Therapeutic Uses.** The clinical indications for use of letrozole in breast cancer treatment are the same as for anastrozole (Table 68-1).

In addition, improved progression-free survival is observed when HR⁺ advanced stage breast cancer is treated with letrozole in combination with a CDK4/6 inhibitor (Chapter 67) (Finn et al., 2015; Hortobagyi et al., 2016).

- **Exemestane.** Exemestane is a more potent, orally administered analogue of the natural aromatase substrate androstenedione and lowers estrogen levels more effectively than does its predecessor, formestane. Exemestane irreversibly inactivates aromatase and is a “suicide substrate” type 1 inhibitor of aromatase. The clinical uses and side-effect profile of exemestane are similar to that detailed in the section for the AI anastrozole. Exemestane-specific information is as follows:
 - **ADME.** Orally administered exemestane is rapidly absorbed from the GI tract; its absorption is increased by 40% after a high-fat meal. Exemestane has a terminal $t_{1/2}$ of about 24 h. It is extensively metabolized in the liver, ultimately to inactive metabolites. One metabolite, 17-hydroxyexemestane, has weak androgenic activity that may contribute to antitumor activity. Although active metabolites are excreted in the urine, no dosage adjustments are recommended in patients with renal dysfunction.
 - **Therapeutic Uses.** The clinical indications for use of exemestane in breast cancer treatment are the same as for anastrozole (Table 68-1). In addition, the use of the mTOR inhibitor everolimus (Chapter 67) with exemestane has been approved for treatment of advanced-stage breast cancer that has progressed on nonsteroidal type 2 AIs (Yardley et al., 2013).

GnRH Agonists. Synthetic GnRH analogues (e.g., triptorelin, goserelin, leuprolide; Table 68-2) have greater receptor affinity and reduced susceptibility to enzymatic degradation than the naturally occurring decapeptide GnRH molecule and are 100-fold more potent GnRH agonists than the native decapeptide. They are used in the adjuvant treatment of breast cancer or metastatic disease for women who have functioning ovaries; typically, they are used in combination with either tamoxifen or AIs. Continuous administration of GnRH agonists downregulates GnRH receptors in the pituitary gland. This suppresses the release of the gonadotropins FSH and LH from the pituitary and prevents follicular maturation

in the ovary. Serum estrogen levels are reduced to those seen in postmenopausal women or in women after oophorectomy.

ADME. GnRH agonists are administered as an injection once a month or every 3 or 6 months. There is an initial rise in LH and FSH levels, but after 14–21 days of therapy, a sustained decrease in serum LH and estrogen is observed.

Therapeutic Uses. In the adjuvant setting, recent studies have demonstrated a benefit for GnRH agonists when given in conjunction with either AIs or tamoxifen in very young or higher-risk premenopausal women (Regan et al., 2016). In addition, these drugs can be given with tamoxifen, AIs, or fulvestrant in premenopausal women with metastatic breast cancer.

Toxicity. Side effects are generally related to hypoestrogenism (i.e., hot flashes, vaginal dryness, decreased libido, osteoporosis, amenorrhea, and dyspareunia). The side effects of GnRH agonists are potentially reversible on cessation of therapy. AI use in premenopausal women combined with ovarian suppression with GnRH analogues increases menopausal symptoms and sexual dysfunction and thus benefits and risks must be carefully considered (Burstein et al., 2016).

Drugs That Target the Progesterone Receptor

Progestational agents (see Chapter 44 for details) are mainly used as secondary agents in hormonal therapy for metastatic hormone-dependent breast cancer and are also used in the management of endometrial carcinoma previously treated by surgery and radiotherapy. Progesterone binds to the PR present in target tissues, such as breast and the endometrium (Chapter 44). Activation of the PR by progestins in the endometrium is antiproliferative.

Medroxyprogesterone acetate is available for oral administration; an alternative oral progestational agent is *megestrol acetate*. Beneficial effects have been observed in one-third of patients with endometrial cancer. The response of breast cancer to megestrol is predicted by both the presence of HRs (ER and PR) and the evidence of response to a prior hormonal treatment. The effect of progestin therapy in breast cancer appears to be dose dependent, with some patients demonstrating second responses following dose escalation of megestrol. Clinical use of progestins in breast cancer has been largely superseded by the advent of tamoxifen and AIs. An additional use of progestins is to stimulate appetite and restore a sense of well-being in cachectic patients with advanced stages of cancer and AIDS.

Hormone Therapy of Prostate Cancer

Androgens stimulate the growth of normal and cancerous prostate cells. The critical role of androgens for prostate cancer growth was established in 1941 and led to the awarding of a Nobel Prize in 1966 to Dr. Charles Huggins. These findings established androgen deprivation therapy (ADT) as the mainstay of treatment for patients with advanced prostate cancer. ADT is also given in conjunction with radiation therapy or following surgery for some men with regionally localized intermediate- to high-risk disease. In patients with metastasis, ADT is typically the standard first-line treatment. ADT is accomplished via surgical castration (bilateral orchiectomy) or medical castration (using GnRH agonists or antagonists). Other hormone therapy approaches that are used as second-line treatment include antiandrogens, estrogens, and inhibitors of steroidogenesis. In the advanced setting, ADT is not a curative treatment but does prolong survival. ADT alleviates cancer-related symptoms and provides important quality-of-life benefits, including reduction of bone pain and reduction of rates of pathological fracture, spinal cord compression, and ureteral obstruction.

Disease progression despite ADT signifies the development of castration-resistant prostate cancer (CRPC). In CRPC, the AR can be overexpressed or mutated and can be activated by weak adrenal androgens or from androgens produced locally in tumors. Therefore, antiandrogens (competitive antagonists of androgens at the AR), inhibitors of steroidogenesis, or estrogens are frequently employed as second-line hormone therapies and are associated with improvements in symptoms and quality of life and with prolongation in survival (Ritch and Cookson, 2016). Antiandrogens are typically administered concurrently with GnRH analogues or in men who have undergone orchiectomy. When patients

become refractory to further hormonal therapies, their disease is considered androgen independent.

Common side effects of androgen deprivation include vasomotor instability, loss of libido, impotence, gynecomastia, fatigue, anemia, weight gain, decreased insulin sensitivity, altered lipid profiles, osteoporosis and fractures, and loss of muscle mass. ADT is associated with a slight but significant increased risk of diabetes and coronary heart disease. Skeletal-related events due to ADT may be mitigated by bisphosphonate therapy (see Chapter 48). Antiandrogens, when compared with GnRH agonists, cause more gynecomastia, mastodynia, and hepatotoxicity but less vasomotor flushing and loss of bone mineral density. Estrogens cause a hypercoagulable state and increase cardiovascular mortality in patients with prostate cancer and are no longer standard treatment options.

Androgen Deprivation Therapy

GnRH Agonists and Antagonists. The most common form of ADT involves chemical suppression of the pituitary gland with GnRH agonists (see previous section). GnRH agonists in common use for prostate cancer include *leuprolide*, *goserelin*, *triptorelin*, *histrelin*, and *nafarelin* (Table 68–2). Long-acting preparations are available in doses that are approved for 3-, 4-, and 6-month administrations.

The GnRH agonists bind to GnRH receptors on pituitary gonadotropin-producing cells, causing an initial release of both LH and FSH and a subsequent increase in testosterone production from testicular Leydig cells. After 1 week of therapy, GnRH receptors are downregulated on the gonadotropin-producing cells, causing a decline in the pituitary response. The fall in serum LH leads to a decrease in testosterone production to castrate levels within 3–4 weeks of the first treatment. Subsequent treatments maintain testosterone at castrate levels.

ADT is given in patients with localized intermediate- to high-risk prostate cancer in conjunction with radiation therapy or in some cases following surgery. In patients with metastasis, ADT is typically the standard first-line treatment either alone or in combination with chemotherapy. In patients with CRPC, ADT is used in conjunction with antiandrogens. This combination therapy is referred to as *combined androgen blockade*. The theoretical advantage is that the GnRH agonist will deplete testicular androgens, while the antiandrogen component competes at the receptor with residual androgens made by the adrenal glands. Combined androgen blockade provides maximal relief of androgen stimulation. Several trials suggested a benefit in 5-year survival, but toxicity and costs associated are higher than with ADT alone.

Toxicity. During the transient rise in LH, the resultant testosterone surge may induce acute stimulation of prostate cancer growth and a “flare” of symptoms from metastatic deposits. Patients may experience an increase in bone pain, spinal cord compression, or obstructive bladder symptoms lasting for 2–3 weeks. The flare phenomenon can be effectively counteracted with concurrent administration of 2–4 weeks of oral antiandrogen therapy, which may inhibit the action of the increased serum testosterone levels. Besides avoidance of the initial flare, GnRH antagonist therapy offers no apparent advantage compared with GnRH agonists. The early GnRH antagonists *cetrorelix* and *abarelix* (no longer marketed), although effective, are now rarely used for prostate cancer because of the risk for severe systemic allergic reactions. A newer GnRH antagonist, *degarelix*, is not associated with systemic allergic reactions and is approved for prostate cancer in the U.S.

Drugs That Target the Androgen Receptor. Antiandrogens bind to ARs and competitively inhibit the binding of testosterone and dihydrotestosterone, thereby preventing AR nuclear translocation and inhibiting transcription of downstream androgen-responsive genes. Unlike castration, antiandrogen therapy by itself does not decrease LH production; therefore, testosterone levels are normal or increased. Men treated with antiandrogen maintain some degree of potency and libido and do not have the same spectrum of side effects seen with castration. However, antiandrogen therapy is typically given in combination with ADT. Antiandrogens are classified as steroidal, including *cypoterone* or nonsteroidal, including *enzalutamide*, *flutamide*, *bicalutamide*, and *nilutamide*.

Enzalutamide. Enzalutamide is the most recently FDA-approved second-generation antiandrogen. It prolongs survival in patients with metastatic CRPC when given to chemotherapy naïve patients or after docetaxel therapy (Beer et al., 2014; Scher et al., 2012). Enzalutamide is a synthetic nonsteroidal antiandrogen that has 5- to 8-fold higher binding affinity for the AR compared to bicalutamide (Tran et al., 2009). Similar to other antiandrogens, enzalutamide prevents binding of androgens to the AR and reduces binding of AR to DNA and to AR coactivator proteins (see Chapter 45). Enzalutamide can also prevent translocation of AR into the cell nucleus and induces cell apoptosis.

- **ADME.** Enzalutamide has improved efficacy and potency compared to older antiandrogens. Enzalutamide is given orally once daily with a $t_{1/2}$ of approximately 6 days. Steady-state levels are achieved in 28 days. CYP2C8 is primarily responsible for the formation of the active metabolite *N*-desmethyl enzalutamide.
- **Toxicity.** Similar to other antiandrogens, enzalutamide has negative effects on sexual function. Other notable side effects include gynecomastia, breast pain, fatigue, diarrhea, headache, and hot flashes. Enzalutamide crosses the blood-brain barrier, and seizures occur infrequently in approximately 1% of patients. Resistance to AR inhibitors develops frequently through mechanisms such as gene rearrangement, mutation, and acquired AR splice variants (Li et al., 2013). Studies are ongoing with newer AR-blocking agents that may overcome resistance to current antiandrogen therapies (Moilanen et al., 2015; Smith et al., 2016).

Bicalutamide. The agent bicalutamide is given once daily in conjunction with a GnRH agonist. Bicalutamide has a $t_{1/2}$ of 5–6 days. Bicalutamide undergoes glucuronidation to inactive metabolites, and the parent compound and metabolites are eliminated in bile and urine. The $t_{1/2}$ of bicalutamide is increased in severe hepatic insufficiency and is unchanged in renal insufficiency. Bicalutamide is well tolerated at higher doses and has reduced toxicity and improved tolerability and pharmacokinetic profiles relative to flutamide and nilutamide. Daily bicalutamide is significantly inferior compared with surgical or medical castration and should not be used as monotherapy of prostate cancer.

Nilutamide. Nilutamide is given orally once daily. It has an elimination $t_{1/2}$ of 45 h and is metabolized to five products that are all excreted in the urine. Common side effects include mild nausea, alcohol intolerance (5%–20%), and diminished ocular adaptation to darkness (25%–40%); rarely, interstitial pneumonitis occurs.

Flutamide. Flutamide is given orally three times per day. It has a $t_{1/2}$ of 5 h; its major metabolite, hydroxyflutamide, is biologically active. Common side effects include diarrhea, breast tenderness, and nipple tenderness. Less commonly, nausea, vomiting, and hepatotoxicity occur. Rare reports of fatal hepatotoxicity have been observed. It is used infrequently as it has the least-favorable toxicity profile of the antiandrogens.

Drugs That Inhibit Androgen Synthesis. In the castrate state, AR signaling, despite low steroid levels, supports continued prostate cancer growth. AR signaling may occur due to androgens produced from nongonadal sources, AR gene mutations, or AR gene amplification. Nongonadal sources of androgens include the adrenal glands and the prostate cancer cells themselves (see Figure 68–3). Androstenedione, produced by the adrenal glands, is converted to testosterone in peripheral tissues

and tumors. Intratumoral de novo androgen synthesis also may provide sufficient androgen for AR-driven cell proliferation. Thus, inhibitors of androgen synthesis may be useful as secondary therapy in reducing AR signaling.

Ketoconazole. Ketoconazole is an antifungal agent that also inhibits both testicular and adrenal steroidogenesis by blocking CYP 11A and primarily CYP17 (17 α -hydroxylase). Ketoconazole is administered off label as secondary hormone therapy to reduce adrenal androgen synthesis in CRPC. Diarrhea and hepatic enzyme elevations limit its use as initial hormone therapy; consequent poor patient compliance reduces its efficacy. Oral ketoconazole is coadministered with hydrocortisone to compensate for inhibition of adrenal steroidogenesis. Ketoconazole has limited use in practice due to its toxicity.

Abiraterone. Abiraterone is used with prednisone for the treatment of CRPC in patients who are chemotherapy naïve or in those who have received previous docetaxel. In both settings, it prolongs survival (de Bono et al., 2011; Ryan et al., 2015).

- **Mechanism of Action.** Abiraterone is an irreversible inhibitor of 17 α -hydroxylase and C-17,20-lyase (CYP17A1) activity in testicular, adrenal and prostatic cancer tissue (Figure 68–3). Abiraterone inhibition of CYP17A1 reduces the conversion of pregnenolone and progesterone to their 17 α -hydroxy derivatives and reduces the synthesis of DHEA and androstenedione. Thus, circulating levels of testosterone drop to almost-undetectable levels after abiraterone administration. Abiraterone also has some activity as an AR antagonist and inhibitor of other steroid synthetic enzymes and CYP450s. Overall, abiraterone has greater potency and selectivity than ketoconazole.
- **ADME.** Abiraterone is the active metabolite of abiraterone acetate. With continuous administration, abiraterone increases ACTH levels, resulting in mineralocorticoid excess. Oral abiraterone acetate is administered with prednisone to counteract adrenal suppression. Abiraterone should be taken on an empty stomach. Abiraterone C_{max} and AUC are both increased more than 10-fold when a single dose of abiraterone acetate is administered after food compared to a fasted state.
- **Toxicity.** Side effects include hepatotoxicity, joint swelling, hypokalemia, vasomotor symptoms, diarrhea, cough, hypertension, arrhythmia, urinary frequency, dyspepsia, and upper respiratory tract infection. Resistance to abiraterone, similar to enzalutamide, can occur through selection of tumor cells expressing constitutively active AR splice variants (Antonarakis et al., 2014).

Estrogens

High estrogen levels can reduce testosterone to castrate levels in 1–2 weeks via negative feedback on the hypothalamic-pituitary axis. Estrogen also may compete with androgens for steroid HRs and may thereby exert a cytotoxic effect on prostate cancer cells. Although estrogens reduce bone loss and are as effective as orchiectomy for metastatic prostate cancer, they are no longer used clinically because of their risk for serious and potentially fatal side effects (e.g., myocardial infarctions, strokes, pulmonary emboli) as well as impotence and lethargy.

Acknowledgment: Paul Calabresi, Bruce Chabner, Beverly Moy, Richard J. Lee, and Matthew Smith contributed to this chapter in recent editions of this book. We have retained some of their text in the current edition.

The eye is a specialized sensory organ that is relatively secluded from systemic access by the blood-retinal, blood-aqueous, and blood-vitreous barriers. As a consequence, the eye exhibits some unusual pharmacodynamic and pharmacokinetic properties.

Extraocular Structures

The eye is protected by the eyelids and by the orbit, a bony cavity of the skull that has multiple fissures and foramina that conduct nerves, muscles, and vessels (Figure 69–1). In the orbit, connective (i.e., *Tenon's capsule*) and adipose tissues and six extraocular muscles support and align the eyes for vision. The retrobulbar region lies immediately behind the eye (or *globe*). Understanding ocular and orbital anatomy is important for safe periocular drug delivery, including subconjunctival, sub-Tenon, and retrobulbar injections.

The external surface of the eyelids is covered by a thin layer of skin; the internal surface is lined with the palpebral portion of the conjunctiva, which is a vascularized mucous membrane continuous with the bulbar conjunctiva. At the reflection of the palpebral and bulbar conjunctivae is a space called the *fornix*, located superiorly and inferiorly behind the upper and lower eyelids, respectively. Topical medications usually are placed in the inferior fornix, also known as the *inferior cul-de-sac*.

The lacrimal system consists of secretory glandular and excretory ductal elements (Figure 69–2). The secretory system is composed of the main *lacrimal gland*, which is located in the temporal outer portion of the orbit, and accessory glands located in the conjunctiva. The lacrimal gland is innervated by the autonomic nervous system (Table 69–1 and Chapter 8). The parasympathetic innervation is clinically relevant because a patient may complain of dry eye symptoms while taking medications with anticholinergic side effects, such as tricyclic antidepressants (see Chapter 15), antihistamines (see Chapter 39), and drugs used in the management of Parkinson disease (see Chapter 18). Muscarinic cholinergic and α -adren-ergic receptors that mediate responses of several pupillary muscles from autonomic nerves also provide means of dilating the pupil for examination of posterior structures.

Tears constitute a functionally trilaminar lubrication barrier covering the conjunctiva and cornea. The anterior tear layer is composed primarily of lipids; the middle aqueous layer, produced by the main lacrimal gland and accessory lacrimal glands, constitutes about 98% of the tear film. Adherent to the corneal epithelium, the posterior layer is a mixture of mucins produced by goblet cells in the conjunctiva. Tears also contain nutrients, enzymes, and immunoglobulins to support and protect the cornea. The tear drainage system starts through small puncta located on the medial aspects of both the upper and lower eyelids (see Figure 69–2). With blinking, tears enter the puncta and continue to drain through the canaliculi, lacrimal sac, nasolacrimal duct, and then into the nose. The nose is lined by a highly vascular mucosal epithelium; consequently, topically applied medications that pass through this nasolacrimal system have direct access to the systemic circulation.

Ocular Structures

The eye is divided into anterior and posterior segments (Figure 69–3A). Anterior segment structures include the cornea, limbus, anterior and posterior chambers, trabecular meshwork, canal of Schlemm (Schlemm's canal), iris, lens, ciliary zonule, and ciliary body. The posterior segment includes the vitreous, retina, choroid, sclera, and optic nerve.

Anterior Segment

Cornea and Drug Access

The cornea is a transparent and avascular tissue organized into five (or six) layers (Figure 69–3B). Representing an important barrier to foreign matter, including drugs, the hydrophobic epithelial layer comprises five or six cell layers. The basal epithelial cells lie on a basement membrane that is adjacent to Bowman's layer, a distinct sheet of collagen fibers. Constituting about 90% of the corneal thickness, the stroma, a hydrophilic layer, is organized with collagen lamellae synthesized by keratocytes. Beneath the stroma lies Descemet's membrane, the basement membrane of the corneal endothelium. A new corneal layer, Dua's layer, has been proposed—a

distinct thin, but strong, collagen layer between the stroma and Descemet's membrane (Dua et al., 2013). Lying most posteriorly, the endothelium is a monolayer of cells adhering to each other by tight junctions. These cells maintain corneal dehydration by active transport processes and serve as a hydrophobic barrier. *Hence, drug absorption across the cornea requires penetration of the trilaminar hydrophobic-hydrophilic-hydrophobic domains of the various anatomical layers.*

At the periphery of the cornea and adjacent to the sclera lies a transitional zone (1- to 2-mm wide) called the *limbus*. Limbal structures include the conjunctival epithelium, which contains the corneal epithelial stem cells; Tenon's capsule; episclera; corneoscleral stroma; canal of Schlemm; and trabecular meshwork (see Figure 69–3B). Limbal blood vessels, as well as the tears, provide important nutrients and immunological defense mechanisms for the cornea. The anterior chamber holds about 250 μL of aqueous humor. The peripheral anterior chamber angle is formed by the cornea and the iris root. The trabecular meshwork and canal of Schlemm are located just above the apex of this angle. The posterior chamber, with about 50 μL of aqueous humor, is defined by the boundaries of the ciliary body processes, posterior surface of the iris, and lens surface.

Aqueous Humor Dynamics and Regulation of Intraocular Pressure

Aqueous humor is secreted by the ciliary processes and flows from the posterior chamber, through the pupil, and into the anterior chamber and leaves the eye primarily by the trabecular meshwork and canal of Schlemm, thence to an episcleral venous plexus and into the systemic circulation. This conventional pathway accounts for 80%–95% of aqueous humor outflow and is the main target for cholinergic drugs used in glaucoma therapy. Another outflow pathway is the uveoscleral route (i.e., fluid flows through the ciliary muscles and into the suprachoroidal space), which is the target of selective prostanoids (see Glaucoma in this chapter).

The peripheral anterior chamber angle is an important anatomical structure for differentiating two forms of glaucoma: *open-angle glaucoma*, which is by far the most common form of glaucoma in the U.S., and *angle-closure or closed-angle glaucoma*. Current medical therapy of open-angle glaucoma is aimed at decreasing aqueous humor production or increasing aqueous outflow. The preferred management for angle-closure glaucoma is surgical iridectomy, by either laser or incision, but short-term medical management may be necessary to reduce the acute IOP elevation and to clear the cornea prior to surgery. Long-term IOP reduction may be necessary, especially if the peripheral iris has permanently covered the trabecular meshwork.

In anatomically susceptible eyes, anticholinergic, sympathomimetic, and antihistaminic drugs can lead to partial dilation of the pupil and a change in the vectors of force between the iris and the lens. The aqueous humor then is prevented from passing from the posterior chamber

Figure 69–1 Anatomy of the globe in relation to the orbit and eyelids. Routes of administration of anesthesia are represented by the blue needles.

Figure 69–2 Anatomy of the lacrimal system.

through the pupil to the anterior chamber. The change in the lens-iris relationship leads to an increase in pressure in the posterior chamber, causing an anterior bowing of the iris, causing the iris root to be pushed against the angle wall, thereby covering the trabecular meshwork and closing the filtration angle and markedly elevating the IOP. The result is known as an acute attack of *pupillary-block angle-closure glaucoma*.

Iris and Pupil

The iris is the most anterior portion of the uveal tract, which also includes the ciliary body and choroid. The anterior surface of the iris is the stroma, a loosely organized structure containing melanocytes, blood vessels, smooth muscle, and parasympathetic and sympathetic nerves. Differences in iris color reflect individual variation in the number of melanocytes located in the stroma. Individual variation may be an important consideration for ocular drug distribution due to drug-melanin binding (see Distribution). The posterior surface of the iris is a densely pigmented bilayer of epithelial cells. Anterior to the pigmented epithelium, the dilator smooth muscle is oriented radially and is innervated by the sympathetic nervous system (Figure 69–4), which causes *mydriasis* (dilation). At the pupillary margin, the sphincter smooth muscle is organized in a circular band with parasympathetic innervation, which, when stimulated, causes *miosis* (constriction). The use of pharmacological agents to dilate normal pupils and to evaluate the pharmacological response of the pupil is summarized in Table 69–2. Agents affecting sympathetic neurotransmission

in the eye are also used for the diagnostic evaluation of Horner syndrome and anisocoria.

Ciliary Body

The ciliary body serves two very specialized roles:

- Production and secretion of aqueous humor by the epithelial bilayer
- Accommodation by the ciliary muscle

The anterior portion of the ciliary body (*pars plicata*) comprises 70–80 ciliary processes with intricate folds. The posterior portion is the *pars plana*. The ciliary muscle is organized into outer longitudinal, middle radial, and inner circular layers. Coordinated contraction of this smooth muscle apparatus by the parasympathetic nervous system causes the zonular fibers suspending the lens to relax, allowing the lens to become more convex and to shift slightly forward. This process, known as *accommodation*, permits focusing on near objects and may be pharmacologically blocked by muscarinic cholinergic antagonists through a process called *cycloplegia*. Contraction of the ciliary muscle also puts traction on the scleral spur and hence widens the spaces within the trabecular meshwork. This last effect accounts for at least some of the IOP-lowering effect of directly acting and indirectly acting parasympathomimetic drugs. Blockade of β adrenergic receptors of the ciliary epithelium decreases production of aqueous humor.

TABLE 69–1 ■ AUTONOMIC PHARMACOLOGY OF THE EYE AND RELATED STRUCTURES

TISSUE	ADRENERGIC RECEPTORS		CHOLINERGIC RECEPTORS	
	SUBTYPE	RESPONSE	SUBTYPE	RESPONSE
Corneal epithelium	β_2	Unknown	M ^a	Unknown
Corneal endothelium	β_2	Unknown	Undefined	Unknown
Iris radial muscle	α_1	Mydriasis		
Iris sphincter muscle			M ₃	Miosis
Trabecular meshwork	β_2	Unknown		
Ciliary epithelium ^b	α_2/β_2	Aqueous production		
Ciliary muscle	β_2	Relaxation ^c	M ₃	Accommodation
Lacrimal gland	α_1	Secretion	M ₂ , M ₃	Secretion
Retinal pigment epithelium	α_1/β_2	H ₂ O transport/unknown		

^aAlthough acetylcholine and choline acetyltransferase are abundant in the corneal epithelium of most species, the function of acetylcholine in this tissue is unknown.

^bThe ciliary epithelium also is the target of carbonic anhydrase inhibitors. Carbonic anhydrase isoenzyme II is localized to both the pigmented and nonpigmented ciliary epithelium.

^cAlthough β_2 adrenergic receptors mediate ciliary body smooth muscle relaxation, there is no clinically significant effect on accommodation.

Figure 69-3 A. Anatomy of the eye. B. Enlargement of the anterior segment, revealing the cornea, angle structures, lens, and ciliary body. (Adapted with permission from Riordan-Eva P. Anatomy and embryology of the eye. In: Riordan-Eva P, Whitcher JP, eds. *Vaughan & Asbury's General Ophthalmology*. 17th ed. McGraw-Hill, New York, 2008. Copyright © 2008 by The McGraw-Hill Companies, Inc. All rights reserved.)

Lens

The lens is suspended by the *ciliary zonule*, specialized fibers emanating from the ciliary body. The lens is about 10 mm in diameter and is enclosed in a capsule. The bulk of the lens is composed of fibers derived from proliferating lens epithelial cells located under the anterior portion of the lens capsule. These lens fibers are continuously produced throughout life. Aging, in addition to certain medications, such as corticosteroids, and certain diseases, such as diabetes mellitus, cause the lens to become opacified, which is termed a *cataract*.

Posterior Segment

Because of the anatomical and vascular barriers to both local and systemic access, drug delivery to the eye's posterior pole is particularly challenging.

Sclera and Choroid

The outermost coat of the eye, the sclera, covers the posterior portion of the globe. The external surface of the scleral shell is covered by an episcleral vascular coat, Tenon's capsule, and the conjunctiva. The tendons of the six extraocular muscles insert collagen fibers into the superficial

Figure 69-4 Sympathetic (A) and parasympathetic (B) innervation of the eye. The system is symmetrical, but the schematic is drawn asymmetrically to show all the parts. Input from the retinas is also shown asymmetrically, one medial and one lateral region (Adapted with permission from Wybar KC, Kerr-Muir M. *Bailliere's Concise Medical Textbooks, Ophthalmology*. 3rd ed. Bailliere Tindall, New York, 1984. Copyright © Elsevier).

scleral. Numerous blood vessels pierce the sclera through emissaria to supply and drain the choroid, ciliary body, optic nerve, and iris. Inside the scleral shell, a capillary network (vascular choroid) nourishes the outer retina. Between the outer retina and the capillary network lie Bruch's membrane and the retinal pigment epithelium, whose tight

TABLE 69-2 ■ EFFECTS OF PHARMACOLOGICAL AGENTS ON THE PUPIL		
CLINICAL SETTING	DRUG	PUPILLARY RESPONSE
Normal	Sympathomimetic drugs	Dilation (mydriasis)
Normal	Parasympathomimetic drugs	Constriction (miosis)
Horner syndrome	Cocaine 4%–10%	No dilation
Preganglionic Horner syndrome	Hydroxyamphetamine 1%	Dilation
Postganglionic Horner syndrome	Hydroxyamphetamine 1%	No dilation
Adie's pupil	Pilocarpine 0.05%–0.1% ^a	Constriction
Normal	Opioids (oral or intravenous)	Pinpoint pupils

Topically applied ophthalmic drugs unless otherwise noted.
^aThis percentage of pilocarpine is not commercially available and usually is prepared by the physician administering the test or by a pharmacist. This test also requires that no prior manipulation of the cornea (i.e., tonometry for measuring intraocular pressure or testing corneal sensation) be done so that the normal integrity of the corneal barrier is intact. Normal pupils will not respond to this weak dilution of pilocarpine; however, an Adie's pupil manifests a denervation supersensitivity and is responsive to this dilute cholinergic agonist.

junctions provide an outer barrier between the retina and the choroid. The retinal pigment epithelium serves many functions, including vitamin A metabolism, phagocytosis of the rod outer segments, and multiple transport processes.

Retina

The retina is a thin, transparent, highly organized structure of neurons, glial cells, and blood vessels; it contains the photoreceptors and the rhodopsin-based G protein signaling system. The elevated IOP of glaucoma damages and causes the death of the ganglion cells (the optic nerve) that connect the retina and the brain. Glutamate, acting on NMDA receptors, can stimulate this process (Sucher et al., 1997). In theory, this offers a target for neuroprotective agents to protect against cell death, but to date no treatment other than IOP lowering has demonstrated any benefit in treating glaucoma.

Vitreous

Approximately 80% of the eye's volume is the vitreous, a clear medium containing collagen type II, hyaluronic acid, proteoglycans, glucose, ascorbic acid, amino acids, and a number of inorganic salts.

Optic Nerve

The optic nerve is a myelinated nerve conducting the retinal output to the CNS. It comprises an intraocular portion, visible as the optic disk in the retina; an intraorbital portion; an intracanalicular portion; and an intracranial segment. The nerve is ensheathed in meninges continuous with the brain. It is susceptible to a variety of insults, ranging from traumatic to toxic (ethambutol, methanol, ethanol) to nutritional (vitamin B₁₂ and folic acid deficiency) to infectious, neoplastic, and inflammatory. At present, pharmacological treatment of optic neuropathies usually is based on management of the underlying disease. For example, arteritic ischemic optic neuropathy (giant cell arteritis) is best treated with systemic glucocorticoids and optic neuritis with intravenous glucocorticoids (Beck and Gal, 2008; Volpe, 2008). Glaucomatous optic neuropathy is medically managed by decreasing IOP.

Pharmacokinetics and Toxicology of Ocular Therapeutic Agents

Drug Delivery Strategies

There are a number of formulations of agents and routes of drug administration that are unique to the eye (Figures 69–1 and Table 69–3).

Several formulations prolong the time a drug remains on the surface of the eye. These include gels, ointments, solid inserts, soft contact lenses,

and collagen shields. *Prolonging the time in the cul-de-sac beneath the eyelid enhances drug absorption.* Ophthalmic gels (e.g., pilocarpine 4% gel) release drugs by diffusion following erosion of soluble polymers. Ointments usually contain mineral oil and a petrolatum base and are helpful in delivering antibiotics, cycloplegic drugs, or miotic agents. Solid inserts, such as the ganciclovir intravitreal implant, provide a *zero-order* rate of delivery by steady-state diffusion, whereby drug is released at a more constant rate over a prolonged period of time rather than as a bolus. Drug molecules may also be encapsulated in nanoparticles for controlled release on the ocular surface.

ADME

The ADME pharmacokinetic principles determine the time course of drug action in the eye; however, the routes of ocular drug administration, the flow of ocular fluids, and the architecture of the eye introduce other variables specific to the eye. Most ophthalmic medications are formulated to be applied topically. Drugs also may be injected by subconjunctival, sub-Tenon's, intracorneal, intracameral, intravitreal, and retrobulbar routes.

Absorption. After topical instillation of a drug, the rate and extent of absorption are determined by the dwell time of the drug in the cul-de-sac and precorneal tear film, elimination by nasolacrimal drainage, drug binding to tear proteins, drug metabolism by tear and tissue proteins, and diffusion across the cornea and conjunctiva. A drug's residence time may be prolonged by changing its formulation or vehicle. Residence time also may be extended by blocking the egress of tears from the eye by closing the tear drainage ducts with flexible silicone (punctal) plugs. Nasolacrimal drainage contributes to systemic absorption of topically administered ophthalmic medications. Absorption from the nasal mucosa avoids first-pass metabolism by the liver; thus, topical ophthalmic medications can cause significant systemic side effects, especially when used frequently or chronically. Possible absorption pathways of an ophthalmic drug following topical application to the eye are shown schematically in Figure 69–5.

Transcorneal and transconjunctival/scleral absorption are the desired routes for localized ocular drug effects. The drug concentration gradient between the tear film and the cornea and conjunctival epithelium provides the driving force for passive diffusion across these tissues. Other factors that affect a drug's diffusion are the size of the molecule, chemical structure, and steric configuration. Transcorneal drug penetration is a differential solubility process; the cornea resembles a trilaminar “fat-water-fat” structure corresponding to the epithelial, stromal, and endothelial layers, respectively. The epithelium and endothelium represent barriers for hydrophilic substances; the stroma is a barrier for hydrophobic compounds. Hence, an amphipathic agent with both hydrophilic and lipophilic properties is best suited for transcorneal absorption. Drug penetration into the eye is

TABLE 69–3 ■ SOME CHARACTERISTICS OF OCULAR ROUTES OF DRUG ADMINISTRATION

ROUTE	ABSORPTION PATTERN	SPECIAL UTILITY	LIMITATIONS AND PRECAUTIONS
Topical	Prompt, depending on formulation	Convenient, economical, relatively safe	Compliance, corneal and conjunctival toxicity, nasal mucosal toxicity, systemic side effects from nasolacrimal absorption
Subconjunctival, sub-Tenon, and retrobulbar injections	Prompt or sustained, depending on formulation	Anterior segment infections, posterior uveitis, cystoid macular edema	Local toxicity, tissue injury, globe perforation, optic nerve trauma, central retinal artery or vein occlusion, direct retinal drug toxicity with inadvertent globe perforation, ocular muscle trauma, prolonged drug effect
Intraocular (intracameral) injections	Prompt	Anterior segment surgery, infections	Corneal toxicity, intraocular toxicity, relatively short duration of action
Intravitreal injection or device	Absorption circumvented, immediate local effect, potential sustained effect	Endophthalmitis, retinitis, age-related macular degeneration	Retinal toxicity

Figure 69–5 Drugs applied to the surface of the eye have multiple routes to the systemic circulation.

approximately linearly related to its concentration in the tear film. Certain disease states, such as corneal epithelial defects and corneal ulcers, may alter drug penetration. Medication absorption usually is increased when an anatomical barrier is compromised or removed.

Distribution. Topically administered drugs may undergo systemic distribution primarily by nasal mucosal absorption and possibly via local ocular distribution by transcorneal/transconjunctival absorption. Following transcorneal absorption, the aqueous humor accumulates the drug, which then is distributed to intraocular structures and potentially to the systemic circulation via the trabecular meshwork pathway (see Figure 69–3B). Melanin binding of certain drugs is an important factor in some ocular compartments. For example, the mydriatic effect of a adrenergic agonists is slower in onset in humans with darkly pigmented irides compared to those with lightly pigmented irides; drug-melanin binding is a potential reservoir for sustained drug release. Another clinically important consideration for drug-melanin binding involves the retinal pigment epithelium. In the retinal pigment epithelium, accumulation of chloroquine (see Chapter 49) causes a toxic retinal lesion known as a “bull’s-eye” maculopathy, which is associated with a decrease in visual acuity. To reduce the risk of retinal toxicity from chloroquine and related substances (e.g., hydroxychloroquine), patients receiving chronic therapy should receive periodic eye exams and lifetime cumulative doses should generally be limited to 460 g of chloroquine and 1000 g of hydroxychloroquine.

Metabolism. Biotransformation of ocular drugs may be significant; a variety of enzymes, including esterases, oxidoreductases, lysosomal enzymes, peptidases, glucuronide and sulfate transferases, GSH-conjugating enzymes, COMT, MAO, and 11 β -hydroxysteroid dehydrogenase are found in the eye. The esterases are of particular interest, permitting development of ester prodrugs for enhanced corneal permeability (e.g., *latanoprost* is a prodrug for PGF_{2a} used for glaucoma management; *loteprednol* is a prednisolone analogue engineered to have limited systemic effects due to metabolic inactivation within the eye).

Toxicity

Most local toxic effects are due to hypersensitivity reactions or to direct toxic effects on the cornea, conjunctiva, periocular skin, and nasal mucosa. Eye drops and contact lens solutions commonly contain antimicrobial preservatives such as benzalkonium chloride, chlorobutanol,

cause a punctate keratopathy or toxic ulcerative keratopathy. All ophthalmic medications are potentially absorbed into the systemic circulation (Figure 69–5), so systemic side effects may occur.

Ophthalmic Uses of Drugs

Chemotherapy of Microbial Diseases in the Eye

Bacterial Infections

Infectious diseases of the skin, eyelids, conjunctivae, and lacrimal excretory system are encountered regularly. Periocular skin infections are divided into preseptal and postseptal or orbital cellulitis. Depending on the clinical setting (e.g., preceding trauma, sinusitis, age of patient, relative immunocompromised state), oral or parenteral antibiotics may be administered in addition to topical medications. A number of antibiotics are formulated for topical ocular use (Table 69–4).

Dacryoadenitis, an infection of the lacrimal gland, is most common in children and young adults; it may be bacterial (typically *Staphylococcus aureus*, *Streptococcus* spp.) or viral (seen in mumps, infectious mononucleosis, influenza, and herpes zoster). When bacterial infection is suspected, systemic antibiotics usually are indicated.

Dacryocystitis is an infection of the lacrimal sac. In infants and children, the disease usually is unilateral and secondary to an obstruction of the nasolacrimal duct. In adults, dacryocystitis and canaliculitis infections may be caused by *S. aureus*, *Streptococcus* spp., diphtheroids, *Candida* spp., and *Actinomyces israelii*. Any discharge from the lacrimal sac should be sent for smears and cultures. Systemic antibiotics typically are indicated.

Infectious processes of the eyelids include *hordeolum* and *blepharitis*. A hordeolum, or sty, is an infection of the meibomian, Zeis, or Moll glands in the eyelids. The typical offending bacterium is *S. aureus*, and the usual treatment consists of warm compresses and topical antibiotic (gel, drops, or ointment). Blepharitis is a common bilateral inflammatory process of the eyelids characterized by irritation and burning, usually associated with a *Staphylococcus* sp. Local hygiene is the mainstay of therapy; topical antibiotics frequently are used. Systemic tetracycline, doxycycline, minocycline, erythromycin, and azithromycin often are effective in reducing severe eyelid inflammation but must be used for weeks to months.

Conjunctivitis is an inflammatory or infectious process of the conjunctiva that varies in severity from mild hyperemia to severe purulent discharge. The more common causes of conjunctivitis include viruses, allergies, environmental irritants, contact lenses, and chemicals. Less common causes include other infectious pathogens, immune-mediated reactions, associated systemic diseases, and tumors of the conjunctiva or eyelid. Commonly reported infectious agents are adenovirus and herpes simplex virus, followed by other viral (e.g., enterovirus, coxsackievirus, measles virus, varicella zoster virus) and bacterial sources (e.g., *Neisseria* spp., *Streptococcus pneumoniae*, *Haemophilus* spp., *S. aureus*, *Moraxella lacunata*, and chlamydial spp.). *Rickettsia*, fungi, and parasites, in both cystic and trophozoite form, are rare causes of conjunctivitis. Effective management is based on selection of an appropriate antibiotic for suspected bacterial pathogens. Unless an unusual causative organism is suspected, bacterial conjunctivitis is treated empirically with a broad-spectrum topical antibiotic without obtaining a culture.

Keratitis, or corneal inflammation or infection, can occur at any level of the cornea. Myriad microbial agents may cause infectious keratitis, including bacteria, viruses, fungi, spirochetes, and parasites. Severe infections with tissue loss (corneal ulcers) generally are treated more aggressively than infections without tissue loss (corneal infiltrates). Mild, small, more peripheral infections usually are not cultured, and the eyes are treated with broad-spectrum topical antibiotics. In more severe, central, or larger infections, corneal scrapings for cultures and sensitivities are performed, and the patient is immediately started on intensive hourly, around-the-clock topical antibiotic therapy. A commercially available broad-spectrum antibiotic may be given, but in severe infections, specially formulated fortified antibiotics are often used. The goal of treatment is to eradicate the

TABLE 69-4 ■ TOPICAL ANTIBACTERIAL AGENTS COMMERCIALY AVAILABLE FOR OPHTHALMIC USE

AGENT	FORMULATION ^a	TOXICITY	INDICATIONS FOR USE
Azithromycin	1% solution	H	Conjunctivitis
Bacitracin	500 units/g ointment	H	Conjunctivitis, blepharitis, keratitis, keratoconjunctivitis, corneal ulcers, blepharoconjunctivitis, meibomianitis, dacryocystitis
Besifloxacin	0.6% suspension		Conjunctivitis
Chloramphenicol	1% ointment	H, BD	Conjunctivitis, keratitis
Ciprofloxacin	0.3% solution, 0.3% ointment	H, D-RCD	Conjunctivitis, keratitis, keratoconjunctivitis, corneal ulcers, blepharitis, blepharoconjunctivitis, meibomianitis, dacryocystitis
Erythromycin	0.5% ointment	H	Superficial ocular infections involving the conjunctiva or cornea; prophylaxis of ophthalmia neonatorum
Gatifloxacin	0.3% and 0.5% solutions	H	Conjunctivitis
Gentamicin	0.3% solution, 0.3% ointment	H	Conjunctivitis, blepharitis, keratitis, keratoconjunctivitis, corneal ulcers, blepharoconjunctivitis, meibomianitis, dacryocystitis
Levofloxacin	0.5% solution	H	Conjunctivitis
	1.5% solution	H	Corneal ulcers
Moxifloxacin	0.5% solution	H	Conjunctivitis
Ofloxacin	0.3% solution	H	Conjunctivitis, corneal ulcers
Sulfacetamide	10% solution, 10% ointment	H, BD	Conjunctivitis, other superficial ocular infections
Polymyxin B combinations ^b	Various solutions and ointments		Conjunctivitis, blepharitis, keratitis
Tobramycin ^c	0.3% solution, 0.3% ointment	H	External infections of the eye and its adnexa

BD, blood dyscrasia; D-RCD, drug-related corneal deposits; H, hypersensitivity.

^aFor specific information on dosing, formulation, and trade names, refer to the *Physicians' Desk Reference for Ophthalmic Medicines*, which is published annually.

^bPolymyxin B is formulated for delivery to the eye in combination with bacitracin, neomycin, gramicidin, oxytetracycline, or trimethoprim. See Chapters 56–59 for further discussion of these antibacterial agents.

^cTobramycin is formulated for delivery to the eye in combination with dexamethasone or loteprednol etabonate.

infection and reduce the amount of corneal scarring and the chance of corneal perforation and severe decreased vision or blindness. The initial medication selection and dosage are adjusted according to the clinical response and culture/sensitivity results. In the case of culture-proven bacterial keratitis that has been treated with appropriate topical antibiotics for a several days but still has significant inflammation, judicious topical steroids can be used with close follow-up to decrease corneal scarring.

Endophthalmitis is a potentially severe and devastating inflammatory, and usually infectious, process involving the intraocular tissues. When the inflammatory process encompasses the entire globe, it is called *panophthalmitis*. Endophthalmitis usually is caused by bacteria or fungi or rarely by spirochetes. The typical case occurs during the early postoperative course after intraocular surgery, following trauma, or rarely by endogenous seeding in an immunocompromised host or intravenous drug user. Acute postoperative endophthalmitis requires a prompt vitreous tap for smears and cultures and empirical injection of intravitreal antibiotics. In cases of endogenous seeding, parenteral antibiotics have a role in eliminating the infectious source; systemic antibiotics are helpful in reducing the risk of endophthalmitis following a traumatic open-globe injury (Ahmed et al., 2012). Vitrectomy (i.e., specialized surgical removal of the vitreous) is indicated in some cases (Endophthalmitis Vitrectomy Study Group, 1995; Schiedler et al., 2004).

Viral Infections

Antiviral drugs used in ophthalmology are summarized in Table 69-5 (see Chapter 62 for details of these agents). The primary indications for the use of antiviral drugs in ophthalmology are viral keratitis, herpes zoster ophthalmicus, and retinitis. There currently are no antiviral agents indicated for the treatment of viral conjunctivitis caused by adenoviruses, which usually has a self-limited course and typically is treated

by symptomatic relief of irritation, but topical ganciclovir gel may be of some benefit (Yabiku et al., 2011).

Viral keratitis, an infection of the cornea that may involve either the epithelium or stroma, is most commonly caused by herpes simplex type I and varicella zoster viruses. Less common viral etiologies include herpes simplex type II, Epstein-Barr virus, and CMV. The topical antiviral agents trifluridine and ganciclovir are both indicated for the treatment of epithelial disease due to herpes simplex infection, but trifluridine is more toxic to the corneal epithelium. Topical glucocorticoids are contraindicated in herpetic epithelial keratitis due to active viral replication. In contrast, for herpetic disciform keratitis (predominantly a cell-mediated immune reaction), topical glucocorticoids often accelerate recovery. For recurrent herpetic stromal keratitis, there is clear benefit from treatment with oral antivirals such as acyclovir in reducing the risk of recurrence (Herpetic Eye Disease Study Group, 1997, 1998; Young et al., 2010).

Herpes zoster ophthalmicus is a latent reactivation of a varicella zoster infection in the first division of the trigeminal cranial nerve. Systemic acyclovir, valacyclovir, and famciclovir are effective in reducing the severity and complications of herpes zoster ophthalmicus (Cohen and Kessler, 2016).

Viral retinitis may be caused by herpes simplex virus, CMV, adenovirus, and varicella zoster virus. With antiretroviral therapy (see Chapter 64), CMV retinitis does not appear to progress when specific anti-CMV therapy is discontinued, but some patients develop an immune recovery uveitis. Treatment usually involves long-term parenteral administration of antiviral drugs. Intravitreal ganciclovir, injected or implanted as an insert, is an effective alternative to systemic use. Acute retinal necrosis and progressive outer retinal necrosis, most often caused by varicella zoster virus, can be treated by combinations of oral, intravenous, and intravitreal administration of antiviral medications (Newman and Gooding, 2013).

TABLE 69-5 ■ ANTIVIRAL AGENTS FOR OPHTHALMIC USE

GENERIC NAME	ROUTE OF ADMINISTRATION	OCULAR TOXICITY	INDICATIONS FOR USE
Trifluridine	Topical (1% solution)	Punctate keratopathy, hypersensitivity	Herpes simplex keratitis and keratoconjunctivitis Dosed initially 9 times a day Corneal toxicity can occur
Ganciclovir	Topical (0.15% gel) Intravenous infusion, intravitreal injection, ^a and intravitreal implant (4.5 mg)		Herpes simplex keratitis Cytomegalovirus retinitis
Acyclovir	Oral, intravenous (200-mg capsules, 400- and 800-mg tablets)		Herpes zoster ophthalmicus Herpes simplex iridocyclitis
Valacyclovir	Oral (500- and 1000-mg tablets)		Herpes simplex keratitis ^a Herpes zoster ophthalmicus
Famciclovir	Oral (125-, 250-, and 500-mg tablets)		Herpes simplex keratitis ^a Herpes zoster ophthalmicus
Foscarnet	Intravenous Intravitreal ^a		Cytomegalovirus retinitis
Valganciclovir	Oral (450-mg tablets)		Cytomegalovirus retinitis
Cidofovir	Intravenous		Cytomegalovirus retinitis

^aOff-label use. For additional details, see Chapter 62.

Fungal Infections

The only currently available topical ophthalmic antifungal preparation is natamycin, a polyene. Other antifungal agents may be extemporaneously compounded for topical, subconjunctival, corneal intrastromal, intracameral, or intravitreal routes of administration (Table 69-6; see also Chapter 61). As with systemic fungal infections, the incidence of ophthalmic fungal infections has risen with the growing number of immunocompromised hosts. Fungal infections can involve the cornea, sclera, intraocular structures, canalicula, and orbit. Risk factors for fungal keratitis include trauma, chronic ocular surface disease, contact lens wear, and immunosuppression (including topical steroid use). When fungal infection is suspected, samples of the affected tissues are obtained for smears, cultures, and sensitivities, and this information is used to guide drug selection.

Protozoal Infections

Parasitic infections involving the eye usually manifest themselves as a form of *uveitis*, an inflammatory process of either the anterior or posterior segments and, less commonly, as conjunctivitis, keratitis, and retinitis. In the U.S., the most commonly encountered protozoal infections include *Acanthamoeba* and *Toxoplasma gondii*. In contact lens wearers who develop keratitis, physicians should be highly suspicious of the presence of *Acanthamoeba*. Risk factors for *Acanthamoeba* keratitis include poor contact lens hygiene, wearing contact lenses in a pool or hot tub, and ocular trauma. Treatment usually consists of a combination of topical agents. The aromatic diamidines—propamidine isethionate in topical aqueous and ointment forms (not commercially available in the U.S.)—have been used successfully to treat this relatively resistant infectious keratitis. The cationic antiseptic agent polyhexamethylene biguanide also is used in drop form for *Acanthamoeba* keratitis; alternatively, topical chlorhexidine can be used; both drugs need to be prepared by a specialty compounding pharmacy. Oral imidazoles (e.g., itraconazole, fluconazole, ketoconazole, voriconazole) often are used in addition to the topical medications. Resolution of *Acanthamoeba* keratitis often requires many months of treatment (Chew et al., 2011; Hoti and Tandon, 2011).

Treatment of *toxoplasmosis* is indicated when inflammatory lesions encroach on the macula and threaten central visual acuity. Several regimens have been recommended with concurrent use of systemic

steroids: (1) pyrimethamine, sulfadiazine, and folinic acid (leucovorin); (2) pyrimethamine, sulfadiazine, clindamycin, and folinic acid; (3) sulfadiazine and clindamycin; (4) clindamycin; and (5) trimethoprim-sulfamethoxazole with or without clindamycin. Other protozoal infections (e.g., giardiasis, leishmaniasis, malaria) and helminth infections are less common eye pathogens in the U.S. Systemic pharmacological management as well as vitrectomy may be indicated for selected parasitic infections (Maenz et al., 2014).

Ophthalmic Use of Autonomic Agents, Eicosanoids, and Carbonic Anhydrase Inhibitors

Autonomic drugs are used extensively for diagnostic and surgical purposes and for the treatment of glaucoma, uveitis, and strabismus. The autonomic agents used in ophthalmology and the responses (i.e., mydriasis, cycloplegia) to muscarinic cholinergic antagonists are summarized in Table 69-7. Table 69-8 presents some characteristics of eicosanoids used in ophthalmology.

Glaucoma

Glaucoma is characterized by progressive loss of retinal nerve fiber layer tissue and visual field loss. The optic nerve acquires a characteristic loss of the neuroretinal rim, frequently referred to as “cupping.” The prevalence of the disease is growing as populations age and increase around the world (Tham et al., 2014). Risk factors include increased IOP, positive family history of glaucoma, African American heritage, and possibly myopia, diabetes, and hypertension. Reducing IOP can delay glaucomatous nerve or field damage. Although markedly elevated IOPs (e.g., > 30 mm Hg) usually will lead to optic nerve damage, the optic nerves in certain patients (*ocular hypertensives*) apparently can tolerate IOPs in the mid-to-high 20s. Other patients have progressive glaucomatous optic nerve damage despite having IOPs in the normal range; this form of the disease sometimes is called *normal- or low-tension* glaucoma. Regardless of the initial level, reducing the IOP delays or prevents disease progression (Collaborative Normal-Tension Study Group, 1998a, 1998b; Ederer et al., 2004; Heijl et al., 2002; Kass et al., 2002; Miglior et al., 2005). At present, the pathophysiological processes involved in glaucomatous optic nerve damage and the relationship to aqueous humor dynamics are not understood. Current

TABLE 69-6 ■ ANTIFUNGAL AGENTS FOR OPHTHALMIC USE

DRUG CLASS AGENT	METHOD OF ADMINISTRATION	INDICATIONS FOR USE
Polyenes		
Amphotericin B ^a	0.1%–0.5% (typically 0.15%) topical solution	Yeast and fungal keratitis and endophthalmitis
	0.8- to 1-mg subconjunctival	Yeast and fungal endophthalmitis
	2- to 10-μg intrastromal corneal and intracameral	Yeast and fungal keratitis
	5- to 10-μg intravitreal injection	Yeast and fungal endophthalmitis
	Intravenous	Yeast and fungal endophthalmitis
Natamycin	5% topical suspension	Yeast and fungal blepharitis, conjunctivitis, keratitis
Imidazoles		
Fluconazole ^a	Oral, intravenous	Yeast keratitis and endophthalmitis
Itraconazole ^a	Oral	Yeast and fungal keratitis and endophthalmitis
Ketoconazole ^a	Oral	Yeast keratitis and endophthalmitis
Miconazole ^a	1% topical solution	Yeast and fungal keratitis
	5- to 10-mg subconjunctival	Yeast and fungal endophthalmitis
	10-μg intravitreal injection	Yeast and fungal endophthalmitis
Voriconazole	Oral, intravenous, intravitreal	Yeast and fungal keratitis and endophthalmitis
	Intrastromal, corneal, and intracameral	Yeast and fungal keratitis

^aOff-label use. Only natamycin is commercially available and labeled for ophthalmic use. All other antifungal drugs are not labeled for ophthalmic use and must be formulated for the given method of administration. For further dosing information, refer to the *Physicians' Desk Reference for Ophthalmic Medicines*. For additional discussion of these antifungal agents, see Chapter 61.

pharmacotherapies are targeted at decreasing the production of aqueous humor at the ciliary body and increasing outflow through the trabecular meshwork and uveoscleral pathways. There is no consensus on the best IOP-lowering technique (Musch et al., 2011).

A stepped medical approach depends on the patient's health, age, and ocular status, with knowledge of systemic effects and contraindications for all medications. A stepped medical approach may begin with a *topical PG* analogue (Table 69-8).

Due to their once-daily dosing, low incidence of systemic side effects, and potent IOP-lowering effect, PG analogues have largely replaced β adrenergic receptor antagonists as first-line medical therapy for glaucoma. The PG analogues consist of latanoprost (Figure 69-6), travoprost, bimatoprost, tafluprost, and unoprostone (discontinued in the U.S.). PGF_{2a} reduces IOP but has intolerable local side effects. Modifications to the chemical structure of PGF_{2a} have produced analogues with a more acceptable side-effect profile. PGF_{2a} and its analogues (prodrugs that are

hydrolyzed to PGF_{2a}) bind to receptors for PGF_{2a} (FP receptors) that link to the G_{q/11}-PLC-IP₃-Ca²⁺ pathway. This pathway is active in isolated human ciliary muscle cells. Other cells in the eye also may express FP receptors. Theories of IOP lowering by PGF_{2a} range from altered ciliary muscle tension to effects on trabecular meshwork cells to release of matrix metalloproteinases and digestion of extracellular matrix materials that may impede outflow tracts.

The β receptor antagonists (Table 69-7) are currently the next most common topical medical treatment. Nonselective β blockers bind to both β_1 and β_2 receptors and include timolol, levobunolol, metipranolol, and carteolol. The β_1 -selective antagonist betaxolol is available for ophthalmic use but is less efficacious than the nonselective β blockers because the β receptors of the eye are largely of the β_2 subtype. However, betaxolol is less likely to cause breathing difficulty due to blockade of pulmonary β_2 receptors. In the eye, the targeted tissues are the ciliary body epithelium and blood vessels, where β_2 receptors account for 75%–90% of the total population. How β blockade leads to decreased aqueous production and reduced IOP is uncertain. Production of aqueous humor seems to be activated by a β receptor-mediated cyclic AMP-PKA pathway; β blockade blunts adrenergic activation of this pathway. Another hypothesis is that β blockers decrease ocular blood flow, which decreases the ultrafiltration responsible for aqueous production.

When there are medical contraindications to the use of PG analogues or β receptor antagonists, other agents, such as an α_2 adrenergic receptor agonist (see Table 69-7) or topical CAI (Table 69-9), may be used as first-line therapy. The α_2 adrenergic agonists appear to decrease IOP by reducing aqueous humor production and by enhancing both conventional (via an α_2 receptor mechanism) and uveoscleral outflow (perhaps via PG production) from the eye. The α_2 adrenergic agonist and clonidine derivative apraclonidine is a relatively selective α_2 adrenergic agonist that is highly ionized at physiological pH, does not cross the blood-brain barrier, and is thus relatively free of the CNS effects of clonidine. Brimonidine is a selective α_2 adrenergic agonist that is lipophilic, enabling easy corneal penetration. Both apraclonidine and brimonidine reduce aqueous production and may enhance some uveoscleral outflow. Both appear to bind to pre- and postsynaptic α_2 receptors. By binding to the presynaptic receptors, the drugs reduce the amount of neurotransmitter release from sympathetic nerve stimulation and thereby lower IOP. By binding to postsynaptic α_2 receptors, these drugs stimulate the G_i pathway, reducing cellular cyclic AMP production, thereby reducing aqueous humor production.

The development of a **topical CAI** was prompted by the poor side-effect profile of oral CAIs. Dorzolamide and brinzolamide both work by inhibiting CA (isoform II), which is found in the ciliary body epithelium. Inhibition of CA reduces the formation of bicarbonate ions, which reduces fluid transport and thus IOP (Table 69-9).

Any of these four drug classes can be used as additive second- or third-line therapy. In fact, the β receptor antagonist timolol has been combined with the CAI dorzolamide in a single medication and with the α_2 adrenergic agonist brimonidine. A recently released combination of brinzolamide/brimonidine is also an option. A latanoprost/timolol combination is widely available. Such combinations reduce the number of drops needed and may improve compliance.

Topical miotic agents (see Table 69-7) are less commonly used today because of their numerous side effects and inconvenient dosing. Miotics lower IOP by causing muscarinic-induced contraction of the ciliary muscle, which facilitates aqueous outflow. They do not affect aqueous production. Pilocarpine and carbachol are cholinomimetics that stimulate muscarinic receptors and are referred to as having a direct mechanism of action. Indirect agents such as echothiophate are organophosphate inhibitors of acetylcholinesterase. Echothiophate is relatively stable in aqueous solution and, by virtue of its quaternary ammonium structure, is positively charged and poorly absorbed. If combined topical therapy fails to achieve the target IOP or fails to halt glaucomatous optic nerve damage, then *systemic therapy with a CAI* is a final medication option before resorting to laser or incisional surgical treatment. The best-tolerated oral preparation is acetazolamide in sustained-release capsules (see Chapter 25), followed by methazolamide. The least well tolerated are acetazolamide tablets.

TABLE 69-7 ■ AUTONOMIC DRUGS FOR OPHTHALMIC USE

DRUG CLASS	FORMULATION	INDICATIONS	SIDE EFFECTS
Cholinergic agonists			
Acetylcholine	1% solution	Miosis in surgery	Corneal edema
Carbachol	0.01%, 1.5%, 3% solution	Miosis in surgery, glaucoma	Corneal edema, miosis, induced myopia, decreased vision, brow ache, retinal detachment
Pilocarpine	1%, 2%, and 4% solution	Glaucoma, miosis induction, miosis in surgery	Same as for carbachol
Anticholinesterase agents			
Echothiophate	0.125% solution	Glaucoma, accommodative esotropia	Retinal detachment, miosis, cataract, pupillary block, glaucoma, iris cysts, brow ache, punctal stenosis
Muscarinic antagonists			
Atropine	1% solution, 1% ointment	Cycloplegia, mydriasis, ^a cycloplegic retinoscopy, ^b dilated funduscopic exam, ^b iritis, uveitis	Photosensitivity, blurred vision; long acting (1 week or longer)
Scopolamine	0.25% solution	Cycloplegia, mydriasis, iritis, uveitis, nystagmus ^b	Same as for atropine but the effect lasts several days
Homatropine	2% and 5% solution	Cycloplegia, mydriasis, iritis, ^b uveitis	Same as for scopolamine but does not last as long
Cyclopentolate	Solution (0.5%–2%), also with phenylephrine	Cycloplegia, mydriasis ^a	Same as for atropine but effect lasts ~ 1 day
Tropicamide	0.5% and 1% solution, also with hydroxyamphetamine	Cycloplegia, mydriasis ^a	Same as for atropine but effect lasts several hours; commonly used for office exams
α Adrenergic agonists			
Phenylephrine	2.5% and 10% solution	Mydriasis, vasoconstriction, decongestion, ^b uveitis, glaucoma	α Adrenergic agonist effect lasts several hours; 2.5% used with tropicamide for office exams
Apraclonidine	0.5% and 1% solution	Glaucoma, ocular hypertension	α adrenergic agonist; side effects: allergy (conjunctival hyperemia), dry mouth, sleepiness
Brimonidine (α ₂ selective)	Solution (0.1%–0.2%); 0.33% gel; also with timolol or brinzolamide	Glaucoma, ocular hypertension	Same as for apraclonidine; causes respiratory depression in young children
Naphazoline	0.1% solution	Decongestant	Contraindicated in closed-angle glaucoma; safety/efficacy not established in the young (neonate to adolescent); use in infants may result in CNS depression, coma, marked reduction in body temperature; use with caution in patients with hypertension, cardiac disease, hyperthyroidism, diabetes, or infection or trauma in eye
Tetrahydrozoline	0.05% solution	Decongestant	Contraindicated in closed-angle glaucoma; safety/efficacy not established in neonates and children < 6 years; use with caution in patients with coronary artery disease, hypertension, hyperthyroidism, or diabetes
β Adrenergic antagonists			
Betaxolol (β ₁ selective)	0.25% suspension, 0.5% solution	Glaucoma, ocular hypertension	Reduced incidence of respiratory problems compared to timolol
Timolol	Solution, gel (0.25%, 0.5%); also with brimonidine, dorzolamide, latanoprost	Glaucoma, ocular hypertension	Side effects: exacerbation of respiratory problems (asthma and chronic obstructive pulmonary disease), bradycardia, depression, impotence
Carteolol	1% solution	Glaucoma, ocular hypertension	Same as timolol
Levobunolol	0.25% and 0.5% solution	Glaucoma, ocular hypertension	
Metipranolol	0.3% solution	Glaucoma, ocular hypertension	

^aMydriasis and cycloplegia, or paralysis of accommodation, of the human eye occurs after one drop of atropine 1%, scopolamine 0.5%, homatropine 1%, cyclopentolate 0.5% or 1%, and tropicamide 0.5% or 1%. Recovery of mydriasis is defined by return to baseline pupil size to within 1 mm. Recovery of cycloplegia is defined by return to within 2 -diopters of baseline accommodative power. The maximal mydriatic effect of homatropine is achieved with a 5% solution, but cycloplegia may be incomplete. Maximal cycloplegia with tropicamide may be achieved with a 1% solution. Times to development of maximal mydriasis and to recovery, respectively, are as follows: for atropine, 30–40 min and 7–10 d; for scopolamine, 20–130 min and 3–7 d; for homatropine, 40–60 min and 1–3 d; for cyclopentolate, 30–60 min and 1 d; for tropicamide, 20–40 min and 6 h. Times to development of maximal cycloplegia and to recovery, respectively, are as follows: for atropine, 60–180 min and 6–12 d; for scopolamine, 30–60 min and 3–7 d; for homatropine, 30–60 min and 1–3 d; for cyclopentolate, 25–75 min and 6 h to 1 d; for tropicamide, 30 min and 6 h.

^bOff-label use. Refer to *Physicians' Desk Reference for Ophthalmic Medicines* for specific indications and dosing.

TABLE 69-8 ■ PROSTAGLANDIN ANALOGUES FOR OPHTHALMIC USE

AGENT	FORMULATION	INDICATIONS	SIDE EFFECTS
Latanoprost (the most commonly used glaucoma medication)	0.005% solution; also with timolol (0.05%)	Glaucoma, ocular hypertension	Once-daily dosing can cause lash growth; may cause allergic conjunctival hyperemia, permanent ↑ iris pigmentation, orbital fat atrophy
Travoprost	0.004% solution		Same as latanoprost but generally less irritating to corneal epithelium
Bimatoprost	0.01% solution, 0.03% solution		
Tafluprost	0.0015% solution; preservative-free, single-dose dropperettes		

Toxicity of Antiglaucoma Agents. Ciliary body spasm is a muscarinic cholinergic effect that can lead to induced myopia and a changing refraction due to iris and ciliary body contraction as the drug effect waxes and wanes between doses. Headaches can occur from the iris and ciliary body contraction. The α_2 agonists, effective in IOP reduction, can cause a vasoconstriction-vasodilation rebound phenomenon, leading to a red eye. Ocular and skin allergies from topical epinephrine, apraclonidine, and brimonidine are common (epinephrine for ophthalmic use is no longer marketed in the U.S.). Brimonidine is less likely to cause ocular allergy and therefore is more commonly used. These agents can cause CNS depression and apnea in neonates and are contraindicated in children less than 2 years of age. Systemic absorption of α_2 agonists and β adrenergic antagonists can induce all the side effects of systemic administration. The use of CAIs systemically may give some patients significant problems with malaise, fatigue, depression, paresthesias, and nephrolithiasis; the topical CAIs may minimize these relatively common side effects.

Uveitis

Inflammation of the uvea, or uveitis, has both infectious and noninfectious causes, and medical treatment of the underlying cause (if known), in addition to the use of topical therapy, is essential. Cyclopentolate, tropicamide, or sometimes even longer-acting antimuscarinic agents such as atropine, scopolamine, and homatropine frequently are used to prevent posterior synechia formation between the lens and iris margin and to relieve ciliary muscle spasm that is responsible for much of the pain associated with anterior uveitis.

If posterior synechiae already have formed, an α adrenergic agonist may be used to break the synechiae by enhancing pupillary dilation. A solution of scopolamine 0.3% in combination with 10% phenylephrine is available for this purpose. Two others, 1% hydroxyamphetamine hydrobromide combined with 0.25% tropicamide and 1% phenylephrine in combination with 0.2% cyclopentolate, are indicated only for induction of mydriasis. Topical steroids usually are adequate to decrease inflammation but sometimes must be supplemented with systemic steroids.

Strabismus

Strabismus, or ocular misalignment, has numerous causes and may occur at any age. Besides causing *diplopia* (double vision), strabismus in children may lead to *amblyopia* (reduced vision). Nonsurgical efforts to treat

amblyopia include occlusion therapy, orthoptics, optical devices, and pharmacological agents.

An eye with *hyperopia*, or farsightedness, must constantly accommodate to focus on distant images. In some hyperopic children, the synkinetic accommodative-convergence response leads to excessive convergence and a manifest *esotropia* (turned-in eye). The brain rejects diplopia and suppresses the image from the deviated eye. If proper vision is not restored by about 6–8 years of age, the brain never learns to process visual information from that eye. The result is that the eye appears structurally normal but does not develop normal visual acuity and is therefore amblyopic. This is a fairly common cause of visual disability. In this setting, atropine (1%) instilled in the preferred seeing eye produces cycloplegia and the inability of this eye to accommodate, thus forcing the child to use the amblyopic eye (Pediatric Eye Disease Investigator Group, 2002, 2003). Echthiophate iodide also has been used in the setting of accommodative strabismus. Accommodation drives the near reflex, the triad of miosis, accommodation, and convergence. An irreversible cholinesterase inhibitor such as echthiophate causes miosis and an accommodative change in the shape of the lens; hence, the accommodative drive to initiate the near reflex is reduced, and less convergence will occur.

Surgical and Diagnostic Uses

For certain surgical procedures and for clinical funduscopy examination, it is desirable to maximize the view of the retina and lens. Muscarinic cholinergic antagonists and sympathomimetic agents frequently are used singly or in combination for this purpose (see Table 69-7). Intraoperatively, there are circumstances in which miosis is preferred, and two cholinergic agonists are available for intraocular use, acetylcholine and carbachol. Patients with myasthenia gravis may first present to an ophthalmologist with complaints of double vision (diplopia) or eyelid droop (ptosis); the *edrophonium test* is helpful in diagnosing these patients (see Chapter 10). Intraoperatively, trypan blue is marketed (as 0.06% and 0.15% ophthalmic solutions) to facilitate visualization of the anterior lens capsule during cataract surgery and for staining the retinal surface during surgical vitrectomy to guide the excision of tissue.

Anti-inflammatory, Immunomodulatory, and Antimitotic Drugs

Glucocorticoids

Glucocorticoids have an important role in managing ocular inflammatory diseases (Table 69-10 and Table 69-11). The chemistry and pharmacology of glucocorticoids are described in Chapter 46.

Therapeutic Uses. The glucocorticoids formulated for topical administration to the eye are dexamethasone, prednisolone, fluorometholone, loteprednol, rimexolone, and difluprednate. Because of their anti-inflammatory effects, topical corticosteroids are used in managing significant ocular allergy, external eye inflammatory diseases associated with some infections and ocular cicatricial pemphigoid, anterior uveitis, and

Figure 69-6 Latanoprost.

TABLE 69-9 ■ CARBONIC ANHYDRASE INHIBITORS FOR OPHTHALMIC USE

AGENT	FORMULATION	INDICATIONS	SIDE EFFECTS
Acetazolamide	Tablets (125, 250 mg); slow release (500 mg) Intravenous	Acute ↑ IOP, glaucoma	Paresthesias (hands, feet), upset stomach, hypokalemia, allergic rash, kidney stones Rare: aplastic anemia
Methazolamide	Tablets (25, 50 mg)	Glaucoma	Same as acetazolamide but generally fewer paresthesias and stomach upset
Dorzolamide	2% solution; also in combo with timolol (0.5%)	Glaucoma, ocular hypertension	Causes burning, stinging, and a metallic taste
Brinzolamide	1% suspension; also in combo with brimonidine (0.2%)	Glaucoma, ocular hypertension	Causes less burning, stinging, and metallic taste than dorzolamide

postoperative inflammation following refractive, corneal, and intraocular surgery. After glaucoma filtering surgery, topical steroids can delay the wound-healing process by decreasing fibroblast infiltration, thereby reducing potential scarring of the surgical site. Steroids commonly are given systemically and by sub-Tenon's capsule injection to manage posterior uveitis. Intravitreal injection of steroids is used to treat ARMD, diabetic retinopathy, and cystoid macular edema. An intravitreal triamcinolone formulation is approved for ocular inflammatory conditions unresponsive to topical corticosteroids and visualization during vitrectomy. Parenteral steroids followed by tapering oral doses is the preferred treatment of optic neuritis. Two ophthalmic implants, fluocinolone and dexamethasone, are marketed for the treatment of chronic, noninfectious uveitis; a dexamethasone implant is also indicated for the treatment of macular edema.

Toxicity. Ocular complications include the development of posterior subcapsular cataracts, secondary infections, and secondary open-angle glaucoma. There is a significant increase in the risk for developing secondary glaucoma when there is a positive family history of glaucoma. In the absence of a family history of open-angle glaucoma, only about 5% of normal individuals respond to topical or long-term systemic steroids with a marked increase in IOP. With a positive family history, however,

moderate-to-marked steroid-induced IOP elevations may occur in up to 90% of patients. Some topical steroids (e.g., loteprednol) have been developed that reduce, but do not eliminate, the risk of elevated IOP.

Nonsteroidal Anti-inflammatory Agents

Pharmacological properties of NSAIDs are presented in Chapter 38. Five topical NSAIDs are approved for ocular use: flurbiprofen, ketorolac, diclofenac, bromfenac, and nepafenac.

The NSAIDs are supplied as solutions and suspensions for topical ocular use to reduce ocular inflammation and cystoid macular edema. Flurbiprofen is used to counter unwanted intraoperative miosis during cataract surgery. Ketorolac is given for seasonal allergic conjunctivitis. A combination ketorolac/phenylephrine intraocular solution is available to add to intraoperative ophthalmic irrigation solutions to decrease miosis during cataract surgery. Diclofenac is used for postoperative inflammation and pain. Both ketorolac and diclofenac are effective in treating cystoid macular edema occurring after cataract surgery and in controlling pain after corneal refractive surgery. Bromfenac and nepafenac are indicated for treating postoperative pain and inflammation after cataract surgery. Topical and systemic NSAIDs occasionally have been associated with sterile corneal melts and perforations, especially in older patients with ocular surface disease, such as dry eye syndrome.

TABLE 69-10 ■ GLUCOCORTICOIDS FOR TOPICAL APPLICATION TO THE EYE

AGENT	FORMULATION	INDICATIONS
Dexamethasone	0.1% suspension; 0.1% (sodium phosphate) solution; 0.4% canalicular insert	Steroid-responsive inflammatory conditions of the palpebral and bulbar conjunctiva, cornea, and anterior segment; infective conjunctivitis to reduce edema and inflammation when hazard of steroid use is acceptable; corneal injury from chemical, radiation, or thermal burns or penetration of foreign object; post-operative inflammation
Difluprednate	0.05% emulsion	Ocular pain; postoperative ocular inflammation; uveitis
Fluorometholone	0.1%, 0.25% suspension; 0.1% ointment	Allergic conjunctivitis; giant papillary conjunctivitis; keratitis; ocular burns; postoperative ocular inflammation; uveitis; vernal keratoconjunctivitis
Loteprednol etabonate	0.2%, 0.5% suspension; 0.5% gel; 0.5% ointment	Allergic conjunctivitis; cyclitis; giant papillary conjunctivitis; iritis; keratitis; ocular pain; postoperative ocular inflammation, uveitis ^a
Prednisolone acetate Prednisolone sodium phosphate	0.12%, 1% suspension 1% solution	Allergic conjunctivitis and marginal corneal ulcer; anterior segment inflammation; bacterial conjunctivitis; chorioretinitis; cyclitis; endophthalmitis; Graves' ophthalmopathy; herpes zoster ocular infection (with antiviral therapy); iritis; nonspecific and superficial punctate keratitis; postoperative ocular inflammation; optic neuritis; sympathetic ophthalmia; diffuse posterior uveitis; vernal keratoconjunctivitis; corneal injury from chemical, radiation, thermal burns; or penetration of foreign objects: commonly used after ocular surgery.
Rimexolone	1% suspension	Postoperative ocular inflammation; uveitis; vernal keratoconjunctivitis ^a

^aOff-label use.

TABLE 69-11 ■ GLUCOCORTICOIDS FOR SUB-TENON'S, INTRAVITREAL, AND SYSTEMIC USE

AGENT	FORMULATION	METHOD OF ADMINISTRATION	INDICATION
Triamcinolone	Solutions and suspensions for injection, 3 to 40 mg/mL	Sub-Tenon's, ^a intracameral, ^a intravitreal	Ocular inflammation, ocular surgery, uveitis
Betamethasone	Oral syrup (0.12 mg/mL); suspension for IM injection (6 mg/mL)	Sub-Tenon's ^a	Corticosteroid-responsive ophthalmic disorders: allergic conjunctivitis and marginal corneal ulcer, anterior segment inflammation, chorioretinitis, conjunctivitis, endophthalmitis, ^a Graves' ophthalmopathy, herpes zoster ocular infection, iritis, keratitis, postoperative ocular inflammation, optic neuritis, diffuse posterior uveitis, vernal keratoconjunctivitis
Dexamethasone	Oral preps (0.5–1 mg/mL); tablets (0.5–6 mg); injectable solution (4 mg/mL, 10 mg/mL)	Oral, intravenous, intramuscular	Allergic conjunctivitis, allergic marginal corneal ulcer, anterior segment inflammation, chorioretinitis, cyclitis, endophthalmitis, ^a Graves' ophthalmopathy, giant papillary conjunctivitis, herpes zoster ocular infection, iritis, keratitis, superficial punctate keratitis, postoperative ocular inflammation, optic neuritis, diffuse choroiditis, sympathetic ophthalmia, vernal keratoconjunctivitis, or corneal injury (corneal abrasion)
Dexamethasone	0.7-mg ophthalmic implant	Intravitreal	Ocular inflammation due to macular edema following retinal vein occlusion, including branch retinal vein occlusion or central retinal vein occlusion and for the treatment of noninfectious uveitis affecting the posterior segment of the eye
Fluocinolone acetonide	0.19-mg ophthalmic implant	Intravitreal	Diabetic macular edema in patients who had no clinically significant rise in intraocular pressure when treated with corticosteroids
Fluocinolone acetonide	0.59-mg ophthalmic implant	Intravitreal	For the treatment of chronic noninfectious uveitis affecting the posterior segment of the eye
Methylprednisolone	Tablets (2–32 mg): 20-mg/mL, 40-mg/mL, suspension for IM injection (80 mg/mL); sodium succinate solution for IM/IV injection (40–1000 mg)	Oral, intravenous, intramuscular	For the systemic treatment of ophthalmic disorders, including allergic conjunctivitis, allergic marginal corneal ulcer, anterior segment inflammation, chorioretinitis, endophthalmitis, ^a Graves' ophthalmopathy, herpes zoster ocular infection, iritis, keratitis, postoperative ocular inflammation, optic neuritis, diffuse posterior uveitis, or vernal keratoconjunctivitis
Prednisone	1 mg/mL, 5 mg/mL oral solution; 1-, 2.5-, 5-, 10-, 20-, 50-mg tabs; 1-, 2-, 5-mg delayed-release tabs	Oral	Inflammatory conditions such as endophthalmitis, ^a optic neuritis, allergic conjunctivitis, keratitis, allergic corneal ulcer, iritis, chorioretinitis, anterior segment inflammation, uveitis, choroiditis, or sympathetic ophthalmia
Prednisolone	Orally disintegrating tablets (10–30 mg); syrup and oral solution (1–3 mg/mL)	Oral	Systemic treatment of corticosteroid-responsive eye disorders

^aOff-label use.

IM, intramuscular; IV, intravenous.

Antihistamines and Mast Cell Stabilizers

H₁ antagonists (see Chapter 32) and mast cell stabilizers are used to treat the manifestations of ocular allergies. Pheniramine (see Chapter 32) and antazoline (discontinued in the U.S.) are formulated in combination with naphazoline, a vasoconstrictor, for relief of allergic conjunctivitis; emedastine difumarate also is used. Cromolyn sodium has found some use in treating conjunctivitis that is thought to be allergen mediated, such as vernal conjunctivitis. The mast cell stabilizer lodoxamide tromethamine is available for ophthalmic use for the treatment of ocular inflammatory states such as vernal conjunctivitis and keratitis. Nedocromil, primarily a mast cell stabilizer with some antihistaminic properties, is also used. Likewise, olopatadine hydrochloride, ketotifen fumarate, bepotastine,

azelastine, and alcaftadine are H₁ antagonists with mast cell-stabilizing properties. Epinastine antagonizes H₁ and H₂ receptors and exhibits mast cell-stabilizing activity.

Immunosuppressants

Topical *cyclosporine* (Table 69-12) is approved for the treatment of chronic dry eye associated with inflammation. Use of cyclosporine is associated with decreased inflammatory markers in the lacrimal gland, increased tear production, and improved vision and comfort. Topical lifitegrast (Table 69-12) is approved to treat the signs and symptoms of dry eye disease. Lifitegrast inhibits an integrin, lymphocyte function-associated antigen 1 (LFA-1), from binding to intercellular adhesion molecule 1 (ICAM-1) which is thought to down-regulate inflammation mediated by

TABLE 69–12 ■ IMMUNOSUPPRESSIVE AND ANTIMITOTIC AGENTS FOR OCULAR USE

AGENT	FORMULATION	INDICATION	COMMENTS
Cyclosporine	0.05% emulsion	Dry eye	Dosed in preservative-free individual dropperettes
Lifitegras	5% solution	Dry eye	Dosed in preservative-free individual dropperettes
Interferon α_{2b}	Topical solution (1 million IU/mL); subconjunctival injection (3 million IU/0.5 mL; not in the U.S.)	Conjunctival tumors ^a Conjunctival papilloma	See Chapters 34 and 35
5-Fluorouracil	50-mg/mL solution	Glaucoma surgery	Used intraoperatively and postoperatively to prevent subconjunctival scarring Inhibits corneal epithelial healing; cannot be used if there is corneal abrasion
Mitomycin	0.2 mg/mL for topical application	Glaucoma surgery Pterygium surgery Corneal scarring and surface ablation surgery	Generally used as a subconjunctival application intraoperatively to prevent scarring More commonly used than 5FU in glaucoma surgery; not for injection Used topically on the cornea

T lymphocytes. *Interferon α_{2b}* is used off label in the treatment of conjunctival papilloma and certain conjunctival tumors.

Antimitotic Agents

In glaucoma surgery, the antineoplastic agents 5FU and mitomycin (Table 69–12; see details of mechanism in Chapter 66) improve the success of filtration surgery by limiting the postoperative wound-healing process.

Therapeutic Uses. Mitomycin is used intraoperatively as a single subconjunctival application at the trabeculectomy site. 5FU may be used intraoperatively at the trabeculectomy site or subconjunctivally during the postoperative course (Fluorouracil Filtering Surgery Study Group, 1996). Both agents work by limiting the healing process; sometimes this can result in thin, ischemic, avascular tissue that is prone to breakdown. The resultant leaks can cause hypotony (low IOP) and increase the risk of infection. In corneal surgery, mitomycin has been used topically. Mitomycin can be used to reduce the risk of scarring after procedures to remove corneal opacities and prophylactically to prevent corneal scarring after photorefractive and phototherapeutic keratectomy. Mitomycin also is used to treat certain conjunctival and corneal tumors and to decrease recurrence after pterygium excision. Caution is advocated when using mitomycin in light of the potentially serious delayed ocular complications.

Agents Used in Ophthalmic Surgery

Presurgical Antiseptics

Povidone iodine is formulated as a 5% sterile ophthalmic solution for use prior to surgery to prepare periocular skin and irrigate ocular surfaces, including the cornea, conjunctiva, and palpebral fornices. Following irrigation, the exposed tissues are flushed with sterile saline. Hypersensitivity to iodine is a contraindication.

Viscoelastic Substances

The viscoelastic substances are agents that assist in ocular surgery by maintaining spaces, moving tissue, and protecting surfaces. These substances are prepared from hyaluronate, chondroitin sulfate, or hydroxypropylmethylcellulose and share varying degrees of the following important physical characteristics: viscosity, shear flow, elasticity, cohesiveness, and coatability. Complications associated with viscoelastic substances are related to transient elevation of IOP after surgery.

Ophthalmic Glue

Cyanoacrylate tissue adhesive, while not FDA approved for the eye, is widely used in the management of corneal ulcerations and perforations.

Fibrin sealants are increasingly being used on the ocular surface to secure tissue such as conjunctiva, amniotic membrane, and lamellar corneal grafts.

Anterior Segment Gases

Sulfur hexafluoride (SF_6) and perfluoropropane gases are used as vitreous substitutes during retinal surgery. In the anterior segment, they are used in nonexpansile concentrations to treat Descemet's detachments, typically after cataract surgery. These detachments can cause mild-to-severe corneal edema. The gas is injected into the anterior chamber to push Descemet's membrane up against the stroma, where ideally it reattaches and clears the corneal edema. Similarly, these gases can be used after endothelial keratoplasty to help the lamellar graft adhere to the posterior cornea. SF_6 is an interesting molecule: octahedral geometry about the central S; a dense (6.1 g/mL) gas; odorless and nonflammable; industrial use; and a potent greenhouse gas with a long atmospheric $t_{1/2}$.

Vitreous Substitutes

Several compounds, including gases, perfluorocarbon liquids, and silicone oils, are available as vitreous substitutes (Table 69–13). Their primary use is reattachment of the retina following vitrectomy and membrane-peeling procedures for complicated proliferative vitreoretinopathy and traction retinal detachments. The use of expansile gases carries the risk of complications from elevated IOP, subretinal gas, corneal edema, and cataract formation. The gases are absorbed over a period of days (for air) to 2 months (for perfluoropropane).

The liquid perfluorocarbons (specific gravity 1.76–1.94) are denser than vitreous and are helpful in flattening the retina when vitreous is present. Silicone oil (polydimethylsiloxanes) is used for long-term tamponade of the retina. Complications from silicone oil use include glaucoma, cataract formation, corneal edema, corneal band keratopathy, and retinal toxicity.

Surgical Hemostasis and Thrombolytic Agents

Hemostasis has an important role in most surgical procedures and usually is achieved by temperature-mediated coagulation. Intravitreal administration of thrombin can assist in controlling intraocular hemorrhage during vitrectomy. When used intraocularly, a potentially significant inflammatory response may occur that can be minimized by thorough irrigation after hemostasis is achieved.

During intraocular surgeries to assist evacuation of a hyphema, subretinal clot, or nonclearing vitreous hemorrhage, tPA (Chapter 27) has been used off label. tPA also has been administered subconjunctivally and intracamerally (i.e., controlled intraocular administration into the anterior segment) to lyse blood clots obstructing a glaucoma filtration site. The main complication related to the use of tPA is bleeding.

TABLE 69–13 ■ VITREOUS SUBSTITUTES

AGENT	DURATION OR VISCOSITY
Nonexpansile gases	
Air	Duration, 5–7 days
Ar, CO ₂ , He, Kr, N ₂ , O ₂	
Xe	Duration, 1 day
Expansile gases	
Sulfur hexafluoride (SF ₆)	Duration, 10–14 days
Octafluorocyclobutane (C ₄ F ₈)	
Perfluoromethane (CF ₄)	Duration, 10–14 days
Perfluoroethane (C ₂ F ₆)	Duration, 30–35 days
Perfluoropropane (C ₃ F ₈)	Duration, 55–65 days
Perfluoro- <i>n</i> -butane (C ₄ F ₁₀)	
Perfluoropentane (C ₅ F ₁₂)	
Silicone oils^a	
Nonfluorinated silicone oils	Viscosity: 1000–30,000 cs
Fluorosilicone	Viscosity: 1000–10,000 cs
“High-tech” silicone oils	May terminate as trimethylsiloxyl or polyphenylmethyl-siloxane; viscosity not reported

cs, centistoke (unit of viscosity).

^aFor further information, see Parel and Villian, 1994.

Botulinum Toxin Type A in the Treatment of Strabismus, Blepharospasm, and Related Disorders

Two botulinum toxin type A preparations are marketed in the U.S.: onabotulinumtoxinA and abobotulinumtoxinA. OnabotulinumtoxinA is FDA approved for the treatment of strabismus and blepharospasm associated with dystonia, facial wrinkles (glabellar lines), bladder dysfunction and urinary incontinence, upper limb spasticity, axillary hyperhidrosis, spasmodic torticollis (cervical dystonia), and chronic migraine. By preventing acetylcholine release at the neuromuscular junction, botulinum toxin A usually causes a temporary paralysis of the locally injected muscles. Complications related to this toxin include double vision (diplopia), eyelid droop (ptosis), and, rarely, potentially life-threatening distant spread of toxin effect from the injection site (hours to weeks after administration).

Agents Used to Treat Blind and Painful Eye

Retrobulbar injection of either absolute or 95% ethanol may provide relief from chronic pain associated with a blind and painful eye. Retrobulbar chlorpromazine also has been used off label. This treatment is preceded by administration of local anesthesia. Local infiltration of the ciliary nerves provides symptomatic relief from pain, but other nerve fibers may be damaged, causing paralysis of the extraocular muscles, including those in the eyelids, or neuroparalytic keratitis. The sensory fibers of the ciliary nerves may regenerate, and repeated injections sometimes are needed to control pain.

Ocular Side Effects of Systemic Agents

Certain systemic drugs have ocular side effects. These can range from mild and inconsequential to severe and vision threatening (Li et al., 2008; Pula et al., 2013). Examples are listed in the sections that follow.

IOP and Glaucoma

The antiseizure drug topiramate can cause choroidal effusions leading to angle-closure glaucoma.

Retina

Numerous drugs have toxic side effects on the retina. The antiarthritides and antimalarial medicines hydroxychloroquine and chloroquine can

cause central retinal toxicity by an unknown mechanism. With normal dosages, toxicity does not appear until about 6 years after the drug is started. Stopping the drug will not reverse the damage but generally will prevent further toxicity. Tamoxifen can cause crystalline maculopathy. The antiseizure drug vigabatrin causes progressive and permanent bilateral concentric visual field constriction in a high percentage of patients.

Optic Nerve

The PDE5 inhibitors sildenafil, vardenafil, and tadalafil inhibit PDE5 in the corpus cavernosum to help achieve and maintain penile erection (Chapter 45) and to treat pulmonary arterial hypertension (Chapter 31). The drugs also mildly inhibit PDE6, which controls the levels of cyclic GMP in the retina (see Figure 69–9), causing a bluish haze or light sensitivity. Multiple medications, including ethambutol, chloramphenicol, and rifampin, can cause toxic optic neuropathy characterized by gradually progressive bilateral central scotomas and vision loss. Systemic or ocular steroids can cause elevated IOP and glaucoma. If the steroids cannot be stopped, glaucoma medications, and even filtering surgery, often are required.

Anterior Segment

Steroids have been implicated in cataract formation. Tamoxifen, among other others, has also been associated with cataracts. Rifabutin, if used in conjunction with clarithromycin or fluconazole for treatment of *Mycobacterium avium* complex opportunistic infections in HIV-positive persons, is associated with an iridocyclitis and even hypopyon. These conditions resolve with steroids or by stopping the medication.

Ocular Surface

Isotretinoin has a drying effect on mucous membranes and is associated with dry eye and severe dysfunction of the meibomian gland.

Cornea, Conjunctiva, and Eyelids

The cornea, conjunctiva, and eyelids can be affected by systemic medications. One of the most common drug deposits found in the cornea is from the cardiac medication amiodarone. It deposits in the inferior and central cornea in a whorl-like pattern termed *cornea verticillata*, appearing as fine tan or brown pigment in the epithelium. The deposits seldom affect vision and are rarely a cause to discontinue the medication. The deposits disappear slowly when the medication is stopped. Other medications, including indomethacin, atovaquone, chloroquine, and hydroxychloroquine, can cause a similar pattern. The phenothiazines, including chlorpromazine and thioridazine, can cause brown pigmentary deposits in the cornea, conjunctiva, and eyelids. They typically do not affect vision. The ocular deposits generally persist after discontinuation of the medication and can even worsen. Tetracyclines can cause a yellow discoloration of the light-exposed conjunctiva. Systemic minocycline can induce a blue-gray scleral pigmentation that is most prominent in the interpalpebral zone. Certain chemotherapeutic agents, such as cytarabine, can cause temporary corneal toxicity.

Agents Used to Assist in Ocular Diagnosis

A number of agents are used in an ocular examination (e.g., mydriatic agents, topical anesthetics, dyes to evaluate corneal surface integrity); to facilitate intraocular surgery (e.g., mydriatic and miotic agents, topical and local anesthetics); and to help in making a diagnosis in cases of anisocoria and retinal abnormalities (e.g., intravenous contrast agents). The autonomic agents have been discussed previously. The diagnostic and therapeutic uses of topical and intravenous dyes and of topical anesthetics are discussed in the material that follows.

Anterior Segment and External Diagnostic Uses

Epiphora (excessive tearing) and surface problems of the cornea and conjunctiva are commonly encountered external ocular disorders. The dyes *fluorescein*, *rose bengal*, and *lissamine green* are used in evaluating these problems. Fluorescein (Figure 69–7; available as 10% and 25% solutions for injection and as an impregnated paper strip) reveals epithelial defects of the cornea and conjunctiva and aqueous humor leakage that may occur after trauma or ocular surgery. In the setting of epiphora, fluorescein is used to determine the patency of the nasolacrimal system. In addition, this dye is used in *applanation tonometry* (IOP measurement) and to assist

Figure 69–7 The diagnostic dye fluorescein.

in determining the proper fit of rigid and semirigid contact lenses. Fluorescein in combination with proparacaine or benoxinate is available for procedures in which a disclosing agent is needed in conjunction with a topical anesthetic. Fluorexon, a high-molecular-weight fluorescent solution, is used when fluorescein is contraindicated (as when soft contact lenses are in place). *Rose bengal* and *lissamine green* (available as saturated paper strips) stain devitalized tissue on the cornea and conjunctiva.

Posterior Segment Diagnostic Uses

The integrity of the blood-retinal and retinal pigment epithelial barriers may be examined directly by retinal angiography using intravenous administration of either *fluorescein sodium* or *indocyanine green*. These agents commonly cause nausea and may precipitate serious allergic reactions in susceptible individuals.

Treatment of Retinal Neovascularization, Macular Degeneration, and Vitreomacular Traction

The medical treatment of retinal neovascularization has been changing rapidly in the past several years and will likely continue to do so (Agarwal et al., 2015). Current treatment employs agents that inhibit the actions of VEGF (Table 69–14). *Verteporfin* is approved for photodynamic therapy of the exudative form of ARMD with predominantly classic choroidal neovascular membranes. Verteporfin also is used in the treatment of predominantly classic choroidal neovascularization caused by conditions such as pathological myopia and presumed ocular histoplasmosis syndrome. Verteporfin is administered intravenously; once it reaches the choroidal circulation, the drug is light activated by a nonthermal laser source. Activation of the drug in the presence of O₂ generates free radicals, which cause vessel damage and subsequent platelet activation, thrombosis, and occlusion of choroidal neovascularization. The *t*_{1/2} of the drug is 5–6 h; it is eliminated predominantly in the feces. Potential side effects include headache, injection site reactions, and visual disturbances. The drug causes

temporary photosensitization; patients must avoid exposure of the skin or eyes to direct sunlight or bright indoor lights for 5 days after receiving verteporfin.

Pegaptanib, a selective VEGF antagonist, is approved for neovascular (wet) ARMD. VEGF₁₆₅ induces angiogenesis and increases vascular permeability and inflammation, which actions likely contribute to the progression of the neovascular (wet) form of ARMD, a leading cause of blindness. Pegaptanib inhibits VEGF₁₆₅ binding to VEGF receptors. Pegaptanib (0.3 mg) is administered once every 6 weeks by intravitreal injection into the eye to be treated. Following the injection, patients should be monitored for elevation in IOP and for endophthalmitis. Rare cases of anaphylaxis/anaphylactoid reactions have been reported.

Aflibercept is a recombinant fusion protein, consisting of portions of human VEGF receptors 1 and 2, that acts as a soluble decoy receptor for VEGF-A. It is approved for the neovascular (wet) form of ARMD as well as macular edema following retinal vein occlusion or associated with diabetic retinopathy. Depending on the underlying disease, aflibercept (2 mg) is administered once every month by intravitreal injection into the eye for 3–5 months, followed by 2 mg once every 8 weeks. Serious side effects may include eye pain or redness, swelling, vision problems, photosensitivity, headaches, sudden numbness on one side of the body, confusion, and problems with speech and balance. The drug is contraindicated in patients who have an active eye infection or active ocular inflammation.

Bevacizumab is a monoclonal murine antibody that targets VEGF-A and thereby inhibits vascular proliferation and tumor growth (see Chapter 67). Intracocular use is considered off label but is routinely done. *Ranibizumab* is a variant of bevacizumab that has had the Fab domain affinity matured. Both drugs are delivered by intravitreal injection and often are used on a weekly or monthly basis for maintenance therapy. Both have been associated with the risk of cerebral vascular accidents. The enormous cost difference between these similar antibodies has sparked a debate about the cost-effectiveness of treatment strategies (Shaikh et al., 2015; Stein et al., 2014), especially in light of recent data indicating similar visual acuity outcomes for each medicine (CATT Research Group, 2011).

Ocriplasmin is a proteolytic enzyme that is used to treat vitreomacular traction. It works to dissolve the vitreous and relieve traction on the macula in the center of the retina. An interesting side effect is the possibility of lens subluxation from zonular dehiscence.

Anesthetics in Ophthalmic Procedures

Topical anesthetic agents used clinically in ophthalmology include proparacaine and tetracaine drops, lidocaine gel (see Chapter 22), and intranasal cocaine. Cocaine may be used intranasally in combination with topical anesthesia for cannulating the nasolacrimal system. Lidocaine and

TABLE 69–14 ■ ANTI-VEGF AGENTS FOR OCULAR USE			
AGENT	FORMULATION	INDICATION	COMMENTS
Verteporfin	2-mg/mL reconstituted solution for intravenous infusion	Retinal neovascularization associated with macular degeneration	Dosed according to body surface area Activated by a cool laser as it circulates in the retinal circulation Causes photosensitization and propensity for sunburn
Pegaptanib	0.3-mg intravitreal injection	Same as verteporfin	Binds to the 165 isoform of VEGF
Aflibercept	2 mg/0.5 mL–intravitreal injection	Same as verteporfin <i>plus</i> DME or for the treatment of diabetic retinopathy in patients with DME	A decoy receptor for VEGF-A
Bevacizumab	1.25-mg intravitreal injection	Same as aflibercept	First anti-VEGF antibody commercially available; generally used off label as first-line therapy Made by compounding pharmacies
Ranibizumab	0.3 mg/0.5 mL–intravitreal injection	Same as aflibercept	A variant of bevacizumab

bupivacaine are used for infiltration and retrobulbar block anesthesia for surgery. Potential complications and risks relate to allergic reactions, globe perforation, hemorrhage, and vascular and subdural injections. Both preservative-free lidocaine (1%), which is introduced into the anterior chamber, and lidocaine jelly (2%), which is placed on the ocular surface during preoperative patient preparation, are used for cataract surgery performed under topical anesthesia. Most inhalational agents and CNS depressants are associated with a reduction in IOP. An exception is ketamine, which has been associated with an elevation in IOP. In the setting of a patient with a ruptured globe, the anesthesia should be selected carefully to avoid agents that depolarize the extraocular muscles, which may result in expulsion of intraocular contents.

Wetting Agents, Tear Substitutes, Osmotic Agents

The current management of dry eyes usually includes instilling artificial tears and other ophthalmic lubricants. In general, tear substitutes are hypotonic or isotonic solutions composed of electrolytes, surfactants, preservatives, and some viscosity-increasing agent that prolongs the residence time in the cul-de-sac and precorneal tear film.

Common viscosity agents include cellulose polymers, polyvinyl alcohol, polyethylene glycol, polysorbate, mineral oil, glycerin, and dextran. The tear substitutes are available as preservative-containing or preservative-free preparations. The viscosity of the tear substitute depends on its exact formulation and can range from watery to gel like. Some tear formulations also are combined with a vasoconstrictor, such as naphazoline, phenylephrine, or tetrahydrozoline. The lubricating ointments are composed of a mixture of white petrolatum, mineral oil, liquid or alcohol lanolin, and sometimes a preservative. These highly viscous formulations cause considerable blurring of vision; consequently, they are used primarily at bedtime, in critically ill patients, or in very severe dry eye conditions. A hydroxypropyl cellulose ophthalmic insert that is placed in the inferior cul-de-sac and dissolves during the day is available to treat dry eyes.

Local eye disease, such as blepharitis, ocular rosacea, ocular pemphigoid, chemical burns, or corneal dystrophies, may alter the ocular surface and change the tear composition. Appropriate treatment of the symptomatic dry eye includes treating the accompanying disease and possibly the addition of tear substitutes, punctal plugs (see Absorption), or ophthalmic cyclosporine (see Immunosuppressants). There also are a number of systemic conditions that may manifest themselves with symptomatic dry eyes, including Sjögren syndrome, rheumatoid arthritis, vitamin A deficiency, Stevens-Johnson syndrome, and trachoma. Treating the systemic disease may not eliminate the symptomatic dry

eye complaints; chronic therapy with tear substitutes, ophthalmic cyclosporine, insertion of punctal plugs, placement of dissolvable collagen implants, or surgical occlusion of the lacrimal drainage system may be indicated. Ophthalmic cyclosporine can be used to increase tear production in patients with ocular inflammation associated with keratoconjunctivitis sicca.

The main osmotic drugs for ocular use are glycerin, mannitol, and hypertonic saline. Glycerin and mannitol are used for short-term management of acute rises in IOP. Sporadically, these agents are used intraoperatively to dehydrate the vitreous prior to anterior segment surgical procedures. Many patients with acute glaucoma do not tolerate oral medications because of nausea; therefore, intravenous administration of mannitol or acetazolamide may be preferred over oral administration of glycerin. These agents should be used with caution in patients with congestive heart failure or renal failure.

Corneal edema is a clinical sign of corneal endothelial dysfunction, and topical osmotic agents may effectively dehydrate the cornea. NaCl is available in either aqueous or ointment formulations. Topical glycerin also is available; however, because it causes pain on contact with the cornea and conjunctiva, its use is limited to urgent evaluation of filtration-angle structures. In general, when corneal edema occurs secondary to acute glaucoma, the use of an oral osmotic agent to help reduce IOP is preferred over topical glycerin, which simply clears the cornea temporarily. Reducing the IOP will help clear the cornea more permanently to allow both a view of the filtration angle by gonioscopy and a clear view of the iris as required to perform laser iridotomy.

Vitamin A and the Visual Cycle

Vitamin deficiencies can alter eye function, especially a deficiency of vitamin A (Table 69-15). In vision, the functional form of vitamin A is *retinal*; its deficiency interferes with vision in dim light, contributing to a condition known as *night blindness* (nyctalopia).

Chemistry

Retinoid refers to the chemical entity *retinol* and other closely related naturally occurring derivatives. Retinoids, which exert most of their effects by binding to specific nuclear receptors and modulating gene expression, also include structurally related synthetic analogues that need not have retinol-like (vitamin A) activity. The purified plant pigment carotene (pro-vitamin A) is a protean source of vitamin A. β -Carotene is the most active

TABLE 69-15 ■ OPTHALMIC EFFECTS OF SELECTED VITAMIN DEFICIENCIES AND ZINC DEFICIENCY

DEFICIENCY	EFFECTS IN ANTERIOR SEGMENT	EFFECTS IN POSTERIOR SEGMENT
Vitamin		
A (retinol)	Conjunctiva (Bitot spots, xerosis)	Retina (nyctalopia, impaired rhodopsin synthesis), retinal pigment epithelium (hypopigmentation)
	Cornea (keratomalacia, punctate keratopathy)	
B ₁ (thiamine)	—	Optic nerve (temporal atrophy with corresponding visual field defects)
B ₆ (pyridoxine)	Cornea (neovascularization)	Retina (gyrate atrophy)
B ₁₂ (cyanocobalamin)	—	Optic nerve (temporal atrophy with corresponding visual field defects)
C (ascorbic acid)	Lens (? cataract formation)	—
E (tocopherol)	—	Retina and retinal pigment epithelium (? macular degeneration)
Folic acid	—	Vein occlusion
K	Conjunctiva (hemorrhage)	Retina (hemorrhage)
	Anterior chamber (hyphema)	
Zinc	—	Retina and retinal pigment epithelium (? macular degeneration)

Retinal Cells and the Visual Cycle

proteins and respond optimally to light of different wavelengths. Several review articles summarized the process of photoreception (Kefalov, 2012; Saari, 2016). Figure 69–9 summarizes the signaling pathway initiated by absorption of a photon by 11-*cis*-retinal in rods.

Vitamin A Deficiency

Vitamin A is an essential nutrient with multiple functions in the body, including the eye (Sommer and Vyas, 2012). Humans deficient in vitamin A lose their ability for dark adaptation. Rod vision is affected more than cone vision. On depletion of retinol from liver and blood, usually at plasma concentrations of retinol of less than 0.2 mg/L (0.70 μ M), the concentrations of retinol and rhodopsin in the retina fall. Unless the deficiency

is overcome, opsin, lacking the stabilizing effect of retinal, decays, and anatomical deterioration of the rod outer segment occurs.

Vitamin A and Epithelial Structures

In the presence of retinol or retinoic acid, basal epithelial cells are stimulated to produce mucus. Excessive concentrations of the retinoids lead to the production of a thick layer of mucin, the inhibition of keratinization, and the display of goblet cells. In the absence of vitamin A, goblet mucous cells disappear and are replaced by basal cells that have been stimulated to proliferate. These undermine and replace the original epithelium with a stratified, keratinizing epithelium. The suppression of normal secretions leads to irritation and infection. Reversal of these changes is achieved by the administration of retinol, retinoic acid, or other retinoids. When this process happens in the cornea, severe hyperkeratinization (xerophthalmia) may lead to permanent blindness (McLaren and Kraemer, 2012). Common causes of vitamin A deficiency include malnutrition and bariatric surgery.

Retinoic acid influences gene expression by combining with nuclear receptors (see Figures 3–12 and 6–8). There are two families of retinoid receptors: the RARs and the RXRs. The endogenous RXR ligand is 9-*cis*-retinoic acid.

Therapeutic Uses of Vitamin A

Nutritional vitamin A deficiency causes *xerophthalmia*, a progressive disease characterized by *nyctalopia* (night blindness), *xerosis* (dryness), and *keratomalacia* (corneal thinning), which may lead to corneal perforation. Vitamin A therapy can reverse xerophthalmia; however, rapid, irreversible blindness ensues once the cornea perforates. Vitamin A also is involved in epithelial differentiation and may have a role in corneal epithelial wound healing. The current recommendation for retinitis pigmentosa is to administer 15,000 IU of vitamin A palmitate daily under the supervision of an ophthalmologist and to avoid high-dose vitamin E. Clinical studies suggested a reduction in the risk of progression of some types of ARMD by high doses of vitamin C (500 mg), vitamin E (400 IU), β -carotene (15 mg), cupric oxide (2 mg), and zinc (80 mg) (Age-Related Eye Disease Research Group, 2001a, 2001b; Chew et al., 2014), although substituting lutein/zeaxanthin for β -carotene may be more appropriate (Age-Related Eye Disease Study Research Group, 2007; Age-Related Eye Disease Study 2 [AREDS2] Research Group, 2014).

MISCELLANEOUS AGENTS

Principles of Dermatological Pharmacology

The skin is a biologically active, multifunctional, and multicompartiment organ. Medications can be applied to the skin for two purposes: to directly treat disorders of the skin and to deliver drugs to other tissues. Effective and safe use of topical pharmacological therapies requires an understanding of skin physiology and factors influencing percutaneous drug absorption and metabolism (Hwa et al., 2011; Wolff et al., 2008). General features of skin structure and percutaneous absorption pathways are outlined in Figure 70–1.

Nonpharmacological therapy is also used for treatment of skin diseases. This includes the use of parts of the electromagnetic spectrum applied by various sources, such as lasers, X-rays, visible light, and infrared light. These approaches may be used alone or to enhance the penetration or alter the nature of drugs and prodrugs. Freezing and ultrasound are other physical therapies that alter epidermal structure for direct treatment or to enhance percutaneous absorption of drugs. Chemicals are also used to decrease the effect of various wavelengths of UV light and ionizing radiation on the skin.

Structure of Skin

Stratum Corneum

The stratum corneum is the major barrier to percutaneous absorption of drugs and to the loss of water from the body. It may be considered

the “nonliving” portion of the epidermis. The stratum corneum differs in thickness at different body sites, with the palm and sole the thickest followed by the general body stratum corneum, facial and postauricular area, and the eyelid and scrotum.

A drug may partition into the stratum corneum and form a reservoir that will diffuse into the rest of skin even *after* topical application of the drug has ceased.

Living Epidermis

The living layers of the epidermis (stratum basale, stratum spinosum, and stratum granulosum) with metabolically active cells comprise a layer about 100 μm thick (Figure 70–1). Intercalated in the living epidermis are pigment-producing cells (melanocytes), neuroendocrine cells (Merkel cells), dendritic APCs (Langerhans cells), and other immune cells (γ - δ T cells). In diseased epidermis, many additional immunological cells, including lymphocytes and polymorphonuclear leukocytes, may be present and be directly affected by applied drugs.

Dermis and Its Blood Vessels

The dermis provides mechanical strength and flexibility to the skin. It is composed primarily of fibroblasts and an extracellular matrix, including collagen, proteoglycans, glycoproteins, and, in the upper dermis, elastic fibers. Cells within the dermis that may be targets for drugs include mast cells (permanent residents and producers of many inflammatory

VDR:	vitamin D receptor
VZV:	varicella zoster virus

mediators) and infiltrating immune cells producing cytokines. The dermis also contains networks of nerves, blood vessels, and adnexal structures. The superficial capillary plexus between the epidermis and dermis is the site of the majority of the systemic absorption of cutaneous drugs (see Figure 70–1). There are large numbers of lymphatics as well. Hair follicles form a lipid-rich pathway for drug absorption but only constitute 0.1% of

the total skin area, so this is not the primary route of absorption. Sweat glands are not known as a pathway for the absorption of drugs, but some drugs (e.g., griseofulvin) are excreted to the skin by this route. Below the dermis is the hypodermis or subcutaneous tissue, which provides insulation, cushioning, and an energy reservoir.

Mechanisms of Percutaneous Absorption

Percutaneous absorption occurs primarily through a tortuous intercellular route, with transcellular or appendageal routes playing a much smaller role. Passage through the stratum corneum is the rate-limiting step for percutaneous absorption. Preferable characteristics of topical drugs include

- low molecular mass (≤ 500 Da);
- adequate solubility in both oil and water; and
- a high partition coefficient so the drug will selectively partition from the vehicle to the stratum corneum (Hwa et al., 2011; Tran, 2013).

Except for very small particles, water-soluble ions and polar molecules do not penetrate significantly through intact stratum corneum. The exact amount of drug entering or leaving the skin in clinical situations usually is not measured; rather, the clinical end point (e.g., reduction in inflammation) usually is the desired effect.

A hydrated stratum corneum allows more percutaneous absorption and often is achieved through the selection of drugs formulated in occlusive vehicles such as ointments and the use of plastic films, wraps, or bags for the hands and feet and shower or bathing caps for the scalp. Alternatively, medications that are impregnated on patches or tapes may be used. Occlusion may be associated with increased growth of bacteria and resultant infection (folliculitis) or maceration and breakdown of the epidermis. Absorption of most drugs across the skin is a passive process; heat generally increases penetration. Ultrasonic energy, electric currents (iontophoresis), minimally invasive microneedling, and fractional or ablative lasers also can be used to increase percutaneous absorption (Tran, 2013).

Transdermal drug delivery bypasses hepatic first-pass metabolism; however, the epidermis contains a variety of enzyme systems capable of metabolizing drugs that reach this compartment. A specific CYP isoform, CYP26A1, metabolizes retinoic acid and may control its level in the skin (Baron et al., 2001). In addition, transporter proteins that influence influx (OATP) or efflux (MDR [multidrug resistance transporter], P-glycoprotein) of certain xenobiotics are present in human keratinocytes (Baron et al., 2001). Genetic variants of enzymes that regulate the cellular influx and efflux of methotrexate have been associated with toxicity and effectiveness in patients with psoriasis (Warren et al., 2008).

Pharmacologic Implications of Epidermal Structure

When proposing topical application of medications, the healthcare provider must consider multiple factors, including proper dosage and frequency of application, extent and condition of the permeability barrier, patient age and weight, physical form of the preparation to be applied, and whether intralesional or systemic administration should be used (Table 70–1). Various drug vehicles have specific advantages and disadvantages (Table 70–2). Newer vehicles, such as liposomes and microgel formulations, can enhance solubilization of certain drugs, thereby enhancing topical penetration and diminishing irritancy (Rosen et al., 2014). *Children have a greater ratio of surface area to mass than adults do, so the same amount of topical drug can result in greater systemic exposure. Pre-term infants have a markedly impaired barrier function until the epidermis keratinizes completely* (Hwa et al., 2011). *Many dermatological diseases also compromise barrier function, leading to increased percutaneous absorption.*

Glucocorticoids

Glucocorticoids have immunosuppressive and anti-inflammatory properties. They are administered locally through topical and intralesional routes and systemically through intramuscular, intravenous, and oral routes. Mechanisms of glucocorticoid action are discussed in Chapter 46.

Figure 70-1 *Cutaneous drug absorption.* After application of a drug to the surface of the skin (stratum corneum), evaporation and structural/compositional alterations may occur that affect the drug's ultimate bioavailability. The stratum corneum limits drug diffusion into the lower layers and thence into the body. A number of absorptive routes are possible, singly or in combination: between the cells of the stratum corneum (*intercellular*), across the corneal cellular layer (*transcellular*), and into the concavity of a hair follicle (*follicular*) with its associated sebaceous glandular cells and arrector pili muscle that is innervated by the sympathetic branch of the autonomic nervous system. Melanocytes and Langerhans cells are accessible in the lower epidermis. In the epidermal and dermal layers, drugs may also reach the eccrine glands (sweat glands) and their ducts. Permeation to the dermis brings a drug in contact with lymphatics (in green) and cutaneous vessels carrying arterial and venous blood (red and blue, respectively). These vessels provide an absorptive route into the general circulation. Deeper permeation to the hypodermis may also occur.

Topical Glucocorticoids

Topical glucocorticoids have been grouped into seven classes in order of decreasing potency (Table 70-3). Potency traditionally is measured using a vasoconstrictor assay in which an agent is applied to skin under occlusion, and the area of skin blanching is assessed. Other assays of glucocorticoid potency involve suppression of erythema and edema after experimentally induced inflammation and the psoriasis bioassay, in which the effect of steroid on psoriatic lesions is quantified.

Therapeutic Uses

Many inflammatory skin diseases respond to topical or intralesional administration of glucocorticoids. Absorption varies amongst body sites and with the vehicle of the formulation. The steroid is selected on the basis of its potency, the site of involvement, and the severity of the skin disease. Often,

a more potent steroid is used initially, followed by a less potent agent. Twice-daily application of topical glucocorticoids suffices; more frequent application does not improve response. Moderately potent to very potent topical corticosteroids are effective with once-daily versus twice-daily application in atopic dermatitis, and patient adherence may be improved with once-daily regimens (Williams, 2007). In general, only nonfluorinated glucocorticoids should be used on the face or in occluded areas such as the axillae or groin. Intralesional preparations of glucocorticoids include insoluble preparations of triamcinolone acetonide and triamcinolone hexacetonide, which solubilize gradually and therefore have a prolonged duration of action.

Toxicity

Chronic use of class 1 topical glucocorticoids can cause skin atrophy, striae, telangiectasias, purpura, and acneiform eruptions. Because perioral

TABLE 70-1 ■ IMPORTANT CONSIDERATIONS WHEN A DRUG IS APPLIED TO THE SKIN

How does the vehicle affect the penetration?
How much of the drug penetrates the skin?
What are the intended pharmacological targets?
What host and genetic factors influence drug function in the skin?
What are the predicted adverse effects (local, systemic)?

dermatitis and rosacea can develop after the use of fluorinated compounds on the face, they should not be used on this site. Occlusion increases the risk of HPA axis suppression.

Systemic Glucocorticoids

Systemic glucocorticoid therapy is used for severe dermatological illnesses and generally is reserved for allergic contact dermatitis to plants (e.g., poison ivy) and for life-threatening vesiculobullous dermatoses such as pemphigus vulgaris and bullous pemphigoid. Chronic administration of oral glucocorticoids is problematic, given the side effects associated with their long-term use (see Chapter 46).

Daily morning dosing with prednisone generally is preferred, although divided doses occasionally are used to enhance efficacy. Fewer side effects

are seen with alternate-day dosing; if chronic therapy is required, prednisone usually is tapered to every other day as soon as practical. Pulse therapy using large intravenous doses of methylprednisolone sodium succinate is an option for severe resistant pyoderma gangrenosum, pemphigus vulgaris, systemic lupus erythematosus with multisystem disease, and dermatomyositis. The dose of intravenous methylprednisolone usually is 0.5–1 g given over 2–3 h. More rapid infusion has been associated with increased rates of hypotension, electrolyte shifts, and cardiac arrhythmias.

Toxicity and Monitoring

Oral glucocorticoids have numerous systemic effects, as discussed in Chapter 46. Most side effects are dose dependent.

Retinoids

Retinoids comprise natural and synthetic compounds that exhibit vitamin A–like biological activity or bind to nuclear receptors for retinoids. Characteristics of topical and systemic retinoids are summarized in Tables 70–4 and 70–5, respectively.

Tretinoin (all-trans-retinoic acid; vitamin A acid)

TABLE 70-2 ■ VEHICLES FOR TOPICALLY APPLIED DRUGS

	OINTMENT	CREAM	GEL	LOTION/SOLUTION/FOAM
Physical basis	Solid or liquid dispersed in nonaqueous base	Oil-in-water emulsion	Water-soluble emulsion with gelling agent	Lotion-suspended drug Solution-dissolved drug base Foam drug with surfactant as foaming agent and propellant
Solubilizing medium	Anhydrous to < 20% water	20%–80% water	Contains water-soluble polyethylene glycols May have alcoholic solvent	May be aqueous or alcoholic
Pharmacological advantage	Protective oil film on skin	Leaves concentrated drug at skin surface	Concentrates drug at surface after evaporation	
Advantages for patient	Spreads easily Slows water evaporation	Spreads and removes easily No greasy feel	Nonstaining Greaseless Typically clear appearance	Low residue on scalp or other hairy areas May have cooling effect when evaporates
Locations on body	Avoid intertriginous areas	Most locations	Scalp and other hairy locations	Scalp and other hairy locations
Disadvantages	Greasy Stains clothes	Needs preservatives	Needs preservatives Can be drying, especially if high alcohol content	Can be drying May burn if alcohol content Foams tend to be more expensive due to more complex delivery system
Occlusion	Moderate to high Increases skin moisture	Low	None	None
Composition notes	Oleaginous base (e.g., white petrolatum) or Absorption base (e.g., hydrophilic petrolatum)	Requires humectants (glycerin, propylene glycol, polyethylene glycols) to keep moist when applied Long-chain alcohol (e.g., stearyl alcohol) in oil phase for stability and smooth feel	Microspheres or microsponges can be formulated in gels	

TABLE 70-3 ■ POTENCY OF SELECTED TOPICAL GLUCOCORTICOIDS

	CLASS OF DRUG	GENERIC NAME, FORMULATION

First-generation retinoids include retinol (vitamin A), tretinoin (all-*trans*-retinoic acid; vitamin A acid), isotretinoin (13-*cis*-retinoic acid), and alitretinoin (9-*cis*-retinoic acid). Second-generation retinoids, also known as aromatic retinoids, include acitretin. Third-generation retinoids were designed to optimize receptor-selective binding and include tazarotene, bexarotene, and adapalene.

- **Mechanism of Action.** Retinoids exert their effects on gene expression by activating two families of receptors, *RARs* and *RXRs*, which are members of the steroid receptor superfamily. Both retinoid receptor families have three isoforms (α , β , and γ), which are expressed in unique

combinations in individual tissues and cells. On binding to a retinoid, *RARs* and *RXRs* form heterodimers (*RAR-RXR*) that subsequently bind specific DNA sequences called *RAREs* that activate transcription of genes whose products produce both the desirable pharmacological effects and the unwanted side effects of these drugs (see Tables 6-5, 70-4 and 70-5, and Figure 6-13).

- **Targeted Therapeutic Actions.** Retinoids that target *RARs* predominantly affect cellular differentiation and proliferation, whereas retinoids that target *RXRs* predominantly induce apoptosis. Hence, tretinoin, adapalene, and tazarotene, which target *RARs*, are used in acne, psoriasis, and photoaging (disorders of differentiation and proliferation), whereas bexarotene and alitretinoin, which target *RXRs*, are used in CTCL and Kaposi sarcoma, respectively, to induce apoptosis of malignant cells.
- **Retinoid Toxicity.** Acute retinoid toxicity is similar to vitamin A intoxication. Side effects of systemic retinoids include dry skin, nosebleeds from dry mucous membranes, conjunctivitis, reduced night vision, hair loss, alterations in serum lipids and transaminases, hypothyroidism, inflammatory bowel disease flare, musculoskeletal pain, pseudotumor cerebri, and mood alterations. *RAR*-selective retinoids are more associated with mucocutaneous and musculoskeletal symptoms, whereas *RXR*-selective retinoids induce more physiochemical changes. Because all oral retinoids are potent teratogens, they should be used carefully in females of childbearing potential and not in pregnant patients.

Topical Retinoids

Through incompletely understood mechanisms, topical retinoids correct abnormal follicular keratinization, reduce *Propionibacterium acnes* counts, and reduce inflammation, thereby making them the cornerstone of acne therapy. Topical retinoids are first-line agents for noninflammatory (comedonal) acne and often are combined with other agents in the management of inflammatory acne.

Fine wrinkles and dyspigmentation, two important features of photoaging, are also improved with topical retinoids. Within the dermis, this is believed to result from inhibition of AP-1, which normally activates synthesis of matrix metalloproteinases in response to UV irradiation (Thielitz and Gollnick, 2008). In the epidermis, retinoids induce epidermal hyperplasia in atrophic skin and reduce keratinocyte atypia.

Toxicity and Monitoring

Adverse effects of all topical retinoids include erythema, desquamation, burning, and stinging (see relative irritancy in Table 70-4). These effects often decrease with time and are lessened by concomitant use of emollients. Patients also may experience photosensitivity reactions (enhanced reactivity to UV radiation) and have a significant risk for severe sunburn. Although there is little systemic absorption of topical retinoids and no alteration in plasma vitamin A levels with their use, topical retinoids are not recommended for use during pregnancy.

Available Agents; Clinical Use

Tretinoin (all-*trans*-retinoic acid) is photolabile and should be applied once nightly for acne and photoaging. Benzoyl peroxide also inactivates tretinoin and should not be applied simultaneously. Formulations with copolymer microspheres or prepolyolprepolymer 2 that gradually release tretinoin to decrease irritancy are available and are less susceptible to oxidation by benzoyl peroxide and photodegradation.

Adapalene has similar efficacy to tretinoin, but unlike tretinoin, it is stable in sunlight or the presence of benzoyl peroxide and tends to be less irritating.

Tazarotene is approved for the treatment of psoriasis, photoaging, facial wrinkles, and acne vulgaris. Tazarotene gel, applied once daily, may be used as monotherapy or in combination with other medications, such as topical corticosteroids, for the treatment of localized plaque psoriasis. Topical corticosteroids improve the efficacy of therapy and reduce the side effects of burning, itching, and skin irritation that are commonly associated with tazarotene.

Alitretinoin is a retinoid that binds all types of retinoid receptors, both *RARs* and *RXRs*. It is approved for treatment of cutaneous lesions

TABLE 70-4 ■ TOPICAL RETINOIDS

DRUG	FORMULATION	RECEPTOR SPECIFICITY	PREGNANCY CATEGORY	IRRITANCY
Tretinoin	0.02%, 0.025%, 0.05%, 0.1% cream 0.01%, 0.025%, 0.04% gel 0.05%, 0.1% solution	RAR- α , RAR- β , RAR- γ	C	++
Tazarotene	0.05%, 0.1% cream 0.05%, 0.01% gel	RAR- α , RAR- β , RAR- γ	X	++++
Adapalene	0.1%, 0.3% cream 0.1%, 0.3% gel 0.1% solution	RAR- β , RAR- γ	C	+
Alitretinoin	0.1% gel	RAR- α , RAR- β , RAR- γ	D	++
Bexarotene	1% gel	RXR- α , RXR- β , RXR- γ	X	+++

of Kaposi sarcoma, with its application titrated up from twice daily to three or four times daily as tolerated. Alitretinoin should not be applied concurrently with insect repellants containing diethyltoluamide (DEET) because it may increase DEET absorption.

Bexarotene is approved for early-stage (IA and IB) CTCL. Its application is titrated up from every other day to two to four times daily over several weeks to improve patient tolerance. Concurrent application of bexarotene with insect repellants containing DEET is not recommended because it may increase DEET absorption.

Systemic Retinoids

Systemic retinoids (Table 70-5) are approved for the treatment of acne, psoriasis, and CTCL (Desai et al., 2007).

Therapeutic Uses and Contraindications

Off-label uses include ichthyosis, Darier disease, pityriasis rubra pilaris, rosacea, hidradenitis suppurativa, chemoprevention of malignancy, lichen sclerosus, subacute lupus erythematosus, and discoid lupus erythematosus. Absolute contraindications include use by women who are pregnant, planning to become pregnant, or breastfeeding. Relative contraindications include leukopenia, alcoholism, hyperlipidemia, hypercholesterolemia, hypothyroidism, and significant hepatic or renal disease.

Toxicity and Monitoring

Acute toxicities may include mucocutaneous or laboratory abnormalities; bony changes may occur after chronic use at high doses. Mucocutaneous side effects may include cheilitis, xerosis, blepharoconjunctivitis, cutaneous photosensitivity, photophobia, myalgia, arthralgia, headaches, alopecia, nail fragility, and increased susceptibility to staphylococcal infections. Some patients develop a "retinoid dermatitis" characterized by erythema, pruritus, and scaling. Very rarely, patients may develop pseudotumor cerebri, especially when systemic retinoids are combined with tetracyclines. There are reports that chronic administration at higher doses can cause diffuse idiopathic skeletal hyperostosis (DISH) syndrome, premature epiphyseal closure, and other skeletal abnormalities (Desai et al., 2007).

Systemic retinoids are highly teratogenic. There is no safe dose during pregnancy. Prescribing of isotretinoin in the U.S. is restricted via the risk-mitigation iPLEDGE system.

Serum lipid elevation is the most common laboratory abnormality. Less common laboratory abnormalities include elevated transaminases, decreased thyroid hormone, and leukopenia. A baseline evaluation of serum lipids, serum transaminases, and CBC should be obtained prior to starting any systemic retinoids. These laboratory values are usually subsequently checked monthly for the first 3–6 months and once every 3 months thereafter. In addition, two negative pregnancy tests on separate occasions are required for females of childbearing potential prior to starting acitretin or isotretinoin; bexarotene requires one negative pregnancy test within the week prior to initiating therapy. Monthly pregnancy tests should be obtained for females of childbearing potential.

Available Agents and Clinical Use

Isotretinoin is approved for the treatment of recalcitrant and nodular acne vulgaris. The drug has remarkable efficacy in severe acne and may induce prolonged remissions after a single course of therapy. Clinical effects generally are noted within 1–3 months of starting therapy. Approximately one-third of patients will relapse, usually within 3 years of stopping therapy. Although most relapses are mild and respond to conventional management with topical and systemic antiacne agents, some may require a second course of isotretinoin. Systemic absorption is improved when taken with a high-fat meal. An isotretinoin-Lidose formulation (a eutectic mixture of drug and lipids in a hard gelatin capsule) may be given without respect to meals.

Acitretin is approved for use in the cutaneous manifestations of psoriasis. Clinical effect may begin within 4–6 weeks, with the full clinical benefit occurring at 3–6 months. Acitretin has a $t_{1/2}$ of about 50 h; however, when combined with alcohol, acitretin is esterified in vivo to produce etretinate, which has a $t_{1/2}$ of more than 3 months. It is not known how much alcohol (i.e., cough syrup or other alcohol-based medications) is required to induce this conversion. Thus, female patients of childbearing potential should avoid pregnancy for 3 years after receiving acitretin to avoid retinoid-induced embryopathy.

TABLE 70-5 ■ SYSTEMIC RETINOIDS

DRUG	RECEPTOR SPECIFICITY	DOSING RANGE	$t_{1/2}$
Isotretinoin	No clear receptor affinity	0.5–2 mg/kg/d	10–20 h
Etretinate	RAR- α , RAR- β , RAR- γ	0.25–1 mg/kg/d	80–160 d
Acitretin	RAR- α , RAR- β , RAR- γ	0.5–1 mg/kg/d	50 h
Bexarotene	RXR- α , RXR- β , RXR- γ	300 mg/m ² /d	7–9 h

Bexarotene is a retinoid that selectively binds RXRs. Oral and topical formulations of bexarotene are approved for use in patients with CTCL. Bexarotene reportedly induces apoptosis of malignant cells (Jawed et al., 2014). Because CYP3A4 metabolizes bexarotene, inhibitors of CYP3A4 (e.g., imidazole antifungals, macrolide antibiotics) will increase and inducers of CYP3A4 (e.g., rifamycins, carbamazepine, dexamethasone, efavirenz, phenobarbital) will decrease plasma levels of bexarotene. Side effects are more common than with other retinoids, with an increased incidence of significant lipid abnormalities and hypothyroidism secondary to a reversible RXR-mediated suppression of TSH gene expression, pancreatitis, leukopenia, and GI symptoms. Thyroid function should be measured before initiating therapy and periodically thereafter.

Vitamin Analogues

Calcipotriene

Calcipotriene is a topical vitamin D analogue that is used in the treatment of psoriasis.

Mechanism of Action

Calcipotriene exerts its effects through the VDR (see Chapter 48). On binding the VDR, the drug-receptor complex associates with the RXR- α and binds to vitamin D response elements on DNA, increasing expression of genes that modulate epidermal differentiation and inflammation, leading to improvement in psoriatic plaques (Menter et al., 2009a).

Therapeutic Use

Calcipotriene is applied twice daily to plaque psoriasis on the body, often in combination with topical corticosteroids. Hypercalcemia and hypercalciuria may develop when the cumulative weekly dose exceeds the

recommended 100 g/week limit and resolves within days of discontinuation of calcipotriene (Menter et al., 2009a). Calcipotriene also causes perilesional irritation and mild photosensitivity. Concomitant administration of topical corticosteroids will reduce the irritation. Calcipotriene has been used off label for multiple conditions, including morphea, vitiligo, and congenital ichthyoses.

β -Carotene

β -Carotene is a precursor of vitamin A that is in green and yellow vegetables. No β -carotene products are currently FDA approved. Dietary supplementation with β -carotene is used in dermatology to reduce skin photosensitivity in patients with erythropoietic protoporphyria. The mechanism of action is not established but may involve an antioxidant effect that decreases the production of free radicals or singlet oxygen. A meta-analysis concluded that β -carotene, vitamin A, and vitamin E, given singly or combined with other antioxidant supplements, did not provide any benefit in lowering mortality or decreasing the risk of cerebrovascular accident. In addition, use of β -carotene and vitamin E led to an increase in all-cause mortality (Bjelakovic et al., 2012). The FDA's maximum recommended therapeutic dose (MRTD) for β -carotene is 0.05 mg/kg/d.

Photochemotherapy

Phototherapy and photochemotherapy are treatment methods in which UV or visible radiation is used to induce a therapeutic response either alone (phototherapy) or in the presence of an exogenous photosensitizing drug (photochemotherapy) (Table 70-6). Patients treated with these modalities should be monitored for concomitant use of other potential photosensitizing medications, such as phenothiazines, thiazides, sulfonamides, NSAIDs, sulfonyleureas, tetracyclines, and benzodiazepines.

TABLE 70-6 ■ PHOTOCHEMOTHERAPY METHODS

	PUVA	PHOTOPHERESIS	PHOTODYNAMIC THERAPY
Target	Broad cutaneous area	Peripheral blood leukocytes	Focal cutaneous sites
Photosensitizing agent	Methoxsalen (8-methoxypsoralen)	Methoxsalen (8-methoxypsoralen)	Protoporphyrin IX

^aControversial.

^bBased on fetal toxicity in pregnant rats. No adequate studies in humans.

CNS, central nervous system; CTCL, cutaneous T cell lymphoma; GI, gastrointestinal; HSV, herpes simplex virus; UVA, ultraviolet A.

The UV radiation region may be subdivided into UVA1 (340–400 nm), UVA2 (320–340 nm), UVB (290–320 nm), and UVC (100–290 nm). UVC radiation is almost completely absorbed by the ozone layer and atmosphere so that measurable amounts do not reach Earth's surface. UVA and UVB exposure can cause sunburns, photoaging, and skin cancer development. UVB is the most erythrogenic and melanogenic, and it is the major action spectrum for sunburn, tanning, skin cancer, photoaging, and cutaneous vitamin D synthesis. UVA is only a thousandth as erythrogenic as UVB but penetrates more deeply into the skin and contributes substantially to photoaging and photosensitivity diseases. UVA is also able to penetrate clouds and glass, so exposure may occur even in the shade or while indoors. Both UVA and UVB cause photoimmune suppression, an effect that is utilized for therapy of certain dermatological conditions.

PUVA: Psoralens and UVA

The PUVA combines UVA light with photosensitizing compounds called psoralens. Orally administered methoxsalen (8-methoxypsoralen) followed by UVA (PUVA) is FDA approved for the treatment of vitiligo and psoriasis. It is also used off label in several other inflammatory or lymphoproliferative cutaneous disorders (Totonchy and Chiu, 2014).

Chemistry and Mechanism of Action

Psoralens are lipophilic, naturally occurring furocoumarins found in some plants. Synthetic versions are also available. The action spectrum for PUVA is between 320 and 340 nm. Psoralens intercalate into the DNA strand, and two distinct photoreactions take place on UVA exposure. Type I reactions involve the oxygen-independent photoaddition of psoralens to pyrimidine bases in DNA. Type II reactions are oxygen dependent and involve the transfer of energy to molecular oxygen, creating reactive oxygen species. Through incompletely understood mechanisms, these phototoxic reactions stimulate melanocytes and induce antiproliferative, immunosuppressive, and anti-inflammatory effects.

Pharmacokinetics

Formulations of solubilized *methoxsalen* in a gel matrix are absorbed rapidly after oral administration, whereas older microcrystalline forms are absorbed slowly and incompletely. Fatty foods slow absorption and decrease peak blood levels. There is significant, but saturable, first-pass elimination in the liver. Peak photosensitivity varies significantly between individuals but typically is maximal 1–2 h after ingestion. Methoxsalen has a serum $t_{1/2}$ of about 1 h, but the skin remains sensitive to light for 8–12 h.

Therapeutic Uses

Oral *methoxsalen* is available as a single 10-mg strength either as soft gelatin capsules (solubilized) or hard gelatin capsules (micronized crystals). The dose is 10–70 mg, depending on weight (0.4–0.6 mg/kg), taken about 1.5–2 h before UVA exposure. Though administration with food can decrease absorption, it may minimize nausea. Topical application of psoralens followed by UVA exposure (topical PUVA) is also used for treatment. A lotion containing 1% methoxsalen is available for topical application for vitiligo. The methoxsalen lotion or capsules can be diluted in bathwater and used topically for localized palmoplantar (soak PUVA) or more diffuse (bath PUVA) areas to minimize systemic absorption. An extracorporeal solution is available for CTCL (see Photopheresis).

Approximately 70%–100% of psoriatic patients have clearing or virtual clearing of skin disease within about 24 treatments with PUVA. Remission typically lasts 3–6 months; thus, patients often require maintenance therapy with intermittent PUVA or other agents. Vitiligo typically requires between 150 and 300 treatments. Localized vitiligo can be treated with topical PUVA and more extensive disease with systemic administration. PUVA also is employed off label in the treatment of atopic dermatitis, alopecia areata, lichen planus, and urticaria pigmentosa.

Toxicity and Monitoring

The major side effects of PUVA are listed in Table 70–6. Phototoxicity is characterized by erythema, edema, blistering, and pruritus. Ocular toxicity can be prevented by wearing UVA-blocking glasses on the day of treatment. The risk of nonmelanoma skin cancer is dose dependent, with

the greatest risk in those receiving more than 200–250 treatments (Totonchy and Chiu, 2014). There is a possible association between extensive PUVA exposure and melanoma, but there has been conflicting evidence regarding this association.

Photopheresis

Extracorporeal photopheresis (ECP) is a process in which extracorporeal peripheral blood mononuclear cells are separated using a leukapheresis-based method then exposed to UVA radiation in the presence of methoxsalen (Perotti and Sniecinski, 2015). Methoxsalen is injected directly into the extracorporeal plasma before radiation and reinfusion. The treated lymphocytes are returned to the patient, undergoing apoptosis over 48–72 h. The ECP is used for CTCL and off label for various other T-cell-mediated diseases, including graft-versus-host disease, transplantation rejection, and scleroderma. Patients receive ECP therapy on two consecutive days every 2–4 weeks, and intervals are increased as the patient improves (Jawed et al., 2014). ECP can be combined with adjunctive therapies, including PUVA, topical chemotherapy, systemic chemotherapy, radiation, biological agents, and retinoids.

Photodynamic Therapy

Photodynamic therapy combines the use of photosensitizing drugs and visible light for the treatment of dermatological disorders. Two drugs are approved for topical PDT: aminolevulinic acid and methylaminolevulinate. However, methylaminolevulinate is currently not commercially available in the U.S. Both are prodrugs that are converted into protoporphyrin IX within living cells (Figure 70–2). In the presence of specific wavelengths of light (see Table 70–6) and O_2 , protoporphyrin produces reactive oxygen species that oxidize cell membranes, proteins,

Figure 70–2 Heme biosynthesis pathway. **A.** Under physiological conditions, heme inhibits the enzyme δ -aminolevulinic acid (δ -ALA) synthase by negative feedback. However, when ALA is provided exogenously, this control point is bypassed, leading to excessive accumulation of protoporphyrin IX and heme. **B.** Heme.

and mitochondrial structures, leading to apoptosis. The epidermis, sebaceous glands, and neoplastic cells accumulate more porphyrin than other cutaneous cells and structures, providing some preferential targeting of therapy (Rkein and Ozog, 2014). PDT is approved for use on precancerous actinic keratosis. It is also used off label for superficial nonmelanoma skin cancers, acne, and photorejuvenation. Incoherent (nonlaser) and laser light sources have been used for PDT. The wavelengths chosen must include those within the action spectrum of protoporphyrin (see Table 70–6) and ideally those that permit maximum skin penetration. Light sources in use emit energy predominantly in the blue portion (maximum porphyrin absorption) or the red portion (better tissue penetration) of the visible spectrum. Because the $t_{1/2}$ of the accumulated porphyrins is about 30 h, patients should protect their skin from sunlight and intense light for at least 48 h after treatment to prevent phototoxic reactions.

Sunscreens

Sunscreens provide temporary photoprotection from the acute and chronic effects of sun exposure. They are an important component of a comprehensive sun protection approach along with minimizing sun exposure and using photoprotective gear. The regular use of sunscreen is efficacious in reducing photocarcinogenesis and photoaging (Mancebo et al., 2014). The SPF is defined as the ratio of the minimal dose of incident sunlight that will produce erythema (sunburn) on skin with the sunscreen in place to the dose that evokes the same reaction on skin without the sunscreen. SPF is primarily a measure of UVB protection and does not provide information regarding UVA coverage. In 2011, the FDA published new guidelines for labeling and effectiveness testing of sunscreens (Mancebo et al., 2014). UVA protection is now assessed using the CW method, and products with a CW of 370 nm or greater may be labeled as “broad spectrum.” Sunscreens providing broad-spectrum coverage with an SPF 15 or greater may include a claim on their labeling that use “decreases risk of skin cancer and early aging caused by the sun.” Sunscreens should be applied liberally 15–30 min prior to sun exposure and reapplied every 2 h. If activities involve swimming or sweating, water-resistant sunscreens are recommended and should be reapplied every 40 or 80 min depending on their labeling.

The major active ingredients of available sunscreens include organic agents (“chemical blockers”) that absorb UV radiation in the UVB or UVA ranges, then convert it to heat energy and inorganic agents (“physical blockers”) that contain particulate materials that act by scattering or reflecting visible, UV, and infrared radiation to reduce its transmission to the skin. The current FDA-approved active sunscreen ingredients are listed next.

Inorganic Agents

The two inorganic agents available in the U.S. are zinc oxide and titanium dioxide. They provide UVA and UVB protection. Newer microsize and nanosize particle formulations are less opaque and more cosmetically appealing.

Organic UVA Filters

Currently available UVA filters in the U.S. include benzophenones (oxybenzone, dioxybenzone, sulisobenzene); dibenzoylmethanes (avobenzone); anthralates (meradimate); and camphors (ecamsule). Additional UVA filters are used in other countries but are not currently available in the U.S.

Organic UVB Filters

There are numerous UVB filters, including aminobenzoates (PABA and padimate O); cinnamates (cinoxate, octinoxate); salicylates (trolamine salicylate, homosalate, octisalate); octocrylene; and ensulizole.

Antihistamines

Histamine (see Chapter 39) is a potent vasodilator, bronchial smooth muscle constrictor, and stimulant of nociceptive itch receptors. Additional chemical itch mediators acting as pruritogens on C fibers include

neuropeptides, prostaglandins, serotonin, acetylcholine, and bradykinin. Furthermore, receptor systems (e.g., vanilloid, opioid, and cannabinoid receptors) on cutaneous sensory nerve fibers may modulate itch and offer novel future targets for antipruritic therapy.

Histamine is in mast cells, basophils, and platelets. Human skin mast cells express H_1 , H_2 , and H_4 receptors but not H_3 receptors. Both H_1 and H_2 receptors are involved in wheal formation and erythema, whereas only the H_1 receptor agonists cause pruritus (see Chapter 39). However, blockade of H_1 receptors does not totally relieve itching, and combination therapy with H_1 and H_2 antagonists may be superior to the use of H_1 antagonists alone.

Oral antihistamines, particularly H_1 receptor antagonists, have anticholinergic activity and are sedating (see Chapter 39), making them useful for the control of pruritus. First-generation sedating H_1 receptor antagonists include *hydroxyzine, diphenhydramine, promethazine, and cyproheptadine* (Simons and Simons, 2008). *Doxepin* is a good alternative to traditional oral antihistamines for severe pruritus. A 5% topical cream formulation of doxepin, which can be used in conjunction with low- to moderate-potency topical glucocorticoids, also is available. The antipruritic effect from topical doxepin is comparable to that of low-dose oral doxepin therapy. Allergic contact dermatitis to doxepin has been reported. Topical diphenhydramine formulations available OTC also carry a significant risk of allergic contact dermatitis. *Second-generation H_1 receptor antagonists* lack anticholinergic side effects and are described as nonsedating largely because they do not cross the blood-brain barrier (Simons and Simons, 2008). They include *cetirizine, levocetirizine, loratadine, desloratadine, and fexofenadine*.

Antimicrobial Agents

Antibiotics

Antibiotic agents are frequently used to treat SSTIs. Several antimicrobial agents, such as tetracyclines, macrolides, and dapsone, also have anti-inflammatory properties, which make them useful for noninfectious conditions, such as acne vulgaris, rosacea, granulomatous diseases, neutrophilic dermatoses, and autoimmune bullous diseases (Bhatia, 2009).

Topical agents are very effective for the treatment of superficial bacterial infections and acne vulgaris (Drucker, 2012). Systemic antibiotics also are prescribed commonly for acne and deeper bacterial infections. The pharmacology of individual antibacterial agents is discussed in Section VI, Chemotherapy of Microbial Diseases. Only the topical and systemic antibacterial agents principally used in dermatology are discussed here.

Acne

Acne vulgaris is the most common dermatological disorder treated with either topical or systemic antibiotics (Eichenfield et al., 2013). The gram-positive anaerobe *Propionibacterium acnes* is a component of normal skin flora that proliferates in the obstructed, lipid-rich lumen of the pilosebaceous unit, where O_2 tension is low. *Propionibacterium acnes* generates free fatty acids from sebum and interacts with toll-like receptors, which promotes microcomedo formation and inflammatory lesions (Das and Reynolds, 2014). Suppression of cutaneous *P. acnes* with antibiotic therapy is correlated with clinical improvement.

Topical antimicrobials commonly used in acne include benzoyl peroxide, clindamycin, erythromycin, and antibiotic–benzoyl peroxide combinations. Topical monotherapy with clindamycin or erythromycin is not recommended due to a slower onset of action and potential for development of bacterial resistance; therefore, addition of benzoyl peroxide or use of combination antibiotic–benzoyl peroxide products is recommended to improve efficacy and decrease emergence of antibiotic-resistant bacteria (Eichenfield et al., 2013). Other topical antimicrobials used in treating acne include azelaic acid, dapsone, metronidazole, sulfacetamide, and sulfacetamide/sulfur combinations.

Systemic therapy is prescribed for patients with acne vulgaris that is more extensive or resistant to topical therapy. There are data to support the

1280 use of tetracyclines (doxycycline, minocycline, tetracycline); macrolides (azithromycin, erythromycin); and trimethoprim-sulfamethoxazole. Other antibiotics that decrease the extent of the infection or the inflammatory response to *P. acnes* may be effective as well. Antibiotics usually are administered once or twice daily, and 6–8 weeks is required for visible clinical results, with maximum effect sometimes requiring 3–6 months (Eichenfield et al., 2013). Doses are tapered after control is achieved. Concomitant use with topical benzoyl peroxide may decrease development of antibiotic-resistant bacteria.

The tetracyclines are the most commonly employed antibiotics because they are inexpensive, effective, and safe. They should not be used during pregnancy or in patients younger than 8 years. Although agents in the tetracycline class are antimicrobials, efficacy in acne may be more dependent on anti-inflammatory activity. Minocycline and doxycycline have better GI absorption than tetracycline and may be given with food to minimize GI side effects. Minocycline may be less photosensitizing than either tetracycline or doxycycline. Minocycline's adverse effects may include vestibular toxicity, hyperpigmentation of the skin and mucosa, serum sickness-like reactions, and drug-induced lupus erythematosus. With all the tetracyclines, vaginal candidiasis is a common complication that is readily treated with administration of antifungal drugs.

Cutaneous Bacterial Infections

Numerous organisms may cause cutaneous infections ranging from benign to life-threatening. Clinical presentation and treatment depend on the depth of cutaneous involvement, immune status of the patient, causative organism, and local antibiotic resistance patterns (Rajan, 2012; Stevens et al., 2014). Gram-positive organisms, including *Staphylococcus aureus* and *Streptococcus pyogenes*, are the most common cause of SSTIs. Patients who are diabetic or immunosuppressed are at risk for severe, recurrent, or atypical infections.

Topical Therapy. Topical therapy is frequently used for superficial bacterial infections, wounds, and burns. The use of topical antibiotics on clean surgical wounds without signs of infection is not recommended as it does not reduce the rate of infection compared to nonantibiotic ointment or no ointment, and there is a risk of contact dermatitis to topical antibiotics (Levender et al., 2012) and counterproductive selection of resistant bacterial strains.

Mupirocin. Mupirocin inhibits protein synthesis by binding to bacterial isoleucyl-tRNA synthetase. Mupirocin is effective for treatment of *S. aureus* and *S. pyogenes*, but it is inactive against normal skin flora or anaerobes. Mupirocin is available as a 2% ointment or cream, applied two or three times daily for 5–10 days. The recommended regimen for impetigo is twice daily for 5 days (Stevens et al., 2014). A nasal formulation is indicated to eradicate MRSA nasal colonization. It is applied intranasally twice a day for 5 days and often combined with daily chlorhexidine or dilute sodium hypochlorite washes for the body. Prolonged suppression may be achieved with repeat monthly courses.

Retapamulin. Retapamulin selectively inhibits bacterial protein synthesis by interacting at a unique site on the 50S subunit of bacterial ribosomes. It is active against multiple gram-positive organisms, including *S. aureus* and *S. pyogenes*, and against anaerobes. Retapamulin ointment 1% is FDA approved for the topical treatment of impetigo caused by susceptible strains of *S. aureus* or *S. pyogenes* in patients 9 months or older. The recommended regimen for impetigo is twice daily for 5 days (Stevens et al., 2014).

Bacitracin, Neomycin, and Polymyxin B. These agents are sold alone or in various combinations with other ingredients (e.g., hydrocortisone, lidocaine, or pramoxine) in a number of OTC formulations. Bacitracin inhibits staphylococci, streptococci, and gram-positive bacilli. Neomycin is active against staphylococci and most gram-negative bacilli. Polymyxin B is active against aerobic gram-negative bacilli, including *Pseudomonas aeruginosa*. Both bacitracin and neomycin are relatively common causes of allergic contact dermatitis, especially in patients with stasis dermatitis or otherwise disrupted skin (Drucker, 2012).

Gentamicin. Gentamicin is an aminoglycoside that inhibits protein synthesis by binding to the 30S subunit of bacterial ribosomes. It has activity

for certain gram-positive bacteria, including *S. aureus*, and gram-negative bacteria, including *P. aeruginosa*. Gentamicin sulfate 0.1% cream or ointment may be applied three or four times daily to affected areas.

Silver Sulfadiazine. Silver sulfadiazine binds to bacterial DNA and inhibits replication. It is bactericidal against gram-positive bacteria, including MRSA, and gram-negative bacteria, including *P. aeruginosa*. Silver sulfadiazine is most frequently used in the treatment of partial-thickness burns or lower extremity venous stasis ulcers. However, recent studies have failed to demonstrate efficacy in these settings (Miller et al., 2012). Rarely, argyria has developed in patients using silver sulfadiazine over extensive areas of the body (Browning and Levy, 2008).

Mafenide. Mafenide acetate is a topical sulfonamide, although its mechanism of action may be distinct from other sulfonamides. Mafenide is approved as adjunctive therapy for burn wounds and is available as either an 85-mg/g cream or as a 5% topical solution supplied as 50-g packets of powder that must be reconstituted. It exerts broad bacteriostatic action against many gram-positive and gram-negative organisms, including *P. aeruginosa* and some anaerobes. The high solubility of mafenide allows it to diffuse easily through eschar and devascularized tissue, which is beneficial for treating subeschar burn wound infection. Mafenide and its metabolites inhibit carbonic anhydrase, so treated patients may be at risk for metabolic acidosis, especially if they have renal failure or if mafenide is applied to large surface areas. Other potential adverse effects include pain or burning sensation with application, facial edema, allergic contact dermatitis, and rarely hemolytic anemia in patients with G6PD deficiency.

Systemic Therapy. Deeper or complicated SSTIs typically require systemic administration of antimicrobials, which are also useful for superficial infections with diffuse involvement or that are not responding to topical therapy. Because SSTIs are most commonly caused by streptococcal and staphylococcal species, penicillins (especially β -lactamase-resistant β -lactams) and cephalosporins are the systemic antibiotics used most frequently in their treatment. A growing concern is the increased incidence of SSTIs with hospital- and community-acquired MRSA and drug-resistant pneumococci. Common outpatient treatment options for MRSA include clindamycin, doxycycline, and trimethoprim-sulfamethoxazole. When coverage for both MRSA and streptococci is needed, clindamycin alone or the combination of either doxycycline or trimethoprim-sulfamethoxazole with a β -lactam may be used (Stevens et al., 2014). Clindamycin should not be used as empiric therapy if local resistance rates are greater than 10%–15% (Stevens et al., 2014). Treatment options for more severe or complicated SSTIs that provide coverage for MRSA include vancomycin, linezolid, quinupristin-dalfopristin, and daptomycin. More recent additions to this armamentarium include dalbavancin, oritavancin, telavancin, tedizolid, and ceftaroline.

Antifungal Agents

Fungal infections are amongst the most common causes of skin disease in the U.S., and numerous effective topical and oral antifungal agents have been developed. The pharmacology, uses, and toxicities of antifungal drugs are discussed in Chapter 61. This section addresses the management of common superficial cutaneous mycoses. Recommendations for cutaneous antifungal therapy are summarized in Table 70–7. Topical antifungal agents used for superficial mucocutaneous mycoses are listed in Table 70–8.

Dermatophyte Infections of the Skin (Tinea Corporis, Cruris, and Pedis)

The dermatophyte infections (tinea corporis, cruris, and pedis) generally respond to topical antifungals, including allylamines (naftifine, terbinafine); benzylamines (butenafine); azoles (econazole, luliconazole); and ciclopirox (Rotta et al., 2013). Allylamines and benzylamines may provide a more sustained clinical cure compared to azole antifungals (Rotta et al., 2013). Bacterial superinfection of tinea pedis can occur, and antifungal agents such as econazole and ciclopirox that also provide some bacterial coverage may be useful in those situations. Systemic therapy with terbinafine, fluconazole, itraconazole, or griseofulvin is used

TABLE 70-7 ■ RECOMMENDED CUTANEOUS ANTIFUNGAL THERAPY

CONDITION	TOPICAL THERAPY	ORAL THERAPY
Tinea corporis, localized	Azoles, allylamines, benzylamines	—
Tinea corporis, widespread	—	Griseofulvin, terbinafine, itraconazole, fluconazole
Tinea capitis	—	Griseofulvin, terbinafine, itraconazole, fluconazole
Tinea pedis	Azoles, allylamines, benzylamines	Griseofulvin, terbinafine, itraconazole, fluconazole
Onychomycosis	—	Terbinafine, itraconazole, fluconazole
Candidiasis, localized	Azoles, nystatin	—
Candidiasis, widespread and mucocutaneous	—	Itraconazole, fluconazole
Tinea versicolor, localized	Azoles, allylamines	—
Tinea versicolor, widespread	—	Itraconazole, fluconazole

when there is more extensive cutaneous involvement or a poor response to topical therapy.

Dermatophyte Infections of the Hair and Follicles

Dermatophyte infections of the hair (tinea capitis) or follicularly based infections of the skin (Majocchi granuloma) require systemic therapy. Griseofulvin has been the traditional medication for tinea capitis, and treatment failure is often related to inadequate dosage or length of treatment. Terbinafine may be more effective for *Trichophyton tonsurans*, which is the most common cause of tinea capitis in the U.S. (Elewski et al., 2008). Fluconazole and itraconazole are also effective (Gupta and Paquet, 2013).

Onychomycosis

Onychomycosis is a fungal infection of the nails that is commonly caused by dermatophytes or candida. Onychomycosis is most effectively treated with systemic therapy (de Sa et al., 2014). Fungal infection should be confirmed prior to initiating oral therapy. There are other causes of nail dystrophy, and approximately one-third of nails with clinically suspected onychomycosis do not have fungal infection (Mehregan and Gee, 1999). *Terbinafine* is the most effective treatment of dermatophyte onychomycosis, with typical adult dosing of 250 mg daily for 6 weeks for fingernails and 12 weeks for toenails. Terbinafine remains in the nails for several weeks after medication administration has ceased, and some studies have utilized pulsed dosing of terbinafine 500 mg daily for 1 week per month for 3 months based on this finding. *Itraconazole* is another effective option for dermatophyte onychomycosis and is more effective than terbinafine for candidal onychomycosis. Itraconazole persists in the nail for 6–9 months after administration has ceased. Traditional adult dosing for itraconazole is 200 mg daily for 12 weeks; however, pulsed dosing is an alternative option because itraconazole of its long persistence after administration has ceased. Itraconazole pulsed dosing is 400 mg daily for 1 week per month for 2 months for fingernails and 3 months for toenails, which may be more effective than traditional dosing with fewer side effects. *Fluconazole* is an alternative option that may be useful in patients who cannot use terbinafine or itraconazole. *Griseofulvin*, used in the past, is less efficacious and requires much longer treatment courses; it is no longer a preferred option. Topical antifungals approved for onychomycosis include *ciclopirox*

lacquer, *efinaconazole*, and *tavaborole*. These topical antifungals require a 48-week treatment course. They may be useful for patients with mild-to-moderate onychomycosis not involving the nail matrix or in patients who are not candidates for systemic therapy (Gupta et al., 2014).

Cutaneous Candidiasis

Cutaneous candidiasis is typically treated with topical azole antifungals or nystatin when localized. Systemic azole antifungals such as fluconazole or itraconazole may be needed for more recalcitrant or severe cases.

Malassezia Infections

Pityriasis versicolor and *seborrheic dermatitis* are caused by *Malassezia* (pityrosporum) species and are frequently treated with azole antifungals in cream or shampoo formulations. Topical ciclopirox and terbinafine are also approved for use. Additional topical therapies include selenium sulfide, pyrithione zinc, sodium sulfacetamide, and sulfur with or without salicylic acid. Oral fluconazole or itraconazole are sometimes used for pityriasis versicolor when diffuse or resistant. Oral terbinafine does not reach adequate concentrations in the superficial stratum corneum to be effective.

Antiviral Agents

Viral infections of the skin by HPV, HSV, molluscum contagiosum virus, and VZV are common and produce a variety of lesions, including warts or blisters. Acyclovir, famciclovir, and valacyclovir are often used systemically to treat HSV and VZV infections (see Chapter 62). Cidofovir and foscarnet are useful for treating acyclovir-resistant HSV. Topically, acyclovir, docosanol, penciclovir, and combination acyclovir/hydrocortisone are available for treating mucocutaneous HSV; however, they are less effective than systemic therapies (Sarnoff, 2014). Acyclovir is also available as a 50-mg buccal tablet for herpes labialis to be applied as a single dose to the upper gum just above the incisor tooth within 1 h of prodromal symptoms.

Cidofovir is used off label topically or intralesionally as treatment of anogenital warts caused by HPV. Topical cidofovir 1% gel or cream must be obtained through a compounding pharmacy. It is applied once daily for 5 consecutive days every other week for a maximum of six cycles. Additional treatments for genital warts are nonspecific cytoreductive or immunomodulatory therapies, which are discussed in further detail in other sections. Cytoreductive modalities include topical use of cryotherapy, podophyllin (podophyllum resin) or podofilox (podophyllotoxin), and trichloroacetic acid. Topical immunomodulatory therapies include imiquimod and sinecatechins. Also, intralesional or systemic interferons α_{2b} , α_{n3} , and β may be useful for treating refractory or recurrent genital warts, but their use is limited by pain with multiple injections for intralesional use and by potential for severe side effects with systemic use (Smith et al., 2007).

Agents Used to Treat Infestations

Infestations with ectoparasites such as lice and scabies are common throughout the world. These conditions have a significant impact on public health in the form of disabling pruritus, secondary infection, and, in the case of the body louse, transmission of life-threatening illnesses such as typhus. Topical and oral medications are available to treat these infestations (Diamantis et al., 2009).

- **Permethrin** is a synthetic pyrethroid that interferes with insect Na^+ transport proteins, causing neurotoxicity and paralysis. Resistance due to mutations in the transport protein has been reported and appears to be increasing. A 5% cream is available by prescription for the treatment of scabies, and a 1% lotion or cream rinse is available OTC for the treatment of lice. Permethrin is approved for use in infants 2 months or older. Other OTC agents used in the treatment of lice are pyrethrins plus piperonyl butoxide in various formulations and acetic acid plus isopropanol shampoo.
- **Lindane** is an organochloride compound that induces neuronal hyperstimulation and eventual paralysis of parasites. Due to several cases of neurotoxicity in humans, the FDA has labeled lindane as a second-line drug in treating pediculosis and scabies and has highlighted the

TABLE 70-8 ■ TOPICAL ANTIFUNGAL AGENTS FOR SUPERFICIAL MUCOCUTANEOUS MYCOSES

GENERIC NAME	FORMULATIONS	FDA-APPROVED INDICATIONS	NOTES
Polyenes			
Nystatin	Topical (0.1 megaunit/g): Powder, ointment, cream	Cutaneous and mucocutaneous candidiasis	Orally administered nystatin lacks appreciable systemic absorption; it is used for local treatment of oral cavity and GI tract candidiasis
	Oral: Suspension (0.1 megaunit/g) Capsule or tablet (0.5 megaunit)	Oral cavity candidiasis Nonesophageal GI candidiasis	
Azoles			
Butoconazole	Vaginal cream, 2%	Vulvovaginal candidiasis	
Clotrimazole	Oral lozenge, 10 mg	Oropharyngeal candidiasis	
	Vaginal cream, 1% or 2%	Vaginal candidiasis	
	Cream, ointment, solution; 1%	Rx: <i>Candida albicans</i> , pityriasis versicolor OTC: tinea	
Econazole	Cream, 1% Foam, 1%	Tinea; cutaneous candidiasis, pityriasis versicolor Tinea pedis in patients ≥ 12 years	
Efinaconazole	Solution, 10%	Toenail onychomycosis	
Ketoconazole	2% foam, gel; 1% shampoo 2% shampoo, gel Cream, 2%	Seborrheic dermatitis Pityriasis versicolor Tinea; pityriasis versicolor, seborrheic dermatitis, cutaneous candidiasis	
Luliconazole	1% cream	Tinea	
Miconazole	2% cream, lotion, ointment, powder, solution, spray	Tinea	
	Vaginal suppository, 100 or 200 mg 2% or 4% vaginal cream	Vulvovaginal candidiasis	
Oxiconazole	1% cream, lotion	Tinea; pityriasis versicolor	
Sertaconazole	2% cream	Tinea pedis in pts ≥ 12 years	
Sulconazole	1% cream, solution	Tinea; pityriasis versicolor	
Terconazole	0.4%, 0.8% vaginal cream; 80-mg vaginal suppository	Vulvovaginal candidiasis	
Tioconazole	6.5% vaginal ointment	Vulvovaginal candidiasis	
Allylamines			
Naftifine	1% or 2% cream, gel	Tinea	
Terbinafine	1% cream, gel, spray	Tinea; pityriasis versicolor	
Benzylamines			
Butenafine	1% cream	Rx: pityriasis versicolor OTC: tinea	
Hydroxypyridones			
Ciclopirox	8% topical solution/lacquer	Onychomycosis	
	1% shampoo	Seborrheic dermatitis	
	0.77% gel	Tinea; seborrheic dermatitis	
Oxaboroles			
Tavaborole	5% topical solution	Toenail onychomycosis	
Miscellaneous			
Selenium sulfide	1% shampoo, lotion; 2.5% lotion; 2.25% foam	Seborrheic dermatitis; pityriasis versicolor	
Gentian violet	1% or 2% topical solution	Abrasions, minor cuts, surface injuries, superficial fungal infections of the skin	Stains skin and clothing purple
Tolnaftate	1% cream, powder, topical solution	Tinea; pityriasis versicolor	

(Continued)

TABLE 70-8 ■ TOPICAL ANTIFUNGAL AGENTS FOR SUPERFICIAL MUCOCUTANEOUS MYCOSES (CONTINUED)

GENERIC NAME	FORMULATIONS	FDA-APPROVED INDICATIONS	NOTES
Undecylenic acid	10%–25% topical powder, cream, solution, soap	Tinea	
Miscellaneous Combination Products			
Bensal HP	Topical ointment: 3% salicylic acid in base containing benzoic acid, oak bark, polyethylene glycol		
Whitfield's	Topical ointment: 6% benzoic acid, 3% salicylic acid		
Versiclear	Topical lotion: 25% sodium thiosulfate, 1% salicylic acid, 10% isopropyl alcohol, menthol, propylene glycol, EDTA, colloidal alumina		
Castellani Paint Modified	Topical liquid: basic fuchsin, phenol, resorcinol, acetone. Also as colorless solution containing alcohol but without basic fuchsin		
Fungi-nail	Topical liquid: 1% resorcinol, 2% salicylic acid, 2% chloroxylenol, 0.5% benzocaine, 50% isopropyl alcohol		
Exoderm	Topical soap: 10% sulfur, 3% salicylic acid		

potential for neurotoxicity in children and adults weighing less than 50 kg and patients with underlying skin disorders such as atopic dermatitis and psoriasis. Lindane is contraindicated in premature infants and patients with seizure disorders.

- **Malathion** is an organophosphate that inhibits acetylcholinesterase in lice, causing paralysis and death. It is approved for treatment of head lice in children 6 years and older. The current formulation of malathion lotion contains 78% isopropyl alcohol and is flammable. Detailed information on malathion's actions and adverse effects may be found in Chapter 10.
- **Benzyl alcohol** 5% lotion is approved for the treatment of lice in patients 6 months and older. Benzyl alcohol inhibits lice from closing their respiratory spiracles, which allows the vehicle to obstruct the spiracles and causes the lice to asphyxiate. There may be less potential for development of resistance with this mechanism of action compared to traditional pesticides.
- **Ivermectin** is an anthelmintic drug (see Chapter 55) approved for oral treatment of onchocerciasis and strongyloidiasis. Recently, topical ivermectin 0.5% lotion was approved to treat lice in patients 6 months or older and 1% cream to treat rosacea. Ivermectin is also effective in the off-label treatment of scabies. Because ivermectin does not cross the human blood-brain barrier, there is no major CNS toxicity; minor CNS side effects with oral administration may include dizziness, somnolence, vertigo, and tremor. Topical administration may cause local irritant effects, such as conjunctivitis, eye irritation, dry skin, or skin-burning sensation, although these occurred in fewer than 1% of patients during clinical trials. For both scabies and lice, ivermectin typically is given at an oral dose of 200 µg/kg, which may be repeated in 1 week. In cases of crusted scabies, longer treatment cycles of oral ivermectin may be needed, sometimes in addition to topical keratolytics and scabicides (Ortega-Loayza et al., 2013). It should not be used in children weighing less than 15 kg.
- **Spinosad** 0.9% topical suspension is approved for treatment of head lice in patients 6 months or older. Spinosad causes CNS excitation and involuntary muscle contractions, leading to insect paralysis and death.

Less effective topical treatments for scabies and lice include 10% cro-tamiton cream and lotion and extemporaneously compounded 5%–10% precipitated sulfur in petrolatum. Precipitated sulfur may be useful for patients in whom other therapies are contraindicated or not approved; it is typically applied once daily for 3–5 consecutive days.

Antimalarial Agents

The antimalarial agents chloroquine, hydroxychloroquine, and quina-craine are used in dermatology to treat dermatoses such as cutaneous lupus erythematosus, cutaneous dermatomyositis, polymorphous light

eruption, porphyria cutanea tarda, and sarcoidosis (only hydroxychloro-quine is FDA approved for treating lupus erythematosus). The mechanism by which antimalarial agents exert their anti-inflammatory therapeutic effects is uncertain but may involve inhibition of endosomal toll-like receptor signaling, resulting in reduced B-cell and dendritic cell activation (Kalia and Dutz, 2007). The usual dosages of antimalarials are hydroxy-chloroquine 200 mg twice a day (maximum of 6.5 mg/kg/d); chloroquine 250–500 mg/d (maximum of 3 mg/kg/d); and quinacrine 100–200 mg/d. Patients with porphyria cutanea tarda require lower doses of antimalari-als to avoid severe hepatotoxicity. There is strong evidence that smoking decreases the effectiveness of antimalarials in the treatment of cutaneous lupus erythematosus, so smoking cessation is important (Chasset et al., 2015). Clinical improvement may be delayed for several months. If there is no improvement after 3 months of hydroxychloroquine, then quina-craine may be added (in the U.S., quinacrine must be obtained through compounding pharmacies). Dose-dependent ocular toxicity occurs with chloroquine more often than hydroxychloroquine and is rare to nonexis-tent with quinacrine. The potential toxic effects of antimalarial agents are described further in Chapter 53.

Cytotoxic and Immunosuppressant Drugs

Cytotoxic and immunosuppressant drugs are used in dermatology for immunologically mediated diseases such as psoriasis, autoimmune blis-tering diseases, and leukocytoclastic vasculitis. See Table 70-9 for their mechanisms of action.

Antimetabolites

Methotrexate is used for moderate-to-severe psoriasis. It suppresses immunocompetent cells in the skin, and it also decreases the expres-sion of CLA-positive T cells and endothelial cell E-selectin, which may account for its efficacy. Methotrexate is useful in treating a number of other dermatological conditions, including atopic dermatitis, pityria-sis lichenoides et varioliformis, lymphomatoid papulosis, sarcoidosis, pemphigus vulgaris, pityriasis rubra pilaris, lupus erythematosus, der-matomyositis, and CTCL.

Methotrexate often is used in combination with phototherapy and photochemotherapy or other systemic agents. Widely used oral regimens include 10–25 mg once weekly as a single dose or as three divided doses given at 12-h intervals, with similar effectiveness using either regimen, or intramuscular administration of 10–25 mg injected once weekly (maxi-mum of 30 mg/week) (Menter et al., 2009b).

Doses must be decreased for patients with impaired renal clearance. *Methotrexate should not be administered with probenecid, trimethoprim-sulfamethoxazole, salicylates, or other drugs that can compete with it for protein binding and thereby raise plasma concentrations to levels that*

TABLE 70-9 ■ MECHANISM OF ACTION FOR SELECTED CYTOTOXIC, IMMUNOSUPPRESSIVE, AND IMMUNOMODULATORY DRUGS

Methotrexate	Dihydrofolate reductase inhibitor
Fluorouracil	Blocks methylation in DNA synthesis
Cyclophosphamide	Alkylates and cross-links DNA
Mechlorethamine hydrochloride	Alkylating agent
Carmustine	Cross-links in DNA and RNA
Vinblastine	Inhibits microtubule formation
Bleomycin	Induction of DNA strand breaks
Azathioprine	Purine synthesis inhibitor
Mycophenolate mofetil	Inosine monophosphate dehydrogenase inhibitor
Cyclosporine	Calcineurin inhibitor
Tacrolimus	Calcineurin inhibitor
Pimecrolimus	Calcineurin inhibitor
Sirolimus	mTOR inhibitor
Imiquimod	Interferon α induction via toll-like receptor 7
Dapsone	Inhibits neutrophil migration, oxidative burst
Thalidomide	Cytokine modulation

may result in bone marrow suppression. Fatalities have occurred because of concurrent treatment with methotrexate and NSAIDs. Methotrexate exerts significant antiproliferative effects on the bone marrow; therefore, CBCs should be monitored serially. Providers administering methotrexate should be familiar with the use of folinic acid (leucovorin) to rescue patients with hematological crises caused by methotrexate-induced bone marrow suppression. Careful monitoring of liver function tests is necessary to assess for methotrexate-induced hepatotoxicity. Liver biopsy may be recommended after a 3.5- to 4-g cumulative dose in patients without other risk factors versus 1–1.5 g in patients with higher risk (e.g., obesity, diabetes) (Menter et al., 2009b). Patients with abnormal liver function tests, symptomatic liver disease, or evidence of hepatic fibrosis should not use this drug. Methotrexate is contraindicated during pregnancy and lactation. Many clinicians routinely administer folic acid to ameliorate side effects of methotrexate.

Fluorouracil is used topically in multiple actinic keratoses, actinic cheilitis, Bowen disease, and superficial BCCs not amenable to other treatments (Micali et al., 2014). 5FU is applied once or twice daily for 2–8 weeks, depending on the indication. The treated areas may become severely inflamed during treatment, but the inflammation subsides after the drug is stopped. Intralesional injection of 5FU has been used off label for keratoacanthomas, warts, and porokeratoses (Good et al., 2011).

Alkylating Agents

Cyclophosphamide is an effective cytotoxic and immunosuppressive agent. Both oral and intravenous preparations of cyclophosphamide are used in dermatology. Cyclophosphamide is FDA approved for treatment of advanced CTCL (Jawed et al., 2014).

Other uses include treatment of pemphigus vulgaris, bullous pemphigoid, cicatricial pemphigoid, paraneoplastic pemphigus, pyoderma gangrenosum, toxic epidermal necrolysis, Wegener granulomatosis, polyarteritis nodosa, Churg-Strauss angiitis, Behçet disease, scleromyxedema, and cytophagic histiocytic panniculitis. The usual oral dosage is 2–2.5 mg/kg/d in divided doses, and there often is a 4- to 6-week delay in onset of action (Meurer, 2012). Alternatively, intravenous pulse administration of cyclophosphamide may offer advantages, including lower cumulative dose and a decreased risk of bladder cancer.

Cyclophosphamide has many adverse effects (see Chapter 66), including the risk of secondary malignancy and myelosuppression, and is used only in the most severe, recalcitrant dermatological diseases.

Mechlorethamine hydrochloride and **carmustine** are used topically to treat CTCL (Jawed et al., 2014). It is important to monitor CBCs and liver function tests because systemic absorption can cause bone marrow suppression and hepatitis. Other side effects include allergic contact dermatitis, irritant dermatitis, secondary cutaneous malignancies, and pigmentary changes. Carmustine also can cause erythema and posttreatment telangiectasias.

Microtubule Inhibitors

Vinblastine is approved for systemic use in Kaposi sarcoma and advanced CTCL. Intralesional vinblastine also is used to treat Kaposi sarcoma (Regnier-Rosencher et al., 2013).

Podophyllin (podophyllum resin) is a mixture of chemicals from the plant *Podophyllum peltatum* (mandrake or May apple) that contains podophyllotoxin (podofilox), which binds to microtubules and causes mitotic arrest in metaphase (Fathi and Tsoukas, 2014). In the U.S., it must be obtained through a compounding pharmacy. Podophyllum resin 25% is applied topically by a physician and left in place for no longer than 2–6 h weekly for the treatment of anogenital warts. Irritation and ulcerative local reactions are the major side effects. It should not be used in the mouth or during pregnancy. It is recommended that the use of provider-administered podophyllum resin be replaced by the purified podophyllotoxin (podofilox) for patient-administered use. Podofilox is available as a 0.5% gel or solution for at-home application two times daily for 3 consecutive days, repeated weekly as needed for up to four cycles.

Other Cytotoxic Agents

Bleomycin is used off label intralesionally for palliative treatment of squamous cell carcinoma and recalcitrant warts and has cytotoxic and pro-inflammatory effects. Intralesional injection of bleomycin into the digits has been associated with a vasospastic response that mimics Reynaud phenomenon. Other potential adverse reactions include local skin necrosis and flagellate hyperpigmentation. Systemic bleomycin has been used off label for Kaposi sarcoma (see Chapter 66) (Regnier-Rosencher et al., 2013).

Liposomal anthracyclines (specifically doxorubicin) may provide first-line monotherapy for advanced Kaposi sarcoma (Regnier-Rosencher et al., 2013).

Ingenol mebutate gel, an extract from the plant *Euphorbia peplus*, is FDA approved for actinic keratosis (Micali et al., 2014). In experimental studies, it was reported to rapidly cause mitochondrial swelling and apoptosis of dysplastic keratinocytes. The gel is applied once daily for 2–3 consecutive days. Adverse effects may include local skin irritation, pain, pruritus, and infection at application site; periorbital edema; nasopharyngitis; and headache. Cases of allergic contact dermatitis and reactivation of herpes zoster have been reported.

Azathioprine and Mycophenolate Mofetil

Azathioprine is discussed in Chapter 35. In dermatological practice, the drug is used off label as a steroid-sparing agent for autoimmune and inflammatory dermatoses, including pemphigus vulgaris, bullous pemphigoid, dermatomyositis, atopic dermatitis, chronic actinic dermatitis, lupus erythematosus, psoriasis, pyoderma gangrenosum, and Behçet disease.

Azathioprine is cleaved to 6MP, which in turn is converted to additional metabolites that inhibit de novo purine synthesis (see Figure 51-5 and Chapter 66). The level of thiopurine S-methyltransferase (TPMT) enzyme activity should be measured before initiating azathioprine therapy because low levels of TPMT activity are associated with increased drug toxicity (see Chapter 66). In general, the starting dosage is 1–2 mg/kg/d. Careful laboratory monitoring is important, especially in those with diminished TPMT activity.

Mycophenolate mofetil and mycophenolate sodium are immunosuppressants approved for prophylaxis of organ rejection in patients with

renal, cardiac, and hepatic transplants (see Chapter 35). Mycophenolate mofetil is a prodrug that is hydrolyzed to mycophenolic acid by plasma esterases; the salt of the acid, mycophenolate sodium, is available in an enteric-coated formulation. Mycophenolic acid functions as a specific inhibitor of T- and B-lymphocyte activation and proliferation through inhibition of inosine monophosphate dehydrogenase, thereby reducing GMP synthesis by the *de novo* purine synthetic pathway. Lymphocytes are vulnerable due to their lack of the salvage pathway for purine synthesis. The drug also may enhance apoptosis.

Mycophenolate mofetil is used off label increasingly to treat inflammatory and autoimmune diseases in dermatology; dosages typically range from 2 to 3 g/d orally in adults or 30–50 mg/kg/d in pediatric patients, given in divided doses twice daily. This agent is particularly useful as a corticosteroid-sparing agent in the treatment of autoimmune blistering disorders and has been used effectively in the treatment of inflammatory diseases such as psoriasis, atopic dermatitis, and pyoderma gangrenosum. Isolated cases of PML and pure red cell aplasia have been reported in solid organ transplant patients receiving mycophenolate mofetil. The most common side effects of mycophenolate mofetil are dose-dependent GI symptoms (e.g., diarrhea, nausea, and abdominal pain). Enteric-coated mycophenolate sodium improves GI tolerability; the enteric coating delays absorption until the medication reaches the small intestine rather than occurring in the stomach.

Calcineurin Inhibitors

The mechanisms of action and clinical pharmacology of calcineurin inhibitors are described in Chapter 35, and Figure 35–2 shows their main molecular effects as immunosuppressants.

Cyclosporine is a potent immunosuppressant isolated from the fungus *Tolypocladium inflatum*. Cyclosporine is FDA approved for the treatment of psoriasis. A modified microemulsion formulation has increased bioavailability and more consistent absorption than the original formulation. Other cutaneous disorders that typically respond well to cyclosporine are atopic dermatitis, alopecia areata, epidermolysis bullosa acquisita, pemphigus vulgaris, bullous pemphigoid, lichen planus, and pyoderma gangrenosum. The usual oral dosage of the modified formulation is 2.5 to 5 mg/kg/d, often given in two divided doses (Menter et al., 2009b; Sidbury et al., 2014).

Hypertension and renal dysfunction are the major adverse effects associated with the use of cyclosporine. These risks can be minimized by monitoring serum creatinine (which should not rise more than 30% above baseline), calculating creatinine clearance or glomerular filtration rate in patients on long-term therapy or with a rising creatinine, maintaining a daily dose of less than 5 mg/kg, and regularly monitoring blood pressure. Alternation with other therapeutic modalities may diminish cyclosporine toxicity. Patients with psoriasis who are treated with cyclosporine are at increased risk of cutaneous, solid organ, and lymphoproliferative malignancies. The risk of cutaneous malignancies is compounded in patients who have received phototherapy with PUVA.

Tacrolimus is available in a topical form for the treatment of skin disease and also is marketed in oral and injectable formulations. Systemic tacrolimus has shown some efficacy in the off-label treatment of inflammatory skin diseases such as psoriasis, pyoderma gangrenosum, and Behçet disease. When tacrolimus is administered systemically, the most common side effects are hypertension, nephrotoxicity, neurotoxicity, GI symptoms, hyperglycemia, and hyperlipidemia.

Topical formulations (0.03% and 0.1%) of tacrolimus ointment are approved for the treatment of atopic dermatitis in adults and in children 2 years or older for 0.03% ointment and 16 years or older 0.1% ointment. Other uses include for treatment of intertriginous psoriasis, vitiligo, mucosal lichen planus, graft-versus-host disease, allergic contact dermatitis, and rosacea. Ointment is applied to the affected area two times daily and generally is well tolerated. Common side effects at the site of application are transient erythema, burning, and pruritus. Other adverse effects include skin tingling, flu-like symptoms, headache, alcohol intolerance, folliculitis, acne, and hyperesthesia. Systemic absorption generally is very low and decreases with resolution of the dermatitis. Topical tacrolimus

should be used with extreme caution in patients with Netherton syndrome; these patients may develop elevated blood levels of the drug after topical application (Eichenfield et al., 2014).

Pimecrolimus (as a 1% cream) is approved for the treatment of atopic dermatitis in patients 2 years and older. Its mechanism of action and side-effect profile are similar to those of tacrolimus. It has low-to-negligible systemic absorption after topical application.

Tacrolimus and pimecrolimus are approved as second-line agents for short-term and intermittent treatment of atopic dermatitis in patients unresponsive to, or intolerant of, other treatments. Unlike topical corticosteroids, they do not carry the risk of skin atrophy and may be especially useful as steroid-sparing agents or for use on sensitive skin sites (e.g., eyelids, face, skin folds) or areas with steroid-induced atrophy.

mTOR Inhibitors

Sirolimus causes immunosuppressive and antiproliferative effects through inhibition of mTOR as part of the PI3 kinase/Akt/mTOR pathway (see Figures 3–16, 35–2, and 67–4). The mTOR inhibitors are established treatments for posttransplant immunosuppression (Chapter 35) and as antineoplastic agents for malignancies such as renal and hepatocellular carcinoma (Chapter 67). Off-label use of mTOR inhibitors in dermatology includes treatment of tuberous sclerosis complex, pachyonychia congenita, complex vascular anomalies, and inflammatory dermatoses such as systemic sclerosis (Fogel et al., 2015). Systemic mTOR inhibitors may be associated with several side effects, with dermatologic side effects amongst the most common, including stomatitis, mucositis, inflammatory cutaneous eruptions, and nail changes such as paronychia (Fogel et al., 2015). Topical formulations have been used to decrease the risk of side effects associated with systemic therapy. Newer semisynthetic analogues of sirolimus such as everolimus and temsirolimus are available and have improved water solubility and efficacy.

Immunomodulators and Anti-inflammatory Agents

Imiquimod exerts immunomodulatory effects by acting as a ligand at toll-like receptors in the immune system and inducing the cytokines IFN- α , TNF- α , and IL-1, IL-6, IL-8, IL-10, and IL-12.

Imiquimod cream is available in 2.5%, 3.75%, and 5% strengths. Approved for the treatment of genital warts, imiquimod 5% cream is applied to genital or perianal lesions three times a week until resolution of warts or up to a 16-week period (and repeated as necessary) (Fathi and Tsoukas, 2014). Imiquimod also is approved for the treatment of actinic keratosis, with various regimens used (Micali et al., 2014). No more than 36 single-use packets per 16-week course of therapy should be prescribed for actinic keratoses. The 5% cream is also FDA approved for the treatment of superficial BCCs at a dosage of five applications/week for 6 weeks. Off-label applications include the treatment of nongenital warts, molluscum contagiosum, extramammary Paget disease, and Bowen disease. Irritant reactions occur in virtually all patients; the degree of inflammation parallels therapeutic efficacy.

Sinecatechins are partially purified green tea extracts containing a mixture of 85%–95% catechins and other green tea components. They are approved for the topical treatment of external genital and perianal warts in immunocompetent patients more than 18 years of age. The mechanism of action is unclear but may include a combination of antioxidant, antiviral, antiangiogenic, proapoptotic, and immunomodulatory activities. The sinecatechin 15% ointment is applied three times daily for up to 16 weeks until clearance of the warts. The most common side effects are local skin reactions, including erythema, pruritus or burning, pain, superficial ulceration, and edema, with the intensity of local reactions peaking between 2 and 4 weeks of use. Local site reactions may be indicative of a positive clinical response, and patients are encouraged to treat through them as tolerated.

Dapsone is used in dermatology for its anti-inflammatory properties, particularly in sterile (noninfectious) pustular diseases of the skin (Zhu

1286 and Stiller, 2001). Dapsone prevents the respiratory burst from myeloperoxidase, suppresses neutrophil migration by blocking integrin-mediated adherence, inhibits adherence of antibodies to neutrophils, and decreases the release of eicosanoids and blocks their inflammatory effects. Dapsone is discussed further in Chapter 60.

Dapsone is approved for oral use in dermatitis herpetiformis and leprosy and for topical use in acne vulgaris. It is also particularly useful in the off-label treatment of linear IgA dermatosis, bullous systemic lupus erythematosus, erythema elevatum diutinum, and subcorneal pustular dermatosis. In addition, reports indicate efficacy in patients with acne fulminans, pustular psoriasis, lichen planus, Hailey-Hailey disease, pemphigus vulgaris, bullous pemphigoid, cicatricial pemphigoid, leukocytoclastic vasculitis, Sweet syndrome, granuloma faciale, relapsing polychondritis, Behçet disease, urticarial vasculitis, pyoderma gangrenosum, and granuloma annulare.

The initial oral dosage is 50 mg/d, followed by increases of 25 mg/d at weekly intervals, titrated to the minimal dosage necessary for effect. Potential side effects of dapsone include methemoglobinemia and hemolysis (G6PD level should be checked in all patients). The H₂ blocker cimetidine inhibits numerous CYPs and thereby reduces the *N*-hydroxylation of dapsone to the hydroxylamine metabolite that causes the methemoglobinemia. Other toxicities of dapsone include agranulocytosis, peripheral neuropathy, and psychosis.

Thalidomide is an anti-inflammatory, immunomodulatory, and antiangiogenic agent experiencing resurgence in the treatment of dermatological diseases (Wu et al., 2005). For details of its actions, see Chapter 36 under Immunostimulants and Figure 66–2 and associated text.

Thalidomide is FDA approved for the treatment of erythema nodosum leprosum. Reports also suggest its efficacy in actinic prurigo, aphthous stomatitis, Behçet disease, Kaposi sarcoma, the cutaneous manifestations of lupus erythematosus, and prurigo nodularis and uremic prurigo. Thalidomide has been associated with increased mortality when used to treat toxic epidermal necrolysis. In utero exposure can cause limb abnormalities

(phocomelia), as well as other congenital anomalies. *Thalidomide should never be taken by women who are pregnant or who could become pregnant while taking the drug. It also may cause an irreversible neuropathy. Because of its teratogenic effects, thalidomide use is restricted and requires both pharmacists and physicians to register in a risk evaluation and mitigation strategy (REMS) program. Newer analogues of thalidomide are available, including lenalidomide and pomalidomide.*

Targeted Immunotherapies for Psoriasis and Atopic Dermatitis

Targeted immunotherapies, including biological agents, are rapidly evolving for the treatment of psoriasis, as the underlying pathogenesis is better understood (Table 70–10). In addition, biological therapy for atopic dermatitis is on the horizon. The appeal of these targeted therapies is that they specifically target the activities of T lymphocytes and cytokines that mediate inflammation, whereas traditional systemic therapies are broadly immunosuppressive or cytotoxic. The pathogenesis of psoriasis and atopic dermatitis is discussed briefly next, followed by the relevant targeted therapies. Targeted therapies are discussed in further detail in Chapter 35.

Psoriasis is a chronic immune-mediated inflammatory disorder involving the innate and adaptive immune systems, with resultant abnormal keratinocyte proliferation (Figure 70–3). Psoriasis is not limited to the skin, as there can be psoriatic arthritis and other systemic manifestations. Previously thought to be primarily Th1 mediated, more recent developments demonstrate that the Th17/IL-17 pathway plays the most significant role (Girolomoni et al., 2012). Mediators of inflammation, such as IL-23, TNF- α , and IL-17 are key targets for therapy (Girolomoni et al., 2012; Sobell and Leonardi, 2014). In addition, therapies such as inhibitors of Jak and cyclic nucleotide PDEs) are useful to decrease expression or signal transduction of inflammatory cytokines (Sobell and Leonardi, 2014).

TABLE 70–10 ■ BIOLOGICAL AGENTS FOR PSORIASIS

	ETANERCEPT	ADALIMUMAB	INFLIXIMAB	USTEKINUMAB	SECUKINUMAB
Structural class	Receptor-antibody fusion protein	Human mAb	Chimeric mAb	Human mAb	Human mAb
Components	p75 TNF receptor and Fc IgG ₁	IgG ₁	Variable region of mouse mAb on human IgG ₁	IgG ₁	IgG ₁
Binding site	TNF- α	TNF- α	TNF- α	p40 subunit of IL-12 and IL-23	IL-17A
Method of administration	SC	SC	IV	SC	SC
Adult dosing for psoriasis	50 mg twice weekly \times 3 months, then 50 mg weekly	80 mg loading dose week 0, then 40 mg biweekly starting week 1	5 mg/kg at weeks 0, 2, and 6, then every 8 weeks	\leq 100 kg: 45 mg weeks 0, 4, then every 12 weeks \geq 100 kg: 90 mg weeks 0, 4, then every 12 weeks	300 mg at weeks 0, 1, 2, 3, 4, then every 4 weeks
Pregnancy category	Adequate studies in pregnant women show no evidence of risk for increased fetal abnormalities				B ^b
Efficacy in psoriasis^a	47%	53%	76%–80%	67%–76%	75%–87%

^aProbability (%) of Psoriasis Area and Severity Index score of 75 after 12 weeks of therapy at the dosing described in the table (Tzu and Kerdell, 2008).

^bNo embryo-fetal toxicity in mice and non-human primates; no adequate, well controlled studies in pregnant women; use only if benefit justifies potential risk to fetus.

Figure 70-3 Immunopathogenesis of psoriasis. Psoriasis is a prototypical inflammatory skin disorder in which specific T-cell populations are stimulated by as-yet-undefined antigen(s) presented by APCs. The dendritic APCs, T cells, keratinocytes, and other cells release pro-inflammatory chemokines and cytokines, such as TNF- α , IFN- γ , IL-23, and IL-17, which ultimately induce keratinocyte hyperproliferation and sustain chronic inflammation.

Atopic dermatitis is a chronic skin disorder characterized by epidermal barrier dysfunction and immune-mediated inflammation. Patients often develop asthma and allergic rhinitis as well. Acute atopic dermatitis is Th2 cell mediated, associated with cytokines IL-4, IL-5, and IL-13, while chronic atopic dermatitis also involves Th1 cell-mediated activity, associated with cytokines IL-12 and IFN- γ . Topical corticosteroids and calcineurin inhibitors are common therapies, and several of the traditional immunosuppressants have been used for more severe or resistant cases (Eichenfield et al., 2014; Sidbury et al., 2014). Targeted therapies show promise for the future treatment of atopic dermatitis (Beck et al., 2014).

Tumor Necrosis Factor Inhibitors

Blockade of TNF- α reduces inflammation, decreases keratinocyte proliferation, and decreases vascular adhesion, resulting in improvement in psoriatic lesions. Because TNF- α inhibitors alter immune responses, patients on all anti-TNF- α agents are at increased risk for serious infection and for malignancies. Other adverse events include exacerbation of congestive heart failure and demyelinating disease in predisposed patients. All patients should be screened for tuberculosis, history of demyelinating disorder, cardiac failure, active infection, or malignancy prior to therapy. TNF- α inhibitors include monoclonal antibodies directed against TNF- α (adalimumab, infliximab) or a soluble TNF receptor that can bind TNF- α (etanercept) (see Chapter 35). All TNF- α inhibitors are able to bind both soluble and membrane-bound TNF, but the monoclonal antibodies against TNF- α with an IgG₁ Fc portion are also able to activate complement-dependent cytotoxicity on binding of membrane-bound TNF- α . This may explain the increased efficacy of these agents in comparison to etanercept for treating granulomatous conditions as well as the higher risk of infection with their use.

Etanercept is a soluble, recombinant, fully human TNF receptor fusion protein consisting of two molecules of the ligand-binding portion of the TNF receptor (p75) fused to the Fc portion of IgG₁. It binds both TNF- α and TNF- β . Etanercept is approved for plaque psoriasis and psoriatic arthritis in adults. Studies have shown etanercept to be safe and efficacious for pediatric psoriasis at dosing of 0.8 mg/kg (maximum 50 mg) once weekly (Bellodi Schmidt and Shah, 2015).

Infliximab, a mouse-human chimeric IgG₁ monoclonal antibody directed against human TNF- α , is approved for treatment of chronic severe plaque psoriasis and psoriatic arthritis. The administration of infliximab via intravenous infusion can be a limiting factor; however, compared to other TNF- α inhibitors, its onset of action may be faster and efficacy greater. Neutralizing antibodies to infliximab may develop and lead to decreased efficacy over time. Concomitant administration of

methotrexate or glucocorticoids may suppress this neutralizing antibody formation.

Adalimumab is a human IgG₁ monoclonal antibody directed against TNF- α ; thus, the risk for development of neutralizing antibodies is reduced compared to infliximab. Adalimumab is approved for treatment of plaque psoriasis and psoriatic arthritis in adults. Safety of adalimumab in pediatric patients for psoriasis is supported by its use in other conditions, such as juvenile idiopathic arthritis (Bellodi Schmidt and Shah, 2015). Adalimumab is also approved for treatment of hidradenitis suppurativa.

Golimumab and **certolizumab pegol** are TNF- α inhibitors that are currently approved for psoriatic arthritis but not psoriasis. However, studies of these medications for psoriatic arthritis also demonstrated improvement of plaque psoriasis, and a phase III trial of certolizumab pegol for plaque psoriasis demonstrated efficacy. Golimumab is a fully human monoclonal antibody against TNF- α with a longer $t_{1/2}$ than other TNF- α inhibitors. Certolizumab pegol is a pegylated Fab fragment of a human monoclonal antibody against TNF- α . Because certolizumab pegol lacks the Fc portion, it is not able to activate complement-mediated cytotoxicity.

IL-12/23 Inhibitors

Ustekinumab is a human IgG₁ monoclonal antibody directed against the common p40 subunit of IL-12 and IL-23. IL-12 promotes Th1 activity and related TNF- α and IFN- γ production, while IL-23 activates Th17 cells that produce IL-17A, which regulates tissue inflammation and autoimmune responses. **Ustekinumab** is approved for treatment of moderate-to-severe plaque psoriasis and psoriatic arthritis. After initial doses at weeks 0 and 4, it is administered every 12 weeks for the maintenance phase of therapy, which may be ideal for some patients. Studies have shown **ustekinumab** to be safe and efficacious in adolescent patients at the same dosing as adults (Bellodi Schmidt and Shah, 2015).

IL-17 Inhibitors

Keratinocytes are the major target for IL-17 in psoriasis, with IL-17 stimulation causing increased keratinocyte expression of inflammatory cytokines and other effects that contribute to epidermal hyperproliferation and barrier dysfunction. Clinical trials have demonstrated that IL-17 inhibitors are very efficacious for plaque psoriasis.

Secukinumab is a fully human IgG_{1k} monoclonal antibody against IL-17A approved for the treatment of moderate-to-severe plaque psoriasis in adults. Additional IL-17 inhibitors in phase III clinical trials include **ixekizumab**, a humanized IgG₁ monoclonal antibody against IL-17A, and **brodalumab**, a human monoclonal antibody against the IL-17 receptor

1288 (anti-IL-17RA), which prevents binding and activity of IL-17. The most common adverse effects for IL-17 inhibitors are nasopharyngitis, upper respiratory tract infection, and diarrhea. There is the potential for increased mucocutaneous candidiasis infections, although this was not common during clinical trials.

PDE4 Inhibitors

Apremilast is an oral PDE4 inhibitor that increases intracellular cyclic AMP levels, thereby decreasing expression of inflammatory cytokines such as TNF- α and IL-23 and increasing expression of anti-inflammatory cytokines such as IL-10. Apremilast is approved for treatment of moderate-to-severe plaque psoriasis and psoriatic arthritis in adults. It has also shown efficacy for atopic dermatitis in a pilot study. The most common side effects are weight loss and depression.

Jak Inhibitors

Janus kinases are tyrosine kinases involved in cytokine receptor signaling, and Jak inhibition leads to decreased downstream activity of STAT, which modulates transcription of genes involved in cell growth, proliferation, and differentiation.

Tofacitinib is an oral Jak inhibitor approved for use in rheumatoid arthritis in adults. It has demonstrated efficacy for psoriasis in clinical trials and for atopic dermatitis in a pilot study.

IL-4 Inhibitors

Dupilumab is a fully human monoclonal antibody against the α subunit of IL-4R that inhibits both IL-4 and IL-13 signaling as they each exert their action through binding an IL-4R α /IL-13R α 1 receptor complex (Beck et al., 2014). IL-4 and IL-13 are important mediators of the Th2 immune response that is involved in acute atopic dermatitis. Dupilumab has shown promising results in clinical trials, demonstrating significant improvement in disease severity and fewer skin infections compared to placebo (Beck et al., 2014). The most frequent adverse effects are nasopharyngitis and headache.

Intravenous Immunoglobulin

Intravenous immunoglobulin is prepared from fractionated pooled human sera derived from thousands of donors with various antigenic exposures (see Chapter 36). Preparations of IVIG are composed of more than 90% IgG, with minimal amounts of IgA, soluble CD4, CD8, HLA molecules, and cytokines. In dermatology, IVIG is used off label as an adjuvant or rescue therapy for autoimmune bullous diseases, toxic epidermal necrolysis, connective tissue diseases, vasculitis, urticaria, atopic dermatitis, and graft-versus-host disease (Smith et al., 2007).

Although the mechanism of action of IVIG is not understood fully, proposed mechanisms include suppression of IgG production, accelerated catabolism of IgG, neutralization of complement-mediated reactions, neutralization of pathogenic antibodies, downregulation of inflammatory cytokines, inhibition of autoreactive T lymphocytes, inhibition of immune cell trafficking, and blockage of Fas-ligand/Fas-receptor interactions (Smith et al., 2007). IVIG is contraindicated in patients with severe selective IgA deficiency (IgA < 0.05 g/L). These patients may possess anti-IgA antibodies that place them at risk for severe anaphylactic reactions. Other relative contraindications include congestive heart failure and renal failure.

Targeted Antineoplastic Agents

Recent advances in understanding the molecular pathways and genetic alterations underlying cancer development have allowed for the rapid emergence of oncotherapeutic agents targeted against the specific molecules involved in tumor pathogenesis (Iwasaki et al., 2012; Jawed et al., 2014; John and Cowey, 2015). They are often better tolerated than conventional

chemotherapeutic medications; however, adverse effects do still occur, with cutaneous toxicities amongst the most common. These therapies are discussed in further detail in Chapter 67.

Targeted Therapies for Basal Cell Carcinoma

Basal cell carcinoma is the most common malignancy in humans, and exposure to UV radiation plays a large role in its development, with intermittent, intense exposure increasing risk more than cumulative exposure. Some genetic disorders, such as nevoid BCC syndrome, predispose to BCC development as well. Typically, BCCs exhibit an indolent growth pattern with local invasion and tissue destruction over time, but metastasis is extremely rare. Nearly all BCCs have aberrant *hedgehog* pathway signaling, which leads to persistent activation and uncontrolled proliferation of basal cells (Iwasaki et al., 2012).

Vismodegib and **sonidegib** are *smoothened* inhibitors, which block activation of the hedgehog pathway (Iwasaki et al., 2012). They are approved for use in patients with locally advanced, metastatic, or recurrent disease that cannot be adequately managed with surgery or radiation therapy. They have also been used in patients with nevoid BCC syndrome. The most common side effects are muscle spasms, dysgeusia, alopecia, and diarrhea. The hedgehog pathway is vital to normal fetal development, so extreme caution is needed in women of reproductive potential, and men should be cautioned regarding potential for exposure and fetal harm through semen.

Targeted Therapies for Cutaneous T-Cell Lymphoma

Denileukin difitox is a fusion protein composed of diphtheria toxin fragments A and B linked to the receptor-binding portion of IL-2. It is approved for treatment of advanced CTCL in patients with more than 20% of T cells expressing the surface marker CD25 (a subunit of the IL-2R), but it is not currently commercially available (Jawed et al., 2014).

The IL-2R is present on malignant and activated T cells but not resting B and T cells. Following binding to the IL-2R, denileukin difitox is internalized by endocytosis. The active fragment of diphtheria toxin is then released into the cytosol, where it inhibits protein synthesis via ADP ribosylation of elongation factor-2 (EF-2), leading to cell death. The response rate is 30%. Adverse effects include pain, fevers, chills, nausea, vomiting, and diarrhea; immediate hypersensitivity reaction in 60% of patients; and capillary leak syndrome in 20%–30% of patients.

Histone deacetylase inhibitors approved for treatment of progressive, persistent, or recurrent CTCL refractory to other systemic therapies include *vorinostat* and *romidepsin*. The exact mechanism of antineoplastic effect is not fully characterized; however, inhibition of HDAC may restore expression of tumor suppressor or cell cycle regulatory genes with resultant cell cycle arrest, differentiation, and apoptosis of cancer cells (Jawed et al., 2014). The partial response rate is approximately 30%–35%, with uncommon complete response. The most common side effects are GI symptoms, fatigue, and hematologic abnormalities.

Alemtuzumab is a humanized monoclonal antibody directed against CD52, which is found on immune cells, including T and B cells. Binding of alemtuzumab to CD52 causes neutrophil-mediated, antibody-dependent cellular toxicity (Jawed et al., 2014). It has been effectively used off label for CTCL and may be a secondary treatment option for patients with CTCL refractory to other therapies. It is commonly associated with infusion reactions and causes prolonged immunosuppression. Early studies reported opportunistic infections, so antimicrobial prophylaxis is recommended.

Targeted Therapies for Melanoma

Until recently, therapies for metastatic melanoma had low response rates along with either high toxicity or no effect on long-term survival. There has been rapid development of several new therapeutic options for metastatic or unresectable melanoma, primarily geared toward inhibition of mutated, abnormally activated tyrosine kinases that drive growth or enhancing immune function to combat malignant cells by

inhibiting immune checkpoints (John and Cowey, 2015). These therapies include BRAF inhibitors (vemurafenib, dabrafenib), MEK inhibitors (trametinib), CTLA4 inhibitors (ipilimumab), and programmed death-1 inhibitors (pembrolizumab, nivolumab). These targeted treatments are discussed further in Chapter 67. An additional novel therapy for unresectable melanoma is talimogene laherparepvec (T-Vec), an oncolytic immunotherapy derived from genetically modified attenuated HSV type 1. It is administered by intralesional injection and is designed to selectively replicate within tumors and produce GM-CSF to enhance systemic antitumor immune responses. Talimogene is contraindicated in pregnancy and in immunosuppressed patients.

Treatment of Pruritus

Pruritus (itching) occurs in a multitude of dermatological disorders, including xerosis (dry skin), atopic dermatitis, urticaria, and infestations. Itching also may be a sign of internal disorders, including malignant neoplasms, chronic renal failure, and hepatobiliary disease. In addition to treating the underlying disorder, a general approach to the treatment of pruritus can be made by classifying pruritus into one of four clinical categories (Table 70–11).

TABLE 70–11 ■ AGENTS USED FOR THE TREATMENT OF PRURITUS

Pruritoceptive pruritus: Itch originating in the skin due to inflammation or other cutaneous disease

- Emollients—Repair of barrier function
- Coolants (menthol, camphor, calamine)—Counterirritants
- Capsaicin—Counterirritant
- Antihistamines—Inhibit histamine-induced pruritus
- Topical steroids—Direct antipruritic and anti-inflammatory effects
- Topical immunomodulators—Anti-inflammatories
- Phototherapy—Reduced mast cell reactivity and anti-inflammatory effects
- Thalidomide—Anti-inflammatory through suppression of excessive TNF- α

Neuropathic pruritus: Itch due to disease of afferent nerves

- Carbamazepine—Blockade of synaptic transmission and use-dependent Na⁺ channels
- Gabapentin, pregabalin—mechanism unclear; thought to decrease transmission of nociceptive sensations by binding to the α -2- δ subunit of voltage-dependent Ca²⁺ channels
- Topical anesthetics (EMLA, benzocaine, pramoxine)—Inhibit nerve conduction via decreased nerve membrane permeability to sodium

Neurogenic pruritus: Itch that arises from the nervous system without evidence of neural pathology

- Thalidomide—Central depressant
- Opioid receptor antagonists (naloxone, naltrexone)—Decrease opioidergic tone
- Tricyclic antidepressants—Decrease pruritus signaling through alteration in neurotransmitter concentrations
- SSRIs—Decrease pruritus signaling through alteration in neurotransmitter concentrations

Psychogenic pruritus: Itch due to psychological illness

- Anxiolytics (benzodiazepines)—Relieve stress-reactive pruritus
- Antipsychotic agents (chlorpromazine, thioridazine, thiothixene, olanzapine)—Relieve pruritus with impulsive qualities
- Tricyclic antidepressants—Relieve depression and insomnia related to pruritus
- SSRIs—Relieve pruritus with compulsive qualities

Drugs for Hyperkeratotic Disorders

Keratolytic agents reduce hyperkeratosis through myriad mechanisms (e.g., breaking of intercellular junctions, increasing stratum corneum water content, increasing desquamation). Common disorders treated with keratolytics include psoriasis, seborrheic dermatitis, xerosis, ichthyoses, and verrucae.

α -Hydroxy acids can reduce the thickness of the stratum corneum by solubilizing components of the desmosome, activating endogenous hydrolytic enzymes, and drawing water into the stratum corneum, thereby facilitating cell separation. They also appear to increase glycosaminoglycans, collagen, and elastic fibers in the dermis and are used in various formulations to reverse photoaging. The FDA requires that cosmetics containing α -hydroxy acids be labeled with a sunburn alert warning that the product may increase sensitivity to the sun. α -Hydroxy acids used include glycolic, lactic, malic, citric, hydroxycaproic, hydroxycapric, and mandelic.

Salicylic acid functions through solubilization of intercellular “cement,” reducing keratinocyte adhesion, and softening the stratum corneum. Salicylism may occur with widespread and prolonged use, especially in children and patients with renal or hepatic impairment. Salicylate toxicity has been reported with application of as little as 1%–2% salicylic acid in neonates when applied multiple times per day over a large body surface area (Madan and Levitt, 2014). Salicylic acid, while chemically not a true β -hydroxy acid, often is listed as such on cosmetic labels. Other β -hydroxy acid ingredients in cosmetics include β -hydroxybutanoic acid, δ -tropic acid, and trethocanic acid. Sun protection should accompany the topical application of these agents.

Urea, at low concentrations, increases skin absorption and retention of water, leading to increased flexibility and softness of the skin. At concentrations greater than 40%, urea denatures and dissolves proteins and is used to dissolve calluses or avulse dystrophic nails.

Sulfur is keratolytic, antiseptic, antiparasitic, and antiseborrheic. It exerts its keratolytic effect by reacting with cysteine within keratinocytes, producing cystine and hydrogen sulfide (H₂S). H₂S breaks down keratin, causing dissolution of the stratum corneum.

Propylene glycol (as 60%–100% aqueous solutions) increases the water content of the stratum corneum and enhances desquamation. It is most effective in disorders with retention hyperkeratosis.

Drugs Affecting Hair Growth

Androgenic Alopecia

Androgenetic alopecia, commonly known as male and female pattern baldness, is the most common cause of hair loss in adults older than 40 years. The frequency and severity increase with age and may begin during puberty in some patients. It is a genetically inherited trait with variable expression. In susceptible hair follicles, dihydrotestosterone (DHT) binds to the androgen receptor, and the hormone-receptor complex activates the genes responsible for the gradual transformation of large terminal follicles into miniaturized vellus follicles. Treatment of androgenetic alopecia is aimed at reducing hair loss and maintaining existing hair (Varothai and Bergfeld, 2014).

Minoxidil, originally developed as an antihypertensive agent (see Chapter 28), was noted to be associated with hypertrichosis in some patients. Topical minoxidil is available as a 2% solution and a 5% solution or foam. Minoxidil enhances follicular size, resulting in thicker hair shafts, and stimulates and prolongs the anagen phase of the hair cycle, resulting in longer and increased numbers of hair. Treatment must be continued or any drug-induced hair growth will be lost. Allergic and irritant contact dermatitis can occur, and care should be taken in applying the drug because hair growth may emerge in undesirable locations. This is reversible on stopping the drug. Patients should be instructed to wash their hands after applying minoxidil. Patients with increased sulfotransferase enzyme activity are most likely to respond to minoxidil treatment; this may be a useful predictive test in the future (Roberts et al., 2014).

Finasteride inhibits the type II isozyme of 5 α -reductase, the enzyme that converts testosterone to DHT (see Figure 45–3) and that is found in hair follicles. Balding areas of the scalp are associated with increased DHT levels and smaller hair follicles than nonbalding areas. Orally administered finasteride (1 mg/d) variably increases hair growth in men over a 2-year period. Finasteride is approved for use only in men but has been used off label for female pattern hair loss (Varothai and Bergfeld, 2014). Finasteride use in women is limited by its teratogenicity. Pregnant women should not be exposed to the drug because of the potential for inducing genital abnormalities in male fetuses. Adverse effects of finasteride include decreased libido, erectile dysfunction, ejaculation disorder, and decreased ejaculate volume. There have been postmarketing surveillance reports of persistent sexual dysfunction after stopping the medication. As with minoxidil, new hair growth will be lost when finasteride is discontinued. **Dutasteride** (0.5 mg/day) is a combined type I and type II isozyme 5 α -reductase inhibitor that has similar or greater efficacy, but side effects may be more common (Varothai and Bergfeld, 2014).

Spironolactone is an aldosterone antagonist and K⁺-sparing diuretic; it also has antiandrogen activity. It is used off label for female pattern alopecia at dosages of 50–200 mg/d (Varothai and Bergfeld, 2014). Women of reproductive potential should not receive spironolactone without reliable contraception because spironolactone can cause feminization of a male fetus.

Other Agents

Eflornithine is an ornithine decarboxylase (ODC) inhibitor approved for the reduction of excessive and unwanted facial hair in women. ODC is the rate-limiting enzyme in the synthesis of polyamines, which are important in cellular migration, differentiation, and proliferation. Levels of ODC activity are higher in proliferating cells, such as in follicular matrix cells in anagen phase, and inhibiting ODC decreases hair growth. Eflornithine 13.9% cream is applied twice daily and is intended to be used along with the patient's preferred hair removal method to slow hair regrowth.

Bimatoprost is a prostaglandin analogue approved for topical treatment of hypotrichosis of the eyelashes by increasing their growth, including length, thickness, and darkness. The prostaglandin-mediated increase in eyelash growth was serendipitously noted during the use of intraocular prostaglandin analogues for glaucoma. The proposed mechanism of eyelash growth is by an increase in the fraction of hairs in, and the duration of, the anagen phase. Increased pigmentation of the hairs is thought to occur due to stimulation of melanin production without an increase in the number of melanocytes. Importantly, brown pigmentation of the iris and eyelid skin may occur, and the increased iris pigmentation may be permanent.

Treatment of Hyperpigmentation

The agents discussed are most effective on hormonally or light-induced pigmentation within the epidermis. They have limited efficacy on postinflammatory pigmentation within the dermis. Sun protection or avoidance is a vital component of any treatment regimen (Sheth and Pandya, 2011).

Hydroquinone (1,4-dihydroxybenzene) decreases melanocyte pigment production by inhibiting tyrosinase, the initial enzyme in the melanin biosynthetic pathway. In addition, it causes degradation of melanosomes and destruction of melanocytes by production of reactive oxygen radicals. Formulations containing 1.5%–2% hydroquinone are available OTC; 3%–4% hydroquinone formulations are available by prescription. Penetration enhancers and sunscreen ingredients are added to some formulations. A combination prescription product consisting of hydroquinone 4%, fluocinolone 0.01%, and tretinoin 0.05% is available. Adverse effects may include dermatitis and ochronosis.

Azelaic acid, a dicarboxylic acid isolated from cultures of *Malassezia furfur*, inhibits tyrosinase activity but is less effective than hydroquinone. Because it has mild comedolytic, antimicrobial, and anti-inflammatory properties, it also is often used in acne and papulopustular rosacea, especially in patients with postinflammatory hyperpigmentation.

Mequinol (4-hydroxyanisole) is a competitive inhibitor of tyrosinase. It was approved as a 2% prescription product in combination with 0.01%

tretinoin and vitamin C for skin lightening, but it is not currently commercially available.

Monobenzone (monobenzyl ether of hydroquinone) causes *permanent* depigmentation and should *not* be used for routine hormonally induced or postinflammatory hyperpigmentation. A 20% cream is approved for final depigmentation therapy of extensive vitiligo affecting at least more than 50% body surface area; it is rarely used and not currently commercially available.

Glycolic acid is an α -hydroxy acid used in chemical peels for disorders of pigmentation. It is thought to work by inhibiting tyrosinase in a pH-independent manner and to cause exfoliation by decreasing keratinocyte adhesion. Potential side effects are erythema, desquamation, and postinflammatory hyperpigmentation. Glycolic acid peels are best used as adjunctive therapy along with other topical therapy in patients with refractory epidermal hyperpigmentation (Sheth and Pandya, 2011).

Miscellaneous Agents

Capsaicin is an alkaloid derived from plants of the *Solanaceae* family (i.e., hot chili peppers). Capsaicin interacts with the transient receptor potential vanilloid (TRPV1) receptor on C-fiber sensory neurons. TRPV1 is a ligand-gated nonselective cation channel of the TRP family, modulated by a variety of noxious stimuli. Chronic exposure to capsaicin first stimulates and then desensitizes this channel to capsaicin and diverse other noxious stimuli. Capsaicin also causes local depletion of substance P, an endogenous neuropeptide involved in sensory perception and pain transmission. Capsaicin (cream, lotion, gel, roll-on, and transdermal patch) is FDA approved for the temporary relief of minor aches and pains associated with backache, strains, and arthritis. It is also approved in patch form by prescription for postherpetic neuralgia and is used for off-label treatment of painful diabetic neuropathy and some forms of pruritus.

Bentoquatam (quaternium-18 bentonite) is a mixture of quaternium-18 (quaternary ammonium chloride salts made from the fatty acids of tallow) and bentonite clay. This organoclay mixture is approved for OTC use as a topical barrier to prevent allergic contact dermatitis to the urushiol resin of poison ivy, oak, or sumac. The 5% topical lotion must be applied prophylactically at least 15 min prior to potential risk for exposure to urushiol and reapplied every 4 h.

Coal tar is a distillation product from coal, a mixture of over 10,000 compounds. It is used in dermatology primarily for the treatment of inflammatory skin conditions such as psoriasis, seborrheic dermatitis, and atopic dermatitis or other forms of eczematous dermatitis. The mechanism of action is unknown although it is known to suppress DNA synthesis. Coal tar has anti-inflammatory, antimicrobial, and antipruritic activity. In addition, it has a photosensitizing effect within the UVA and visible light spectrum between wavelengths of 330 and 550 nm. Multiple formulations and products are available commercially or through compounding, including those containing crude coal tar, coal tar extracts, or coal tar solution (Sandhu and Schwartz, 2011). Coal tar solution, also known as liquor carbonis detergens (LCD), is an alcohol extract of coal tar emulsified with polysorbate 80 to yield a more cosmetically acceptable product. Coal tar may be used in combination with UVB phototherapy (e.g., Goeckerman regimen), topical salicylic acid, or topical corticosteroids. Coal tar products are often poorly tolerated by patients due to its unpleasant odor, messiness, and potential for staining of clothing. It can also cause folliculitis or irritant contact dermatitis. Though occupational exposures to coal tar have been associated with malignancies (e.g., scrotal cancer), patients with psoriasis or atopic dermatitis who are treated with topical coal tar products have not exhibited increased risk of cancer (Menter et al., 2009a).

Anthralin (dithranol), a synthetic version of chrysarobin, is derived from the bark of the Brazilian araroba tree and is used in the treatment of psoriasis and alopecia areata; its mechanisms of action are unclear (Menter et al., 2009a). Use of anthralin has been limited by the potential to cause irritant contact dermatitis and to stain skin, hair, nails, fabrics, and household items.

Brimonidine (0.33% topical gel) is an α_2 adrenergic agonist approved for once-daily treatment of persistent erythema of rosacea. It causes temporary vasoconstriction, and rebound erythema has been reported. α_1 Adrenergic agonists such as oxymetazoline have been used off label topically for erythematotelangiectatic rosacea as well.

Propranolol and timolol are nonselective β adrenergic antagonists traditionally used for cardiovascular disease. These agents are also effective in treating infantile hemangiomas and become the preferred treatment of

infantile hemangiomas requiring intervention (Chen et al., 2013). Topical timolol drops and gel-forming solution are available but do not adequately treat deeper lesions.

Acknowledgment: Eric L. Wyatt, Steven H. Sutter, Lynn A. Drake, Lindy P. Fox, Hans F. Merk, David R. Bickers, and Lowell Goldsmith have contributed to this chapter in earlier editions of this book. We have retained some of their text in the current edition.

Drug Facts for Your Personal Formulary: Dermatological Agents

Drugs	Therapeutic Uses	Clinical Pharmacology and Tips
Glucocorticoids—Table 70–3 and Chapter 46		
<i>Topical glucocorticoids</i>	<ul style="list-style-type: none"> • Psoriasis • Atopic dermatitis • Other inflammatory skin diseases 	<ul style="list-style-type: none"> • Occlusion increases absorption • May cause skin atrophy, striae, periorificial dermatitis, folliculitis • Limit to ≤ 2–3 weeks of use • Avoid potent corticosteroids on face and genital areas • Systemic glucocorticoids for severe disease; see Chapter 46
Retinoids		
<i>Topical retinoids</i> (see Table 70–4)	<ul style="list-style-type: none"> • Acne • Facial wrinkling and photodamage • Psoriasis • Cutaneous KS (<i>alitretinoin</i>) • CTCL (<i>bexarotene</i>) 	<ul style="list-style-type: none"> • Start every-other-night application to reduce likelihood of skin irritation • Decreased activity in presence of sunlight or BPO except <i>adapalene</i> and <i>azarotene</i> • Avoid concurrent application of DEET due to potential increased DEET absorption
<i>Oral Retinoids</i> (see Table 70–5)	<ul style="list-style-type: none"> • Psoriasis (<i>acitretin</i>) • Acne (<i>isotretinoin</i>) • CTCL (<i>bexarotene</i>) 	<ul style="list-style-type: none"> • Teratogenic: pregnancy should be avoided during and for 1 month (3 years for acitretin) after cessation of treatment • Multiple potential side effects, including cheilitis, dermatitis, conjunctivitis, myalgias, arthralgias, epistaxis, decreased night vision, hyperlipidemia
Topical Vitamin D Analogues		
Calcipotriene	<ul style="list-style-type: none"> • Psoriasis 	<ul style="list-style-type: none"> • Potential hypercalcemia and hypercalciuria • May cause lesional or perilesional irritation
Photochemotherapeutic Agents (see Table 70–6)		
Biological Agents for Psoriasis—Table 70–10		
Antihistamines for Urticaria: see Chapter 39		
Topical Antimicrobial Agents for Acne and Rosacea		
Azelaic acid	<ul style="list-style-type: none"> • Acne • Rosacea 	<ul style="list-style-type: none"> • MOA: comedolytic, antibacterial, anti-inflammatory • Also useful for postinflammatory hyperpigmentation due to acne
Benzoyl peroxide	<ul style="list-style-type: none"> • Acne 	<ul style="list-style-type: none"> • MOA: antibacterial, mildly comedolytic • Skin irritation with higher concentrations
Clindamycin	<ul style="list-style-type: none"> • Acne • Rosacea (off label) 	<ul style="list-style-type: none"> • MOA: antibacterial, anti-inflammatory • Bacterial resistance likely if used as monotherapy, use with benzoyl peroxide
Dapsone	<ul style="list-style-type: none"> • Acne 	<ul style="list-style-type: none"> • MOA: anti-inflammatory • Use with benzoyl peroxide causes orange-brown staining of skin or hair • G6PD testing not needed
Erythromycin	<ul style="list-style-type: none"> • Acne • Rosacea (off label) 	<ul style="list-style-type: none"> • MOA: antibacterial, anti-inflammatory • Bacterial resistance likely if used as monotherapy, use with benzoyl peroxide
Metronidazole	<ul style="list-style-type: none"> • Rosacea 	<ul style="list-style-type: none"> • MOA: anti-inflammatory
Sulfacetamide \pm sulfur	<ul style="list-style-type: none"> • Acne • Rosacea 	<ul style="list-style-type: none"> • MOA: antibacterial, anti-inflammatory; sulfur also keratolytic • Use with benzoyl peroxide causes orange-brown staining of clothing but not skin • Sulfur may have pungent odor
Topical Antimicrobial Agents for Infection		
Bacitracin, neomycin, polymyxin B, gentamicin	<ul style="list-style-type: none"> • Superficial bacterial skin infections 	<ul style="list-style-type: none"> • See Section VI, Chemotherapy of Microbial Diseases • Topical use restricted for superficial infections • Not indicated in clean surgical wounds • May cause contact dermatitis (especially bacitracin, neomycin, mafenide) • Mafenide inhibits carbonic anhydrase and can cause metabolic acidosis • Efficacy of silver sulfadiazine questionable

Drug Facts for Your Personal Formulary: *Dermatological Agents (continued)*

Drugs	Therapeutic Uses	Clinical Pharmacology and Tips
Topical Antimicrobial Agents for Infection		
Mupirocin, retapamulin	<ul style="list-style-type: none"> Superficial bacterial skin infections due to <i>S. aureus</i> or <i>S. pyogenes</i> Intranasal decolonization of MRSA 	
Mafenide acetate	<ul style="list-style-type: none"> Adjunctive therapy for burn wounds 	
Silver sulfadiazine	<ul style="list-style-type: none"> Prevention or treatment in partial-thickness burns or venous stasis ulcers 	
Topical Antifungal Agents—Table 70–8 (see Chapter 61 for oral antifungal agents)		
Antiviral Agents		
Topical Antivirals: Acyclovir Docosanol Penciclovir	<ul style="list-style-type: none"> Orolabial HSV Genital HSV, initial episode (acyclovir) 	<ul style="list-style-type: none"> See Chapter 62
Oral Antivirals: Acyclovir Famciclovir Valacyclovir	<ul style="list-style-type: none"> VZV HSV 	
Agents for Infestations		
Benzyl alcohol	<ul style="list-style-type: none"> Head lice 	<ul style="list-style-type: none"> MOA: inhibits closure of respiratory spiracles, subsequent obstruction by mineral oil vehicle causes asphyxiation of lice
Ivermectin	<ul style="list-style-type: none"> Head lice Scabies (oral) 	<ul style="list-style-type: none"> MOA: binds glutamate-gated chloride channels, causing hyperpolarization of nerve or muscle cells of parasite
Lindane	<ul style="list-style-type: none"> Scabies Lice 	<ul style="list-style-type: none"> MOA: neuronal hyperstimulation, eventual parasite paralysis Potential neurotoxicity with prolonged use or in patients with impaired skin barrier (e.g., atopic dermatitis)
Malathion	<ul style="list-style-type: none"> Head lice 	<ul style="list-style-type: none"> MOA: acetylcholinesterase inhibitor causing neuromuscular paralysis Flammable due to high alcohol content
Permethrin	<ul style="list-style-type: none"> Scabies Lice 	<ul style="list-style-type: none"> MOA: interferes with Na⁺ transport, causing neurotoxicity and paralysis Approved for infants ≥ 2 months May cross-react with sunflower family plants to cause allergic contact dermatitis
Spinosad	<ul style="list-style-type: none"> Head lice 	<ul style="list-style-type: none"> MOA: causes CNS excitation and involuntary muscle contractions leading to parasite paralysis
Crotamiton	<ul style="list-style-type: none"> Scabies 	<ul style="list-style-type: none"> MOA: unknown Less effective than other agents but has additional antipruritic effect
Precipitated sulfur	<ul style="list-style-type: none"> Scabies 	<ul style="list-style-type: none"> MOA: unknown Poor odor and mild skin irritation Considered safe in pregnancy and infants
Systemic Cytotoxic, Immunosuppressant, and Immunomodulatory Agents		
Methotrexate	<ul style="list-style-type: none"> Psoriasis Off label for multiple inflammatory dermatoses 	<ul style="list-style-type: none"> See Chapter 66
Cyclophosphamide	<ul style="list-style-type: none"> CTCL Off label for severe autoimmune blistering dermatoses 	<ul style="list-style-type: none"> See Chapter 66
Vinblastine	<ul style="list-style-type: none"> Kaposi sarcoma CTCL 	<ul style="list-style-type: none"> See Chapter 66
Doxorubicin	<ul style="list-style-type: none"> Kaposi sarcoma 	<ul style="list-style-type: none"> See Chapter 66
Azathioprine	<ul style="list-style-type: none"> Off label for inflammatory and autoimmune blistering disorders 	<ul style="list-style-type: none"> MOA: inhibition of de novo purine synthesis to decrease T-cell and B-cell activation and proliferation TPMT enzyme activity should be measured before initiation
Mycophenolate mofetil and mycophenolic acid	<ul style="list-style-type: none"> Off label for inflammatory and autoimmune blistering disorders 	<ul style="list-style-type: none"> MOA: inhibition of de novo purine synthesis to decrease T-cell and B-cell activation and proliferation Most common side effect is GI upset
Cyclosporine	<ul style="list-style-type: none"> Psoriasis Off label for multiple inflammatory dermatoses 	<ul style="list-style-type: none"> MOA: calcineurin inhibition Potential side effects: hypertension, renal dysfunction, hypertrichosis, gingival hyperplasia, tremor

Systemic Cytotoxic, Immunosuppressant, and Immunomodulatory Agents (continued)		
<i>mTOR inhibitors</i>	<ul style="list-style-type: none"> Off-label use in tuberous sclerosis, complex vascular malformations, and inflammatory dermatoses 	<ul style="list-style-type: none"> MOA: mTOR inhibition Potential side effects: stomatitis, mucositis, inflammatory cutaneous eruptions, nail changes
Dapsone	<ul style="list-style-type: none"> Dermatitis herpetiformis Leprosy Neutrophilic dermatoses (off label) 	<ul style="list-style-type: none"> See Chapter 60
Thalidomide	<ul style="list-style-type: none"> Erythema nodosum leprosum Off label for prurigo nodularis, cutaneous lupus erythematosus, Behçet disease 	<ul style="list-style-type: none"> See Chapter 36
Topical or Intralesional Cytotoxic, Immunosuppressant, and Immunomodulatory Agents		
5-Fluorouracil	<ul style="list-style-type: none"> Actinic keratoses Superficial basal cell carcinoma Warts (off label) 	<ul style="list-style-type: none"> See Chapter 66
Bleomycin	<ul style="list-style-type: none"> Squamous cell carcinoma (off label) Recalcitrant warts (off label) 	<ul style="list-style-type: none"> See Chapter 66
Alkylating agents <i>Carmustine</i> <i>Mechlorethamine</i>	<ul style="list-style-type: none"> CTCL 	<ul style="list-style-type: none"> See Chapter 66
Podophyllum resin and podofilox	<ul style="list-style-type: none"> Genital warts 	<ul style="list-style-type: none"> MOA: microtubule inhibition to cause mitotic arrest in metaphase Side effects: irritation and ulcerative local reactions
Ingenol mebutate	<ul style="list-style-type: none"> Actinic keratoses 	<ul style="list-style-type: none"> MOA: mitochondrial swelling and apoptosis of dysplastic keratinocytes
Imiquimod	<ul style="list-style-type: none"> Genital warts Actinic keratoses Superficial basal cell carcinoma 	<ul style="list-style-type: none"> MOA: activates TLR-7, inducing cytokines and upregulating immune response Potential local skin reaction or systemic flu-like symptoms
Sinecatechins	<ul style="list-style-type: none"> Genital warts 	<ul style="list-style-type: none"> MOA: uncertain Potential local skin reactions, including erythema, pruritus, swelling that peaks between 2 and 4 weeks of use
mTOR inhibitors	<ul style="list-style-type: none"> Off-label use in tuberous sclerosis, complex vascular malformations, and some inflammatory dermatoses 	<ul style="list-style-type: none"> Topical mTOR inhibitors not currently commercially available but may be compounded Topical use may decrease potential for side effects seen with systemic use
<i>Topical calcineurin inhibitors</i> Pimecrolimus Tacrolimus	<ul style="list-style-type: none"> Psoriasis Atopic dermatitis Other inflammatory skin diseases 	<ul style="list-style-type: none"> MOA: Decreased T-cell activation No skin atrophy Useful in sensitive areas such as face and skinfolds Common application site reactions (e.g., burning) decreases with continued use
Targeted Immunotherapies for Psoriasis and Atopic Dermatitis		
TNF- α inhibitors; IL-12/23 inhibitors; IL-17 inhibitors; PDE4 inhibitors; Jak inhibitors	<ul style="list-style-type: none"> Psoriasis Atopic dermatitis: off-label use of PDE4 inhibitors, Jak inhibitors 	<ul style="list-style-type: none"> See Chapter 35
Targeted Antineoplastic Agents		
Smoothered inhibitors Histone deacetylase inhibitors	<ul style="list-style-type: none"> Basal cell carcinoma CTCL 	<ul style="list-style-type: none"> See Chapter 67
BRAF inhibitors; MEK inhibitors; CTLA4 inhibitors; programmed death 1 inhibitors	<ul style="list-style-type: none"> Melanoma 	<ul style="list-style-type: none"> See Chapter 67
Topical Agents for Hyperkeratotic Disorders		
Alpha-hydroxy acids Glycolic acid Lactic acid	<ul style="list-style-type: none"> Hyperkeratotic disorders 	<ul style="list-style-type: none"> MOA: reduced keratinocyte adhesion by promoting degradation of corneodesmosomes Potential skin irritation
Salicylic acid	<ul style="list-style-type: none"> Hyperkeratotic disorders 	<ul style="list-style-type: none"> MOA: reduced keratinocyte adhesion by affecting desmosomal adhesion proteins Potential skin irritation Potential salicylate toxicity with heavy use
Urea	<ul style="list-style-type: none"> Hyperkeratotic disorders 	<ul style="list-style-type: none"> MOA: increased hydration of stratum corneum, enhancing desquamation Potential skin irritation
Sulfur	<ul style="list-style-type: none"> Hyperkeratotic disorders 	<ul style="list-style-type: none"> MOA: possibly through interaction with cysteine, causing reduction to hydrogen sulfide, which may break down keratin Pungent odor

Drug Facts for Your Personal Formulary: *Dermatological Agents (continued)*

Drugs	Therapeutic Uses	Clinical Pharmacology and Tips
Topical Agents for Hyperkeratotic Disorders		
Propylene glycol	• Hyperkeratotic disorders	• MOA: increased hydration of stratum corneum, enhancing desquamation
Retinoids	• Hyperkeratotic disorders	• MOA: stimulation of keratinocyte turnover • Potential skin irritation
Agents Affecting Hair Growth		
Minoxidil, topical	• Androgenetic alopecia	• MOA: not fully determined; stimulates and prolongs anagen phase • Requires continued use to sustain effect
Finasteride, oral Dutasteride, oral	• Androgenetic alopecia • Hirsutism (off label)	• MOA: inhibition of 5- α reductase to decrease conversion of testosterone to DHT • Side effects: decreased libido, sexual dysfunction, hypotension
Spironolactone, oral	• Hirsutism (off label) • Female pattern alopecia (off label)	• MOA: aldosterone antagonist with antiandrogenic activity • Side effects: breast tenderness, menstrual irregularities, increased urination • Feminization of male fetus
Eflornithine, topical	• Unwanted facial hair in women	• MOA: ornithine decarboxylase inhibition to decrease hair growth • Slows hair growth; use in combination with hair removal methods
Bimatoprost, topical	• Hypotrichosis of the eyelashes	• MOA: prostaglandin analogue that increases percentage of hairs in anagen phase • May cause brown pigmentation of eyelid and iris (permanent)

Please note that there are numerous additional off-label uses of medications in dermatological conditions. MOA, mechanism of action.

- Penicillamine; Trientine
- Deferoxamine; Deferasirox; Deferiprone

Humans are exposed to chemicals from their environment daily. Fortunately, mammals have evolved mechanisms to protect themselves from toxic effects of many exogenous chemicals, including the xenobiotic transport and metabolic mechanisms described in Chapters 4–7. While the human body is relatively well adapted to deal with xenobiotics, there are situations in which such environmental agents may cause significant toxicity. The industrial revolution and the development of chemical industries have increased human exposures to chemicals that were previously infrequent or absent. Concern about environmental toxicants has stimulated interest and research in environmental toxicology, the study of how chemicals in our environment adversely affect human health; and in occupational toxicology, the study of how chemicals in the workplace affect human health. Many authoritative textbooks are available in these areas. This chapter does not attempt a thorough coverage; rather, it sets forth a few basic principles, briefly discusses carcinogens and chemoprevention, and then focuses on the pharmacotherapy of heavy metal intoxication.

Assessment and Management of Environmental Risk

Environmental exposures to *xenobiotics* involve large populations exposed to many toxicants at low doses over long periods of time, which poses challenges for assessing the risks from those exposures. Thus, the focus of environmental risk assessment is on the low end of the dose-response curve, using experiments based on chronic exposures. Unlike drugs, which are given to treat a specific disease and should have benefits that outweigh the risks, environmental toxicants are usually only harmful. In addition, exposures to environmental toxicants usually are involuntary, there is uncertainty about the severity of their effects, and people are much less willing to accept their associated risks.

Epidemiology and *toxicology* provide complimentary approaches to predict the toxic effects of environmental exposures. Epidemiologists monitor health effects in humans and use statistics to associate those effects with exposure to an environmental stress, such as a toxicant. Toxicologists perform laboratory studies to examine potential toxic mechanisms of a chemical and to predict whether it is likely to be toxic to humans. Each of these approaches has strengths and weaknesses, and information from

both is integrated into *environmental risk assessment*. Risk assessment is used to develop management approaches, such as laws and regulations, to limit exposures to environmental toxicants to a level that is considered safe.

Epidemiological Approaches to Risk Assessment

Epidemiologists use a variety of study designs to look for statistical associations between environmental exposures, including chemical exposures, and health outcomes. This approach has the advantage of examining the effects of real-world exposures to humans but can be expensive and subject to biases and confounding effects.

Epidemiological Studies

Several types of epidemiological studies are used to assess risks, each with its own set of strengths and weaknesses.

- *Ecological studies* correlate frequencies of exposures and health outcomes between different geographical regions. These studies are inexpensive and are effective for generating hypotheses but are subject to confounders and are not effective for establishing causality.
- *Cross-sectional studies* examine the prevalence of exposures and outcomes at a single point in time. Such studies are an inexpensive way to determine an association but do not provide a temporal relationship and are not effective for establishing causality. They also can be subject to bias, as a health outcome under study might cause someone to eliminate his or her exposure.
- *Case-control studies* start with a group of individuals affected by a disease; this group then is matched to another group of unaffected individuals for known confounding variables. Questionnaires often are used to evaluate past exposures. This method also is relatively inexpensive and is good for examining rare outcomes because the end point is known. However, case-control studies rely on assessments of past exposures, which can be unreliable and subject to bias.
- *Cohort studies* measure exposures in a large group of people and follow that group for a long time to measure health outcomes. These studies are not as susceptible to bias and are better than case-control studies at establishing causality. However, they are expensive, particularly when measuring rare outcomes, because a large study population is required to observe sufficient disease to obtain statistical significance.

Abbreviations

ARE: antioxidant response element
ATSDR: Agency for Toxic Substances Disease Registry
BAL: British anti-Lewisite (dimercaprol)
BLL: blood lead level
CaNa₂EDTA: calcium disodium ethylenediaminetetraacetic acid
CDC: Centers for Disease Control and Prevention
COX-2: cyclooxygenase 2; prostaglandin H synthase II
CV: cardiovascular
DMPS: sodium 2,3-dimercatopropane sulfonate
EEG: electroencephalogram
EPA: United States Environmental Protection Agency
ER: estrogen receptor
GI: gastrointestinal
GSH: reduced glutathione
GST: glutathione S-transferase
IARC: International Agency for Research on Cancer
IM: intramuscular
IV: intravenous
LOAEL: lowest adverse effect level
MCL: maximum contaminant level
MeHg⁺: methyl mercury
MMA: monomethylarsenic
NOAEL: no adverse effect level
NOx: nitrogen oxides
NQO1: quinone reductase
NTP: National Toxicology Program
PG: prostaglandin
RfD: reference dose
ROS: reactive oxygen species
SC: subcutaneous

- *Clinical trials* (see Chapter 1) cannot be used to directly measure the effects of environmental toxicants (for obvious ethical reasons) but can be used to examine the effectiveness of an interventional strategy for reducing both exposures and disease.

Biomarkers

Because of the difficulties in assessing human exposures and the long times required to clinically observe effects on health, epidemiologists often rely on biomarkers in risk assessment. Different types of biomarkers provide different information useful for risk assessment. Biomarkers aim to be *specific*, only detecting the change in affected individuals, and *sensitive*, detecting the change in all affected individuals.

- *Biomarkers of exposure* provide information about dose or duration of exposures. Blood and urine concentrations of a chemical or its metabolite measure recent exposures, while levels in hair and toenails can measure exposure over a period of months. An example of an unusual exposure biomarker is X-ray fluorescent measurement of bone lead levels, which estimates lifetime exposure to lead.
- *Biomarkers of toxicity* are used to measure toxic effects at a subclinical level. Examples include measurement of liver enzymes in serum, changes in the quantity or contents of urine, and performance on specialized exams for neurological or cognitive function.
- *Biomarkers of susceptibility* are used to predict which individuals are likely to develop toxicity in response to a given chemical. Examples include single-nucleotide polymorphisms in genes for metabolizing enzymes involved in the activation or detoxification of a toxicant.
- Some biomarkers simultaneously provide information on exposure, toxicity, or susceptibility. For example, the measurement in the urine of N7-guanine adducts from aflatoxin B₁ provides evidence of both exposure and a toxic effect (in this case, DNA damage).

Toxicological Approaches to Risk Assessment

Toxicologists use model systems, including experimental animals, to examine the toxicity of chemicals and predict their effects on humans. Toxicologists typically must test chemicals at higher doses than would be observed in the environment to see enough occurrences of a toxic outcome to obtain statistical significance. As a result, there is often uncertainty about the effects of very low doses of chemicals. To determine the applicability of model systems, toxicologists also study the mechanisms involved in the toxic effects of chemicals, with the goal of predicting whether that mechanism would occur in humans.

To predict the toxic effects of environmental chemicals, toxicologists perform *subchronic studies* (3 months of treatment for rodents) and *chronic studies* (2 years for rodents) in at least two different animal models. Doses for these studies are based on shorter preliminary studies, with the goal of having one concentration that does not have a significant effect, one concentration that results in statistically significant toxicity at the low end of the dose-response curve, and one or more concentrations that will have moderate-to-high levels of toxicity. A theoretical dose-response curve for an animal study is shown in Figure 71-1.

An animal study provides two numbers that estimate the risk from a chemical:

- The *NOAEL* is the highest dose used that does not result in a statistically significant increase in negative health outcomes.
- The *LOAEL* is the lowest dose that results in a significant increase in toxicity.

The NOAEL is divided by 10 for each source of uncertainty to determine a RfD, which is commonly used as a starting point for determining regulations on human exposures to chemicals. The modifiers used to determine the RfD are based on the uncertainties between experimental and human exposure. The most common modifiers used are for interspecies variability (human to animal) and interindividual variability (human to human), in which case $RfD = NOAEL/100$. Other modifiers can be used to account for specific experimental uncertainties, such as the unavailability of data from chronic studies. The use of factors of 10 in the denominator for determination of RfD is an application of the “precautionary principle,” which attempts to limit human exposure by assuming a worst-case scenario for each unknown variable.

A major concern with animal studies is that they do not detect effects at low concentrations. Typically, they are designed to obtain statistical significance with a 10%–15% increase in an outcome. As a result, there is considerable uncertainty about what occurs below that level, as demonstrated in Figure 71-1. Toxicologists often assume that there is a threshold dose below which there is no toxicity. However, the shape of the dose-response curve below the NOAEL is not known with certainty and represents a point of departure (POD). The existence of a threshold dose assumes that there are cellular defenses that prevent toxicity at concentrations below a given level, and that they can be overwhelmed. Some carcinogens may not exhibit a threshold, while others for which defense mechanisms exist do and other toxicants with specific molecular targets (e.g., lead) do not exhibit a threshold. Ideally, mechanistic studies should be done to predict which dose-response curve is most likely to fit a given chemical.

Toxicologists perform mechanistic studies to understand how a chemical might cause toxicity. Computer modeling using a compound's three-dimensional structure to determine quantitative structure-activity relationships (QSAR) is commonly performed on both drugs and environmental chemicals. QSAR approaches can determine which chemicals are likely to exhibit toxicities or bind to specific molecular targets. Cell-based approaches in prokaryotes and eukaryotes are used to determine whether a compound damages DNA or causes cytotoxicity. DNA damage and the resulting mutagenesis often are determined with the Ames test, which uses *Salmonella typhimurium* strains with specific mutations in the gene needed to synthesize histidine. These strains are treated with chemicals in the presence or absence of a metabolic activating system (usually hepatic xenobiotic metabolizing enzymes). If a compound is a

Figure 71-1 LOAEL and NOAEL. The theoretical dose-response curve from an animal study demonstrates the NOAEL and the LOAEL. Below the NOAEL level, there is considerable uncertainty regarding the shape of the response curve; thus, the NOAEL represents the *point of departure* (POD). The dose response could continue linearly below this point to reach a threshold dose (T) where there would be no harmful effects from the toxicant, or it could have a number of different possible inflection points. Each of these curves would have very different impacts on human populations. *Statistically significant toxicity.

mutagen in the Ames test, it reverts the mutation in the histidine operon and allows the bacteria to form colonies on plates with limited histidine. Gene chip microarrays assess gene expression in cells or tissues from animals treated with a toxicant and provide a useful tool to identify the molecular targets and pathways altered by toxicant exposures. The susceptibility of knockout mice to a toxicant can help to determine whether the knocked-out genes are involved in the mechanism of toxicity.

Carcinogens and Chemoprevention

Carcinogenesis

The IARC classifies the carcinogenicity of compounds into groups based on risk assessments using epidemiologic, human exposure, animal, and mechanistic data. Chemicals in *group 1* are known human carcinogens; *group 2A* are chemicals that are probably carcinogenic in humans; *group 2B* are chemicals that are possibly carcinogenic in humans; *group 3* are chemicals for which data are lacking to suggest a role in carcinogenesis; and *group 4* are those for which the data indicate that they are unlikely to be carcinogens. Table 71-1 provides examples of group 1 carcinogens.

The transformation of a normal cell to a malignancy is a multistage process, and exogenous chemicals can act at one or more of these stages. A classic model of chemical carcinogenesis is *tumor initiation* followed by *tumor promotion*. In this model, an initiator causes gene mutations that increase the ability of cells to proliferate and avoid apoptosis. A promoter does not directly modify genes but changes signaling pathways or the extracellular environment to increase survival, proliferation, or invasiveness of precancerous cells. Although this model is an oversimplification of the many processes of carcinogenesis, it demonstrates the types of changes that must occur for a normal cell to transform into cancer. Chemical carcinogens cause cancer through genotoxic and nongenotoxic mechanisms (Figure 71-2).

Genotoxic carcinogens initiate tumor formation through damage to DNA. Typically, genotoxic carcinogens undergo metabolism in a target tissue to a reactive intermediate. This reactive intermediate can directly

damage DNA via covalent reaction to form a DNA adduct. Alternatively, it can indirectly damage DNA through the formation of ROS, which can oxidize DNA or form lipid peroxidation products that react with DNA (Mena et al., 2009). If DNA damage from a genotoxic carcinogen is not repaired prior to DNA replication, a mutation can result. If this mutation is in a key tumor suppressor gene or proto-oncogene, it can provide advantages in proliferation or survival. Alternatively, mutations to DNA repair genes can increase the probability that future mutations will occur. With the right extracellular environment, mutations in key genes will allow a cell to proliferate faster than surrounding normal cells and possibly develop into malignant cancer.

Benzo[a]pyrene, a key carcinogen in tobacco smoke, is an example of a genotoxic carcinogen that forms both direct DNA adducts and ROS. Benzo[a]pyrene is oxidized by CYPs to a 7,8-dihydrodiol, which represents a proximate carcinogen (a more carcinogenic metabolite). This metabolite either can undergo a second oxidation step by a CYP to form a diol epoxide, which readily reacts with DNA, or can undergo oxidation by aldo-keto reductases to form a catechol, which will redox cycle to form ROS (Conney, 1982; Penning, 2009).

Nongenotoxic carcinogens increase the incidence of cancer without damaging DNA, and most agents in this category are tumor promoters. Many nongenotoxic carcinogens bind to receptors that stimulate proliferation or other tumor-promoting effects, such as tissue invasion or angiogenesis. For example, phorbol esters mimic diacylglycerol and activate PKC isoforms. This in turn stimulates MAPK pathways, leading to proliferation, invasiveness, and angiogenesis (Chapter 3 presents these signaling pathways). In most normal cells, prolonged activation of this pathway stimulates apoptosis, but cells with defective apoptotic mechanisms due to preceding mutation(s) are resistant to this effect. Estrogenic carcinogens activate ER α and stimulate proliferation and invasiveness of estrogen-responsive cells. Chronic inflammation is another mechanism of nongenotoxic carcinogenesis. Inflammatory cytokines stimulate PKC signaling, leading to proliferation, invasiveness, and angiogenesis. Irritants such as asbestos are examples of carcinogens that work through inflammation. Chronic exposure to hepatotoxic chemicals (or chronic liver diseases) also causes nongenotoxic carcinogenesis by stimulating compensatory proliferation to repair the liver damage. This damage and repair process increases the likelihood of DNA damage causing a mutation, causes chronic inflammation, and selects for initiated cells that proliferate faster or are less sensitive to cell death.

Many compounds can also act as complete carcinogens because repeated exposure can cause tumor initiation and promotion. Examples of complete carcinogens include benzo[a]pyrene and ultraviolet radiation.

Tumor initiation also may occur through nongenotoxic mechanisms. For example, some heavy metals do not directly react with DNA but interfere with proteins involved in DNA synthesis and repair, increasing the likelihood that an error will be made during replication. Nongenotoxic carcinogens also can cause heritable changes to gene expression by altering the methylation state of cytosines in 5'-CpG-3' islands of gene promoters. Methylation can silence tumor suppressor genes, while demethylation of proto-oncogenes can increase their expression. These *epigenetic* effects can occur through sustained transcription or silencing of a gene.

Some chemicals enhance the carcinogenesis of other chemicals and thus act as *cocarcinogens*. These chemicals can increase the absorption or change the metabolism of other chemicals, increasing the probability that they form active metabolites in target tissues. They can also interfere with DNA repair, increasing the occurrence of mutations from a second genotoxic carcinogen. For example, ethanol acts as a solvent and increases the absorption of tobacco carcinogens, increasing the risk of head and neck cancers in people who both smoke and drink. Ethanol also depletes GSH, limiting target cells' ability to detoxify reactive metabolites of carcinogens and ROS.

Chemoprevention

Drugs that interfere with the carcinogenic process to prevent cancer before it is diagnosed are termed *chemopreventive agents* (Szabo, 2006;

TABLE 71-1 ■ EXAMPLES OF IMPORTANT GROUP 1 CARCINOGENS*

CARCINOGEN CLASS	EXAMPLE	SOURCE	MECHANISM
Genotoxic			
Nitrosamines	Nicotine-derived nitrosaminoketone (NNK)	Tobacco products	Metabolic activation to form DNA adducts
Polycyclic aromatic hydrocarbons	Benzo[a]pyrene	Fossil fuel combustion, tobacco smoke, charbroiled food	Metabolic activation to form DNA adducts or ROS
Aromatic amines	2-Aminonaphthalene	Dyes	Metabolic activation to form DNA adducts
Fungal toxins	Aflatoxin B ₁	Corn, peanuts, and other food	Metabolic activation to form DNA adducts
Nongenotoxic			
Liver toxicants	Ethanol	Beverages, environment	Toxicity and compensatory proliferation; depletion of GSH
Phorbol esters	Tetradecanoyl phorbol acetate	Horticulture; rubber and gasoline production	Activation of PKC isoforms
Estrogens	Diethylstilbestrol	Drugs, environment	Activation of estrogen receptor signaling
Metals	Arsenic	Environment, occupation	Inhibition of DNA repair; activation of signal transduction pathways
Irritants	Asbestos	Environment, occupation	Stimulation of inflammation; formation of ROS
Dioxins	2,3,7,8 tetrachlorodibenzo-p-dioxin (TCDD)	Waste incineration, herbicides, paper-pulp bleaching	Activation of the aryl hydrocarbon (Ah) receptor

*Compounds in this table are classified as group 1 carcinogens by IARC, with the exception of the phorbol esters, which have not been examined.

William et al., 2009). The chemoprevention concept was pioneered during the 1960s by Wattenberg and others, who observed that dietary constituents, such as *t*-butyl hydroquinone, could prevent cancer in rodents (Wattenberg, 1966). Chemoprevention strategies often are based on epidemiological studies on nutrition, where there are many examples of clear protective effects of plant-based foods and drinks on the incidence of various types of cancer (Fahey and Kensler, 2007). By isolating the active compounds from protective plants, researchers hope to understand their protective mechanisms and develop drugs to prevent cancer. Chemoprevention is an emerging field; a number of compounds for the prevention of cancer are in clinical trials (Table 71-2). Most chemicals tested for chemoprevention have not exhibited a benefit, and in some cases they have increased the risk of cancer (Potter, 2014). There are currently no drugs approved for chemoprevention of environmental carcinogenesis, but there are approved drugs to prevent carcinogenesis due

to endogenous estrogen (tamoxifen and raloxifene) and viruses (hepatitis B and human papillomavirus vaccines).

Chemopreventive agents can interfere with initiation or promotion (Figure 71-2). One mechanism of anti-initiation is prevention of carcinogen activation. Isothiocyanates inhibit CYPs involved in activating many carcinogens and also upregulate genes controlled by the antioxidant response element (ARE); the ARE-responsive genes include γ -glutamyl-cysteine synthase light chain (which catalyzes the rate-determining step in GSH synthesis) and quinone reductase. Increased expression of ARE-regulated genes is predicted to increase the detoxification of proximate carcinogens. Isothiocyanates also stimulate apoptosis of p53-deficient cells via the formation of cytotoxic DNA adducts.

Compounds that act as antioxidants may provide protection because many carcinogens work through the generation of ROS. Some compounds simultaneously prevent carcinogen activation and act as antioxidants.

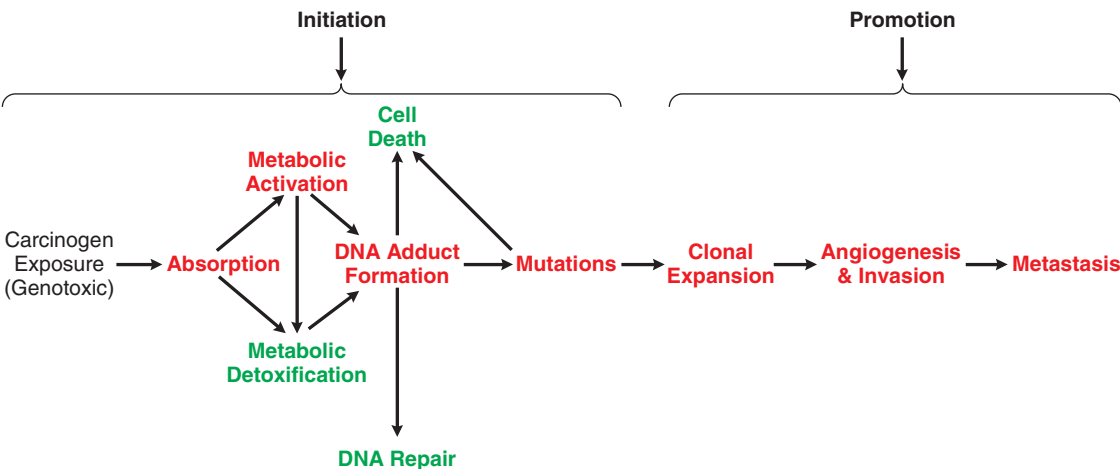

Figure 71-2 Carcinogenesis: initiation and promotion. There are multiple steps that occur between the exposure to a genotoxic carcinogen and the development of cancer. Processes in red lead to the development of cancer, while those in green reduce the risk. Nongenotoxic carcinogens act by enhancing steps leading to cancer or inhibiting protective processes. A chemopreventive agent acts by inhibiting steps leading to cancer or by increasing protective processes.

TABLE 71-2 ■ CHEMOPREVENTIVE AGENTS BEING STUDIED IN HUMANS

CHEMOPREVENTIVE CLASS	EXAMPLE COMPOUND	NATURAL SOURCE OR TYPE OF DRUG	CANCER TYPE(S)	MECHANISM	CURRENT STATUS
Isothiocyanates	Phenethyl isothiocyanate	Cruciferous vegetables	Liver, lung, breast, etc.	↓ CYP, ↑ GSH, ↑ NQO1, ↑ apoptosis	Phase 2 clinical trials
Synthetic drugs that modify metabolism	Oltipraz	Antischistosomal drug	Liver, lung	↓ CYP, ↑ GSH, ↑ NQO1	Beneficial effects on biomarkers in phase 2 clinical trials
Flavonoids and other polyphenols	Catechin	Green tea, red wine, berries, cacao, etc.	Lung, cervical, etc.	↓ ROS, ↓ CYP, ↑ GSH, ↑ NQO1	Phase 2 clinical trials
Other plant compounds	Curcumin	Turmeric (curry)	Colorectal, pancreatic, etc.	↓ ROS, ↓ CYP, ↑ GSH, ↑ NQO1	Phase 2 clinical trials
Other plant compounds	Chlorophyllin	All plants	Liver	Reaction with active intermediates, ↓ ROS, ↓ CYP	Beneficial effects on biomarkers in phase 2 clinical trials
Other antioxidants	α-Tocopherol (vitamin E)	Food	Prostate	Antioxidant, anti-inflammatory	Phase 3 clinical trials found ↑ prostate cancer with α-tocopherol
Antihormonal therapies	Tamoxifen	Adjuvant for breast cancer	Breast	Inhibit ERα in breast	FDA approved for chemoprevention
NSAIDs (see Chapter 38)	Aspirin	Anti-inflammatory drugs	Colorectal, etc.	Inhibit PG formation	Phase 3 trials of aspirin for prevention of cardiovascular disease observed ↓ cancer; phase 3 trials for cancer prevention are ongoing
COX-2 selective inhibitors (see Chapter 38)	Celecoxib	Anti-inflammatory drugs	Colorectal, etc.	Inhibit PG formation	Phase 3 trial found ↓ cancer but unacceptable side effects for prevention

For example, flavonoids and other polyphenols found in a wide variety of plants are potent antioxidants that also inhibit CYPs and induce expression of ARE-regulated genes. Chlorophyll and other compounds can protect against carcinogens by binding to or reacting with carcinogens or their metabolites and preventing them from reaching their molecular target.

Inflammation is a potential target for chemoprevention through interference with promotion. In phase 3 studies, the COX-2 inhibitor celecoxib demonstrated efficacy at reducing the risk of colorectal cancer. However, this benefit was offset by an increased risk of death due to cardiovascular events, forcing the early termination of the trial (William et al., 2009). Studies examining long-term treatment with aspirin for cardiovascular benefits found that aspirin also reduces the incidence of colorectal adenomas and overall cancer mortality. A phase 3 clinical trial is under way to examine this effect. Naturally occurring compounds such as α-tocopherol have also been hypothesized to exert chemoprevention by reducing inflammation. However, α-tocopherol actually increased the risk of prostate cancer in a phase 3 trial (Potter, 2014).

Another approach to chemoprevention is disruption of nuclear receptor signaling. Retinoids reduce the incidence of head and neck cancers, and is one of the first successful uses of chemoprevention in humans (Evans and Kaye, 1999; William et al., 2009). Retinoids are also effective for the treatment for acute promyelocytic leukemia (see Section VII). However, in large clinical trials, retinoids increased the incidence of lung cancer, particularly amongst women, and had other unacceptable toxicities (Omenn et al., 1996).

The selective ER modulators tamoxifen and raloxifene reduced the incidence of breast cancer in high-risk women in large phase 3 clinical trials and are approved for chemoprevention in these patients (Vogel et al., 2006). The success of selective ER modulators for chemoprevention provides a proof-of-principle that the development of compounds based on mechanistic predictions of antipromotion activity can lead to effective drugs for the prevention of cancer.

Aflatoxin B₁

Agents are being developed as chemopreventants of hepatocarcinogenesis mediated by aflatoxin B₁. Aflatoxins are produced in regions with hot and wet climates by *Aspergillus flavus*, a fungus that is a common contaminant of foods, especially corn, peanuts, cottonseed, and tree nuts. As a result of exposure to aflatoxin, human hepatocellular carcinoma is a serious problem in subtropical and tropical regions of Latin America, Africa, and Southeast Asia. Human exposure to aflatoxin in the U.S. is rare and not thought to have a significant impact on health (IARC, 2002).

ADME

Aflatoxin B₁ is readily absorbed from the GI tract and initially distributed to the liver, where it undergoes extensive first-pass metabolism (Guengerich et al., 1996). Aflatoxin B₁ is metabolized by CYPs 1A2 and 3A4 to yield either an 8,9-epoxide or products hydroxylated at the 9 position (aflatoxin M₁) or 3 position (aflatoxin Q₁; Figure 71-3). While the hydroxylation products are detoxification products, the 8,9-epoxide reacts with DNA and is responsible for aflatoxin carcinogenesis. The 8,9-epoxide is short lived and undergoes detoxification via nonenzymatic hydrolysis or conjugation with GSH. Aflatoxin M₁ enters the circulation and is excreted in urine and milk.

Toxicity

Aflatoxin B₁ primarily targets the liver, although it also is toxic to the GI tract and hematological system. High-dose exposures result in acute necrosis of the liver, leading to jaundice and, in many cases, death. Acute toxicity from aflatoxin is rare in humans and requires consumption of milligram quantities of aflatoxin per day for multiple weeks. Chronic exposure to aflatoxins results in cirrhosis of the liver and immunosuppression.

Carcinogenicity

Based on increased incidence of hepatocellular carcinoma in humans exposed to aflatoxin and on supporting animal and mechanistic data,

Figure 71-3 *Metabolism and actions of aflatoxin B₁.* Following absorption, aflatoxin B₁ undergoes activation by CYPs to its 8,9-epoxide, which can be detoxified by GSTs or by spontaneous hydration. Alternatively, it can react with cellular macromolecules such as DNA and protein, leading to toxicity and cancer. Oltipraz, green tea polyphenols (GTPs), and isothiocyanates (ITCs) decrease aflatoxin carcinogenesis by inhibiting the CYPs involved in activating aflatoxin and increasing the synthesis of the cofactor GSH for GSTs involved in detoxification.

IARC has classified aflatoxin B₁ as a known human carcinogen (group 1) (IARC, 2002). Aflatoxin exposure and the hepatitis B virus work synergistically to cause hepatocellular carcinoma. Aflatoxin or hepatitis B exposure alone increases the risk of hepatocellular carcinoma 3.4- or 7.3-fold, respectively; those exposed to both have a 59-fold increased risk of cancer compared to unexposed individuals (Groopman et al., 2005).

Aflatoxin primarily forms DNA adducts at deoxyguanosine residues, reacting at either the N1 or N7 position (IARC, 2002); the 8,9-epoxide of aflatoxin B₁ readily reacts with amines. The N7-guanine adduct mispairs with adenine, leading to G → T transversions. Human aflatoxin exposure is associated with hepatocellular carcinomas bearing an AGG-to-AGT mutation in codon 249 of the *p53* tumor suppressor gene, resulting in the replacement of an arginine with cysteine (Hussain et al., 2007).

Several mechanisms for the synergistic interaction between hepatitis B and aflatoxin are under investigation (Sylla et al., 1999). The X gene of the hepatitis B virus encodes a protein, HBx, that binds to and inhibits *p53*, resulting in suppressed nucleotide excision repair of aflatoxin B₁ adducts (Hussain et al., 2007). Hepatitis B also alters the metabolism of aflatoxin B₁ by upregulating CYP genes, including CYP3A4, and decreases GSH S-transferase activity. In addition, hepatocellular proliferation to repair damage done by hepatitis B infection increases the likelihood that aflatoxin-induced DNA adducts will cause mutations. The hepatotoxic and tumor-promoting effects of hepatitis B also could provide a more favorable environment for the proliferation and invasion of initiated cells.

Chemoprevention of Aflatoxin-Induced Hepatocellular Carcinoma

The relationship between aflatoxin metabolism and its carcinogenicity makes it an appealing target for chemopreventive strategies that modify its metabolism (Figure 71-3). Inhibiting CYP activity or increasing GSH conjugation will reduce the intracellular concentration of the 8,9-epoxide and prevent DNA adduct formation (Groopman et al., 2008; Kensler et al., 2004). Oltipraz, an antischistosomal drug, potently inhibits CYPs and induces genes regulated by the ARE that are involved in GSH synthesis. Oltipraz increases the excretion of the *N*-acetylcysteine aflatoxin conjugate, indicating enhanced GSH conjugation of the epoxide. At 500 mg/week, oltipraz reduced the levels of aflatoxin M₁, consistent with inhibition of CYP activity.

Green tea polyphenols (GTPs) also have been used to modify aflatoxin metabolism in exposed human populations. Individuals receiving a daily dose of 500 or 1000 mg (equivalent to 1 or 2 L of green tea) demonstrated a small decline in the formation of aflatoxin-albumin adducts and a large

increase in the excretion of the *N*-acetylcysteine aflatoxin conjugate, consistent with a protective effect.

Another approach used for the chemoprevention of aflatoxin hepatocarcinogenesis is the use of “interceptor molecules.” *Chlorophyllin*, a mixture of water-soluble chlorophyll salts, binds tightly to aflatoxin in the GI tract, forming a complex that is not absorbed. In vitro, chlorophyllin inhibits CYP activity and acts as an antioxidant. In a phase 2 trial, administration of 100 mg of chlorophyllin with each meal reduced aflatoxin-N7-guanine adduct levels in the urine. Because of the strong interaction between hepatitis B and aflatoxin in carcinogenesis, the hepatitis B vaccine reduces the sensitivity of people to the induction of cancer by aflatoxin. Primary prevention of aflatoxin exposure through hand or fluorescent sorting of crops to remove those with fungal contamination also reduces human exposure. A cost-effective primary prevention approach is to improve food storage to limit the spread of *Aspergillus flavus*, which requires a warm and humid environment.

Water and Air Pollution

The U.S. EPA protects the public from water and airborne pollutants by enforcing compliance with the Clean Water Act (protects the public and the environment from water pollution); the Safe Drinking Water Act (ensures the quality of the drinking water); and the Clean Air Act (to protect the public from air pollutants). Under these laws, the EPA combines scientific risk assessment with economic analyses and other factors to develop regulations on the release or presence of specific pollutants to limit their effect on human health and the environment.

Toxicity screening of many water contaminants has led to the development of maximum contaminant levels (MCLs) for drinking water. To protect against potential adverse health effects, a primary MCL sets a level for a contaminant that must not be exceeded. The primary MCL is based on consideration of the toxic dose-response curve and on whether a sufficiently sensitive analytical method exists to measure the contaminant for compliance purposes. A secondary MCL is not enforced but is established for aesthetic value (e.g., taste, color, odor) that may not affect health. Currently, there is concern about pharmaceutical waste in the water supply, but MCLs have not been set for these compounds.

The EPA also monitors six priority air pollutants (CO, Pb, NO_x, O₃, particulate matter, and SO₂) that they have determined play the largest role in human health effects from air pollution. The EPA sets National Ambient Air Quality Standards in which local levels of these pollutants may not be exceeded within a given time frame. Measurements made by stationary

air monitors provide daily air quality data and also lead to warnings (e.g., ozone awareness days), which advise citizens to stay indoors. Fine particles, smaller than 2.5 μm in diameter (PM_{2.5}) are particularly concerning as they penetrate deep into the lung and can cause or exacerbate respiratory or cardiovascular illness.

Metals

Metals are an important class of environmental toxicants; they are ubiquitous environmental contaminants that come from both natural and anthropogenic sources. The CDC lists arsenic, mercury, and lead as the top three pollutants of concern, based on their toxicity and levels of human exposure. Although the toxicity of high levels of exposure to metals has long been known, the effects of low-dose chronic exposure to metals have only recently been appreciated. Many of the toxic metals in the environment also are carcinogens (Table 71–3). In addition, several essential metals also are toxic under conditions of overdose. Copper and iron are associated with toxicities, primarily targeting the liver through generation of ROS.

Lead

Chronic exposure to very low levels of lead has major deleterious effects, particularly for children.

Exposure

Despite substantial improvements over the past four decades, lead exposure remains a major concern, especially for children. In the U.S., paint containing lead for use in and around households was banned in 1978, while the use of tetraethyl lead in gasoline was phased out between 1976 and 1996. Despite these bans, past use of lead carbonate and lead oxide in paint and tetraethyl lead in gasoline remain the primary sources of lead exposure. Lead is not degradable and remains in dust, soil, and the paint of older homes. Young children are exposed to lead by nibbling sweet-tasting paint chips or ingesting dust and soil in and around older homes. Renovation or demolition of older buildings may cause substantial lead exposure. Removal of lead from gasoline reduced lead levels in air by more than 90% between 1982 and 2002, but lead fallout from air pollution remains in soils, particularly in urban environments. Lead was also commonly used in plumbing and can leach into drinking water. Lead exposure also has been traced to other sources, such as inhalation of dusts and fumes at firing ranges, retained bullets, artists' paint pigments, ashes and fumes from painted wood, lead-glazed pottery, lead toys, non-Western folk medicines, cosmetics, jewelers' wastes, home battery manufacture, and lead type (ATSDR, 2007b). BLLs in children have steadily decreased since the

1970s, when the mean level was 15 $\mu\text{g}/\text{dL}$. Currently, the average BLL in children is at 1.3 $\mu\text{g}/\text{dL}$.

The CDC recently updated its recommendations to reflect the modern understanding that *there is no safe level of lead exposure for children* (CDC, 2012). The CDC no longer provides a "level of concern," as any lead exposure to a child is concerning. Instead, the CDC emphasizes primary prevention of lead exposure in all children and recommends that children with a BLL that places them in the top 2.5% (currently $\geq 5 \mu\text{g}/\text{dL}$) be identified as in need of exposure reduction and additional screening. They did not change the existing recommendation that physicians consider chelation therapy for children with a BLL above 45 $\mu\text{g}/\text{dL}$.

Occupational exposure to lead also has decreased because of protective regulations. Occupational exposure generally is through inhalation of lead-containing dust and lead fumes. Workers in lead smelters and storage battery factories are at the greatest risk for lead exposure. Other workers at risk for lead exposure are those associated with steel welding or cutting, construction, rubber and plastic industries, printing, firing ranges, radiator repair shops, and any industry where lead is flame soldered (ATSDR, 2007b).

Chemistry and Mode of Action

Lead exists in its metallic form and as divalent or tetravalent cations. Divalent lead is the primary environmental form; inorganic tetravalent lead compounds are not found naturally. Organo-lead complexes primarily occur with tetravalent lead and include the gasoline additive tetraethyl lead.

Lead toxicity results from molecular mimicry of other divalent metals (Garza et al., 2006), principally zinc and calcium. Because of its size and electron affinity, lead alters protein structure and can inappropriately activate or inhibit protein function.

ADME

Lead exposure occurs through ingestion or inhalation. GI absorption of lead varies considerably with age and diet. Children absorb a much higher percentage of ingested lead (~40% on average) than adults (<20%). Absorption of ingested lead is drastically increased by fasting. Dietary calcium or iron deficiencies increase lead absorption, suggesting that lead is absorbed through divalent metal transporters. The absorption of inhaled lead (~90%) generally is much more efficient than through dietary intake. Tetraethyl lead is readily absorbed through the skin, but transdermal absorption does not occur with inorganic lead.

About 99% of lead in the bloodstream binds to hemoglobin. Lead initially distributes in the soft tissues, particularly in the tubular epithelium of the kidney and the liver. Over time, lead is redistributed and deposited in bone, teeth, and hair. About 95% of the adult body burden of lead is

TABLE 71–3 ■ TOXIC METALS WITH FREQUENT ENVIRONMENTAL OR OCCUPATIONAL EXPOSURE^a

METAL	CERCLA PRIORITY ^b	COMMON SOURCE OF EXPOSURE	ORGAN SYSTEMS MOST SENSITIVE TO TOXICITY	IARC CARCINOGEN CLASSIFICATION
As	1	Drinking water	CV, skin, multiple other	Group 1, carcinogenic to humans—liver, bladder, lung
Pb	2	Paint, soil	CNS, blood, CV, renal	Group 2A, probably carcinogenic
Hg	3	Air, food	CNS, renal	Group 2B, possibly carcinogenic (MeHg ⁺); group 3, not classifiable (Hg ⁰ , Hg ²⁺)
Cd	7	Occupational, food, smoking	Renal, respiratory	Group 1, carcinogenic to humans—lung
Cr ⁶⁺	18	Occupational	Respiratory	
Be	42	Occupational, water	Respiratory	
Co	49	Occupational, food, water	Respiratory, CV	Group 2B, possibly carcinogenic
Ni	53	Occupational	Respiratory, skin (allergy)	Group 1, carcinogenic (soluble Ni compounds); group 2B, possibly carcinogenic (metallic Ni)—lung

^aThe ATSDR has both detailed monographs and brief summaries for each of these compounds (available at <https://www.atsdr.cdc.gov>). The IARC also has monographs available (<http://monographs.iarc.fr>).

^bCERCLA, Comprehensive Environmental Response, Compensation, and Liability Act.

1304 found in bone. Growing bones will accumulate higher levels of lead and can form lead lines visible by radiography. Bone lead is slowly reabsorbed into the bloodstream, which can be accelerated when calcium levels are depleted, including during pregnancy. Small quantities of lead accumulate in the brain, mostly in gray matter and the basal ganglia. Lead readily crosses the placenta.

Lead is excreted primarily in the urine. The concentration of lead in urine is directly proportional to its free concentration in plasma (~1% of the total BLL). Lead is excreted in milk and sweat and deposited in hair and nails. The serum $t_{1/2}$ of lead is 1–2 months, with a steady state achieved in about 6 months. Lead accumulates in bone, where its $t_{1/2}$ is estimated at 20–30 years.

Health Effects

Although the effects of high-dose lead poisoning have been known for more than 2000 years, the insidious toxicities of chronic low-dose lead poisoning (BLL < 20 µg/dL) have only recently been discovered. Lead is a nonspecific toxicant; the most sensitive systems are the nervous, hematological, cardiovascular, and renal systems (Table 71–4). Uncovering the effects of low-level lead exposure on complex health outcomes, such as neurobehavioral function and blood pressure, has been the subject of extensive research and the object of considerable public concern.

TABLE 71–4 ■ HEALTH EFFECTS OF LEAD

BLL (µg/dL)	HEALTH EFFECT
Children	
<10	Inhibition of neural development Increased blood pressure Hearing loss Inhibition of hemoglobin synthesis enzymes Short stature Delayed sexual maturation (girls)
>10	Immunological effects (increased IgE)
>15	Increased erythrocyte protoporphyrin Decreased vitamin D
>30	Depressed nerve conduction velocity
>40	Anemia
>45	Chelation therapy warranted
>60	Colic
>70	Encephalopathy
Adults	
<10	Increased blood pressure Inhibition of hemoglobin synthesis enzymes Decreased glomerular filtration
>20	Increased erythrocyte protoporphyrin
>30	Hearing loss Enzymuria/proteinuria
>40	Peripheral neuropathy Reduced fertility Altered thyroid hormone levels Neurobehavioral effects
>50	Anemia
>60	Colic Chelation therapy warranted
>100	Encephalopathy

Neurotoxic Effects. The biggest concerns with low-level lead exposure are cognitive delays and behavior changes in children (ATSDR, 2007b; Bellinger and Bellinger, 2006). The developing nervous system is very sensitive to the toxic effects of lead, with effects persisting down to the lowest measurable levels of lead (Cranfield et al., 2003; Lanphear et al., 2005).

Lead neurotoxicity primarily results from inhibition of Ca²⁺ transporters and channels and altered activities of Ca²⁺ responsive proteins, including PKC and calmodulin (Bellinger and Bellinger, 2006; Garza et al., 2006). These actions limit the normal activation of neurons in response to Ca²⁺ release and cause inappropriate production or release of neurotransmitters. Lead affects multiple neurotransmitter pathways, including the dopaminergic, cholinergic, and glutaminergic systems. At high concentrations, lead causes disruption of membranes, including the blood-brain barrier, increasing their permeability to ions.

Lead alters brain development by interfering with the pruning of synapses, neuronal migration, and the interactions between neurons and glial cells. Neurotransmitter release and PKC signaling determine which synapses are maintained and which are lost during brain development; this process is disrupted by lead. Lead-induced alterations in brain development can result in decreased IQ, poor performance on exams, language and motor deficits, and behavioral problems such as distractibility, impulsivity, aggression, short attention span, and inability to follow simple sequences of instructions (ATSDR, 2007b; CDC, 2014). There is no evidence for a threshold; associations are evident even at the lowest measurable BLL (Figure 71–4). The cognitive and behavioral changes caused by lead vary considerably among children and may depend on the timing of exposure.

Children with very high BLL (>70 µg/dL) are at risk for encephalopathy. Symptoms of lead-induced encephalopathy include lethargy, vomiting, irritability, anorexia, and vertigo, which can progress to ataxia, delirium, and eventually coma and death. Mortality rates for lead-induced encephalopathy are about 25%, and most survivors develop long-term sequelae such as seizures and severe cognitive deficits.

Adults can also develop encephalopathy from lead exposure, although they are less sensitive than children. Workers chronically exposed to lead can develop neuromuscular deficits, termed *lead palsy*. Symptoms of lead palsy, including wrist drop and foot drop, were commonly associated with painters and other lead-exposed workers during previous eras but are rare today. Lead induces degeneration of motor neurons, usually without affecting sensory neurons. Studies in older adults have shown associations between lead exposure and decreased performance on cognitive function tests, suggesting that lead accelerates neurodegeneration due to aging (ATSDR, 2007b).

Figure 71–4 Effect of childhood lead exposure on IQ. Childhood exposure to lead shows a nonlinear dose-response relationship, with a steeper curve at low concentrations of lead (estimated dose-response curve based on data from Lanphear et al., 2005, and Canfield et al., 2003). For comparison, the average BLL from three iterations of the National Health and Nutritional Examination Survey are shown (Wheeler and Brown, 2013).

Cardiovascular and Renal Effects. Elevated blood pressure is a lasting effect of low-level lead exposure (BLL < 10 µg/dL). Adults who were exposed to lead during infancy and childhood have elevated blood pressure even in the absence of a recent exposure (ATSDR, 2007b). Lead exposure is associated with an increased risk of death due to cardiovascular and cerebrovascular disease (Schober et al., 2006).

In the kidney, low-level lead exposure (BLL < 10 µg/dL) depresses glomerular filtration. Higher levels (>30 µg/dL) cause proteinuria and impaired transport, while very high levels (>50 µg/dL) cause permanent physical damage, including proximal tubular nephropathy and glomerulosclerosis. Impaired glomerular filtration and elevated blood pressure are closely interrelated and likely have causative effects on one another (ATSDR, 2007b).

The cardiovascular effects of lead are thought to involve the production of ROS, which react with NO to prevent vasodilation (Vaziri and Khan, 2007). It is not known how lead reduces glomerular filtration rate, although there is evidence that lead targets kidney mitochondria and interferes with the electron transport chain (ATSDR, 2007b).

Other Effects. Lead causes both immunosuppression and increased inflammation, primarily through changes in helper T-cell and macrophage signaling; these effects can occur at low BLLs in children (Dietert and Piepenbrink, 2006). Lead inhibits the activity of several enzymes involved in the biosynthesis of heme; this effect persists down to very low BLL (<10 µg/dL; Figure 71–5). Chronic high-dose lead intoxication is associated with hypochromic microcytic anemia, which is observed more frequently in children and is morphologically similar to iron-deficient anemia. Acute high-dose lead exposure affects the smooth muscle of the gut, producing intestinal symptoms, termed *lead colic*.

Carcinogenesis. The IARC classifies lead in group 2A, “probably carcinogenic to humans” (IARC, 2006). Epidemiological studies show associations between lead exposure and cancers of the lung, brain, kidney, and stomach. Rodents exposed to lead develop kidney tumors, and some rats develop gliomas. Lead is not mutagenic but increases clastogenic events. Lead carcinogenesis may result from inhibition of DNA-binding zinc-finger proteins, including those involved in DNA repair and synthesis. Lead is a good example of a nongenotoxic carcinogen.

Treatment

The most important response to lead poisoning is to remove the source of lead exposure. Supportive measures should be undertaken to relieve symptoms.

Chelation therapy is warranted for children and adults with very high BLL (>45 µg/dL and >60 µg/dL, respectively) or acute symptoms of lead poisoning (Ibrahim et al., 2006). For children with a BLL above 45 µg/dL but below 70 µg/dL, oral chelation is recommended. A BLL above 70 µg/dL in a child is a medical emergency requiring hospitalization and immediate intravenous chelation (American Academy of Pediatrics, 2005). Although chelation therapy is effective at lowering BLL and relieving acute symptoms of lead poisoning, it does not reduce the chronic effects of lead beyond the benefit of lead abatement alone (Rogan et al., 2001). In rats, chelators enhance mobilization of lead from the soft tissues to the brain and may increase the adverse neurodevelopmental effects of lead (Andersen and Aaseth, 2002).

Mercury

Mercury is a unique metal in that it is a liquid at room temperature. Mercury has been used industrially since ancient Greece due to its capacity to amalgamate with other metals, and mercury’s toxicity was noted by Hippocrates. Mercury also was used as a therapeutic drug for several centuries. Its use for the treatment for syphilis inspired Paracelsus’s observation that “the dose makes the poison,” one of the central concepts of toxicology, and also gave rise to the cautionary expression: “A night with Venus, a year with Mercury.” The phrase “mad as a hatter” originated from the exposure of hatters to metallic mercury vapor during production of felt for hats using mercury nitrate. While the phrase likely inspired the character of the Mad Hatter in *Alice in Wonderland*, his symptoms are not consistent with mercury exposure.

Exposure

Inorganic mercury cations and metallic mercury are found in the Earth’s crust, and mercury vapor is released naturally into the environment through volcanic activity and off-gassing from soils. Mercury also enters the atmosphere through human activities, such as combustion of fossil fuels and gold mining. In 2011, the EPA set the first standards to reduce mercury emissions from coal-fired power plants. Once in the air, metallic mercury is photo-oxidized to inorganic mercury, which can then be deposited in aquatic environments in rain. Microorganisms can then conjugate inorganic mercury to form methyl mercury. Methyl mercury concentrates in muscle and other tissues and will bioaccumulate up the food chain (Figure 71–6). As a result, mercury concentrations in aquatic organisms at the top of the food chain, such as swordfish or sharks, are high (ATSDR, 1999).

The primary source of exposure to Hg⁰ in the general population is vaporization of Hg⁰ in dental amalgam. Human exposure to organic mercury primarily is through the consumption of fish. Other foods contain inorganic mercury at low levels (ATSDR, 1999).

Workers are exposed to Hg⁰ and inorganic mercury, most commonly through exposure to vapors. The highest risk for exposure is in the chloralkali industry (i.e., bleach) and in other chemical processes in which mercury is used as a catalyst. Mercury is a component of many devices, including alkaline batteries, fluorescent bulbs, thermometers, and scientific equipment, and exposure occurs during the production of these devices. Dentists also are exposed to Hg⁰ from amalgam. Hg⁰ can be used to extract gold during mining, which results in substantial occupational exposure. Mercuric salts are used as pigments in paints (ATSDR, 1999).

Thimerosal is an antimicrobial agent used as a preservative in some vaccines. Its use is controversial because it releases ethyl mercury, which is chemically similar to methyl mercury. Some parents have expressed concern that thimerosal might contribute to autism. Even though these concerns were based on a long-discredited report, the American Academy of Pediatrics and the U.S. Public Health Service issued a call for thimerosal’s replacement in vaccines to improve the prevalence of vaccination, and thimerosal was removed from childhood vaccines in 2001 (Ball et al., 2001). Concurrently, studies found no association between thimerosal use in vaccines and negative outcomes, and thimerosal is still used

Figure 71–5 Actions of lead on heme biosynthesis.

Figure 71-6 Mobilization of mercury in the environment. Metallic mercury (Hg^0) is vaporized from Earth's surface both naturally and through human activities such as burning coal. In the atmosphere, Hg^0 is oxidized to form divalent inorganic mercury (Hg^{2+}), which falls to the surface in rain. Aquatic bacteria can methylate Hg^{2+} to form methyl mercury (MeHg^+). MeHg^+ in plankton is consumed by fish. Because of its lipophilicity, MeHg^+ bioaccumulates up the food chain.

in influenza vaccines (Heron and Golding, 2004). The FDA maintains a listing of the thimerosal content in vaccines (<http://www.fda.gov/BiologicsBloodVaccines/SafetyAvailability/VaccineSafety/UCM096228>).

Chemistry and Mode of Action

There are three general forms of mercury of concern to human health. Metallic, or elemental, mercury (Hg^0) is the liquid metal found in scientific equipment and dental amalgam; it is volatile, and exposure is often to the vapor. Inorganic mercury can be either monovalent (mercurous, Hg^{1+}) or divalent (mercuric, Hg^{2+}) and forms a variety of salts. Organic mercury compounds consist of divalent mercury complexed with one or two alkyl groups. Methyl mercury (MeHg^+), which is formed environmentally from inorganic mercury by aquatic microorganisms, is of most concern. Both Hg^{2+} and MeHg^+ readily form covalent bonds with sulfur, which causes most of the biological effects of mercury. At very low concentrations, mercury reacts with sulfhydryl residues on many proteins and disrupts their functions. Microtubules are particularly sensitive to the toxic effects of mercury, which disrupts their formation and can catalyze their disassembly (Clarkson, 2002). There also may be an autoimmune component to mercury toxicity.

ADME

The vapor of Hg^0 is readily absorbed through the lungs (~70%–80%), but GI absorption of Hg^0 is negligible. Once absorbed, Hg^0 distributes throughout the body and crosses membranes, such as the blood-brain barrier and the placenta, via diffusion. Hg^0 is oxidized by catalase in cells to form Hg^{2+} . Shortly after exposure, some Hg^0 is eliminated in exhaled air. After a few hours, distribution and elimination of Hg^0 resemble the properties of Hg^{2+} . Hg^0 vapor can be oxidized to Hg^{2+} in the brain and retained (ATSDR, 1999).

Gastrointestinal absorption of mercury salts varies depending on the individual and on the particular salt and averages about 10%–15%. Hg^{1+} will form Hg^0 or Hg^{2+} in the presence of sulfhydryl groups. Hg^{2+} is primarily excreted in the urine and feces; a small amount also can be reduced to Hg^0 and exhaled. With acute exposure, the fecal pathway predominates, but following chronic exposure, urinary excretion becomes more important. All forms of mercury also are excreted in sweat and breast milk and deposited in hair and nails. The $t_{1/2}$ for inorganic mercury is approximately 1–2 months (ATSDR, 1999).

Complexes between MeHg^+ and cysteine resemble methionine and can be recognized by transporters for that amino acid and taken across

membranes (Ballatori, 2002). Orally ingested MeHg^+ is almost completely absorbed from the GI tract. MeHg^+ readily crosses the blood-brain barrier and the placenta and distributes fairly evenly to the tissues, although concentrations are highest in the kidneys (ATSDR, 1999). MeHg^+ can be demethylated to form inorganic Hg^{2+} . The liver and kidney exhibit the highest rates of demethylation, but this also occurs in the brain. MeHg^+ is excreted in the urine and feces, with the fecal pathway dominating. The $t_{1/2}$ for MeHg^+ is about 2 months. The toxicodynamic properties of MeHg^+ are thought to result from molecular mimicry.

Health Effects

Metallic Mercury. Inhalation of high levels of Hg^0 vapor over a short duration is acutely toxic to the lung. Respiratory symptoms of Hg^0 exposure start with cough and tightness in the chest and can progress to interstitial pneumonitis and severely compromised respiratory function. Other initial symptoms include weakness, chills, metallic taste, nausea, vomiting, diarrhea, and dyspnea. Acute exposure to high doses of Hg^0 is also toxic to the CNS, with symptoms similar to those of chronic exposure (Figure 71-7).

Toxicity to the nervous system is the primary concern with chronic exposure to Hg^0 . Symptoms include tremors (particularly of the hands); emotional lability (irritability, shyness, loss of confidence, and nervousness); insomnia; memory loss; muscular atrophy; weakness; paresthesia; and cognitive deficits. These symptoms intensify and become irreversible with increases in duration and concentration of exposure. Other common symptoms of chronic mercury exposure include kidney damage, tachycardia, labile pulse, severe salivation, and gingivitis.

Inorganic Salts of Mercury. Ingestion of Hg^{2+} salts is intensely irritating to the GI tract, leading to vomiting, diarrhea, and abdominal pain. Acute exposure to Hg^{1+} or Hg^{2+} salts (typically in suicide attempts) leads to renal tubular necrosis, resulting in decreased urine output and often acute renal failure. Chronic exposures also target the kidney, with glomerular injury predominating.

Organic Mercury. The CNS is the primary target of MeHg^+ toxicity. Symptoms of high-dose MeHg^+ exposure include visual disturbances, ataxia, paresthesia, fatigue, hearing loss, slurring of speech, cognitive deficits, muscle tremor, movement disorders, and, following severe exposure, paralysis and death. The developing nervous system exhibits increased sensitivity to MeHg^+ . Children exposed in utero can develop severe symptoms, including mental retardation and neuromuscular deficits, even in

Figure 71-8 Arsenic in drinking water. **A.** World map demonstrating regions where there is increased arsenic exposure in drinking water. **B.** Map of Bangladesh demonstrating arsenic concentrations in drinking water in samples from wells across the country. (Adapted from a report produced by the British Geological Survey and the Department of Public Health Engineering [Bangladesh] undertaking a project funded by the U.K. Department for International Development. Any views expressed are not necessarily those of DFID.)

arsenate, and arsenic trioxide are not well absorbed. Water-soluble arsenic compounds are readily absorbed via inhalation and ingestion. GI absorption of arsenic dissolved in drinking water is more than 90% (ATSDR, 2007a). At low doses, arsenic is fairly evenly distributed throughout the tissues of the body. Nails and hair, due to their high sulfhydryl content, exhibit high concentrations of arsenic. After an acute high dose (i.e., fatal

poisoning), arsenic is preferentially deposited in the liver and, to a lesser extent, kidney, with elevated levels also observed in the muscle, heart, spleen, pancreas, lungs, and cerebellum. Arsenic readily crosses the placenta and blood-brain barrier.

Arsenic undergoes biotransformation in humans and animals (Figure 71-9). Trivalent compounds can be oxidized back to pentavalent

Figure 71-9 Metabolism of arsenic. AS3MT, arsenite methyltransferase; DMA^V, dimethylarsinic acid; GSH, reduced glutathione; GSSG, oxidized glutathione; MMA^{III}, monomethylarsonous acid; MMA^V, monomethylarsonic acid; SAH, S-adenosyl-L-homocysteine; SAM, S-adenosyl-L-methionine.

compounds, but there is no evidence for demethylation of methylated arsenicals. Humans excrete much higher levels of MMA compounds than most other animals (ATSDR, 2007a). Because the pentavalent methylated arsenic compounds have greatly reduced toxicity, the methylation pathway was long thought to be a detoxification pathway. However, the trivalent methylated arsenicals actually are more toxic than inorganic arsenite due to an increased affinity for sulfhydryl groups, and formation of MMA^{III} now is considered a bioactivation pathway (Aposhian and Aposhian, 2006).

Elimination of arsenicals by humans primarily is in the urine, although some is also excreted in feces, sweat, hair, nails, skin, and exhaled air. Compared to most other toxic metals, arsenic is excreted quickly, with a $t_{1/2}$ of 1–3 days. In humans, ingested inorganic arsenic that appears in urine is a mixture of 10%–30% inorganic arsenicals, 10%–20% monomethylated forms, and 60%–80% dimethylated forms.

Health Effects

With the exception of arsine gas, the various forms of inorganic arsenic exhibit similar toxic effects. Inorganic arsenic exhibits a broad range of toxicities and has been associated with effects on every organ system tested (ATSDR, 2007a). Humans also are exposed to large organic arsenic compounds in fish, which are relatively nontoxic. Humans are the most sensitive species to the toxic effects of inorganic arsenic. Acute exposure to large doses of arsenic (>70–180 mg) often is fatal. Death immediately following arsenic poisoning typically is the result of its effects on the heart and GI tract. Death sometimes occurs later as a result of arsenic's combined effect on multiple organs.

Cardiovascular System. Acute and chronic arsenic exposure cause myocardial depolarization, cardiac arrhythmias, and ischemic heart disease; these are known side effects of arsenic trioxide for the treatment for leukemia. Chronic exposure to arsenic can cause peripheral vascular disease, the most dramatic example of which is “blackfoot disease,” a condition characterized by cyanosis of the extremities, particularly the feet, progressing to gangrene. Blackfoot disease is endemic in regions of Taiwan, where well water contains arsenic at levels of 170 to 800 µg/L. Arsenic dilates capillaries and increases their permeability; this causes edema after acute exposures and is likely responsible for peripheral vascular disease following chronic exposure.

Skin. Dermal symptoms often are diagnostic of arsenic exposure. Arsenic induces hyperkeratinization of the skin (including formation of multiple corns or warts), particularly of the palms of the hands and the soles of the feet. It also causes areas of hyperpigmentation interspersed with spots of hypopigmentation. These symptoms can be observed in individuals exposed to drinking water with arsenic concentrations of at least 100 µg/L and are typical in those chronically exposed to much higher levels. Hyperpigmentation can be observed after 6 months of exposure; hyperkeratinization takes years. Children are more likely to develop these effects than adults (ATSDR, 2007a; Mead, 2005).

Gastrointestinal Tract. Acute or subacute ingestion of high-dose arsenic is associated with GI symptoms ranging from mild cramping, diarrhea, and vomiting to GI hemorrhaging and death. GI symptoms are caused by increased capillary permeability, leading to fluid loss. At higher doses, fluid forms vesicles that can burst, leading to inflammation and necrosis of the submucosa and then rupture of the intestinal wall. GI symptoms are not observed with chronic exposure to lower levels of arsenic.

Nervous System. The most common neurological effect of acute or subacute arsenic exposure is peripheral neuropathy involving both sensory

and motor neurons. This effect is characterized by the loss of sensation in the hands and feet, often followed by muscle weakness. Neuropathy occurs several days after exposure and can be reversible following cessation of exposure, although recovery usually is not complete. Arsenic exposure may cause intellectual deficits in children (Wasserman et al., 2007). Acute high-dose arsenic exposure causes encephalopathy in rare cases, with symptoms that can include headache, lethargy, mental confusion, hallucination, seizures, and coma.

Other Noncancer Toxicities. Acute and chronic arsenic exposures induce anemia and leukopenia, likely via direct cytotoxic effects on blood cells and suppression of erythropoiesis. Arsenic also may inhibit heme synthesis. In the liver, arsenic causes fatty infiltrations, central necrosis, and cirrhosis of varying severity. The action of arsenic on renal capillaries, tubules, and glomeruli can cause severe kidney damage. Inhaled arsenic is irritating to the lungs, and ingested arsenic may induce bronchitis progressing to bronchopneumonia in some individuals. Chronic exposure to arsenic is associated with an increased risk of diabetes.

Carcinogenesis. Regions with very high arsenic levels in drinking water consistently have substantially higher rates of skin cancer, bladder cancer, and lung cancer. There also are associations between arsenic exposure and other cancers, including liver, kidney, and prostate tumors. Inhalation exposure to arsenic in occupational settings causes lung cancer. IARC classifies arsenic as “carcinogenic to humans (Group 1).”

The developing fetus and young children may be at increased risk of arsenic carcinogenesis because humans exposed to arsenic in utero and in early childhood have a greatly elevated risk of lung cancer (Smith et al., 2006). Studies in rodents also have observed increased cancer risks from in utero exposure and suggest that the second trimester of pregnancy represents a critical susceptibility window (Waalkes et al., 2007).

Arsenic does not directly damage DNA; rather, arsenic is thought to work through changes in gene expression, DNA methylation, inhibition of DNA repair, generation of oxidative stress, or altered signal transduction pathways (Hartwig et al., 2002; Salnikow and Zhitkovich, 2008). Arsenic compounds can act as tumor promoters or cocarcinogens in rodents, particularly when combined with ultraviolet light. In humans, exposure to arsenic potentiates lung tumorigenesis from tobacco smoke. Smokers in regions with high concentrations of arsenic in the drinking water have a 5-fold increased risk of cancer over smokers living in low-arsenic regions (Ferrecio et al., 2000). Arsenic cocarcinogenesis may involve inhibition of proteins involved in nucleotide excision repair (Hartwig et al., 2002; Salnikow and Zhitkovich, 2008). Arsenic also has endocrine-disrupting activities on several nuclear steroid hormone receptors, enhancing hormone-dependent transcription at very low concentrations and inhibiting it at slightly higher levels.

Arsine Gas

Arsine gas, formed by reduction of arsenic in an industrial setting, is a rare cause of poisonings. Arsine induces rapid and often-fatal hemolysis, which probably results from arsine combining with hemoglobin and reacting with O₂. A few hours after exposure, patients can develop headache, anorexia, vomiting, paresthesia, abdominal pain, chills, hemoglobinuria, bilirubinemia, and anuria. Jaundice appears after 24 h. Arsine induces renal toxicities that can progress to kidney failure. Approximately 25% of cases of arsine exposure result in death.

Treatment

Following acute exposure to all forms of arsenic, the patient should be stabilized and further absorption of the poison should be prevented.

1310 Close monitoring of fluid levels is important because arsenic can cause fatal hypovolemic shock. Chelation therapy is effective following short-term exposure to arsenic but has little or no benefit in chronically exposed individuals. Exchange transfusion to restore blood cells and remove arsenic is often warranted following arsine gas exposure (Ibrahim et al., 2006).

Cadmium

Cadmium was discovered in 1817 and first used industrially in the mid-20th century. Cadmium is resistant to corrosion and exhibits useful electrochemical properties, which has led to its use in electroplating, galvanization, plastics, paint pigments, and nickel-cadmium batteries.

Exposure

In the general population, the primary source of exposure to cadmium is through food, with an estimated average daily intake of 50 µg. Cadmium also is found in tobacco and tobacco smoke; a cigarette contains 1–2 µg of cadmium (Jarup and Akesson, 2009). Workers in smelters and other metal-processing industries can be exposed to high levels of cadmium, particularly by inhalation.

Chemistry and Mode of Action

Cadmium exists as a divalent cation and does not undergo oxidation-reduction reactions. There are no covalent organometallic complexes of cadmium of toxicological significance. The mechanism of cadmium toxicity is not fully understood. Like lead and other divalent metals, cadmium can replace zinc in zinc-finger domains of proteins and disrupt them. Through an unknown mechanism, cadmium induces formation of ROS, resulting in lipid peroxidation and GSH depletion. Cadmium also upregulates inflammatory cytokines and may disrupt the beneficial effects of NO.

ADME

Cadmium is not well absorbed from the GI tract (1.5%–5%) but is absorbed via inhalation (~10%). Cadmium primarily distributes first to the liver and later the kidney, which together account for 50% of the absorbed dose. Cadmium distributes fairly evenly to other tissues but does not cross the blood-brain barrier or the placenta. Cadmium primarily is excreted in the urine and exhibits a $t_{1/2}$ of 10–30 years (ATSDR, 2012b).

Health Effects

Toxicity. Acute cadmium toxicity is due to local irritation along the absorption route. Inhaled cadmium causes respiratory tract irritation with severe, early pneumonitis accompanied by chest pains, nausea, dizziness, and diarrhea. Toxicity may progress to fatal pulmonary edema. Ingested cadmium induces nausea, vomiting, salivation, diarrhea, and abdominal cramps; the vomitus and diarrhea often are bloody.

Symptoms of chronic cadmium toxicity vary by exposure route. The lung is an important target of inhaled cadmium, while the kidney is a major target of cadmium from both inhalation and ingestion.

Cadmium bound to metallothionein is transported to the kidney, where it can be released. Renal toxicity results from increased excretion of low-molecular-weight proteins, especially β_2 microglobulin and retinol-binding protein. Cadmium also causes glomerular injury, with a resulting decrease in filtration. Chronic occupational exposure to cadmium is associated with an increased risk of renal failure and death. There is no evidence for a threshold level for cadmium's effects on the kidney; cadmium levels consistent with normal dietary exposure can cause renal toxicity, including a reduction in glomerular filtration rate and creatinine clearance (Jarup and Akesson, 2009).

Workers with long-term inhalation exposure to cadmium exhibit decreased lung function. Symptoms include bronchitis and fibrosis of the lung, leading to emphysema. The exact cause of cadmium-induced lung toxicity is not known but may result from inhibition of the synthesis of α_1 antitrypsin. Chronic obstructive pulmonary disease causes increased mortality in cadmium-exposed workers.

When accompanied by vitamin D deficiency, cadmium exposure increases the risks for fractures and osteoporosis. This may be an effect of cadmium interfering with calcium and phosphate homeostasis due to its renal toxicity.

Carcinogenicity. Chronic occupational exposure to inhaled cadmium increases the risk of developing lung cancer (IARC, 1993; NTP, 2004). The mechanism of cadmium carcinogenesis is not fully understood. Cadmium causes chromosomal aberrations in exposed workers and treated animals and human cells. It also increases mutations and impairs DNA repair in human cells (NTP, 2004). Cadmium substitutes for zinc in DNA repair proteins and polymerases and may inhibit nucleotide excision repair, base excision repair, and the DNA polymerase responsible for repairing single-strand breaks (Hartwig et al., 2002). There is evidence that cadmium also alters cell signaling pathways and disrupts cellular controls of proliferation (Waisberg et al., 2003). Thus, cadmium acts as a nongenotoxic carcinogen.

Treatment

Treatment for cadmium poisoning is symptomatic. Patients who have inhaled cadmium may require respiratory support. Patients with kidney failure as a result of cadmium poisoning may require a transplant. There is no evidence for clinical benefit from chelation therapy following cadmium poisoning, and chelation therapy may result in adverse effects (ATSDR, 2012b).

Chromium

Chromium is an industrially important metal used in a number of alloys, particularly stainless steel, which contains at least 11% chromium. Chromium can be oxidized to multiple valence states, with trivalent (Cr^{III}) and hexavalent (Cr^{VI}) being the two forms of biological importance. Chromium exists almost exclusively as the trivalent form in nature, and Cr^{III} is an essential metal involved in the regulation of glucose metabolism. Cr^{VI} is thought to be responsible for the toxic effects of chromium (ATSDR, 2012a).

Exposure

Exposure to chromium in the general population primarily is through the ingestion of food, although there also is exposure from drinking water and air. Workers are exposed to chromium during chromate production, stainless steel production and welding, chromium plating, ferrochrome alloy and chrome pigment production, and in tanning industries. Exposure usually is to a mixture of Cr^{III} and Cr^{VI} .

Chemistry and Mode of Action

Chromium occurs in its metallic state or in any valence state between divalent and hexavalent. Cr^{III} is the most stable and common form. Cr^{VI} is corrosive and is readily reduced to lower valence states. The primary reason for the different toxicological properties of Cr^{III} and Cr^{VI} is thought to be differences in their absorption and distribution. Hexavalent chromate resembles sulfate and phosphate and can be taken across membranes by anion transporters. Once inside the cell, Cr^{VI} undergoes a series of reduction steps, ultimately forming Cr^{III} , which is thought to cause most of the toxic effects. Trivalent chromium readily forms covalent interactions with DNA. Hexavalent chromium also induces oxidative stress and hypersensitivity reactions.

ADME

Absorption of inhaled chromium depends on its solubility, valence state, and particle size. Smaller particles are deposited deeper in the lungs. Absorption into the bloodstream of hexavalent and soluble forms is higher than the trivalent or insoluble forms, with the remainder often retained in the lungs. Approximately 50%–85% of inhaled Cr^{VI} particles (<5 µm) are absorbed. Absorption of ingested chromium is less than 10% and varies depending on water solubility. Cr^{VI} crosses membranes by facilitated transport, while Cr^{III} crosses by diffusion. Cr^{VI} is distributed to all of the tissues and crosses the placenta. The highest levels are attained in the liver, kidney, and bone; Cr^{VI} is also retained in erythrocytes. Excretion primarily is through urine, with small amounts also excreted in bile and breast milk and deposited in hair and nails. The $t_{1/2}$ of ingested Cr^{VI} is about 40 h; the $t_{1/2}$ of Cr^{III} is about 10 h (ATSDR, 2012a).

Health Effects

Toxicity. Acute exposure to very high doses of chromium causes death via damage to multiple organs, particularly the kidney. Chronic low-dose

chromium exposure causes toxicity at the site of contact. Workers exposed to inhaled chromium develop symptoms of lung and upper respiratory tract irritation, decreased pulmonary function, and pneumonia. Chronic exposure to chromium via ingestion, including after mucociliary clearance of inhaled particles, causes symptoms of GI irritation (oral ulcer, diarrhea, abdominal pain, indigestion, and vomiting). Cr^{VI} is a dermal irritant and can cause ulceration or burns. Low-dose exposure by any route causes some individuals to become sensitized. These individuals will develop allergic dermatitis following dermal exposure to chromium, including products containing metallic chromium. Chromium-sensitized workers often also develop asthma following inhalation exposure (ATSDR, 2012a).

Carcinogenicity. The Cr^{VI} compounds are group 1 known human carcinogens (IARC, 1990). There is insufficient evidence for carcinogenesis from metallic and trivalent chromium (classified in IARC group 3). Workers exposed to Cr^{VI} via inhalation have elevated incidence of and mortality from lung and nasal cancer. Environmental exposure to Cr^{VI} in drinking water increases the risk of developing stomach cancer.

There are multiple potential mechanisms for chromium carcinogenicity (Salnikow and Zhitkovich, 2008). Reduction of Cr^{VI} to Cr^{III} occurs with concomitant oxidation of cellular molecules. Ascorbate is the primary reductant, but other molecules, including GSH, lipids, proteins, and DNA, also can be oxidized. Cr^{III} forms a large number of covalent DNA adducts, primarily at the phosphate diester backbone. The DNA adducts are not very mutagenic and are repaired by nucleotide excision repair. It is thought that the high level of nucleotide excision repair activity following chromium exposure contributes to carcinogenesis, either by preventing repair of mutagenic lesions formed by other carcinogens or through the formation of single-strand breaks due to incomplete repair. Chromium also forms cross-links between DNA and protein. Chronic inflammation due to chromium-induced irritation also may promote tumor formation.

Treatment

There are no standard protocols for treatment for acute chromium poisoning. One approach that has shown promise in rodents is the use of reductants such as ascorbate, GSH, or *N*-acetylcysteine to reduce Cr^{VI} to Cr^{III} after exposure but before absorption to limit bioavailability (ATSDR, 2012a). These compounds and EDTA also increase urinary excretion of chromium after high-dose exposure, particularly if given soon enough to prevent uptake into cells. Exchange transfusion to remove chromium from plasma and erythrocytes may be beneficial.

Treatment for Metal Exposure

The most important response to environmental or occupational exposures to metals is to eliminate the source of the exposure. It also is important to stabilize the patient and provide symptomatic treatment.

Treatment for acute metal intoxications often involves the use of chelators. A chelator is a compound that forms stable complexes with metals, typically as five- or six-membered rings. Formation of complexes between chelators and metals should prevent or reverse metal binding to biological ligands. The ideal chelator should be highly soluble in water, be resistant to biotransformation, reach sites of metal storage, form stable and nontoxic complexes with toxic metals, and be readily excreted as a metal-chelator complex. A low affinity for the essential metals calcium and zinc also is desirable because toxic metals often compete with these metals for protein binding.

In cases of acute exposure to high doses of most metals, chelation therapy reduces toxicity. However, following chronic exposure, chelation therapy does not show clinical benefits beyond those of cessation of exposure alone and, in some cases, does more harm than good. Chelation therapy may increase the neurotoxic effects of heavy metals and is only recommended for acute poisonings. The structures of the most commonly used chelators are shown in Figure 71–10.

Ethylenediaminetetraacetic Acid

EDTA and its various salts are effective chelators of divalent and trivalent metals. CaNa_2EDTA is the preferred EDTA salt for metal poisoning, provided that the metal has a higher affinity for EDTA than

Figure 71–10 Structures of chelators commonly used to treat acute metal intoxication.

calcium. CaNa_2EDTA is effective for the treatment of acute lead poisoning, particularly in combination with dimercaprol, but is not an effective chelator of mercury or arsenic in vivo.

Chemistry and Mode of Action

The pharmacological effects of CaNa_2EDTA result from chelation of divalent and trivalent metals in the body. Accessible metal ions with a higher affinity for CaNa_2EDTA than Ca^{2+} will be chelated, mobilized, and usually excreted. Because EDTA is charged at physiological pH, it does not significantly penetrate cells. CaNa_2EDTA mobilizes several endogenous metallic cations, including zinc, manganese, and iron. Additional supplementation with zinc following chelation therapy may be beneficial. The most common therapeutic use of CaNa_2EDTA is for acute lead intoxication. CaNa_2EDTA does not provide clinical benefits for the treatment of chronic lead poisoning.

CaNa_2EDTA is available as edetate calcium disodium (Calcium Disodium Versenate). Intramuscular administration of CaNa_2EDTA results in good absorption, but pain occurs at the injection site; consequently, the chelator injection often is mixed with a local anesthetic or administered intravenously. For intravenous use, CaNa_2EDTA is diluted in either 5% dextrose or 0.9% saline and is administered slowly by intravenous drip. A dilute solution is necessary to avoid thrombophlebitis.

ADME

Less than 5% of CaNa_2EDTA is absorbed from the GI tract. After intravenous administration, CaNa_2EDTA has a $t_{1/2}$ of 20–60 min. In blood, CaNa_2EDTA is found only in the plasma. CaNa_2EDTA is excreted in the urine by glomerular filtration, so adequate renal function is necessary for successful therapy. Altering either the pH or the rate of urine flow has no effect on the rate of excretion. There is very little metabolic degradation of EDTA. The drug is distributed mainly in the extracellular fluids; little gains access to the spinal fluid (5% of the plasma concentration).

Toxicity

The principal toxic effect of CaNa_2EDTA is on the kidney. Repeated large doses of the drug can eventually cause degeneration of proximal tubular cells. The early renal effects usually are reversible, and urinary abnormalities disappear rapidly with cessation of treatment. The most likely mechanism of toxicity is chelation of essential metals, particularly zinc, in proximal tubular cells. To minimize nephrotoxicity, adequate urine

1312 production should be established prior to and during treatment with CaNa_2EDTA . For patients with lead encephalopathy and cerebral edema, CaNa_2EDTA can lead to a potentially fatal increase in intracranial pressure following intravenous administration. Intramuscular administration is preferred for these patients.

Rapid intravenous administration of a form lacking calcium, such as Na_2EDTA , causes hypocalcemic tetany. However, a slow infusion ($<15\text{ mg/min}$) administered to a normal individual elicits no symptoms of hypocalcemia because of the availability of extracirculatory stores of Ca^{2+} . In contrast, CaNa_2EDTA can be administered intravenously with no untoward effects because the change in the concentration of Ca^{2+} in the plasma and total body is negligible.

Other side effects associated with CaNa_2EDTA include malaise, fatigue, and excessive thirst, followed by the sudden appearance of chills and fever and subsequent myalgia, frontal headache, anorexia, occasional nausea and vomiting, and rarely, increased urinary frequency and urgency. CaNa_2EDTA is teratogenic in laboratory animals, probably as a result of zinc depletion; it should be used in pregnant women only under conditions in which the benefits clearly outweigh the risks (Kalia and Flora, 2005). Other possible effects include sneezing, nasal congestion, and lacrimation; glycosuria; anemia; dermatitis with lesions strikingly similar to those of vitamin B_6 deficiency; transitory lowering of systolic and diastolic blood pressures; prolonged prothrombin time; and T-wave inversion on the electrocardiogram.

Dimercaprol

Dimercaprol was developed during World War II as an antidote to lewisite, a vesicant arsenical war gas, hence its alternative name, British anti-Lewisite (BAL). Arsenicals and other heavy metals form a stable and relatively nontoxic chelate ring with dimercaprol.

Chemistry and Mode of Action

The pharmacological actions of dimercaprol result from formation of chelation complexes between its sulfhydryl groups and metals. Dissociation of dimercaprol-metal complexes and oxidation of dimercaprol occur in vivo. The sulfur-metal bond may be labile in the acidic tubular urine, which may increase the delivery of metal to renal tissue and increase toxicity. The dosage regimen should maintain a concentration of dimercaprol in plasma adequate to favor the continuous formation of the more stable 2:1 (BAL-metal) complex. However, because of pronounced and dose-related side effects, excessive plasma concentrations must be avoided. The concentration in plasma therefore must be maintained by repeated dosage until the metal is excreted. Dimercaprol is most beneficial when given very soon after exposure to the metal because it is more effective in preventing inhibition of sulfhydryl enzymes than in reactivating them. Dimercaprol limits toxicity from arsenic, gold, and mercury, which form mercaptides with essential cellular sulfhydryl groups. It also is used in combination with CaNa_2EDTA to treat lead poisoning. Dimercaprol should not be used in iron, cadmium, or selenium poisoning because the resulting metal complexes are more toxic than the metal alone, especially to the kidneys.

ADME

Dimercaprol is given by deep intramuscular injection as a 100-mg/mL solution in peanut oil and should not be used in patients who are allergic to peanuts. Peak dimercaprol concentrations in blood are attained in 30–60 min. The $t_{1/2}$ is short, and metabolic degradation and excretion essentially are complete within 4 h. Dimercaprol and its chelates are excreted in both urine and bile. Dimercaprol is contraindicated for use following chronic exposures to heavy metals because it does not prevent neurotoxic effects. There is evidence in laboratory animals that dimercaprol mobilizes lead and mercury from various tissues to the brain (Andersen and Aaseth, 2002). This effect may be due to the lipophilic nature of dimercaprol and is not observed with its more hydrophilic analogues described further in the chapter (see Succimer and Sodium 2,3-Dimercaptopropane-1-sulfonate).

Toxicity

Side effects occur in about 50% of subjects receiving 5 mg/kg intramuscularly. Dimercaprol causes a rise in systolic and diastolic arterial pressures,

accompanied by tachycardia. The pressure rises immediately but returns to normal within 2 h. Dimercaprol also can cause anxiety and unrest, nausea and vomiting, headache, a burning sensation in the mouth and throat, a feeling of constriction or pain in the throat and chest, conjunctivitis, blepharospasm, lacrimation, rhinorrhea, salivation, tingling of the hands, a burning sensation in the penis, sweating, abdominal pain, and the occasional appearance of painful sterile abscesses at the injection site. The dimercaprol-metal complex breaks down easily in an acidic medium; production of alkaline urine protects the kidney during therapy. Children react similarly to adults, although about 30% also may experience a fever that disappears on drug withdrawal. Dimercaprol is contraindicated in patients with hepatic insufficiency, except when this condition is a result of arsenic poisoning.

Succimer

Succimer (2,3-dimercaptosuccinic acid [DMSA]) has been approved in the U.S. for treatment of children with BLL greater than 45 $\mu\text{g/dL}$. Because of its oral availability, improved toxicity profile, and selective chelation of heavy metals, succimer also is used off label for the treatment of adults with lead poisoning and for the treatment for arsenic and mercury intoxication, although no large clinical trials have been undertaken for these indications.

Chemistry and Mode of Action

Succimer is an orally effective chelator that is chemically similar to dimercaprol but contains two carboxylic acids that modify the spectrum of absorption, distribution, and chelation of the drug. It has an improved toxicity profile over dimercaprol.

ADME

After absorption, succimer is biotransformed to a mixed disulfide with cysteine (Aposhian and Aposhian, 2006). Succimer lowers BLL and attenuates lead toxicity. The succimer-lead chelate is eliminated in both urine and bile. The fraction eliminated in bile can undergo enterohepatic circulation.

Succimer has several desirable features over other chelators. It is orally bioavailable, and because of its hydrophilic nature, it does not mobilize metals to the brain or enter cells. It also does not significantly chelate essential metals such as zinc, copper, or iron. As a result of these properties, succimer exhibits a much better toxicity profile relative to other chelators. Animal studies suggest that succimer also is effective as a chelator of arsenic, cadmium, mercury, and other toxic metals (Andersen and Aaseth, 2002; Kalia and Flora, 2005).

Toxicity

Succimer is much less toxic than dimercaprol. The most commonly reported adverse effects are nausea, vomiting, diarrhea, and loss of appetite. In a few patients, rashes necessitate discontinuation of therapy. Transient elevations in hepatic transaminases have been observed with succimer treatment.

Sodium 2,3-Dimercaptopropane-1-sulfonate

Another dimercapto compound, DMPS, is used for the chelation of heavy metals. DMPS is not approved by the FDA but is approved for use in Germany. DMPS is available from compounding pharmacies and is used by some doctors in the U.S.

Chemistry and Mode of Action

DMPS is a clinically effective chelator of lead, arsenic, and especially mercury. It is orally available and is rapidly excreted, primarily through the kidneys. It is negatively charged and exhibits distribution properties similar to those of succimer. DMPS is less toxic than dimercaprol but mobilizes zinc and copper and thus is more toxic than succimer. In a small clinical trial, DMPS exhibited some clinical benefit for the treatment for chronic arsenic poisoning (Kalia and Flora, 2005), but more thorough clinical studies are needed.

Penicillamine; Trientine

Penicillamine is an effective chelator of copper, mercury, zinc, and lead and promotes the excretion of these metals in the urine. Penicillamine

is indicated for use in patients with Wilson disease (excess body burden of copper due to diminished excretion) and is used in other heavy metal intoxications. Penicillamine is more toxic and is less potent and selective for chelation of heavy metals relative to other available chelation drugs. It is therefore not a first-line treatment for acute intoxication with lead, mercury, or arsenic. However, because it is inexpensive and orally bioavailable, it often is given at fairly low doses following treatment with CaNa_2EDTA or dimercaprol to ensure that the concentration of metal in the blood stays low following the patient's release from the hospital.

ADME

Penicillamine is well absorbed (40%–70%) from the GI tract. Food, antacids, and iron reduce its absorption. Peak concentrations in blood are obtained 1–3 h after administration. Penicillamine is relatively stable in vivo compared to its unmethylated parent compound cysteine. Hepatic biotransformation is responsible for degradation of penicillamine; very little drug is excreted unchanged. Metabolites are found in both urine and feces. *N*-Acetylpenicillamine is more effective than penicillamine in protecting against the toxic effects of mercury, presumably because it is more resistant to metabolism.

Therapeutic Use

Penicillamine is available for oral administration. For chelation therapy, the usual adult dose is 1–1.5 g/d in four divided doses, given on an empty stomach to avoid interference by metals in food. Penicillamine is used in Wilson disease, cystinuria, and rheumatoid arthritis (rarely). For the treatment for Wilson's disease, 1–2 g/d usually is administered in four divided doses. The urinary excretion of copper should be monitored to determine whether the dosage of penicillamine is adequate.

Toxicity

Penicillamine induces cutaneous lesions, including urticaria, macular or papular reactions, pemphigoid lesions, lupus erythematosus, and dermatomyositis. It also causes dryness and scaling. Cross-reactivity with penicillin may be responsible for some episodes of urticarial or maculopapular reactions with generalized edema, pruritus, and fever that occur in as many as one-third of patients taking penicillamine. Hematological reactions may be fatal and include leukopenia, aplastic anemia, and agranulocytosis. Renal toxicity induced by penicillamine usually is manifested as reversible proteinuria and hematuria, but it may progress to nephrotic syndrome with membranous glomerulopathy. Rare fatalities have been reported from Goodpasture syndrome. Severe dyspnea, although uncommon, has been reported from penicillamine-induced bronchoalveolitis. Myasthenia gravis also has been induced by long-term therapy with penicillamine. A specific schedule for physical and laboratory monitoring for skin, blood, kidney, lung, liver, and other toxicities is published in the manufacturer's product labeling.

Penicillamine is a teratogen in laboratory animals, but for pregnant women with Wilson disease, the benefits outweigh the risks. Less serious side effects include nausea, vomiting, diarrhea, dyspepsia, anorexia, and a transient loss of taste for sweet and salt, which is relieved by supplementation of the diet with copper. Contraindications to penicillamine therapy include pregnancy in the absence of Wilson disease, renal insufficiency, or a previous history of penicillamine-induced agranulocytosis or aplastic anemia. Penicillamine increases the requirement for pyridoxime; supplementation with 25 mg daily is advised.

Trientine

Trientine (triethylenetetramine dihydrochloride) is an acceptable alternative for patients with Wilson disease who are intolerant of penicillamine. Trientine is effective orally. Maximal daily doses of 2 g for adults or 1.5 g for children are taken in two to four divided portions on an empty stomach. Iron deficiency may occur during trientine therapy; this can be overcome with short courses of iron therapy, but iron and trientine should not be ingested within 2 h of each other.

Deferoxamine; Deferasirox; Deferiprone

Chemistry and Mode of Action

Deferoxamine is isolated as the iron chelate from *Streptomyces pilosus* and is treated chemically to obtain the metal-free ligand. Deferoxamine (deferoxamine mesylate, Desferal) has a remarkably high affinity for ferric iron ($K_a = 10^{31} \text{ M}^{-1}$) coupled with a very low affinity for calcium ($K_a = 10^2 \text{ M}^{-1}$). In vitro, it removes iron from hemosiderin and ferritin and, to a lesser extent, from transferrin. Iron in hemoglobin or cytochromes is not removed by deferoxamine.

ADME and Therapeutic Use

Deferoxamine is poorly absorbed after oral administration, and parenteral (intravenous, intramuscular, or subcutaneous) administration is required. For acute iron toxicity, intramuscular administration is preferred, except for patients in cardiovascular collapse or shock. For patients in shock, the drug is administered intravenously at 10–15 mg/kg/h by constant infusion for the first 1000 mg. If additional treatment is needed beyond 1000 mg, it should be administered at a rate not to exceed 125 mg/h. Faster rates of infusion usually are associated with hypotension. For acute iron poisoning without cardiovascular collapse or shock, deferoxamine should be given intramuscularly at a dose of 50 mg/kg with a maximum dose of 1 g. Subsequent doses of 500 mg may be given, if needed, every 4–12 h. Hypotension also can occur with the intramuscular route. For chronic iron intoxication (e.g., thalassemia), subcutaneous administration is recommended. Continuous subcutaneous administration should be given to achieve a dose of 1–2 g/d. The duration of the infusion (8–24 h) should be individualized to the patient. Poorly compliant patients with thalassemia can be given deferoxamine by slow intravenous infusion (rate not to exceed 15 mg/kg/h) prior to or after receiving transfusion. Deferoxamine may also be administered via an intramuscular dose of 0.5–1.0 g/d. Deferoxamine is not recommended in primary hemochromatosis; phlebotomy is the treatment of choice. Off label, deferoxamine has also been used for the chelation of aluminum in dialysis patients.

Deferoxamine is metabolized to unknown products by plasma enzymes. The parent drug and its metabolites are readily excreted in the urine.

Toxicity

Deferoxamine can cause a number of allergic reactions, including pruritus, wheals, rash, and anaphylaxis. Other adverse effects include dysuria, abdominal discomfort, diarrhea, fever, leg cramps, and tachycardia. Occasional cases of cataract formation have been reported. Deferoxamine may cause neurotoxicity during long-term, high-dose therapy for transfusion-dependent thalassemia major; both visual and auditory changes have been described. A “pulmonary syndrome” has been associated with high-dose (10- to 25-mg/kg/h) deferoxamine therapy; tachypnea, hypoxemia, fever, and eosinophilia are prominent symptoms. Contraindications to the use of deferoxamine include renal insufficiency and anuria; during pregnancy, the drug should be used only if clearly indicated.

Deferasirox; Deferiprone

Deferasirox and deferiprone are oral chelators that are FDA approved to treat chronic iron overload in patients receiving transfusions. Deferasirox is also indicated for the treatment for chronic iron overload in nontransfusion-dependent thalassemia syndromes. Because of their oral availability, these drugs may allow for better compliance rates for patients with thalassemia. Both drugs form an uncharged chelate with iron and appear to be more effective than deferoxamine at reducing cardiac iron. However, both carry black-box warnings (deferasirox for renal failure, hepatic failure, GI hemorrhage; deferiprone for agranulocytosis, neutropenia), and there are currently insufficient data to recommend replacing deferoxamine as the first-line treatment for chronic iron overload.

ELECTRONIC PRESCRIBING

ELIMINATING ERRORS IN DRUG ORDERS

Latin Not Spoken Here

In writing prescriptions, use English (in the U.S.) or the dominant language of the patient. Latin is no longer the international language of medicine, but a number of commonly used abbreviations derive from obsolete Latin usage and persist in prescription writing. Avoid using them. Non utuntur Latini.

Some Latin seems firmly embedded in pharmacy practice. “Rx” is said to be an abbreviation for the Latin word *recipere*, meaning “take” or “take thus,” as a direction to a pharmacist, preceding the physician’s “recipe” for preparing a medication. The abbreviation “Sig” for the Latin *Signatura*, is used on the prescription to mark the directions for administration of the medication.

Who Can Prescribe Medicines?

Prescription writing in the U.S. is regulated by state boards of pharmacy. In many states, healthcare practitioners other than MD and DO physicians can write prescriptions, although in some cases narcotics are excluded. Licensed dentists, podiatrists, PAs, nurse practitioners, pharmacists, and clinical psychologists can prescribe medications under various circumstances.

Current Practice

The prescription consists of the *superscription*, the *inscription*, the *subscription*, the *signa*, and the *name and signature of the prescriber*, all contained on a single form (Figure AI-1). The *superscription* includes the date the prescription order is written; the name, address, weight, and age of the patient; and the Rx (*Take*). The body of the prescription, or *inscription*, contains the name and amount or strength of the drug to be dispensed or the name and strength of each ingredient to be compounded.

The *subscription* is the instruction to the pharmacist, usually consisting of a short sentence, such as “dispense 30 tablets.” The *signa* or “Sig” is the instruction for the patient regarding how to take the prescription, interpreted and transposed onto the prescription label by the pharmacist. In the U.S., prescriptions should always be written in English. Many physicians continue to use Latin abbreviations, such as, “1 cap tid pc.” This will be interpreted by the pharmacist as “take one capsule three times daily after meals.” However, the use of Latin abbreviations for these directions

only mystifies the prescription and is discouraged. The pharmacist should always write the label in English (or, as appropriate, in the language of the patient). The use of such abbreviations or symbols is a confounding practice; many serious dispensing errors can be traced to the use of abbreviations.

Avoid the instruction “take as directed.” Such directions assume an understanding on the part of the patient that may not be realized and are inadequate for the pharmacist, who must determine the intent of the physician before dispensing the medication. Including directions provides an additional measure of safety for the patient because the pharmacist can confirm the correct medication is being dispensed for the prescribed regimen. The best directions to the patient will include a reminder of the intended purpose of the medication by including such phrases as “for relief of pain” or “to relieve itching.” The correct route of administration is reinforced by the choice of the first word of the directions. For an oral dosage form, the directions should begin with *take* or *give*; for externally applied products, the word *apply*; for suppositories, *insert*; and for eye, ear, or nose drops, *place* is preferable to “instill.”

Include Patient Information and Dosage Calculations

The patient’s name and address are needed on the prescription order to ensure that the correct medication goes to the proper patient and also for identification and recordkeeping. For medications whose dosage involves a calculation, a patient’s pertinent factors, such as weight, age, or body surface area, also should be listed on the prescription; both the calculated dose and the dosage formula used, such as “240 mg every 8 h (40 mg/kg/d),” should be included to allow another healthcare professional to double check the prescribed dosage. Pharmacists always should recalculate dosage equations when filling such prescriptions. Medication orders in hospitals and some clinic settings, such as those for antibiotics or anti-seizure medications that are sometimes difficult to adequately dose (e.g., phenytoin), can specify the patient diagnosis and desired drug and request dosing by the clinical pharmacist. This is commonly done for drugs with significant adverse effect potential, such as vancomycin.

Proper Use of Prescription Pad

Prescription pad blanks normally are imprinted with a heading that gives the name of the physician and the address and phone number of the practice site (Figure AI-1). When using institutional blanks that do not bear

Abbreviations

ACE: angiotensin-converting enzyme
CAS: Chemical Abstract Service
CSA: Controlled Substances Act
DEA: Drug Enforcement Agency
DO: doctor of osteopathy
DTC: direct-to-consumer
FDA: Food and Drug Administration
IOM: Institute of Medicine
ISMP: Institute for Safe Medication Practices
MD: doctor of medicine
NDC: National Drug Code
PA: physician's assistant
RN: registry number
USAN: U.S. Adopted Name
USP: U.S. Pharmacopeia
USP MERP: U.S. Pharmacopeia Medication Errors Reporting Program
USP/NF: USP/National Formulary

the physician's information, the physician always should print his or her name and phone number on the face of the prescription to facilitate communication with other healthcare professionals should questions arise.

All prescriptions should be written in ink; this practice is compulsory for schedule II prescriptions (e.g., narcotics) under the U.S. CSA of 1970 (see Box AI-1 and Controlled Substances, further in this appendix).

The date of the prescription is an important part of the patient's medical record, and it can assist the pharmacist in recognizing potential problems. For example, when an opioid is prescribed for pain due to an injury and the prescription is presented to a pharmacist 2 weeks after issuance, the drug may no longer be indicated. When opioid treatment is to include periods longer than the period covered by the first prescription, a second

prescription may be issued with a "do not fill before" date. Compliance behavior also can be estimated using the dates when a prescription is filled and refilled (or reissued). When writing the original prescription, the physician should designate the number of refills allowed or mark none. For maintenance medications without abuse potential, it is reasonable to write for a 1-month supply and to mark the prescription form for refills to be dispensed over a period sufficient to supply the patient until the next scheduled visit to the physician. A statement such as "refill prn" (refill as needed) is not appropriate, as it could allow the patient to misuse the medicine or neglect medical appointments. If no refills are desired, *zero* (not "0") or *none* should be written in the refill space to prevent alteration of the prescriber's intent. Refills for controlled substances are discussed in Refills under Controlled Substances.

Concern about the rising cost of healthcare has favored the dispensing of so-called generic drugs. A drug is called by its generic name (in the U.S., this is the USAN) or the manufacturer's proprietary name, called the *trademark*, *trade name*, or *brand name*. In most U.S. states, pharmacists have the authority to dispense generic drugs rather than brand-name medications. The physician can request that the pharmacist not substitute a generic for a branded medication by indicating this on the prescription ("do not substitute"); this generally is unnecessary because the U.S. FDA requires that generic medications meet the same standards for safety and efficacy as their brand-name counterparts. Bioequivalence standards are a challenge to implement for newer medications such as biologics (Bate et al., 2016) but are critically needed; both brand-name drugs and generics are increasingly in short supply (Mazer-Amirshahi et al., 2014).

In some jurisdictions, prescriptions may not be filled with a generic substitution unless specifically permitted on the prescription. Occasions when substituting generic medications is discouraged are limited to products with specialized release systems and narrow therapeutic indices or when substantial patient confusion and potential noncompliance may be associated with substitution.

Choice and Amount of Drug Product Dispensed

Inappropriate choice of drugs by physicians is a problem in prescribing. Physicians must rely on unbiased sources when seeking drug information

Superscription { Inscription { Subscription {	Date: <u>April 10, 2010</u>	Aptus Medical Arts W.E. Hansen 123 Homestead Pl. Suite 2 Searchlight, NV 89046

Figure AI-1 The prescription. The prescription must be accurately and legibly prepared to identify the patient, the medication to be dispensed, and the mode of drug administration. Avoid abbreviations and Latin; they lead to dispensing errors. Include the therapeutic purpose in the subscription (e.g., "for control of blood pressure") to prevent errors in dispensing. For example, the use of losartan *for the treatment of hypertension* may require 100 mg/d (1.4 mg/kg/d), whereas *for treatment of congestive heart failure*, the dose of this angiotensin II receptor antagonist generally should not exceed 50 mg/d. Including the therapeutic purpose of the prescription also can assist patients in organizing and understanding their medications. Including the patient's weight on the prescription can be useful in avoiding dosing errors, particularly when drugs are administered to children.

BOX AI-1 ■ Controlled Substance Schedules

Schedule I (examples: heroin, methylene dioxymethamphetamine, lysergic acid diethylamide, mescaline, and all salts and isomers thereof):

1. High potential for abuse.
2. No accepted medical use in the U.S. or lacks accepted safety for use in treatment in the U.S. May be used for research purposes by properly registered individuals.

Schedule II (examples: morphine, oxycodone, fentanyl, meperidine, dextroamphetamine, cocaine, amobarbital):

1. High potential for abuse.
2. Has a currently accepted medical use in the U.S.
3. Abuse of substance may lead to severe psychological or physical dependence.

Schedule III (examples: anabolic steroids, nalorphine, ketamine, certain schedule II substances in suppositories, mixtures, or limited amounts per dosage unit):

1. Abuse potential less than substances in schedule I or schedule II.
2. Has a currently accepted medical use in the U.S.
3. Abuse of substance may lead to moderate-to-low physical dependence or high psychological dependence.

Schedule IV (examples: alprazolam, phenobarbital, meprobamate, modafinil):

1. Abuse potential less than substances in schedule III.
2. Has a currently accepted medical use in the U.S.
3. Abuse of substance may lead to limited physical or psychological dependence relative to substances in schedule III.

Schedule V (examples: buprenorphine, products containing a low dose of an opioid plus a nonnarcotic ingredient such as cough syrup with codeine^a and guaifenesin, antidiarrheal tablets with diphenoxylate and atropine):

1. Low potential for abuse relative to schedule IV.
2. Has a currently accepted medical use in the U.S.
3. Some schedule V products may be sold in limited amounts without a prescription at the discretion of the pharmacist; however, if a physician wishes a patient to receive one of these products, it is preferable to provide a prescription.

^aAlthough codeine is a schedule II drug, its dosage in cough syrups is regarded as sufficiently low to permit their classification as schedule V substances.

that will influence their prescribing habits; use of the original medical literature and online resources such as the Cochrane evidentiary reviews (<http://www.cochrane.org>) will ensure instruction of the prescriber's best judgment. The amount of a drug to be dispensed should be clearly stated and should be only that needed by the patient. Excessive amounts should never be dispensed because this not only is expensive for the patient but also may lead to accumulation of medicines, which can lead to harm to the patient or members of the patient's family if used inappropriately. *Better to require several refills of a prescription than to prescribe and dispense more than necessary at one time.*

Controlled Substances

In the U.S., the DEA within the Department of Justice is responsible for the enforcement of the federal CSA. The DEA regulates each step of the handling of controlled substances from manufacture to dispensing (21 U.S.C. § 811). The law provides a system that is intended to prevent diversion of controlled substances from legitimate uses. Substances that come under the jurisdiction of the CSA are divided into five schedules (Box AI-1); individual states may have additional schedules. Physicians must be authorized to prescribe controlled substances by the board of pharmacy in the jurisdiction in which they are licensed, and they must be

registered with the DEA or exempted from registration as defined under the CSA. The number on the certificate of registration must be indicated on all prescription orders for controlled substances. Criminal prosecution and penalties for misuse generally depend on the schedule of a substance and the amount of drug in question.

Prescribing Controlled Substances

To be valid, a prescription for a controlled substance must be issued for a *legitimate medical purpose* by an *individual practitioner* acting in the *usual course of his or her professional practice*. An order that does not meet these criteria is not considered a legitimate prescription within the meaning of the law and thus does not protect either the physician who issues it or the pharmacist who dispenses it. Most states prohibit physicians from prescribing controlled substances for themselves. *It is prudent to follow this guideline even if compliance is not mandated by law.*

Specific requirements, both state and federal, apply to prescriptions for schedule II drugs. For example, all such prescriptions must be written in ink, and refills of schedule II drugs are not allowed. Whether intended for schedule II or lesser scheduled medications, prescriptions for controlled substances must, by law, include the patient's full name and address and the practitioner's full name, address, and DEA registration number. The prescription must also include the drug name, strength, quantity, directions for use, and the number of refills, if allowed (based on the category of the drug). The CSA requires that all orders for controlled substances be dated as of, and signed on, the day issued and prohibits filling or refilling orders for substances in schedules III and IV beyond more than 6 months after their date of issuance. State agencies may impose additional regulations, such as requiring that prescriptions for controlled substances be printed on triplicate or state-issued prescription pads or restricting the use of a particular class of drugs for specific indications. All medical personnel should be familiar with the latest CDC recommendations for prescribing opioids for chronic pain (Table 20-7).

Oral Orders

Prescriptions for schedule III, IV, and V medications may be telephoned to a pharmacy by a physician in the same manner as a prescription for a noncontrolled substance, although it is in the physician's best interest to keep his or her DEA number as private as possible (see Preventing Diversion). Schedule II prescriptions may be telephoned to a pharmacy only in *emergency* situations, that is:

- Immediate administration is necessary.
- No appropriate alternative treatment is available.
- It is not reasonably possible for the physician to provide a written prescription prior to the dispensing.

For an emergency prescription, the quantity must be limited to the amount adequate to treat the patient during the emergency period, and the physician must have a written prescription delivered to the pharmacy for that emergency within 72 h. If mailed, the prescription must be postmarked within 72 h. The pharmacist must notify the DEA if this prescription is not received.

Refills

No prescription order for a schedule II drug may be refilled under any circumstance (CFR Title 21 §1306). Pre-dated original prescriptions may be used when therapy beyond the period covered by the first prescription is needed, but these are generally discouraged. For schedule III and IV drugs, refills may be issued either orally or in writing, not to exceed five refills or 6 months after the issue date, whichever comes first. Beyond this time, a new prescription must be ordered. For schedule V drugs, there are no restrictions on the number of refills allowed, but if no refills are noted at the time of issuance, a new prescription must be made for additional drug to be dispensed.

Preventing Diversion

Prescription blanks often are stolen and used to sustain abuse of controlled substances. To prevent this type of diversion, prescription pads should be

1320 protected in the same manner as one would protect a personal checkbook. A prescription blank should never be presigned for a staff member to fill in at a later time. Also, a minimum number of pads should be stocked, and they should be kept in a locked, secure location. If a pad or prescription is missing, it should be reported immediately to local authorities and pharmacies. Ideally, the physician's full DEA number should not be preprinted on the prescription pad because anyone in possession of a valid DEA number may find it easier to commit prescription fraud. Some physicians may intentionally omit part or all of their DEA number on a prescription and instead write "pharmacist call to verify" or "call for registration number." This practice works only when the pharmacist may independently verify the authenticity of the prescription, and patients must fill the prescription during the prescriber's office hours. Pharmacists can ascertain the authenticity of a physician's DEA number using an algorithm.

Another method employed by the drug seeker is to alter the face of a valid prescription to increase the number of units or refills. By spelling out the number of units and refills authorized instead of giving numerals, the prescriber essentially removes this option for diversion. Controlled substances should not be prescribed excessively or for prolonged periods, as the continuance of a patient's addiction is not a legitimate medical purpose.

Weed

Twenty-nine U.S. states and the District of Columbia have placed marijuana, classified by the FDA as a schedule I substance, in a special category by decriminalizing its possession and sale for medical use. In these jurisdictions, patients and caregivers are exempt from prosecution by state law, contrary federal law notwithstanding. Nine of these jurisdictions, AL, CA, CO, MA, ME, NV, OR, WA, and the District of Columbia—permit the possession of marijuana for recreational use. This legal difference of opinion between state and federal regulation is the source of considerable controversy (Leyton, 2016). Generally, the most stringent law takes precedence, whether it is federal, state, or local.

The Prescription as a Commodity

Prescribers must be aware that patients may visit their doctor to "get" a prescription. In many patient-physician interactions, a prescription can be seen as the currency or mandatory product of the visit. Physicians must educate each patient about the importance of viewing medicines as something to be used only when really needed, and that remaining on a particular medicine when in stable condition may be preferable to seeking the newest medications available. The federal FDA Modernization Act of 1997 permits the use of print and television advertising of prescription drugs. The law requires that all drug advertisements contain (amongst other things) summary information relating to side effects, contraindications, and effectiveness. The benefits of these types of DTC advertising are controversial (Mintzes, 2012). Prescription drug advertising has alerted consumers to the existence of new drugs and the conditions they treat, but it has also increased consumer demand for drugs. This demand has increased the number of prescriptions being dispensed (raising sales revenues) and has contributed to the higher pharmaceutical costs borne by health insurers, government, and consumers. In the face of a growing demand for particular brand-name drugs driven by advertising, physicians and pharmacists must be able to counsel patients effectively and provide them with evidence-based drug information.

The Special Case of Seniors

Seniors represent just over 14% of the population, but consume 40% of prescription drugs and 35% of all over-the-counter drugs. On average, individuals 65 to 69 years old take nearly 14 prescriptions per year; individuals aged 80 to 84 take an average of 18 prescriptions per year; 15% to 25% of drug use in seniors is considered unnecessary or otherwise inappropriate (Hwang et al., 2001). Adverse drug reactions are more common in the elderly and, together with noncompliance, are responsible for 28% of hospitalizations of the elderly, at a cost exceeding \$180 billion annually.

Each year, 32,000 seniors suffer hip fractures caused by medication-related problems (Iuga and McGuire, 2014).

Drug Standards and Classification

The U.S. Pharmacopeial Convention, Incorporated, is a nongovernmental organization that disseminates authoritative standards and information on medicines and other healthcare technologies. This organization is home to the USP, which, together with the FDA, the pharmaceutical industry, and health professions, establishes authoritative drug standards. These standards are enforceable by the FDA and governments of other countries and are recognized worldwide. Drug monographs are published in the USP/NF, the official drug standards compendia that organize drugs into categories based on pharmacological actions and therapeutic uses. The USP also provides chemical reference standards to carry out the tests specified in the USP/NF. For example, a drug to be manufactured and labeled in units must comply with the USP standard for units of that compound. Such standards are essential for agents possessing biological activity, such as insulin or antibody-based medications.

The USP also is home to the *USP Dictionary of U.S. Adopted Names (USAN) and International Drug Names*. This compendium is recognized throughout the healthcare industry as the authoritative dictionary of drugs. Entries include one or more of the following: U.S. Adopted Names, official drug names for the NF, previously used official names, International Nonproprietary Names, British Approved Names, Japanese Accepted Names, trade names, and other synonyms. In addition to names, the records in this file contain other substance information, such as CAS, RN, molecular formula, molecular weight, pharmacological or therapeutic category, drug sponsor, reference information, and structure diagram, if available. The USP maintains an electronic website that can be accessed for useful information on drug naming, classification, and standards (<http://www.usp.org>).

In the U.S., drug products also are coded under the NDC. The NDC serves as a universal product identifier for drugs used in humans. The current edition of the NDC Directory is limited to prescription drugs and a few selected over-the-counter products. Each drug product listed under the Federal Food, Drug, and Cosmetic Act is assigned a unique 10-digit, 3-segment number. This number, the NDC number, identifies the labeler/vendor, product, and package size. The labeler/vendor code is assigned by the FDA. The second segment, the product code, identifies a specific strength, dosage form, and formulation for a particular drug company. The third segment, the package code, identifies package sizes. Both the product and package codes are assigned by the manufacturer. In addition to classification of drugs by therapeutic category, drugs also are grouped by control schedule. Drug schedules in the U.S. are listed in Box AI-1 and discussed under Controlled Substances.

The FDA also categorizes drugs that may be used in pregnant women. These categories are similar to those used in other countries and provide guidance based on available science. The categories range from A to X, in increasing order of concern:

- **Pregnancy Category A:** Adequate and well-controlled studies have failed to demonstrate a risk to the fetus in the first trimester of pregnancy (and there is no evidence of risk in later trimesters). Because of the obvious nature of the risk associated with the use of medications during gestation, the FDA requires a body of high-quality data on a drug before it can be considered for Pregnancy Category A. Drugs in this category include levothyroxine and folic acid.
- **Pregnancy Category B:** Animal reproduction studies have failed to demonstrate a risk to the fetus, and there are no adequate and well-controlled studies in pregnant women, OR animal studies have shown an adverse effect, but adequate and well-controlled studies in pregnant women have failed to demonstrate a risk to the fetus in any trimester. Drugs in this category include metformin and hydrochlorothiazide and should be prescribed only as needed for maternal health.
- **Pregnancy Category C:** Animal reproduction studies have shown an adverse effect on the fetus, and there are no adequate and well-controlled

studies in humans, but potential benefits may warrant use of the drug in pregnant women despite potential risks. Drugs in this category include tramadol and gabapentin. They should be prescribed in pregnancy only when benefit clearly outweighs risk.

- **Pregnancy Category D:** There is positive evidence of human fetal risk based on adverse reaction data from investigational or marketing experience or studies in humans, but potential benefits may warrant use of the drug in pregnant women despite potential risks. Drugs in this category, such as alprazolam and clonazepam, are not recommended for use during pregnancy and should be prescribed in pregnancy only if absolutely necessary.
- **Pregnancy Category X:** Studies in animals or humans have demonstrated fetal abnormalities or there is positive evidence of human fetal risk based on adverse reaction data from investigational or marketing experience, and the risks involved in use of the drug in pregnant women clearly outweigh potential benefits. Drugs such as warfarin, methotrexate, and statins fall into this category and must not be used during pregnancy or in women likely to become pregnant.

Physicians should realize that the pregnancy categories by themselves provide little guidance for the physician treating pregnant women. Prescribers must understand the embryology, physiology, and pharmacology involved in each instance of drug use during pregnancy. For example, ACE inhibitors such as captopril cause developmental toxicity (category X), but only after the first trimester. A physician's primary responsibility remains treating the pregnant patient. However, the risks of withholding treatment to the mother because of possible risks to the fetus have to be considered as well. The practitioner should rely on medical evidence when making these decisions.

Drugs also are grouped by their potential for misuse under British and U.N. legal classifications as class A, B, or C. The classes are linked to maximum legal penalties in a descending order of severity, from A to C.

Compliance

Compliance is the extent to which the patient follows a regimen prescribed by a healthcare professional. The patient is the final and most important determinant of how successful a therapeutic regimen will be and should be engaged as an active participant who has a vested interest in its success. Whatever term is used—*compliance*, *adherence*, *therapeutic alliance*, or *concordance*—physicians must promote a collaborative interaction between doctor and patient in which each brings an expertise that helps to determine the course of therapy. The patient's quality-of-life beliefs may differ from the clinician's therapeutic goals, and the patient will have the last word every time when there is an unresolved conflict.

Hundreds of variables that may influence compliance behavior have been identified. A few of the most frequently cited are in Box AI-2, along with some suggestions for improving compliance, although none guarantees 100% compliance.

Noncompliance may be manifest in drug therapy as intentional or accidental errors in dosage or schedule, overuse, underuse, early termination of therapy, or not having a prescription filled; therapeutic failures can result (Malek and Grosset, 2015). Noncompliance always should be considered in evaluating potential causes of inconsistent or nonexistent response to therapy. The reported incidence of patient noncompliance usually is in the range of 30%–60%; the rate for long-term regimens is about 50% and can be improved by medication management (Klein et al., 2009).

The Patient-Provider Relationship

Patient satisfaction with the physician has a significant impact on compliance behavior. Patients are more likely to follow instructions and recommendations when their expectations for the patient-provider relationship and for their treatment are met. These expectations include not only clinical but also interpersonal competence; thus, cultivating good interpersonal and communication skills is essential.

BOX AI-2 ■ Suggestions for Improving Patient Compliance

- Provide respectful communication; ask how patient takes medicine.
 - Develop satisfactory, collaborative relationship between physician and patient; encourage pharmacist involvement.
 - Provide and encourage use of medication counseling.
 - Give precise, clear instructions, with most important information given first.
- Support oral instructions with easy-to-read written information.
- Simplify whenever possible.
- Use mechanical compliance aids as needed (sectioned pillboxes or trays, compliance packaging, color coding).
- Use optimal dosage form and schedule for each individual patient.
- Assess patient's literacy, language, and comprehension and modify educational counseling as needed. Be culturally aware and sensitive. To improve compliance, don't rely on patient's own knowledge of disease alone.
- Find solutions when physical or sensory disabilities are present (use nonsafety caps on bottles, use large type on labels and written material, place tape marks on syringes).
- Enlist support and assistance from family and caregivers.
- Use behavioral techniques such as goal setting, self-monitoring, cognitive restructuring, skills training, contracts, and positive reinforcement.

When deciding on a course of therapy, it can be useful to discuss a patient's habits and daily routine as well as the therapeutic options with the patient. This information may suggest cues for remembrance. A lack of information about a patient's lifestyle can lead to situations such as prescribing a medication to be taken with meals three times daily for a patient who only eats twice a day or a medication to be taken each morning for a patient who works a night shift and sleeps during the day. Rarely is there only one treatment option for a given problem, and it may be better to prescribe an adequate regimen that the patient will follow instead of an ideal regimen that the patient will not. Attempts should be made to resolve collaboratively any conflicts that may hinder compliance. Whenever possible, the family should be aware of the physician's treatment plan in order to assist with compliance.

Patients and Their Beliefs

Patients are more likely to be compliant when they *perceive* that they are susceptible to the disease, that the disease may have serious negative impact, that the therapy will be effective, that the benefits outweigh the costs, and when they believe in their own ability to execute the therapy. The *actual* severity of and susceptibility to an illness are not necessarily an issue; rather, the patient's perception of severity affects compliance. Patients' beliefs can lead them to deliberately alter their therapy, whether for convenience, for personal experiments, because of a desire to remove themselves from the sick role, as a means to exercise a feeling of control over their situation, or for other reasons. This reinforces the need for precise communication and a good patient-provider relationship to facilitate the provision of additional or corrective education when the beliefs would suggest poor compliance as an outcome (Hsiao et al., 2012; Nieuwlaet et al., 2014).

Pharmacists have a legal and professional responsibility to offer medication counseling and can educate and support patients by discussing prescribed medications and their use. Because they often see the patient more frequently than does the physician, pharmacists who take the time to inquire about a patient's therapy can help identify compliance and other problems, educate the patient, and notify the physician as appropriate (Phatak et al., 2016). Indeed, data from the Asheville Project indicates that a pharmacist-based medication management program provides significant advantages with respect to compliance, health outcomes, and cost (Bunting and Cranor, 2006).

Elderly patients often face a number of barriers to compliance related to their age: increased forgetfulness and confusion; altered drug disposition and higher sensitivity to some drug effects; decreased social and financial support; decreased dexterity, mobility, or sensory abilities; and the use of a greater number of concurrent medicines (both prescription and over the counter) whose attendant toxicities and interactions may cause decreased mental alertness or intolerable side effects. There are drugs known to be inappropriate to prescribe to elderly patients and some that may adversely affect compliance (Aparasu and Mort, 2000). Despite these obstacles, evidence does not show that elderly patients in general are significantly less compliant than any other age group. Physicians must be careful in choosing medications for the elderly. Pharmacists must pay particular attention to thorough and compassionate counseling for elderly patients and should assist patients in finding practical solutions when problems, such as polypharmacy, are noted (Mansur, 2016).

The Therapy

Increased complexity and duration of therapy are perhaps the best-documented barriers to compliance. The patient for whom multiple drugs are prescribed for a given disease or who has multiple illnesses that require drug therapy will be at higher risk for noncompliance, as will the patient whose disease is chronic. The frequency of dosing of individual medications also can affect compliance behavior. Simplification, whenever possible and appropriate, is desirable.

The effects of the medication can make adherence less likely, as in the case of patients whose medicines cause confusion or other altered mental states. Unpleasant side effects from the medicine may influence compliance in some patients, but are not necessarily predictive, especially if patient beliefs or other positive factors tend to reinforce adherence to the regimen. A side effect that is intolerable to one patient may be of minor concern to another. The cost of medicine can be a heavy burden for patients with limited economic resources, and healthcare providers should be sensitive to this fact (Restrepo et al., 2008). Mobile phones and tablets running drug formulary/therapeutic applications can provide the costs of medications, as can physicians who are familiar with the patient's insurance plan. Mobile phone systems and wearables that provide reminders and collect patient response information and physiological data are being introduced and may become more popular as patients and providers become increasingly tech savvy (Parmanto et al., 2013). Such technology may soon be capable of carrying patient genetic information that may assist the physician in choosing medications based on knowledge of a patient's ability to metabolize a specific drug efficiently or that such treatment may interfere with an existing treatment (Weiss and Shin, 2016). Effective treatments that do not produce unwanted effects will improve compliance.

Electronic Prescribing

The era of e-prescribing eliminates some of the subjective features of prescribing. Thus, if the proper information is entered correctly in the electronic system, medication errors due to illegible handwriting, incorrect dose, incorrect medication for medical condition, and drug interactions can be reduced because each prescription can be linked to high-quality drug databases that check that the information on the prescription is appropriate for the patient (e.g., age, weight, gender, condition, laboratory values, disease being treated, concurrent medications) and that known warnings and potential problems are brought to the attention of the physician, pharmacist, and patient. Such systems must not be used as a substitute for personal attention to the individual patient by healthcare workers but rather as an adjunct measure that ensures safe, high-quality, efficient care. Sadly, the participation of human beings in the process has not eliminated errors, even in the university hospital setting (Al Tehewy et al., 2016). Physicians and pharmacists must remember that only when the seriousness of their mutual responsibilities are front and center in their minds will patient safety be ensured.

BOX AI-3 ■ Prescribing Practices to Avoid Adverse Drug Events

- Write all orders legibly using metric measurements of weight and volume.
- Include patient age and weight on the prescription, when appropriate, so dosage can be checked.
- Use Arabic (decimal) numerals rather than Roman numerals (e.g., does “IL-II” mean “IL-11” or “IL-2”); in some instances, it is preferable for numerals to be spelled out.
- Use leading zeros (0.125 milligrams, not .125 milligrams); never use trailing zeros (5 milligrams, not 5.0 milligrams).
- Avoid abbreviating drug names; abbreviations may lead to misinterpretation.
- Avoid abbreviating directions for drug administration; write out directions clearly in English.
- Be aware of possibilities for confusion in drug names. Some drug names sound alike when spoken and may look alike when spelled out. The U.S. Pharmacopeial Convention Medication Errors Reporting Program maintains a current list of 750 drug names that can be confused (<http://www.usp.org>). Alliterative drug names can be particularly problematic when giving verbal orders to pharmacists or other healthcare providers.
- Provide the patient's diagnosis on the prescription order to prevent dispensing errors based on sound-alike or look-alike drug names. For example, an order for administration of magnesium sulfate must not be abbreviated “MS,” as this may result in administration of morphine sulfate. Including the therapeutic purpose or the patient's diagnosis can prevent this error.
- Write clearly. Both physician and pharmacist share in the responsibility for preventing adverse drug events by writing prescriptions clearly (*When in doubt, write it out!*) and questioning intent whenever an order is ambiguous (*When in doubt, check it out!*). *Pharmacists must clarify their concerns with prescribers, not patients.*
- Think.
- Think again.

Eliminating Errors in Drug Orders

The IOM estimates that the annual number of medical errors in the U.S. that result in death is between 44,000 and 98,000 (Kohn, 2001). Although there is some controversy about these estimates, it is clear that the large number of medical errors includes medication errors resulting in adverse events, including death. Databases of anonymously reported errors are maintained jointly by the ISMP, the USP MERP, and the FDA's MedWatch program. Adverse drug events occur in about 3% of hospitalizations, and this number is larger for special populations, such as those in pediatric and neonatal intensive care units. By examining aspects of prescription writing that can cause errors and then modifying prescribing habits accordingly, the physician can increase the probability that the patient will receive the correct prescription. By being alert to common problems that can occur with medication orders and communicating with the patient's physician, pharmacists and other healthcare professionals can assist in reducing medication errors. Proper prescribing practices (Box AI-3) can help to prevent adverse drug events.

INDIVIDUALIZATION OF DOSAGE

This appendix provides a summary of basic pharmacokinetic information pertaining to small-molecule drugs that are in common clinical use and are delivered to the systemic circulation by parenteral or nonparenteral administration. Because of space limitations, this list cannot be exhaustive. Drugs designed exclusively for topical administration and not to be significantly absorbed into the bloodstream (e.g., ophthalmic and some dermal applications; Chapters 69 and 70) are not included. A few other selection criteria have influenced the makeup of the list, but, in general, the authors have tried to include one or more representative drugs in each of the therapeutic areas in this text, based on distinct mechanism(s) of action. In some instances, drugs may be excluded because pharmacokinetics are not relevant to their therapeutic management. An obvious case is when drug efficacy is not apparently correlated with drug concentration in a reversible fashion (e.g., some cytotoxic anticancer drugs).

Often, the issue comes down to deciding which of the many drugs within a class should be selected. This is particularly problematic when the choices are largely therapeutic equivalents. Two criteria that have proven useful are prevalence of use and uniqueness of mechanism of action. For the present edition, we have consulted the top 200 selling drugs in 2015 for usage data. Drugs that fall into that list and meet the criteria mentioned were generally selected. We have also consulted all new FDA drug approvals between 2010 and 2015. As mentioned, a drug used less may be included if it has a different mechanism of action than the frequently used drugs, some additional actions that offer a unique therapeutic advantage, or a more acceptable side-effects profile. Pharmacokinetic data for many older drugs not included in this appendix can be found in earlier editions of this book.

With rare exceptions (e.g., interferons), recombinant therapeutic proteins have been excluded from this compilation. In many cases, the therapeutic protein is directed to interact with specific tissue or cellular targets with exquisite affinity; as a result, clinical efficacy seldom correlates with circulating drug concentration, and pharmacokinetics are not considered critical in guiding its dosing. For example, for a number of therapeutic antibodies, the antibody is administered at a fixed dose at prolonged intervals that allow for its near-complete clearance (e.g., infliximab). There is again the constraint of space limitation; hence, it was decided that the appendix should focus on small-molecule drugs.

A major objective of this appendix is to present pharmacokinetic data in a format that informs the clinician of the essential characteristics of drug disposition that form the basis of drug-dosage regimen design. Table AII-1 contains quantitative information about the absorption, distribution, and elimination of drugs; the effects of some disease states, age, pregnancy, and gender on these processes, where significant; and the

correlation of efficacy and toxicity with drug concentrations in blood/plasma. The general principles that underlie the design of appropriate maintenance dose and dosing interval (and, where appropriate, the loading dose) for the average patient are described in Chapter 2. Their application using the data in Table AII-1 for individualization of dosage regimens is presented here.

To use the data that are presented, one must understand clearance concepts and their application to drug-dosage regimens. One also must know average values of clearance as well as some kinetic measures of drug absorption and distribution. The text that follows defines the eight basic parameters that are listed in the tabular material for each drug and key factors that influence these values in both normal subjects and patients with renal or liver disease. It obviously would be more straightforward if there were a consensus on a standard value for a given pharmacokinetic parameter; instead, literature estimates usually vary over a wide range, and a consensus set of pharmacokinetic values has been reached for only a limited number of drugs.

In Table AII-1, a single set of values for each parameter and its variability in a relevant population has been selected from the literature, based on the scientific judgment of the authors. Most data are in the form of a study population mean value \pm 1 standard deviation (mean \pm SD). However, some data are presented as mean and range of values (in parentheses) observed for the study population (i.e., the lowest and highest value reported). There are times when data are reported as a geometric mean with a 95% confidence interval or a coefficient of variation (in percentage). If sufficient data were available, we present a range of mean values obtained from different studies of similar design in parentheses, sometimes below the primary study data. Occasionally, only a single mean value for the study population was available in the literature and is reported as such. Finally, some drugs can be administered intravenously in an unmodified form and orally as a prodrug. When relevant information about both the prodrug and the active molecule are needed, we have included both, using an abbreviation to indicate the species that was measured, followed by another abbreviation in parentheses to indicate the species that was dosed [e.g., $G(V)$ indicates a parameter for ganciclovir after administration of the prodrug, valganciclovir].

A number of approved drugs are actually the active metabolite or stereoisomer of an earlier marketed drug. For example, desloratadine is the *O*-desmethyl metabolite of loratadine, and esomeprazole is the active *S*-enantiomer of omeprazole. Unless the parent drug and the active metabolite offer distinct therapeutic advantages, only the more established or more commonly used drug is listed, and relevant information on its alternate active form is presented in the same table. This approach has

Abbreviations

AUC: area under the plasma drug concentration–time curve
CKD-EPI: Chronic Kidney Disease Epidemiology Collaboration
CPIC: Clinical Pharmacogenetics Implementation Consortium
CYP: cytochrome P450
DIDB: Drug Interaction Database Program
FDA: Food and Drug Administration
MDRD: Modification of Diet in Renal Disease
NDA: New Drug Application

permitted us to include more drugs in the appendix, it is hoped without undue confusion. The only exception is with prednisone and prednisolone, which undergo interconversion in the body.

Unless otherwise indicated in footnotes, data reported in the table are those determined in healthy adults. The direction of change for these values in particular disease states is noted below the average value. In previous editions, we have included disease states where studies have shown no change or clinically insignificant change for a particular pharmacokinetic measure. For the sake of space and consistency, we have eliminated the results of negative studies; hence, when a disease state is not listed, it implies no significant change or no information is available. One or more references are provided for each of the established drugs, typically an original journal publication, a review on its clinical pharmacokinetics, or web-based drug database; the last two secondary sources provide a broader range of papers for the interested reader. In some instances (e.g., many new drug approvals), we have relied on unpublished data provided by the drug sponsor in its NDA files or package labeling submitted to the U.S. FDA. This information can be accessed at Drugs@FDA: FDA Approved Drug Products (<https://www.accessdata.fda.gov/scripts/cder/daf/>). After searching by drug name, pharmacokinetic data are found most often in the Clinical Pharmacology and Biopharmaceutics section. Recent standardization in the presentation of data supporting the NDA in this section makes this an increasingly valuable resource.

Tabulated Pharmacokinetic Parameters

Each of the eight parameters presented in Table AII–1 was discussed in detail in Chapter 2. The following discussion focuses on the format in which the values are presented as well as on physiological or pathological factors that influence the parameters.

Bioavailability

The *extent of oral bioavailability* is expressed as a percentage of the administered dose. This value represents the percentage of the administered dose that is available to the systemic circulation—the fraction of the oral dose that reaches the arterial blood in an active or prodrug form, expressed as a percentage (0–100). *Fractional availability* F , which appears elsewhere in this appendix, denotes the same parameter; this value varies from 0 to 1. T_{\max} as a measure of the *rate of availability* is also presented in the table. The extent of availability is needed for the design of an oral dosage regimen to achieve a specific target blood concentration. Values for multiple routes of administration are provided, when appropriate and available. In most cases, the tabulated value represents an absolute oral bioavailability that has been determined from a comparison of AUC between the oral dose and an intravenous reference dose. For those drugs for which intravenous administration is not feasible, an approximate estimate of oral bioavailability based on secondary information (e.g., urinary excretion of unchanged drug, especially when the nonrenal route of elimination is minimal) is presented, or the column is left blank (denoted by a long dash [—]). A dash also will appear when a drug is given by parenteral administration only.

A low oral bioavailability may result from a poorly formulated dosage form that fails to disintegrate or dissolve in the gastrointestinal fluid;

has degradative loss of drug in the gastrointestinal fluid; has poor mucosal permeability, including active efflux transport of drug back into the lumen; has first-pass metabolism during transit through the intestinal epithelium; or there is first-pass hepatic metabolism or biliary excretion (see Chapter 2). In the case of drugs with extensive first-pass metabolism, hepatic disease may increase oral availability because hepatic metabolic capacity decreases or because vascular shunts develop around the liver.

Urinary Excretion of Unchanged Drug

The second parameter in Table AII–1 is the amount of drug eventually excreted unchanged in the urine, expressed as a percentage of the administered dose. Values represent the percentage expected in a healthy young adult (creatinine clearance ≥ 100 mL/min). When possible, the value listed is that determined after bolus intravenous administration of the drug, for which bioavailability is 100%. If the drug is given orally, this parameter may be underestimated due to incomplete absorption of the dose; such approximated values are indicated with a footnote. The parameter obtained after intravenous dosing is of greater utility because it reflects the fractional contribution of renal clearance to total body clearance irrespective of bioavailability.

Renal disease is the primary factor that causes changes in this parameter. This is especially true when alternate pathways of elimination are available; thus, as renal function decreases, a greater fraction of the dose is available for elimination by other routes. Because renal function generally decreases as a function of age, the percentage of drug excreted unchanged also decreases with age when alternate pathways of elimination are available. In addition, for a number of weakly acidic and basic drugs with pK_a values within the normal range for urine pH, changes in urine pH will affect their rate or extent of urinary excretion (see Chapter 2).

Binding to Plasma Proteins

The tabulated value is the percentage of drug in the plasma that is bound to plasma proteins at concentrations of the drug that are achieved clinically. In almost all cases, the values are from measurements performed in vitro (rather than from ex vivo measurements of binding to proteins in plasma obtained from patients to whom the drug had been administered). When a single mean value is presented, it signifies that there is no apparent change in percentage bound over the range of plasma drug concentrations resulting from the usual clinical doses. In cases in which saturation of binding to plasma proteins is approached within the therapeutic range of plasma drug concentrations, a range of bound percentages is provided for concentrations at the lower and upper limits of the range. For some drugs, there is disagreement in the literature about the extent of plasma-protein binding; in those cases, the range of reported values is given.

Plasma-protein binding is affected primarily by disease states, notably hepatic disease, renal impairment, and inflammatory diseases, that alter the concentration of albumin, α_1 -acid glycoprotein, or other proteins in plasma that bind drugs. Uremia also changes the apparent binding affinity of albumin for some drugs. Disease-induced changes in plasma-protein binding can dramatically affect the volume of distribution, clearance, and elimination $t_{1/2}$ of a drug. In regard to clinical relevance, it is important to assess the change in unbound drug concentration or AUC, particularly when only unbound drug can cross biological barriers and gain access to the site of action.

Plasma Clearance

Systemic clearance of total drug from plasma or blood (see Equations 2–4, 2–5, and 2–7 in Chapter 2) is given in Table AII–1. Clearance varies as a function of body size and therefore most frequently is presented in the table in units of milliliters/minute/kilogram of body weight. Normalization to measures of body size other than weight may at times be more appropriate, such as normalization to body surface area in infants to better reflect the growth and development of the liver and kidneys. However, weight is easy to obtain, and its use often offsets any small loss in accuracy of clearance estimate, especially in adults. Exceptions to this rule are the anticancer drugs, for which dosage normalization to body surface area is

conventionally used. When unit conversion was necessary, we used individual or mean body weight or body surface area (when appropriate) from the cited study, or if this was not available, we assumed a body mass of 70 kg or a body surface area of 1.73 m² for healthy adults.

For the few drugs that exhibit saturation kinetics following therapeutic doses, K_m and V_{max} are given and represent, respectively, the plasma concentration at which half of the maximal rate of elimination is reached (in units of mass/volume) and the maximal rate of elimination (in units of mass/time/kilogram of body weight). K_m must be in the same units as the concentration of drug in plasma (C_p).

In almost all cases, clearances based on plasma concentration data are presented in Table AII-1 because drug analysis most often is performed on plasma samples. The few exceptions where clearance from blood is presented are indicated by footnote. Clearance estimates based on blood concentration may be useful when a drug concentrates in the blood cells.

To be accurate, clearances must be determined after intravenous drug administration. When only nonparenteral data are available, the ratio of CL/F is given; values offset by the fractional availability F are indicated in a footnote. When a drug, or its active isomer for racemic compounds, is known to be a substrate for a CYP or drug transporter, this information is provided in a footnote. This information is important for understanding pharmacokinetic variability due to genetic polymorphisms and for predicting metabolically based drug-drug interactions, although these factors are beyond the scope of this table. For clinically relevant pharmacogenetic information, the reader is referred to CPIC Guidelines listed on the PharmGKB website (<https://www.pharmgkb.org/>). The reader is referred to a comprehensive database for drug-drug interaction information (DIDB) (<https://www.druginteractioninfo.org/>). The former site is open access, whereas the latter can be accessed by a licensing agreement.

Volume of Distribution

The total body volume of distribution at steady state V_{ss} is given in Table AII-1 and is expressed in units of liters/kilogram or in units of liters/square meter for some anticancer drugs. Again, when unit conversion was necessary, we used individual or mean body weights or body surface area (when appropriate) from the cited study, or if such data were not available, we assumed a body mass of 70 kg or a body surface area of 1.73 m² for healthy adults.

When estimates of V_{ss} were not available, values for V_{area} are provided; V_{area} represents the volume at equilibrated distribution during the terminal elimination phase. Unlike V_{ss} , V_{area} varies when drug elimination changes, even though there is no change in extravascular distribution. Because we may wish to know whether a particular disease state influences either the clearance or the tissue distribution of the drug, it is preferable to define volume in terms of V_{ss} , a parameter that is less likely to depend on changes in the rate of elimination. Occasionally, the condition under which the distribution volume was obtained was not specified in the primary reference; this is denoted by the absence of a subscript.

As with clearance, V_{ss} usually is defined in the table in terms of concentration in plasma rather than blood. Further, if data were not obtained after intravenous administration of the drug, a footnote will make clear that the apparent volume estimate, V_{ss}/F or V_{area}/F , is offset by the fractional availability.

Half-Life

Half-life $t_{1/2}$ is the time required for the plasma concentration to decline by one-half when elimination is first order. It also governs the rate of approach to steady state and the degree of drug accumulation during multiple dosing or continuous infusion. For example, at a fixed dosing interval, the patient will be at 50% of steady state after one half-life, 75% of steady state after two half-lives, 93.75% of steady state after four half-lives, and so on. Determination of $t_{1/2}$ is straightforward when drug elimination follows a monoexponential pattern (i.e., one-compartment model). However, for a number of drugs, plasma concentration follows a multiexponential pattern of decline over time. The mean value listed in Table AII-1 corresponds to an effective rate of elimination that covers the clearance of a major fraction of the absorbed dose from the body. In many cases,

this $t_{1/2}$ refers to the rate of elimination in the terminal exponential phase. For a number of drugs, however, the $t_{1/2}$ of an earlier phase is presented, even though a prolonged $t_{1/2}$ may be observed later at very low plasma concentrations when extremely sensitive analytical techniques are used. If the latter component accounts for 10% or less of the AUC, predictions of drug accumulation in plasma during continuous or repetitive dosing will be in error by no more than 10% if this longer $t_{1/2}$ is ignored. Equation 2-19 in Chapter 2 provides for an estimate of the effective $t_{1/2}$ that predicts time to steady state for multicompartmental drug kinetics. It is this $t_{1/2}$ of accumulation during multiple dosing that is given in Table AII-1.

Half-life usually is independent of body size because it is a function of the ratio of two parameters, clearance and volume of distribution, each of which is proportional to body size. It also should be noted that the $t_{1/2}$ is preferably obtained from intravenous studies, if feasible, because the $t_{1/2}$ of decline in plasma drug concentration after oral dosing can be influenced by prolonged absorption, such as when slow-release formulations are given. If the $t_{1/2}$ is derived from an oral dose, this will be indicated in a footnote of Table AII-1.

Time to Peak Concentration

Because clearance concepts are used most often in the design of multiple-dosage regimens, the extent rather than the rate of availability is more critical to estimate the average steady-state concentration of drug in the body. In some circumstances, the degree of fluctuation in plasma drug concentration (i.e., peak and trough concentrations), which govern drug efficacy and side effects, can be greatly influenced by modulation of drug absorption rate through the use of sustained- or extended-release formulations. Controlled-release formulations often permit a reduction in dosing frequency from three or four times daily to once or twice daily. There also are drugs that are given on an acute basis (e.g., for the relief of breakthrough pain or to induce sleep), for which the rate of drug absorption is a critical determinant of onset of effect. Thus, information about the expected average time to achieve maximal plasma or blood concentration and the degree of interindividual variability in that parameter have been included in Table AII-1.

The time required to achieve a maximal concentration T_{max} depends on the rate of drug absorption into blood from the site of administration and the rate of elimination. From mass balance principles, T_{max} occurs when the rate of absorption equals the rate of elimination from the reference compartment. Prior to this time, absorption rate exceeds elimination rate, and the plasma concentration of drug increases. After the peak is reached, elimination rate exceeds the absorption rate and, at some point, defines the terminal elimination phase of the concentration-time profile.

The rate of drug absorption following oral administration will depend on the formulation and physicochemical properties of the drug, its permeability across the mucosal barrier, and the intestinal villous blood flow. For an oral dose, some absorption may occur very rapidly within the buccal cavity, esophagus, and stomach, or absorption may be delayed until the drug reaches the small intestine or until the local pH in the intestine permits drug release from the dosage formulation. In the most extreme case, the rate of absorption can be sufficiently controlled by the drug formulation to permit sustained or extended delivery as the dosage form traverses the entire length of the gastrointestinal tract. In some instances, the terminal elimination of drug from the body following a peak concentration reflects the slower rate of absorption and not elimination.

When more than one type of drug formulation is available commercially, we provide absorption information for both the immediate- and extended-release formulations. Not surprisingly, the presence of food in the gastrointestinal tract can alter both the rate and the extent of drug availability. We indicate with footnotes when the consumption of food near the time of drug ingestion may have a significant effect on the drug bioavailability.

Peak Concentration

There is no general agreement about the best way to describe the relationship between the concentration of drug in plasma and its effect. Many different kinds of data are present in the literature, and use of a single-effect

1328 parameter or effective concentration is difficult. This is particularly true for antimicrobial agents because the effective concentration depends on the identity of the microorganism causing the infection. It also is important to recognize that concentration-effect relationships are most easily obtained at steady state or during the terminal log-linear phase of the concentration-time curve, when the drug concentration(s) at the site(s) of action are expected to parallel those in plasma. Thus, when attempting to correlate a blood or plasma level to effect, the temporal aspect of distribution of drug to its site of action must be taken into account.

Despite these limitations, it is possible to define the minimum effective or toxic concentrations for some of the drugs currently in clinical use. However, in reviewing the list of drugs approved within the past 5 years, it is rare to find a declaration of an *effective concentration range*, even in the manufacturer's package labeling. Thus, it is necessary to infer therapeutic concentrations from concentrations observed following *effective dosage* regimens. For a given dosage regimen, a time-averaged steady-state blood or plasma concentration (i.e., C_{ss} as estimated by dividing the mean AUC by the duration of the dosing interval) and the associated interindividual variability might be one appropriate parameter to report; however, such data often are not available. Also, C_{ss} does not take into account the onset and offset of effect during fluctuation of plasma drug concentration over a dosing interval. In some instances, drug efficacy may be more closely linked with peak concentration than with the average or trough concentration, and differences in peak concentration for special populations (e.g., elderly) sometimes are associated with increased incidence of drug toxicity.

For practical reasons, the most commonly reported parameter, C_{max} (peak concentration), rather than effective or toxic concentrations, is presented in Table AII-1. This provides a more consistent body of information about drug exposure from which one can infer, if appropriate, efficacious or toxic blood levels. Although the value reported is the highest that would be encountered in a given dose interval, C_{max} can be related to the trough concentration C_{min} through appropriate mathematical predictions (see Equation 2-20 in Chapter 2). Because peak levels will vary with dose, we have attempted to present concentrations observed with a customary dose regimen that is recognized to be effective in the majority of patients. When a higher or lower dose rate is used, the expected peak level can be adjusted by assuming dose proportionality, unless nonlinear kinetics are indicated. In some instances, only limited data pertaining to multiple dosing are available, so single-dose peak concentrations are presented. When specific information is available about an effective therapeutic range of concentrations or about concentrations at which toxicity occurs, it has been incorporated in a footnote.

It is important to recognize that significant differences in C_{max} will occur when comparing similar daily-dose regimens for an immediate-release and extended-release product. Indeed, the extended-release product sometimes is administered to reduce peak-trough fluctuations during the dosing interval and to minimize swings between potentially toxic or ineffective drug concentrations. Again, we report C_{max} for both immediate- and extended-release formulations, when available. In addition to parent drug concentrations, we have included information on any active metabolite that circulates at a concentration that may contribute to the overall pharmacological effect, particularly those active metabolites that accumulate with multiple dosing. Likewise, for chiral drugs whose stereoisomers differ in their pharmacological activity and clearance characteristics, we present information on concentrations of the individual enantiomers or the active enantiomer that contributes most to the drug's efficacy.

Alterations of Parameters in the Individual Patient

Dose adjustments for an individual patient should be made according to the manufacturer's recommendation in the package labeling when available. This information generally is available when disease, age, or race has a significant impact on drug disposition, particularly for drugs that have been introduced within the past 15 years. In some cases, a significant difference in drug disposition from the "average" adult can be expected

but may not require dose adjustment because of a sufficiently broad therapeutic index. In other cases, dose adjustment may be necessary, but no specific information is available. Under these circumstances, an estimate of the appropriate dosing regimen can be obtained based on pharmacokinetic principles described in Chapter 2.

Unless otherwise specified, the values in Table AII-1 represent mean values for populations of normal adults; it may be necessary to modify them for calculation of dosage regimens for individual patients. The fraction available F and clearance CL would need to be adjusted to compute a maintenance dose necessary to achieve a desired average steady-state concentration. To calculate the loading dose, knowledge of the volume of distribution is needed. The estimated $t_{1/2}$ is used in deciding a dosing interval that provides an acceptable peak-trough fluctuation; note that this may be the apparent $t_{1/2}$ following dosing of a slowly absorbed formulation. The values reported in the table and the adjustments apply only to adults; exceptions are footnoted. Although the values at times may be applied to children who weigh more than about 30 kg (after proper adjustment for size; see Clearance and Volume of Distribution, presented in the following material), it is best to consult pediatrics textbooks or other sources for definitive advice.

For each drug, changes in the parameters caused by certain disease states are noted within the eight segments of the table. In all cases, the qualitative direction of changes is noted, such as " \downarrow LD," which indicates a significant decrease in the parameter in a patient with chronic liver disease. The relevant literature and the package label should be consulted for more definitive, quantitative information for dosage adjustment recommendations.

Plasma Protein Binding

Most acidic drugs that are extensively bound to plasma proteins are bound to albumin. Basic lipophilic drugs, such as propranolol, often bind to other plasma proteins (e.g., α_1 -acid glycoprotein and lipoproteins). The degree of drug binding to proteins will differ in pathophysiological states that cause changes in plasma protein concentrations. Significant pharmacokinetic effects from a change in plasma protein binding are denoted under clearance or volume of distribution.

Although pharmacokinetic parameters based on total drug or metabolite concentrations often are reported, it is important to recognize that in many cases it is the concentration of *unbound drug* that drives access to the site of action and the degree of pharmacological effect. Remarkable changes in the total plasma concentration may accompany disease-induced alteration in protein binding; however, the clinical outcome is not always affected because an increase in free fraction also will increase the apparent clearance of an orally administered drug and of a low-extraction drug dosed intravenously. Under such a scenario, the time-averaged unbound plasma concentration over a dosing interval at steady state will not change with reduced or elevated plasma protein binding, despite a significant change in time-averaged total drug concentration. If so, no adjustment of daily maintenance dose is needed.

Clearance

For drugs that are partly or predominantly eliminated by renal excretion, plasma clearance changes in accordance with the renal function of an individual patient. This necessitates dosage adjustment that is dependent on the fraction of normal renal function remaining and the fraction of drug normally excreted unchanged in the urine. The latter quantity appears in the table; the former can be estimated as the ratio of the patient's estimated or measured creatinine clearance CL_{cr} to a normal value (100 mL/min/1.73 m²). Because urinary creatinine clearance is not routinely measured, it is often estimated from standardized serum creatinine concentration C_{cr} using the MDRD Study equation for CL_{cr} less than 60 mL/min/1.73 m².

$$CL_{cr} \text{ (mL/min/1.73 m}^2\text{)} = 175 \cdot (C_{cr})^{-1.154} \cdot (\text{Age})^{-0.203} \cdot (0.742 \text{ if female}) \cdot (1.212 \text{ if African American}) \quad (\text{Equation A-1})$$

Note that Equation A-1 does not require body weight as the CL_{cr} estimate is normalized to average adult body surface; proportionate

scaling is needed for adjustment to a different body surface area. Convenient calculators are available for the MDRD equation and the CKD-EPI equation for more accurate estimation of CL_{cr} greater than 60 mL/min/1.73 m² (e.g., <https://www.niddk.nih.gov/health-information/health-communication-programs/nkdep/lab-evaluation/gfr/estimating/Pages/estimating.aspx>).

The fraction of normal renal function $rf_{x_{pt}}$ is estimated from the following:

$$rf_{x_{pt}} = \frac{CL_{cr,pt}}{100 \text{ mL/min}} \quad (\text{Equation A-2})$$

A more accurate measure of $rf_{x_{pt}}$ seldom is necessary because, given the considerable degree of interindividual variation in nonrenal clearance, the adjustment of clearance is an approximation. The following equation for adjustment of clearance uses the quantities discussed:

$$rf_{pt} = 1 - [fe_{nl} \cdot (1 - rf_{x_{pt}})] \quad (\text{Equation A-3})$$

where fe_{nl} is the fraction of systemic drug excreted unchanged in normal individuals (see Table AII-1). The renal factor rf_{pt} is the value that, when multiplied by normal total clearance CL_{nl} from the table, gives the total clearance of the drug adjusted for the impairment in renal function.

Example

The clearance of vancomycin in a patient with reduced renal function (creatinine clearance = 25 mL/min for an average-size adult) may be estimated as follows:

$$\begin{aligned} rf_{x_{pt}} &= \frac{25 \text{ mL/min}}{100 \text{ mL/min}} = 0.25 \\ fe_{nl} &= 0.79 \text{ (see listing for vancomycin)} \\ rf_{pt} &= 1 - [0.79 \cdot (1 - 0.25)] = 0.41 \\ CL_{pt} &= (1.3 \text{ mL/min/kg}) \cdot 0.41 \\ &= 0.53 \text{ mL/min/kg} \end{aligned}$$

Importantly, such a clearance adjustment should be regarded only as an initial step in optimizing the dosage regimen; depending on the patient's response to the drug, further individualization may be necessary.

Conventionally, clearance is adjusted for the size of the patient to reflect a difference in the mass of the eliminating organ. For orally administered drugs, the applicability of such an adjustment may be limited by the available dosage strengths of commercial formulations. In some cases, scored tablets can be split, or commercial tablet splitters are used to increase the range of available dosage strengths. However, this practice should be followed only with the recommendation of the pharmacist because splitting a tablet sometimes can compromise the bioavailability of a product.

With the exception of certain oncolytic agents, the data presented in the table are normalized to weight. Thus, interindividual variability in the weight-normalized clearance reflects a variation in the intrinsic metabolic or transport clearance and not the size of the organ. Further, these differences can be attributed to variable expression/function of metabolic enzymes or transporters. However, it is important to recognize that liver mass and total enzyme/transporter content may not increase or decrease in proportion to weight in obese or malnourished individuals. Alternative approaches such as normalization by body surface area or other measures

of body mass may be more appropriate. For example, many of the drugs used to treat cancer are dosed according to body surface area (see Chapters 65 and 66). In the tabulation, if the literature reported dose per body surface area, we present the data in the same unit. If the cited clearance data were not normalized, but the preponderance of the literature utilized body surface area, we followed the practice of using values of body surface area from the literature source or a standard of 1.73 m² for a healthy adult.

Volume of Distribution

Volume of distribution should be adjusted for the modifying factors indicated in Table AII-1 as well as for body size. Again, the data in the table most often are normalized to weight. Unlike clearance, volume of distribution in an individual usually is proportional to weight itself. Whether this applies to a specific drug depends on the actual sites of distribution of drug; no absolute rule applies.

Whether to adjust volume of distribution for changes in binding to plasma proteins cannot be decided in general; the decision depends critically on whether the factors that alter binding to plasma proteins also alter binding to tissue proteins. Qualitative changes in volume of distribution, when they occur, are indicated in the table.

Half-Life

Half-life may be estimated from the adjusted values of clearance CL_{pt} and volume of distribution V_{pt} for the patient:

$$t_{1/2} = \frac{0.693 \cdot V_{pt}}{CL_{pt}} \quad (\text{Equation A-4})$$

Because $t_{1/2}$ has been the parameter most often measured and reported in the literature, qualitative changes for this parameter almost always are given in the table.

Individualization of Dosage

By using the parameters for the individual patient, calculated as described in the previous section, initial dosing regimens may be chosen. The maintenance dosage rate may be calculated with Equation 2-17 in Chapter 2, using the estimated values for CL and F for the individual patient. As described previously, the target concentration may have to be adjusted for changes in plasma protein binding in the patient, as described in Plasma Protein Binding. The loading dose may be calculated using Equation 2-21 and estimates for V_{ss} and F . A particular dosing interval may be chosen; the maximal and minimal steady-state concentrations can be calculated by using Equations 2-20, and these calculated concentrations can be compared with the known efficacious and toxic concentrations for the drug. As with the target concentration, these values may need to be adjusted for changes in the extent of plasma protein binding. Use of Equations 2-20 and 2-21 also requires estimates of values for F , V_{ss} , and K ($K = 0.693/t_{1/2}$) for the individual patient.

Note that these adjustments of pharmacokinetic parameters for an individual patient are suggested for the rational choice of initial dosing regimen. As indicated in Chapter 2, steady-state measurement of drug concentrations in the patient then can be used as a guide to further adjust the dosage regimen. However, optimization of a dosage regimen for an individual patient ultimately will depend on the clinical response produced by the drug.

TABLE AII-1 ■ PHARMACOKINETIC DATA

Key: Unless otherwise indicated by a specific footnote, the data are presented for the study population as a mean value \pm 1 standard deviation, a mean and range (lowest-highest in parentheses) of values, a range of the lowest-highest values, or a single mean value. ACE, angiotensin-converting enzyme; Aged, aged; AIDS, acquired immunodeficiency syndrome; C_{max} , peak concentration; CYP, cytochrome P450; F or Fem, female; HIV, human immunodeficiency virus; IM, intramuscular; IV, intravenous; LD, chronic liver disease; M, male; MAO, monoamine oxidase; NAT, N-acetyltransferase; Neo, neonate; Obes, obesity; PDR54, *Physicians' Desk Reference*, 54th ed. Montvale, NJ, Medical Economics Co., 2000; PDR58, *Physicians' Desk Reference*, 58th ed. Montvale, NJ, Medical Economics Co., 2004; Pneu, pneumonia; PO, oral administration; Preg, pregnant; Prem, premature infants; Rac, racemic mixture of stereoisomers; RD, chronic renal disease; SC, subcutaneous; Smk, smoking; ST, sulfotransferase; T_{max} , peak time; UGT, UDP-glucuronosyl transferase. Other abbreviations are defined in the text section of this appendix.

BIOAVAILABILITY (ORAL) (%)	URINARY EXCRETION (%)	BOUND IN PLASMA (%)	CLEARANCE (mL/min/kg)	VOL. DIST. (L/kg)	HALF-LIFE (hours)	PEAK TIME (h)	PEAK CONCENTRATION

Amphotericin B^a							
<5	2–5	>90	0.46 ± 0.20 ^b	0.76 ± 0.52 ^c	18 ± 7 ^d	—	1.2 ± 0.33 µg/mL ^e

^aData for amphotericin B shown. ^bData for eight children (ages 8 months to 14 years) yielded a linear regression, with *CL* decreasing with age: *CL* = −0.046 · Age (years) + 0.86. Newborns show highly variable *CL* values. ^cVolume of central compartment. *V_s* increases with dose from 3.4 L/kg for a 0.25-mg/kg dose to 8.9 L/kg for a 1.5-mg/kg dose. Also available as liposomal encapsulated formulations (Abelcet and Ambisome). Amphotericin distribution and *CL* properties of these products are different from the nonencapsulated form; they have a terminal *t*_{1/2} of 173 ± 78 and 110–153 h, respectively; however, an effective steady-state concentration can be achieved within 4 days. ^d*t*_{1/2} for multiple dosing. In single-dose studies, a prolonged dose-dependent *t*_{1/2} is seen. ^eFollowing a 0.5-mg/kg IV dose of amphotericin B given as a 1-h infusion, once daily for 3 days. Whole-blood concentrations (free and liposome encapsulated) of 1.7 ± 0.8 µg/mL and 83 ± 35 µg/mL were reported following a 5-mg/kg/d IV dose (presumed 60- to 120-min infusion) of Abelcet and Ambisome, respectively.

References: Gallis HA, et al. Amphotericin B: 30 years of clinical experience. *Rev Infect Dis*, 1990, 12:308–329. *PDR54*, 2000, pp. 1090–1091, 1654.

Apixaban							
~50	17–30	87	0.77–0.84 ^{a,b}	0.38–0.42 ^b	3.7–8.4 ^{b,c}	3–4 ^d	34–110 ng/mL ^d

^aCleared from blood primarily by CYP3A-dependent metabolism. ^bCalculated assuming 70-kg body weight; range of mean values for single intravenous doses of 0.5–5 mg.

^cApparent *t*_{1/2} after oral dose is ~12 h because of slow absorption. ^dFollowing a single 5-mg oral dose to 16 healthy adults.

Reference: Zheng SS, et al. Pharmacodynamics, pharmacokinetics and clinical efficacy of apixaban in the treatment of thrombosis. *Expert Opin Drug Metab Toxicol*, 2016, 12: 575–580. Drugs@FDA: FDA Approved Drug Products (<http://www.accessdata.fda.gov/scripts/cder/daf/>), Apixaban (Eliquis).

Aripiprazole^a							
87	<1	>99	0.83 ± 0.17 ^{b,c}	4.9 ^c	47 ± 10	3.0 ± 0.6 ^d	242 ± 36 ng/mL ^d

^aThe major metabolite, dehydro-aripiprazole, has affinity for D₂ receptors similar to parent drug; found at 40% of parent drug concentration in plasma; *t*_{1/2} is 94 h. No significant gender differences. ^bEliminated primarily by CYP2D6- and CYP3A4-dependent metabolism. CYP2D6 poor metabolizers exhibit increased exposure (80%) to parent drug but reduced exposure (30%) to the active metabolite. ^c*CL/F* and *V/F* at steady state reported. ^dFollowing a 15-mg oral dose given once daily for 14 days.

References: DeLeon A, et al. Aripiprazole: a comprehensive review of its pharmacology, clinical efficacy, and tolerability. *Clin Ther*, 2004, 26:649–666. Mallikaarjun S, et al. Carbamazepine^a							
78 ± 24 ^b	3	74 ± 6	0.73 ± 0.3 ^b	1.1 ± 0.3 ^b	20 ± 9 ^b	—	11.2–11.7 (2–18) µg/mL ^c
^a A metabolite, carbamazepine-10,11-epoxide, is equipotent in animal studies. Its formation is catalyzed primarily by CYP3A and secondarily by CYP2C8. ^b Data from 92 patients receiving carbamazepine oral therapy for treatment of epilepsy and given stable isotope-labeled carbamazepine intravenously. Carbamazepine induces its own metabolism; for a single dose, CL/F = 0.36 ± 0.07 mL/min/kg and t _{1/2} = 36 ± 5 h. ^c Mean steady-state C _{max} is similar following either dosing of immediate-release carbamazepine four times a day or extended-release carbamazepine once daily (800–1600 mg/d). Concentration following a daily 200-mg oral dose (immediate release) given to adult patients with epilepsy reported. <i>References:</i> Marino SE, et al. TABLE AII-1 ■ PHARMACOKINETIC DATA (CONTINUED)

BIOAVAILABILITY (ORAL) (%)	URINARY EXCRETION (%)	BOUND IN PLASMA (%)	CLEARANCE (mL/min/kg)	VOL. DIST. (L/kg)	HALF-LIFE (hours)	PEAK TIME (h)	PEAK CONCENTRATION
Clopidogrel^a							
— ^b	—	Clo: 98	—	—	Clo: 4–6	Clo: 0.5–1	Clo ^d
					AM: 0.5 ^c	AM: 1.0 ^d	EM: 3.8 ± 2.5 ng/mL
							IM: 6.8 ± 3.6 ng/mL
							PM: 18 ± 14 ng/mL
							AM ^d
							EM: 39 ± 15 ng/mL
							IM: 26 ± 11 ng/mL
							PM: 24 ± 6 ng/mL

^aClopidogrel (Clo) is a prodrug that is converted to a minor unstable active metabolite (AM) via two sequential cytochrome P450-dependent reactions. The majority of the dose is converted rapidly to an inactive hydrolytic product by esterases. Although multiple P450 isoforms contribute to the formation of AM, blood levels of AM have been associated with the CYP2C19 genotype and phenotype status, with poor metabolizers (PM) exhibiting lower levels, on average, than extensive metabolizers (EM). Formation of AM accounts for ≤ 10% of the administered dose and may be dose dependent due to saturable metabolism. ^bThe absolute bioavailability of Clo is unknown. There is one report of food greatly enhancing the systemic exposure of Clo following oral administration. ^cThe reported value may represent disappearance of high levels of metabolite formed during first pass and not the terminal $t_{1/2}$, which should be formation limited. ^dFollowing a single 300-mg loading dose of Clo.

Dronabinol (delta-9-tetrahydrocannabinol)^a

6 ± 3 ^b	<1%	97	8.6 ± 2.1	8.9 ± 4.2	20 ± 4 ^c	2.5 (0.5–4) ^d	2.96 ± 1.81 ng/mL ^d
--------------------	-----	----	-----------	-----------	---------------------	--------------------------	--------------------------------

^aDronabinol is a synthetic delta-9-tetrahydrocannabinol (delta-9-THC) that is also the active component of cannabis. Dronabinol is extensively metabolized and undergoes extensive first-pass metabolism. It has an active metabolite, 11-OH-delta-9-THC, which is present at about equal concentrations in plasma as THC. Biliary excretion of dronabinol metabolites appears to be a major route of elimination. Only 21% ± 3% of total radioactivity after intravenous dose is recovered in urine, with > 50% recovered in feces. ^bPulmonary administration of delta-9-THC has a bioavailability of 18%–29%. Bioavailability as high as 20% after oral administration has been reported. ^cDronabinol elimination is characterized by multicompartment kinetics, with distribution $t_{1/2}$ of 4 h and terminal $t_{1/2}$ of 25–36 h. ^dFollowing a single oral dose of 5-mg gelatin capsule. Median and range reported for T_{max} .

Ezetimibe^a							
—	~2	>90 ^b	6.6 ^c	1.5 ^c	28–30 ^d	1 ^e	122 ng/mL ^e
			↓ Aged, RD, LD				

^aEzetimibe is extensively metabolized to a glucuronide, which is more active than ezetimibe in inhibiting cholesterol absorption. Clinical effects are related to the total plasma concentration of ezetimibe and ezetimibe-glucuronide, with ezetimibe concentrations being only 10% of the total. ^bFor ezetimibe and ezetimibe-glucuronide. ^cCL/F and a volume for the central compartment (V/F) for total (unconjugated and glucuronide conjugate) ezetimibe reported. ^dEzetimibe undergoes significant enterohepatic recycling, leading to multiple secondary peaks. An effective $t_{1/2}$ is estimated. ^eTotal (unconjugated and glucuronide conjugate) ezetimibe following a 10-mg oral dose given once daily for 10 days.

Hydrocodone^a

—	EM: 10.2 ± 1.8	—	EM: 11.1 ± 3.57 ^b	—	EM: 4.24 ± 0.99 ^b	EM: 0.72 ± 0.46 ^c	EM: 30 ± 9.4 ng/mL ^c
	PM: 18.1 ± 4.5		PM: 6.54 ± 1.25 ^b		PM: 6.16 ± 1.97 ^b	PM: 0.93 ± 0.59 ^c	PM: 27 ± 5.9 ng/mL ^c

^aData from healthy male and female subjects. The metabolism of hydrocodone to hydromorphone (more active) is catalyzed by CYP2D6. Subjects were phenotyped as extensive metabolizers (EM) and poor metabolizers (PM). ^b*CL*/*F* and *t*_{1/2} reported for oral dose. ^cFollowing a 10-mg oral dose (syrup). Maximal hydromorphone concentrations are higher in EM than in PM (5.2 vs. 1.0 ng/mL).

Reference: Otton SV, et al. CYP2D6 phenotype determines the metabolic conversion of hydrocodone to hydromorphone. *Clin Pharmacol Ther*, 1993, 54:463–472.

Hydromorphone^a

PO: 42 ± 23	6	7.1	14.6 ± 7.6	2.90 ± 1.31 ^b	2.4 ± 0.6	IV: — ^c	IV: 242 ng/mL ^c
SC: ~80						PO: 1.1 ± 0.2 ^c	PO: 11.8 ± 2.6 ng/mL ^c

^aData from healthy male subjects. Extensively metabolized. The principal metabolite, 3-glucuronide, accumulates to much higher (27-fold) levels than the parent drug and may contribute to some side effects (not antinociceptive). ^b*V*_{area} reported. ^cFollowing a single 2-mg IV (bolus, sample at 3 min) or 4-mg oral dose.

↑ Food ^b							

^aMetabolized predominantly by CYP3A4 to an active metabolite, hydroxyitraconazole, and other sequential metabolites. ^bRelative to oral dosing with food. ^cBlood CL is 9.4 mL/min/kg. CL is concentration dependent; the value given is nonsaturable range. $K_m = 330 \pm 200$ ng/mL, $V_{max} = 2.2 \pm 0.8$ pg · mL⁻¹ · min⁻¹ · kg⁻¹. Apparent CL/F at steady state reported to be 5.4 mL · min⁻¹ · kg⁻¹. ^d V_{area} reported. Follows multicompartment kinetics. Does not appear to be concentration dependent. ^e $t_{1/2}$ for the nonsaturable concentration range. ^f $t_{1/2}$ at steady state reported to be 64 h. ^gFollowing a 200-mg oral dose given daily for 4 days to adults.

Loratadine^a							
L: — ^b	L: Negligible	L: 97	L: 142 ± 57 ^d	L: 120 ± 80 ^d	L: 8 ± 6	L (L): 2.0 ± 2.0 ^e	L (L): 3.4 ± 3.4 ng/mL ^e
			↓ LD		↑ LD	DL (L): 2.6 ± 2.9 ^e	DL (L): 4.1 ± 2.6 ng/mL ^e
DL: — ^b	DL: —	DL: 82–87 ^c	DL: 14–18 ^d	DL: 26 ^d	DL: 21–24	DL (DL): 3.2 ± 1.8 ^f	DL (DL): 4.0 ± 2.1 ng/mL ^f
						HDL (DL): 4.8 ± 1.9 ^f	HDL (DL): 2.0 ± 0.6 ng/mL ^f
			↓ RD, LD				

^aLoratadine (L) is converted to a major active metabolite, desloratadine (DL). Almost all patients achieve higher plasma concentrations of DL than of L. DL (Claritin) is approved for similar clinical indications as L. DL is eliminated by metabolism to an active metabolite, 3-hydroxydesloratadine (HDL). ~7%–20% of patients were slow metabolizers of DL; frequency varies with ethnicity. ^bBioavailability of L and DL is not known; L is probably low due to extensive first-pass metabolism. ^cPlasma protein binding of HDL is 85%–89%. ^dCL/F and V_{area}/F reported. For DL, oral CL/F calculated from AUC data following a single 5- to 20-mg oral dose given to healthy adults. ^eMean for L and DL following a 10-mg oral L dose (Claritin-D 24 h) given once daily for 7 days to healthy adults. ^fMean for DL and HDL following a 5-mg oral DL dose (Claritin) given once daily for 10 days to healthy adults.

^aRacemic mixture; no information on relative kinetics of the enantiomers. ^bAbsolute bioavailability is not known; reported values of > 85% represent comparison of oral tablet to solution. ^cCL/F and V_d/F reported. ^dRange of mean values from different studies following a single 1000-mg oral dose (SD) and mean following a 250-mg oral dose given once weekly for 4 weeks (MD).

Reference: Karbwang J, et al. Clinical pharmacokinetics of mefloquine. *Clin Pharmacokinet*, 1990, 19:264–279.

Meperidine^a							
52 ± 3	~5 (1–25) ^b	58 ± 9 ^c	17 ± 5	4.4 ± 0.9	3.2 ± 0.8 ^d	IM: <1 ^e	IV: 0.67 µg/mL ^e
↑ LD		↓ Aged, RD	↓ LD, RD, Prem, Neo	↑ Aged, Prem	↑ LD, Prem, Neo, Aged, RD		IM: ~0.7 µg/mL ^e

^aMeperidine undergoes cytochrome P450-dependent N-demethylation to normeperidine. The metabolite is not an analgesic but is a potent central nervous system-excitatory agent and is associated with adverse side effects of meperidine. ^bMeperidine is a weak base ($pK_a = 8.6$) and is excreted to a greater extent in the urine at low urinary pH and to a lesser extent at high urinary pH. ^cCorrelates with the concentration of α₁-acid glycoprotein. ^dA longer $t_{1/2}$ (7 h) also is observed. ^eFollowing a continuous 24-mg/h IV infusion or 100-mg IM injection every 4 h to steady state. Postoperative analgesia occurs at 0.4–0.7 µg/mL.

Reference: Edwards DJ, et al. Clinical pharmacokinetics of pethidine: 1982. *Clin Pharmacokinet*, 1982, 7:421–433.

Mercaptopurine^a							
12 ± 7 ^b	22 ± 12	19	11 ± 4 ^c	0.56 ± 0.38	0.90 ± 0.37		IV: 6.9 µM ^d
						PO (–): 2.4 ± 0.4 ^d	PO (–): 0.74 ± 0.28 µM ^d
						PO (+): 2.8 ± 0.4 ^d	PO (+): 3.7 ± 0.6 µM ^d

^aInactive prodrug is metabolized intracellularly to 6-thioinosinate. Pharmacokinetic values for mercaptopurine are reported. ^bIncreases to 60% when first-pass metabolism is inhibited by allopurinol (100 mg three times daily). ^cMetabolically cleared by xanthine oxidase and thiopurine methyltransferase (polymorphic). Despite inhibition of intrinsic CL by allopurinol, hepatic metabolism is limited by blood flow, and CL is thus little changed by allopurinol. ^dFollowing an intravenous infusion of 50 mg/m²/h to steady state in children with refractory cancers or a single oral dose of 75 mg/m² with (+) or without (–) allopurinol pretreatment.

^aPlasma concentrations of the 7-hydroxy metabolite approach those of the parent drug. Metabolite may have both therapeutic and toxic effects. ^bBioavailability is dose dependent and may be as low as 20% when doses are > 80 mg/m². ^cIntramuscular bioavailability is only slightly higher. ^dMethotrexate clearance is mediated by several transporters, including organic anion transporters (OATs). ^eExhibits triexponential elimination kinetics. A shorter *t*_{1/2} (2 h) is seen initially, and a longer (52 h) terminal *t*_{1/2} has been observed with increased assay sensitivity. ^fFollowing a 15-mg SC dose given once weekly to steady state in adult patients with inflammatory bowel disease. Initial steady-state concentrations in young (1.5–22 years) leukemia patients receiving a 500-mg/m² loading dose given over 1 h followed by an infusion of 196-mg/m²/h for 5 h.

^aMethylphenidate is available as a racemate and the active (+)-dextro-enantiomer dexmethylphenidate. Methylphenidate and dexmethylphenidate are extensively metabolized, primarily through ester hydrolysis to ritalinic acid. Data for individual enantiomers following racemate administration to healthy adult male subjects. No significant gender differences. ^bThe (+)-enantiomer exhibits dose-dependent kinetics at high doses of racemate, with an ~50% reduction in *CL/F* between a 10- and 40-mg dose. ^cWhen dexmethylphenidate is given alone, its *t*_{1/2} is 2.2 h and *T*_{max} is 1–1.5 h. ^dFollowing a single 40-mg oral dose (immediate release). Longer *T*_{max} (3–5 h) and lower *C*_{max} reported for sustained-release oral formulation.

TABLE AII-1 ■ PHARMACOKINETIC DATA (CONTINUED)

BIOAVAILABILITY (ORAL) (%)	URINARY EXCRETION (%)	BOUND IN PLASMA (%)	CLEARANCE (mL/min/kg)	VOL. DIST. (L/kg)	HALF-LIFE (hours)	PEAK TIME (h)	PEAK CONCENTRATION
Metoprolol^a							
38 ± 14 ^b	10 ± 3 ^b	11 ± 1	15 ± 3 ^b	4.2 ± 0.7	3.2 ± 0.2 ^b	EM: ~2 ^c	EM: 99 ± 53 ng/mL ^c
↑ LD			↑ Preg	↑ Fem	↑ LD, Neo	PM: ~3 ^c	PM: 262 ± 29 ng/mL ^c
↓ Preg			↑ Fem				
^a Data for racemic mixture reported. Metabolism of less active <i>R</i> -(+)-enantiomer ($CL/F = 28$ mL/min/kg; $V_{area}/F = 7.6$ L/kg; $t_{1/2} = 2.7$ h) is slightly faster than that of more active <i>S</i> -(-)-enantiomer ($CL/F = 20$ mL/min/kg; $V_{area}/F = 5.5$ L/kg; $t_{1/2} = 3$ h). ^b Metabolically cleared by CYP2D6 (polymorphic). Compared to extensive metabolizers (EM), individuals who are poor metabolizers (PM) have a lower CL/F and a longer $t_{1/2}$ (7.6 ± 1.5 vs. 2.8 ± 1.2 h) and excrete more unchanged drug in urine (15% ± 7% vs. 3.2% ± 3%) due to reduced hepatic metabolism. ^c C_{3h} following a single 100-mg oral dose in CYP2D6 EM and PM patients with hypertension. Plasma concentrations of the more active <i>S</i> -enantiomer are ~35% higher than the <i>R</i> -antipode in CYP2D6 EM. No stereochemical difference was observed in PM subjects. EC_{50} for decreased heart rate during peak submaximal exercise testing was 16 ± 7 ng/mL; EC_{50} for decreased systolic blood pressure during exercise testing was 25 ± 18 ng/mL. TABLE AII-1 ■ PHARMACOKINETIC DATA (CONTINUED)

BIOAVAILABILITY (ORAL) (%)	URINARY EXCRETION (%)	BOUND IN PLASMA (%)	CLEARANCE (mL/min/kg)	VOL. DIST. (L/kg)	HALF-LIFE (hours)	PEAK TIME (h)	PEAK CONCENTRATION
Montelukast^a							
62	<0.2	>99	0.70 ± 0.17 ^b	0.15 ± 0.02	4.9 ± 0.6	3.0 ± 1.0 ^d	542 ± 173 ng/mL ^d
			↓ LD ^c		↑ LD ^c		

^aData from healthy adult subjects. No significant gender differences. ^bMontelukast is metabolized by CYP3A4 and CYP2C9. ^cCL/F is reduced by 41%, mild-to-moderate hepatic impairment with cirrhosis. ^dFollowing a single 10-mg oral dose.

References: PDR54, 2000, p. 1882. Zhao JJ, et al. Pharmacokinetics and bioavailability of montelukast sodium (MK-0476) in healthy young and elderly volunteers. *Biopharm Drug Dispos*, 1997, 18:769–777.

Morphine^a							
PO: 24 ± 12	4 ± 5	35 ± 2	24 ± 10	3.3 ± 0.9	1.9 ± 0.5	IM: 0.2–0.3 ^b	IV: 200–400 ng/mL ^b
IM: ~100		↓ LD	↓ RD, Prem	↓ RD	↑ Neo, Prem	PO-IR: 0.5–1.5 ^b	IM: ~70 ng/mL ^b
						PO-SR: 3–8 ^b	PO-IR: 10 ng/mL ^b
							PO-SR: 7.4 ng/mL ^b

^aMainly cleared by UGT2B7-dependent glucuronidation to morphine 3-glucuronide and to an active metabolite, morphine-6-glucuronide; the latter urinary excretion = 14% ± 7% and $t_{1/2}$ = 4.0 ± 1.5 h. Steady-state ratio of active metabolite to parent drug after oral dosing = 4.9 ± 3.8. In renal failure, $t_{1/2}$ increases to 50 ± 37 h, resulting in significant accumulation of active glucuronide metabolite. ^bFollowing a single 10-mg IV dose (bolus with 5-min blood sample), a 10-mg/70-kg IM, a 10-mg/70 kg immediate-release oral (PO-IR) dose, or a 50-mg sustained-release oral dose (PO-SR). Minimum analgesic concentration is 15 ng/mL.

Moxifloxacin^a							
86 ± 1	21.9 ± 3.6	39.4 ± 2.4	2.27 ± 0.24 ^b	2.05 ± 1.15	15.4 ± 1.2	2.0 (0.5–6.0) ^c	2.5 ± 1.3 µg/mL ^c

^aData from healthy adult male subjects. ^bMoxifloxacin is metabolically cleared by ST and UGT. ^cFollowing a single oral 400-mg dose.

Reference: Stass H, et al. Pharmacokinetics and elimination of moxifloxacin after oral and intravenous administration in man. *J Antimicrob Chemother*, 1999, 43(suppl B):83–90.

Mycophenolate^a							
MM: ~0	MPA: <1	MPA: 97.5	MM: 120–163	MPA: 3.6–4 ^c	MM: <0.033	MPA: 1.1–2.2 ^d	MPA: 8–19 µg/mL ^d
MPA: 94		↓ RD ^b	MPA: 2.5 ± 0.4 ^c		MPA: 16.6 ± 5.8		
			↓ RD ^b				

^aData from healthy adult male and female subjects and organ transplant patients. No significant gender differences. Mycophenolate mofetil (MM) is rapidly converted to the active mycophenolic acid (MPA) after intravenous and oral doses. Kinetic parameters refer to MM and MPA after a dose of MM. MPA metabolized by UGT to MPA-glucuronide (MPAG). MPA undergoes enterohepatic recycling; MPAG is excreted into bile and presumably is hydrolyzed by gut flora and reabsorbed as MPA. ^bAccumulation of MPA and MPAG and increased unbound MPA; severe renal impairment. ^cCL/F and V_{area}/F reported for MPA. ^dRange of mean MPA C_{max} and T_{max} from different studies following a 1- to 1.75-g oral dose given twice daily to steady state in renal transplant patients.

References: Bullingham R, et al. Effects of food and antacid on the pharmacokinetics of single doses of mycophenolate mofetil in rheumatoid arthritis patients. *Br J Clin Pharmacol*, 1996, 47:513–516. Bullingham RE, et al. TABLE AII-1 ■ PHARMACOKINETIC DATA (CONTINUED)

BIOAVAILABILITY (ORAL) (%)	URINARY EXCRETION (%)	BOUND IN PLASMA (%)	CLEARANCE (mL/min/kg)	VOL. DIST. (L/kg)	HALF-LIFE (hours)	PEAK TIME (h)	PEAK CONCENTRATION
Oxaliplatin^a							
— ^b	— ^c	90 ^d	49 (41–64) ^e	1.5 (1.1–2.1)	0.32 (0.27–0.46) ^f	—	Ox: 0.33 (0.28–0.38) µg Pt/mL
							PtDC: 0.008 (0.004–0.014) µg Pt/mL ^g

^aOxaliplatin is an organoplatinum complex; Pt is coordinated with diaminocyclohexane (DACH) and an oxalate ligand as a leaving group. Oxaliplatin (Ox) undergoes nonenzymatic biotransformation to reactive derivatives, notably Pt(DACH)Cl₂ (PtDC). Antitumor activity and toxicity are thought to relate to the concentration of oxaliplatin and PtDC in plasma ultrafiltrate (i.e., unbound concentration). ^bFor intravenous administration only. ^c~54% of the platinum eliminated is recovered in urine. ^dBinding to plasma proteins is irreversible. ^eCL of total platinum is much lower; ~2–4 mL/min/kg. ^fThe elimination of platinum species in plasma follows a triexponential pattern. The quoted $t_{1/2}$ reflects the $t_{1/2}$ of the first phase, which is the clinically relevant phase. The $t_{1/2}$ for the slower two phases are 17 and 391 h. ^gSteady-state plasma ultrafiltrate concentration of Ox and PtDC after an 85-mg/m² IV infusion over 2 h during cycles 1 and 2.

References: PDR58, 2004, pp. 3024–3025. Shord SS, et al. Oxaliplatin biotransformation and pharmacokinetics: a pilot study to determine the possible relationship to neurotoxicity. *Anticancer Res*, 2002, 22:2301–2309.

Oxcarbazepine^a							
—	O: <1	—	O: 67.4 ^b	—	O: ~2	HC: 2–4 ^c	HC: 8.5 ± 2.0 µg/mL ^e
	HC: 27	HC: 45	HC: ↓ RD, ^c Aged		HC: 8–15		
			HC: ↑ Child ^d		HC: ↑ RD, Aged		

^aData from healthy adult male subjects. No significant gender differences. Oxcarbazepine (O) undergoes extensive first-pass metabolism to an active metabolite, 10-hydroxycarbazepine (HC). Reduction by cytosolic enzymes is stereoselective (80% *S*-enantiomer, 20% *R*-enantiomer), but both show similar pharmacological activity. ^bCL/F for O reported. HC eliminated by glucuronidation. ^cAUC for HC increased, moderate-to-severe renal impairment. ^dAUC for HC decreased, children < 6 years of age. ^eFollowing a 300-mg oral oxcarbazepine dose given twice daily for 12 days.

Oxybutynin^a							
1.6–10.9	<1	—	8.1 ± 2.3 ^b	1.3 ± 0.4 ^b	IV: 1.9 ± 0.35 ^{b,c}	IR: 5.0 ± 4.2 ^d	IR: 12.4 ± 4.1 ng/mL ^d
						XL: 5.2 ± 3.7 ^d	XL: 4.2 ± 1.6 ng/mL ^d

^aData from healthy female subjects. No significant gender differences. Racemic mixture; anticholinergic activity resides predominantly with *R*-enantiomer; no stereoselectivity exhibited for anti-spasmodic activity. Oxybutynin undergoes extensive first-pass metabolism to *N*-desethyloxybutynin (DEO), an active, anticholinergic metabolite. Metabolized primarily by intestinal and hepatic CYP3A. Racemic oxybutynin kinetic parameters reported. ^bData reported for a 1-mg IV dose, assuming a 70-kg body weight. A larger volume (2.8 L/kg) and longer $t_{1/2}$ (5.3 h) reported for a 5-mg IV dose. ^cExhibits a longer apparent $t_{1/2}$ following oral dosing due to absorption rate-limited kinetics: immediate-release (IR) $t_{1/2}$ = 9 ± 2 h; extended-release (XL) $t_{1/2}$ = 14 ± 3 h. The apparent $t_{1/2}$ for DEO was 4.0 ± 1.4 h and 8.3 ± 2.5 h for the IR and XL formulations, respectively. ^dFollowing a dose of 5-mg IR given three times daily or 15-mg XL given once daily for 4 days. Peak DEO levels at steady state were 45 and 23 ng/mL for IR and XL, respectively.

References: Gupta SK, et al. Pharmacokinetics of an oral once-a-day controlled-release oxybutynin formulation compared with immediate-release oxybutynin. *J Clin Pharmacol*, 1999, 39:289–296. PDR54, 2000, p. 507.

Oxycodone^a							
CR: 60–87 ^b	— ^c	45	12.4 (9.2–15.4)	2.0 (1.1–2.9)	2.6 (2.1–3.1) ^d	CR: 3.2 ± 2.2 ^e	CR: 15.1 ± 4.7 ng/mL ^e
IR: 42 ± 7 ^b						IR: 1.6 ± 0.8 ^e	IR: 15.5 ± 4.5 ng/mL ^e

^aOxycodone is metabolized primarily by CYP3A4/5, with a minor contribution from CYP2D6. Oxymorphone is an active metabolite produced by CYP2D6-mediated O-dealkylation. The circulating concentrations of oxymorphone are too low to contribute significantly to the opioid effects of oxycodone. Data from healthy male and female subjects reported. ^bValues reported for OXYCONTIN [oxycodone controlled release (CR)] and immediate-release (IR) tablets. ^cUp to 19% excreted unchanged after an oral dose.

^dThe apparent $t_{1/2}$ for the CR oral formulation is ~5 h; this most likely reflects absorption-limited terminal elimination kinetics. ^eFollowing 10 mg of OXYCONTIN (CR) given twice daily to steady state or a 5-mg IR tablet given every 6 h to steady state.

TABLE AII-1 ■ PHARMACOKINETIC DATA (CONTINUED)

BIOAVAILABILITY (ORAL) (%)	URINARY EXCRETION (%)	BOUND IN PLASMA (%)	CLEARANCE (mL/min/kg)	VOL. DIST. (L/kg)	HALF-LIFE (hours)	PEAK TIME (h)	PEAK CONCENTRATION
Paliperidone^a							
28 (oral ER) ^{b,c}	59 (51–67) (oral ER)	74	3.70 ± 1.04 ^d	9.1 ^d (oral ER)	28.4 ± 5.1 ^d (oral ER)	22 (2.0–24) ^d (oral ER)	10.7 ± 3.3 ng/mL ^d (oral ER)
		↓ LD	↑ LD ^e				
					25–49 days (IM PP) ^f	13 days (IM PP)	

^aPaliperidone, otherwise known as the 9-hydroxy active metabolite of risperidone, is marketed as an oral extended-release (ER) tablet (Invega) or in the form of its water-insoluble palmitate ester as a once-monthly long-acting IM injection (Invega Sustenna). Paliperidone is a racemate; its enantiomers have similar pharmacological profiles. The (+)- and (–)-enantiomers of paliperidone interconvert, reaching an AUC (+) to (–) ratio of ~1.6 at steady state. ^bHigh-fat/high-caloric meal increased C_{max} and AUC by 60% and 54%, respectively. ^cNo data on the absolute bioavailability of IM paliperidone palmitate (IM PP). The initiation regimen for Invega Sustenna (234 mg/156 mg in the deltoid muscle on day 1/day 8) produces paliperidone concentrations matching the range observed with 6- to 12-mg oral ER paliperidone. ^dAt steady-state during once-daily doses of 3 mg, assuming an average body weight of 73 kg. V_d is estimated from CL/F and $t_{1/2}$. ^ePatients with moderate hepatic impairment showed a modest increase in clearance and plasma free fraction with no significant change in unbound AUC. ^fThe apparent long terminal $t_{1/2}$ of paliperidone following IM depot injection reflects the slow dissolution of paliperidone palmitate and release of active paliperidone.

Drugs@FDA. Invega label approved on April 27, 2007; Invega Sustenna label approved on July 31, 2009. Available at: <http://www.accessdata.fda.gov/scripts/cder/DrugsatFDA/>. Accessed January 1, 2010.

Pantoprazole^a							
77 (67–89)	— ^b	98	2.8 ± 0.9	0.17 ± 0.04	1.1 ± 0.4	2.6 ± 0.9	2.5 ± 0.7 µg/mL ^c
			↓ LD		↑ LD		

^aPantoprazole is available as a racemic mixture of (+) and (–) isomers. Pantoprazole is cleared primarily by CYP2C19 (polymorphic)-dependent metabolism. Poor metabolizers (PM) exhibit profound differences in CL (lower) and $t_{1/2}$ (higher) compared to extensive metabolizers (EM). In CYP2C19 EM, no significant differences in the pharmacokinetics of (+) and (–) pantoprazole were observed, whereas in CYP2C19 PM, the CL of (–) pantoprazole was significantly greater than that of (+) pantoprazole. ^bNo unchanged drug recovered in urine. ^cFollowing a single 40-mg oral dose.

Stereoselective pharmacokinetics of pantoprazole, a proton pump inhibitor, in extensive and poor metabolizers of S-mephenytoin. *Clin Pharmacol Ther*, 2001, 69:108–113.

Paroxetine							
Dose dependent ^a	<2	95	8.6 ± 3.2 ^{a,b}	17 ± 10 ^c	17 ± 3 ^d	5.2 ± 0.5 ^e	EM: ~130 nM ^e
			↓ LD, Aged		↑ LD, Aged		PM: ~220 nM ^e

^aMetabolized by CYP2D6 (polymorphic); undergoes time- and dose-dependent autoinhibition of metabolic CL in extensive metabolizers (EM). ^b CL/F reported for multiple dosing in EM. Single-dose data are significantly higher. In CYP2D6 poor metabolizers (PM), CL/F = 5.0 ± 2.1 mL/min/kg for multiple dosing. ^c V_{area}/F reported. ^dData reported for multiple dose in EM. In PM, $t_{1/2}$ = 41 ± 8 h. ^eEstimated mean C_{max} following a 30-mg oral dose given once daily for 14 days to adults phenotyped as CYP2D6 EM and PM. There is a significant disproportional accumulation of drug in blood when going from single to multiple dosing due to autoinactivation of CYP2D6.

References: PDR54, 2000, p. 3028. Sindrup SH, et al. The relationship between paroxetine and the sparteine oxidation polymorphism. *Clin Pharmacol Ther*, 1992, 51:278–287.

Phenobarbital							
100 ± 11	24 ± 5 ^a	51 ± 3	0.062 ± 0.013	0.54 ± 0.03	99 ± 18	2–4 ^b	13.1 ± 4.5 µg/mL ^b
		↓ Neo	↑ Preg, Child, Neo	↑ Neo	↑ LD, Aged ↓ Child		

^aPhenobarbital is a weak acid (pK_a = 7.3); urinary excretion is increased at an alkaline pH; it also is reduced with decreased urine flow. ^bMean steady-state concentration following a 90-mg oral dose given daily for 12 weeks to patients with epilepsy. Levels of 10–25 µg/mL provide control of tonic-clonic seizures, and levels of at least 15 µg/mL provide control of febrile convulsions in children. Levels > 40 µg/mL can cause toxicity; 65–117 µg/mL produce stage III anesthesia—comatose but reflexes present; 100–134 µg/mL produce stage IV anesthesia—no deep-tendon reflexes.

Prednisolone							
82 ± 13	26 ± 9 ^a	90–95 (<200 ng/mL) ^b	1.0 ± 0.16 ^c	0.42 ± 0.11 ^c	2.2 ± 0.5	1.5 ± 0.5 ^f	458 ± 150 ng/mL ^f
	↑ Aged	~70 (>1 µg/mL)	↓ Aged, ^d LD ^d	↓ Aged, Obes ^d	↑ Aged ^d		
		↓ Aged, LD					

^aPrednisolone and prednisone are interconvertible; an additional 3% ± 2% is excreted as prednisone. ^bExtent of binding to plasma proteins is dependent on concentration over range encountered. ^cTotal CL increases as protein binding is saturated. CL of unbound drug increases slightly but significantly with increasing dose. ^dChanges are for unbound drug. ^eV increases with dose due to saturable protein binding. ^fFollowing a 30-mg oral dose given twice daily for 3 days to healthy adult male subjects. The ratio of prednisolone/prednisone is dose dependent and can vary from 3 to 26 over a prednisolone concentration range of 50–800 ng/mL.

References: Frey BM, et al. Clinical pharmacokinetics of prednisone and prednisolone. *Clin Pharmacokinet*, 1990, 19:126–146. Rohatagi S, et al. Pharmacokinetics of methylprednisolone and prednisolone after single and multiple oral administration. *J Clin Pharmacol*, 1997, 37:916–925.

Prednisone							
80 ± 11 ^a	3 ± 2 ^b	75 ± 2 ^c	3.6 ± 0.8 ^d	0.97 ± 0.11 ^d	3.6 ± 0.4 ^d	P: 2.1–3.1 ^e	P: 62–81 ng/mL ^e
						PL: 1.2–2.6 ^e	PL: 198–239 ng/mL ^e

^aMeasured relative to equivalent intravenous dose of prednisolone (PL). ^bAn additional 15% ± 5% excreted as PL. ^cIn contrast to PL, there is no dependence on concentration.

^dKinetic values for prednisone (P) often are reported in terms of values for PL, its active metabolite. However, the values cited here pertain to P. ^eRange of mean data for P and PL following a single 10-mg oral dose given as different proprietary formulations to healthy adults.

Pregabalin							
≥90 ^a	90–99	0	0.96–1.2 ^{b,c}	0.5	5–6.5	1 ^a	8.5 µg/mL ^e
			↓ RD ^d				

^aBioavailability does not vary with dose up to 600 mg. T_{max} is delayed from 1 to 3 h and C_{max} decreased by 25%–30% when pregabalin is given with food. No change in AUC or extent of absorption is noted. ^bPregabalin undergoes minimal metabolism; an N-methylated metabolite has been identified in urine and accounts for 0.9% of oral dose. ^cMean renal clearance in healthy young subjects ranges from 67 to 81 mL/min and assuming 70-kg body weight. Pregabalin pharmacokinetics is dose independent and predictable from single to multiple dosing. ^dPregabalin clearance is proportional to CL_{cr} ; hence, dosage can be adjusted in accordance to CL_{cr} in renal dysfunction. Plasma pregabalin decreased by ~50% after 4 h of hemodialysis. ^eSteady-state concentration in healthy subjects receiving 200-mg pregabalin every 8 h.

Propranolol^a							
26 ± 10	<0.5	87 ± 6 ^b	16 ± 5 ^{c,d}	4.3 ± 0.6 ^c	3.9 ± 0.4 ^c	P: 1.5 ^e	P: 49 ± 8 ng/mL ^e
↑ LD		↑ Preg, Obes	↑ LD	↑ Obes, Fem	↓ LD	HP: 1.0 ^e	HP: 37 ± 9 ng/mL ^e
		↓ LD	↓ LD, Obes, Fem				

^aRacemic mixture. For *S*(–)-enantiomer (100-fold more active) compared to *R*(+)-enantiomer, CL is 19% lower and V_{area} is 15% lower because of a higher degree of protein binding (18% lower free fraction); hence, there is no difference in $t_{1/2}$. ^bActive metabolite, 4-hydroxypropranolol (HP). ^cDrug is bound primarily to α_1 -acid glycoprotein, which is elevated in a number of inflammatory conditions. ^dBased on blood measurements; blood-to-plasma concentration ratio = 0.89 ± 0.03. ^eCYP2D6 catalyzes the formation of HP; CYP1A2 is responsible for most of the *N*-desisopropyl metabolite; UGT catalyzes the major conjugation pathway of elimination. ^fPropranolol (P) and HP following a single 80-mg oral dose given to healthy adults. Plasma accumulation factor was 3.6-fold after 80 mg was given four times daily to steady state. A concentration of 20 ng/mL gave a 50% decrease in exercise-induced cardioacceleration. Antianginal effects manifest at 15–90 ng/mL. A concentration up to 1000 ng/mL may be required for control of ventricular arrhythmias.

Raloxifene^a							
2 ^b	<0.2	>95	735 ± 338 ^c	2348 ± 1220 ^c	28 (11–273)	6 ^d	0.5 ± 0.3 ng/mL ^d
			↓ LD				

^aData from postmenopausal women. Undergoes extensive first-pass metabolism (UGT catalyzed) and enterohepatic recycling. ^b~60% absorption from the gastrointestinal tract; not significantly affected by food. ^cCL/F and V/F reported for an oral dose. ^dFollowing a single 1-mg/kg oral dose.

References: Hochner-Celnikier D. Pharmacokinetics of raloxifene and its clinical application. *Eur J Obstet Gynecol Reprod Biol*, 1999, 85:23–29. PDR54, 2000, p. 1583.

Raltegravir							
≥31.8 ± 9.4 ^a	8.8 ± 4.7	83	16.1 (11.4, 22.6 ^b) ^c	–	α: 0.92 ± 0.21 ^d	1.0 ^e	4.5 (2.0, 10.2) µM ^e
					β: 12.5 ± 4.6 ^d		

^aThe absolute oral bioavailability of raltegravir has not been determined. This minimum extent of oral absorption is based on recovery of radioactivity in urine following oral administration of ¹⁴C-labeled raltegravir in healthy human subjects. ^bRaltegravir undergoes *O*-glucuronidation mediated largely by UGT1A1 and to a lesser extent by UGT1A3 and UGT1A9. Raltegravir AUC is only modestly elevated in individuals with UGT1A1*28/*28 genotype compared to *1/*1 genotype. ^cGeometric mean (95% confidence interval) of pharmacokinetic parameters following a single 400-mg oral dose. Apparent oral clearance (CL/F) is listed. ^dPlasma concentration time course of raltegravir exhibits multiphasic washout kinetics. Initial (α) and terminal (β) $t_{1/2}$ s are reported because the early phase accounts for a large portion of the AUC from time 0 to ∞. ^eMedian for T_{max} and geometric mean (95% confidence interval) for C_{max} following a 400-mg twice-daily monotherapy regimen for 10 days in treatment-naïve patients with HIV-1 infection.

TABLE AII-1 ■ PHARMACOKINETIC DATA (CONTINUED)

BIOAVAILABILITY (ORAL) (%)	URINARY EXCRETION (%)	BOUND IN PLASMA (%)	CLEARANCE (mL/min/kg)	VOL. DIST. (L/kg)	HALF-LIFE (hours)	PEAK TIME (h)	PEAK CONCENTRATION
Ramelteon^a							
1.8 ^b	<0.1%	82	13.1 ^c	1.05	P: 1.3 ± 0.5 ^e	P: 1.6 ± 0.5	P: 6.9 ± 7.8 ng/mL ^{e,f}
			↓ Aged, LD ^d		M: 2.3 ± 0.5 ^e		M: 110 ± 29 ng/mL ^{e,f}
					↑ Aged		

^aRamelteon undergoes primary oxidative metabolism followed by glucuronidation as secondary metabolism. CYP1A2 is the major enzyme involved in oxidative metabolism; CYP3A and CYP2C9 also are involved as minor enzymes. Remarkable elevation in C_{max} and AUC were observed with the concurrent administration of the strong CYP1A2 inhibitor fluvoxamine. The M-II metabolite contributes to the hypnotic effects of ramelteon. M-II has 1/5th to 1/10th the affinity of ramelteon as an agonist for the melatonin receptors (MT-1 and MT-2); however, it circulates at 20- to 100-fold higher concentrations relative to ramelteon. ^bPoor systemic availability of ramelteon is due to extensive first-pass metabolism. C_{max} and AUC are elevated by a high-fat meal; T_{max} is slightly delayed. ^cCalculated assuming 70-kg body weight. Although note shown, interindividual variability is notably large. ^dFour- and 10-fold elevation in AUC in mild and moderate hepatic impairment. ^eP = parent drug; M = M-II metabolite. ^f C_{max} following a single 16-mg oral dose of ramelteon in young adult subjects. There is no measurable accumulation of parent drug or active metabolite because of their short elimination $t_{1/2}$.

^aData from healthy adult male subjects. ^bUndergoes extensive oxidative and conjugative metabolism. CYP2C8 and CYP3A4 to a minor degree have been implicated in the metabolism of repaglinide. Repaglinide is also a substrate of organic anion transport protein (OATP)1B1, which is believed to contribute to the hepatic uptake of repaglinide. ^cCL/F reduced, severe renal impairment. ^dCL/F reduced, moderate-to-severe LD. ^eFollowing a single 4-mg oral dose (tablet).

References: Hatorp V, et al. Unavailability of repaglinide, a novel antidiabetic agent, administered orally in tablet or solution form or intravenously in healthy male volunteers. *Int J Clin Pharmacol Ther*, 1998, 36:636–641. Hatorp V, et al. Single-dose pharmacokinetics of repaglinide in subjects with chronic liver disease. *J Clin Pharmacol*, 2000, 40:142–152. Marbury TC, et al. Pharmacokinetics of repaglinide in subjects with renal impairment. *Clin Pharmacol Ther*, 2000, 67:7–15. van Heiningen PN, et al. Absorption, metabolism and excretion of a single oral dose of ¹⁴C-repaglinide during repaglinide multiple dosing. *Eur J Clin Pharmacol*, 1999, 55:521–525.

^aValues reported for studies conducted in asymptomatic HIV-positive men. ^bAt steady state, red blood cell-to-plasma concentration ratio is ~60. ^cFollowing multiple oral dosing, CL/F decreases by > 50%, and a long terminal $t_{1/2}$ of 150 ± 50 h is observed. ^dFollowing a 1200-mg oral ribavirin capsule (R) given daily for 7 days to adult subjects seropositive for HIV or a 600-mg oral Rebetron dose given twice daily to steady state to adults with hepatitis C infection.

References: Morse GD, et al. Single-dose pharmacokinetics of delavirdine mesylate and didanosine in patients with human immunodeficiency virus infection. *Antimicrob Agents Chemother*, 1997, 47:169–174. PDR54, 2000, p. 2836. Roberts RB, et al. Ribavirin pharmacodynamics in high-risk patients for acquired immunodeficiency syndrome. *Clin Pharmacol Ther*, 1987, 42:365–373.

^aActive desacetyl metabolite. ^bAbsolute bioavailability is not unknown, although some studies indicate complete absorption. Such reports presumably refer to rifampin plus its desacetyl metabolite because considerable first-pass metabolism is expected. ^c $t_{1/2}$ is shorter (1.7 ± 0.5) and CL/F is higher after repeated administration. Rifampin is a potent enzyme (CYP3A and others) inducer and appears to autoinduce its own metabolism. ^dNot observed with 300-mg doses, but pronounced differences with 900-mg doses. $t_{1/2}$ is longer with high single doses. ^eFollowing a 600-mg dose given once daily for 15–18 days to patients with tuberculosis.

Reference: Israili ZH, et al. Pharmacokinetics of antituberculosis drugs in patients. *J Clin Pharmacol*, 1987, 27:78–83.

^aHigh-fat meal. ^bEliminated primarily by CYP1A2-dependent metabolism; metabolites are inactive. Involvement of CYP1A2 may contribute to ethnic (lower CL/F in Japanese) and gender (lower CL in women) differences and inductive effects of smoking (higher CL in smokers). ^cFollowing a 50-mg oral dose given twice daily to steady state.

Single- and multiple-dose pharmacokinetics of riluzole in white subjects. *J Clin Pharmacol*, 1997, 37:820–827. PDR58, 2004, p. 769. Wokke J. Riluzole. *Lancet*, 1996, 348:795–799.

^aThe active metabolite, 9-hydroxyrisperidone, is the predominant circulating species in extensive metabolizers and is equipotent to parent drug. 9-Hydroxyrisperidone has a $t_{1/2}$ of 20 ± 3 h. In extensive metabolizers, 35% ± 7% of an intravenous dose is excreted as this metabolite; its elimination is primarily renal and therefore correlates with renal function. Formation of 9-hydroxyrisperidone is catalyzed by CYP2D6. ^bParameters reported for extensive metabolizers. In poor metabolizers, F is higher; ~20% of an intravenous dose is excreted unchanged, 10% as the 9-hydroxy metabolite; CL is slightly < 1 mL/min/kg, and $t_{1/2}$ is similar to that of the active metabolite, ~20 h. ^c77% for 9-hydroxyrisperidone. ^dChanges in elderly subjects due to decreased renal function affecting the elimination of the active metabolite. ^eMean steady-state C_{min} for risperidone (R) and total active (TA) drug, risperidone + 9-OH-risperidone, following a 3-mg oral dose given twice daily to patients with chronic schizophrenia. No difference in total active drug levels between CYP2D6 extensive and poor metabolizers.

References: Cohen LJ. Risperidone. *Pharmacotherapy*, 1994, 14:253–265. Heykants J, et al. The pharmacokinetics of risperidone in humans: a summary. *J Clin Psychiatry*, 1994, 55(suppl):13–17.

^aAbsolute bioavailability unknown (>60% absorbed); food elicits a 15% increase in oral AUC for capsule formulation. ^bRitonavir is extensively metabolized primarily by CYP3A4. It also appears to induce its own CL with single-dose (SD) to multiple-dose (MD) administration. ^cCL/F, V_{area} /F, and $t_{1/2}$ reported for oral dose. ^dCL/F reduced slightly and $t_{1/2}$ increased slightly, moderate liver impairment. ^eFollowing a 600-mg oral dose given twice daily to steady state.

TABLE AII-1 ■ PHARMACOKINETIC DATA (CONTINUED)

BIOAVAILABILITY (ORAL) (%)	URINARY EXCRETION (%)	BOUND IN PLASMA (%)	CLEARANCE (mL/min/kg)	VOL. DIST. (L/kg)	HALF-LIFE (hours)	PEAK TIME (h)	PEAK CONCENTRATION
Sofosbuvir^a							
— ^b	— ^c	~82 ^d	—	—	0.68 (0.53–1.00) ^e	1.00 (0.50–1.50) ^e	1356 (63.0) ng/mL
			↓ RD ^f				

^aSofosbuvir is sequentially metabolized to a pharmacologically active nucleoside analogue triphosphate; the active metabolite is undetected in plasma. The first hydrolytic step appears to be rapid (much of it may occur during first pass), yielding the intermediate metabolite GS-566500, which can either be fully activated by kinases to GS-461203 or inactivated by phosphatase activity to GS-331007. ^bThe absolute oral bioavailability of sofosbuvir in humans is not known. Administration with a high-fat meal increases systemic sofosbuvir exposure by 67%–91%, although this is not thought to be clinically meaningful. ^c3.5% of the oral dose is recovered as unchanged sofosbuvir in urine; the true fraction excreted unchanged may be much higher, depending on the absolute bioavailability. ^dAlso reported to be 62%–65% based on in vitro ultrafiltration experiments. ^eMean (25th and 75th quartiles or CV%) reported following administration of 400-mg oral sofosbuvir, given once a day for 27 days. ^fSystemic exposure (AUC) of sofosbuvir and GS-566500 increased 171% and 244%, respectively, in patients with severe renal impairment; smaller increases seen with less severe disease.

↓ Food				↑ LD	↑ LD		
^a Drug disposition parameters calculated from blood concentrations. Data from liver transplant patients reported. Metabolized by CYP3A; also a substrate for P-glycoprotein. ^b A similar bioavailability ($F = 21\% \pm 19\%$) reported for kidney transplant patients; $F = 16\% \pm 7\%$ for normal subjects. Low oral bioavailability likely due to incomplete intestinal availability. ^c Different values for plasma protein binding reported. Concentrates in blood cells; blood-to-plasma concentration ratio = 35 (12–67). ^d Slightly higher V_{ss} and $t_{1/2}$ reported for kidney transplant patients. Because of the very high and variable blood-to-plasma concentration ratio, markedly different V_{ss} values are reported for parameters based on plasma concentrations. ^e Following a single 7-mg oral dose given to healthy adults. Consensus target C_{min} at steady state are 5–20 ng/mL.

Pharmacokinetics of tacrolimus in liver transplant patients. <i>Clin Pharmacol Ther</i> , 1995, 57:281–290. <i>PDR54</i> , 2000, pp. 1098–1099.							
Tadalafil							
—	—	94	0.59 ^{a,b}	0.89 ^b	17.5	2 ^d	378 ng/mL ^d
			↓ RD ^c				
^a Eliminated primarily by CYP3A4-dependent metabolism. ^b CL/F and V/F reported. ^c AUC increased in patients with mild or moderate (2-fold) and severe (4-fold) renal insufficiency. ^d Following a single 20-mg oral dose.							
References: Curran M, et al. Tadalafil. <i>Drugs</i> , 2003, 63:2203–2212; discussion 2213–2214. Product labeling: Cialis [®] (tadalafil tablets). Lilly Icos, Bothell, WA, 2004.							
Tamoxifen^a							
—	<1	>98	1.4 ^{b,c}	50–60 ^b	4–11 days ^d	5 (3–7) ^e	120 (67–183) ng/mL ^e
^a Has active metabolites; 4-hydroxytamoxifen and 4-hydroxy-N-desmethyltamoxifen (endoxifen) are minor metabolites that exhibit affinity for the estrogen receptor that is greater than that of parent <i>trans</i> -tamoxifen. The $t_{1/2}$ of all metabolites are rate limited by tamoxifen elimination. ^b CL/F and V_{area}/F reported. ^c The major pathway of elimination, N-demethylation, is catalyzed by CYP3A. Polymorphic CYP2D6 catalyzes the 4-hydroxylation step key to metabolite activity. ^d $t_{1/2}$ consistent with accumulation and approach to steady state. Significantly longer terminal $t_{1/2}$ s are observed. ^e Average C_{ss} following a 10-mg oral dose given twice daily to steady state.

TABLE AII-1 ■ PHARMACOKINETIC DATA (CONTINUED)

BIOAVAILABILITY (ORAL) (%)	URINARY EXCRETION (%)	BOUND IN PLASMA (%)	CLEARANCE (mL/min/kg)	VOL. DIST. (L/kg)	HALF-LIFE (hours)	PEAK TIME (h)	PEAK CONCENTRATION
Temsirolimus^a							
—	4.6 ^b	— ^c	3.8 ± 0.6 ^d	3.3 ± 0.5 ^d	12.8 ± 1.1	—	595 ± 102 ng/mL ^e

^aTemsirolimus, a water-soluble ester analogue of sirolimus or rapamycin, is available for intravenous use. Following intravenous administration, temsirolimus is converted to sirolimus; blood AUC of sirolimus is 3-fold higher than that of temsirolimus at the recommended dose of 25 mg for the treatment of advanced renal cell carcinoma. Both temsirolimus and sirolimus inhibit mTOR kinase activity and undergo oxidative metabolism mediated by CYP3A. ^bRecovery of radioactivity after a single intravenous dose of [¹⁴C]-temsirolimus. ^cBoth temsirolimus and sirolimus partition extensively into blood cells; a major fraction of temsirolimus and sirolimus in plasma is bound to plasma proteins. ^dBased on CL of 16.1 ± 2.5 L/h and V_{ss} of 232 ± 36 L at a dose of 25 mg, assuming an average body weight of 70 kg. All pharmacokinetic assessments are based on whole-blood concentration. ^eFollowing the first dose of a 25-mg/week regimen.

^a87.1 ± 5.5% of radioactivity is excreted in urine after an oral dose of [¹⁴C]-varenicline. Minimal first-pass metabolism is expected. ^bVarenicline is cleared mostly by renal excretion with minimal metabolism. Organic cation transporter 2 (OCT2) is involved in renal tubular secretion, as evidenced by inhibition of varenicline renal clearance by cimetidine, a known OCT2 inhibitor. ^cCL/F and V_z/F estimated from steady-state AUC and t_{1/2} during 1-mg twice-daily dosing of varenicline in healthy adult smokers and assuming an average body weight of 70 kg. ^dAfter the first dose of a multiple-dosing regimen. An accumulation factor of 2.85 ± 0.73 was reported.

Venlafaxine,^a Desvenlafaxine^b							
10–45	V: 4.6 ± 3.0	V: 27 ± 2	22 ± 10 ^d	7.5 ± 3.7 ^d	4.9 ± 2.4	V: 2.0 ± 0.4	V: 167 ± 55 ng/mL ^e
	ODV: 29 ± 7 ^c	ODV: 30 ± 12 ^c			10.3 ± 4.3 ^c	ODV: 2.8 ± 0.8 ^c	ODV: 397 ± 81 ng/mL ^e
			↓ LD, RD		↑ LD, RD		

^aVenlafaxine (V) is available as a racemic mixture; antidepressant activity resides with the *l*-(–)-enantiomer and its equipotent *O*-desmethyl metabolite (formation catalyzed by CYP2D6–polymorphic). Parameters for the derived *O*-desmethylvenlafaxine (ODV) are included. ^b*O*-Desmethyl metabolite is marketed as desvenlafaxine in an extended-release formulation as a successor to V. It has a higher oral bioavailability (80%), with a T_{max} of 7.5 h. Desvenlafaxine has a much lower CL (3.5 mL/min/kg) and a smaller V_{ss} (3.4 L/kg). Its reported t_{1/2} matches that observed for metabolite derived from V. ^cValues for ODV after V dosing. ^dCL/F and V_{ss}/F reported. ^eMean data for V and ODV following a 75-mg oral dose (immediate-release tablet) given three times daily for 3 days to healthy adults. T_{max} for an extended-release formulation is 5.5 (V) and 9 (DV) h.

References: Klamerus KJ, et al. Introduction of a composite parameter to the pharmacokinetics of venlafaxine and its active *O*-desmethyl metabolite. *J Clin Pharmacol*, 1992, 32:716–724. *PDR54*, 2000, p. 3237.

Verapamil^{a,b}							
Oral: 22 ± 8	<3	90 ± 2	15 ± 6 ^{c,d}	5.0 ± 2.1	4.0 ± 1.5 ^c	IR: 1.1 ^e	IR: 272 ng/mL ^e
SL: 35 ± 13		↓ LD	↓ LD	↑ LD	↑ LD	XR: 5.6–7.7 ^c	XR: 118–165 ng/mL ^e
↑ LD							

^aRacemic mixture; (–)-enantiomer is more active. Bioavailability of (+)-verapamil is 2.5-fold greater than that for (–)-verapamil because of a lower CL (10 ± 2 vs. 18 ± 3 mL/min/kg). Relative concentration of the enantiomers changes as a function of route of administration. ^bActive metabolite, norverapamil, is a vasodilator but has no direct effect on heart rate or P-R interval. At steady state (oral dosing), AUC is equivalent to that of parent drug (t_{1/2} = 9 ± 3 h). ^cMultiple dosing causes a greater than 2-fold decrease in CL/F and prolongation of t_{1/2} in some studies, but no change of t_{1/2} in others. ^dVerapamil is a substrate for CYP3A4, CYP2C9, and other CYPs and for the efflux transporter P-glycoprotein. ^eMean data following a 120-mg oral conventional tablet (IR) given twice daily or range of data following a 240-mg oral extended-release (XR) dose given once daily, both for 7–10 days to healthy adults. EC₅₀ for prolongation of P-R interval after an oral dose of racemate is 120 ± 20 ng/mL; the value for intravenous administration is 40 ± 25 ng/mL. After oral administration, racemate concentrations > 100 ng/mL cause > 25% reduction in heart rate in Atr Fib, > 10% prolongation of P-R interval, and > 50% increase in duration of exercise in angina patients. A level of 120 ± 40 ng/mL (after intravenous administration) was found to terminate reentrant supraventricular tachycardias.

Vinorelbine							
27 ± 12 ^a	11	87 (80–91)	21 ± 7	76 ± 41 ^b	42 ± 21 ^b	1.5 ± 1.0 ^c	114 ± 43 ng/mL ^c
			↓ LD				1130 ± 636 ng/mL ^d

^aFor liquid-filled gelatin capsules. ^bElimination kinetics of vinorelbine follow a three-compartment model with extensive tissue distribution. Values for the terminal elimination phase are reported. ^cFollowing a single 100-mg/m² oral dose (gel capsule). ^dFollowing a single 30-mg/g IV infusion over 15 min.

Reference: Leveque D, et al. Clinical pharmacokinetics of vinorelbine. *Clin Pharmacokinet*, 1996, 37:184–197.

(Continued)

TABLE AII-1 ■ PHARMACOKINETIC DATA (CONTINUED)

BIOAVAILABILITY (ORAL) (%)	URINARY EXCRETION (%)	BOUND IN PLASMA (%)	CLEARANCE (mL/min/kg)	VOL. DIST. (L/kg)	HALF-LIFE (hours)	PEAK TIME (h)	PEAK CONCENTRATION
Voriconazole							
96	<2	58	3.8 ^{a,b}	1.6 ^b	6.7 ^b	PO: 1.1 ^d	PO: 2356 ng/mL ^d
↓ Food			↓ LD ^c				IV: 3621 ng/mL ^e

^aMetabolized mainly to an inactive *N*-oxide by CYP2C19 (major), CYP3A4, and CYP2C9. ^bElimination is dose and time dependent. Pharmacokinetic parameters determined at steady state are reported. Mean *CL* was reduced (64%), *V_{ss}* reduced (32%), and *t_{1/2}* increased (16%) with 12 days of twice-daily 3-mg/kg IV administration. Also, *CL* decreased 41% when dose was increased from 200 to 300 mg twice daily. ^c*CL* reduced in patients with mild-to-moderate hepatic insufficiency. ^dFollowing a 3-mg/kg oral dose given twice daily for 12 days. ^eFollowing a 3-mg/kg IV infusion over 1-h given twice daily for 12 days.
